In this study, we report a combined adsorption/biodegradation approach to enable rapid removal and subsequent biodegradation of aromatic hydrocarbons. By incorporating a very small amount of Pseudomonas sp. NCIB 9816-4 into an ORMOSIL gel, we are working to develop a low-cost, yet effective biohybrid material to remove hydrocarbons repeatedly and regenerate the adsorbent capacity of the material, without significant loss in effectiveness over time. The focus of this preliminary study was to combine a mass transport model with experimental data to inform the final design of the material and determine how the distribution coefficient (K_d) will affect biodegradation.

METHODS

Cell growth and harvesting

Pseudomonas sp. NCIB 9816-11 was inoculated from a Luria Broth (LB) plate culture into 5 mL of LB and incubated at 28C for 8 hours. 1 mL of the culture was then placed into 300 mL Mineral Salts Broth (MSB) with 0.8g succinate and incubated overnight with shaking at 200 rpm. To induce naphthalene dioxygenase, 0.7g salicylic acid was added 2 hrs prior to harvest. Cells were harvested by centrifugation at 6000 x g for 15 minutes.

Initial Rate Measurement

Pseudomonas sp. NCIB 9816 is a naturally occurring bacterium which can degrade over 100 aromatic hydrocarbons[3]. Here, we used naphthalene as a substrate in combination with a knockout mutant strain, NCIB 9816-11, which lacks a dihydrogenase enzyme and accumulates *cis*-naphthalene dihydrodiol. The rate of naphthalene biocatalysis was determined by measuring the oxygen consumption within a sealed chamber. Oxygen consumption was measured using an Oxygraph Oxytherm System (Hansatech Instruments Ltd., United Kingdom).The chamber was filled with 3 mL of naphthalene in Phosphate buffered saline (PBS) and 10 mg cells were added. The system was allowed to equilibrate for 1 minute before measurement was started to ensure that the rates were linear within the range tested.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Oxygen consumption was measured for 5 minutes for each sample. Samples were performed in triplicate.

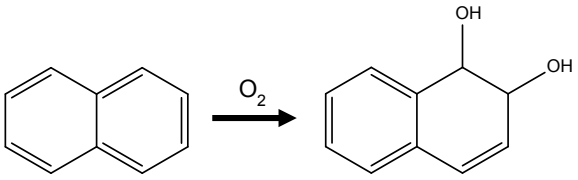

Figure 1: Naphthalene dihydroxylation by NCIB 9816-11

Mass Transport Modelling

The diffusion, reaction, and adsorption processes were modelled using a partial differential equation of the form:

$$\frac{\partial C}{\partial t} = \frac{\left[D_e \nabla^2 C - \frac{V'_{max} \rho_c C}{K_m + C}\right]}{\varepsilon + K_d \rho} \quad (1a)$$

with initial condition:

$$C(x,t) = 0, t \leq 0 \quad (1b)$$

and boundary conditions:

$$\frac{\partial C}{\partial t} = 0, x = 0, t \geq 0 \quad (1c)$$

$$C(x,t) = 250\ \mu M, x = L, t \geq 0 \quad (1d)$$

A semi-infinite slab was simulated using Matlab (Mathworks, Inc., Natick, MA, USA), in order to resemble future experimental setups. The model was solved numerically for a period of 10^5 seconds, with a range of K_d values.

RESULTS

The initial rate experiments revealed that the reaction with whole cells obeyed Michaelis-Menten kinetics (Figure 2). V'_{max} amd K_m can be seen in Table 1. The modelling results showed a reduction in naphthalene degradation with increasing K_d (Figure 3). At short time-scales, this difference was negligible, likely due to the low concentration of naphthalene in the gel. As the naphthalene diffused into the gel, the disparity increased. At long time-scales, the rate of degradation appeared to decrease, possibly due to a large amount of adsorbed naphthalene.

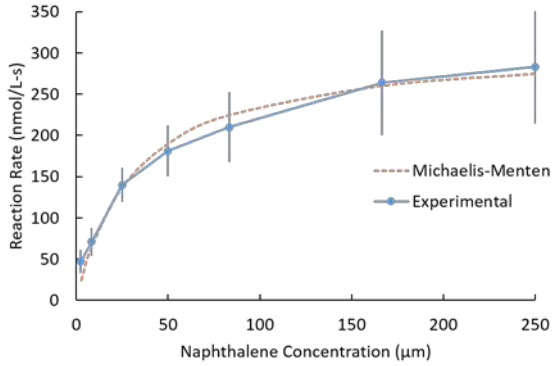

Figure 2: Free cell kinetics of *Pseudomonas sp* NCIB 9816-11 biodegrading naphthalene, measured by oxygen consumption, with 10 mg cells in a 3 mL volume.

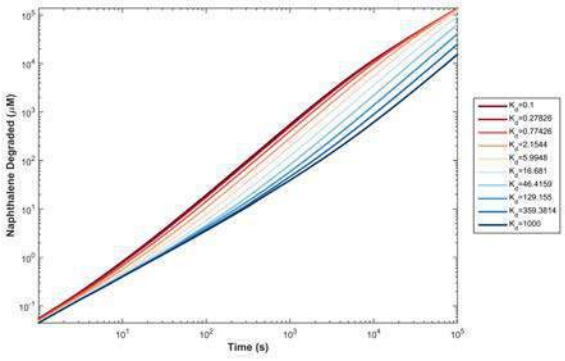

Figure 3: Model results for naphthalene biodegradation over time with an infinite bath of 250 µM naphthalene on a semi-infinite slab containing a cell loading of ρc=10-4 g-cells/mL gel.

DISCUSSION

In order for the system to be both highly adsorptive and regenerative, the cell loading (reaction rate) and adsorptivity (K_d) of the gel must be tuned. Based on the model, we see that having a gel which is excessively adsorptive may hinder the overall biodegradation and thus take longer to regenerate. Furthermore, a high K_d acts to reduce the diffusion through the porous media. Experimental measurement of K_d will be required to determine the optimal cell loading.

Future work will focus on synthesis and characterization of the adsorbent silica gel to determine what values of K_d can be achieved and optimization of the cell loading to minimize cost.

Table 1: Model parameters

Symbol	*Definition*	*Value*	*Units*
C	Naphthalene concentration		µM
D_e	Effective Diffusion Coefficient for Naphthalene	1 x 10^{-4}	mm^2/s
V'_{max}	Maximum specific reaction velocity	3.09x10^{-5}	mol/(L-s-g-cell)
K_m	Michealis-Menten Constant	3.14x10^{-5}	mol/L
ρ_c	Cell loading		g-cells/mL
ρ	Gel Density	0.35	g/mL
ε	Gel Porosity	0.8	mL/g
K_d	Distribution Coefficient	10^{-1}-10^{3}	L/mol
L	Thickness	3	mm

INTRODUCTION

Approximately 10% of all strokes are related to cerebral aneurysms. Untreated cerebral aneurysms may rupture, leading to hemorrhage with a high mortality rate of 50% [1,2]. Saccular aneurysms can usually be removed from the circulation by either surgical clipping or endovascular coiling. In contrast, fusiform aneurysms cannot be treated by these methods, since the vessel wall in this case is bulged circumferentially. The alternative methods involve reduction of the blood flow to the lesion by proximal or distal occlusion, in order to induce thrombotic occlusion of aneurysm. This indirect aneurysm occlusion usually requires sacrificing flow to the distal vasculature as it alters the flow dynamics [3]. Such treatment is particularly challenging for the fusiform aneurysms of the basilar artery as it can result in occlusion of the basilar side branches (brainstem perforators), thus causing stroke. Therefore, the indirect occlusion methods require careful modeling studies prior to procedure and understanding of the advantages and disadvantages of different interventional options for the flow alteration is crucial.

Recently, image-based computational fluid dynamics (CFD) in patient-specific geometries combined with *in vivo* velocimetry (*e.g.*, 4D MRV) has been shown to be a viable method to examine the flow fields resulting from different interventions [3,4]. Useful information from flow simulation such as shear stress, flow patterns and flow residence time can assist in making clinical decisions [5]. However, more progress is required to develop an ultimate computational tool which can reliably predict postoperative thrombus deposition. For example, due to the complexity of the geometry and the flow in patient-specific models, our understanding of flow alteration is mostly qualitative, which may result in ambiguity when treatment outcomes are compared. In the case of fusiform cerebral aneurysms, a good evaluation of surgical options is impossible without understanding of flow in small vessels and perforators. In this work, a method is presented for quantification of post-surgical flow through different parts of aneurysmal geometries.

METHODS

The computational analysis was conducted on basilar artery aneurysm patients recruited using institutionally approved IRB consent. The patient-specific preoperative vascular models were constructed from high-resolution, contrast-enhanced MRA data. The computational domain included the aneurysms with its proximal and distal vessels. Since the aneurysms in this study were located in a region of the basilar artery with small side branches, idealized geometries of several brainstem perforators and anterior inferior cerebellar arteries (AICAs) were added to the models. One representative case will be described here due to space limitations. The computational model is shown in Figure 1 (a), and a Digital subtraction angiography (DSA) image, showing the filling of the basilar artery with contrast is shown in panel (b).

Alternative postoperative geometries were created by modifying the preoperative model. Treatment options considered in this study included clipping of specific vessels to reduce the blood flow to the basilar aneurysm. The interventions were virtually modeled by removing vessel segments that would be surgically clipped.

The flow fields were determined by solving the transient Navier-Stokes equations using a finite-volume solver, ANSYS FLUENT 16. The advection-diffusion equation was coupled with the flow simulation in order to model transport of a passive scalar variable, representing flow of a virtual contrast agent, through the flow domain [5]. The virtual contrast following the blood flow is used as a method for the flow

visualization, and indicates flow residence time in different parts of the model. A computational mesh of tetrahedral elements was generated over the domain. Patient-specific flow waveforms obtained from PC-MRI were used at the inlet boundaries and the outlet pressure was set to zero for all of the outlets. For transport of the contrast, the inlet boundary condition was a constant value and the entire domain was initialized with a zero contrast concentration. For postoperative simulations, the inlet flow rates were adjusted assuming that the same amount of blood flow was required by distal vessels before and after the procedure. After solving the flow field and the contrast transport, an in-house post-processing program was used to find the ratio of the volume filled with virtual contrast to the total volume of various distal vessels and regions of interest.

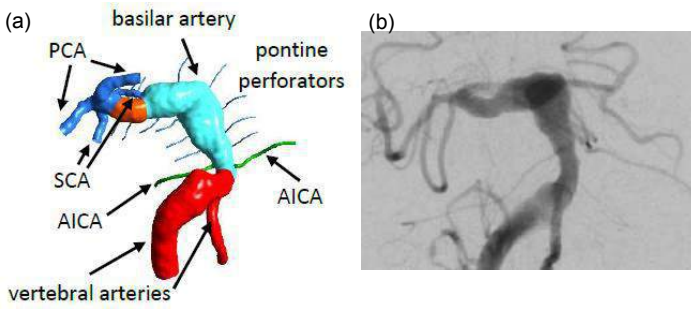

Figure 1: (a) Image-based model showing different components, (b) DSA showing filling of the basilar aneurysm with contrast.

RESULTS

Three interventional options that would reduce the flow through the basilar artery were considered in this study. Those are the occlusion of the left posterior cerebral artery (PCA), clipping of both PCAs, or clipping of the basilar artery proximal to the superior cerebral arteries (SCAs). In the rest of this report, the methods will be referred to as option 1, 2, and 3, respectively. The flow simulations were conducted for the duration of 10 cardiac cycles (total time of 5.2 s) for the preoperative and postoperative cases.

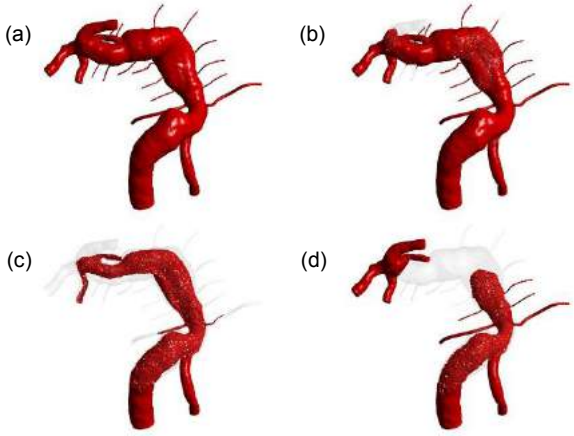

Figure 2: Comparison of virtual contrast transport for (a) postoperative, (b) option 1, (c) option 2, and (d) option 3

Figure 2 shows the transport of virtual contrast within the computational domain at the end of tenth cardiac cycle. The areas filled with red color indicate the regions where the concentration of virtual contrast is above a threshold (in this case 0.5). This method can be used to decide which segments of the vasculature receive sufficient blood flow following the treatment. For example, it is clear that while option 2 (panel c) was better than option 1 (panel b) in reducing blood flow through the aneurysm, it was less effective in feeding the brainstem perforators. It should be noted that in panel (d) the blood to the basilar apex (upper region of the model) was supplied through the right PCA from a bypass connecting it to the anterior circulation.

A quantitative comparison among various options is shown in Figure 3. For each option, the ratio of the volume filled with contrast to the total volume is presented for the basilar aneurysm and the left AICA. As shown, if option 1 is applied, after approximately eight cardiac cycles (4 second), the basilar aneurysm is almost completely filled with virtual contrast, which makes this option inefficient in reducing the basilar flow. Options 2 and 3 reduce the virtual contrast volume in the aneurysm by 50% and 75%, respectively. Also, it can be seen from Figure 3 (b) that option 3 is a better flow scenario as compared to option 2 since the left AICA is filled with contrast after seven cycles.

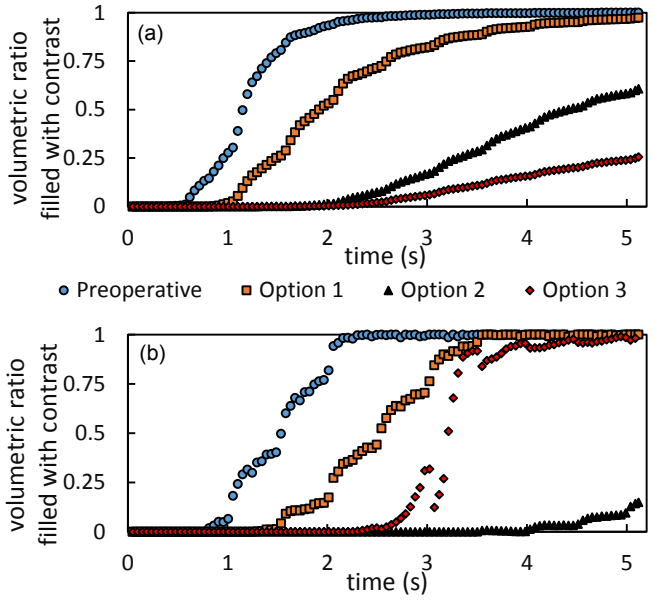

Figure 3: Volumetric ratio of (a) basilar aneurysm and (b) left AICA filled with virtual contrast

DISCUSSION

Three flow altering surgeries were considered in this study and compared against each other. The best interventional option would be the one that reduces the blood flow to the aneurysm in order to induce thrombotic occlusion while preserving the flow the AICAs and perforators. A quantitative method for the evaluation of the postoperative flow was proposed by coupling the transport of a virtual contrast with velocity field. These results show that image-based CFD models can provide guidance in evaluation of alternative treatment options for cerebral aneurysms.

INTRODUCTION

There are multiple mechanisms that can lead to ischemic stroke. One well-established cause is plaque rupture, which accounts for approximately 15% of all ischemic strokes [1], during which a tear in the fibrous cap of an atherosclerotic plaque exposes the highly thrombogenic necrotic core material. This mechanism generally occurs in lesions called thin-cap fibroatheromas (TCFAs), characterized by a thin fibrous cap covering a large necrotic core [2]–[4]. Though these morphological characteristics provide a good framework for identifying vulnerable plaques, the true test of plaque vulnerability is whether or not the mechanical strength of the tissue can withstand the physiological loading conditions to which it is subjected.

Characterizing the material response of the fibrous cap at failure may provide insight into the mechanism and likelihood of plaque rupture. This study undertakes a qualitative and quantitative approach to analyze the mechanical failure behavior of atherosclerotic plaque tissue. We aim to quantitatively characterize the fracture behavior of fibrous caps using the CTOD metric to assess fracture toughness. To the authors' knowledge, this is the first application of CTOD in vascular tissue.

METHODS

The current study was approved by the IRB at Greenville Health System and all patients gave written informed consent. Human carotid endarterectomy specimens were obtained from 8 patients at the time of surgery at Greenville Memorial Hospital. Two plaque specimens generated multiple samples from the same patients (Samples III and IV; Samples VII and VIII). The excised specimens were immediately immersed in Belzer UW Cold Storage Solution (Bridge to Life Ltd., Columbia, SC) and were kept cool until testing. All mechanical testing was completed within 48 hours of tissue harvest.

The fibrous cap was isolated for mechanical testing by dissection from the remaining plaque. The tissue was oriented in the circumferential direction and mounted into a set of metal grips with 100 grit sandpaper on the inner surface. The grips were connected to a Bose 3200 Test Instrument, and a miniature single edge notch tension (MSENT) test was performed on each sample. An initial notch between 45% - 70% of the overall width of the tissue was made with a scalpel perpendicular to the direction of the applied load. Cyclical controlled displacement was applied such that the tissue tore in several cycles of small tears, each approximately 0.4 mm in length. The crack tip opening displacement (CTOD) was calculated at several points during tearing by measuring the distance between the intersections of a 90 degree vertex centered at the crack tip with the crack edges, as first suggested by Rice [5]. Additionally, the circumferential Cauchy stress in the uncracked segment was calculated at the initiation of tearing in each cycle.

After mechanical testing, the samples were fixed in a solution of 4% paraformaldehyde in 0.1 M phosphate buffer, pH 7.4, embedded in paraffin, and sectioned at a thickness of 5 μm. Picrosirius Red staining was conducted to determine the collagen content in each sample.

Significant relationships between measured parameters were assessed using linear regression to test the null hypothesis that the slope is equal to zero. The null hypothesis was rejected, with statistical significance, if $P < 0.05$.

RESULTS

In each specimen, the CTOD increased with increasing crack growth (Figure 1). Nearly all the initial CTOD values are clustered

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

around 0.5 mm, with the exception of samples IV and X, which have higher initial CTOD values (0.96 mm and 1.01 mm, respectively).

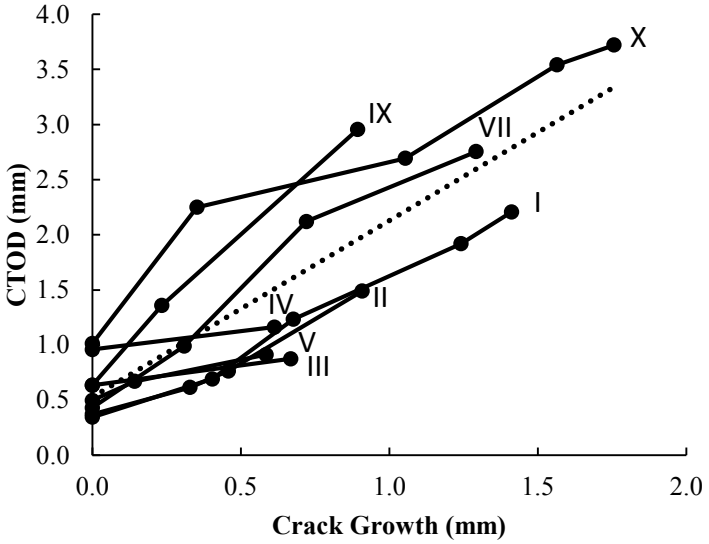

Figure 1: CTOD increases with crack growth. The median [IQR 1, IQR 3] initial CTOD is 0.54 [0.42, 0.71] mm, and the median [IQR 1, IQR 3] slope of the CTOD curve is 1.30 [0.59, 1.51].

Two samples (VI and VIII) exhibited a high degree of blunting such that a 90 degree vertex never intersected the edges of the crack and CTOD could not be determined. However, the radius of curvature of the crack tip at the initiation of tearing was measured in all samples to assess the degree of crack tip blunting. The median [IQR 1, IQR 3] radius of curvature of the crack tip at initial tearing was 0.24 [0.13, 0.27] mm.

The stress in the uncracked segment was calculated at the initiation of tearing for each cycle (Figure 2). Several samples exhibited very consistent stress values over multiple tearing cycles (VI, IX, and X), while other samples exhibited variation in stress values between consecutive cycles (I, II, V, VII), as shown in Figure 2. Because atherosclerotic tissue can be heterogeneous [6], this variation is not surprising.

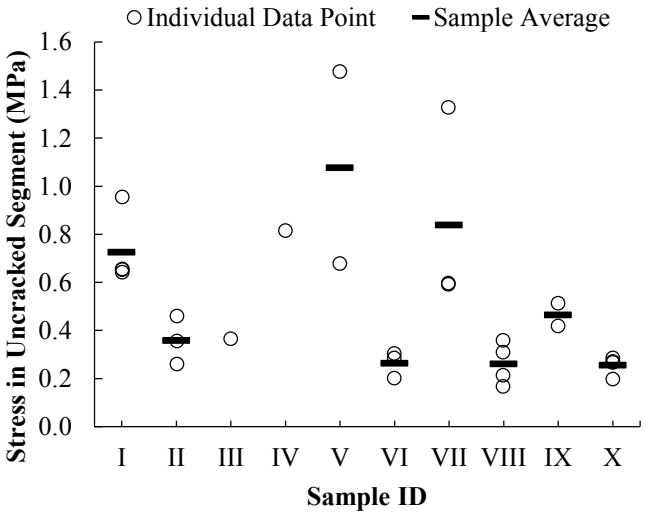

Figure 2: Stress in the uncracked segment. The median [IQR 1, IQR 3] values of stress are 0.366 [0.279 0.648] MPa.

Collagen content was measured in each specimen after mechanical testing and compared to calculated stress in the uncracked segment, initial CTOD, and initial radius of curvature at the crack tip. The median [IQR 1, IQR 3] values of collagen content are 32.8 [30.0, 42.0] percent. There is a statistically significant proportional relationship between collagen content and the stress in the uncracked segment ($p < 0.05$ that slope is zero). The radius of curvature at the crack tip is a measure of the degree of blunting at the crack tip and is shown to have a statistically significant inverse relationship with collagen content ($p < 0.05$). There is also a statistically significant relationship between collagen content and initial CTOD ($p < 0.05$). The results suggest that samples with higher collagen content begin tearing with a sharper crack tip and exhibit higher stresses at the initiation of tearing.

DISCUSSION

To the authors' knowledge, this is the first study that has investigated the fracture behavior of fibrous cap tissue and the first to use CTOD as a fracture parameter in vascular tissue. Materials that fracture at a higher stress are considered to be stronger than materials that fracture at a lower stress. A material with a higher CTOD is considered more resistant to fracture than a material with a lower CTOD. The results from this study show that tissues with a greater collagen content fail at a higher stress, but a smaller CTOD, than those with a lower collagen content. These divergent fracture parameters suggest a conflicting ranking of mechanical strength of fibrous caps. Generally, fibrous cap stability has been assessed by the stress at which failure occurs, rather than the CTOD or the strain, but our results suggest that stress may not always be the most appropriate metric to use.

This study shows, for the first time, that CTOD can be used as a comparative metric for fracture toughness in atherosclerotic fibrous cap samples from individual patients. Collagen content is important in determining the mechanical behavior and response of fibrous caps in atherosclerosis. High collagen content is associated with a sharper crack tip, suggesting that collagen fibers may impede blunting of the crack tip. These results show that analyzing the stress in fibrous caps only provides part of the picture when considering the problem of plaque rupture. The strain, or deformation, which a fibrous cap is able to withstand is also an important aspect of plaque stability which is often ignored in the analysis of plaque rupture.

POSITIVE AND NEGATIVE CUES FOR MODULATING NEURITE DYNAMICS AND RECEPTOR EXPRESSION TO IMPROVE PERIPHERAL NERVE REGENERATION

Melissa R. Wrobel (1), Harini G. Sundararaghavan (1)

(1) Biomedical Engineering
Wayne State University
Detroit, MI, USA

INTRODUCTION

Following injury, axons have the capacity to regenerate at rates of 2-5 mm/day [1]. Yet, each year more than 200,000 peripheral nerve injury (PNI) patients require surgical intervention, contributing $150 billion to annual US healthcare costs [2]. Furthermore, as the injury exceeds a critical defect size of ~3cm, current treatments such as coaptation, autografts, and allografts are insufficient to achieve full functional recovery. Tissue engineered nerve guide conduits have emerged as a promising alternative to current treatments. However, most research groups focus only on delivery of growth promoting factors to encourage neurite regeneration, when combined positive *and negative* cues more faithfully recapitulate the *in vivo* environment during PNI repair.

Chondroitin sulfate proteoglycans (CSPGs) are extracellular matrix (ECM) molecules traditionally studied as barriers to regeneration in the central nervous system. However, CSPGs are also released by endothelial, inflammatory, and Schwann cells following injury in the peripheral nervous system. Few groups have explored the effect of CSPGs on retraction of peripheral neurons. Therefore, the objectives in this study were to quantify the effects of a characteristic CSPG, Chondroitin Sulfate A (CSA), on axon extension and retraction in real-time, to measure the ability of CSA to induce cell-substrate receptor expression in peripheral neurons using flow cytometry, and to investigate the ability of a novel biomaterial, derived from porcine spinal cord matrix (SCM), to improve neurite outgrowth in the presence of the inhibitory CSA. We hypothesized that CSPGs prime neurons for growth by inducing the upregulation of receptors, especially of the Syndecan family, and we are interested in exploiting this property as part of a PNI repair strategy.

METHODS

Spinal Cord Matrix Isolation: Our novel adhesive substrate was derived by isolating proteins from frozen, closed herd porcine spinal cords. Cords were disinfected, washed, digested in 0.2M acetic acid, then salt precipitated and lyophilized for the final product. Dried matrix was dissolved in acetic acid for the following cell experiments.

Cell Culture: Dissociated chick embryo dorsal root ganglion (DRG) neurons were plated (6000 cells/cm^2) in a 24-well tissue culture plastic plate coated with either 5 μg/cm^2 spinal cord matrix (SCM, experimental condition) or laminin (LAM, positive control) via adsorption or left uncoated (denoted TCP, negative control). Neurons were cultured for 2 days in serum free media (SFM) supplemented with 50 ng/mL nerve growth factor (NGF) and either with (+) or without (-) 10 μg/mL Chondroitin Sulfate A (CSA).

Time Lapse and Fluorescence Microscopy: Neurite dynamics were recorded using a Nikon inverted microscope with a micro-incubation chamber (37C, 5% CO_2). At 48 hours, cells were fixed (4% paraformaldehyde) and stained with anti-neurofilament and 4',6-diamidino-2-phenylindole (DAPI) to visual neurites and nuclei, respectively.

Video and Image Analysis: Final neurite lengths were measured from fluorescent micrographs and average neurite extension and retraction rates (μm/min) and retraction frequency (%) were measured from the time lapse videos. Neurite length was measured as a straight line from the center of the neuron cell body to the neurite tip. The change in neurite length between each video frame was used to determine if the neurite was actively extending, retracting, or remaining unchanged/ stalled ($< \pm 5$μm). To analyze frequency of retraction, the three types of neurite movement were then reported as percentages of a given neurite's total movements. All measurements were analyzed with ImageJ.

Flow Cytometry: Flow cytometry was used to determine the effect of CSA on Syndecan-3 (SYN-3) receptor expression in the DRG neurons (protocol adapted from [3]). Briefly, cells were cultured on TCP in SFM with NGF and 10 μg/mL CSA, as above. After 48 hours, neurons were detached from the plate using Accutase. The cell suspension was washed, fixed, and incubated in an anti-receptor antibody against

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

SYN-3 followed by a fluorescent secondary antibody. Samples were analyzed using an Attune Acoustic Focusing Cytometer. Neurons cultured without CSA were used to determined basal expression levels of SYN-3. Syndecan receptor expression levels are reported using fluorescence intensity histograms and the median fluorescence intensity (MFI) normalized to cells that were not exposed to CSA using the equation:

$$(MFI^{+CSA} - MFI^{-CSA})/MFI^{-CSA} \times 100\% \quad (1)$$

where MFI^{+CSA} is the median fluorescence intensity of the treated cells and MFI^{-CSA} is the median fluorescence intensity of the untreated cells.

Statistical Analysis: Sample means were compared using ANOVA and Fisher's LSD post hoc analysis. Data is reported as mean ± standard error with statistical significance $p<0.05$, unless noted.

RESULTS

Final neurite lengths were significantly reduced in the presence of the CSA for neurons grown on all substrates (*). However, neurons grown on SCM with CSA were significantly longer then all conditions except LAM-CSA and SCM-CSA (#), including those cells on TCP *without* CSA treatment, suggesting that our matrix promotes neurite growth even in the presence of a soluble inhibitor. Summarized results and example fluorescent micrographs shown in Figure 1A and 1B.

Neurites spent an average of 17.7 ± 2.8% of their "time" (meaning of the video frames) retracting for all culture conditions tested ($p = 0.22$). However, neurons cultured on the SCM spent significantly more time actively extending, complemented by a significant decrease in the time the neurites spent stalled/unmoving, compared to both control substrates. This trend was maintained for conditions with and without the CSA. A complete summary of neurite movements for cells grown in each of the six culture conditions is presented in Figure 1C and 1D.

Average neurite extension and retraction rates were also measured from the time lapse videos. Extension rates (range: 0.87-1.00 μm/min) were statistically similar between all six experimental conditions ($p = 0.19$) Surprisingly, however, neurites grown on the SCM had significantly increased retraction rates compared to the two control substrates even though these cells had the longest final neurite lengths overall. These results suggest that significantly increased outgrowth on the SCM over both controls (fluorescence microscopy result) can be attributed to the neurites' increased extension frequency over time spent stalled (video microscopy result) rather than changes in neurite growth rates.

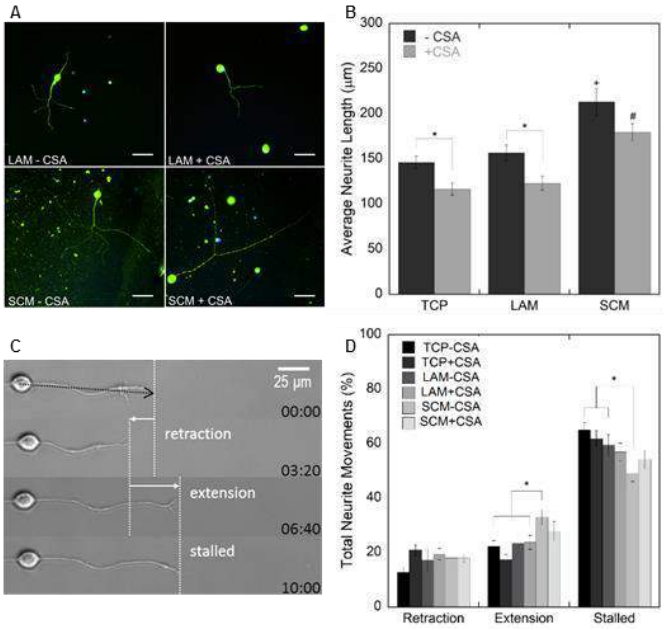

Figure 1. (A) DRG neurons stained with anti-NF (green) and DAPI (blue). Scale bars = 50 μm. (B) Quantified neurite outgrowth after 48 hours. $p<0.05$; $n>95$ neurites per condition. (C) Time lapse video stills illustrate the three types of neurite movements analyzed. Time in hh:mm. (D) Quantification of neurites' time spent extending, retracting, or stalled as a percentage of the neurites' total movements. * $p<0.05$; $n>18$ neurites per condition.

Next we investigated the influence of CSA on SYN-3 receptor expression using flow cytometry. The results revealed a 21.5 ± 7.6% increase in SYN-3 expression for the neurons treated with CSA compared to the untreated controls ($p=0.037$; unpaired t-test) indicating that SYN-3 receptors were significantly influenced by the presence of the CSA. Figure 2 contains a representative fluorescence intensity histogram showing increased SYN-3 expression for CSA-treated cells as evidenced by the peak shift.

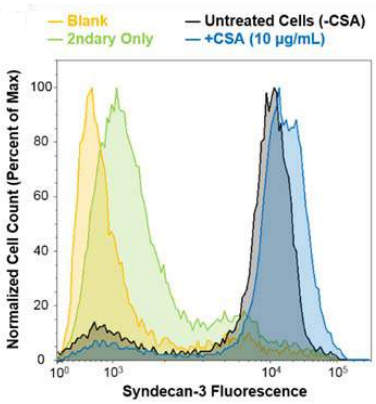

Figure 2. Increased expression of SYN-3 receptors on CSA-treated DRG neurons at 2 days (n=6).

DISCUSSION

In this study, we have demonstrated the effectiveness of porcine spinal cord matrix as an adhesive substrate for peripheral nerve outgrowth particularly for overcoming inhibition by chondroitin sulfate using time resolved and quantified retraction data. Additionally, this was the first look at the influence of a CSPG on syndecan receptor expression in one of very few flow cytometry studies with chick embryo DRG neurons. Furthermore, the CSA-induced upregulation of SYN-3 receptors elucidates at least one positive role for Schwann cell deposited CSPGs following PNI. We have hypothesized several mechanisms by which the upregulated receptors could mediate the improved outgrowth observed on the SCM. First, we speculate that the upregulated syndecans bind to sulfated glycosaminoglycans present in the SCM, allowing extending neurites to maintain strong adhesion to the substrate without saturating other key binding receptors. Secondly, the CSA-induced syndecans could act as co-receptors for the binding of integrins mediating improved focal adhesion formation. Finally, the increased syndecan receptors could stimulate neurite outgrowth by sequestering NGF in the media at the cells' surface.

Other studies have used CSA specifically as an inhibitory molecule in the study of axon behavior. Unfortunately, those studies typically look at blocking the CSPG's effects pharmacologically through enzymatic degradation or downstream signaling inhibitors. We propose that these methods may be counteractive for treating PNI because they would alter the CSA-syndecan response measured here and ultimately may alter the cells ability to bind to ECM well during regeneration. In the future, we propose to exploit CSPGs, coupled with the growth-permissive SCM, as part of tissue engineered scaffold that could potentially direct and accelerate neurite outgrowth better in large nerve gaps than current popular strategies.

INTRODUCTION

Although tendons are important in mediating movement, the cellular and molecular processes governing tendon formation remain largely unknown. Studies of gene function in tendon have been severely limited by the absence of a standard *in vitro* system to facilitate experiments that combine multiple mutations, physical manipulations and nimble gene mis-expression strategies. To address these limitations, we adapted a method from the Kadler lab [1] for generating 3D tendon-like structures for use with mouse embryonic cells, thereby harnessing the strength of mouse genetics for *in vitro* studies. Using this model, we induced tenogenic differentiation of mouse embryonic fibroblasts (MEFs) by TGFβ supplementation, and optimized parameters to direct *in vitro* recombination of conditional mutant cells using an adenovirus encoding Cre recombinase (AdCre). Using Smad4 flox/flox MEFs as a proof of concept study, we demonstrated efficacy of our optimized platform for testing gene function and showed that while TGFβ-induced proliferation depends on downstream Smad signaling, the tenogenic effects of TGFβ appear independent of Smads.

METHODS

For all studies, the ScxGFP tendon reporter [2] was used in all mouse lines to enable cell sorting and visualization of tenogenesis. Mouse embryonic fibroblasts (MEFs) are a heterogeneous population and encompass cells from multiple lineages. In preliminary studies, we were unable to generate constructs using all the cells as isolated. Therefore, to obtain cells with high tenogenic relevance, MEFs were generated from ScxGFP embryos and sorted by FACS following a single 20hr pulse of 20ng/mL TGFβ2 (to re-induce GFP expression in responsive cells, ~45%). Sorted MEFs were further expanded (2-3 passages) before use. To fabricate constructs, custom plates were prepared as in [1] (**Fig 1**). Briefly, Sylgard was cured in 6-well plates and two suture segments pinned ~10mm apart. In each well, sorted MEFs were seeded into fibrin gel at 750K per construct as a continuous layer and maintained in DMEM with 10% FBS, 1% PS and 200 μM ascorbic acid. Gels were allowed to contract for 7-14 days until a linear construct had formed (T0) and subsequently cultured for an additional 10-14 days (T10-14). In Study 1, we characterized wild type (WT) constructs in the presence or absence of 10 ng/mL TGFβ2. Preliminary studies showed optimal tenogenesis with minimal chondrogenesis when TGFβ2 was introduced after T0. In Study 2, MEFs from Rosa TdTomato (RosaT) Cre reporter embryos and Scx f/f; RosaT embryos were used for dosage and timing studies to optimize recombination using an adenovirus for Cre recombinase (AdCre, 2 day incubation). In Study 3, recombination of Smad4 f/f; RosaT MEFs was subsequently carried out using MOI 100 AdCre added prior to construct formation (T-14) and 10 ng/mL TGFβ2 added after construct formation (T0 to T14) (**Fig 1**).

RESULTS

Study 1: In the absence of TGFβ2, control MEFs spontaneously re-expressed ScxGFP, which had been lost with expansion after sorting. MEFs cultured in TGFβ2 exhibited a more elongated, fibroblastic morphology compared with controls, aligning in the direction of tension. TGFβ treatment also increased construct size. Interestingly, while ScxGFP+ cells were uniformly distributed in controls, ScxGFP+ cells were localized in the outer regions of TGFβ constructs. Because DAPI staining showed fewer cells in the central regions, we evaluated apoptosis by TUNEL, which surprisingly revealed the presence of apoptotic cells in control but not TGFβ2 constructs. Cell counts of DAPI stained nuclei further confirmed a dramatic loss of cells from T0 to T14 in control constructs, while TGFβ2 treatment improved cell number (**Fig 2**).

Study 2: Increasing concentrations of AdCre resulted in increasing numbers of Tomato+, recombined cells. Functional recombination was supported by PCR showing increasing amounts of Scx-/- DNA, indicating generation of null cells. Using MOI 10, we found that AdCre added at T-14 resulted in uniform distribution of Tomato+ cells; however, AdCre added at T0 resulted in recombination only at the periphery (**Fig 3**). Using optimized parameters of MOI 100 dose and T-14 timing, we found that constructs can be generated with high numbers of recombined, labeled cells with minimal toxicity (not shown).

Study 3: Since all canonical TGFβ signaling is mediated by the Smad4, we deleted Smad signaling using AdCre as a proof of concept study to test the efficacy of our system for interrogating gene function. Both WT and Smad4 Mut groups formed viable constructs within 14 days and transverse sections at T0 showed that WT and Mut constructs were indistinguishable (not shown). Interestingly, Smad4 Mut constructs failed to grow in response to TGFβ2 stimulation, indicating that the proliferative activity of TGFβ2 in this context is likely mediated by Smad signaling. However, ScxGFP expression was enhanced in Mut-TGFβ2 compared to Mut controls, and the peripheral cells were organized circumferentially around the construct, a pattern which was also observed in WT TGFβ2 constructs. TEM imaging of T14 constructs showed that collagen fibrils were relatively homogeneous within each group, indicative of an immature matrix phenotype, however fibril density appeared higher in TGFβ2 treated groups (not shown). Quantification of fibril diameter revealed increased diameter with TGFβ2 for both WT and Mut groups relative to controls. Interestingly, while control Mut fibrils were smaller in size compared to control WT, Mut-TGFβ2 fibrils were significantly larger compared to WT TGFβ2 fibrils (**Fig 4**). **Collectively, this data suggests that while the proliferative effect of TGFβ depends on Smad signaling, the tenogenic effects of TGFβ treatment may be independent of Smad.**

DISCUSSION

In this work, we developed a system using existing technologies to study gene function in an *in vitro* model of tendon formation, with Smad4 as a proof of concept case study. The use of conditional cells allows control over the timing and extent of recombination through AdCre. While AdCe activity is transient, genetic deletion by Cre is specific and permanent, enabling long-term studies that would not be possible using siRNA silencing. The presence of the RosaT reporter allele to label cells also facilitates studies of interactions between WT and mutant cells. Our results suggest that the tenogenic activity of TGFβ (which has been widely reported [3-5]) may be independent of Smads; however additional data such as tendon/cartilage marker expression, biochemical content, and mechanical properties will be required to confirm this hypothesis and is the focus of ongoing studies.

INTRODUCTION

Interim lower leg prosthetics are important since they allow amputees to begin rehabilitation before receiving a definitive prosthetic. This allows patients to return to a normal walking gait in a relatively short amount of time. Changes proposed by the Durable Medical Equipment Medicare Administrative Contractor (DME MAC) for Jurisdiction A, NHIC Corp, to Medicare's Lower Limb Prosthesis Plan (LCD DL 33787), would eliminate coverage for the interim prosthetic.[1]

Physical therapists (PTs) have identified the high cost of prosthetic legs as barrier to their access, and expect delays to a patient's rehabilitation. Contemporary prosthetics are expensive because each is created individually to match its intended patient, and often outfitted with microprocessors and hydraulics to enable ankle actuation. In order to prevent the cost of these necessary prosthetics from being transferred to the patient, PTs require a new prosthetic that could be owned by the clinic and used for many patients. For this reason, the engineering and PT departments at the University of Mount Union are collaborating to design a new lower leg interim prosthetic.

The clients for this project (Century Oak Care Center, Cleveland, OH) would like a prosthetic leg that could be adjusted to fit below-the-knee amputees ranging in height from 147 cm (4'-10") to 183 cm (~6') and in weight from 68 kg (150 lbs.) to 160 kg (~350 lbs.). Multiple prosthetic legs will be used in a therapy gym where walking will be the most rigorous activity. Afterward, the device with be sanitized, and fit onto the next patient for immediate use. As additional constraints, this device must be lightweight, withstand the loading and wear from use, and the prototype must cost less than $1000.

PRODUCT DESIGN

The design of the prosthetic was simplified to three main components: the socket interface, pylon, and articulating ankle (Fig. 1a). A scoring matrix was used to select the best design concepts measured by the complexity, durability, marketability, adaptability to different patients, and the ease of sanitation between patients use. Since the prosthetic will be adjustable, its height will vary from 42 cm to 53 cm. For an average person (5'-10") with an amputation 15 cm below the knee, the device would have a height of approx. 52 cm and weight of 1.9 kg (~4.3 lbs.). This compares reasonably to the weight of an average limb, which is 5.8% of a person's overall body weight, and to other prosthetics, which weigh between 4-6 lbs.[2]

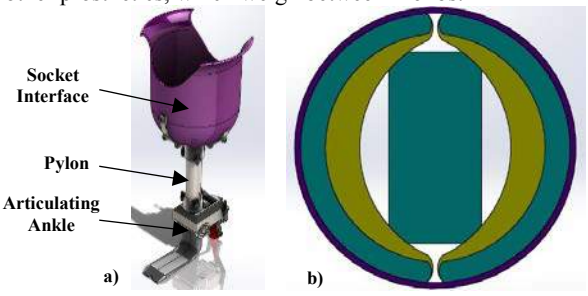

Figure 1: The interim prosthetic (a) consists of three components. The top view (b) shows the arrangement of the air bladders both empty (blue) and inflated (yellow).

Socket Interface: The socket will be formed by molding thermoplastic around the cast of a generic residual limb, and lined with a series of three 9"x5" neoprene air bladders along the inner wall (Fig. 1b). These bladders will be sewn together in a vinyl lining, and attached to the thermoplastic with Velcro strips. This simple attachment will allow the socket lining to be removed for sanitation between patients. The

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

bladders will be inflated to different volumes by connecting a small hand pump to tubes extending through the cast, allowing the prosthetic to fit residual limbs of different sizes, and accommodate swelling during healing.

The maximum pressure experienced by the air bladders was estimated by simplifying the limb-bladder interface to two spheres in contact. For this analysis, elastic moduli of 60 kPa and 15 MPa were assigned to the residual limb and the air bladder, respectively, and a compressive force of 1280 N was applied[3]. This analysis yielded a maximum pressure of 165 kPa at the interface, which is 53% lower than the average pain threshold for a residual limb of 350 kPa[4]. Using a tensile strength of 3.45 MPa for the neoprene air bladders, the factor of safety was calculated to 1.3.

A stainless steel socket crown was designed to disperse the patient's weight across the socket. Using finite element analysis (ANSYS, Canonsburg, PA), a force of 778 N was applied to the bottom of the crown, with the bolt holes of the crown fixed in all directions. This analysis resulted in a factor of safety of 1.5 for the socket crown, and 15 for the thermoplastic.

Pylon: Since the pylon will act as the primary transmitter of force to the ankle, a prefabricated titanium pylon (Streifeneder USA, Tampa, FL) was selected to support 160 kg.

Changing the pylon will provide the means for adjusting the height of the prosthetic. Pylons will range from 6.5 cm – 17 cm, to accommodate a wide-range of users of different height and amputation location. As an example, a 9.5 cm pylon would be used for a 1.8 m patient, whereas an 8.0 cm pylon would be used for a 1.5 m patient.

Articulating Ankle: The ankle was designed with purely mechanical components to mimic a normal walking gait. Striking of the silicone heel column will release the foot from its locked position. Two springs (2.0" length, 0.375" OD, and 0.048" wire) will force the foot into contact with the ground. The combination of three-pin aluminum gears (~2.5 cm in diameter and 2.5 cm thick) in conjunction with a locking-ratchet mechanism (Fig. 2) allows the ankle to rotate in one direction. When the foot returns to its initial joint angle, the rotation of foot becomes locked for the remainder of the cycle (Fig 3).

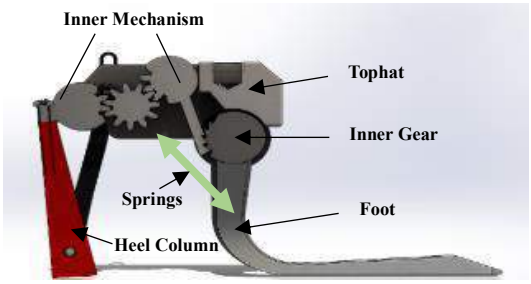

Figure 3: The gear-based ratchet system allows the joint to rotate during gait.

The ankle was designed to handle a maximum force of 778 N. Using a finite element analysis, a load of 778 N was applied to the top section of the ankle housing, and the gear insertions were fixed. Within the assembly, the minimum factor of safety was calculated to 2.5.

BUDGET & MARKET ANALYSIS

It is estimated that by 2030, there will be nearly 58,000 amputations per year in the United States stemming from the geriatric population alone[5]. Most of these patients will not receive a definitive prosthetic until 4 to 12 months after their amputation[6]. This delay is caused by the individual patient's activity level, weight-bearing tolerance, and limb shrinkage[5]. If the proposed changes to the Medicare benefit by the DME MAC are approved, PT clinics will need an interim prosthetic device to facilitate rehabilitation.

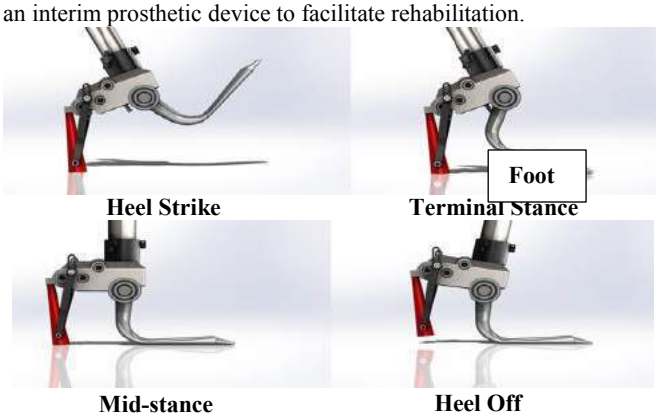

Figure 3: During the normal gait of the prosthetic, the force from the heal strike will unlock the ratchet mechanism. The ankle will articulate until locking at mid-stance.

One of the primary goals of this project was to offset increases in cost to both the amputees and rehabilitation clinics. To this end, this device was designed to be purchased by and housed at rehabilitation centers. In this scenario, the device would be used by many patients, eliminating the need for insurance to cover individual interim prosthetics. The adjustable socket interface also eliminates the need for new socket casts over time.

From communication with PTs, it was determined that rehabilitation centers would be willing to spend between $1500 and $2500 for this prosthetic device. The materials to create a working prototype cost $905, with the articulating ankle accounting for 56%, the socket interface 25%, and the pylon subassembly 19% of this cost. Once the prototype is completed and tested, a more in depth market analysis will be performed. The cost of manufacturing and machining expenditures will be explored to determine an acceptable retail price that is both profitable and affordable. As a preliminary estimate, these devices would be priced at approximately $2200.

CONCLUSION

As designed, this new interim prosthetic leg satisfies all of the original criteria specified from the client. The socket interface lined with air bladders and interchangeable pylons, allows the device to be used by multiple patients, and the articulating ankle will allow for a functional walking gait for patients up to 160 kg (~350 lb). Given the potential changes to Medicare coverage and the growing rates of amputations in the geriatric population, this device could be a marketable product once completed.

ACKNOWLEDGEMENTS

We would like to thank the Century Oak Care Center for identifying the need for this project, and Barry Minor of the Hanger Clinic in Alliance, Ohio for providing insight into how prosthetics interact with patients.

INTRODUCTION

Stroke is the second leading cause of disability affecting 5 million people globally per year [1]. The primary cause of adult disability is cerebral vascular stroke, from which more than 80% of survivors suffer hemiparesis in their upper limb. This form of partial paralysis often results in hand function impairments impacting the patient's ability to perform tasks of daily living such as grasping items, writing and indicating objects [2]. A common clinical approach for successful rehabilitation and recovery of motor function, after a brain injury, such as a stroke, is through performing highly repetitive tasks [3]. However, even after extensive rehabilitation, compromised hand function is likely a reality the patient must face. Nearly 66% of hemiplegic stroke patients fail to fully regain motor function in the paretic arm when evaluated 6 months post stroke [3].

The conventional repetitive rehabilitation training for stroke patients is performed with physiotherapists directly moving the affected hand. This large amount of physical interaction with physiotherapists results in a long and costly recovery process [3]. This method also does not provide accurate gauging of a patients progress as the manual therapy is highly subjective to the therapist's judgment of progress. Recently the introduction of robotic training systems, such as hand exoskeletons, may alleviate some of the difficulties associated with the manual physiotherapy methods. Robotic systems are capable of performing the necessary repetitive motions for successful rehabilitation without a large amount of therapist intervention.

Currently, literature hosts a number of exoskeleton systems for hand rehabilitation [3]. However these systems are largely experimental, high cost and inaccessible to clinicians and stroke patients. Our client identified the limitations of existing exoskeletal technologies. They requested our assistance in the development of a mechanical exoskeletal system capable of being 3D printed, and released open-source. The design must be able to be coupled with their existing electromyography control system for use in hand rehabilitation with clinical and potential take-home applications.

PRODUCT DESIGN

The exoskeletal system is comprised of two main systems; the first is the mechanical system, which was the primary focus of our design scope, and the electrical system which was developed by the client outside the scope of our work. Although beyond the scope of our design, it is important to note that the electrical system utilizes commercially available components including an Arduino microcontroller and electromyography sensors (EMGs) along with a LCD display and a push-button interface that allows the wearer to select and perform various grasping patterns.

The client required the mechanical system to be adjustable in size between the 5th and 95th percentile male hand, provide a minimum 90° of total flexion for each finger, have a built in safety mechanism to prevent possible injury, be compatible with their existing electronics system and provide minimal obstruction to the underside of the wearer's hand.

A Cable Actuated Rigid Body System (CARBS) was designed, using Solidworks CAD software, for direct export and ease of fabrication on a 3D deposition printer. It utilizes a 3D printable rigid body over-structure, worn on top of the patient's hand, which actuates each finger through the use of a two cable system (Figure 1). Its design allowed the removal of obstruction to the underside of the hand allowing the user's finger tips and palm access to cutaneous feedback when performing the repetitive tasks. The two cable system along with the rigid linkages create a biomimetic concept with the two cables simulating the flexor and extensor tendons of the finger while the linkages simulate the phalanges of the finger. Utilizing the client specified servomotor (HS-55, Hitec RCD) and a dual-groove pulley the linkage of each finger is able to be flexed by retracting the lower-flexor, cable and extending the upper-extensor, cable causing flexion of the device.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

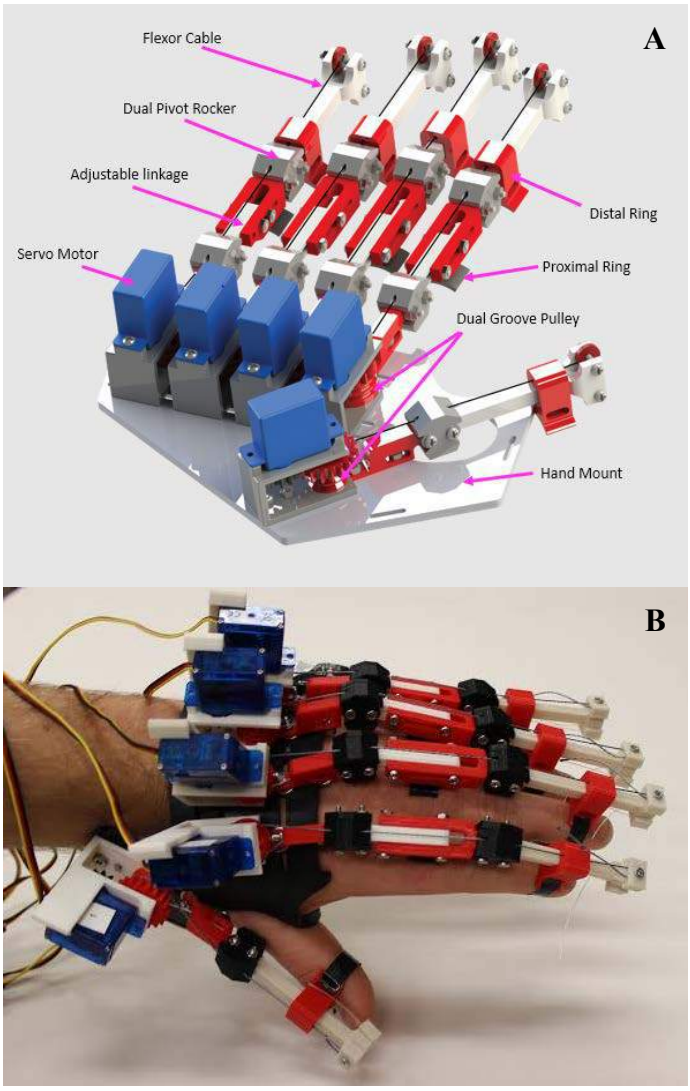

Figure 1: A) Cad Render of the Cable Actuated Rigid Body System (CARBS) with critical components identified. B) Prototyped system mounted to a user's hand.

To extend the linkages of the hand the extensor cable is retracted while the flexor cable is extended causing the device to open. The rotation of the device occurs at a dual pivoting rocker link which simulates the knuckles of the wearer's hand. The rocker links were designed with physical stops which limit total flexion of each joint in the finger to 60° flexion and 5° hyperextension. This results in a maximum total range of motion of 120° flexion and 10° hyperextension for each finger (2 rockers are used per finger, and 60° flexion/5° hyperextension for the thumb, 1 rocker is used for the thumb). To achieve movement of the user's digits distal and proximal rings were designed to mount into the finger linkages of the CARBS and attach to the wearers fingers via hook and loop straps. The distal and proximal rings provide two primary functions in the devices operation; the first is to transmit the movement of the CARBS into movement of the patient's digits and the second is to provide an arc length compensation for the device. Due to the separation of the CARBS' neutral axis and the neutral axis of the patient's digits, the distal and proximal rings were designed to translate longitudinally along the linkages to compensate for the difference in arc length changes during flexion of the CARBS and the hand.

To create adjustability in the device both the finger linkages and the hand mount were designed with sliding adjustment points. The finger linkages use a two pin and slot link which allows the distal rocker to be positioned on the wearer's finger such that when flexed it is located directly above the second joint of the finger. The hand mount grooves allow each of the finger linkages to be translated such that they can be centered along each of the fingers to ensure proper fitment. Using these two methods of adjustment the system is able to be fitted to 97% of the total population including and surpassing the original goal of the 5th to 95th percentile male hand.

BUDGET & MARKET ANALYSIS

Typically the costs of a rehabilitative device, like an exoskeleton, are not covered by a patient's benefits or insurance and the purchase is often times an out of pocket expense. The implications of high cost were addressed by our client prior to the development of the device and the intent is to release the product as a low cost, open source alternative in order to alleviate the financial burden of purchasing a r ehabilitative exoskeleton. As such, the desired cost of mechanical components was set to $500 CA. The complete budget when coupled with the client's electronics package was set to a maximum allowable cost of $1000 CA.

As an open-sourced technology the project was built with the intent of being accessible for free to any patient, and/or clinician. Consequently, the focus of the project was to minimize manufacturing cost as much as possible in order to ensure complete accessibility. The resulting manufacturing cost for the mechanical system was $91 CA. The client's completed electronics package was determined to have a cost of $291 resulting in a total cost of $382 for the complete exoskeletal device.

Through a study of existing exoskeletal devices it was determined that the only commercially available device offering similar functionality as our design has a cost in the range of $48,000 CA.[4] which makes our 3D printed open-source concept an accessible and highly cost effective alternative to existing technologies.

BIOMECHANICAL ANALYSIS OF KICKS IN SOCCER AND KICKS IN FOOTBALL

INTRODUCTION

Two of the most popular sports in the world are football and soccer. Both sports are similar in the fact that kicking is a main part of the sport. The two kicks are similar with a few differences. For the purpose of this study, the typical soccer kick starts with a curved approach toward the ball; this corresponds to a "free kick" during play. One can identify three steps during this approach: a long stride with the plant foot (non-kicking foot), a long stride with the kicking foot, and a long stride with the plant foot. After the ball is kicked, the kicking leg crosses the sagittal plane of the body instead of going straight. The kicking foot can make contact with the ball at different parts of the foot (top of the foot, near the medial arch, or the medial aspect of the heel) [1]. The football kick is used for either kickoffs or for field goals during the game. The most common football kick involves taking 3 steps back from the ball and then 2 steps to the left. The kicker then approaches the ball in a manner similar to that for the soccer kick following three steps but in a straight path; these three steps are identified by a short stride with the plant foot as a jab type step, a long stride with the kicking foot, and a long stride with the plant foot. After the ball is kicked the kicking leg continues its swing without crossing the sagittal plane of the body and following a curved path [2]. The kicking right foot can make contact with the ball only with the middle of the top of the foot.

The purpose of this study is to determine the differences in the two kicking styles and how they affect the kinematics of the kicking leg and trunk along with the effects of ground reaction forces on the plant foot.

METHODS

Three team members performed the kicks in a lab environment. A 10-camera Raptor-E motion analysis system and a synchronized force plate were used to collect kinematic and force plate data. Seventeen reflective markers were placed on each individual according to the Helen Hayes arrangement for the lower body [3]. In addition, two markers were placed on the most lateral point of the left and right acromia, respectively. A line joining the midpoint between these two points and the midpoint between the greater trochanters was used to define the trunk segment. The foot, shank, and thigh segments were defined according to [3]. Ankle, knee, and hip angles were then calculated. Also, trunk flexion-extension and left-right bending angles were calculated.

Each team member used their right foot to kick and their left foot as the plant foot. During each kick style the ground reaction forces (GRF) of the plant (non-kicking) foot were simultaneously collected and normalized with respect to body weight. Because the ball was simply used as a focus point rather than as part of the kicking motion, a foam block was used in place of a ball to prevent damage to the lab's camera system. For both kicking styles, the team member began by standing on the force plate next to the ball. The participant then took three steps backwards and two steps to the left to find their starting position. As discussed in the introduction, the team member moved directly towards the ball for the football kick and in a curved, sweeping path for the soccer kick. In both instances, the plant foot landed on the force plate next to the designated location of the ball.

Five phases can be identified in each kick: approach, pre-swing, connect, post-swing and recovery phases as portrayed in figure 1. The approach phase starts with the first step of the plant foot moving towards the ball and ends at the point where the plant foot lands on the force plate. As mentioned earlier, the approach phase entails the three steps as the kicker moves toward the ball and ends at the instant the kicking leg starts its' wind up. The preswing phase encompasses the wind up of the kick and ends just before contact with the ball. The connect phase ends at the point where the kicking foot comes in contact with the ball; at this instant the kicking leg passes the plant leg.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The post-swing phase ends at the instant where the kicking leg finishes its ascent and the recovery phase ends at the instant where the kicking foot comes in contact with the ground.

RESULTS

Figure 1 depicts the five phases of both kicks. The results reported in tables 1 and 2 represent averages among the three team members. Table 1 lists the maximum average values for trunk flexion-extension and left-right bending. It also includes the maximum average values for hip flexion-extension and ab- adduction, and ankle plantar and dorsi-flexion for the kicking leg for both soccer and football kicks. It also includes the maximum and minimum knee flexion angles. Table 2 lists the maximum average values of the normalized (w.r.t. body weight) vertical, anterior-posterior, and medial-lateral components of the ground reaction forces of the non-kicking leg

DISCUSSION

Results show noticeable differences in the ground reaction forces (GRF) on the planted left leg with larger vertical and medial components during the football kick. A larger posterior component of the GRF was observed during the soccer kick. The larger GRF vertical component observed during the football kick suggests that this kick is more forceful overall when compared to the soccer kick. Also, the larger posterior GRF component on the planted leg observed during the soccer kick suggests that a more neutral-to-posteriorly-canted stance is required in the soccer kick than in the football kick. This further suggests that this posture when kicking the ball helps in improving the possibility of scoring a goal since a relatively smaller maximum reach height is required by the ball to score the goal.

The trunk was flexed more during the football kick than during the soccer kick with maximum flexion occurring during the post swing phase of the kick. On the other hand, the trunk was extended more during the soccer kick with maximum extension occurring during the connect phase of the kick.

The right hip (hip of kicking leg) was abducted and adducted more during the soccer kick with the maximum abduction and maximum adduction occurring during the connect phase and the post-swing phase, respectively. On the other hand, the ankle of the kicking foot was plantar flexed and dorsi flexed more during the football kick with maximum plantar flexion and maximum dorsi flexion occurring during the connect phase and the pre-swing phases, respectively.

The large plantar flexion angles observed during the football kick during the connect and post swing phases confirms the need for a more pointed toe during the kick; doing so would help to increase proper contact with the 1st metatarsal for maximum energy transfer as detailed in [2]. Also the large hip abduction and adduction angles observed during the soccer kick confirms that an increased amount of leg cross-over is used during a soccer kick, which is utilized more in the "sweeping" style of soccer kick and when trying to curve the ball [1]

Future work includes involving college players in this study to determine how their performances can be improved.

INTRODUCTION

Post-traumatic joint stiffness (PTJS) due to elbow injury is a challenging clinical problem due to the anatomical and biomechanical complexity of the elbow [1,2]. Injury to the elbow disturbs joint congruity and often leads to functional impairment due to tissue contracture and stiffness. While it remains unclear how each of the peri-articular joint structures (e.g. ligaments, tendons, muscles) are affected in PTJS, changes to the capsule have been consistently implicated as a contributing factor [3,4,5]. Biologically, elbow capsule tissue in human PTJS showed increased cellularity, thickness and disorganized collagen [3,4,6,7]. Increased production and abnormal organization of collagen was also observed in posterior knee capsules in a rabbit model of PTJS [8].

Recently, our group developed an animal model of PTJS in the rat elbow, that established a model system to enable investigation of clinical injuries specific to the elbow [9]. Biomechanical results in our model mimicked symptoms common to human PTJS flexion-extension and pronation-supination (i.e. decreased range of motion and neutral zone length), which persisted long-term following joint remobilization, demonstrating a permanent contracture within the elbow. However, we have not examined biological changes in our model to determine if they match what is observed in human patients. The purpose of this study was to evaluate the histological properties of the anterior capsule and determine if these changes correlate with the altered mechanics in elbow PTJS.

METHODS

In this IACUC approved study, male Long-Evans rats (300-343g) underwent surgery to replicate soft tissue injuries seen in subluxation/dislocation, namely an anterior capsulotomy and lateral collateral ligament transection [9]. Injured limbs were immobilized for six weeks, after which half of the animals were sacrificed (immobilization only or IM), while the other half were remobilized with unrestricted cage activity for six weeks (immobilization-remobilization or IM-RM) [8]. Control animals were allowed unrestricted cage activity.

Elbow joints were subjected to mechanical testing using protocols described previously for flexion-extension (F-E) [9] and pronation-supination (P-S) [10] (F-E: n=10-18/group; P-S: n=6-13/group). Force and displacement were converted to torque and angular position and loading curves were analyzed for total ROM and NZ length (angular span of functional range). After mechanical testing, elbow joints (n=3/group) were prepared for histological assessment as described previously [9]. Sagittal sections were cut and stained with hematoxylin and eosin (H&E), toluidine blue (TB) and picrosirius red (PR).

A blind analysis of the anterior capsule was performed for the H&E slides by a musculoskeletal pathologist and semi-quantitative scores were assigned for biological characteristics of interest [9]. Capsule thickness was measured and reported semi-qualitatively since these values can vary for sections cut at different depths: thickness values were averaged across each group, normalized by the control capsule thickness and converted to a symbolic grading scheme for comparison between groups. Anterior capsules of the TB and PR sections were analyzed qualitatively for cellularity, collagen density and debris (particles) within the synovial fluid.

RESULTS

In flexion-extension, injured limbs demonstrated significantly decreased total range of motion and neutral zone length compared to control and contralateral (CL) limbs for both IM and IM-RM (Figure 1). In pronation-supination, injured limbs showed significantly decreased total range of motion and neutral zone length compared to CL for both IM and IM-RM (Figure 1).

H&E staining revealed an increase in the amount of adhesions, cellularity and thickness of the IM capsule compared to control and CL

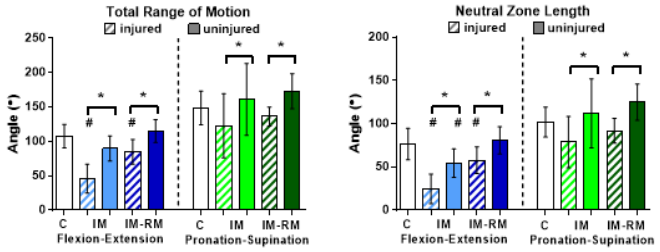

Figure 1: Persistent significant decrease in joint mechanics from immobilization (IM) to immobilization-remobilization (IM-RM) for both flexion-extension and pronation-supination. (average ± standard deviation, C = control, # = different from control, * = different from contralateral limb, $p < 0.05$)

Table 1: Histological evaluation of H&E stained anterior

	Adhesion	Cellularity	Inflammation	Thickness	Vascularity
Control	-	+	-	-	+
IM	+	++	-	++	+
IM CL	-	+	-	-	+
IM-RM	+	+	-	+++	+
IM-RM CL	-	+	-	-	+

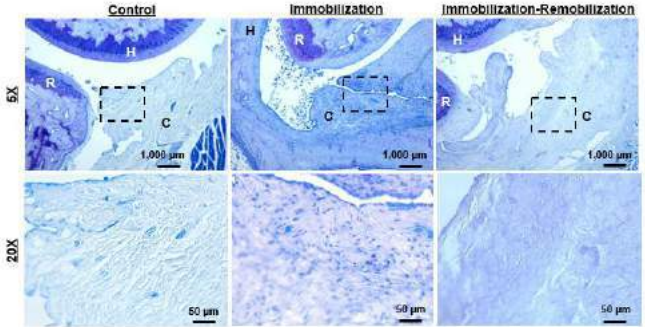

Figure 2: Representative sagittal histology sections for toluidine blue at 5X and 20X. (H = humerus, R = radius, C = capsule)

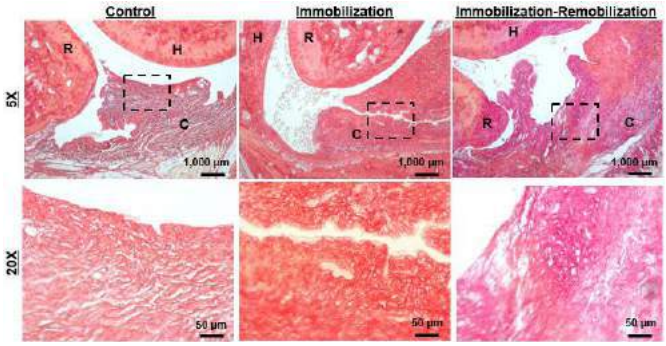

Figure 3: Representative sagittal histology sections for picrosirius red at 5X and 20X. (H = humerus, R = radius, C = capsule)

(Table 1). IM-RM capsule also exhibited increased adhesions and thickness compared to control and CL; however, cellularity decreased while the thickness increased from IM to IM-RM. Signs of inflammation were not present in any group; however, this is likely because of the relatively late time points evaluated.

TB staining demonstrated IM anterior capsule had a large increase in cellularity and debris within the synovial fluid cavity compared to control (Figure 2). IM-RM anterior capsule not only showed decreased cellularity compared to IM but also had a lower number of cells than the control.

PR staining showed an increase in collagen density for both IM and IM-RM anterior capsule (Figure 3). While the collagen density was increased continuously throughout the entire IM capsule, the IM-RM capsule had regions of higher and moderate density. Both TB and PR staining demonstrated an increase in debris in the synovial fluid cavity for IM, followed by a decreased in debris for IM-RM.

DISCUSSION

This study shows that our rat elbow model of PTJS exhibits biological changes similar to the human condition, including an increase in collagen density, capsular thickness and a temporary increase in cellularity as the total range of motion and neutral zone length remains significantly decreased from IM to IM-RM.

Human capsule tissue exhibits hypercellularity with the development of PTJS [3,5], which was evident in capsule of IM animals in this study. The IM-RM capsule demonstrated a return to normal levels of cells following remobilization, similar to reports by Doornberg et al. in contracted human elbows [11] and by Abdel et al. in a rabbit knee contracture model [12], where the number of myofibroblasts initially increased then decreased at longer times. While Hildebrand et al. found that myofibroblasts and mast cells remained elevated from the acute to chronic stage in their rabbit knee contracture model, the cellularity did not increase past four weeks [5].

Since mechanical parameters (i.e. total and functional range of motion) remain significantly impaired long-term, yet cellularity returns to normal levels, these results indicate that cells are not responsible for the permanently altered joint mechanics. Instead persistent contracture appears to be caused by the increased and disorganized collagen. The initial increase in cellularity may lead to increased collagen and capsular thickness, but a lack of increasing vascularity (Table 1) may then contribute to the decreased cell number. Both IM and IM-RM capsules exhibited disorganized collagen and larger capsular thickness, consistent with previous work in human elbow capsule and rabbit knee models of PTJS [4,7,8], which may contribute directly to altered joint mechanics. While this work focused on the capsule, we are currently investigating how the other peri-articular tissues are contributing to joint dysfunction.

In conclusion, this study shows that our animal model of PTJS mimics biomechanical and biological features of the human condition, validating its use in evaluating the pathogenesis of the PTJS. The increased disorganized collagen and thickness likely contribute to persistent decrease in total range of motion and neutral zone length in both F-E and P-S. Future work evaluating genetic expression and collagen content will help identify the specific biological change in the elbow responsible for contracture, so better prevention and treatment strategies can be developed.

MODELLING CORNEAL MECHANICAL BEHAVIOR WITH A BIPHASIC TRANSVERSELY ISOTROPIC POROVISCOELASTIC CONSTITUTIVE MODEL

H. Hatami-Marbini (1)

(1) Department of Mechanical & Industrial Engineering, University of Illinois at Chicago, Chicago, Illinois 60607

INTRODUCTION

The cornea is a hydrated soft tissue which transmits the incident light while acting as a resilient barrier to the mechanical forces. We have recently investigated the mechanical behavior of the cornea using unconfined compression experiments [1]. In this experimental technique, a circular specimen is immersed in a bathing solution and is compressed between two rigid platens. Over the past few decades, different types of mixture theories have been proposed to curve-fit the experimental measurements and subsequently determine the material properties [2]. The simplest model, the linear isotropic biphasic theory, was proposed in 1980 [3]. In this model, the tissue is assumed to be made up of a solid phase with linear elastic behavior and an incompressible viscous fluid phase. While the linear isotropic biphasic theory has been successfully used to describe the creep and stress-relaxation behaviors of various soft tissues, there is a substantial difference between the model predictions and unconfined compression experimental measurements of the corneal tissue [3,4].

The stromal layer, which is made up of thin parallel-to-the-surface collagen lamellae embedded in a proteoglycan matrix, is primarily responsible for the mechanical strength of the cornea. It has been well-developed that the stromal microstructure is transversely isotropic [1]. Because of this particular microstructure, it is expected that the parallel-to-the-surface properties (in plane of material isotropy) to be different that those in the normal direction. Based on this observation, a linear transversely isotropic biphasic model was employed to analyze the unconfined compression experimental measurements. It was observed that this experimental and computational technique resulted in a relatively accurate estimate of the corneal out-of-plane modulus, in-plane modulus, and permeability coefficient as a function of thickness [1,4]. Nevertheless, it was also seen that the linear transversely isotropic biphasic theory could not fully curve-fit the experimental stress relaxation history in unconfined compression. Since the primary ingredients of the stromal layer are viscoelastic, the objective of the present work was to develop an analytical model which is able to account for the intrinsic viscoelasticity of the tissue constituents. For this purpose, a linear transversely isotropic poroviscoelastic theory was created by combining a viscoelastic material law with the transversely isotropic biphasic model. The predictions of the proposed model were compared against those of the linear transversely isotropic, viscoelastic, and cone-wise viscoelastic theory.

METHODS

In biphasic mixture theory, the tissue is considered as a binary mixture of an incompressible solid phase and an incompressible fluid phase. Therefore, the total stress can be written as [5]

$$\boldsymbol{\sigma} = -p\mathbf{I} + \boldsymbol{\sigma}^{vs} \tag{1}$$

where I is identity vector, p is the fluid pressure, and $\boldsymbol{\sigma}^{vs}$ is the stress vector of the solid phase. The intrinsic viscoelastic properties of the solid phase is described with an integral type viscoelastic model, i.e.

$$\boldsymbol{\sigma}^{vs} = \int_{-\infty}^{t} g(t-\tau)\mathbf{S}^{eq^{-1}} : d\boldsymbol{\varepsilon}(\tau) \tag{2}$$

where $\mathbf{S}_{eq}$ is the compliance matrix and g(t) is given by

$$g(t) = 1 + c\left(E(-t/\tau_1) - E(-t/\tau_2)\right) \tag{3}$$

where $E(x) = -\int_{-x}^{\infty} e^{-t}/t \, dt$.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

It can be shown that the governing equations of the biphasic model simplify to

$$\frac{\partial^2 \bar{u}_r}{\partial r^2} + \frac{\partial \bar{u}_r}{r\partial r} - \left(\frac{1}{r^2} + f\right)\bar{u}_r = \frac{f}{2} r \bar{\varepsilon}_{zz}$$
$$\frac{\partial \bar{p}}{\partial r} = \frac{s}{\kappa}\left(\bar{u}_r + \frac{\bar{r}}{2}\bar{\varepsilon}_{zz}\right) \quad (4)$$

where κ is the permeability coefficient, overbar denotes Laplace transformed quantities, s is the Laplace transform variable, f is expressed in terms of material coefficients [5]. The above equation can be solved for a circular button tested in an unconfined compression and obtain the closed-form solution for the radial displacement u_r and p in Laplace domain. The total compressive stress is given by

$$\bar{\sigma} = \frac{1}{\pi r_0^2}\int_0^{r_0} (-\bar{p} + \bar{\sigma}_{zz}) 2\pi r dr \quad (5)$$

which can be inverted back to the time domain using a numerical Laplace inversion algorithm.

In order to assess the model, unconfined compression experiments were conducted on porcine samples. Briefly, porcine eyes were obtained from a local slaughter house and corneal discs from the central corneal region were punched. An RSA-G2 machine (TA instruments, Delaware) was used to perform unconfined compression experiments. For this purpose, a compressive tare stress was used to determine the initial thickness of the samples and stress-relaxation tests were conducted by bringing the head down. A compressive strain of 5% with a strain rate equal to 0.1/s was used. In order to find the material constants and curve-fit the experimental data, a multidimensional curve-fitting was carried out.

RESULTS

It is first noted that the model proposed here reduces to the linear transversely isotropic biphasic theory by adjusting the material parameters [5]. Figure 1 shows a typical behavior of the porcine corneal stroma under unconfined compression. In this plot, the symbols show the total experimental reaction stress and the lines show the numerical model predictions. The theoretic fits were obtained using different constitutive models, i.e. linear isotropic, transversely isotropic, isotropic viscoelastic and transversely isotropic viscoelastic models. It is seen that the present model resulted a significant improvement in curve-fitting the unconfined compression experiments ($R^2 = 0.99$).

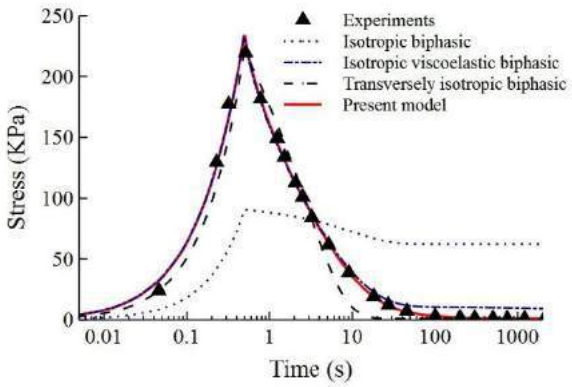

Figure 1: The unconfined compression response of the cornea and the theoretical curve-fits obtained from the linear isotropic biphasic, isotropic viscoelastic biphasic, transversely isotropic biphasic, and transversely isotropic viscoelastic (present model) theories. The horizontal axis is plotted in logarithmic scale to depict a better comparison between different models.

DISCUSSION

The primary objective of the present work was to create a linear transversely isotropic biphasic poroviscoelastic model for the mechanical behavior of the corneal tissue in unconfined compression and investigate whether this model would be able to give a better representation of the experimental data. We have previously shown that the linear isotropic biphasic model cannot represent the unconfined compression response of the cornea [4]. Because of the transversely isotropic microstructure of the corneal stroma, a linear transversely isotropic biphasic model was used in a recent study to model the stress-relaxation of cornea in unconfined compression experiments [4]. Nevertheless, despite the significant improvement, it was observed that even this model was not able to fully capture the experimental stress relaxation behavior. Since collagen fibrils and the proteoglycan matrix are both viscoelastic, we hypothesized that a linear transversely isotropic poroviscoelastic model should give a better theoretical representation of the constitutive behavior of the corneal tissue and subsequently a more accurate assessment of the material properties. This model includes the contributions from both the fluid flow and the intrinsic viscoelasticity to the overall stress-relaxation under unconfined compression. It is noted that although the poroviscoelastic model formulation presented here has nine material constants: five elastic parameters, one permeability coefficient, and three viscoelastic parameters, the shear modulus does not enter the formulation in modelling the unconfined compression experiments and needs to be determined separately [6]. In Figure 1, the behavior of the cornea under unconfined compression is shown. It is clear that the proposed model resulted in a significant improvement over other models. It also needs to be mentioned that the model predictions are comparable with those obtained using a biphasic-CLE-QLV model [7] (Results not shown).

INTRODUCTION

Surgical bioprosthetic valve experience has demonstrated the importance of proper leaflet coaptation, the absence of which could change the leaflet kinematics and lead to early structural deterioration of the leaflets [1, 2, 3]. The leaflets are known to coapt nominally in a circular configuration. Finite element analyses (FEA) of elliptical configurations of heart valve frames have shown an increase in leaflet stresses and strains compared to circular configuration [4, 5, 6]. We also observed leaflet coaptation differences with the elliptical configurations, in particular the existence of sagging versus stretched leaflets in the same valve configuration [5, 6]. Leaflet coaptation patterns have also been shown computationally to influence fatigue damage [7]. To better evaluate the relative performance of nominal, sagging, and stretched leaflets, we conducted accelerated wear testing (AWT) using circular and elliptical valve configurations.

METHODS

Accelerated Wear Testing: AWT was conducted on six 25 mm bovine pericardial surgical aortic valves (Model 2800 from Edwards Lifesciences) using Dynatek Dalta's M6 Durability Tester. Two samples were tested in a circular configuration as controls and four were tested in annularly distorted elliptical configurations that are well beyond the design requirements for a surgical valve. Two of the four elliptical valves had a commissure on the major axis (EMaj), and the remaining two had a commissure on the minor axis (Emin, see Figure 1). Average aspect ratios (AR: major to minor axis ratio) of two valves were 1.04±0.02 for Circ, 1.35±0.01 for EMaj, and 1.27±0.05 for Emin configurations. These aspect ratios were chosen because of potential differences between elliptical configurations in deformable valves, but neither has been shown to be applicable to a non-deformable surgical valve such as the test valve in the clinical setting. AWT was conducted in 0.9 % saline solution with 0.02% sodium azide bacteriostat at 37^{o}C for 123 million (M) cycles at rates ranging from 980 to 1066 rpm. Differential pressures were taken using Endevco pressure transducers. Although the minimum target differential pressure required was 100 m mHg per ISO 5840-3 standard, the mean differential pressure in the six chambers ranged from 129 to 194 mmHg, with a mean percent cycle time above target ranging from 5.25 to 9.86 percent. The valves were removed from the tester and visually examined at 0, 41, 80, and 123 million cycles.

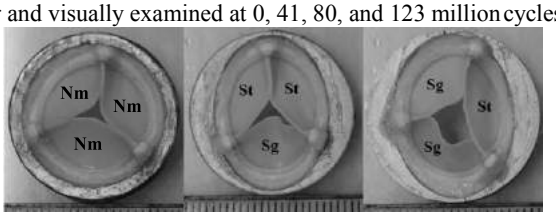

Figure 1: Left: Circular configuration (Circ); **Center:** Elliptical Major configuration (EMaj); **Right:** Elliptical Minor configuration (Emin); nominal, sagging, and stretched leaflets are denoted as "Nm", "Sg" and "St" respectively.

Ultimate Tensile Strength (UTS) Testing: After 123M cycles, a rectangular sample (~18 x 6 mm) with rounded edges was cut from the center of each leaflet of all valves. The sample thickness was measured using an optical microscope and each sample was pulled to failure at 120 mm/min. The working length of the samples between the chucks was typically 8-9 mm, and samples underwent ten cycles of preconditioning up to 5% strain prior to being pulled to failure. UTS testing was performed on three circular nominal leaflets (not fatigued, control), six circular nominal fatigued leaflets, six sagging leaflets, and six stretched leaflets.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Two main modes of leaflet damage were observed in AWT as indicated in Figure 2: (1) Leaflet tear at the commissure posts (CMT), and (2) leaflet tears at the free edge (FET). Fabric tear exposing the underlying commissure metal post (CMPE) was also observed, but did not affect leaflet integrity in most cases. CMTs occurred in all leaflet types irrespective of valve configuration. Leaflet thinning at the free edge and FETs occurred in all six sagging leaflets and only one stretched leaflet of EMaj and Emin shaped valves but it did not occur in the nominal leaflets of circular valves. CMPEs were observed in the commissure posts of all leaflet types irrespective of valve configuration. All six valves achieved complete opening and closing of the leaflets throughout testing, as shown with one EMaj valve in Figure 3 below.

Figure 2: Left: commissure tear (CMT); **Center:** free edge tear (FET) in a sagging leaflet; **Right:** commissure post exposed (CMPE);

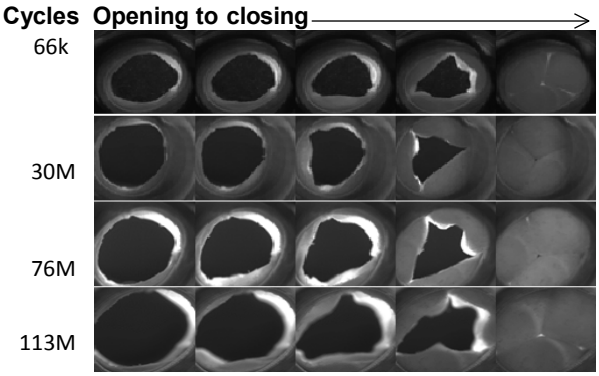

Figure 3: Images showing complete opening and closing of one EMaj valve in the AWT with cycling (top to bottom rows). Note orientations of St and Sg leaflets are not the same in all rows.

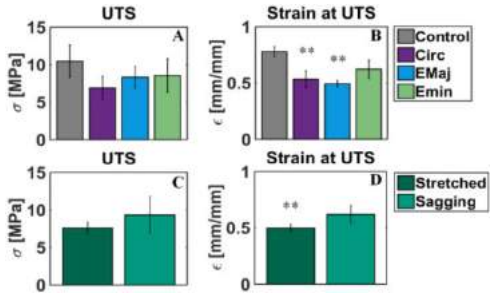

Figure 4: A) UTS by valve configuration; **B)** Strain at UTS by valve configuration; **C)** UTS for all stretched and sagging leaflets; **D)** Strain at UTS for all stretched and sagging leaflets; Error bars represent standard error; Asterisks (**) indicate statistically significant difference from the not fatigued control, P ≤0.1

The average UTS was not significantly different in the fatigued nominal, sagging, and stretched leaflets compared to the not fatigued control as shown in Figure 4. Although not significant, the average UTS and average strain at UTS was lower in the stretched leaflets than the sagging leaflets of elliptical configurations.

DISCUSSION

Conditions in our AWT system (mounting of the valves, high differential pressures, and extreme elliptical configurations for a surgical valve) produced a high damage rate as demonstrated by a single CMPE initiated failure (with the commissure pulling out) with one circular configuration valve with nominal, well-coapted leaflets. These conditions were not typical of those used in determination of long-term durability of a bioprosthetic valve, and the present results cannot be used to assess the longevity or failure modes of the surgical valves. Instead, these results are limited to understanding the nature of damage caused by stretched and sagging leaflets, and underscoring the importance of designing for complete coaptation.

CMTs in all leaflet types appeared to initiate at the bend of the commissure metal post closer to the leaflet belly and propagate towards the commissure closer to the free edge. The CMTs and CMPEs existed in all leaflet types and the severity of these failures was independent of valve configuration.

FETs occurred only in the sagging and stretched leaflets of elliptical configurations and not in the nominal leaflets of circular configurations. Leaflet thinning appeared to begin in the outermost fibrous layers of the pericardial tissue and progresses inwards towards the serous layer of the tissue, which finally resulted in a complete leaflet FET. Leaflet thinning at the free edge was noted in all sagging (Sg) leaflets; in some cases leaflet thinning was also noted in the belly region of the stretched (St) leaflets. Sagging (Sg) leaflets tore first near the unsupported free edge in each elliptical configuration.

The average UTS was lower for the fatigued leaflets of circular and elliptical configurations compared to the not fatigued leaflets of circular configuration (not statistically significant) showing fatigue inducing damage in all leaflet types (Figure 4). The average UTS and strain at break for the St leaflets were lower than the Sg leaflets showing possible leaflet damage at the belly with fatigue in St leaflets. This observation was unexpected but it is to be noted that the samples for UTS testing constituted most of the tissue from the leaflet belly (slightly away from the free edge) while the tears for the Sg leaflets occurred after leaflet thinning was initiated at the free edge.

In conclusion, our AWT results show that the sagging leaflets tore at the unsupported free edge before the stretched leaflets in both elliptical configurations, while the nominal leaflets did not see this type of failure. This is initiated by leaflet thinning that appears to be propagating from the ventricular to the aortic side of the leaflets. This study once again highlights the importance of proper leaflet coaptation in the design of a bioprosthetic heart valve. The extent of support between leaflets needs to be considered to improve long-term performance.

INTRODUCTION

Targeting the skin for drug delivery offers several advantages over the oral route, including obviating the need for constant self-administration, easy termination of therapy at any point of time, and potential reduction of side effects. Drug delivery for topical applications using polymeric scaffolds has several advantages over monolithic patches as well as ointments and creams, including better control of delivery kinetics via mass transport from the fibers, the ability to construct multiple layers with different drugs and/or doses, and improved patient comfort and hence better compliance [1]. Here we report on the use of a new,melt co-extrusion process to prepare polymer fibers containing the anti-fungal compound clotrimazole. An advantage over electrospinning, for which we have considerable experience, is that the new process is a continuous one, alleviating problems of rather low throughput for electrospinning.

One of the major disadvantages associated with clotrimazole is its poor aqueous solubility, requiring a hydrophobic carrier such as a non-polar oil for topical administration. Thus, a relatively non-polar polymer, poly(caprolactone) or PCL, was selected as the matrix for the drug since PCL is readily processed by the continuous new co-extrusion approach which has been described in considerable detail elsewhere [2] and thus it is only briefly outlined in Figure 1.

METHODS

Two grades of PEO (Dow POLYOX N80 (Mw = 200 kg/mol) and POLYOX N10 (Mw = 100 kg/mol) was pre-blend using Haake Rheodrive 5000 twin-screw extruder with a weight ratio of 30:70 (N80:N10). PCL and clotrimazole were prepared in the same screw extruder with two different ratios of 96:4 and 92:8 (PCL:Clotrimazole).

The melt flow indexing of blends was prepared to determine the correct correct viscosity match and temperature of co-extrusion of PCL:Clotrimazole and PEO blend.

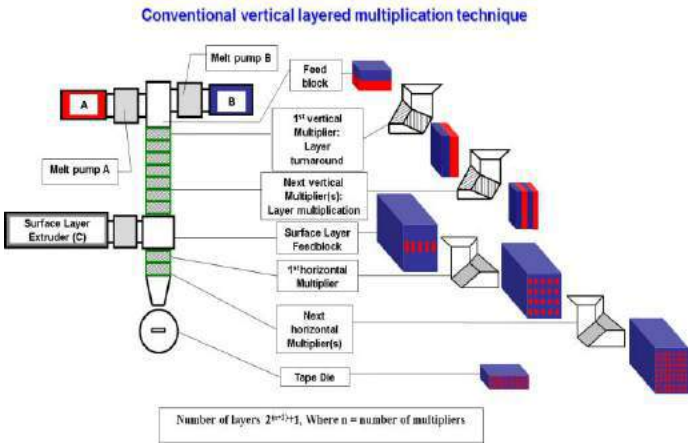

Figure 1. Schematic representation of producing rectangular mats using co-extrusion and two-dimensional multiplication processes.

Briefly, a key feature of the co-extrusion process is a set of multipliers used to drive the controlled stacking of the melts. The overall process can be characterized by four regions: (a) co-extrusion, a region where a molten layer of one polymer is stacked onto a layer of a second polymer; (b) vertical layer multiplication, involving cutting the flow horizontally to double number of vertical layers; (c) the surface-layering region where vertical layers are covered with two surface

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

layers of one of the polymers (or a third, different polymer); and (d) the horizontal layering region, where surface-layered composites stack on the side and on the top of one other by horizontal-layer multipliers. The extrusion was performed at 180°C, at which the viscosities of PCL and PEO match with each other [2].

We have demonstrated that PEO can be removed form co-extruded composites of PCL/Clotrimazole and PEO tape through immersion in distilled water for 7 days followed by drip-drying for 24 h. 95-98% of total PEO can be removed from as-coextruded mats in this manner.

RESULTS

Co-extruded fibers were sputter coated with 10 nm of gold and imaged for shape and size distribution using a scanning electron microscope (SEM, JEOL-JSM-6510LV) to determine the fiber sizes under an emission voltage of 10 kV. We note that the fibers from this process are rectangular (T=(T=2.89±1.23µm, W=0.98±0.65µm) rather than cylindrical due to cutting and layering steps (Figure 2).

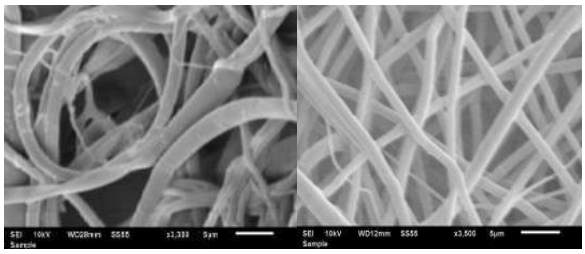

Figure 2. SEM images of co-extruded and electrospun PCL:Clotrimazole fibers with 4% drug loading.

Thermogravimetric analyses were performed using a Q500 TA instruments TGA analyzer. TGA experiments proved that clotrimazole, PCL, and PCL:Clotrimazole blends were stable at the thermal processing temperature as degradation occurs above 200°C. Using the nonisothermal mode of TGA, it was observed that clotrimazole alone begins to decompose above 190°C. This experiments shows that co-extrusion process at 180°C could be suitable for high thermal stability of the clotrimazole at PCL/PEO composite fiber system.

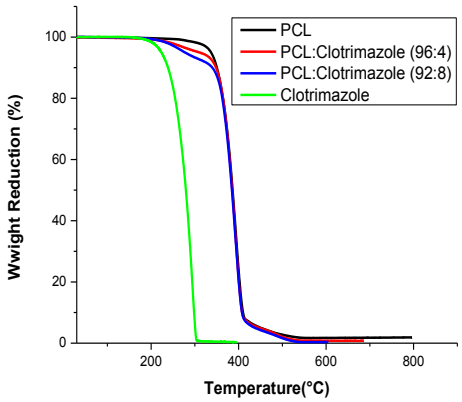

Figure 3: TGA of PCL, Clotrimazole and PCL:Clotrimazole blend in TGA as a function of temperature.

The in-vitro antifungal activity of clotrimazole in electrospun and co-extruded nanofibers was determined against A. fumigatus. A. fumigatus strains used in this study were cultured on plates of Vogel's Minimal Media (VMM). All media preparations were autoclaved for 30 min. In these instances, the A. fumigatus cultures were filled with PCL fiber mats prepared and then incubated for up to 24 h at 37°C, and the zone of inhibitions was measured (Figure 4).

Figure 4: Zones of inhibition from co-extruded fibers of clotrimazole:PCL.

DISCUSSION

The continuous extrusion process has been applied successfully to pharmaceutical formulations, specifically demonstrating incorporation of clotrimazole in PCL scaffolds as a carrier. Drug-releasing scaffold patches represent a potentially attractive opportunity for translation of the co-extrusion scaffolds to clinical applications. The present study demonstrates that clotrimazole has chemical stability with polymers, PEO and PCL, in co-extrusion processing and post-processing. Our findings indicate that the co-extrusion PCL with clotrimazole is capable of providing more sustained release. Clinical translation of this and related polymer/drug systems is in progress. Nanofiber patches could now be used in clinical applications.

ACKNOWLEDGEMENTS

Financial support from the NSF Science and Technology Center for Layered Polymeric Systems (Grant 0423914) is gratefully acknowledged, as is the use of fungal culture facilities in the laboratory of Prof. Mahmoud Ghannoum at CWRU.

INTRODUCTION

Nitinol (NiTi) is a metal alloy commonly known for its unique properties such as super elasticity, shape memory, and fatigue resistance [1]. Because of the wide range of features, Nitinol has become a material of choice for medical devices like endovascular stents. During the manufacturing process however, inclusions can develop on the surface of Nitinol. These inclusions can be present in the form of carbides, oxides, and intermetallic precipitates [2]. The presence of inclusions on a metal surface is undesirable since they act as stress concentrators by virtue of their geometry and are also more susceptible to corrosion in the presence of chlorine ions.

Recent studies have shown that when a nitinol surface is immersed in 6% sodium hypochlorite (NaClO), commonly known as bleach, corrosion of inclusions will occur, resulting in a visible black flocculent [2]. Hence, this method could be used to identify or eliminate inclusions on the surface of Nitinol devices. However, there are concerns that treatment of Nitinol surfaces with NaClO could lead to surface damage. Given that research done on NaClO and its impact on Nitinol is limited, and that Nitinol performance continues to be of significant interest for the medical field, this project is aimed to investigate in a broad context the effect of NaClO on the corrosion and fatigue performance of Nitinol and evaluate the use of NaClO to detect inclusions.

METHODS

In order to evaluate the corrosion and fatigue performance of Nitinol post exposure to NaClO, two different surface finishes of Nitinol wire were used, black oxide (BO) and electropolished (EP), to assess the impact on each surface finish. Nitinol used complied with specifications set per ASTM F2063. Prior to conducting fatigue and corrosion testing, samples were split into two groups and subjected to one of the following: a) Nothing, i.e. As Received, b) NaClO Soaked for 15 minutes followed by a DI water rinse. Rotary bend fatigue testing was used to determine the fatigue life of Nitinol wires at alternating strains of 0.8, 1.0, and 1.2%. Six wire samples from each surface finish were used for each strain level and condition assessed. This test was conducted in a phosphate buffered saline bath at 37^{o}C using Valley Instruments wire fatigue testers (Positool Technologies, OH) until fracture or runout to one million cycles. In order to evaluate the effect of NaClO on the corrosion susceptibility of Nitinol, cyclic potentiodynamic polarization testing was conducted. Six samples from each surface finish and test condition were evaluated per ASTM F2129 using an Interface 1000 potentiostat (Gamry, PA). Scanning electron microscopy (SEM) imaging was performed prior to conducting fatigue and corrosion tests to inspect the surface of as received and NaClO soaked wires using a JSM-6390LV (JEOL, MA).

RESULTS

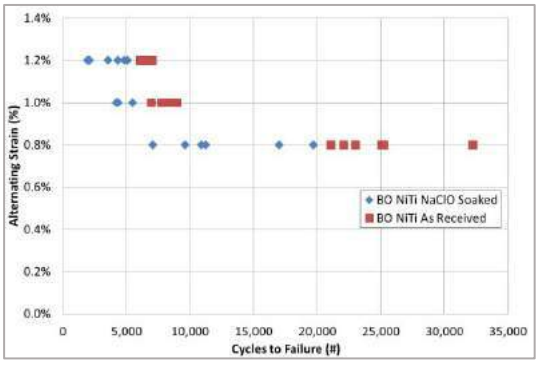

Figure 1: Strain-life diagram for black oxide Nitinol (BO NiTi) showing fatigue performance for As Received and NaClO Soaked conditions.

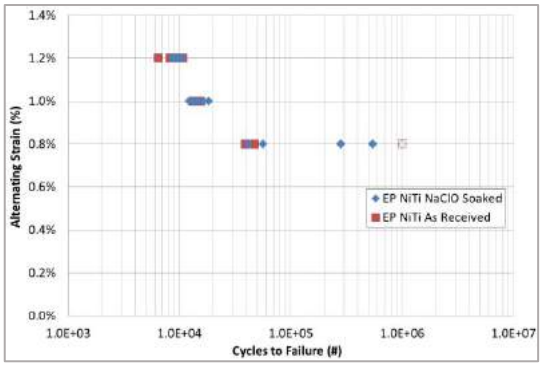

Figure 2: Strain-life diagram for electropolished Nitinol (EP NiTi) showing fatigue performance for As Received and NaClO Soaked conditions. Note that unfilled shapes indicate runouts.

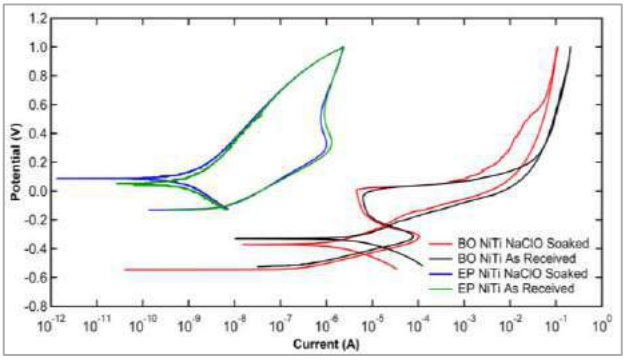

Figure 3: Cyclic potentiodynamic curves for black oxide and electropolished Nitinol (BO NiTi, EP NiTi respectively) for As Received and NaClO Soaked conditions.

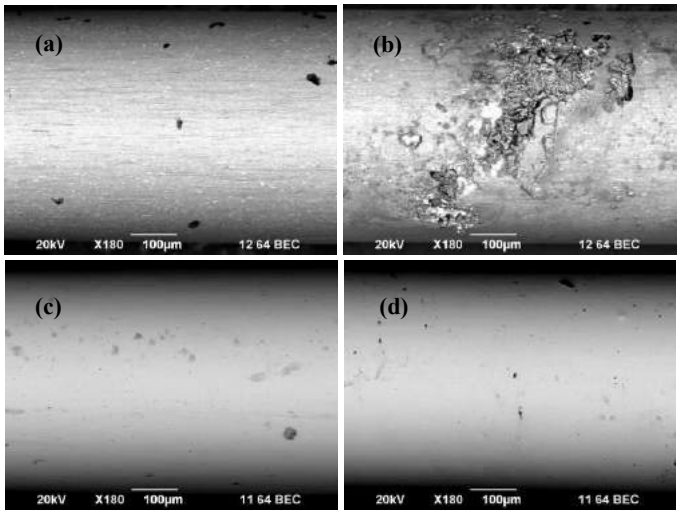

Figure 4: SEM micrographs of Nitinol wires prior to testing per ASTM F2129: (a) BO NiTi As Received, (b) BO NiTi NaClO Soaked, (c) EP NiTi As Received, (d) EP NiTi NaClO Soaked.

Fatigue results for the black oxide Nitinol (BO NiTi) and electropolished Nitinol (EP NiTi) can be seen in Figure 1 and Figure 2, respectively. The number of cycles to fracture between the NaClO soak group and the as received group were compared with an analysis of covariance using strain as a covariate. The NaClO soak was found to have a statistically significant reduction on the fatigue life of the black oxide Nitinol ($p<0.001$), but not on the electropolished Nitinol ($p=0.518$). The as received group had a higher number of runouts (4 of 6) to one million cycles than the NaClO soak group (2 of 6) in the 0.8% strain tests on electropolished Nitinol.

Corrosion test results showed that NaClO soaked and as received black oxide Nitinol samples broke down at similar potentials. As received and NaClO soaked electropolished and black oxide Nitinol samples followed a similar current vs. potential profile (Fig. 3).

Visible black flocculent was not observed in the solution after soaking any of the wire specimens in NaClO. SEM imaging performed on black oxide Nitinol showed that exposure to 6% NaClO triggered corrosion damage in some segments of the wires (Fig. 4b). The 6% NaClO solution did not appear to cause corrosion in the segments of the electropolished Nitinol wires that were observed under SEM (Fig. 4d).

DISCUSSION

Corrosion damage due to NaClO was confirmed with SEM to have occurred on black oxide Nitinol wires after the NaClO soak. However, black flocculent was not observed on any of the Nitinol samples after NaClO soak in contrast with results reported by Rokicki et al. [2]. Corrosive damage to the black oxide Nitinol wires during exposure to 6% NaClO prior to fatigue testing may explain the reduced fatigue performance seen as compared to as received samples. Crack initiation may have occurred where corrosion pits formed and resulted in a decreased fatigue life. There was no significant effect of the NaClO soak on fatigue performance of the electropolished Nitinol wires, although more of the as received wires reached runout than the NaClO soaked wires at the lowest alternating strain tested (0.8%). Since inclusions are known to play an important role in high cycle Nitinol fatigue in particular [3], lower alternating strain values should be examined in future work to obtain larger number of cycles to failure. Such data would be more representative of implanted cardiovascular devices which are expected to survive hundreds of millions of cycles.

The results gathered from ASTM F2129 testing indicate that soaking samples in 6% NaClO did not greatly impact the pitting corrosion behavior.

Overall, exposure of Nitinol to 6% NaClO did not identify surface inclusions and had some detrimental effects to material performance in our testing. Further investigation into this topic, including immersion testing and more fatigue testing, is warranted to provide a better understanding of how NaClO affects other aspects of Nitinol performance.

INTRODUCTION

Ring apophysis fractures (RAFs) are avulsion type fractures to the posterior aspect of the lumbar vertebral body. They initiate at the ring apophysis, propagate either anteriorly or through the vertebral endplate, and occur most frequently in healthy young athletes [1,2]. These fractures present with symptoms such as: low back pain, limited mobility, and often along with intervertebral disc herniation. Patients often cannot recall an extreme event that caused the RAF. This suggests that activities of daily living (ADLs) contribute to these RAFs. The effects of repetitive small movements during ADLs on vertebral fractures is unknown. It is presumed that these fractures may be initiated by normal ADLs, during which the most common movement for the lumbar spine is flexion of less than 15° [3].

To test this hypothesis, white tailed deer (*O.virginianus*) vertebrae, with a similar degree of skeletal maturity and range of motion [4] to adolescent humans, were loaded in cyclic flexion. The immediate goal was to mechanically simulate RAFs under low-load low-angle cyclic loading, in these cervine lumbar 5-vertebra motion segments.

METHODS

Nine 5-vertebra motion segments (L1-L5, 8 male, 1 female, 2.56 ± 0.46 years) were harvested from cervine [5-6] donors (Nolt's Custom Meat Cutting, Lowville, NY) and potted as previously described [5]. X-rays (Multix X-Ray System, Siemens, Berlin, Germany), dual-energy x-ray absorptiometry (DXA) scans (Lunar Prodigy Advance DXA System, GE Healthcare, Little Chalfont, Buckinghamshire, United Kingdom) and micro-computed tomography (μCT) scans (Phoenix Nanotom, General Electric, Wunstorf, Germany) were collected to verify the absence of pre-existing pathologies such as osteophyte formation. The bone mineral density (BMD) was 1.17 ± 0.15 g/cm^2 which is comparable to healthy human bone. Retroreflective markers (4mm hemispheres) were secured to each vertebral body with cyanoacrylate adhesive to enable motion capture. A paint speckle pattern was applied to the cortical shell to enable observation of surface deformation.

Motion segments were cyclically loaded at 2.0Hz past failure; one specimen was loaded at 0.5Hz. Each motion segment was cycled in displacement control between displacement values that corresponded to a neutral position and 15° of flexion (Figure 1). A pinned end condition fixture (Figure 1) was used to allow flexion of the specimen.

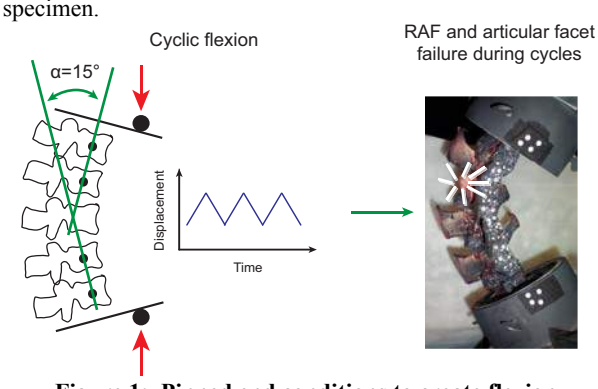

Figure 1: Pinned end conditions to create flexion.

3-D digital image correlation (3D-DIC) and motion capture data were collected during periods of slower (0.1Hz) cycling as appropriate (after cycles 1, 1,000, 3,000, 6,000, 10,000, 12,000, 20,000, and 40,000 if applicable), including one imaging set after failure was aurally and/or visually observed. This slower loading rate during

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

imaging ensured accurate image recording. The area of the load-displacement hysteresis loops was used to quantify damage accumulation. A 4-camera Qualisys motion capture system (Oqus 500 cameras, Qualisys Inc., Sweden), with an accuracy of 0.1mm, was used to measure the regional centroid angle (α) [7] as well as intervertebral angles throughout the test following the ISB standards [8]. 3D-DIC images of the cortical shell were also taken during the slow loading cycles. Clinically relevant fractures were confirmed by x-ray and μCT.

RESULTS

All specimens fractured; at least six had RAFs as confirmed by μCT. Articular facet failure was observed during cyclic loading as early as 1,400 cycles (and as late as 40,000 cycles). RAFs were created in all specimens and it is important to note that the level of the RAF corresponded to the articular facet level failure during cyclic loading. In a representative specimen (Figure 2), the articular facet failure was at the L2/L3 level and the μCT scan confirmed a Type I RAF [1] in the caudal end of the L2 vertebra.

The images from the slow imaging cycles provide evidence of fracture during the cyclic loading. For this specimen, aural and visual observations note that at approximately cycle 25,000 the articular facet joint started to fail at the L2/L3 level. Figure 2 shows a crack in the cortical bone opening during the 30,000th cycle (the next imaging cycle after initial failure).

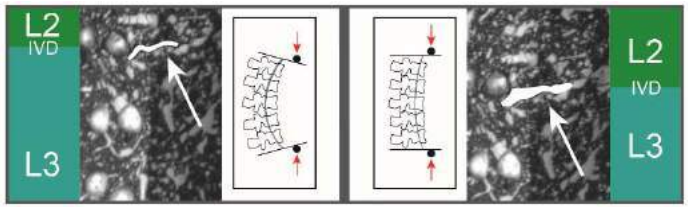

Figure 2: Cortical shell damage on the anterior aspect. The arrow shows an open crack in right image.

The L2/L3 intervertebral angle (from a different specimen) over the cyclic loading confirms a noticeable change in the kinematics of the motion segment (Figure 3a). While the total flexion angle does not change markedly, the slope of the angle curve within a cycle develops an inflection point at about 5° of flexion as the number of cycles increases (Figure 3a, green trace compared to red trace), indicating a change in intervertebral kinematics after fracture.

The hysteresis loop area gradually decreased with increasing cycle number, indicating the accumulation of damage to the 5-vertebra motion segment (Figure 3b and 3c). No observable differences in load-displacement hysteresis loops were observed between the specimens cycled at 2.0Hz and the one at 0.5Hz.

DISCUSSION

RAFs can occur during low-load low-angle cyclic loading as confirmed by kinematic changes, physical evidence observed during loading and images of the cortical shell. The change in kinematics during the experiment, although small, occurred after fracture was observed. This could lead to *in-vivo* kinematics-based methods to predict vertebral fracture location.

Different cycling rates (2.0 and 0.5Hz) were used due to equipment limitations. The similarity of our results at different cycling frequencies does not suggest any cycling rate dependent fracture mode behavior; future testing of additional specimens will confirm this.

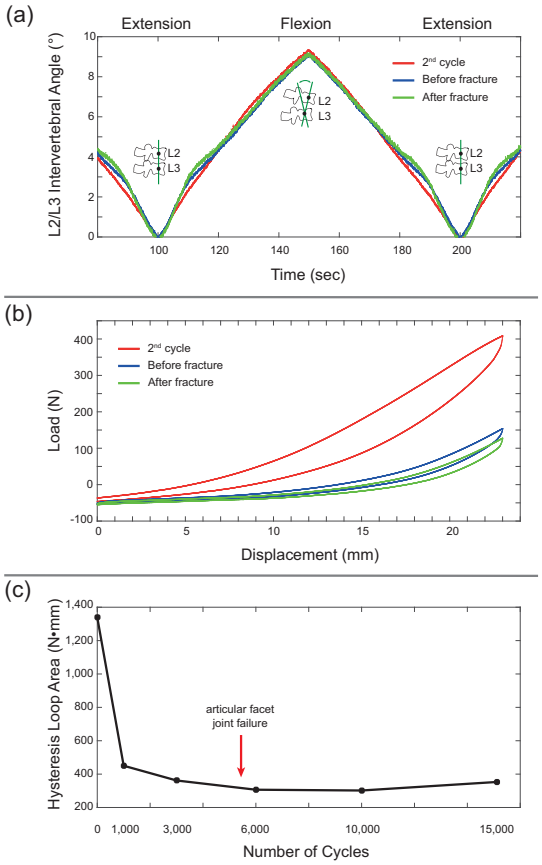

Figure 3: (a) L2/L3 intervertebral angle, (b) Hysteresis loops at the start of the cycling, and before and after fracture, (c) Hysteresis loop area. (Specimen failed at the L2/L3 level.)

To date, this research shows that cycling of small movement ADLs can contribute to RAF. Limitations include a small sample size and the use of cervine specimens (not commonly used as an *in-vivo* model). Future work will include quantifying common parameters used to describe the trabecular geometry prior to failure, and testing more cervine and cadaver specimens, which could include several different postures. Health care providers may need to consider small movement ADLs in fracture prevention education. Patient-specific exercise regimes could be developed to prevent RAFs. This work will ultimately provide the appropriate medical evidence for advanced fracture risk guidance and will improve rehabilitation techniques.

KNEE AND ANKLE BIOMECHANICS DURING SQUATTING WITH HEELS ON AND OFF OF THE GROUND, WITH AND WITHOUT BODY WEIGHT SHIFTING

Jonathan T. Fox[1], Mohamed S. Hefzy[1] and Charles W. Armstrong[2]

INTRODUCTION

Squatting is a common daily activity in many cultures. In western cultures squatting is used in sports, work, and in leisure, and in Asian cultures squatting is also used for daily activities such as using the restroom and waiting.[1] During periods of long squatting activities it is common for people to shift their weight to maintain comfort. Additionally, various postures are often employed when squatting; the two most common being the Asian Squat, which involves the heels remaining on the ground throughout the squat, and the Catcher's Squat in which the heels are raised from the ground throughout the movement. However, neither the biomechanics of body weight shifting nor the specific effects of posture on squatting has been well studied. Furthermore, the muscle activity used to maintain these postures is not well known.

The purpose of this study was thus to examine the biomechanics of the knee and ankle joints with and without body weight shifting during a deep squatting activity while the heels were both on and off the ground positions. This study also looked at the muscle activities associated with each squatting activity.

METHODS

Ten Raptor-E cameras (Motion Analysis, Inc.) were used to collect motion data during squatting while two AMTI force platforms were used to collect ground reaction force data. Additionally, ten Trigno® wireless EMG sensors (Delsys, Inc.) were used to record data from muscle activities. Eight subjects, four males and four females, were each instrumented with twenty-one reflective markers that were placed on the 3rd metatarsal, the medial and lateral malleolus, the calcaneus, the anterior of the shank, the medial and lateral epicondyle, the anterior of the thigh, the grater trochanter, and the anterior-superior iliac spine (ASIS) on both the left and right side of the body, as well as placing one marker on the sacrum. The ten EMG sensors were placed on the bicep femoris, rectus femoris, tibialis anterior, and the medial and lateral head of the gastrocnemius on both the right and left side of the body. The EMG sensors were placed on the skin over the belly of the muscles with the electrodes in the direction of the fibers.

The testing protocol was approved by the IRB of the University of Toledo. Maximum voluntary contraction tests were performed as the subjects sat with their legs restrained while they contracted each muscle one at a time as hard as they could. Once these tasks were completed each of the subjects performed four separate squatting tests. The first test was a stand then squat test keeping the heels on the ground (Asian squat). Subjects squatted down at a self-selected pace and then immediately returned to a standing position. Then the test was repeated while lifting the heels off of the ground (Catcher's squat). The third task was an Asian squat with weight shifting. Subjects squatted down at a self-selected pace and were then verbally instructed to shift their weight to the right, then to the left, back to center, and then finally returned to a standing position. The final task was to repeat the weight shifting squat activity for the Catcher's squat. Each activity was repeated until 5 successful trials were recorded.

The data were collected and processed using the software Cortex (Motion Analysis, Inc.). Cortex simultaneously collected and synchronized the motion, GRF, and EMG data. The KinTools RT kit and Excel were used to calculate the kinetics data, while the EMGworks Analysis software (Delsys, Inc.) and Excel were used to analyze the EMG data. The individual trials from each volunteer were averaged over time to get four sets of data. The data from the four activities were then averaged together to get average male and female

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

volunteer data sets. Finally the trials from all volunteers were averaged together to get one average data set for each squatting activity.

RESULTS

The average results for all subjects are shown in Table 1. Forces and moments are normalized to body mass and given in N/kg and Nm/kg, respectively. Flexion angles are given in degrees, and muscle activities are given as a % of the maximum voluntary contractions.

Table 1: Ground reaction forces, joint moments, joint angles, and average muscle activities as an average for all subjects during all four squatting activities.

		Asian Squat		Catcher's Squat	
		No Shifting	Shifting	No Shifting	Shifting

	Mean L Gastroc	64.8%	62.8%	73.3%	62.0%

DISCUSSION

On average lifting the heels off the ground caused the knee extension moments to increase. The maximum knee flexion angle experienced also increased with lifting the heels off the ground. This implies that performing a Catcher's squat requires both a greater range of motion and a greater knee joint moment. The right leg also experienced a knee extension moment greater than the left leg during the Asian and Catcher's squats. This implies that the volunteers favored their right leg for support during the squatting motion. The right leg also had knee flexion angles that were greater than the left leg during the Asian and Catcher's squats. This could be due either to placing more weight on the right leg, the differences in foot placement, or a combination of both. The data also imply that performing a Catcher's squat requires a greater ankle joint moment, but does not require as great of a range of motion. During the Catcher's squats the volunteers held a more rigid ankle angle in order to hold the position and maintain balance due to lifting their heels off of the ground.

On average shifting weight caused the knee flexion moments to increase during both the Asian and Catcher's squats. As weight was shifting to one side of the body the knee extension moment increased on the same side while decreasing on the contralateral side. This implies that shifting weight from side to side does not greatly change the flexion angle of the knee, but it increases the moment experienced by the knee. The Catcher's squat caused a greater increase in the knee extension moment when weight shifting occurred. This could be due to volunteers being able to shift their weight more easily during the Catcher's squat than during the Asian squat or due to the difference in moment arm between the two positions. The data also imply that shifting weight from side to side decreases the plantarflexion angle of the ankle, but it increases the dorsiflexion angle and the plantarflexion moment experienced by the ankle.

The activity of the quadriceps muscles generally increased as the knee flexion angle increased. On average the quadriceps muscles experienced more activity during the Asian squat than during the Catcher's squat. Weight shifting also increased the activity during both squats. The tibialis anterior muscles activity also generally increased as the knee flexion angle increased, and had decreased activities during weight shifting. Hamstring and both gastrocnemius muscle activities were relatively steady throughout all squatting activities. The gastrocnemius muscles showed a large degree of activity, but they did not change much throughout the squatting motion from the values when the volunteer was standing.

To summarize, it was found that the Catcher's squat caused greater knee extension and plantarflexion moments. The Catcher's squat also had greater knee flexion angles and ankle plantarflexion angles, but had smaller ankle dorsiflexion angles. Additionally, the Catcher's squat caused the muscle activity in the quadriceps and tibialis anterior muscles to decrease, and the muscle activity in the hamstrings and gastrocnemius muscles to increase. Weight shifting caused knee extension moments and ankle plantarflexion moments to increase over the non-weight shifting cases as weight was placed onto one leg. The weight shifting also caused an increase in the ankle dorsiflexion angle and a decrease in the ankle plantarflexion as more weight was placed onto one leg and caused the ankle to shift to support more weight. The quadriceps and hamstring muscle activities increased during weight shifting, but the tibialis anterior and gastrocnemius activity decreased. It was also found, but not shown in the table, that on average the male volunteers also had greater knee flexion angles, and smaller knee extension and ankle plantarflexion moments than the female volunteers. The significance of this work cannot be overlooked, since squatting is a daily activity performed by people throughout the world, and may have implications for the development and response of a variety of orthopedic conditions.

INTRODUCTION

Major League Baseball foul tips have been shown to cause career altering injury to catchers like the case of Joe Mauer [1]. Catcher's first line of defense against foul tips is their mask – traditionally made of steel. Recently a lighter more comfortable titanium mask was introduced. Following their introduction reported concussions due to foul tips spiked, leading many to speculate titanium masks were the cause. In response, many catchers reverted to steel masks [2]. We hypothesize that since the titanium mask is lighter and has a higher yield strength, wearing it will result in higher head injury metrics upon impact with a simulated foul tip. However, the mask material, steel or titanium, is not the only unsettled question with potential relevance to the spike in reported concussions. Even though some studies have looked at the attenuation of both traditional and hockey style masks, none have examined the titanium variant, and there still remains the debate of how all of these mask types compare [3,4,5,6]. Because of this, our study investigates the impact response of four styles of masks (traditional steel, traditional titanium, hockey style, and hockey style with shock adsorption) to assess impact attenuation and compare them based on peak resultant acceleration, Head Injury Criterion (HIC), and Head Impact Power (HIP).

METHODS

To provide a catcher surrogate, a Hybrid III 50th percentile male head form was equipped with a six degree of freedom sensor package at the head's center of gravity as well as a load cell positioned at the joint between the head and neck. The six degree of freedom sensor package measured linear accelerations and angular rates of the head upon impact while the load cell measures the force interactions between the head and neck. The four masks selected for testing were the Wilson Dyna-Lite Titanium Mask, the Wilson Dyna-Lite Steel Mask, the Easton Rival Hockey Style Mask, and the Wilson Shock FX 2.0. A pneumatic cannon was constructed using three inch PVC pipe and used to propel Rawlings Official Major League Baseballs at 50 and 60 PSI, resulting in ball velocities of approximately 70 and 80 MPH. Data collection was conducted using a MeDAQ data acquisition system (Hi-Techniques, USA) sampling at 200 kHz and filtered at 1650 Hz using an eighth order Butterworth filter. A Phantom High Speed Camera (Vision Research, USA) captured video of the impact. The test series consisted of six trials at each speed, impacting the head at the nasion. Twelve trials were completed for each mask, although ultimately some trials were excluded from analysis because the masks were too deformed to provide proper protection. At each speed, three bare head trials were conducted for control analysis. Using MATLAB (MathWorks, USA), a custom analysis suite was constructed for extracting peak resultant acceleration, HIC, and HIP values for each trial, while JMP Pro 11 Statistical Package (SAS, USA) was used to conduct an ANCOVA comparing peak resultant linear acceleration, HIC values, and HIP values between masks. Equations 1 and 2 provide how the HIC and HIP values were calculated respectively.

$$HIC = \left[\frac{1}{t_2 - t_1}\int_{t_1}^{t_2} a(t)dt\right]^{2.5} * (t_2 - t_1) \quad (1)$$

$$HIP = 4.5 * \left(a_x \int a_x(t)dt + a_y \int a_y(t)dt + a_z \int a_z(t)dt\right) + 0.016(\alpha_x \int \alpha_x(t)dt) + 0.024\left(\alpha_y \int \alpha_y(t)dt\right) + 0.022(\alpha_z \int \alpha_z(t)dt) \quad (2)$$

RESULTS

Figures 1 and 2 show resultant linear acceleration and HIP values respectively. These were chosen to represent an injury metrics that use linear acceleration and one that includes angular acceleration.

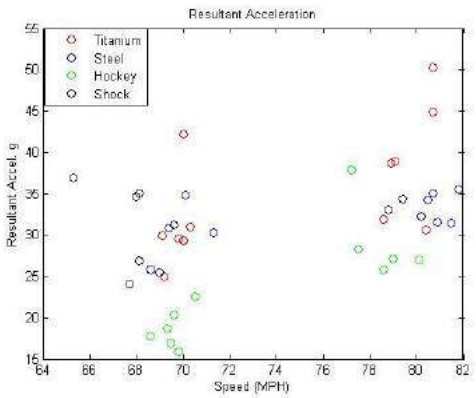

Figure 1: Resultant Acceleration vs. Speed

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

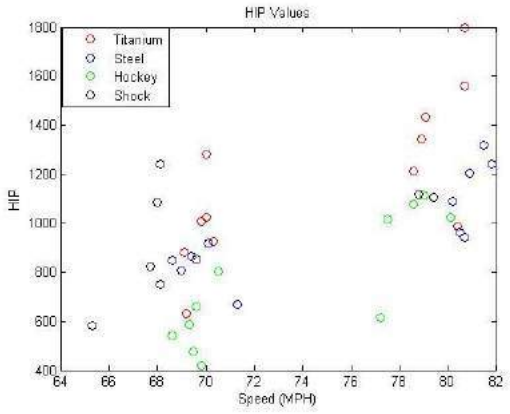

Figure 2: HIP vs. Speed

Results of the ANCOVA tests summarized in Table 1 grouped the masks based on statistical difference. Masks are grouped by numbers and lower numbers indicate better performance.

Table 1: Summary of ANCOVA Statistical Tests Ranked By Performance

		Head Impact Metric		
		Res. Accel.	HIC	HIP
Mask Type	Trad. Steel	2	2	2, 1
	Trad. Titanium	2	3	3
	Hockey Style	1	1	1
	Hockey Shock	2	2	3, 2

The ANCOVA results show that the hockey style mask performed better than each of the other styles for every metric and for each metric the Titanium mask was associated with the groups with the worst performance. Furthermore, the shock absorbing mask had the second worst performance, even though it was a hockey style mask.

DISCUSSION

There are two ideas behind why the hockey style mask performed the best out of the four styles. First, it is one of the heaviest masks which results in lower accelerations. Second, preliminary analysis shows that the material used in the helmet liner plays a large role in how energy from a ball impact is transferred into the head. The foam found within the hockey style mask is more viscoelastic than that found in the other masks. This means it has the potential to absorb more energy upon impact resulting in lower head accelerations. These results provide evidence that contradict the belief that the traditional steel mask is better for frontal foul tips than the hockey style mask.

It was expected that the shock absorbing mask would perform just as well if not better than the hockey style mask. However, the mask deteriorated quickly upon multiple impacts to a point where it would no longer protect the player. This reducing the number of trials conducted with the mask making the statistical analysis more susceptible to variation. The deterioration along with the limited number of trials may have led to the masks poorer performance.

The results support the hypothesis that based on its material properties, the titanium mask results in higher impact metrics compared to three other common mask types. This shows that catchers fear of titanium masks may be warranted. The data however does not provide evidence that wearing titanium masks results in more concussions because of the limitations of this study. Even though these head impact metrics could be compared to injury risk curves found in literature, values found in this test are not representative of an actual catcher wearing a mask. First the only similarities between the Hybrid III head and a human head are the geometry and mass. The various tissues found in the head and their interactions may have significant effects on impact transfer through the mask and into the head that cannot be modeled by the Hybrid III. Furthermore, the load cell depicts interactions between the Hybrid III head and neck during peak acceleration, and since the Hybrid III neck is not perfectly biofidelic, these may be different in human subjects. Finally, while these metrics are currently the best tools we have to correlate head impact and concussion, it is still not fully known how these head metrics relate to concussive impacts.

To ameliorate some of these limitations, future tests will be conducted with cadaveric specimen and detailed helmet design analysis to determine how aspects of each helmet positively and negatively impact performance to provide suggestions to make future helmets safer.

While this study is limited in its ability to correlate helmet design and concussion rate it is a step towards creating a safer playing experience for catchers at all levels. With concussions becoming a growing concern, it is important that helmets are designed not just to meet standards, but to be as safe as practically given by the constraints of game play. From the data collected in this study it is seen that different helmet materials and helmet styles vary in their level of protection from head accelerations after being impacted by a simulated foul tip. It is seen that design changes from the standard traditional steel mask have been both positive and negative with the introduction of the Hockey Style mask and Titanium mask respectively.

AKNOWLEDGEMENTS

I would like to thank the Duke University Department of Biomedical Engineering, the Pratt Fellows Research Program, and the Duke University Undergraduate Research Support Office for their support of this study.

THE EFFECT OF ELECTROPOTENTIAL ON NITINOL FATIGUE LIFE

Shiril Sivan (1, 2), Matthew A. Di Prima (1), Jason D. Weaver (1)

INTRODUCTION

Nitinol is one of the most common metals used for cardiovascular devices primarily because of its excellent shape memory and superelastic properties [1]. The *in vivo* clinical performance of these devices depends of a number of factors which include Nitinol's mechanical properties, fatigue and corrosion resistance, and its ability to withstand the local biological response once the device is implanted. It is well established that the rest potential of a metal surface depends on its local environment [2]. For example, on implantation, a foreign body reaction is initiated during which a cascade of immune and inflammatory cells can alter the local environment by reducing the pH [3]. This will lead to a rise in the metal's rest potential to a more anodic potential. Whereas, in a configuration where there are overlapping stents, the overall electropotential can undergo a cathodic shift if fretting occurs [4]. Hence, the electropotential of a metal surface can vary in response to its surrounding environment. At present, very little is known regarding the effect of voltage on the fatigue life of metal wires. Therefore there is a need to evaluate the effect of electropotential on the fatigue life of Nitinol in-order to determine if fatigue life of Nitinol wires depends on the overpotential enforced.

METHODS

Electropolished Nitinol wires having a diameter of 0.5 mm were used for all experiments. The breakdown potential of the wires was evaluated per ASTM F2129. Potentiodynamic scans were performed from rest potential to at least 800 mV (vs. SCE) and then back to rest potential for the reverse scans. Fatigue life was evaluated at 1.2, 1.0, 0.8 and 0.6 % alternating strain (ε_a) using a rotary bend wire fatigue tester (Blockwise, Tempe, AZ). Wire fatigue tests were conducted at 3600 rpm with the wires submerged partially in phosphate buffered saline (PBS) maintained at 37 ºC. The cut ends of the wire in the wire fatigue tester chucks were insulated using MICCROStop lacquer (Tobler Chemical Division, Hope, AR) to prevent the transfer of any transient electrochemical noise from the wire fatigue testers to the test specimens. All electrochemical measurements were achieved using a three electrode system with graphitic carbon rod as a counter electrode and standard calomel electrode (SCE) as a reference electrode. To test the effect of overpotential on the fatigue life of samples, the rest or open circuit potential (OCP) was first measured for 10 minutes after which the wire was potentiostatically held at the overpotential being investigated. The cycles to failure for ε_a of 1% was evaluated for wires at -500 to +600 mV (vs. SCE) (in steps of 100 mV). To understand the effect of ε_a and overpotential on fatigue performance, SN curves for ε_a of 1.2, 1.0, 0.8, 0.6 were generated for -400, 0, OCP and 400 mV (vs. SCE). Current density was monitored during the potentiostatic tests using either a Princeton Applied Research Model 263 potentiostat or a Gamry Interface 1000 System. For experiments where no voltage was applied, the open circuit potential (OCP) was monitored for 10 minutes after which the fatigue test was initiated and OCP was monitored until the wire failed. To account for variability, 6 samples were used for each test condition.

RESULTS

Of the six samples subjected to ASTM F2129 testing, four had a breakdown potential of approximately 250 mV (vs. SCE) while the other two did not exhibit breakdown. Figure 1(A) shows the rest potential of a Nitinol wire when subjected to alternating strain of 1% with no applied voltage. There is a steep cathodic shift in electropotential of the wire when the fatigue test is initiated. The electropotential of the wire remains stable and then gradually decreases as the fatigue test progresses. This results in a drop in

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

electropotential of the wire from -150 mV (vs. SCE) to -650 mV (vs. SCE). At approximately 140 seconds wire fracture occurs, at which point the fatigue test is terminated. The subsequent recovery of electropotential of the wire is typical recovery of the open circuit potential.

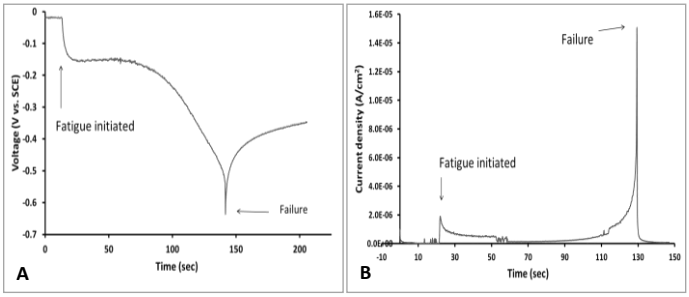

Figure 1: (A) shows a typical voltage transient observed when a Nitinol wire is subjected to alternating strain of 1 % using a rotary bend wire fatigue tester. (B) Shows the current density monitored while a wire was potentiostatically held at 100 mV (vs. SCE) and subjected to alternating strain of 1%.

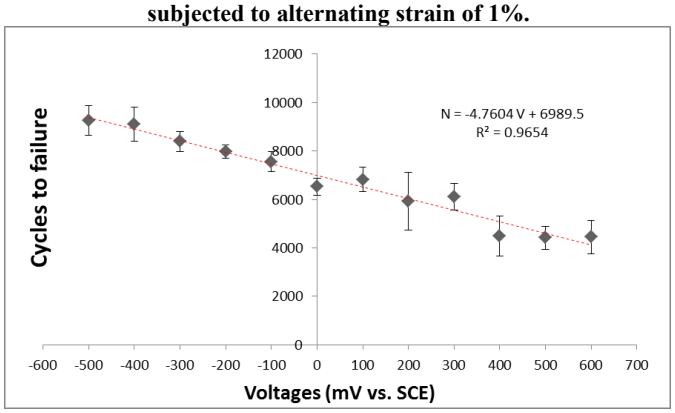

Figure 2: Number of cycles to failure for a Nitinol wire undergoing 1% alternating strain while being potentiostatically held at voltages between -500 mV and +600 mV (vs. SCE).

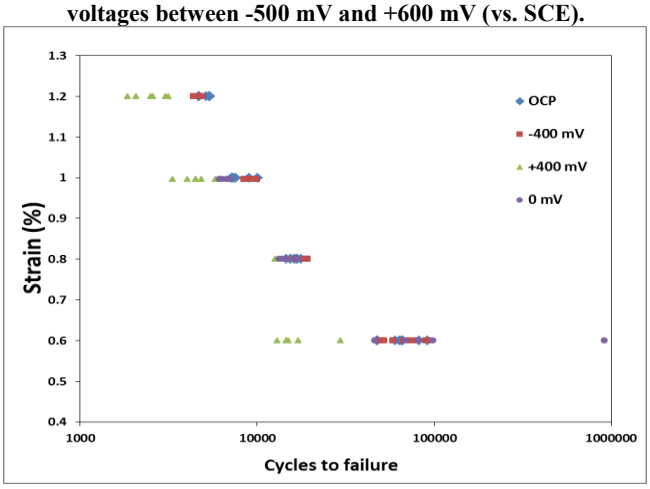

Figure 3: Number of cycles to failure at different alternating strains when no voltage was enforced (OCP), -400, 0 and 400 mV.

The current response of a wire potentiostatically held at 100 mV (vs. SCE) is shown in Figure 1B. The current plateaus after 10 seconds after which the wire fatigue test was initiated. The current density instantaneously rises when fatigue is initiated and decays to reach a steady state. The current density again rises rapidly and ultimately peaks to its highest value as the wire fractures at which point the fatigue test is stopped. This is followed by an immediate drop in current density as the fractured surfaces repassivate. The graph in Fig. 2 shows a linear relationship between number of cycles to failure and electropotential of the wire (R^2 =0.96) ($p < 0.001$) for wires tested at 1.0% alternating strain. The number of cycles to failure for a range of alternating strains, overpotentials and OCP is shown in Figure 3.

DISCUSSION

The results presented in this study show that the overpotential of the wire can have an effect on its fatigue life. More anodic shifts in potential from OCP led to fewer numbers of cycles to failure. Whereas, the more cathodic the shifts from OCP, the greater the number of cycles to failure.

At cathodic potentials, oxidation reactions are suppressed. This results in a larger number of cycles to failure perhaps because fracture initiation and propagation in this regime are predominantly due to surface defects already present on the wire surface. Whereas, at potentials anodic to the OCP, oxidation reactions are enhanced causing the formation of new surface defects from corrosion occurring on the metal surface. This may lead to stress risers which ultimately result in the formation of a crack.

Thus, during the OCP fatigue test shown in Fig. 1A, after the test was initiated the surface oxide on the wire cracked and exposed the underlying metal to the test solution. The surface repassivated instantly resulting in a cathodic shift in the wire's electropotential. Similar behavior was seen on the potentiostatic test where a sudden rise in current density was observed when fatigue was initiated (Fig 1B).

The cathodic potentials and current densities attained here can cause oxidative stress in cells in the local environment [5]. This could initiate an inflammatory reaction during which cells can secrete reactive oxygen species, which is known to not only alter the rest potential of the metal surface but also aggravate corrosion.

The SN curve (Fig. 3) shows clustering of data points for OCP, 0 and -400 mV; whereas cycles for failure for the 400 mV condition are typically lower (except for 0.8 % strain). This may be because the OCP of the Nitinol wire is approximately -150 mV which is closer to 0 and -400 mV; whereas, the breakdown potential for these wires was around 250 mV (closer to 400 mV).

The results of this study have shown that the voltage of the metal wire can influence its fatigue life and should be considered when evaluating medical device durability. This is important because most of the testing currently done assumes that there is no inflammatory reaction or fretting occurring on the implant surface. Voltage excursions away from OCP to more anodic potentials under inflammatory conditions could have a negative impact on the fatigue life and ultimately affect the clinical performance of these devices.

INTRODUCTION

As many as 87% of orthopaedic surgeons choose intramedullary (IM) nailing for closed tibial diaphyseal fractures [1]. While current methods and devices used for this procedure are successful, there is still a need for improvement. Typically nails are only offered in discrete lengths, so hospitals must stock many sizes to accommodate their potential trauma patients. Discretely-sized nails are not only expensive to stock, they often do not fit a patient's IM canal perfectly, leading to non-union of the fractures, mechanical failure of the nail, and delayed rehabilitation [2,3]. An adjustable-length intramedullary nail, specifically for tibial fractures, has been developed to address these issues [2]. In this work, three unique adjustable-length prototypes were tested in both simple quasi-static loading, and have been evaluated further by testing their fatigue properties. Prototype A is distally adjustable, prototype B is proximally adjustable, and prototype C is discretely-distally adjustable via a pin mechanism (Figure 1). This study aims to quantify the differences in expected performance of each prototype. We expect all three to survive fatigue testing and to find a minimal difference in dynamic bending stiffness from the first cycle to the last, indicating complete fatigue survival.

METHODS

Three adjustable-length IM nails were manufactured from surgical stainless steel (316L). The prototypes were tested in 4-point bending, axial, and torsional quasi-static loading. The prototypes were loaded at rates of 0.1 mm/sec (bending and axial) at increments of 1-2 mm up to 5mm, and 0.1 degrees/sec (torsional) at 1 degree increments up to 10 degrees, according to the ASTM standard (ASTM F1264) [4]. All mechanical testing was done on a hydraulic load frame (MTS 809 Axial/Torsional Test System, Eden Prairie, MN). Prior to testing for

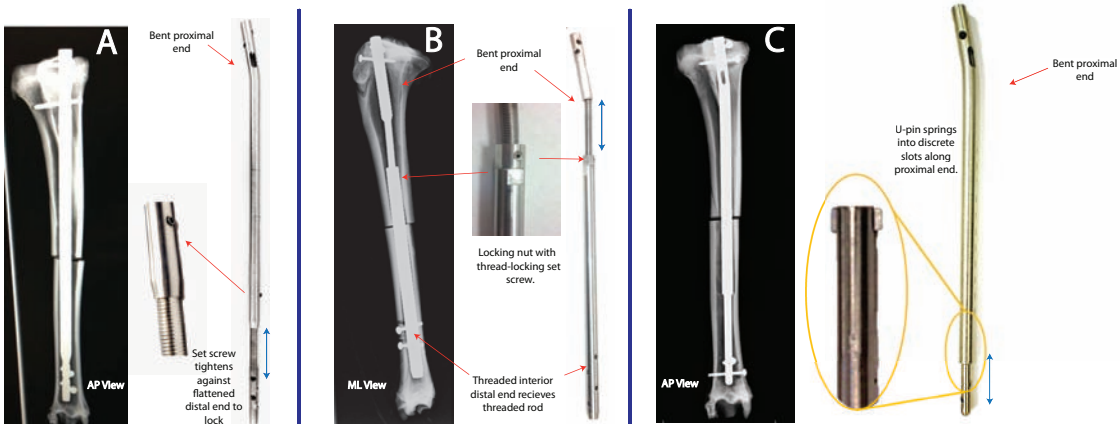

Figure 1 From left to right: Prototypes A (distally-adjustable), B (proximally-adjustable), and C (pin-mechanism). X-rays, models, and adjustment methods shown.

axial and torsional modes, the prototypes were surgically inserted into cervine tibiae specimens (9 specimens, (5 male, 4 female) 2.1 ± 0.6 yrs). All insertions were made under the direction of a board-certified orthopaedic surgeon (AMC). After insertion, the tibiae were potted in Bondo™ (Auto Body Filler, 3M, St. Paul, MN) and then tested either in torsion or axial compression. The load-displacement data from each trial was used along with a custom MATLAB (R2012b, The Mathworks, Natick, MA) code to calculate stiffness (see Equations 1, 2, and 3).

Each prototype was also tested in fatigue loading in a custom-built 4-point bending fixture (Figure 2) and according to ASTM standards [4]. Roller diameter of the fixture was 2.54 cm. Each of the nails were loaded cyclically between 50 N and 500 N (R=0.1) at a frequency of 5 Hz for 1 million cycles performed over multiple days. The test lengths were determined by selecting a section of prototype with no geometric anomalies within three diameter lengths (of the IM Nail) of either outside roller, as outlined in ASTM F1264. Force and displacement data were analyzed via a custom MATLAB code. Bending fatigue limit was determined empirically and hysteresis loops from the first and last cycles were plotted and compared for each prototype. Dynamic bending stiffness was calculated at the beginning and end of each prototype's testing using these loops (both loading and unloading phases), Equation 3, and the RMS method of determining a line of best fit. In addition, peak displacement over time was observed.

$$K_A = {}^{\Delta F}/_{\Delta \delta} \qquad (1)$$

Where F is force in N and δ is displacement in mm.

$$K_T = \Delta M/\Delta\theta \qquad (2)$$

Where M is Torque in Nm and θ is angle in degrees

$$K_{Bending} = \frac{(L+2c)(\Delta F/\Delta\delta)s^2}{12} \qquad (3)$$

Where L is total span, s and c are sub-span (all in mm), F is force in N, and δ is displacement in mm

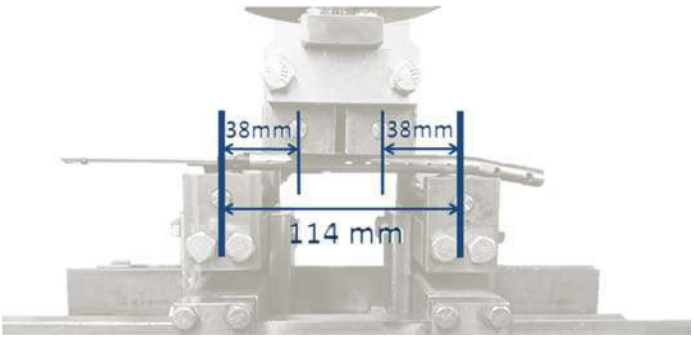

Figure 2: Prototype 2 shown as tested in, with appropriate dimensions labeled.

RESULTS

In quasi-static loading, prototype A's stiffnesses (2.66 N/m axial, 0.46 Nm/degree torsional, and 36.82 Nm^2 bending) were considerably lower than those of prototypes B (1.05 Nm/degree torsional and 80.10 Nm^2 bending) and C (1.49 N/m axial, 2.59 Nm/degree torsional, and 59.02 Nm^2 bending). All three prototypes survived fatigue bending without visual or auditory signs of failure. This indicates that the 4-point bending fatigue limit when cycling at 5 Hz with an applied load of 500 N and R=0.1 is higher than 1 million cycles in all three prototypes. In addition, the dynamic bending stiffness changed by only 1.63 % on average from the first cycle to last cycle for all three types of adjustability. Figure 3 shows a summary of the dynamic bending stiffness at each end of fatigue testing. Peak displacement over all cycles was nearly constant for all prototypes, which supports the result that the dynamic bending stiffness changed minimally.

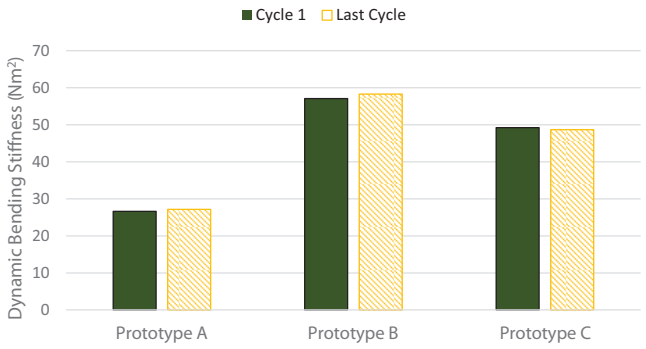

Figure 3: Dynamic bending stiffness of the first (solid green) and last cycle (hatched yellow).

DISCUSSION

All three adjustable length IM nail prototypes survived fatigue testing despite their variance in cross-section, which could create a stress concentrator within the test length. This is well above the expected number of cycles an IM nail would experience before complete bone healing occurs [4]. The minimal change in the hysteresis loops (slope) from cycle 1 to cycle 1 million shows that the structural integrity of the prototypes was not compromised and no plastic deformation or damage occurred. The prototypes' survival through all cycles should serve to supplement proof of safety and effectiveness for eventual FDA 510(k) approval. A successful adjustable-length IM nail that is deemed safe and effective would allow surgeons to repair a patients' long bone fractures more rapidly and accurately. The change to adjustable-length would allow for a better fit in the IM canal which would lead to increased implant performance and therefore a faster rehabilitation process. Regardless of its survival in fatigue testing, prototype A's lower stiffnesses in quasi-static loading suggest it would not perform as well in an *in vivo* setting as the two other methods of adjustability embodied in prototypes B and C. This study is limited by its small sample size and lack of published comparative data. However, even on its own these results indicate that the expected *in vivo* performance of an adjustable-length IM nail is promising and merits further testing.

INTRODUCTION

The anatomy of the anterior cruciate ligament (ACL) and of the posterior cruciate ligament (PCL) has been commonly described as being composed of two bundles [1,2]. The ACL is composed of the anteromedial (AM) and posterolateral (PL) bundles while the PCL is composed of the anterolateral (AL) and posteromedial (PM) bundles. Together the ACL and PCL provide translational and rotational stability to the knee, and the structure and interaction of these ligaments is critical for joint function. Previous work characterizing the mechanical properties of the ACL and PCL has focused predominantly on whole ligament or bundle analyses, and very little work has examined the microstructural organization of these ligaments [3-6]. New sample preparation techniques and imaging technologies developed by our group have enabled more detailed evaluation of material properties of ligament samples. Our recent work quantified the bundle-specific mechanical and microstructural properties of the ACL and PCL [7-9]. For reconstructive surgery of the ACL and PCL, surgeons currently use the same graft materials when repairing the torn ligaments. It is vital to have a better understanding of the material properties of both the ACL and PCL so informed graft choices could be made. Therefore, the purpose of this study was to compare the mechanical and microstructural properties of the ACL and PCL to determine the relative magnitude and heterogeneity of properties in these anatomically proximate ligaments in the knee.

METHODS

Thirty-seven human cadaver knees (avg. age = 42.5 ± 6.2) with no history of trauma or surgery were collected and dissected as previously described [6]. Peripheral soft tissues were removed to expose and isolate the intact ACL and PCL. The division between the two bundles of each ligament was identified, and each bundle was gently isolated and divided into three sections via two incisions in the coronal plane. Each section was then sharply detached from its femoral and tibial attachments, yielding a total of six samples per ligament. Each sample was thinned on a freezing stage microtome to a uniform ~600 micrometer thickness and loaded in a tensile test machine. Using a division-of-focal-plane polarization camera [10], the average direction of collagen orientation (AoP = Angle of Polarization) and the degree to which the fibers are aligned in that direction (DoLP = Degree of Linear Polarization) were quantified on a pixel-wise basis throughout testing (Fig.1). The testing protocol consisted of preconditioning, a stress-relaxation test, and a quasi-static ramp to failure [7]. Microstructural analysis focused on the average (AVG) DoLP and standard deviation (STD) AoP within the central portion of each sample, which was the same region that was tracked optically to compute 2D Lagrangian strains. The ramp to failure data was fit with a bi-linear curve (Fig. 2A), and polarization data were analyzed at specific strain points: zero, transition point, and linear region (i.e., 2X transition strain). Elastic modulus values were computed for the toe- and linear-region of the ramp. Statistical analysis was performed using a linear

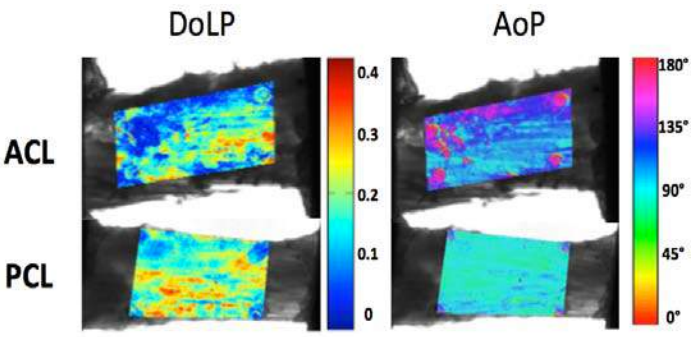

Fig. 1: Representative ACL and PCL samples stretched to 5% strain. DoLP indicates the degree of alignment (averaged through the tissue thickness) and AoP indicates the average angle of collagen alignment.

mixed model for bundle-to-bundle comparisons within each ligament. Unpaired *t*-tests were used to statistically evaluate comparisons between the ACL and PCL. Significance was defined as $p<0.05$.

RESULTS

In the toe-region, modulus values were relatively similar in magnitude between the ACL and PCL and not statistically different (Fig. 2B). In contrast, linear-region moduli were

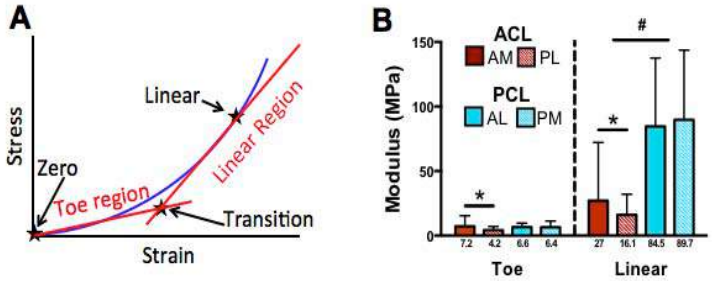

Figure 2: (A) Schematic of a typical stress/strain curve with a bilinear curve fit highlighting the toe- and linear-region moduli, and the zero, transition and linear strain points. (B) Toe-region modulus was similar magnitude in the ACL and PCL, while linear-region modulus was significantly larger in the PCL. The ACL exhibited bundle-bundle differences in both parameters while the PCL were homogeneous (* = statistically significant bundle-bundle differences within ligament; # = significant ACL-PCL differences)

significantly larger for the PCL. Within the ACL, bundle-bundle comparisons were statistically significant for both toe- and linear-region modulus (AM>PL), while there were no bundle-bundle differences in the PCL (AL=PM). Thus, the PCL demonstrates more mechanical homogeneity than the ACL, which exhibits location-specific variation in mechanics. For microstructural properties, STD AoP values were significantly larger for the ACL than the PCL at all three strain points, demonstrating more spread in the angular orientation of collagen (Fig. 3A). The ACL showed significant bundle-bundle differences at transition and linear strains (PL>AM), while there were no interbundle differences for the PCL (AL=PM). STD AoP values decreased for both ligaments from zero to

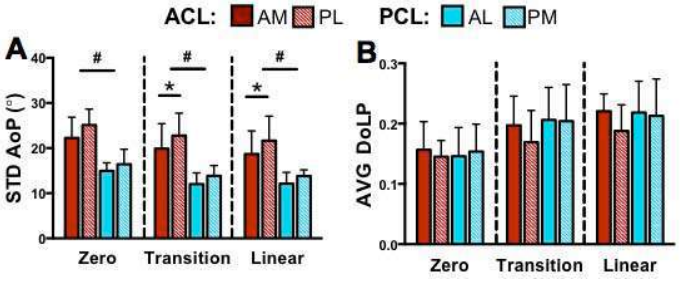

Figure 3: (A) STD AoP was consistently higher for the ACL compared to the PCL, indicating more uniform collagen alignment for the PCL. The ACL exhibited significant bundle-bundle differences at transition and linear points, while the PCL was more homogeneous (B) AVG DoLP was similar for the ACL and PCL with no bundle-bundle differences (* = statistically significant bundle-bundle differences within ligament; # = significant ACL-PCL differences)

transition to linear, indicating collagen realignment during the ramp to failure (Fig. 3A). AVG DoLP values exhibited no differences between the ACL and PCL, and neither ligament showed statistically significant differences between its two bundles (Fig. 3B). AVG DoLP values increased consistently from zero to transition to linear, demonstrating a higher degree of collagen alignment at increasing strain.

DISCUSSION

The microstructural and material properties of the ACL and PCL in the human knee have subtle but potentially important differences. First, there are some differences between the ligaments themselves. The PCL exhibits larger modulus values in the linear region of the stress-strain curve and smaller STD AoP values compared to the ACL. Thus, the PCL exhibits a more uniform distribution of collagen orientation, and a corresponding stiffer mechanical response than the ACL. Second, the ACL demonstrates bundle-bundle differences in mechanical and microstructural parameters while the PCL does not. Thus, the PCL is more homogeneous than the ACL, which demonstrates region-specific variation. The ACL-PCL differences observed in this study may be important for guiding surgical technique and graft choice when reconstructing these ligaments. Further research is necessary to assess how these findings can evaluate current and future graft options for ACL and PCL reconstruction and help optimize surgical techniques and repair strategies.

INTRODUCTION

Cutting edge biomechanical models, such as constrained mixture and multiscale models[1,2], treat individual components of tissues independently, necessitating a firm understanding of the properties of each component. Cell elastic properties are normally reported as Young's modulus[3] but Young's modulus is only valid for isotropic materials undergoing small strains. Vascular smooth muscle cells (VSMCs) are highly anisotropic and undergo large strains *in vivo*. The gold standard for determining tissue-scale anisotropic material properties is biaxial testing. Here, we have developed a method to perform biaxial testing on a single cell, which we used to measure anisotropic mechanical properties of isolated VSMCs and demonstrate that cellular architecture affects the mechanical properties of VSMCs.

METHODS

Substrate fabrication. Micropatterned polyacrylamide-elastomer composites (Fig. 1A inset) were fabricated as described in Simmons et al. and Polio et al. Human umbilical artery vascular smooth muscle cells were obtained from Lonza and cultured at 37 ºC and 5% CO_2. Passages 4-7 were used for experiments. Cells were seeded and cultured overnight in growth medium[6]. Cells were serum starved for >24 hrs prior to stretching.

Cell stretching. Stretching experiments were conducted in Tyrode's buffer at 37 °C as outlined in Fig. 1B (Steps 1-5). Specifically, elastomer membranes were stretched uniaxially (axially and transversely) to 25% (0.5%/s) strain or biaxially to 20% (0.5%/s) strain. Brightfield images of cells and fluorescent images of beads in the top layer of the polyacrylamide gel were obtained during stretch. Cells were then treated with HA-1077 (100 μM) to inhibit contraction. Passive cells were stretched and images were obtained. Cells were then lysed with 0.1% SDS and the substrate was stretched again to obtain cell-free deformation images of the substrate.

Calculation of traction forces and Cauchy stress. A PIV algorithm[7] implemented in ImageJ was used to calculate bead displacements in the top surface of the gel by comparing cell and cell-free images for active and passive stretches. Traction stresses were calculated using an unconstrained Fourier transform traction cytometry algorithm[8]. Traction stress vectors were discretized to 5 x 5 μm^2 grids. Total traction force applied by the cell to the substrate, T_i, in the i-direction was calculated as:

$$T_i = \sum_n A_n |\vec{T}_{i,n}| \quad [1]$$

where A is the discretized unit surface area of the cell and $\vec{T}_i$ are the traction stress vectors. Cell architecture was measured using confocal microscopy and mean Cauchy stress in the central plane of the cell was calculated using measured cross-sections.

RESULTS

We have developed a novel cell-scale biaxial stretcher to determine the mechanical properties of isolated VSMCs (Fig. 1A). The stretcher consists of four grips with independent actuators that can apply any uniaxial or biaxial stretching protocol to a polyacrylamide-elastomer composite. Polyacrylamide gel micropatterning is used to control cellular architecture and fluorescent beads embedded in the gel are used for quantification of cellular traction forces on the substrate.

VSMCs (aspect ratio 1:4) were stretched either uniaxial axially (Fig. 2A), uniaxial transversely (Fig. 2B), or biaxially (Fig. 2C). Bead displacements generated by the cells on the substrate and traction stresses were determined as outlined in Methods. Total traction force applied by the cells, T_i, were calculated using Eqn. [1] for both active and passive stretch. When cells are stretched uniaxial axially, there is a ~2-3 fold increase in traction force in the direction of stretch (T_x) for both active and passive stretch (Fig. 2A iii-iv). However, when cells are stretched transversely there is little change in traction force (T_y) for both active and passive stretch (Fig. 2B iii-iv). These data show that patterned VSMCs exhibit mechanical anisotropy.

To determine the effect of cellular architecture on cell mechanical properties, VSMCs were micropatterned into aspect ratios: 1:1, 1:2, 1:4, 1:8 (Fig. 3A) and stretched uniaxially in either the axial (x) or transverse (y) direction. As the aspect ratio of the cell increases,

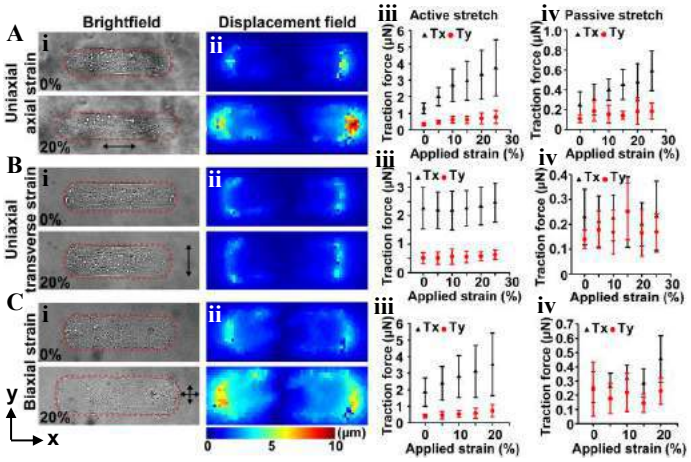

Figure 2. Uniaxial and biaxial stretching of 1:4 aspect ratio VSMCs. (A) Uniaxial axial stretch. (B) Uniaxial transverse stretch. (C) Biaxial stretch. (A-C) (*i*) Brightfield images at 0% and 20% strain. Cells outlined in red. (*ii*) Bead displacement fields at 0% and 20% strain. (*iii*) Traction forces during active stretch. (*iv*) Traction forces during passive stretch. Error bars: standard deviation.

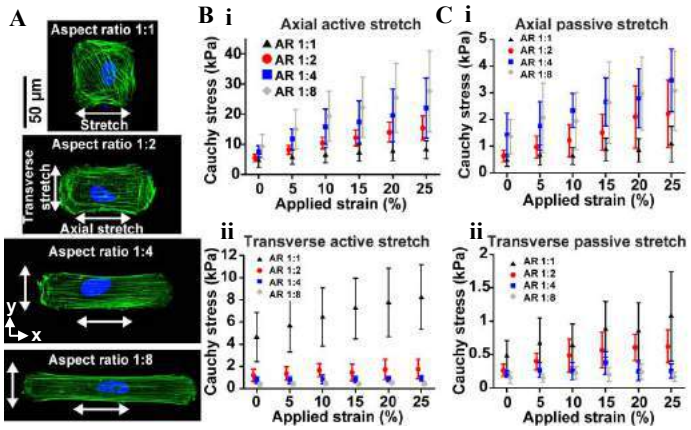

Figure 3. Uniaxial testing of VSMCs. (A) Micropatterned VSMCs. Green: f-actin. Blue: nuclei. (B) Uniaxial active stretch. (C) Uniaxial passive stretch. (B-C) (*i*) Cauchy stress (σ_x) during axial stretch. (*ii*) Cauchy stress (σ_y) during transverse stretch. Error bars: standard deviation.

there is a larger increase in Cauchy stress (σ_x) as the cell is stretched axially and a smaller increase in Cauchy stress (σ_y) when the cell is stretched transversely (Fig. 3B-C). These data show that as aspect ratio increases, the cells become stiffer in the axial direction, along the direction of actin fiber alignment.

DISCUSSION

Patient-specific models (PSMs) of blood vessel mechanics can provide physicians with an additional tool to track aneurysm growth and rupture likelihood[9]. In models utilizing rule-of-mixtures theory, the material properties of each component of blood vessels must be known. Due to a lack of appropriate tools to study and develop constitutive models for VSMCs, current PSMs do not fully incorporate complex cellular mechanical properties, which may limit their capabilities.

Our previous work has shown that cellular architecture affects contractile stress generation in VSMCs[6]. However, the effect of cellular architecture on anisotropic mechanical properties of VSMCs is not fully understood. Here, we show that cell stiffness in the direction of actin fiber alignment increases with cell aspect ratio. Our results suggest that Young's modulus is insufficient to describe the intricate mechanical properties of VSMCs and more complex constitutive models are needed. Future work will include developing a constitutive model that can describe the full 3D mechanical properties of VSMCs.

INTRODUCTION

Injury to the anterior cruciate ligament (ACL) is one of the most serious knee injuries for athletes of all levels, with reported incidence rates between 80,000 and 125,000 per year in the US [1,2]. While over 70% of ACL injuries occur in noncontact situations [3], the exact mechanism is still unknown. However, it is generally believed that some combination of anterior tibial force (AF) [4], valgus knee moment (VM) [3], and internal tibial torque (IT) [5] is present in most non-contact ACL injury scenarios. A second, less understood factor in ACL injury is the role tibiofemoral compression (TFC). While it is believed that TFC plays an important role in ACL injuries, few would argue that these injuries occur without the presence of other forces and moments acting on the knee in conjunction with TFC.

Previous biomechanical studies have examined strain in the ACL with applied AF, VM, and IT at fixed flexion angles [6], but direct measurement of resultant ACL force has not previously been reported during continuous knee flexion under TFC combined application of AF, VM, and IT. Such data are needed to better simulate in vivo sports injury conditions and provide a more complete understanding of ACL injury mechanisms.

The objective of this study was to examine the effects of increasing TFC in combination with AF, VM, and IT (alone and combined) on resultant ACL force and knee kinematics. We hypothesized that TFC would increase ACL force and alter knee kinematics under these simulated ACL injury loading mechanisms.

METHODS

Eight fresh-frozen human cadaveric knee specimens were used, average age of 24.3 years (range 18-34 years). The tibia and femur of each specimen had all soft tissue removed to within 10 cm of the joint line, and both bones were potted in cylindrical molds of PMMA. Using an established technique, the femoral attachment of the ACL was mechanically isolated and attached to a calibrated load cell in order to directly measure resultant ACL force. Using a six degree-of-freedom (DOF) robot, each knee was flexed from 0°-50° while simultaneously seeking target levels of force or moment in the remaining DOFs. Knees were tested with 25N, 200N, and 500N TFC (in that order) combined with application of 1) 45N AF, 2) 5Nm VM, 3) 2Nm IT, and 4) 45N AF + 5Nm VM + 2 Nm IT for each level of TFC. To maintain the mechanical integrity of the ACL/load cell attachment, 350N was the maximum allowable resultant ACL force. Due to the magnitude of ACL force during the combined loading condition at deeper flexion angles, all 500N TFC tests were limited to 0°-30° flexion.

A paired T-test was used to compare 25N TFC to 200N TFC and 200N TFC to 500N TFC at every flexion angle in 5° increments. The level of significance was $p<0.05$.

RESULTS

Resultant ACL force significantly increased with increasing levels of TFC (Figure 1). For each level of TFC, ACL force tended to increase with knee flexion for all loading modes. The combined load of 45N AF + 2Nm IT + 5Nm VM produced the largest amount of resultant ACL force.

Anterior tibial translation significantly increased with increasing levels of TFC (Figure 2), but remained relatively constant with increasing knee flexion for all loading modes. TFC combined with 45N AF alone produced the largest amount of anterior translation.

Both internal tibial rotation (Figure 3) and valgus rotation (Figure 4) showed no significant differences between each level of TFC. Likewise, both internal and valgus tended to increase with increasing flexion for all loading modes. The combined load of 45N AF + 2Nm

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

IT + 5Nm VM produced the largest amounts of both internal and valgus rotation.

DISCUSSION

This study examined the role of TFC on forces generated in the ACL during isolated and combined modes of knee loading relevant to knee injury. To our knowledge, this study represents the first direct measurement of resultant ACL force and knee kinematics using a robotic testing system during continuous knee flexion while maintaining TFC.

We found that during knee flexion, application of valgus moment produced a coupled internal tibial rotation and application of internal torque produced a coupled valgus rotation at all levels of applied TFC.

Our results also show that for all knee loadings, increasing the level of TFC acted to translate the tibia anteriorly with an associated increase in ACL force; internal and valgus rotations associated with these loading modes did not change significantly when the TFC level was increased. It is well recognized that anterior tibial translation is an important mechanism for generating ACL force. Our results demonstrated that TFC activated this mechanism of ACL force generation, even when the ACL had been pre-loaded under the combined AF + IT + VM condition. Since all of our specimens had posteriorly sloping medial and lateral tibial plateaus, the presumed mechanism for ACL force generation during all tests with TFC was anterior tibial displacement produced by tibiofemoral contact force acting on the articular cartilage interfaces.

In summary, the primary effect of TFC for all isolated and combined loading modes was to increase anterior tibial translation, which in turn increased ACL force but did not affect internal or valgus rotations.

INTRODUCTION

Repair of dense connective tissues is limited, given the density of the matrix and the low cellularity of adult tissues [1]. Efforts to augment repair often involve delivering cells and/or growth factors to the wound site via a biomaterial. Electrospinning, a technique that draws polymers into nanofibrous networks, is a versatile platform that offers tunable control over the combinatorial delivery of therapeutics, including their temporal release profile via material degradation and fiber modification. Previously, we fabricated dual-component scaffolds that delivered a matrix-degrading enzyme in a burst-like fashion via the dissolution of water-soluble poly(ethylene oxide) (PEO) nanofibers to expedite integration of the injured knee meniscus [2]. Here, we hypothesized that the addition of slower-degrading fibers composed of hyaluronic acid (HA) [3], a natural polysaccharide, would allow further control of scaffold degradation but that these fibers impede cell infiltration by increasing scaffold density. This study evaluated the time- and enzyme-dependent characteristics of tri-component scaffolds containing poly(ε-caprolactone) (PCL), PEO, and HA, and the migration of adult meniscal cells through these scaffolds. Our results show that the dynamic nature of this microenvironment permits cell migration in the long term, making it a promising material for tissue engineering and drug delivery.

METHODS

Nanofibrous scaffold fabrication and characterization: Composite scaffolds were fabricated through tri-jet electrospinning onto a common rotating mandrel [4] with the following components: poly(ε-caprolactone) (PCL), poly(ethylene oxide) (PEO), and 25% hydroxyethyl methacrylate (HeMA)-modified hyaluronic acid (HA) [3]. Afterwards, scaffolds were crosslinked via UV light and imaged using SEM, where fiber diameter was measured using ImageJ (NIH) (n=4 samples, 50 fibers/sample). To visualize distinct fiber fractions, the PCL, PEO, and HA solutions were doped with rhodamine, fluorescein, and 4',6-diamidino-2-phenylindole (DAPI), respectively, and imaged by fluorescence microscopy. Fiber degradation was evaluated by immersing scaffolds in PBS (~10 mg, 0.5 mm thick) and collecting the eluant at set times (n=3–5 samples). Bulk scaffold mass loss was determined through the dry scaffold weight before and after immersion over 96 hours. The amount of uronic acid, a component of HA, in the supernatant was quantified over 45 days using a modified uronic acid assay [5].

Analysis of cell migration: Cell invasion into nanofibrous composites was evaluated using rhodamine-doped nanofibers spun on glass slides (~20 μm thick). Three randomly aligned substrates were tested: PCL/PEO/PEO (high porosity), PCL/PEO/HA (low porosity), or PCL/PEO/HA treated with 1 mg/mL hyaluronidase (HASE) for 72 hours. Prior to tissue culture, all substrates were washed in PBS to remove the PEO fiber fraction. Adult bovine meniscal explants (5 mm diameter, 3 mm height) were incubated in CellTracker Green for 1 hour and then placed atop substrates to allow for cell egress. After 72 hours in basal media, explants were removed and the egressed cells were stained with DAPI to visualize nuclei. Confocal z-stacks were obtained in the FITC, DAPI, and TRITC channels to visualize cells, corresponding nuclei, and nanofibers. To assess scaffold porosity, the pore area fraction was quantified in Fiji using a central z-slice (n=3 stacks/group). Cell infiltration depth was calculated as the distance between the apical surface of the scaffold and z-centroid location of the nucleus (n=20 cells/group). The average width of nuclei projected in 2D was determined using the Local Thickness plugin in Fiji.

Statistical analysis: Significance was assessed by one-way ANOVA with Tukey's HSD post hoc for pore area fraction, infiltration depth, and average nuclear width ($p \leq 0.05$). Data are

presented as mean ± standard deviation unless specified otherwise.

RESULTS

Composite nanofibrous scaffolds containing poly(ε-caprolactone) (PCL), poly(ethylene oxide) (PEO), and hyaluronic acid (HA) with HeMA functionalization were electrospun (PCL/PEO/HA). SEM micrographs revealed smooth and uniform fibers, with an average fiber diameter of 308 ± 143 nm. Images of fluorescently labeled fibers validated the presence of three discrete populations (Fig. 1C).

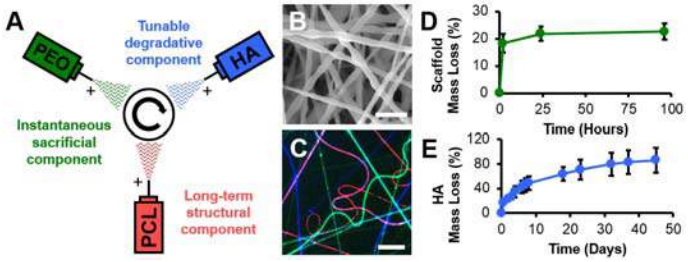

Fig. 1: Controlled fiber degradation from tri-component scaffolds. (A) Electrospinning schematic. (B) SEM micrograph of PCL/PEO/HA scaffold. Scale = 5 µm. (C) Fluorescent image of PCL (red), PEO (green), and HA (blue) fibers. Scale = 20 µm. (D) Bulk scaffold and (E) HA mass loss in PBS (n=3–5 samples).

Degradation of each fiber fraction was time-dependent and occurred independently of one another. After 2 hours in PBS, 18% of the total scaffold mass was lost, likely representing the loss of the PEO via dissolution and diffusion of uncrosslinked HA from the network (Fig. 1D). After 24 hours, mass loss reached 22% and remained constant thereafter, indicating that the majority of PEO had been removed from the scaffold. In contrast, HA degradation showed a more linear profile, with 35% and 60% mass loss after 4 and 16 days (Fig. 1E). After 45 days, only 14% of the HA remained, resulting in a scaffold that was comprised primarily of PCL.

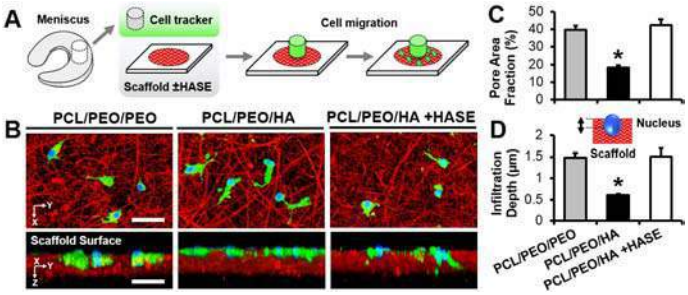

Fig. 2: High porosity scaffolds expedite cell infiltration. (A) Experimental schematic. (B) Images of cells within scaffolds. Scales = 50 µm. (C) Pore area fraction (n=3 samples/group). (D) Cell infiltration depth with schematic inset (mean ± standard error; n=20 cells/group). * = p≤0.05 vs. all other groups.

Adult meniscal cells from explants adhered, spread, and infiltrated into nanofibrous substrates within 72 hours (Fig. 2B). Analysis of cell infiltration into high (PCL/PEO/PEO) and low (PCL/PEO/HA) porosity scaffolds revealed that infiltration depth was affected by nanofiber density. The inclusion of HA fibers reduced the pore area fraction to less than half of the PCL/PEO/PEO substrate, which contained an additional sacrificial PEO fraction (Fig. 2C, p≤0.05). Consequently, infiltration depth was lower for cells on PCL/PEO/HA compared to cells on PCL/PEO/PEO (Fig. 2D, p≤0.05). When HA fibers were selectively removed by hyaluronidase digestion (+HASE), the pore area fraction was restored and cells migrated to a similar extent as on PCL/PEO/PEO (Figs. 2C and 2D, p≤0.05). In addition, cells migrating through PCL/PEO/HA had larger and rounder nuclei than those within PCL/PEO/PEO and PCL/PEO/HA +HASE (Fig. 3A), and contained the greatest average nuclear width among groups (Fig. 3B, p≤0.05). Combining data from all groups revealed a negative linear correlation between average nuclear width and infiltration depth (y = -0.32x + 4; R^2 = 0.35) (Fig. 3C).

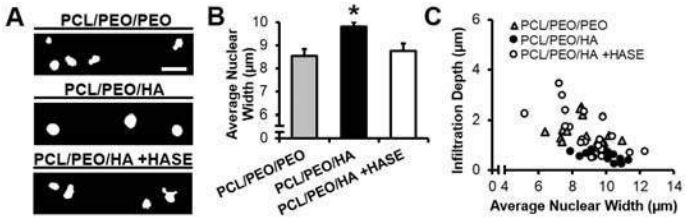

Fig. 3: Nuclear deformation during cell migration. (A) Binarized 2D projections of cell nuclei (top down view). Scale = 20 µm. (B) Average nuclear width (mean ± standard error; n=20 cells/group). * = p≤0.05 vs. all other groups. (C) Infiltration depth as a function of average nuclear width (n=20 cells/group).

DISCUSSION

Cellular colonization is essential for acellular scaffolds that rely on endogenous matrix deposition to bolster mechanical properties and ensure survival in a dynamically loaded environment. However, rapid cell attachment and proliferation on the scaffold surface may prevent cell penetration into the scaffold depth, resulting in a cell-rich outer edge but a necrotic center. As such, achieving sufficient cell density and homogenous distribution within the scaffold are vital steps towards generating functional tissue replacements. Our findings indicate that nuclear deformation and scaffold porosity are necessary for cell migration through nanofibrous microenvironments. In order to pass through confined space, cells must overcome the steric constraints that are imposed on its nucleus, which is 2–4 times stiffer than the surrounding cytoplasm and considered the rate-limiting organelle in migration [6, 7]. Indeed, the majority of mobile cells are characterized by small and deformed nuclei, suggesting that nuclear plasticity plays an essential role in navigating tight interstitia. In this study, modification of HA with HeMA groups promoted fiber degradation in aqueous environments via a hydrolyzable ester group, resulting in a HA mass loss of approximately 80% after 4 weeks. While the addition of HA fibers may be an impediment to migration early on, selective removal of HA with hyaluronidase increased the scaffold porosity and cell infiltration, suggesting that this material will permit cell colonization in the long term. Fibers may be further functionalized to include biofactors, which can be released as the material degrades over time to influence cells in a temporally targeted manner. By designing smart, dynamic scaffolds that reflect the optimal microenvironmental niche for cell and tissue ingrowth over time, ultimately we hope to recapitulate the natural biological cues that direct repair and regeneration of dense connective tissues.

INTRODUCTION

The study of the physiology and pathology of the pelvic organs is a research activity whose aims have increased gradually in recent years. The pelvic floor presents a complex equilibrium related to the mechanical properties of tissues involved and their geometries [1]. Disturbance of such an equilibrium may induce pathophysiology mobility such as genital prolapse, which is a major health problem concerning 30% of the women population [2]. Different anatomical structures seem to play a key role in that balance and the authors have remained on the role of the pelvic muscles. Recently it has been demonstrated that the uterosacral ligaments also play an important role in supporting organs [3, 4]. This complex equilibrium might be impacted by the life events such as aging, pregnancy or delivery.

During pregnancy, a modification of the pelvic floor appears [5]. The main hypothesis of these changes demonstrated previously is the modification of biomechanical properties of the pelvic tissues [6]. Modifications that occur in the parturient lead us to study the sustainable structures to increase our understandings. Computer simulation using Finite Element (FE) method is one tool helping to achieve this through the study of strains and stresses during pregnancy and vaginal delivery. However, it is necessary to have a complete biofidelic model described by all ligaments and muscles to undertake this type of analysis.

The objective of our work falls within this approach using numerical models of a pregnant woman, at different terms of pregnancy, during delivery and during the post-partum period. Firstly, all of these models will be used to observe the geometrical changes during pregnancy. Secondly we can simulate childbirth to analyze the deformations that occur on the pelvic floor during delivery. The analysis of all these results will bring a better understanding of the phenomena involved on those different configurations.

METHODS

Different MRI (Magnetic Resonance Imaging) sequences in T1 and T2 and proton density were performed on a pregnant primiparous woman, without notable medical history. MRI are performed at different terms of pregnancy eg 16, 32, and 38, weeks of gestation (WG) and two months after delivery. These sequences allow us to get a slice imaging of the pelvic cavity used to generate four 3D models representing the pelvis during pregnancy and after delivery. A manual segmentation of the images is achieved on the software AVIZO Standard Edition 7® (VSG Visualization Sciences Group, SAS). It is performed by surgeons and anatomists whose skills can identify with confidence each anatomical structure. All sections are analyzed to select organs, muscles and ligaments useful in the study and the bone structure.

Visually, the MRI slices do not permit easy observations of a possible change in the muscles and ligaments. To distinguish some geometric differences, for each term, a digital model is generated on the basis of our 3D reconstructions. To exploit these representations, it is necessary to transform them into surfaced model to quantify efficiently the possible differences on sustainable structures. It consists in creating B-Splines on each anatomical structure to have a wireframe model on which surfaced patches are applied, defining each organ, muscle and ligament. Eighteen representative structures are identified individually for each term in order to establish with precision the geometrical changes during pregnancy.

The advantage of this model is to make it compatible to perform simulations with FE method (Abaqus/CAE 6.12-2 software). For the numerical simulations, we assign mechanical properties from preliminary works referenced in the literature [7, 8]. Boundary conditions follow also the same protocol as the one established on the study of physiological [1] or pathological mobility [9]. We use an FE

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

model corresponding to the 16WG representation and we perform different changes of the loading conditions to match with the growing weight at 32WG and 38WG. From the FE simulation results, the anatomical structures are analyzed on the deformed mesh to quantify geometrical modifications such as the ligament lengthening and compare it with the geometrical analysis of each MRI.

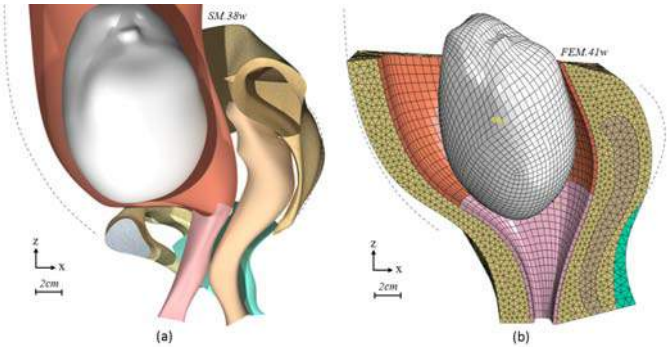

Figure 1: (a) 3D model of the pelvic at 38WG, (b) FE model of delivery with full cervical dilatation and LOA presentation.

The last study uses the geometric model at 38WG that corresponds to the representation of the pelvic floor 3 weeks before delivery. We perform some modifications on the surfaced model to represent a full cervical dilatation (expulsion stage) and model the fetal head in the descent position (figure 1). The imposed trajectory of the head was defined thanks to the geometrical representation at 38WG; displacement and rotational equations are established to match with a left occipito-anterior scenario (LOA) that corresponds to the most common form of cephalic presentation. The trajectory of the fetal head is an input parameter on the FE model and can be modified to correspond to other cephalic configurations to be compared to each other and to investigate their impact on the pelvic system.

Our study can be summarized by the analysis of geometrical modifications, stresses and strains applied on the pelvic floor during pregnancy and after several delivery scenarios. This protocol employed 3 types of analysis:

- Geometrical analysis on the four 3D models from MRI.
- FE analysis during pregnancy with evolution of weight.
- FE analysis during delivery with different configurations.

RESULTS

For the analysis of anatomical sustainable structures from the four MRI models, we initially studied the evolution of the ligamentous system. The first result shows an increase in the length of the uterosacral ligaments (USL) according to the term, followed by a decrease in postpartum. For 16, 32, 38 weeks of gestation, the lengths of the USL are respectively 40mm, 46mm, 51mm. Two months after delivery, there is a decrease in USL size, without return of values observed at the beginning of pregnancy. Regarding the muscular structures of the pelvic floor, our analysis is mainly focused on puborectal levator ani muscle (PLAM). During this analysis, the same type of evolution is observed on the puborectalis muscle which is a part of PLAM. We find an increase in the thickness depending on the pregnancy term, followed by a decrease on postpartum. The decrease observed 2 months after delivery is not so complete because we do not find the values of early pregnancy. Variations on the USL and the puborectalis muscle do not seem to be equivalent to other anatomical structures of suspension where geometrical changes are insignificant compared to them.

The FE analysis performed on our model during pregnancy by changing the weight of uterus also allows us to observe an increase in the USL length. However we do not reach the lengthening levels observed on the previous geometrical analysis based on the 4 MRI models. FE simulations during pregnancy help us to highlight that hyperelasticity of material properties does not return to these strain levels, reflecting that other factors influence the change of anatomical structures during pregnancy. The geometrical modifications do not depend only on weight gain. This finding leads to the contribution of hormonal factors in pelvic changes.

The last FE simulation is focused on the fetal expulsion stage thanks to the passage of fetal head in the parturient canal (Figure 1b). To ensure the computational convergence, a structured mesh is employed in accordance with each delimitation of anatomical structures. During the engagement of the head in the transverse position, the numerical simulation enables us to identify areas with high strain level near the cervix. These stressed areas move near the vagina during the descent and flexion phases. The pelvic floor muscles are highly stressed when the head reaches the vulva. Such simulation will help to a better understanding of the strain mapping within the pelvic system and lead to a better understanding on the consequences of delivery on the mechanical properties of soft tissues since their behavior and damage are strain depending.

DISCUSSION

Through this summarized study, we can notice different changes in the ligamentous and muscular geometries during pregnancy. These preliminary results observed thanks to MRI at different terms have been compared to FE simulations of gestation to highlight that these geometric changes are not only due to loading conditions (pregnancy weight gain). The level of impairment from FE simulations is lower than that observed on MRI, which induces that hormonal factors could be involved. Secondly, this protocol allows us to perform FE simulations of the delivery on a biofidelic model of the entire pelvic cavity, with a refined mesh of the muscles and ligaments. Such a tool is useful to identify the highly stressed areas following the cephalic presentations and the kinematics of the head. This research performed on the whole sustainable structure will help us to take into account the high stress induced damages and identify potential failure areas. Investigating soft tissue injury is the next step leading to better understanding of involved phenomena during delivery and adapted obstetric gesture and surgery.

Current limitations of this study are the imposed trajectory of the head descent. However, the imposed trajectory allows us to analyze the influence of several scenarios to identify strain and stress during labor and delivery complications. The next steps are to use uncontrolled trajectory and estimate the consequences of delivery on the strain induced damageable behavior of all the pelvic structures and finally to reach the patient-specific simulations.

SHAPE OPTIMIZATION OF LUMBAR INTERVERTEBRAL CAGES FEATURING DIFFERENT CROSS-SECTION SHAPES

INTRODUCTION

Intervertebral lumbar fusion using an implanted cage is the gold standard surgical treatment for disc diseases such as disc collapse and spinal cord compression, when more conservative medical therapy fails [1]. Titanium (Ti) alloys are widely used implant materials due to their superior biocompatibility and corrosion resistance [2]. A new Ti cage concept featuring I or H shaped cross-sections was recently proposed, with the intent to allow bone graft paste injection and perfusion secondary to cage implantation. However, subsidence or loosening of high stiffness Ti implants due to stress shielding is a concern [3]. Design optimization is a systematic and iterative technique for designing components which perform optimally with respect to one or more performance metrics. In these cages, we desire a clear pathway for bone graft to be injected into the implants, and perfused into the surrounding intradiscal space as much as possible. Therefore, in this study, we have employed shape optimization to maximize the sizes of cage windows (and simultaneously increase cage compliance to relieve stress shielding), subject to maintaining stresses below a threshold where fatigue failure is a concern.

METHODS

Fig. 1 shows the general shapes of three interbody cage conceptual designs, which consist of an I-shaped cage with a 45° wedge, a hollow cage with a 45° wedge, and a double-configuration (DC) cage with 45° and 60° wedges, which were modelled parametrically in ANSYS Mechanical APDL 15.0. The DC cage (Fig. 1(c)) can be inserted into the intradiscal space in both an I-configuration (principal configuration) and an H-configuration (secondary configuration), thus allowing a single component to provide two height options by manufacturing the implant with unequal width and height. Here, in order to make comparison among these cage designs, the same overall dimensions of 30 mm in length, 11 mm in width, and 11 mm in height were chosen for all the cages, based on the dimensions of existing commercially available lumbar cage designs. As illustrated by Fig. 2, the location (x_1), length (x_2), and width (x_3) of each window on the flanges and webs have a considerable impact on stress concentrations and bone diffusion/fusion, thus they are considered as design variables for shape optimization. Our design objective is to maximize the window sizes by adjusting these design variables to enhance bone graft perfusion and encourage larger mechanical stimuli for bone growth within these cages.

Any candidate cage design must also be able to pass pre-clinical testing, which is often assessed using ASTM standard protocols. Dynamic testing of each candidate implant design was simulated using the configuration described in ASTM F2077. A force-distributed multi-point constraint technique was employed in ANSYS to simulate the connections between the interbody cage and two polyurethane testing blocks. As shown in Fig. 3, two pilot nodes were respectively attached at the geometric centers of the upper and lower testing blocks. A compressive load (F) of 500 N and a fully reversing bending moment (M) with the amplitude of 2750 Nmm was applied on the pilot node of the upper testing block. The pilot node of the lower testing block was fully constrained. The bending moment simulated the effect of the primarily compressive load acting at a distance of half the cage width from the cage center.

All cages were modeled using pure Ti (grade 4) material properties, with a Young's modulus of 104 MPa, Poisson's ratio of 0.3, endurance limit (S_e) of 260 MPa, and yield strength (S_y) of 462 MPa. The Sorderberg's equation considering both effects of stress intensity amplitude (σ_a) and mean stress intensity (σ_m) was slightly

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

modified to establish an infinite-life fatigue criterion (Eq. 1), such that any fatigue factor (k) less than or equal to one was defined as safe,

$$k = \frac{\sigma_a}{S_e} + \frac{\sigma_m}{S_y} \leq 1 \quad (1)$$

The fatigue factors at all nodes of each cage model were calculated based on the stress intensity results solved using ANSYS, but only the maximum nodal fatigue factor was used to evaluate the safety of a candidate cage design. Shape optimization of each cage was performed using the Optimization Toolbox in MATLAB R2015a, and the nonlinear constraints were represented by the proposed infinite-life fatigue criterion (Eq. 1).

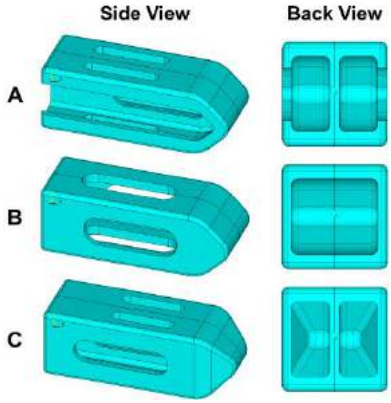

Figure 1: The initial designs of three interbody cages featuring different cross-section shapes. (a) I-shaped cage; (b) Hollow cage; (c) DC cage.

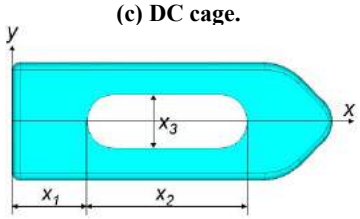

Figure 2: The design variables adopted in the shape optimization, including the location (x_1), length (x_2), and width (x_3) of each window in all cage designs.

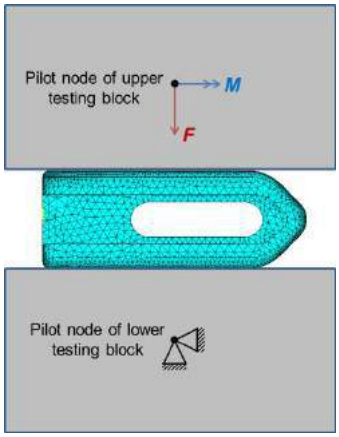

Figure 3: The finite element model of the interbody cage and the dynamic loads applied in the fatigue analysis.

RESULTS

According to the stress analysis results shown in Fig. 4, each of the general cage designs were more stressed after shape optimization than they were initially (Fig. 1), indicating that increasing mechanical stimuli existed within the bone graft space. Although fatigue failure typically occurs at the locations of maximum stress intensity (Fig. 4), the fatigue analysis demonstrated that all cage structures are sufficiently reliable for long term loading, since they satisfy our proposed infinite-life criterion (Eq. 1).

The material volumes of all cages were reduced to accommodate more bone graft with respect to their initial designs. Among these cages, however, the minimum material volume (798 mm^3) and optimal window layouts were obtained for the hollow cage (Fig. 4(b)), where the enlarged windows will promote bone fusion with vertebral endplates and bone graft diffusion through side windows. For the I-shaped cage design (Fig. 4(a)), the web window size was reduced significantly and the flange windows were shifted away from the center of the cage in order to alleviate stress concentrations. Although the window layouts of the DC cage design (Fig. 4(c)) were improved, the shifted windows on the flanges may also cause poor bone fusion with vertebral endplates when using the I-configuration.

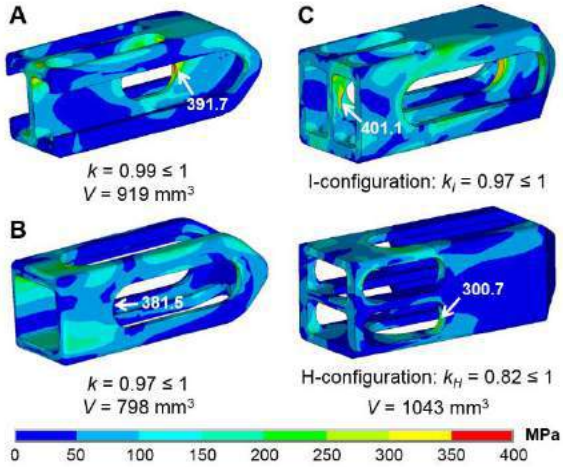

Figure 4: Comparison of the resulting implant shapes and stress distributions of three cage designs after shape optimization. (a) I-shaped cage; (b) Hollow cage; (c) DC cage in both configurations. The fatigue factor (k) of each cage was evaluated using the stress intensity results. The maximum stress locations were marked using white arrows.

DISCUSSION

The larger windows and allowable deformation within these cage designs are expected to promote bone fusion after discectomy surgery. In particular, shape optimization of the hollow cage design (Fig. 4(b)) led to the ideal window layouts for bone fusion and diffusion, as well as meeting the infinite-life fatigue criterion. However, designs developed using optimization techniques are necessarily a product of assumptions relating to what design variables can be modified and what loads are expected. Future work should further validate whether or not each resulting cage design has reached the true global optimum in the feasible design space, and include a greater number of design variables (thus, a larger design space) and a wider variety of loading scenarios to test the performance of candidate implant designs. Experimental validation will also be a focus of future work. In conclusion, we have demonstrated that the bone graft perfusion windows of these cage concepts can be maximized using design optimization, while considering fatigue stresses as a constraint.

INTRODUCTION

Abdominal aortic dissection, manifested as delamination and separation of the media layer from the arterial wall, may direct blood flow into the newly created false lumen, and the blood flow in turn aggravates the delamination in the form of Mode I or mixed-mode failure [1, 2]. Moreover, with the inherent inhomogeneity of the arterial wall along the delamination path, the delaminated media layer may be peeled from the arterial wall in a mixed-mode failure process [3]. Existing studies in the literature have investigated the dissection of the arterial wall, but experimental investigations of arterial wall delamination events and the analyses and numerical simulations of such events have been limited. To this end, two types of delamination experiments on porcine abdominal aorta specimens have been carried out, and these experiments have been simulated numerically using the finite element method and the cohesive zone model approach. A comparison of these two types of experiments and their analyses is presented here.

METHODS

Mechanical Testing

An abdominal aorta sample was isolated from freshly harvested adult porcine kidneys and rinsed with phosphate buffered saline. An approximately 30 mm long segment was cut, following a radial cut imposed onto the sample along the vessel axis, yielding a strip. Two groups of specimens oriented at an angle of 0° and 90° with respect to the circumferential vessel axis were cut from the sample.

Two types of delamination experiments were performed, as shown in Fig. 1. In each case, to initiate a delamination process in the media layer of the arterial wall, a small initial delamination flaw with a straight delamination front was carefully introduced at one end of the specimen inside the media layer. In the "mixed-mode" experiment (see Figs. 1a and 1c), the bottom surface of the lower portion of the specimen was glued to a glass plate in order to restrict its motion during loading, and the proximal end of the upper delaminated portion was peeled away by a micro-clamp. During the delamination process, the delaminated upper portion became almost parallel to the lower portion and to the not-yet delaminated interface (Fig. 1c). In the "Mode I" experiment (see Figs. 1b and 1d), the proximal end of one of the two initially separated portions of the specimen was fixed by tissue glue to a glass plate and the proximal end of the other separated portion was pulled away by a micro-clamp. During the delamination process, the two delaminated portions stay parallel to each other but are approximately perpendicular to the not-yet delaminated interface (Fig. 1d).

During each experiment, the prescribed displacement and reaction load were recorded via the system actuator and load cell (Bose ELF 3200, Biodynamic Co, MN). The delamination process was recorded by a computer vision system in which two cameras were perpendicularly positioned to get both front and side views of the specimen.

Theoretical Framework

The mechanical properties of abdominal aorta depend on the properties and spatial arrangement of elastin and collagen, which are major load bearing structural constituents. We adopt the analytical form of the strain energy density function $\bar{\Psi}$ motivated by the structure of the arterial wall, as stated in the HGO model in [4].

$$\bar{\Psi} = \frac{\mu}{2}(\bar{I}_1 - 3) + \sum_{i=1,2} \frac{k_1}{2k_2}\left[e^{k_2[\kappa \bar{I}_1 + (1-3\kappa)\bar{I}_{4i} - 1]^2} - 1\right] \quad (1)$$

where μ is a stress-like parameter, representing the shear modulus of the amorphous matrix; $\bar{I}_1 = tr(\bar{\boldsymbol{C}})$ is the first invariant of $\bar{\boldsymbol{C}}$ which is the right Cauchy-Green strain tensor; k_1 denotes the relative stiffness of fibers; k_2 is a dimensionless parameter; $\bar{I}_{41}$ and $\bar{I}_{42}$ are tensor invariants equal to the square of the stretch in the direction of two families of fibers, respectively; and κ is the dispersion parameter, describing the dispersion of the two families of fibers in the arterial wall. $\kappa = 0$ when the two families of collagen fibers are parallel to each other and $\kappa = 1/3$ when collagen fibers distribute isotropically.

The cohesive zone model (CZM) is used to characterize the interfacial damage behavior of the arterial tissue, with the form as follows:

$$d = \frac{e\sigma_c\delta_0\left[1-\left(1+\frac{\delta_{max}}{\delta_0}\right)exp\left(-\frac{\delta_{max}}{\delta_0}\right)\right]}{G_c} \quad (2)$$

where $e = \exp(1) \approx 2.71828$ and σ_c denotes the strength of the material; $\delta_0 = \frac{G_c}{e\sigma_c}$ is the maximum effective separation at $t = \sigma_c$; where δ_{max} denotes the maximum effective separation during one delamination cycle (Fig. 2),

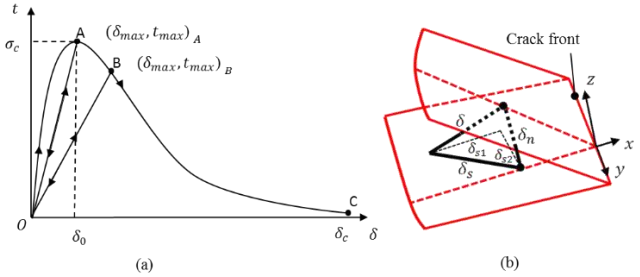

Figure 2. (a) Irreversible exponential cohesive zone model labeled with normalized effective traction and effective separation; (b) a schematic of sliding (δ_s), opening (δ_n) and effective (δ) separations.

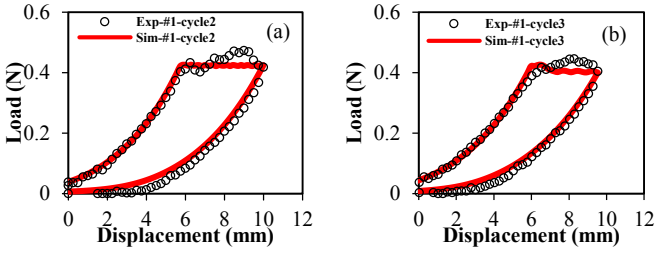
RESULTS

The material parameter values associated with the HGO model for the aortic layer and CZM for the delamination interface were identified by matching simulation predictions of the overall load-displacement curve of cycle 1 from the loading phase and the delamination phase with experimental measurements from the mixed-mode and mode I delamination experiments, respectively [3]. Simulation predictions of the load-displacement curves for cycle 2 and cycle 3 of the delamination experiments are shown in Fig.3a, b and Fig.3c, d, respectively.



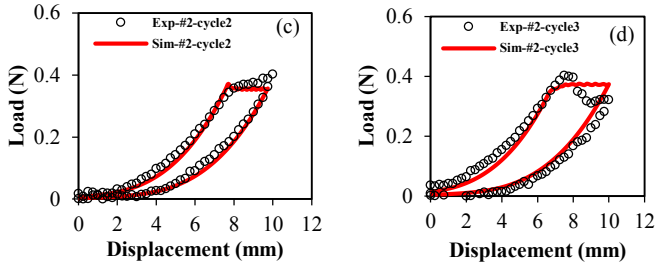


Figure 3. Comparison of predicted load-displacement curves of one loading-unloading cycle with the measured curves. (a) (b) mixed-mode experiment; (c) (d) mode I experiment.

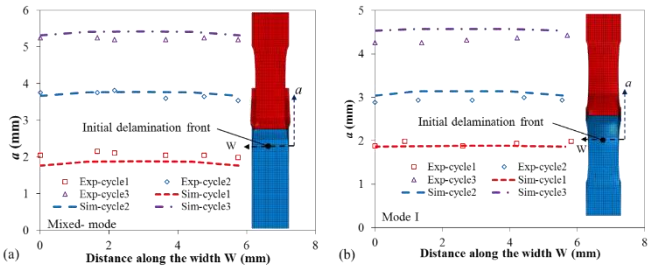

Figure 4. Comparison of predicted and measured delamination front profiles: (a) mixed-mode experiment; (b) mode I experiment.

When the delamination process is in a steady state, the delamination fronts move forward with the separation of two aortic layers. Figure 4 compares the total delamination distances from cycle 1 to cycle 3 with respect to the initial crack front for mixed-mode (Fig. 4a) and mode I (Fig. 4b) experiments, respectively.

DISCUSSION

For both basic science and clinical studies, including disease diagnosis and risk evaluation, it is advantageous to understand the arterial mechanical response during delamination under various loading conditions. The major goals of vascular biomechanics are to determine the appropriate mathematical formulations that describe tissue mechanical properties and interface damage strength, allowing the solution of boundary value problems with predictive power. In this study, the use of an arterial wall structure-motivated constitutive law and a cohesive zone model have enabled the simulation of aortic media delamination behavior based on the critical energy release rate from mechanical testing. This integrated theoretical-experimental approach was demonstrated by comparing the loading-delamination-unloading curves and the crack fronts between numerical simulation predictions and experimental measurements for two types of experiments. The delamination simulation facilitates quantification of the delaminated mechanical response of arterial walls and the understanding of the pathophysiological mechanical performance, and may shed light on the genesis and progression of certain forms of arterial aneurysms and dissections.

PREDICTING FALSE LUMEN THROMBOSIS IN 3D PATIENT-SPECIFIC MODELS OF TYPE B AORTIC DISSECTION

INTRODUCTION

Aortic dissection is a major aortic disease with high morbidity and mortality, which compromises blood perfusion in the entire body. Dissection is caused by a tear on the inner layer of the aortic wall, which allows flow diversion and causes splitting of the wall layers, leading to the formation of a "false lumen" (FL). Type B (distal) dissections are treated either medically or through endovascular stenting (TEVAR). For Type B patients, there is a large variability in post-discharge prognosis, with mortality rates ranging between 48 and 82% [1]. The status of FL (patent, partially or completely thrombosed) was identified as a significant predictor for late outcomes [1, 2]. Partial FL thrombosis is associated with higher mortality rates, due to a possible increase in pressure and a higher risk for expansion and rupture. Yet, complete FL thrombosis is associated with improved prognosis and effective endovascular treatments.

The use of computational methods holds much promise in understanding what conditions favour FL thrombosis in order to optimize treatment strategies. Here we present the application of a hemodynamics-based model to the study of FL thrombosis in patient-specific dissections. Model predictions are based on the distribution of time-averaged hemodynamic parameters and a limited number of transport equations. The model is applied to patient-specific cases following either medical treatment or TEVAR, and FL thrombosis and its effects on flow are simulated under physiological flow conditions. Predicted thrombus growth patterns are compared with follow-up CT scans in order to validate predictions and assess the capability of the model to predict FL thrombosis for different treatment strategies.

METHODS

Patient-specific geometries were reconstructed from CT scans by using the image processing software Mimics (Materialize HQ). Patients were classified into four groups: (i) medically treated, with no thrombosis (NT1); (ii) medically treated with partial FL thrombosis (S1 and S4, obtained from the same patient six months apart); (iii) TEVAR with partial FL thrombosis (I1); and (iv) TEVAR with complete FL thrombosis (C1). All patients were kept under CT surveillance for a period of at least three years, and follow-up CT scans were available for validation.

A hemodynamics-based model was used to predict thrombus formation and growth. The model is based on transport equations for a limited number of variables (e.g. residence time, different forms of platelets, and a coagulant), and predictions are driven by the distribution of time-averaged hemodynamic parameters. Regions of thrombus formation are identified through a low shear threshold. The momentum equation was modified to account for the porosity ϵ of clots, and a source term S_M was added to account for the resistance caused by a growing thrombus to the flow:

$$\rho\frac{\partial\epsilon\mathbf{u}}{\partial t}+\nabla\cdot(\rho\epsilon\mathbf{u}\times\mathbf{u})=-\epsilon\nabla p+\nabla\cdot(\mu\epsilon(\nabla\mathbf{u}+\nabla\mathbf{u}^T))-\epsilon S_M \quad (1)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Each geometric model was discretized into an unstructured mesh, comprising a tetrahedral core and 10 prismatic layers near the walls with a total of approximately 3,000,000 elements. A pulsatile flow waveform was applied at the inlet, and the walls were assumed to be rigid. Zero pressure and/or three-element Windkessel model were imposed at the outlets. A physiological resting platelet concentration of $2.5 \cdot 10^8$ platelets/cm^3 was prescribed at the inlet, with zero concentration for all other species.

RESULTS

Predicted thrombus growth patterns were compared with follow-up CT scans (Figs 1 and 2) and a good agreement was found in all cases. In patient S1 (not shown here), thrombus growth was initiated at the top of FL. The formation of a middle tear in model S4 altered the flow pattern and gave rise to a recirculation zone in-between the proximal and middle tears, resulting in thrombosis on the lateral side of FL. Fast and complete FL thrombosis was observed in patient C1 (Fig 2b), while in patient I1 thrombus was formed much slowly with its FL remaining partially patent (Fig 2a). No thrombus growth was observed in patient NT1.

DISCUSSION

For Type B dissections, FL thrombosis has been recognized as an indicator of patient prognosis [1, 2]. However, no methods are currently available to predict the chances for FL thrombosis and the extent of thrombosis for an individual patient. This study presents the application of a newly developed hemodynamics-based model to the formation and growth of thrombus in patient-specific dissections. Predicted thrombus growth patterns agreed well with in vivo observations from follow-up CT scans, demonstrating that the model is able to capture how different morphologies and flow features may lead to different thrombus growth patterns, and how the expansion of thrombus may affect the flow. While previous computational studies were mostly focused on modeling the complex chain of biochemical processes involved in the coagulation cascade and were more likely to be limited to simple geometries and/or steady flows [3,4], our model can identify regions of potential growth from flow features, allowing us to study physiological flows and geometries of clinical interest. To minimize computational costs, predictions are based on time-averaged parameters and accelerated kinetics. Although this approach is unable to capture real-time growth rates, it is effective in reproducing thrombus growth patterns over time and has been shown to be applicable to both medically and TEVAR treated patients.

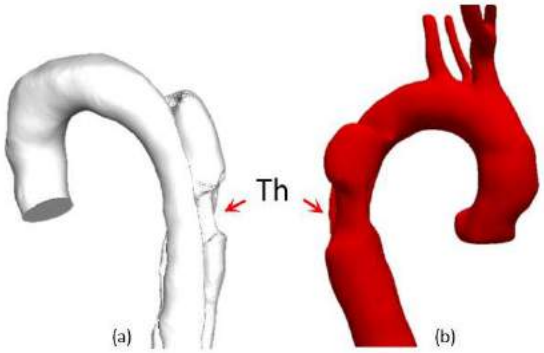

Figure 1: (a) Lumen surface predicted in patient #S4 after FL thrombosis (Th). (b) Follow-up patient geometry reconstructed from CT scans from the same patient.

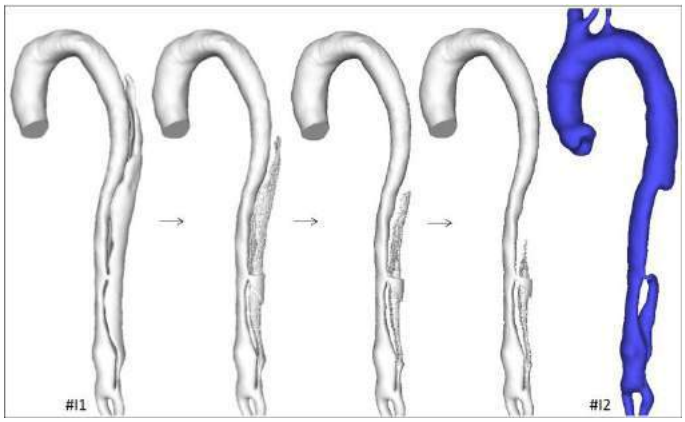
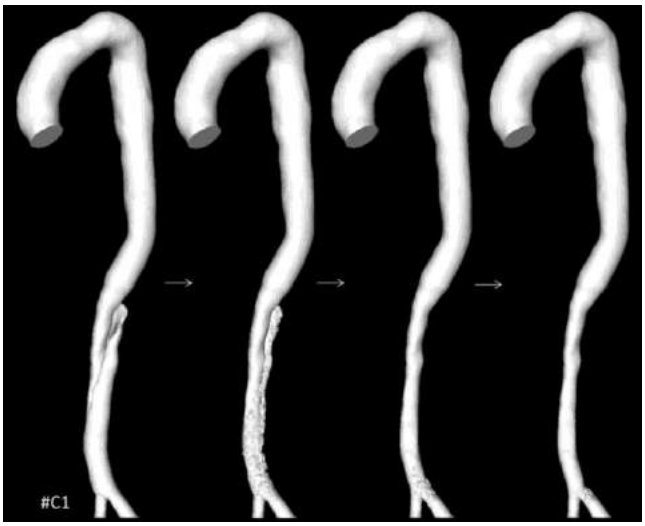


(a)



(b)

Figure 2: Time-evolution of the lumen surface following FL thrombosis in (a) #I1, compared to geometry #I2 extracted from follow-up CT scans from the same patient; and (b) #C1.

This is an on-going research aimed at identifying key parameters inducing FL thrombosis in order to optimize treatment strategies. Further studies will be carried out on more clinical cases.

INTRODUCTION

Alteration in intracranial pressure (ICP) has been associated with various ocular pathologies that cause visual impairment, including glaucoma, idiopathic intracranial hypertension and Visual Impairment and Intracranial Pressure (VIIP) syndrome. While much research has focused on how elevated intraocular pressure (IOP) alters the deformation of optic nerve head (ONH) tissues, it is unclear how ICP alters deformation of ocular tissues and eventually leads to vision loss.

Recently, understanding the effect of elevated ICP on ocular tissues has become a major concern for NASA, where 42% of astronauts that partake in long duration space missions suffer from VIIP syndrome. Astronauts with VIIP syndrome suffer from visual impairment and changes in ocular anatomy that persist after returning to earth (1). It is hypothesized that the cephalad fluid shift that occurs upon entering microgravity increases ICP, which leads to an altered biomechanical environment in the posterior globe and optic nerve sheath, and subsequently VIIP syndrome.

Our goal was to develop a finite element (FE) model to simulate the acute effects of elevated ICP on the posterior eye. Here, we simulated how inter-individual differences in pressures, tissue material properties and ocular geometry affect the deformation of ONH tissues.

METHODS

Our geometric model was an extension of an established model of the posterior eye (2), including the annular scleral ring, pia mater, dura mater, and optic nerve. The pia mater, dura mater and optic nerve were extended posteriorly 10 mm from the ONH. We also included a single central retinal vessel to include the effects of blood pressure (Figure 1). The open-source program Gmsh was used for geometric model creation and mesh generation (3). For all simulations we used the finite element solver FEBio (4). The geometry of the eye for FE analysis was treated as axisymmetric – represented as a 3° wedge about an axis of symmetry passing though the central retinal vessel due to constraints of the FEBio solver.

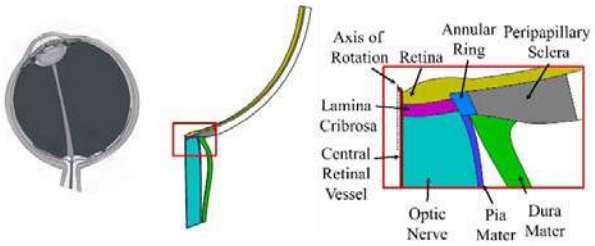

Figure 1: Left: Overview of eye (Acharya et al., 2008.) Center: Axisymmetric geometric model of the posterior eye and optic nerve sheath. Right: zoomed image of the ONH.

The lamina cribrosa, optic nerve, central retinal vessel and retina were modeled as isotropic, linear-elastic and homogenous. The baseline Young's modulus and Poisson ratio for each tissue component were based on previously reported values (2). All other tissues were modeled as a Mooney-Rivlin solid with embedded collagen fibers, distributed according to a von Mises distribution (5).

We adapted a Latin hypercube sampling (LHS) approach to simulate inter-individual variations in the pressures and material parameters. First, using a baseline ocular geometry we considered three ICP conditions: the upright and supine position on earth and an elevated ICP assumed to occur in chronic microgravity or intracranial hypertension. Intraocular pressure (IOP) and mean arterial pressure (MAP) values were provided by Lifetime Surveillance of Astronaut Health (LSAH) Program, NASA Johnson Space Center, from

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

measurements on astronauts in-flight. For each ICP condition (upright, supine and elevated), the IOP, ICP, MAP and twenty material properties were varied independently. Our outcome measures were the peak strains (95th percentile) in the lamina cribrosa, optic nerve and retina, since these peak strains can alter cell phenotype and induce tissue remodeling.

To assess the impact of ocular geometry, we independently varied scleral radius and thickness, two quantities previously reported as being the most influential geometric attributes affecting ONH strains (2). These previous studies focused on the impact of IOP and not ICP; therefore, we also varied the thickness of the pia mater, which is directly affected by changes in ICP. For these additional 6 geometries (Table 1) we specified IOP, ICP, MAP and material properties from the elevated ICP condition of our baseline model.

	Baseline	Low	High
Sclera Radius (mm)	12	9.6	14.4
Sclera Thickness (mm)	0.8	0.64	0.96
Pia Thickness (mm)	0.06	0.048	0.072

Table 1: Baseline, low and high values considered for geometric attributes in sensitivity analysis. Each attribute was varied independently, resulting in 6 additional models.

RESULTS

While investigating how ICP altered the strains within the ONH we found that strains in the lamina cribrosa and retina generally decreased as ICP increased; however, within the optic nerve, the incidence of extreme strains – strains above those experienced in the upright and supine conditions – increased in the elevated ICP condition. Specifically, ~47% of simulations in the elevated ICP condition showed peak strains in the optic nerve that exceeded the most extreme strains expected under terrestrial conditions (Figure 2).

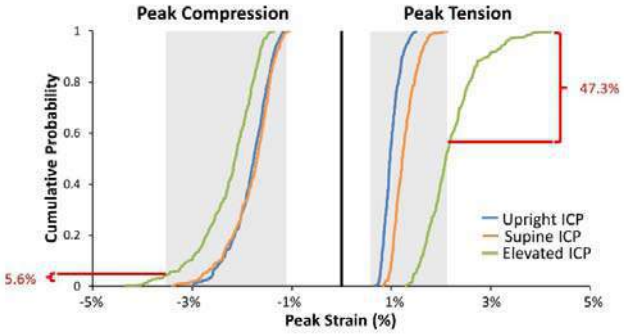

Figure 2: Cumulative probability distributions for predicted peak tensile and compressive strains in the optic nerve across a simulated population of individuals, generated by LHS. Each curve corresponds to one ICP condition, as indicated. The shaded regions show strain ranges expected under terrestrial conditions. The red lines identify the percentage of simulations experiencing "extreme strains" when exposed to elevated ICP in space.

Examining how ocular geometric attributes altered the distributions of peak strains in the elevated ICP condition, we found that the scleral radius had a minor effect on peak strains in the ONH. However, the scleral thickness had a large impact on the strains in the lamina cribrosa. Further, we found that pia mater thickness influenced the peak strains experienced in the optic nerve (Figure 3).

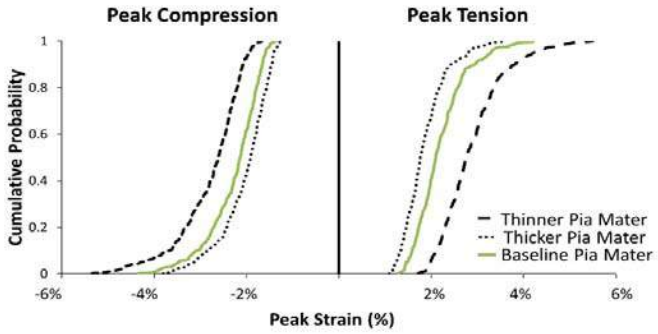

Figure 3: Cumulative probability distributions for the predicted peak tensile and compressive strains in the optic nerve for different pia mater thicknesses. A thinner pia mater resulted in increased peak strain magnitudes in the optic nerve, while a thicker pia mater led to decreased strains. All simulations were performed in the elevated ICP condition (solid green curve).

DISCUSSION

ICP is thought to be involved in VIIP syndrome and several other visual disorders. These results suggest a significant effect of elevated ICP on the optic nerve, resulting in extreme strains which may trigger a mechanobiologic response. The use of a LHS approach with FE modeling is a powerful technique to identify individual-specific risk factors for biomechanical insult to ocular tissues.

In addition, we examined how several geometric attributes influenced the strains experienced under elevated ICP, and found that the radius of the sclera did not have a significant effect on ONH strains as ICP is changed, opposite to what has been previously reported when IOP is elevated (2). However, we found that thickness of the sclera and pia mater altered the peak strains experienced in the lamina cribrosa and optic nerve, respectively. While these geometric changes primarily affected strains experienced in a single region of the ONH, these simulations highlight the importance of different geometric factors (ONH anatomy).

This study had several limitations. First, we assumed an axisymmetric geometry for the posterior eye, which is a simplification and may affect the strains in the optic nerve head tissues. A second limitation was the use of linear-elastic and isotropic tissue models for the complex geometric and biomechanical response of the lamina cribrosa; future work will aim to incorporate more advanced material models. Lastly, we looked at a limited number of geometric attributes that were varied independently. Additional simulations examining other ocular attributes (e.g. dura mater thickness) and varying these attributes simultaneously will improve our understanding of ICP on ONH deformation.

ACKNOWLEDGEMENTS

Financial support from the Georgia Research Alliance and NASA (grant NNX13AP91G) is gratefully acknowledged. We thank Wafa Taiym for providing in-flight measurements of the astronauts' intraocular and blood pressures. We also thank DeVon Griffin and Beth Lewandowski for administrative support.

BLOOD COOLING USING CRYOGENIC NITROGEN

Brian K. Dixon (1), Joseph R. Licwinko (1)

Glassboro, New Jersey, United States

INTRODUCTION

Therapeutic hypothermia involves controlled cooling the patient's body temperature or part of the patient's body. It is used to prevent further organ damage after a traumatic brain injury, stroke, or cardiac arrest. Cooling to between 30 C and 32 C is commonly desired and it is beneficial reach this temperature as quick as possible to prevent further injury. The purpose of cooling the patient is to reduce the metabolic rate of cells, reduce intracranial pressure, and prevent reperfusion injury. [1]

The two types of cooling methods that are used to cool the patient are external and invasive. The CoolGuide Catheter is an invasive method involving a tri-lumen catheter, the design of the catheter is pictured below in figure 1. The two outside lumens are connected at the end of the catheter to allow for a coolant loop and the third center lumen allows for chilled blood to enter the body.

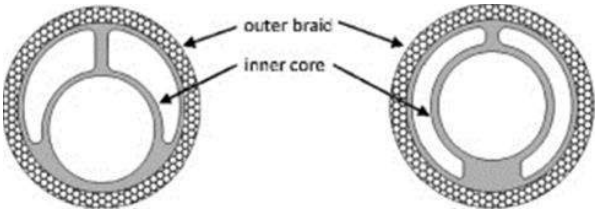

Figure 1: Two designs for the CoolGuide Catheter. The design on the right was modeled due to its partially axisymmetric shape. [2]

The purpose of this study was to explore an avenue to improve on existing blood and tissue cooling technologies, namely the current CoolGuide catheter, by replacing the cooling medium of saline with Cryogenic nitrogen. The main purpose of this change is to try and gain cooling efficiency per length of catheter, and to eliminate the need for a pump, while reducing pressure in the catheter.

METHODS

To compare the cooling power and the pressure drop of the coolant, a 115mm section of the catheter was modeled in COMSOL Multiphysics 5.1. The model was evaluated as steady state to reduce the computational time required to compare the two coolants. To simplify the model the geometry was approximated as 2-D axisymmetric with coolant flow in one direction. This represents a section of the catheter with 160 degrees of axial symmetry. Although the rest of the catheter is important for finding the total cooling power and coolant pressure drop, this approximated model was compared to known experimental results and was used to compare the nitrogen coolant to the traditional saline coolant used in the experiments.

The materials that were used in the model included the COMSOL built-in properties for nitrogen and water. The saline was approximated to have the same properties as water so that it can be modeled simply. The built-in properties for both of these materials have functions that correct of differences in temperature and pressure. This is especially important for the nitrogen as the large temperature changes cause large differences in the density and other material properties. For the purposes of this simulation, blood was modeled as a newtonian fluid with a dynamic viscosity of 3.5 cP [3], a specific heat capacity of 3490 J/(Kg*K) [4], a density of 1042 kg/m^3 [4], [5] (original text), and a thermal conductivity of 0.492 W/(m*K) [6]. Although blood is a non-newtonian fluid, it can be approximated as newtonian as long as the conduit is in is larger than 40–50 mm [7].

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The properties of Teflon were found on the website of the company which developed it, DuPoint. The thermal conductivity for Teflon was 0.25 W/(m*K), the specific heat capacity was 1400 J/(Kg*K), and the density was 2160 kg/m^3[8].

RESULTS

The model with 6.667E-4 kg/s of saline, which was created to be compared to the experimental data [2], predicted 15 watts of cooling. The predicted pressure drop through the catheter with saline coolant was 3.37 Kpa. Although these results do not match the experimental results, the discrepancy can be attributed to the simplification of the geometry and the relative values of the results for nitrogen and saline are expected to be similar in more complex simulations and in experimental work.

With a mass flow rate of 2.22E-4 kg/s of nitrogen, which entered the catheter at 95 K, 35 watts of cooling was predicted. The cooling that was predicted for this flow rate was well above the predicted cooling of 15 watts for the saline model, however, the pressure drop of 57 Kpa was also much higher for this flow rate so it would be inaccurate to determine that the nitrogen is a better coolant from this result. To find a nitrogen flow rate which more closely compares to the saline model, as well as to determine the effect of different nitrogen flow rates, the flow rate of nitrogen was varied from 4.44E-05 kg/s to 2.67E-04 kg/s. The results for each flow rate are shown in table 1.

Table 1: Data from Parametric study of Nitrogen Mass Flow rate. This table shows how the key results are affected by changes in the nitrogen flow rate, and that dropping to flow rate to reduce pressure has a significant effect on the cooling power of the device. For this study the aorta blood flow rate was 0.0575 kg/s, the catheter blood flow rate was 8.33E-04 kg/s, the nitrogen inlet temperature was 95 K, and the body temperature was 310.15 K.

Nitrogen Mass Flow Rate [kg/s]	Pressure Drop [Pa]	Cooling Power [W]	Catheter Outflow Temperature [K]	Aorta Outflow Temperature [K]
4.44E-05	6815	9.88	305.41	309.40
6.67E-05	11424	14.08	303.88	309.22
8.89E-05	16665	17.90	302.51	309.05
1.11E-04	22490	21.41	301.26	308.90
1.33E-04	28801	24.67	300.12	308.75
1.56E-04	35501	27.68	299.05	308.62
1.78E-04	42514	30.49	298.07	308.49
2.00E-04	49830	33.11	297.15	308.38
2.22E-04	57415	35.58	296.27	308.27
2.44E-04	65196	38.05	295.34	308.13
2.67E-04	73075	40.26	294.57	308.02

At a nitrogen mass flow rate of 8.89E-5 kg/s, which resulted in comparable cooling a saline at the same flow rate of 6.667E-4 kg/s used in previous work [2], the pressure drop through the modeled section was 16 KPa. This compares to a pressure drop of 3.37 KPa predicted for the saline. The large pressure drop compared to the saline may be an issue for the nitrogen, as reducing the pressure in the device was one of the primary goals for exploring nitrogen. The results for the pressure drop are not necessarily an accurate representation due to the limited size of the model; further work would be necessary to know how the pressures on the catheter would compare for the nitrogen and the saline. The lowest flow rate of nitrogen tested, 4.44E-5 kg/s, still created a pressure drop over twice that of the saline, and yet resulted in under 10 watts of cooling.

DISCUSSION

Due to the much higher predicted pressure of the coolant for the same cooling power, cryogenic nitrogen was not predicted to be a better coolant then saline. The elimination of the pump using the expansion of evaporating liquid nitrogen can be useful if it is worth the decrease in cooling power of the device. Other cryogenic gases, such as hydrogen, can also be explored to attempt to get better cooling at lower pressures than saline. Another avenue of testing that could be undertaken would be designing a different catheter optimized for use with expanding gas, with either asymmetric lumens for the gas to expand to minimize pressure drop, or utilizing a two piece catheter design, with a short stronger portion to address the increase in pressure that comes from the expanding gas.

It is worth discussing the strengths and limitations of the model used in this study, due to the fact that some of the limitations have the potential for large swings in results. The largest is that this model does not account for the transient behavior of the cooling, and instead relies on comparing the steady state results to the same model run using the current method. This was done to lower the computational burden of the model. Another simplification done to ease computation was the setup of the model as a 2d axisymmetric model, neglecting the return flow of the coolant. Also, by only modeling a section of the catheter, the density of the gas would change considerably more than it does in the model. Future work with more complete models can reduce the error in the results.

A CELL MIGRATION MODEL INTEGRATING THE MECHANICAL STRESS GENERATION AND SENSING WITH BIOCHEMICAL SIGNALS

Hongyan Yuan (1), Kevin K. Parker (2)

INTRODUCTION

Cell migration plays an essential role in many biological processes such as tissue morphogenesis, tumor metastasis, angiogenesis, and wound healing. In recent experiments, mechanical stresses generated by cytoskeleton contraction have been shown to not only move the cell body forward but also play an active role in regulating other components of cell migration such as protrusion, cell-matrix and cell-cell adhesions, and cytoskeletal organization [1-3]. Our understanding of the biochemical aspects of cell migration has advanced greatly over the past decades. However, we know little about how mechanical and biochemical signals are integrated spatially and temporarily across the cell.

In the present work, a mathematical model for cell migration has been developed to study how the mechanical stresses experienced by a cell are integrated with biochemical activities for cell migration.

METHODS

We have formulated mathematical equations to describe various cell activities including cell contraction, cell protrusion and retraction, cell-matrix and cell-cell interactions. Continuum mechanics theory and finite element method are used for calculating cellular stress and traction stress (see Figure 1). Numerical algorithm similar to cellular automaton is used to simulate cell protrusion and retraction. Reaction-diffusion equations are used to describe spatiotemporal evolution of protrusion and retraction signals, and rate equations are used to describe the dynamic remodeling of mechanical properties of cytoskeleton and cell-matrix and cell-cell adhesions. Mechanobiochemical integration will be implemented by coupling the parameters in these equations (see Figure 2).

RESULTS

The finite element simulation results show that the mechanical stresses alone are sufficient to initiate the spatial pattern formation for actomyosin stress fiber organizations, focal adhesion distributions, and lamellipodia extension from an isotropic and homogeneous initial condition. The simulation results suggest that mechanobiochemical couplings at the whole-cell level enable cells to sense their shape. It has been demonstrated that this model can simulate durotaxis in which cell migration direction is guided by the rigidity of the substrate. Furthermore, by adding a cell-cell adhesion component to the single-cell migration model, cell-pair morphogenesis when the shape of the microtissue is constrained was simulated and compared with previous experiments involving cardiac microtissues.

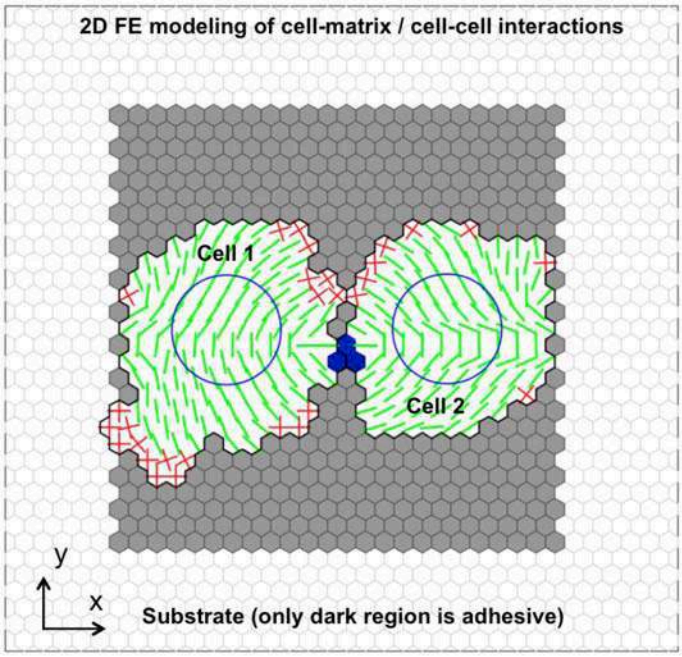

Figure 1: Finite element model of 2D cell migration in a multicellular environment.

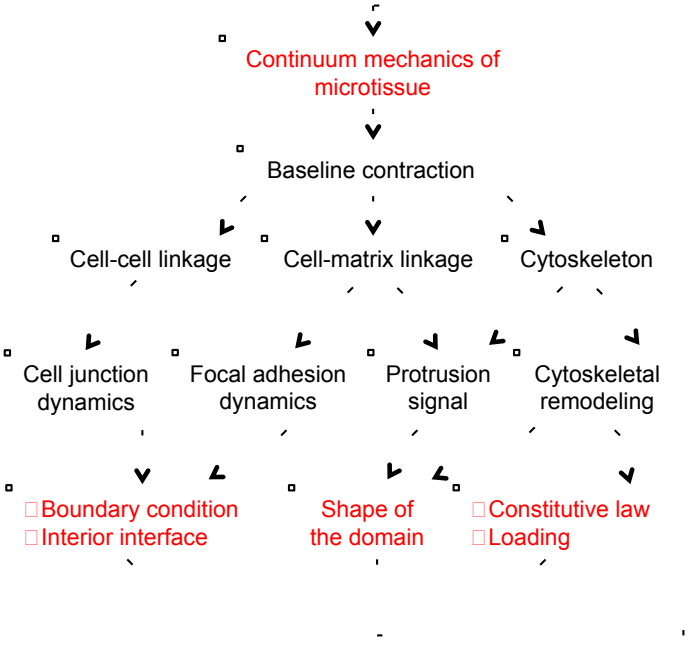

Figure 2: A flow diagram showing the assumptions of mechanobiochemical coupling and integration in cell migration.

DISCUSSION

This whole-cell level model for cell migration can help understand how the interior activities of a cell are merged with active sensing of mechanical cues of the external microenvironment. It can be used to study the effect of mechanical microenvironments in many biological problems such as tissue formation, cancer metastasis, would healing.

INTRODUCTION. Over the past decade, it has been well established that, in addition to soluble factors and extracellular matrix (ECM) ligands, the mechanical cues from the microenvironment can direct stem cell behaviors such as proliferation, migration, and differentiation[1-2]. During connective tissue development, the microenvironment gradually changes from one that is rich in cell-cell interactions to one that is increasingly typified by cell-ECM interactions. In mesenchymal cells, this cell-cell contact is largely mediated through the homotypic interaction of N-Cadherin on adjacent cells. Studies have shown that N-Cadherin can play a large role in stem cell differentiation, as blockade of N-Cadherin expression inhibits limb bud development[3]. Additionally, there is a degree of mechanical crosstalk that exists between integrins (cell-ECM) and cadherins (cell-cell) as they are both coupled to the actin cytoskeleton and can mediate signaling events. However, determining how these signaling modalities converge to regulate cell mechanosensing is currently difficult, as presentation of these cues cannot readily be decoupled *in vivo* or *in vitro*. Culture systems for inducing cell-cell contact are not able to fully decouple cell-cell and cell-ECM inputs, and cannot control for non-cadherin cell-cell interactions that also occur with dense culture (eg. nectins, Notch/Delta, paracrine signaling), making interpretation of downstream signaling convoluted. Here, we developed an engineered hyaluronic acid (HA) hydrogel system that enables independent co-presentation of N-Cadherin and fibronectin adhesive domains (HAVDI and RGD, respectively), while additionally tuning matrix stiffness to study adhesive interactions.

METHODS. Hyaluronic Acid Hydrogels: Methacrylate-modified hyaluronic acid was synthesized and polymerized[5]. Fibronectin adhesive domain ("**RGD**", GCGYG**RGD**SSPG-), N-Cadherin adhesive domain ("**HAVDI**", **HAVDI**GGGC-), and non-functional scrambled HAVDI ("scram", AGVGDHIGC-) peptide sequences were conjugated to methacrylate groups (**Fig. 1**). Traction Force Microscopy (TFM): TFM was performed[6] on 10 kPa MeHA gels modified with 1 mM HAVDI (or scram) and 1 mM RGD. Cell Culture and Immunofluorescence: Juvenile bovine MSCs were isolated from bone marrow and cultured for one passage before being plated on gels for 18 hours prior to fixation and staining. Antibodies used included anti-YAP/TAZ (#sc-101199), anti-RUNX2 (Abcam#76956), anti-Myosin-IIA (Abcam#24762), and an N-Cadherin neutralizing Ab (Sigma# GC4). YAP/TAZ and RUNX2 nuclear-to- cytoplasmic ratios were determined by measuring the average fluorescent intensity in each domain using ImageJ. ROCK was inhibited with 10 μM Y-27632, while Rac1 activity was inhibited with 50 μM NSC-23766, both for 1hr. To introduce constitutively active (CA) Rac1, MSCs were cultured for 1 day prior to adenoviral transduction (LacZ control/CA Rac1 V12) at 750 MOI for 24hrs, followed by transfer to gels. Myosin-IIA content in focal adhesions was visualized by immunostaining and quantification[7]. Osteogenic differentiation was carried out by culturing bMSCs in growth media for one day prior to culture in an osteoinductive media for two days (growth media w/ 0.1 uM dexamethasone, 50 μg/mL A2P, 10 mM β-GP). Statistics: Analysis performed using GraphPad as noted in the legends.

RESULTS. Culture of MSCs on HAVDI/RGD substrates did not significantly alter the cell spread area or induce cadherin clustering or change expression compared to MSCs on scram/RGD gels (data not shown). The YAP/TAZ complex has recently been implicated as a mechanical 'rheostat' in the cell and translocates to the nucleus upon mechanical stimulation[8]. Quantification of the YAP/TAZ nuclear to cytoplasmic ratio revealed that N-Cadherin presentation significantly lowered YAP/TAZ ratios in MSCs on intermediate stiffness substrates

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

(10/15 kPa). but had no effect on YAP/TAZ localization on lower/upper boundaries of substrate stiffness (**Fig. 2A**). Examining the dose-dependence of this response showed that increasing amounts of HAVDI resulted in lower YAP/TAZ ratios (**Fig. 2B**). Blocking extracellular N-Cadherin with a neutralizing antibody prior to seeding completely abrogated these differences in YAP/TAZ nuclear localization on intermediate stiffness gels (**Fig. 2C**). This HAVDI interaction also markedly decreased downstream cell functions, including proliferation (in basal media) and osteogenesis (in osteogenic medium) (**Fig. 2D-E**).

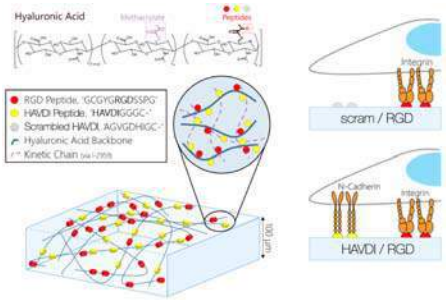

Figure 1- Schematic of MeHA gel platform.

To assess the degree to which N-Cadherin presentation perturbed the mechanical state of the cell, we next examined how the actin cytoskeleton changed in response to HAVDI presentation on 10 kPa gels. TFM showed that cells on HAVDI/RGD substrates exerted ~50% less traction stress on the substrate compared to scrambled controls (**Fig. 3A**). Treatment with NSC-23766 (a pharmacological inhibitor of Rac1 activation) abrogated any differences in YAP/TAZ signal between scram/RGD and HAVDI/RGD conditions (**Fig. 3B**). Conversely, treatment with Y-27632, a ROCK inhibitor that decreases contractility, resulted in less nuclear YAP/TAZ for both groups, without reducing the effect of HAVDI. Combination of both inhibitors further decreased nuclear YAP/TAZ, and abrogated the differences seen with HAVDI presentation. To confirm the hypothesis that HAVDI was inhibiting Rac1 activation, we transduced MSCs with adenoviral constructs containing a constitutively active (CA) version of Rac1. Compared to untreated and LacZ transduced controls, CA Rac1 "rescued" YAP/TAZ signaling in MSCs on 10 kPa HAVDI/RGD gels (**Fig. 3C**). Recently, Pasapera and colleagues showed that Rac1 activity promotes Myosin-IIA incorporation into focal adhesions, leading to maturation of these adhesions and generation of increased contractile forces[7]. Interestingly, this Rac1-dependent incorporation of Myosin-IIA occurred maximally on intermediate stiffness substrates (8.6 kPa), but had minimal effect at upper and lower bounds of substrate stiffness (0.7 and 55 kPa). To determine if HAVDI-induced differences in YAP/TAZ signaling on intermediate stiffness substrates were a result of this mechanism, we determined if there was increased Myosin-IIA incorporation into focal adhesions in our system. Analysis of confocal images of paxillin and Myosin-IIA revealed that, consistent with this mechanism, there was significantly reduced Myosin-IIA in FAs of MSCs with HAVDI presentation (**Fig. 3D**) and blockade of this incorporation with the a PKCβII-inhibitor that acts downstream of Rac1 blocked any differences in YAP/TAZ ratios (data not shown).

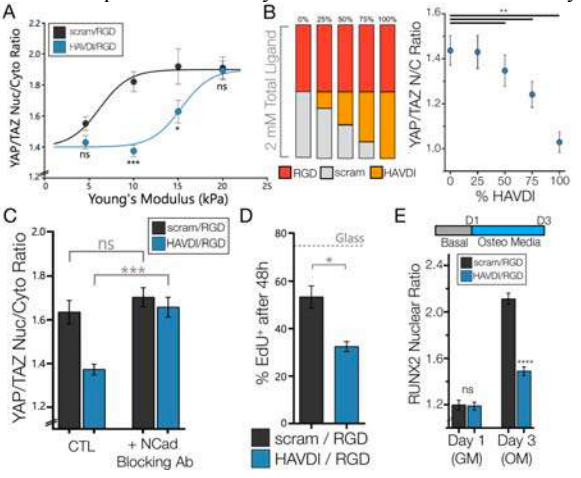

Figure 2- (**A**) YAP/TAZ ratios on scram/RGD and HAVDI/RGD gels (**B**) Dose-dependence of HAVDI presentation on YAP/TAZ ratios. (**C**) YAP/TAZ ratios of MSCs following N-Cadherin blockade. DISCUSSION. Our findings show that, on hydrogels of intermediate stiffness, HAVDI presentation (in the context of constant RGD) decreases the contractile state and YAP/TAZ nuclear localization of mesenchymal progenitors in a Rac1-depdendent fashion, resulting in altered interpretations of ECM stiffness. This change in interpretation of ECM stiffness is concurrent with alterations in downstream stem cell behavior such as proliferation and differentiation. Currently, it is thought that matrix elasticity functions to establish a contractile state in the cell that then drives mechanosensitive pathways towards a particular phenotype (eg. YAP/TAZ promoting lineage commitment). Therefore, any perturbation of the mechanical state of the cell on a given stiffness ECM (HAVDI ligation from N-Cadherin in the case of this work), can offset the mechanosensitive signaling, shifting the response curves. This ECM stiffness "shielding" through N-Cadherin is likely an important component of the development of mesenchymal tissues, and may be relevant in pathologies that disrupt the balance of cell-ECM and cell-cell signaling. These findings may be leveraged towards biomaterials design in order to better direct stem cell behavior.

INTRODUCTION

Chronic neck pain is a debilitating disorder affecting two-thirds of the general population in their lifetime [1]. The spinal nerve root is a common source of pain and can be directly injured via compression by disc herniation, spondylosis, or other spinal traumas [2]. Even transient root compression can lead to chronic pain, in part due to the robust immune response at the injury site and more remotely in the spinal cord [3-5]. Changes in the spinal neuronal and neuroinflammatory responses contribute to the onset *and* maintenance of pain [6,7]. Activation of resident glial cells in the spinal cord, specifically microglia, release many chemical mediators, including inflammatory cytokines and prostaglandins [8], which further facilitate inflammation in the spinal cord and induce and/or sustain pain.

In addition to immune cells, a sub-family of the phospholipase A_2 enzymes, secretory phospholipase A_2 ($sPLA_2$), has an important role in inflammation [9]. PLA_2 enzymes catalyze the hydrolysis of the sn-2 positions of glycerophospholipids in cellular membranes to produce free fatty acids. Inflammatory cytokines induce $sPLA_2$ activity, which generates more free fatty acids that are used in the cyclooxygenase pathway to produce prostaglandins and other inflammatory molecules [10]. Increases in $sPLA_2$ have been reported in painful spinal discs and after disc herniation [11]. Spinal $sPLA_2$ is also upregulated early after spinal cord injury and is hypothesized to exacerbate inflammation and contribute to cell death [12]. Despite evidence suggesting a role for $sPLA_2$ and inflammation at neural injury sites, the role of spinal $sPLA_2$ in pain from trauma to the peripheral nerves is not known.

This study investigated the early neuroinflammatory responses and $sPLA_2$ expression in the spinal cord in the context of pain using a rat model of nerve root compression, with different loading profiles that separately do and do not induce pain. Immunohistochemistry was used to determine both overall $sPLA_2$ expression and to probe its expression in neurons and glia in the spinal cord.

METHODS

All procedures were IACUC-approved. Male Holtzman rats underwent a unilateral C7 dorsal root compression by a 10gf clip for 15 (painful), 3 (non-painful) or 0 (sham) minutes, as described [3,4,13,15]. Behavioral sensitivity to mechanical stimuli was measured in the ipsilateral and contralateral forepaws at baseline (BL) before injury and at 1 day after injury, using von Frey filaments [3,5,13-15]. The difference in sensitivity between the paw ipsilateral to the injury and the one on the contralateral side was determined for BL and day 1; the fold-change difference relative to BL was measured. Sensitivity at day 1 was compared between groups by an ANOVA and Tukey's test.

After behavioral testing on day 1, the C7 spinal cord was harvested (painful n=6; non-painful n=5; sham n=5) and fixed in 4% paraformaldehyde. Tissue from naïve rats (n=2) was also included for normalization. The spinal cord was axially cryosectioned at 14μm and mounted onto slides. Sections were blocked using 10% normal donkey serum (Vector) with 0.3% Triton-X 100 and incubated in antibodies to goat anti-$sPLA_2$ (1:500; Santa-Cruz), rabbit anti-Iba1 (1:500; Wako) and mouse anti-MAP2 (1:250; Covance). Sections were incubated in the corresponding species-matched secondary antibodies. For each rat, 4-6 sections of the ipsilateral and contralateral superficial dorsal horns (DH) were imaged at 20X using an Olympus 5X51 microscope.

To fully characterize $sPLA_2$ expression in the spinal cord, the amount of $sPLA_2$ and that co-labeled with each of Iba1 (microglia) and MAP2 (neurons) was quantified. Using the images of the bilateral dorsal horn, expression of each of $sPLA_2$ and the cellular markers in the superficial laminae of the DH was analyzed as previously detailed [13,15]. Images were cropped to include only the superficial laminae

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

and a custom MATLAB script performed quantitative densitometry to separately count the total percent of pixels positive for each of $sPLA_2$, Iba1 and MAP2; those levels were compared separately between groups and sides, using a two-way ANOVA with Tukey's test. To evaluate the distribution of $sPLA_2$ in neurons and microglia, the total co-localized pixels of $sPLA_2$ and MAP2 and also $sPLA_2$ and Iba1 were quantified. Neuronal and microglial $sPLA_2$ was quantified by dividing the total number of co-localized pixels for each by the total area positive for $sPLA_2$. Differences were detected between groups and sides by separate two-way ANOVA's with Tukey's test.

RESULTS

A 15 minute compression induces sensitivity in the ipsilateral forepaw at day 1, with increases over both a 3 minute compression ($p=0.018$) and a sham procedure ($p=0.026$) (Fig 1). Paralleling pain responses, spinal $sPLA_2$ expression is more robust in the ipsilateral DH of the painful group than in both of the non-painful groups (Fig. 2). Expression of $sPLA_2$ in the ipsilateral DH is significantly increased after painful compression, with greater levels than after non-painful compression and sham ($p<0.001$). After painful injury, that increase in $sPLA_2$ is also elevated ($p<0.001$) over the contralateral DH (Fig. 3). Ipsilateral DH expression of Iba1 is also significantly elevated over the expression in the sham ($p<0.001$) and normal rats ($p=0.007$). Yet, the MAP2 expression is not different between DH sides or across groups.

In addition, DH $sPLA_2$ co-labeling increases after a p ainful injury. Neuronal $sPLA_2$ expression more than triples, which is a significant ($p<0.001$) increase (Fig 3). The extent of neuronal $sPLA_2$ in the ipsilateral DH is 28±0.27% greater than levels in the contralateral DH ($p=0.041$) (Fig. 3). The same expression pattern is evident for microglial $sPLA_2$ ($p<0.001$), with ipsilateral expression greater than other groups and its contralateral expression ($p<0.045$) (Fig 3).

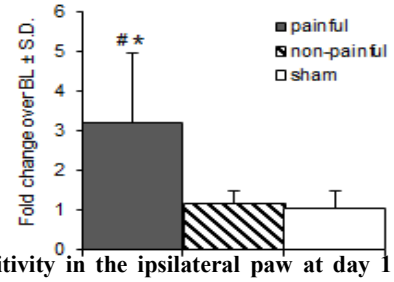

Fig 1. Sensitivity in the ipsilateral paw at day 1 is significantly greater after a painful injury than after a non-painful injury (*p=0.018) and sham (#p=0.026), which are both similar.

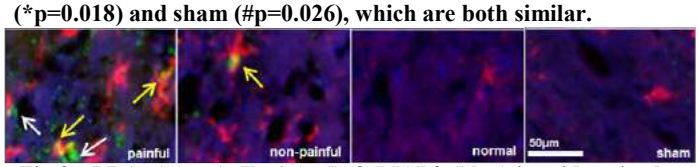

Fig 2. $sPLA_2$ (green), Iba1 (red) & MAP2 (blue) is evident in the ipsilateral DH. Painful injury induces greatest overall, microglial (yellow arrow) & neuronal (white arrow) $sPLA_2$.

DISCUSSION

This study shows that $sPLA_2$ in the spinal cord increases early after a mechanical root injury, in parallel with pain onset (Figs 1-3). The increase in $sPLA_2$ at day 1 occurs in both neurons and microglia (Figs 2 & 3). Together, these results suggest that early production of spinal $sPLA_2$ may contribute to pain from a peripheral neural injury, which is consistent with a report that inhibiting spinal $sPLA_2$ attenuates pain after an inflammatory injection in the rat's paw [10].

Despite a peripheral injury to the nerve root, both $sPLA_2$ and Iba1 expression increase in the spinal cord, while MAP2 expression is unchanged. The increase in Iba1 expression in the ipsilateral DH with pain (Figs 1 & 3) is consistent with a prior study in this same injury model in which infiltration of activated microglia into the spinal cord was also observed at this same time, along with pain [3]. Moreover, MAP2 is not expected to increase since the number of spinal neurons after root injury would not change at this time point and would only *decrease* due to their degeneration [5,15]. Taking these findings together with the overall and cell-specific increases in $sPLA_2$ after painful injury (Fig 3), it can be inferred that both neurons and microglia actively produce *more* $sPLA_2$ in response to a painful injury. It is also possible that the increased $sPLA_2$ may also be due to increased production in microglia that may also be trafficking in to the spinal cord after injury [16]. Regardless of the cell source, the increased spinal $sPLA_2$ may be due to inflammatory cytokines which can activate glial cells and induce different biochemical pain mediators, and are upregulated early in conjunction with pain after root compression [17]. Since it is unknown how soon $sPLA_2$ production begins after injury and how long it persists, additional studies are needed to understand whether it promotes, or is in response to, spinal inflammation and pain onset and/or maintenance. Nonetheless, this work shows that $sPLA_2$ plays an active role in inflammation after painful nerve root injury and may be a potential target to treat chronic pain.

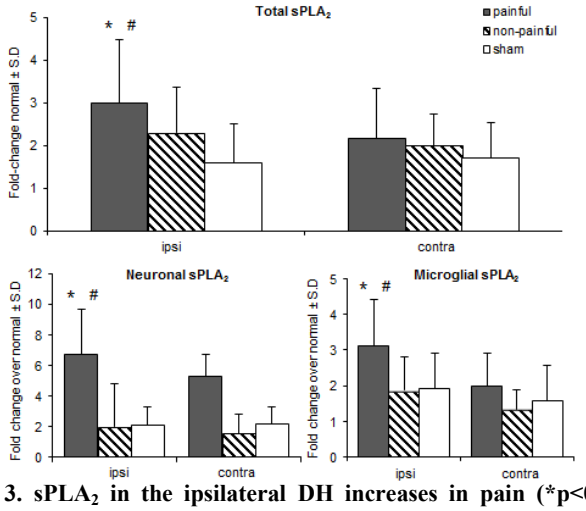

Fig 3. $sPLA_2$ in the ipsilateral DH increases in pain (*p<0.001), with more expression than in the contralateral DH (#p<0.001). Neuronal and microglial $sPLA_2$ also increase (*p<0.001), with greater expression in the ipsilateral DH (#p=0.041).

INTRODUCTION

In recent times, endothelial glycocalyx (GCX) has been a target for the detection and prevention of some pathological conditions including global ischemia and atherosclerosis. GCX location in the vascular system ensures that endothelial cells (EC) are well protected and stimulated. GCX is composed of core proteins (CPs) which form the backbone structure and extensions that connect to CPs called glycosaminoglycans (GAGs) [1]. GAGs are repeating disaccharide units that form GCX components, such as heparan sulphate (HS), chondroitin sulphate (CS), and hyaluronic acid (HA), commonly associated with EC. The function of GCX is very much dependent on the arrangement of the GAGs [2]. All the various GAGs mentioned above play an important role in the function of GCX, but for the scope of this project, we considered HS. HS is the dominant constituent of GCX; it is sulphated, consists of 40-300 sugar residues approximately 20-150 nm in length, and it is attached to the apical CPs syndecans and glypicans [3] and contributes to the overall stability of GCX.

In addition to GCX that helps stabilizes endothelial cells, there exist also inter-endothelial cell gap junction which consists of a group of protein channels that connect neighboring cells. This connection enables the transport of ions and other small molecules across EC. For the purpose of this study, a gap junction protein (GJP) called connexin will be considered. To date over 20 different types of mammalian connexin have been identified, with three of them - connexin37, connexin40 and connexin43 (Cx43) - directly related to EC. There are ongoing studies trying to better understand the relationship between GCX and connexin channels. Some studies have reported the effect of shear stress induces GCX remodeling that has an impact on GJP distribution[4]. A study by Thi *et al* has linked GCX to the organizational changes that occur to EC GJPs due to shear stress applied from blood flow [5]. Here, we extend the study of Thi et al.

Our goal is to investigate the relationship between GCX, namely the HS component, and both organization and function of Cx43. We hypothesize that the degradation of HS from GXC will disrupt CX43 and gap junction function; while subsequent restoration of HS in GCX will restore Cx43 and gap junction channels function.

METHODS

We tested our hypothesis by [I] degradation of HS from rat fat pad endothelial cell (RFPEC) GCX using 15mU/ml of the enzyme Heparanase lll; [II] replacement of HS after enzyme degradation with 59mg/ml of exogenous heparan sulphate; [III]

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

determination of the effect of degradation and replacement of HS on Cx43 distribution at borders between neighboring RFPEC and [IV] quantification of the role of GCX on the opening and closing of gap junction channels, using the well-established Lucifer Yellow dye transfer technique.

RESULTS

The results indicate that the removal of HS from RFPEC GCX causes a statistically significant decrease in membrane localized Cx43 expression from 59.61 ± 3.20% to 30.40 ± 4.65%. Samples in which HS was replaced after degradation showed an increase in membrane Cx43 expression from 30.40 ± 4.65% to 46.45 ± 4.20%, a statistically significant improvement in comparison with enzyme treated samples and control samples. Cell to cell communication as assessed by Lucifer yellow dye showed a 2.6 ± 0.16 cells spread of the dye in control conditions but was reduced to 1.6 ± 0.16 cells in enzyme treated samples, showing a statistical significant decrease in dye spread in comparison with control conditions. However, there was no significant difference between enzymes treated samples and those in which HS was replaced (1.6 ± 0.16 cells and 1.5 ± 0.16 cells respectively).

DISCUSSION

Recent studies have shown the ability to degrade several components of GCX in order to better understand the way its components contribute to its entire integrity [6,7]. There are few studies of GCX regulation of intercellular gap junctional communication. Thi et al [5] performed a well controlled study demonstrating that removal of HS, results in GJPs becoming insensitive to shear stress from the flow of blood which then causes the protein to be displaced. We continued this work by establishing the fact that the removal of HS has the ability to disorganize gap junction protein, namely Cx43, and also the removal of HS greatly reduced the ability of GJP channels to transport ions and molecules between EC. Furthermore, GCX repair with exogenous HS restores gap junction protein placement which is promising for reactivating gap junction channel activity. The inability of Cx43 channels to re-open after HS restoration is not clear. It is known that there exists some connection between GCX and cortical actin web and, downstream, some connection between the actin cortical web and the cell-to-cell junctions. So, it is possible that disruption of GCX from enzymatic degradation or certain disease conditions causes the delocalization of actin cortical web from the cell periphery, which in turn causes the misalignment of junctional proteins like Cx43. Cx43 misalignment would hinder the movement of Lucifer yellow dye, and ions and signaling molecules, across Cx43-containing gap junction channels. In conclusion, we have shown that the structural integrity of EC GJP is also dependent on the state of GCX Heparan Sulphate. The inability to restore GJP communication after HS replacement may involve non-Cx43 GJP (Cx40 and Cx37) and other GAGs (CS and HA), which are outside the scope of this present investigation.

INTRODUCTION

Aortic regurgitation (AR) is a valvular disease in which the aortic valve (AV) leaflets fail to coapt properly, thereby allowing backflow of blood from the aorta to the left ventricle (LV). This backward flow manifests itself as a high velocity jet through the AV into the LV during the ventricular filling phase of the cardiac cycle.

It has been observed that during diastole, a single vortical ring structure is formed as a result of the interaction between the blood and the mitral annulus and leaflets [1], [2]. The part of the vortical ring structure proximal to the inferolateral wall of the LV breaks down as a result of its constant shearing along the myocardium. The remainder of the vortical structure then grows in size until it engulfs the entire LV. This observed flow pattern during diastole has been shown to minimize energy dissipation and maximize the momentum of the inflow jet from the left atrium, while redirecting itself toward the LV outflow tract as it prepares for ejection during the systolic portion of the cardiac cycle [3].

In the presence of AR, the regurgitant jet from the aorta is expected to collide with the trans-mitral filling jet from the left atrium, leading to energy losses. In a simplified form, this phenomenon is expected to resemble the collision of jets of different spatial magnitudes and strengths.

Fluid flow in the LV in the presence of AR has not yet been investigated in a finely controlled setting. In order to the bridge this gap in knowledge, we analyze and quantify the fluid dynamic changes within the LV resulting from the alteration of AR severity.

METHODS

Left Heart Simulator (LHS): The *in vitro* LV model (Figure 1a) used in this work was made from silicone rubber. The model [4] was enclosed in an acrylic chamber (refractive index of 1.49), which was filled with a 36v/v% mixture of glycerin-water solution. This fluid was used to mimic the kinematic viscosity of blood at 37°C (3.5 cSt). The motion of the LV wall was induced via a programmable piston pump connected to the outer chamber housing the LV. Systemic resistance and compliance elements were included in the flow circuit to obtain physiological flow rates and pressures. The same fluid as the blood analogue was used in the outer chamber surrounding the LV.

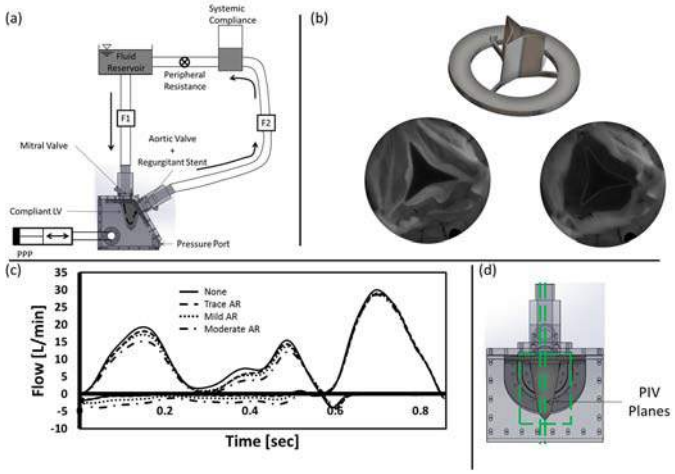

Figure 1: (a) Left heart simulator. (b) AR stent. (c) Flow profiles for control and AR conditions. (d) Schematic of PIV planes.

Aortic Valve: A 23 mm aortic valve excised from a porcine heart was used. The valve was sutured to a 3-pillared stent. To induce AR, a second stent (AR stent) was inserted in to the coaptation zone of the AV preventing full leaflet closure and resulting in central AR (Figure

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

1b). These stents induced AR with regurgitant fractions (RF) ranging from ~5 to ~40% (mild to mild/moderate according to AHA guidelines).

Hemodynamics: The LHS was initially tuned with a competent valve to physiological flow rates and pressures. A cardiac output of 5.0 L/min and aortic pressures of 120/80 mmHg at a heart rate of 70 beats/min were set. Once the LHS was tuned to these conditions, the AR stents were sequentially introduced to the system (Figure 1c). 200 cycles of hemodynamic data (pressures and flow rates) were acquired at 2 kHz using LabView.

Particle Image Velocimetry: Two-component, planar PIV was performed on the central long-axis plane of the LV, which cuts through the center of the mitral and aortic valves (Figure 1d). The fluid inside the LV was seeded with neutrally buoyant fluorescent particles. These particles were illuminated using a laser sheet of 1mm thickness generated from a double-cavity Nd:YAG laser. The particles were imaged with a PIV CCD camera (LaVision, Germany, Imager ProX, 1600 × 1200 pixels). 200 phase-locked PIV data were acquired at 35 time points, spaced 25 ms apart over the cardiac cycle. Metrics calculated include out of plane vorticity and energy dissipation rate (EDR).

RESULTS

Control/NoAR: Figure 2 illustrates the streamlines of intra-ventricular diastolic flow field overlaid on iso-vorticity contours for the control case. It was observed that the trans-mitral pressure gradient during the beginning of the E-wave gave rise to the passive filling of the LV. The trans-mitral jet resulted in a clockwise rotating vortical structure which engulfed the entire LV (Figure 2).

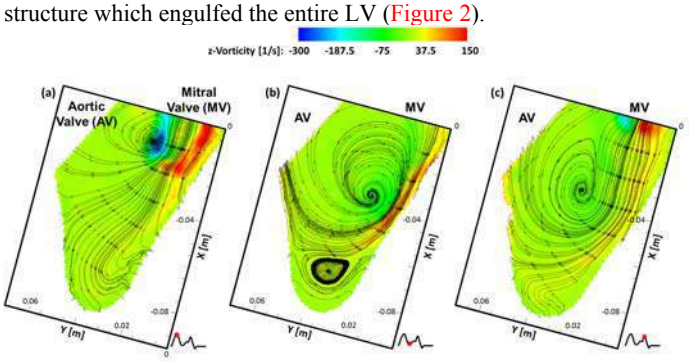

Figure 2: Out-of-plane iso-vorticity contour map overlaid with streamlines of the flow field for the central plane of control case at T = (a) 0.15 s, peak E-wave, (b) 0.275 s, end E-wave, and (c) 0.5 s, peak A-wave

AR: As the pressure inside the LV decreased during the beginning of diastole (the E-wave), the AR jet developed immediately, before the development of the trans-mitral filling jet. The AR jet impinged on the inferolateral wall of the LV (Figure 3). Due to the presence of the strong AR jet, the trans-mitral filling vortex was hindered from developing and growing in strength. Comparing the control and AR cases, it can be clearly observed how the presence of AR would contribute towards destroying the coherent trans-mitral filling vortex. Following the completion of the E-wave, the AR jet completely annihilated the remnant trans-mitral filling vortex generated by the E-wave. The filling of the LV due to the A-wave does not result in a vortical structure, unlike the control case with no regurgitation.

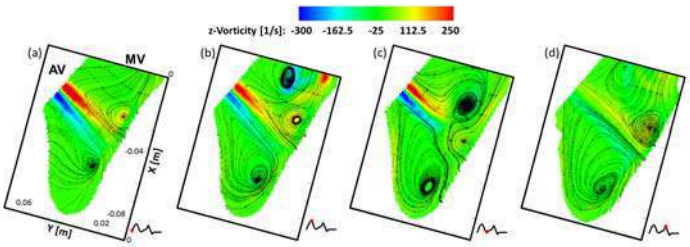

Figure 3: Out-of-plane iso-vorticity contour map overlaid with streamlines of the flow field for the central LVOT plane of AR 2 case at T = (a) 0.05 s, start E-wave, (b) 0.15 s, peak E-wave, (c) 0.275 s, end E-wave, and (d) 0.5 s, peak A-wave.

Energy Losses Due to AR: High EDR values were primarily located close to the AR jet region, the collision region of the AR and trans-mitral jet, and at the location where the AR jet strikes the posterior wall. The spatially averaged EDR at each measured time point in the cardiac cycle showed that EDR increases with increasing AR severity. We speculate that these observations would have an adverse effect on the filling efficiency of the LV. The efficiency of LV filling has been hypothesized to be directly dependent on the dynamics of the trans-mitral E-wave filling vortex [5].

DISCUSSION

The mechanism through which AR hinders the efficient filling of the LV appears to be through the formation of a 'kinematic wall'; a barrier that evidently blocks the flow from the mitral valve into the LV. It was observed that in all the AR cases tested in this work, the regurgitant jet impinged on the inferolateral wall. Similar observations were also noted in canine subjects with induced aortic insufficiency resulting in aortic regurgitation and in human subjects with AR [6]. Viscous energy losses were quantified using EDR, which was sufficient to characterize the energy losses arising due to AR. The temporal variations of EDR suggest that the energy losses are directly correlated to the AR jet's interaction with the trans-mitral E and A-waves. EDR exhibited a bi-phasic behavior coinciding with the E- and A-waves during diastole. Similar results were observed by Stugaard et al. [6].

This study has successfully replicated AR in a bench top *in vitro* setup and performed a parametric characterization of LV diastolic flow in the presence of AR. The flow structures observed in the left ventricle during the diastolic phase of the cardiac cycle drastically change during aortic regurgitation, primarily due to the collision of the regurgitant jet and trans-mitral filling vortex. This collision leads to a marked increase in viscous energy dissipation rates as the aortic regurgitation fraction increases, demonstrating that energy dissipation rate can be used to evaluate severity of aortic regurgitation.

ACKNOWLEDGEMENTS

We thank Ven Air (Terrassa-Barcelona, Spain) for casting the silicone LV.

INTRODUCTION

Computational models have been used as a powerful tool to perform mechanical analysis and identify risk factors and mechanisms which may be associated with plaque progression and rupture [1]. Modeling results and stress/strain predictions are influenced by many complex factors including plaque morphology, components, material properties, and modeling assumptions [2,3]. Since patient-specific vessel material properties are in general not available, most current models used material properties from existing literature [4,5]. It is desirable to have patient-specific material properties in computational models for more accurate stress/strain predictions. In this paper, in-vivo Cine intravascular ultrasound (IVUS) data and 3D IVUS-VH data were acquired from the same patient to construct 3D plaque models with patient-specific vessel material properties determined from Cine IVUS. Results from models with different material parameters were compared.

METHODS

IVUS and IVUS-VH data. IVUS and IVUS-VH data were acquired during cardiac catheterization from one patient (M, age: 58) with informed consent obtained. 3D IVUS-VH data (41 slices) were acquired to construct the 3D model following established procedures [4]. Cine IVUS data were acquired at two different locations to determine vessel material properties (Fig. 1). Cine data were matched with their corresponding IVUS-VH slices. Segmented Cine data contained only lumen contour and wall contour (Fig. 1).

Thin-slice model and 3D vessel model. The IVUS-VH slices (slice 6, 18) registered with Cine IVUS were used to make thin-slice models (3D model using 1 slice data) while the in vivo lumen circumference variations from Cine IVUS were used to determine material parameter values. The thin-slice models were made by adding a thin slice thickness to the 2D data so that the model became 3D and axial stretch could be applied for better parameter estimation. The 3D model for the vessel were used to compare stress/strain differences caused by different material parameter values. A modified Mooney-Rivlin (M-R) model was used to describe the anisotropic material properties of blood vessel:

$$W=c_1(I_1-3)+ c_2(I_2-3)+ D_1\{\exp(D_2(I_1-3))-1\}+K_1/2K_2\ \{\exp(K_2(I_4-1)^2-1)\}.$$

Vessels with plaque were stiffer than healthy vessels, axial shrinkage was set at 5% in this paper for simplicity. Pressure boundary condition was imposed on the lumen surface using patient's arm pressures. The external pressure was set to zero. The thin-slice 3D models and 3D vessel models were solved by ADINA (ADINA R & D, Watertown, MA, USA). Solution procedures and model details can be found in [6,7].

The iterative scheme to determine lumen shrinkage and parameter values. For each thin-slice model, an iterative procedure was used to adjust the parameter values in the M-R model and the circumferential shrinkage rate to match both maximum and minimum Cine lumen circumferences corresponding to systolic and diastolic pressures, respectively. Material parameters c_1=-1312.9 kPa, c_2=114.7 kPa, D_1=629.7 kPa, D_2=2.0, K_1=35.9 kPa, K_2 =23.5 kPa from our previous paper [4] were set as initial estimates of parameter values. The initial lumen shrinkage rate S1 was set to be 10%. At each iteration step, the lumen contour would be shrunk by S1. The slice outer-boundary shrinkage rate was determined using conservation of the vessel volume. Material parameter values would be adjusted so that the lumen circumference matched minimum Cine lumen circumference. The lumen circumference under maximum pressure was obtained and compared with the maximum Cine lumen circumference. If not matched (i.e., error > tolerance), then S1 would be adjusted and the iteration continued. The iterative procedure was set to stop if the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

relative changes of the shrinkage and parameter values were less than 0.01 (1%).

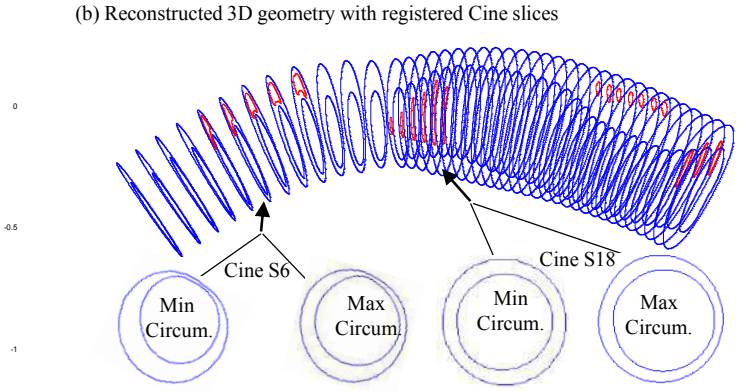

Figure 1: Plots of two sample IVUS images, contours, 3D reconstructed plaque, vessel curvature, Cine data at min and max pressures in two location.

RESULTS

Patient-specific and location-specific material parameter values. Table 1 shows the material parameter values and lumen shrinkage under 5% axial stretch. Cine data indicated that S6 and S18 circumference variations were 3.6% and 4.2%, which means that S18 was soft than S6. Material parameter values for S6 were about twice as high as those of S18.

Figure 2 gives stress and strain plots from 4 models for comparisons. Model 1: using material parameter values given in the Method section [4]; Model 2: using material parameter values from S6; Model 3: using material parameter values from S18; Model 4: Vessel part made of S1-S13 used S6 material values, vessel part made of S14-S41 used S18 material values. Maximum stress values from M1, M2 and M4 were close, while maximum stress from M3 was about 26 %, 41.6%, and 27.4% higher than those from M1, M2 and M4, respectively. Results from strain comparisons were similar.

DISCUSSION AND CONCLUSION

A Cine IVUS-based thin-slice modeling approach was introduced to obtain patient-specific in-vivo vessel material parameter values and shrinkages which are needed for models based on in vivo data. This fills a gap the current literature. Our 3D model results indicate that material parameters have impact on stress and strain calculations. Our results about the material parameter values from Slice 6 and Slice 18 indicated that different locations may have different material parameter values and shrinkages. Axial shrinkage is also an important factor for determining material parameter values.

Table 1. Material parameters, axial shrinkage and lumen shrinkage acquired from two different location by thin 3D model.

Slice 6	Min circumference	Max circumference	Min pressure	Max pressure
Cine lumen	0.9600cm	0.9949cm	70mmHg	130mmHg
Material parameters	C1=-525.16kPa, C2=45.88kPa,	D1=251.88kPa, D2=2.0,	K1=14.36kPa, K2=23.5	
Axial shrinkage	5%	Lumen shrinkage	5.7%	
Slice 18	Min circumference	Max circumference	Min pressure	Max pressure
Cine lumen	1.1969cm	1.2472cm	70mmHg	130mmHg
Material parameters	C1=-262.58kPa, C2=22.94kPa,	D1=125.94kPa, D2=2.0,	K1=7.18kPa, K2=23.5	
Axial shrinkage	5%	Lumen shrinkage	9%

DESIGN OF AN AFFORDABLE OUTDOOR ADD-ON TO A MANUAL WHEELCHAIR FOR DEVELOPING COUNTRIES

S. Dash, V. Sarda, A. Sharma, S. Sujatha

Department of Mechanical Engineering
Indian Institute of Technology Madras
Chennai, India

INTRODUCTION

A wheelchair is one of the most commonly used devices for mobility. Of the estimated 65 million in the world who need a wheelchair, very few, especially in low-resource settings such as developing countries, have access to an appropriate one [1,2]. In many developing countries like India, the terrain can be uneven. The terrain makes it difficult to use a typical manual wheelchair that has two rear wheels for propulsion and two front castors (hereon referred to as 4W wheelchair). 4W wheelchair users complain about the strenuous effort required in bad terrains and there is also the danger of falling out of the wheelchair. Generally, a tricycle is the preferred device for moving in these terrains. A tricycle is more stable than a wheelchair due to its longer base and three-point contact, and propelling it is more efficient than manual wheelchair propulsion [3]. However, a tricycle cannot be used as an indoor device due to its large size. Moreover, transferring from a wheelchair to a tricycle for outdoor mobility becomes cumbersome for the user. The objective of this work is to develop a solution which provides the wheelchair user complete mobility i.e., both indoors and outdoors. We have developed a quick and easy add-on to a manual wheelchair to convert it into a manual hand cycle (tricycle) or a powered scooter. This solution provides the advantages of wheelchair for indoor use and tricycle for outdoor use.

METHODS

Interaction with numerous wheel chair users and a survey of different rural areas with the most uneven terrains in India led to the following requirements that must be met – (1) the solution should be affordable, (2) modular to fit wheelchairs of different designs and sizes, (3) accommodate Indian attire, viz., sarees worn by women, dhotis, lungis, etc., worn by men. and (4) the add-on must ensure a minimum ground clearance of 3-4 inches to ensure that the castor wheels do not come in contact with the ground.

The proposed add-on device is designed such that it can be made using cycle parts to ensure affordability and easy maintenance and/or replacement of parts. The design includes a V-block attachment (called the adapter, Fig. 1) which needs to be attached to the 4W wheelchair intended to be used with the add-on. The adapter allows for various pipe diameters of different conventionally available wheelchairs.

Figure 1: The adapter attached to the wheelchair to enable use of the add-on.

The add-on is designed to be attached from the sides to accommodate Indian attire. The spacing between the side bars is adjustable to accommodate wheelchairs of different widths. Spring-loaded pins on the sides engage with the adapter attached to the wheelchair. The height of the pin self-adjusts such that when the user

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

pulls the device closer, the pin engages with the adapter making it easier for the user to attach the add-on. After engaging the pins, the user needs to push the add-on forward creating a moment on the add-on that is transmitted to the wheelchair to lift the wheelchair and engage the add-on.

Figure 2: Add-on attached to the 4W wheelchair. A pin mechanism engages into the adapter. The white wheels on the add-on enable it to stay upright and move easily for attachment/detachment. The castors of the 4W wheelchair and the wheels of the add-on are lifted off the ground effecting the change to a tricycle.

To disengage the add-on from the wheelchair a lever-cable mechanism similar to brake actuation in bicycles is used to pull up the pins and disengage the add-on. A stand with the small white wheels (Fig. 2) is provided to keep the add-on upright and moveable for attachment and detachment. An improvement planned is to replace the small wheels with castors giving the user more control while engaging the device.

RESULTS

The prototype shown in Fig. 2 has been tested with 5 wheelchair users with Spinal Cord Injury at the Association of People with Disability (APD), Bangalore. We have received positive feedback on the effectiveness of the device. The users found the add-on easy to engage/disengage and the tricycle was easy to use. Improvements were suggested to the ergonomics of the handle. We are improving this and other ergonomic and cosmetic aspects with the second prototype.

DISCUSSION

The 4W wheelchair is the most commonly distributed wheelchair to economically disadvantaged users in India through charitable organizations, government schemes, etc. However, these wheelchairs are put to limited use since the users find it difficult to use them in the uneven terrain around their homes. In many cases, their homes may even be too small for them to use the wheelchair inside, so the devices provided become static chairs, instead of mobility devices. The inability to move around restricts livelihood opportunities, social interactions, and presents secondary health problems.

The proposed add-on provides an affordable, easy and quick solution to give a wheelchair user both indoor and outdoor mobility. The add-on is cost-effective since it uses local, easily available parts and simple manufacturing techniques, stable and can be attached to/detached from a conventional wheel chair in less than 5 seconds. The design is versatile since with the right adapter, any existing 4W wheelchair can benefit from the add-on, unlike other add-ons that are designed for use with a specific wheelchair [4]. It is also more portable than a conventional tricycle.

Limitations include the fact that an existing 4W wheelchair to which the add-on is attached may not be robust enough to traverse long distances on uneven terrain. For instance, the 4W wheelchairs are generally provided with solid tires. These tires are unsuitable for outdoor terrain, where they provide a very rough ride and wear quickly. Therefore, for better utility, we plan to provide the add-on with a set of pneumatic tires to replace the existing solid tires. However, this addition would increase the cost of the device. 4W wheelchairs with more robust frames would also be more durable and we are planning to design one specifically for use with this add-on.

The current design for the add-on meets the requirements of functionality and affordability for rural users and extends the use of a 4W wheelchair they may already have. We are also working on developing a motorized version of the add-on device so that a 4W wheelchair can be used in manual or motorized mode, a need articulated by urban users in India. A provisional patent is pending on the manual and motorized add-on designs.

ACKNOWLEDGEMENTS

We would like to thank the TTK Center for Rehabilitation Research and Device Development (R2D2) and the Central Workshop at IIT Madras, and the Enable Makeathon organized by the International Committee of the Red Cross (ICRC) for providing the resources for the development of this device. We also thank APD, Bangalore for help with the user-testing. We gratefully acknowledge the inputs and contacts enabled by the Spinal Foundation, a self-help group for users with Spinal Cord Injury. We also acknowledge the Wellcome Trust, UK for the funding provided to the Affordable Standing Wheelchair Project, which enabled many of the learnings on this project.

THE EFFECT OF DEGENERATION ON THE SIX DEGREE OF FREEDOM MECHANICAL PROPERTIES OF HUMAN SPINE SEGMENTS

INTRODUCTION

Disc degeneration leads to biochemical and mechanical changes resulting from structural alterations in the nucleus, annulus and endplate. These changes place higher stresses on the annulus fibrosus, theoretically contributing to a more viscoelastic mechanical response. Zirbel et al. found significant differences in spine segment stiffness between degenerative grades during axial rotation, bending, and compression where the difference in stiffness between grades 3 and 5 discs were as high as a factor of 5x [1].

While the effects of degeneration on compression and rotation motions have been studied, to our knowledge there is no data for shear loading, nor across the full suite of six degree of freedom (6DOF) motions on the same spine segments. Clinical research has shown that people with low back pain (a potential consequence of degeneration) experience a 75% greater lateral shear force than those without it [2], indicating the importance of shear loading and its mechanical response [3,4]. A better understanding of this response can lead to improvements in the design of spinal implants and more rigorous finite element models. Furthermore, while stiffness has been reported in most studies, there is limited data on the energy absorption (phase angle) behavior of the segment in 6DOF.

The aim of this study was to determine and compare the 6DOF changes in spine segment stiffness and phase angle between degenerative groups.

METHODS

Fourteen intact functional spinal units (FSUs) were dissected from human lumbar spines (L1-2 x 5, L2-3 x 3, L3-4 x 4, L4-5 x 2, mean (SD) age 76.2 (11) years). Each FSU was tested in ±6DOFs at 0.1 Hz while exposed to physiologic preload (0.5 MPa), hydration (protease-inhibited, phosphate-buffered saline bath) and temperature (37°C) conditions in a hexapod robot [5]. The primary testing axis was driven in position control while the off-axis coupling was minimized in load control. Non-destructive cycle amplitudes were 1.1 MPa compression, 0.6 mm shear, 3° lateral bending, 5° flexion, 2° extension and 2° axial rotation.

Degenerative grade was determined macroscopically, based on the Thompson scale [6]. Data from the final cycle of each test were processed. Stiffness for each DOF was calculated using linear regression to determine the slope over a specific range of the loading portion of the load-displacement curve. Phase angles for each DOF were calculated between the input displacements and measured forces for all cycles using a cross spectral density estimate function.

Separate ANOVAs were performed on the dependent outcome measures of stiffness and phase angle having an independent factor of degenerative grade (mild, moderate, and severe) for each DOF. Post-hoc multiple comparisons using a Bonferroni correction on alpha were performed when significant

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

main effects were present. Paired t-tests between left and right lateral shear, lateral bending, and axial rotation were performed to assess symmetry of DOFs. Significant differences were accepted when $p<0.05$ (2-tailed).

RESULTS

Specimens were classified into grades 3 (N=5), 4 (N=6), and 5 (N=3) and categorized as mild, moderate, and severe degeneration respectively. Paired t-tests to analyse symmetry found no significant differences between left and right lateral shear, lateral bending, and axial rotation ($p>0.05$). The means for left and right were therefore averaged for each of those three DOFs and used in the analysis of the data.

Significant overall effects in stiffness were found between mild and moderately degenerated groups in lateral shear, flexion, and axial rotation ($p<0.020$, Figure 1). Post-hoc tests for lateral shear and axial rotation revealed that moderately degenerated groups had decreased stiffness compared to mild ($p=0.001$). For flexion, the severely degenerated group had a significantly larger stiffness than mild ($p=0.022$). For phase angle, significant overall effects were seen in anterior shear, and axial rotation ($p<0.027$, Figure 2), where phase angles for mild degeneration were less than moderate for both DOFs ($p<0.028$).

DISCUSSION

Degeneration significantly affected lateral shear, axial rotation and flexion for stiffness, and anterior shear and axial rotation for phase angle. The initial decrease in stiffness for shear and axial rotation DOFs could be attributed to an increase in delamination and annular clefts. The stiffness trends for mild and severely degenerated groups were larger than moderate in antero/postero shear, and all bending DOFs, which is consistent with previous research [1] and corresponds to the Kirkaldy-Willis and Farfan instability theory [7]. Trends of stiffness under compression and bending were relatively similar between mild to moderately degenerated groups, and increased from moderate to severe. In these directions, the major stress components are compressive and tensile, where solidification of the nucleus for severe degeneration could theoretically lead to an increased stiffness.

Generally, phase angle increased from mild to moderate degeneration, with a decrease between moderate and severe FSUs for most DOFs. There was little difference in phase angle between moderate and severe degeneration in compression and anterior shear, and this may be caused by increased contact pressure in the posterior elements once the disc becomes moderately degenerated.

Clinically, the identification of the DOFs that are most affected by degeneration could be used in rehabilitation to improve supplemental stabilization of core muscle groups.

SHEAR DEPENDENT SICKLE RED BLOOD CELL ADHESION IN SHEAR GRADIENT HELE SHAW FLOW

INTRODUCTION

The adhesive and biomechanical characteristics of red blood cells play a critical role in vascular occlusions that lead to life-threatening crises in sickle cell disease (SCD). The altered properties of sickle erythrocytes due to the presence of homozygous sickle hemoglobin reduces cellular deformability and increases cell adhesion onto (sub)-endothelium matrix proteins such as Laminin (LN) and Fibronectin (FN) [1]. This sophisticated dynamic process takes place within a wide range of shear rates specific to different types of microvasculature (Fig. 1a). In literature, there have been several approaches to simulate shear rate variance based mostly on discrete shear alterations rather than a continuous gradient. Here, we present a physiologically relevant microfluidic device which creates a shear gradient along the flow direction to investigate the adhesion of sickle Red Blood Cells (sRBC) under continuously transitioning shear rates. We report a new parameter, namely Shear Dependent Adhesion Rate (SDAR), which is significantly greater in RBC-LN interaction particularly for deformable sRBCs suggesting a potential association between cell deformability and shear dependent adhesion. We further report normalized SDAR numbers for each cell type (i.e., deformable cells, non-deformable cells), which indicated that the non-deformable sRBC adhesion to FN is the least shear-dependent. Moreover, those cells required significantly higher shear rates than physiological conditions to be entirely removed from the channels.

METHODS

Hele-Shaw microfluidic device was manufactured using a lamination technique as we described earlier [1]. Briefly, a top plastic cover was assembled onto a functionalized glass slide through a 50 μm thick double sided adhesive film. The adhesive part forms a diverging flow field through which the shear rate constantly reduces to simulate the physics of flow in terms of shear distribution inside branching blood vessels (Fig. 1a&b), especially in post-capillary venules.

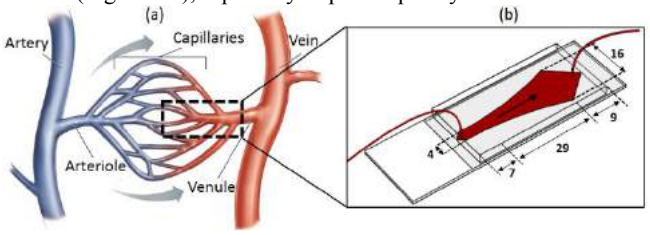

Figure 1: The variable shear-gradient microdevice to probe the shear-dependent adhesion of sRBCs. (a) A schematic view of the human microvasculature system is shown. Every branch has characteristic shear rates determined by the vessel diameter. (b) The shear gradient channel enables shear transition in a continuous manner at a single flow rate. The dimensions are in millimeters.

Numerical simulations were performed (COMSOL 4.3) to characterize the velocity and shear rate profiles in microchannel. Prior to experimental investigations, we chose a rectangular region of interest (ROI) based on computational simulations, in which the average shear rate showed more than a 3-fold reduction along the X axis (Fig. 2a).

RESULTS

We observed greater adhesion of sRBCs at lower shear sites (Fig. 2b), as expected. To assess the extent to which individual sRBC subpopulations respond to shear rate gradient, we plotted the number of adhered cells against the shear rate and fitted a linear curve in FN and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

LN coated channels for both deformable and non-deformable sRBCs. Then, we defined SDAR as the slope of the fitted curve in degrees (Fig. 3). However, the shear effect was suppressed in the case of too few adherent cells, which was observed for some patients. Therefore, we normalized the SDAR based on adhesion in the first sub-region of channels ($nSDAR=\frac{\text{Number of adhered RBCs in a subregion}}{\text{Number of adhered RBCs in first subregion}}x100$).

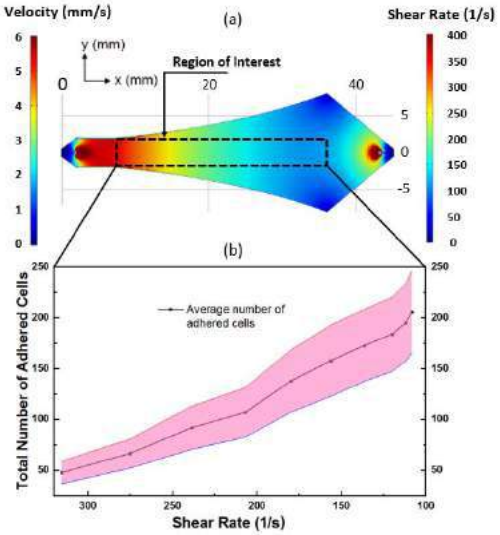

Figure 2: Computational flow simulations and quantified cell numbers in shear gradient channel. (a) The contours of velocity and shear rate were calculated on a plane 10 μm above the bottom surface, and rectangular region of interest (ROI) was chosen in which the experimental data analyses were performed. (b) The total number of adhered cells increases with decreasing shear rate downstream the flow. The shaded region represents standard error of average (n=18).

Deformable cells displayed the highest rate of shear dependent adhesion to LN (Fig. 4a). nSDAR also suggested that those cells are sensitive to changes in shear rate and can be removed significantly more with increasing shear (Fig. 4b). We also observed that non-deformable cells adhered to FN are the least shear-influenced subgroup that often require greater shear rates over the physiological range (~1000 s^{-1}) for complete detachment. Moreover, the relative nSDARs between deformable and non-deformable sRBCs were more pronounced in FN channels, where more deformable cells detached with increasing shear rate than non-deformable cells.

In addition to SDAR and nSDAR parameters, we further calculated the X-axis intercept of the fitted curves obtained for each patient sample, which we defined as Zero-Adhesion Shear Rate (ZASR) (Fig. 5). The intercept point represents the estimated shear rate required to remove all of the adhered RBCs to the specific endothelium protein. We have shown that adhered sRBCs to FN may necessitate ZASR values greater than the typical physiological shear rate of 1000 s^{-1}.

DISCUSSION

We present a new microfluidic platform that allows convenient, one-step analysis of sRBC adhesion at dynamically transitioning continuous shear rates. We have shown that red cell adhesion is influenced by shear rate at different levels depending on cell type and endothelium proteins coated on the channel surface. Based on shear-dependent adhesion analyses, we report patient specific SDAR and nSDAR values, which may help in understanding the dynamic pathophysiology of SCD and importance of shear rate in a sequence of events that eventually lead to vaso-occlusion crises. The flow and shear characteristics in different tissues and organs exhibit a wide range of variations. Therefore, this continuous shear gradient microdevice can be utilized to simulate cell to endothelium protein interactions at shear conditions observed in various organs.

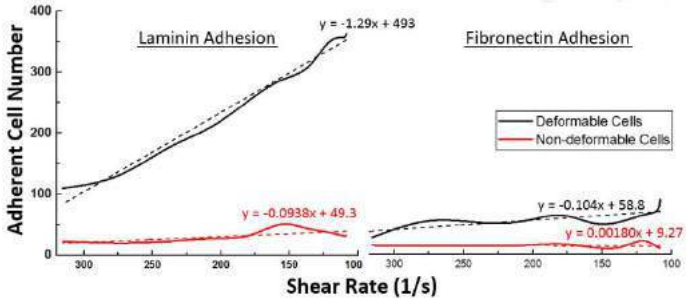

Figure 3: Typical distribution of adhered deformable and non-deformable cell numbers in LN and FN coated microchannels with varying shear rates. Dashed lines represent the linear fitted curves and their equations were used to quantify shear-related adhesion data.

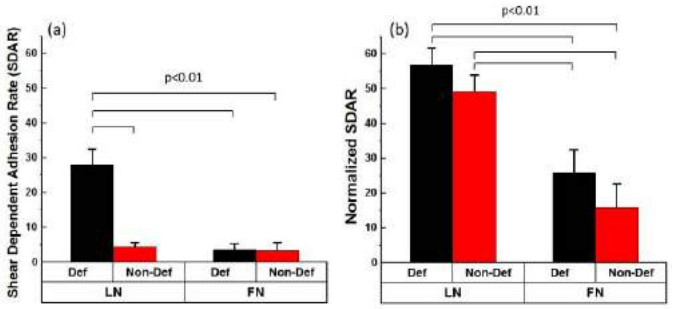

Figure 4: SCD patient based quantification of SDAR and normalized-SDAR values in LN and FN channels. (a) High levels of adhesion amplifies the SDAR for deformable cells. (b) An enhanced shear dependent adhesion was observed in LN channels based on the normalized SDARs. Error bars represent standard error (n=7-18). The statistical significance is based on one-way ANOVA.

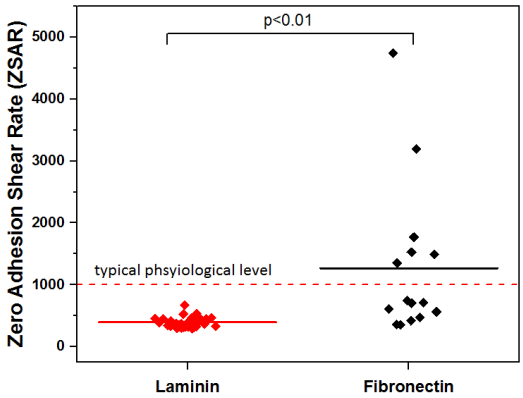

Figure 5: Estimated zero-adhesion shear rates for sRBC adhesion to LN and FN in patients with SCD. In some patients, ZASR is greater than the physiological shear rates in FN channels, which suggests a greater chance of cellular adhesive related clinical events in these patients.

CHARACTERIZATION OF THE FAILURE RESPONSES OF SKIN: COMPARISON OF UNIAXIAL AND EQUIBIAXIAL PLANAR MECHANICS

Samantha N. Schumm (1), Meagan E. Ita (1), Beth A. Winkelstein (1,2)

University of Pennsylvania
Philadelphia, PA, USA

INTRODUCTION

Skin undergoes variable, multi-dimensional loading through physiological movement, surgery, and injury [1]. Skin is multi-layered with an outer epidermal layer and inner dermis, both of which are innervated and contain mechanoreceptors for touch and sensation [2,3]. Cutaneous mechanoreceptors in the skin respond to motions and deformations differently depending on t heir size and morphology, depth in the skin, and whether they are slow- or rapid-adapting nerve fibers [3,4]. For example, the Pacinian corpuscle (PC) is an unmyelinated nerve ending surrounded by membranous lamellae and detects high frequency vibrations with high sensitivity [3,4]. The Ruffini's corpuscles are also mechanoreceptors, but they respond to stretch and little else is known about them [3]. Epidermal innervation is also implicated in pain through altered nerve fiber density [2,5]. Recent simulation of skin using a finite element model of the PC within a fiber network demonstrated the low spatial resolution characteristic of the PC in response to indentation pressure [6]. As such, understanding the mechanical response of skin to different loading conditions is important to defining the local mechanical environment of nerves and mechanoreceptors.

In addition to defining the local mechanics for sensation, macroscopic skin responses have direct implication in wound healing and skin grafting [7,8]. Skin has been reported to exhibit non-linearity in its viscoelastic response [7], which further advocates for its multi-dimensional mechanical characterization, but which is currently lacking for skin tissue. Although parameters like tensile strength, failure strain, and elastic modulus have been defined for skin under uniaxial tension [1,9], there are few studies investigating planar biaxial loading of skin [8]. Accordingly, this study assessed the mechanical response of rat skin subjected to uniaxial and equibiaxial planar loading to evaluate and define any differences in the mechanical behavior of skin due to different loading paradigms. The macroscopic failure mechanics, as well as strain responses at failure, were compared to begin to characterize the mechanical response of skin and also to provide insight into its regional mechanical environments.

METHODS

All procedures were IACUC-approved and used male Holtzman rats (410-446g; n=3). The skin along the dorsal aspect of the rat was shaved and excised by surgical scissors and a scalpel. Square samples (1.5cmX1.5cm) were taken from the area over the shoulder blades. Connective tissue was removed; the thickness was measured with digital calipers in 3 locations and averaged for each sample. Samples were loaded into a custom 574LE2 planar biaxial test system (Test Resources) equipped with 4 linear actuators and 4 load cells oriented orthogonally. Specimens were affixed to each actuator by customized grips and needles to prevent slip (Fig. 1). All samples were oriented with the rostral-caudal direction along the y-axis and the lateral-medial

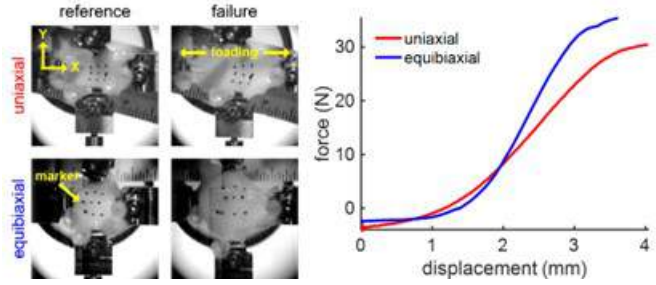

Fig. 1. In uniaxial tests, specimens were clamped on all axes but were loaded along the x-axis; equibiaxial tests were simultaneously distracted in x and y. Failure loads are similar for both test types.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

direction along the x-axis (Fig. 1). A 3x3 grid of markers was applied to the dermal surface to track displacements during loading.

A 5N preload (10% of failure from pilot studies) was applied to both the x- and y-axis. All samples were pre-conditioned using a 2mm peak-to-peak equibiaxial distraction for 30 cycles at 0.5Hz. After pre-conditioning and a rest-period of 5 minutes, samples were randomized to undergo either uniaxial (n=4) or equibiaxial (n=4) tension. Uniaxial testing applied distraction along the primary loading axis at 2mm/s until failure. A 2mm distraction was also applied to the off-loading axis at 2mm/s and maintained for the entire test. Although not typical for uniaxial tensile testing [1,9], constraining the off-loading axis isolated deformation along a primary in-plane axis to both inform constitutive modeling and differentiate axis-dependent mechanical properties. In the equibiaxial tests, both axes were simultaneously distracted to failure at 2mm/s. Force and displacement data were recorded at 100Hz; video data were simultaneously collected at 500Hz using a high-speed camera (Phantom v9.1; Vision Research).

Tissue failure was defined as the first occurrence of any load cell reaching its maximum, regardless of the axis. For each specimen, the force at that time was averaged across all load cells of the loading axes and taken as the force at failure. Failure displacement was similarly calculated. Strains at failure were calculated using the markers, with the reference frame taken at 3sec prior to the start of the test. Marker centroids were digitized in ImageJ, and LS-DYNA calculated the maximum principal strain (MPS) fields at failure [10,11]. The force, displacement, and peak MPS at failure were compared between the uniaxial and equibiaxial tests, using separate t-tests for each outcome.

RESULTS

Sample thickness was 2.87±0.32mm and not different between the two groups (p=0.2). The failure force was not different between uniaxial (39.2±11.2N) and equibiaxial (36.6±5.3N) loading (Figs. 1 & 2). However, the displacement at failure was significantly (p=0.025) lower for equibiaxial loading than for uniaxial loading (Fig. 2). Although the macroscale displacement at failure was lower in equi-biaxial tension, the MPS was higher (Figs. 2 & 3). The peak MPS at failure was significantly different (p=0.039) between the groups, with the mean peak MPS in equibiaxial loading nearly 1/3 greater than the mean peak MPS in uniaxial loading (Fig. 3). Tissue rupture occurred at the grips for all specimens and the location of the first visible rupture did not always coincide with the location of the peak MPS at failure.

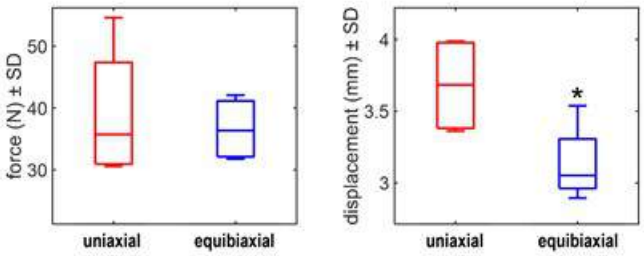

Fig. 2. Force at failure does not differ between load conditions. Displacement at failure is lower (*p=0.025) for equibiaxial testing.

DISCUSSION

This work is the first to characterize the macroscale failure mechanics of rat skin in response to biaxial loading and to define differences in failure responses between two planar loading paradigms. No difference in the failure force of skin was detected between uniaxial and biaxial tension (Fig. 2); but, the mean failure load (37.5±7.9N) for all specimens is less than half of that estimated from a prior study of skin under uniaxial tensile failure (~100N) [1]. Although the two studies used samples from the same region of the rat, our analysis was biased by the selection of the failure point. Defining failure at the *first* occurrence of peak load by any transducer imposes the most conservative definition since it discounts the possibility that other transducers might subsequently reach a higher peak. This same limitation may also underestimate the failure threshold, which could be beneficial for injury applications, but have negative effects in the context of defining the requisite stiffness of skin tissue grafts. As such, continued investigation of this, and alternate methods of failure analysis, is needed to better understand and define the macroscale and regional biomechanical responses of skin under planar loading. Moreover, since failure displacement and strains are different between uniaxial and biaxial conditions (Figs. 2 & 3) and because skin undergoes multi-axial loading *in vivo* in both physiological and injury conditions, continued characterization of its failure, and sub-failure, responses under complex planar loading is needed to define those biomechanical relationships with the most physiological meaning.

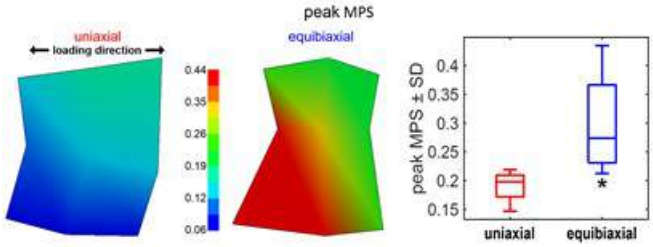

Fig. 3. MPS at failure is more variable and has a greater peak (*p=0.039) for equibiaxial than for uniaxial loading.

Although tissue displacement at failure is greater in uniaxial tension along the loading axis, the corresponding strains at failure are lower in that condition than for equibiaxial tension (Figs. 2 & 3). This counterintuitive result may be attributed to the effect of clamping the off-loading axis which effectively applies a controlled displacement boundary condition that restricts tissue deformation along that axis. Regardless of the biomechanical metrics, applying displacement along both planar axes in equibiaxial tension is a more physiologically relevant test condition for a tissue like skin. Further, cellular responses to macro-mechanical stimuli depend on t he *local* mechanical environment [3,4], which can be described in some cases by strain. For skin in particular, relating the local and regional strains and loads to activation of cutaneous mechanoreceptors, either experimentally or computationally [6,12,13], will provide important insight into this understudied biomechanical system. Certainly, continued work with skin that integrates a variety of mechanical profiles with physiological assessment of the mechanoreceptors embedded within it would begin to define the pathways through which local mechanical stimuli are translated in sensation and/or touch.

INTRODUCTION

Several cardiovascular diseases result in the impairment of the aortic valve function resulting in incomplete leaflet closure and retrograde flow of blood during the diastolic phase of the cardiac cycle. This back flow of blood from the aorta into the left ventricle, clinically referred to as aortic regurgitation (AR), is usually characterized by a high velocity jet which permeates into the left ventricle (LV). AR imposes severe hemodynamic and structural penalties on the normal functioning of the heart leading to diminished effective cardiac output [1] and LV remodeling [2]. In the presence of AR, the retrograde flow of blood from the aorta is expected to collide with the blood flowing into the left ventricle from the left atrium during diastole. Complex intra-ventricular flow patterns are expected due to this collision of a jet with a vortical structure in the LV, resulting in increased viscous energy losses. A recent clinical study by Stugaard et al. [3] concluded that the viscous energy loss in the LV increases with the severity of AR in both human and canine models. Furthermore, this altered flow could result in abnormal shear stress distributions that may be sensed by cardiac tissue [4] to initiate the process of first regional and then global cardiac remodeling.

The high variability in the temporal progression of the disease as well as the multiple confounders that exist with the disease present a significant challenge in gaining an in-depth insight into AR in a clinical or *in vivo* setting. On the contrary, a bench-top *in vitro* study could help parametrically evaluate the effect of AR on the intra-ventricular fluid mechanics and on the functioning of the LV. Such a study could lead to an in-depth understanding of AR and eventually help develop better clinical interventional timing strategies for patients. The fluid mechanics problem of AR is essentially that of the oblique collision between a jet and a vortical structure within a flexible walled constrained environment. However, to understand the fundamental fluid mechanics of AR, it is useful to decouple the fluid-structure interaction in a flexible walled cavity. This allows for a fundamental study while minimizing the complexities of the native LV, such as the motion of the ventricle walls, the asymmetrical shape, and the complex network of chordae tendineae. This work aims to understand the fundamental fluid mechanics of the AR by studying the interaction of a jet with a vortical structure in an unconstrained quiescent medium.

METHODS

The flow loop used in this work is a simplified model of the left heart. It consists of a large tank with the regurgitant jet flow and the MV inflow as shown in Figure 1. Water was used as the working fluid in this study. The flow loop (Figure 1) was fabricated with two separate pumps, a pulsatile pump that is responsible for the mitral inflow vortex, and a steady flow pump that generates the steady regurgitant flow. Two bileaflet mechanical valves are used in the pulsatile part of the flow loop to ensure unidirectional flow. The pulsatile pump was actuated at a frequency of 0.5 Hz, with pauses of 2 seconds and 4 seconds before systole and diastole, respectively. The authors clearly acknowledge that this frequency is not physiological, however, this study attempts to isolate any interactions between cardiac cycles and hence focusing on one cycle at a time. The pulsatile pump was controlled via a LabVIEW program.

These pauses are utilized to ensure a quiescent medium before the ejection of the fluid, as well as to minimize any interactions due to backflow. This creates a max flow rate of 107.17 cc/s (6.43 L/min) through the mitral orifice. Two ultrasonic flow probes were placed

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

before both the entrance length tube and the regurgitation jet tube to measure the flow rates for each case. The AR jet pipe, with an inner diameter of 5.6 mm, was fixed in the LV chamber at a set distance and orthogonal angle from the pulsatile mitral flow.

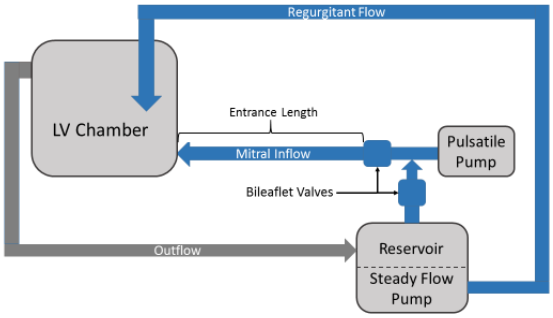

Figure 1: Schematic of the flow loop used in this study

Flow visualization was conducted with a mitral inflow of 107.17 cc/s for all cases, and a variable AR jet ranging from 25.67 to 102.67 cc/s. The ratio of regurgitant jet flow to mitral vortex flow (J/V ratio) for each condition are displayed in the Table below. Blue color dye was used for the AR jet while a pink color dye was used for the mitral inflow (vortex). A high-speed camera was used to capture the interaction between the jet and the vortex.

Regurgitant jet (cc/s)	Max mitral flow (cc/s)	J/V Ratio
25.67	107.17	0.24
51.33	107.17	0.48
77.00	107.17	0.72
102.67	107.17	0.96

RESULTS

The primary result of this study provides a qualitative understanding of the interaction between the jet and the vortex. Figure 2 illustrates flow visualization of the interaction between the jet and vortex at different J/V ratios. The variation in the interaction as the J/V ratio changes is clearly captured in the flow visualization photographs. At the lowest J/V ratio of 0.24, the jet is strongly affected by the vortical structure and it can be observed that the jet deflects towards the mitral inflow orifice. Furthermore, at this J/V ratio the jet is completely entrained into the coherent vortical structure. At a higher J/V ratio of 0.48, the jet structure away from the vortical structure is not affected. However, some entrainment of the jet into the vortical structure can be observed. At a J/V ratio of 0.72, the jet structure is not affected by the presence of the vortex and the entrainment of the jet into the vortex is not observed. Furthermore, the vortical structure appears to be disintegrating due to the interaction. At the highest J/V ratio of 0.96, the jet structure appears to be unaffected by the vortex and the coherent vortical structure disintegrates after the collision with the jet.

DISCUSSION

The results clearly demonstrate the mechanism of interaction of the jet and the vortical structure at different ratios of the jet to vortex flow rates (J/V ratio). As the J/V ratio increases two main changes were observed: a) the entrainment of the jet into the vortex reduces and b) the vortex begins to disintegrate upon interaction with the jet. Here, the J/V ratio can be thought of as the ratio of the strength of the flows; hence, as the J/V ratio increases the jet contributes towards the disintegration of the vortex after the collision.

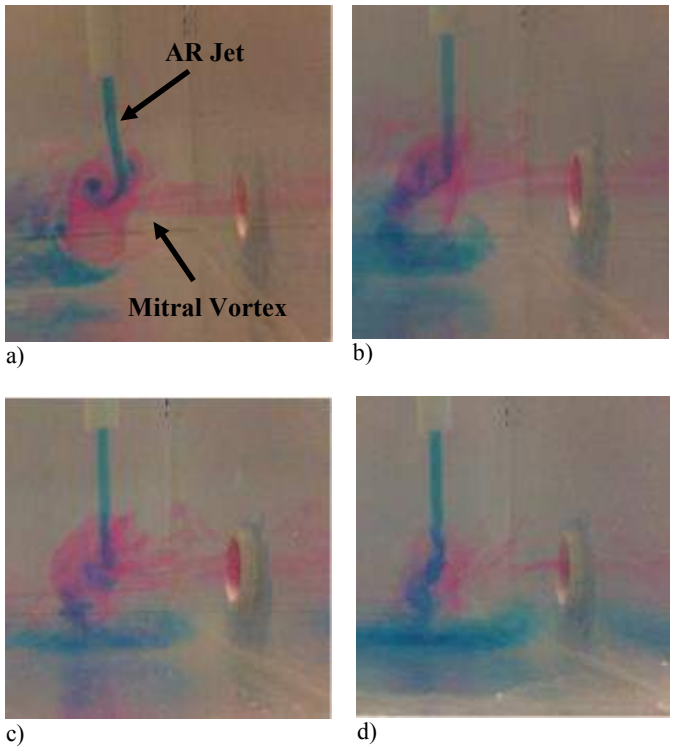

Figure 2: Flow visualization demonstrating the interaction of the jet and a vortical structure at different Jet/Vortex ratios a) J/V = 0.24, b) J/V = 0.48, c) J/V = 0.72, and d) J/V = 0.96. The blue dye indicates jet flow and the pink dye indicates vortex flow.

At the lower J/V ratio, the vortex strength is much greater than the jet strength; hence the induced velocity field of the vortex strongly influences the upstream part of the jet, causing the observed deflection in Figure 1a. Physiologically, the increase in J/V ratio simulates the increasing severity of AR in the LV. These results indicate that as the AR severity increases the physiological flow in the LV in the form of a vortical structure could disintegrate up on collision with the AR jet. This disintegration has a two-fold impact: a) it impairs the capability of the vortical structure to conserve the momentum of the fluid during diastole in preparation for systolic ejection and b) it leads to higher viscous energy loss resulting in a lowering of the efficiency of the LV filling. Furthermore, the increased viscous energy losses manifests itself in the form of increased cardiac loading during systolic ejection. These results will lead to a fundamental understanding of AR which is necessary to develop better metrics to grade AR severity.

INTRODUCTION

Human adipose-derived stromal/stem cells (huASCs) can differentiate along multiple lineage pathways, including adipocytes, chondrocytes, myocytes, neurons and osteoblasts [1]. As new stem-cell-based therapies become the standard of care for a wide variety of diseases, appropriate cryopreservation protocols will be necessary to increase patient access, reduce cost, and enhance the safety and effectiveness of huASCs. Recent studies from our laboratories have described the in vitro cryopreservation of huASCs frozen in a media consisting of minimal amounts of dimethyl sulfoxide (DMSO) and serum (animal or human) [2]. However, the infusion of cells cryopreserved in DMSO has been associated in nearly all patients with nausea, chills, hypotension, dyspnea and cardiac arrhythmia [3]. Therefore, the practical goals of this study are the development and optimization of a serum-free and DMSO-free cryoprotective medium.

Numerous reports in literature suggest that the up regulation of Heat Shock Proteins (HSPs) can provide cytoprotection in various diseases [4, 5]. Instigating the cell's natural cytoprotective mechanisms such as heat shock response could help in alleviating the damages associated with cryopreservation on cells thus reducing the amount of cryoprotectants used. Therefore, this study is aimed to evaluate the effect of heat shock response on cryopreservation of huASCs by determining the optimal expression of heat shock proteins.

METHODS

Cell culture: The huASCs were obtained from Lacell incorporation, New Orleans and cultured till passage 2 using the medium containing DMEM, 10% FBS, and 1% antibiotic in a cell culture incubator at 37 ºC.

Heat shock: The cells were given heat shock by exposing to 43ºC for 1 hour in a cell culture incubator. After the heat shock the cells were allowed to recover in 37ºC incubator for 1, 3, 9, 18 and 48 hours respectively before further analysis.

Western blot: RIPA buffer is used to lyse the cells and the total protein content is estimated using BCA assay kit. For the western blot, 25 ug of protein is loaded per lane in polyacrylamide gel and SDS PAGE is carried out followed by the transferring of proteins on to nitrocellulose membrane. The antibodies (Santa Cruz Biotechnology) for HSP90, HSP70, HSP27, and β-actin in the dilutions of 1: 200, 1: 200, 1: 5000, and 1: 200 were used for blotting.

QPCR: The RNA was isolated using pure link RNA mini kit and the purity is measured using nanodrop instrument. cDNA was synthesized using High Capacity cDNA reverse transcription kit. The synthesized cDNA was used to do QPCR with primers for HSP90, HSP70, HSP27 and cyclophilin B (normalizer).

Cryopreservation/Thawing: The huASCs are cryopreserved at 3, 9, and 18 hour time point post heat shock at a cooling rate of -1°C /min using control rate freezer till -80ºC in different groups with CPAs either DMSO or polyvinylpyrrolidone (PVP) followed by plunging in liquid nitrogen. Thawing was performed using 37ºC water bath incubator by shaking gently for 1-2 minutes.

Cell viability assay: After thawing the cells were cultured for 24 hours. The live cells attached to surface of culture flask were harvested using 0.05% trypsin and the dead floating cells in the medium were

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

collected. The post thaw cell viability was assessed using the apoptosis kit (BD Biosciences) that uses annexin V/ propidium iodide.

RESULTS

QPCR:

Post thaw cell viability: The bar graphs below represents the post thaw cell viability of heat shocked huASCs cryopreserved at different time points after heat shock either with 1% DMSO or PVP.

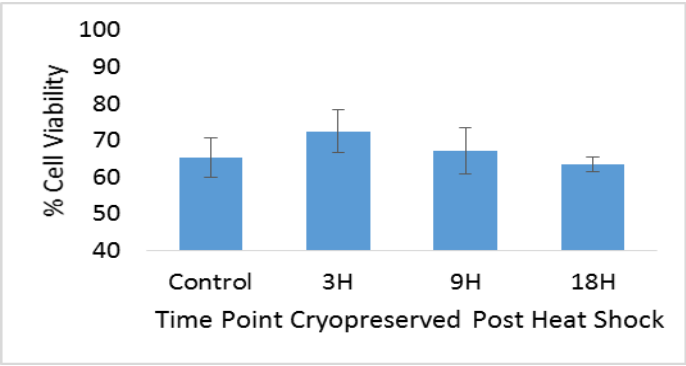

Figure 3: Post Thaw Viability of Heat Shocked huASCs Cryopreserved in 1% DMSO

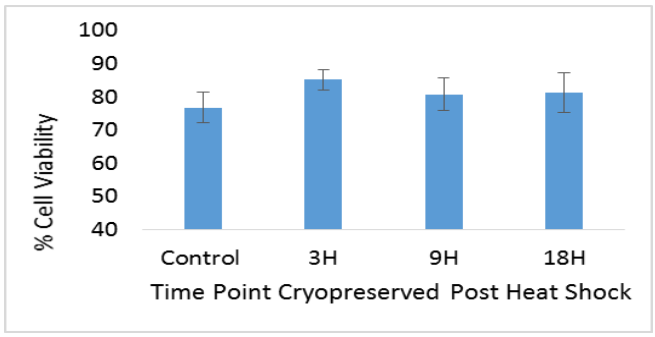

Figure 4: Post Thaw Viability of Heat Shocked ASCs Cryopreserved in 1% DMSO.

DISCUSSION

It is well known that HSPs can be overexpressed by mild thermal stress and act as molecular chaperones which assist in proper folding of misfolded proteins. Several reports suggest that preconditioning the cells to induce the HSPs expression offers the protection against apoptosis, ischemic/reperfusion injuries of heart and brain tissues, and oxidative stress [4].

The QPCR and western blotting results indicate the increase in expression of HSP70 after heat shock. The expression profile of HSP70 post heat shock gradually tends to increase, peaks at 3 hour time point and reaches base level at 48 hours. The huASCs cryopreserved at 3 hour time point resulted in maximal post thaw viability than other time points suggesting that cryopreservation at maximal HSP70 expression improves cryopreservation outcome. The improvement in post thaw viability is found to be function of HSP expression and consistent with different CPAs either intracellular or extracellular (DMSO or PVP). However, the expression of HSP90 and HSP27 showed very little change. Therefore, it can be possible that the increase post thaw viability is a result of HSP70 upregulation, however, it is also possible that there may be other HSPs which are being upregulated as result of heat shock. Our next step would be to determine the expression of other HSPs and also to overexpress HSPs individually or in combinations by genetic engineering tools so that a better cryopreservation protocol to replace CPAs or to minimize their usage could be developed.

RIGHT VENTRICULAR ADAPTATION TO PRESSURE OVERLOAD CONDITIONS IN MICE

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a debilitating disease that lowers the medial survival years of untreated individuals to 2.8 years [1]. It is characterized by the progressive narrowing of pulmonary arteries (PA) throughout the vasculature, which results in the persistently elevated ventricular afterload. The typical cause of death is right ventricular (RV) failure. To better understand the pathogenesis of PAH, including the transition from RV adaptation to RV failure, animal models of PAH are widely used. An early study of pulmonary artery banding (PAB) in mice reported RV chamber dilatation with decreased RV ejection fraction and increased end-diastolic volume resembling RV dysfunction in humans with PAH [2]. However, RV function was not measured comprehensively, such as can be done with the ventricular-vascular coupling (VVC) efficiency, which measures RV mechanical performance in the context of altered RV afterload [3,4]. We hypothesize that 21 days of PAB in mice results in RV hypertrophy and right ventricular-pulmonary vascular uncoupling and tested this hypothesis using invasive measurements of RV structure and function as previously established by our group [5].

METHODS

Adult male C57BL6/J mice (n=10), 10 weeks of age, were subjected to PAB to create severe RV pressure overload. Under anesthesia, a left lateral thoracotomy was performed and a suture was knotted around the main PA. The thorax and skin were then sutured together to close the wound. During surgery, 5 mice died due to bleeding or excessive banding. With the remaining 5 mice, serial ultrasound measurements, such as RV wall thickness (WT), LV percentage of fractional shortening (FS), and LV ejection fraction (EF), and transthoracic echocardiograms on M-mode were collected before surgery (baseline) and after PAB weekly for up to three weeks (21-PAB). Two mice were sacrificed at 14 days and are not included in the analysis below. At 21 days, in a terminal procedure, *in vivo* RV pressure and volume (PV) measurements were obtained in the remaining 3 mice.

The terminal collection of hemodynamic measurements involved an invasive open chest surgery. Before the operation, the mouse was weighed, anesthetized with urethane (to maintain a physiological heart rate), intubated, and ventilated with room air at a set tidal volume and respiratory rate. Following exposure of the RV, a 1.2 F catheter-tipped pressure transducer was introduced into the right carotid artery and into the ascending aorta to monitor systemic blood pressure. A 20-gauge needle was used to puncture the apex of the heart where a 1.2 F admittance PV catheter was then inserted into the RV. Baseline readings of RV PV loops were acquired. Brief inferior vena cava occlusions to alter venous return were then performed to derive RV end-diastolic and end-systolic pressure relations.

Standard hemodynamic variables, such as heart rate (HR), end-diastolic pressure (EDP), end-systolic pressure (ESP), end-diastolic volume (EDV), and end-systolic volume (ESV), and RV function parameters, such as cardiac output (CO), EF, relaxation factor (τ), RV chamber compliance, and stroke volume (SV), were calculated using the baseline PV loops. To assess RV contractility, end-systolic elastance (Ees) derived from the slope of PV loops and preload recruitable stroke work (PRSW) acquired during vena cava occlusion were computed. Ventricular-vascular coupling (VVC) was also evaluated as the ratio between Ees and effective arterial elastance (Ees/Ea). Following hemodynamic data collection, the animals were euthanized and their hearts were excised to determine the mass of RV, LV, and septum (S) needed to calculate Fulton index as the weight ratio of RV and (LV+S).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Comparable RV structure and function data on adult male C57BL6 mice from a prior study [6] are used as control (n=9). For statistical analysis of the ultrasound measurements, a one-way ANOVA ($P<0.05$) was first performed to screen for statistical significance followed by Tukey's HSD multiple comparison test for post hoc analysis in R software. A two-tailed t-test of unequal variance was performed on the invasive hemodynamic measurements using Microsoft Excel.

RESULTS

Over the 3 weeks following PAB, ultrasound measurements showed a trend of increase in RV WT and decrease in LV EF and LV FS, suggesting cardiac remodeling affecting LV contractility in response to PAB (Table 1). Between Day 7 and 21, LV FS was significantly decreased by 43%.

Table 1. RV morphology and LV function of PAB mice

	Baseline	Day 7	Day 13	Day 21
N	3	3	2	3
RV WT, mm	0.50 ± 0.06	0.56 ± 0.08	0.54 ± 0.03	0.63 ± 0.08
LV EF, %	53.23 ± 7.58	79.35 ± 3.15	69.61 ± 8.28	53.04 ± 5.76
LV FS, %	27.59 ± 4.93	47.22 ± 3.07	38.76 ± 6.64	26.97 ± 3.70*

Values are presented as mean ± standard error. N=2 for RV WT measurement at Day 21. *P<0.05 compares values between Day 7 and Day 21.

At the terminal study (Table 2), body weight and heart rate of 21-PAB mice did not differ signficiantly from the control. Fulton index was increased in 21-PAB mice ($P<0.05$) indicating RV hypertrophy. The success of PAB in generating PAH is demonstrated by the dramatically elevated RV ESP ($P<0.05$). Furthermore, RV ESV and EDV increased significantly ($P<0.05$ and $P<0.01$).

CO, EF ($P<0.01$), SV ($P<0.05$), and RV chamber compliance ($P<0.01$) decreased in PAB mice compared to the control. The preload independent index for RV diastolic function τ remained unchanged. No signficant changes in load-independent measures of contractility, Ees and PRSW, were found. VVC efficiency tended to decrease but the change was not significant.

Table 2. Hemodynamic, RV function, and VVC among the study groups

DISCUSSION

This pilot study supports our hypothesis that 21 days of PAB in mice results in RV hypertrophy; while VVC efficiency tended to decrease, the change was not significant, likely due to the small sample size. This study also confirms that 21 days of PAB decreases EF and increases EDV as shown previously after 14 days [2]. The significant increase in RV EDV and decrease in SV coupled with the decrease in EF, as found in 21-PAB here, are associated with poor prognosis in human patients with PAH [7,8]. Taken together, the RV structural and functional changes suggest maladaptive RV remodeling, which will require a larger sample size to validate.

A comparison can be made with identical hemodynamic measurements obtained in a well-established model of severe PAH generated with chronic hypoxia (10% O2) and VEGF receptor inhibitor SU5416 for 28 days (28-HySu) [6]. Despite the shorter exposure time, RV ESP, ESV, and EDV are dramatically higher in 21-PAB compared to 28-HySu. Also, EF, and SV were not significantly diminished in 28-HySu, which confirm that 21-PAB more severely impairs RV structure and function compared to 28-HySu.

Future molecular assays for pathological RV hypertrophy and apoptosis markers, such as Modulatory Calcineurin Interacting Protein-1, natriuretic peptide A, phospholamban, Bax, and caspase-3, can better verify this physiological to pathological transition in mice exposed to 21-PAB [2,9,10]. Additionally, sham thoracotomy will need to be used as control.

In conclusion, this study demonstrates the feasibility of using PAB to cause maladaptive RV remodeling in mice and our ability to comprehensively quantify the changes in RV structure and function with invasive hemodynamic measurements.

ACKNOWLEDGEMENTS

INTRODUCTION

Since 1954 synthetic hydrogels have extensively been used in drug delivery, tissue engineering, separation and adsorption processes, biosensensing, biocatalysis, and bioremediation.[1] Spherical hydrogel microcapsules are particularly attractive due to their transport characteristics and surface properties.

Silica is an ideal material for the synthesis of microspherical hydrogels to encapsulate biological materials as silica gels have favorable mechanical properties, are chemically stable, biocompatible, do not swell, and resist leakage of the encapsulated cells. Silica gels can be formed by sol-gel transformation of a silicon alkoxide.[2] Furthermore, hydrolyzed alkoxide can be combined with silica nanoparticles (SNPs) to produce a silicon alkoxide cross-linked silica nanoparticle gel network with significantly higher porosity.

Hydrogel microspheres are usually produced by creating an emulsion of gel precursors in an immiscible phase and then allowing the precursors to separate out and aggregate followed by gelation. An emulsion consisting of monodisperse silica precursor microspheres can be produced using variety of techniques including turbulent drop breakup, microfluidic devices, membrane emulsification, microchannel emulsification, and extrusion.

Extrusion methods are appealing because they do not require any special microengineering techniques or tools, no large power input, often consist of parts that are cheap and commercially available, and can often be assembled quickly and easily. These systems form an emulsion by extruding microspheres of gel precursor (sol) through a needle or a nozzle into an immiscible phase. After extrusion from the needle precursor microspheres must remain separated until they are gelled to avoid coalescence. In system described here, quasi-steady state microsphere separation was achieved by extruding the microspheres into cross-flowing oil that carried the microspheres downstream maintaining their separation until they gelled.

In order for the extrusion system to produce monodisperse microspheres the flow rate of the gel precursor injected into the cross-flow stream and the flowrate of the cross-flow stream were optimized. At low capillary and Webber numbers drops detach from the needle via dripping while at high capillary and Webber numbers jetting occurs. Monodisperse microspheres are almost always produced in the dripping regime because dripping results from an absolute instability, while jet breakup is governed by a convective instability.

The extrusion system described here was designed for the production of silica gel microspheres by extruding the gel precursor (the sol) continuously from a needle into a cross-flowing stream of mineral oil. After detachment from the needle, the spherical sol travels in the oil stream, maintaining its separation from the other sol spheres until gelation is completed. The system was designed to produce silicon alkoxide cross-linked silica nanoparticle microspheres encapsulating bacteria at a throughput of 12-13 ml per hour.

METHODS

The pH of NexSil 125-40 silica nanoparticle sol was adjusted to 7 by adding 1M HCl.. *E. coli* cells were suspended in isotonic phosphate buffered saline solution (PBS) at a concentration of 1 g /ml. This suspension was then added to the pH neutralized SNP sol. In the meantime, tetraethoxysilane (TEOS) was hydrolyzed by adding 1M hydrochloric acid and water at a 1 : 5.3 : 0.0013 molar ratio of TEOS : water : HCl. At this ratio TEOS hydrolyzes rapidly and condensation reactions occur slowly. Mixing of the silicon alkoxide solution and the SNP cell mixture induced a rapid condensation reaction, which spanned the sol and transitioned it into a gel.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The silicon alkoxide solution and the SNP + cell mixture were filled into 12 ml syringes. The syringes were placed in syringe pumps connected via a Y connection. The outlet of the Y connector was joined to an 18-gauge 1.5" blunt end needle via the residence tube. The extent of polymerization that the gel precursor undergoes before it enters the oil stream can be controlled by adjusting the length of the residence tube. Sol was injected through the needle into the oil crossflow, where it assumed a spherical shape due to the hydrophobic nature of the oil, and the sol microspheres were carried in the oil stream until they gelled.

The emulsion system was tested at oil flow rates: of 10, 6.2, and 4.2 ml/min and gel flow rates of 36, 24, and 12 ml/hr. A gel formula with a 1:1 volumetric ratio of silicon alkoxide solution : SNP sol was used and no PBS or cells were added. The system was then used to encapsulate *E. coli* in a silica gel that has previously been reported to be biocompatible and mechanically strong [3-5]. *E. coli* were suspended in PBS at a concentration of 1g/ml. A 1:7:1 ratio of silicon alkoxide solution : SNPs : cells in PBS was used.

RESULTS

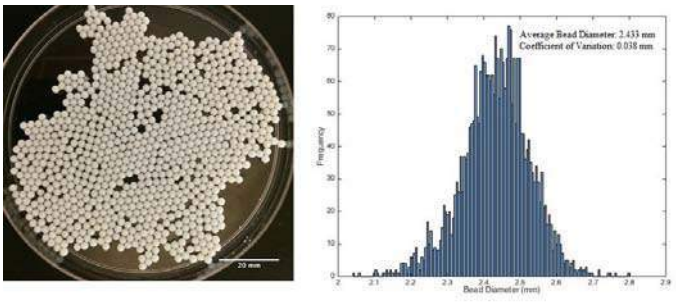

Figure 1: *E. coli* containing microsphere size distribution

Table 1: Silica microsphere sizes produced at three different oil flowrates and three different precursor flowrates

Gel Precursor Flowrate (ml/hr)	Average Microsphere Diameter (mm)	Coefficient of Variation
Slow oil flowrate (4.2 ml/min)		
12	2.50	0.024
24	2.71	0.027
36	2.86	0.048
Medium oil flowrate (6.2 ml/min)		
12	1.89	0.036
24	2.07	0.030
36	2.155	0.029
Fast oil flowrate (10 ml/min)		
12	1.256	0.059
24	1.403	0.064

Microsphere sizes produced using three different oil flowrates and three different precursor flowrates are given in ***Table 1***. Increasing the oil flowrate caused the microsphere diameter to decrease while increasing the coefficient of variation. Increasing the precursor flow rate also increases the microsphere diameter, but not as strongly as the oil flowrate.

The emulsion system was also used to produce silica microspheres that contained encapsulated *E. coli*. The medium oil and medium gel precursor flowrate combination was used and the microspheres are shown in ***Figure 1***. The emulsion system was continuously operated for 100 minutes and produced approximately 65 ml of microspheres.

DISCUSSION

An emulsion system was designed and manufactured to produce silica gel microspheres that contain encapsulated biocatalysts in a diameter range from approximately 1.3 to 2.9 mm. Microsphere size was mainly controlled by the oil flowrate, and the microsphere throughput was determined by the gel precursor flowrate. The emulsion system produced monodisperse microspheres with a coefficient of variation of less than 3% when operated at the optimum oil and precursor flowrate values. This is on par with the coefficient of variation values achieved using microfluidic devices, but much higher in terms of yield. Under all other conditions, the microspheres had a coefficient of variation less than 6.5%, which is a much more narrow size distribution than the microspheres produced using microchannel arrays (considering microspheres in a similar size range), turbulent microsphere breakup, or membrane emulsification.

The throughput of the extrusion system ranges from 12-36 gel ml/hour, which translates to 20-60 ml of microspheres per hour assuming a 60% microsphere packing density. This throughput is much greater than that achieved using single junction microfluidic devices, it is similar to that achieved in typical microchannel devices, and it is much less than that achieved using turbulent microsphere breakup and membrane emulsification.

Microspheres produced containing encapsulated *E. coli* were larger and had a greater CV than microspheres produced with similar flowrates during characterization. The microsphere size and size distribution changed when cells were added because adding cells to the gel precursor changes the formation of the gel network, the precursor density, and the precursor viscosity. Each of these factors affects the microsphere detachment process and the microsphere size.

ACKNOWLEDGEMENTS

A POPULATION DERIVED MECHANOSTATISTICAL MODEL OF THE HUMAN AND SHEEP SPINE TO EVALUATE SPINAL FUSION IMPLANTS

INTRODUCTION

Computational models provide *in silico* solutions to orthopaedic device testing without ethical concerns to inform clinical decisions. The lumbar spine is a complex multi-facet joint, bears most of the body weight, and exhibits numerous degenerative bone and disc problems that are highly suited to computational testing. One solution to degenerative spine complications is a spinal fusion implant that reduces pain by minimising motion between two intervertebrae [1]. Spinal surgeons orient spinal fusion device location and wedge angle in order to minimise bone stress shielding (which leads to bone resorption) and maximise osseointegration of bone into the porous trabecular metal structure of the spinal fusion implant.

In addition to computational models of the human spine, animal models (especially sheep) are often used to evaluate implant devices [2]. Sheep models are popular test subjects as they have similar anatomical characteristics to human spines and hence studies often assume you may translate findings directly to the human condition. However, the loading pattern is often substantially different and performance of implant devices in sheep models may not reflect performance in the implanted human.

The objective of this study is to present a population based mechanostatistical model of the spine in order to evaluate spinal fusion devices on bone remodelling and osseointegration outcomes. The model evaluates disc stress and bone stress shielding for standard spinal fusion devices in both the human and sheep. Bone osseointegration in the spinal fusion device is also predicted using bone diffusion analysis and knowledge of implant stress and strain. Using an optimisation tool the most ideal human spine posture is identified that produces the closest stress and loading conditions to that observed in the implanted sheep. This allows implant outcomes predicted in the sheep to be translated to the human.

METHODS

Figure 1 shows the complete workflow diagram for this study. Three-dimensional finite element (FE) models of the human lumbar spine (L3-L5) were developed using 40 patient CT data sets. The proximal femoral head, sacrum, coccyx and pelvis were included in the simulation, with axial ground reaction loads applied to the distal femur ends to provide physiologically realistic boundary conditions. The Von Mises stresses were then predicted using commercial FE software (Abaqus CAE). The spine model setup was evaluated by predicting and comparing surface bone strains against a cadaver sheep that was strain gauged.

The original lumbar spines were only available in a neutral posture so a range of synthetic postures was generated using an automated procedure. A spine-specific joint coordinate system (JCS) was first computed based on detected geometric features and used for bone transformation. The intervertebral disc was modelled using a Cartesian stiffness matrix to allow for coupled motion. Using a Gilbert-Johnson-Keerthi distance algorithm [3], each vertebrae was then moved to its maximum possible position (e.g. maximum flexion when placing the spine under flexion) until collision was detected in the bone facets. The spine was placed in maximum flexion, extension, medial and lateral tilt.

A Partial Least Squares Regression (PLSR) statistical model was then trained to relate spinal position with computed Von Mises stress in the human. Optimisation was used to iterate through multiple spinal positions to find the best match in Von Mises stress to a sheep lumbar spine model that represents typical experimental conditions.

The optimal human FE model was then modified by inserting a titanium Anterior Lumbar Interbody Fusion (ALIF) device between the L3 and L4 intervertebral disc space. Isotropic elastic formulation was used to simulate the material properties of titanium (Young's

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

modulus: 115 GPa, Poisson's ratio: 0.3). Tissue stress along with potential bone remodelling around the implant was predicted using pressure stress induced mesenchymal cell migration into the implant. The same implant design was integrated into the sheep model for bone stress evaluation. The sheep and human implant models are evaluated to predict implant outcome differences that may be expected when translating the sheep spine to the human condition.

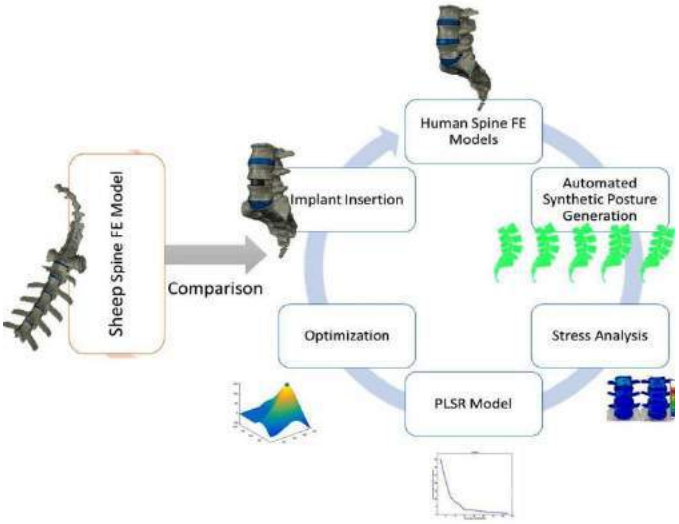

Figure 1: Modelling framework

RESULTS

The automated JCS and posture placement of the spine for each lumbar vertebrae was consistent and robust. Our method conforms to the ISB standard of determining JCS for the lumbar vertebrae [4] An example of the automatically detected JCS of L4 of a random human subject can be seen in Figure 2.

The PLSR model predicted human spinal tissue stress with an average accuracy of 70% after training on the population data set. The spatial pattern of stress was a good match but errors were observed primarily in the peak magnitude values.

All human FE spine models predicted stress levels within the range of those found in literature [5, 6]. Bone remodelling predictions of tissue differentiation and migration levels in the ALIF implant (Figure 3) were consistent with what was observed in clinical studies [7].

Comparing normal stress distributions in the average human and sheep spines, it is evident that the overall Von Mises stress values are higher for sheep. The primary difference observed between the patterns of stress in both models is that the stress distributions are primarily towards the medial vertebrae with higher stress at the vertebral foramen for the human spine. In contrast, stress distributions in the sheep spine were exhibited primarily in the anterior region of the vertebrae.

DISCUSSION

The current study examines the translational relationship of human and sheep spine orthopaedic outcomes and provides a clinically relevant framework for spinal fusion device evaluation. Critical parameters to consider when translating findings between sheep and human models include the size of the vertebrae and the thickness of the intervertebral disc.

The main assumption in this study is the generation of synthetic poses from a population of neutral spine positions. This is due to difficulty in obtaining actual MRI of a population of spinal postures. However, we assume that the spinal postures generated are realistic based on the limited range of motion of the human spine from the literature and the use of the ISB standard JCS. Although spinal discs and vertebrae ligaments were included in the model there were no muscles. Inclusion of muscles may alter the stress pattern and influence bone remodelling prediction.

This study also demonstrates a novel, yet accurate method in automated detection of the JCS for lumbar vertebrae. With the methods presented in this study, clinical evaluations of orthopedic implants can be performed with greater speed and compared with a population of spines.

REPRODUCIBILITY OF MOUSE TRABECULAR BONE MICROSTRUCTURE AT MULTIPLE SKELETAL SITES BY IN VIVO MICRO COMPUTED TOMOGRAPHY IMAGING

Chih-Chiang Chang, Hongbo Zhao, Youwen Yang, Chantal M. de Bakker, Wei-Ju Tseng, X. Sherry Liu

McKay Orthopaedic Research Laboratory
University of Pennsylvania
Philadelphia, PA, USA

INTRODUCTION

Micro computed tomography (μCT) has been widely used to study 3-dimensional (3D) microstructure of bone specimens. In the recent decade, *in vivo* μCT scanners have also become available to monitor longitudinal bone changes in different rodent species [1]. The current *in vivo* μCT scan can obtain images with an isotropic voxel size up to 10.5 μm, which is high enough for direct 3D bone microstructural analyses. For accurate detections of bone microstructure over time, it is critical to understand the reproducibility of these measurements in different scan protocols. Although the reproducibility of the *in vivo* μCT measurements have been reported in rats and mice, the scanning site of these *in vivo* studies have been limited to the proximal tibia [2,3]. The influence of animal reposition and motion artifact associated with *in vivo* scans at other important skeletal sites, such as the lumbar vertebrae and femur, have not been studied. Thus, the goal of this study is to establish a feasible μCT scanning protocol and measurement regime that yield the highest precision in monitoring mouse femoral and vertebral bone in response to diseases and treatments. The first objective of the current study was to investigate the short-term reproducibility of trabecular bone microstructure measurements by utilizing customized scan holders. The second objective was to test whether a 3D image registration can reduce the precision error caused by animal repositioning.

METHODS

Animals: Eight thirteen-week-old female C57BL/6J mice were used in this study. All mice were scanned 4 times at both the 4th lumbar vertebra (L4) and right distal femur within 12 hours (for a total of 32 scans for each site). Each mouse was removed from the holder and allowed to recover from anesthesia between scans. All experiments were approved by IACUC of University of Pennsylvania.

μCT scans: All mice were anesthetized (4.0/2.25% isoflurane) and scanned at the L4 and right femur by an *in vivo* μCT system (vivaCT 40, Scanco Medical AG, Switzerland). An animal fixture was custom-designed by SolidWorks software and manufactured by a 3D printer to minimize motion artifact and ensure that scan sites were positioned in a similar 3D orientation between scans (Fig.1). Before each scan, a 2D scout view was employed to determine the region of interest. For the distal femur, 212 slices below growth plate were scanned at 10.5 μm voxel size. For the L4, 212 slices at the center of L4 were scanned at 15μm resolution. The scanner was operated at 55 kVp energy, 145 μA intensity, and 200 ms integration time and the average time for each scan was about 10 minutes.

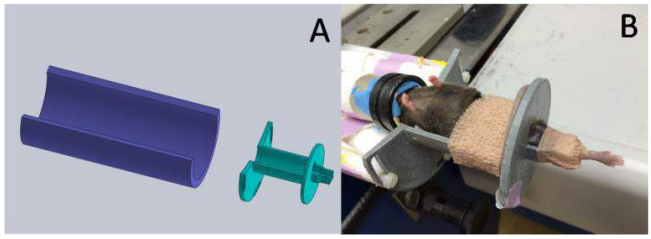

Figure 1: (A) The custom-designed holder for stabilizing the mouse to ensure minimal motion artifacts. (B) Positioning of a mouse for *in vivo* μCT scanning.

Image registration: A two-step image registration method was employed using a landmark-initialized, mutual information based registration kit (National Library of Medicine Insight Segmentation and Registration Toolkit, USA). Based on grayscale images of the baseline and follow-up scans, this registration scheme minimizes the joint entropy and marginal probabilities of the fixed and moving images to derive a transformation matrix **T,** which represents the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

rigid-body transformation, including a 3D rotation and translation, between image coordinates of the baseline and follow-up scans (Fig. 2A). To evaluate the trabecular bone microstructure of the registered baseline and follow-up scans, the trabecular bone compartment of each follow-up scan was semi-automatically contoured and saved as a volume of interest (VOI) mask. Then, the transformation matrix **T** was applied to rotate and translate the VOI mask of the follow-up scan (Fig. 2C). The transformed VOI mask from the follow-up scan corresponded to the same VOI of the baseline scan (Fig. 2D).

Microstructure Analysis: A total of 60 slices of the reconstructed images, corresponding to a 0.63 mm region at the metaphysis region of the distal femur and 60 slices (0.9 mm) of the center of L4 were identified as the VOI at the baseline scan. The corresponding VOI of follow-up scans were identified through image registrations (Fig. 2D). These VOIs were smoothed by a Gaussian filter (sigma=0.6, support=1) and then thresholded with a segmentation threshold corresponding to 387 mgHA/cm^3. Bone volume fraction (BV/TV), trabecular thickness (Tb.Th), trabecular spacing (Tb.Sp), trabecular number (Tb.N), structure model index (SMI), connectivity density (Conn.D), and trabecular volumetric bone mineral density (Tb.vBMD) were evaluated by manufacturer-provided software (Scanco Medical AG, Switzerland).

Statistics: Reproducibility of each measure was evaluated by the root mean square average of the percent of coefficient of variance (RMSCV), and intra-class correlation coefficients (ICC). Paired Student's t-tests were performed to compare the CV of repeat scans before and after image registration.

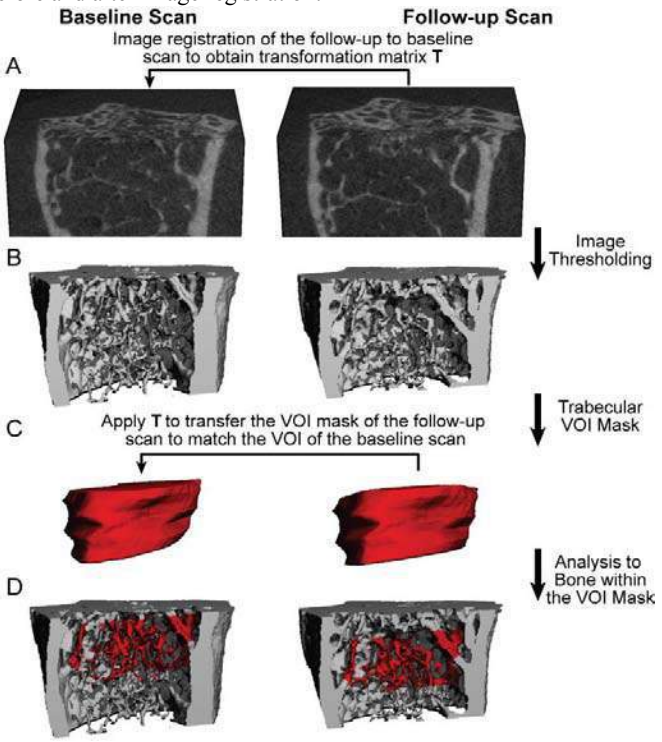

Figure 2: Schematics of the image registration and microstructural analysis of trabecular bone.

RESULTS

Prior to image registration, reasonable reproducibility was found for most parameters. For the femur, the precision errors associated with BV/TV, Tb.N, Tb.Th, Tb.Sp, SMI, and Tb.BMD ranged between 4.0% and 12.4% with an exception for Conn.D (33.5%). Similar results were found for the L4. Moderate to good reproducibility were found for most parameters prior to registration (precision error 6.5-17.6%) with an exception for Conn.D (30.7%).

After image registration, precision errors of most of the measurements for the femur went down (Table 1). Particularly, improvement in precisions of BV/TV, Tb.Th, Tb.BMD for the femur reached statistical significance. There were pronounced improvements in measurement precisions by image registration at the L4. All precision errors except for SMI ($p=0.1$) were significantly reduced after image registration ($p<0.05$). Moreover, ICC for femur represented excellent reliability for most of the parameters, with exceptions for SMI and Conn.D, which were in good to excellent range (0.587-0.958). Similarly, ICCs of all parameters indicated excellent reliability (0.838-0.973) for the L4.

Table 1: Reproducibility for morphological parameters after registration was demonstrated as precision error and ICC.

DISCUSSION

In this study, we developed an *in vivo* μCT scan protocol which can be applied to scan multiple skeletal sites (Femur, Tibia, Vertebrae) for mice and offers an excellent reproducibility by utilizing custom-designed holder and image registration techniques. Previous studies have demonstrated reproducibility for mouse limb and spine *ex vivo* [5]. Reproducibility of *in vivo* μCT measurements has only been evaluated for the mouse tibia [3]. The current protocol overcomes this limitation and provides capability for scanning multiple skeletal sites for mice. According to our results, reasonable precision can be achieved by the standard scan and analysis procedure for most microstructure and density measurements. In addition, 3D image registration helped to reduce precision errors in BV/TV, Tb.Th, and Tb.BMD for the femur and in almost all parameters for the L4. However, reproducibility of Conn.D measurements was moderate for both the femur and vertebra, even after image registration. The elevated precision error in Conn.D has also been reported in previous studies of rat and mouse tibia [2, 3]. This might be because Conn.D measurements are more sensitive to image quality and motion artifacts than other microstructure measurements [5]. Furthermore, the mouse strain used in the current study has a particularly low Conn.D, which also contributed to higher variance in its measurement.

In conclusion, we established an *in vivo* μCT scan and analysis protocol for assessment of longitudinal bone changes at multiple skeletal sites for mice with excellent reproducibility. The current study utilized a mouse strain of low bone mass. We expect to achieve similar or better reproducibility for other mouse strains with similar or higher bone mass.

INTRODUCTION

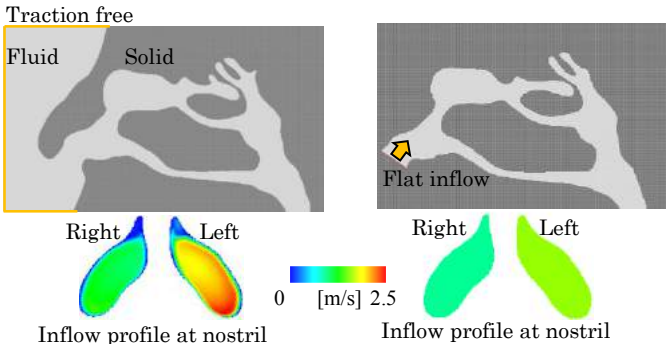
The nose plays an important role by filtering, warming, and humidifying inspired air. Thus, modeling of airflow in the nasal cavities is important for evaluating nasal functions. Recently, experimental studies showed that airflow in nasal cavity has unsteadiness such as laminar to turbulent transitional flow[1, 2]. Computational fluid dynamics (CFD) has enabled detailed simulation of airflow throughout the nasal cavity based on CT scans of individual subjects. Laminar or steady Reynolds-Averaged Navier-Stokes (RANS) models, large eddy simulation (LES) were conducted in most of previous studies[3]. Because of advances in computing performance, direct numerical simulation (DNS) was performed to predict transitional airflow in the nasal cavity without turbulence models[4, 5]. Several studies prescribed simplified flat inflow profile, whereas Taylor et al.[6] showed that the use of truncated inflow in models of nasal inspiration affects the flow within the nasal cavity.

The present study investigates the effect of inflow velocity profile on transitional flow during steady nasal inspiration.

METHODS

The nasal cavities of a healthy male aged 51 years were reconstructed using CT slices. Firstly, virtual boundaries definitions of the nasal airway and external face boundaries were generated applied to the CT image datasets. Then, these segmented images were placed into a 3D polygon model. Finally, a uniform cartesian grids were obtained from the 3D polygon model. The mesh size was defined to 0.05 mm (approx. 4 billion grids) according to Kolmogorov microscale. Non-dimensional wall distance y+-value is estimated at 0.21 in the nasal valve, using the Blasius' correlation instead of wall shear stress to calculate a friction velocity.

The governing equations for the conservation of mass, momentum for the 3D incompressible unsteady flow were solved using FFV-C ver. 2.1.5 (RIKEN), performed on K computer. The third-order MUSCL method was selected for the spatial discretization of the advection term and the first-order forward Euler method was used for the time integration. Figure 1 shows boundary condition. In this study, two patterns boundary conditions were given. (i) A traction-free condition was applied at the entrance to the bounding box upstream of the model, and constant inspiratory flow rate of 230 ml/s was applied at the throat. (ii) A flat velocity profile was applied at nostril, and pressure gradient of zero was applied at throat. The direction of the flat velocity profile and velocity magnitude were defined according to the result of natural velocity profile.



(i) Natural velocity profile **(ii) Flat velocity profile**

RESULTS

Figure 2 shows the contours of instant vorticity magnitude on sagittal plane in the left nasal cavity. The vorticity magnitude distribution of the natural developed velocity profile indicates the structure of flow converging through the nasal vestibule, which forms a high-speed jet at nasal valve and a recirculation region at the top front of nasal cavity. These flow features is confirmed in the case of simplified flat velocity profile. A breakdown of free shear layer between the jet and the recirculation region is confirmed in the natural velocity profile, whereas, in the flat velocity profile, that is not confirmed. The fluctuation of vorticity at the rear of middle nasal meatus (dotted round, figure 2) is confirmed in the both cases. Figure 3 shows contours of turbulence kinematic energy (TKE) on sagittal plane in the left nasal cavity. The high level TKE is confirmed in front of nasal cavity and middle nasal meatus in the natural velocity profile. The maximum value of TKE in front of nasal cavity is 58.4×10^{-3} m^2/s^2 (natural), 2.11×10^{-3} m^2/s^2 (flat).

DISCUSSION

The difference of flow patterns is confirmed to compare the natural developed velocity profile with the simplified flat velocity profile. The remarkable difference is shear layer between the jet and the recirculation region. Though the magnitude of velocity gradient is same degree, the thickness of free shear layer in the natural velocity profile is thinner than that in the flat velocity profile. TKE on the shear layer in the natural velocity profile is one order bigger than that in the flat velocity profile.

The inflow boundary profile is found to affect the stability of a free shear layer behind the nasal valve. Therefore it is important to consider actual inflow velocity profile surrounding the external face to predict transitional flow in the nasal cavity.

INFLUENCE OF PLAQUE STIFFFNESS ON DEFORMATION AND FLOW OF ARTERIAL STENOSIS MODEL FOR PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY

INTRODUCTION

Percutaneous Transluminal Coronary Angioplasty (PTCA) is one of the minimally-invasive procedure for coronary disease. Detailed assessment of the deformation of plaque in a coronary disease during the dilation by PTCA balloon catheter, and recovery of blood flow is important for the development of the balloon catheter and improvement of the procedure. Firstly, we developed the arterial stenosis model as a diseased blood vessel model made of polyvinyl alcohol (PVA) hydrogel (tube portion) and vinyl acetate (plaque portion) [1]. The sticky vinyl acetate was coated by thin PVA layer to avoid adhesion of balloon catheter, but the coating was insufficient. In this study, we changed the material of plaque portion to the oil-based cray, and discussed the influence of plaque stiffness on deformation and flow of the arterial stenosis model.

METHODS

Figure 1 shows the stenosis model. The inner diameter D and the thickness h of straight tube, and the length of stenosis Ls are, 3.5 mm, 1 mm, and 8 mm, respectively. Nominal stenosis severity St and eccentricity Ec is at zero luminal pressure are

$$St_{nominal} = (1 - Ds/D) \times 100 \ [\%], \quad Ec = e/((D - Ds)/2) \times 100 \ [\%]. \quad (1)$$

We used the stenosis models of $St_{nominal}$ = 60 - 80%, and Ec = 100%. Polyvinyl alcohol (PVA) hydrogel was used for healthy straight sections (tube portion). Dimethyl sulfoxide was added to PVA solution before the gelation. The mechanical property of this PVA hydrogel was closer to that of coronary artery [1]. Oil-based cray (Leon cray) was used for the plaque portion to represent the plastic deformation during the dilation by the balloon catheter. There different stiffness of crays were prepared for the plaque portion. Young's modulus E (the average value when 0 to 0.4 of strain) of the crays are 0.3, 0.6, and 1.2 MPa for soft, normal, and hard plaque, respectively. These values are the almost same to that of stenosis model used for stent placement [2]. Figure 2 (A) shows the experimental setup. The working fluid used was water at 24 ˚C. The computer-controlled gear pump was used for the pulsatile flow. The average upstream and downstream pressures were set at 90 mmHg and 70mmHg, respectively. Flow rates and pressures upstream and downstream of the stenosis model were measured. The stenosis model was attached on the sliding surface of rotating eccentric cam to change the curvature of stenosis model (Figure 2 (B)). The rotation of the eccentric cam is in synchronization with pulsatile flow. Luminal area / average curvature, change of curvature radius of the stenosis model were set at 0.08, 10mm, respectively [3]. Firstly, a guide wire was inserted into the stenosis model. Then, the balloon catheter was inserted

Figure 2: Experimental setup.

along the guide wire and pressurized and expanded by the indeflator. Tomographic images of the stenosis model were taken by micro CT before and after the flow experiment.

RESULTS AND DISCUSSION

Figure 3 shows the micro CT images of the stenosis. Plaque part was deformed concavely. We measured luminal area from the images and evaluated true stenosis severity St_{true} :

$$St_{true} = (A_S / A) \times 100\ [\%], \qquad (2)$$

where $A(= \pi D^2/4)$ and A_S are luminal areas of straight portion and apex of stenosis, respectively. Figure 4 shows the reduction of true stenosis severity (St_{true_bi} - St_{true_ad}) after the dilation by the balloon catheter. The reduction was decreased when the true stenosis severity before dilation St_{true_bi} was increased. This is caused that the greater volume of plaque portion becomes difficult to deform to increase the minimum area of stenosis. The reduction for soft plaque is greater than that for normal plaque, because softer cray deforms greater to reduce the stenosis severity. For the measured flow rates, we evaluated the ratios of increase and recovery of flow by dilation of stenosis:

$$R_{QI} = Q_{ave_ad} / Q_{ave_bi}, \quad R_{QR} = Q_{ave_ad} / Q_{ave_st0}, \qquad (3)$$

where Q_{ave_ad} is the average flow rate after the dilation and removal of the catheter, Q_{ave_bi} is average flow rate before the catheter intersection, Q_{ave_st0} is average flow rate when $St_{true} = 0$ % as the no stenosis healthy arterial model. R_{QI} represents the ratio of increase of flow, and R_{QR} represents the ratio of recovery of flow to the healthy condition, by the dilation of plaque in the stenosis model. Figure 5 shows the relationship between stenosis severity St_{true_bi} and the ratios of increase and recovery of flow. R_{QI} increased with an increase in St_{true_bi}. This is explained that the initial flow rate (before insertion and pressurization of balloon) becomes smaller as greater stenosis severity, not influenced by the greater reduction of stenosis severity. There was no greater difference of R_{QI} by changing stiffness of plaque. For the normal and soft plaque, R_{QR} was almost constant and there was no greater difference between two plaques. But R_{QR} was decreased with an increase in $St_{true\ bi}$ of hard plaque. This is considered that the initial flow rate and the reduction of

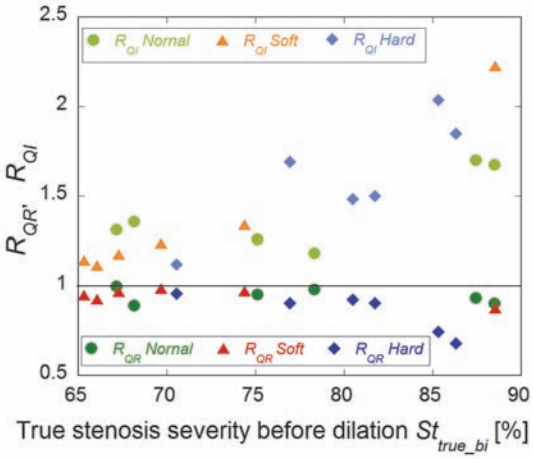

Figure 5: Relationship between true stenosis severity St_{true_bi} and ratios of increase and recovery of flow R_{QI}, R_{QR}.

stenosis severity by the dilation were smaller for greater St_{true_bi} of hard plaque.

INTRODUCTION

The left atrium (LA) is one of the upper chambers of the heart and transports the oxygenated blood from the pulmonary veins (PVs) to the left ventricle (LV) through the mitral valve (MV). Atrial fibrillation is the most common arrhythmia in human beings, which is associated with an increased risk of embolic stroke [1]. However, recent epidemiologic studies suggest that AF may not be responsible for the thromboembolic events [2], but pathologic alterations in the LA structure and function may be causally related to thromboembolism. In fact, many indices of LA structural remodeling are associated with stroke, such as larger LA size [3], larger extent of LA fibrosis [4], lower LA function [5] and lower LA appendage (LAA) function [6] in sinus rhythm. These findings suggest that LA structural remodeling may promote blood flow stasis which leads to thrombus formation embolic stroke. Thus, detailed understanding of the effects of the LA structural remodeling on the blood flow characteristics within the LA is potentially useful for predicting the stroke risk in individual patients.

Computational fluid dynamics (CFD) is a powerful tool to analyze the blood flow characteristics in the heart. However, it is challenging to solve complex fluid-structure interactions using CFD in the LA due to the lack of knowledge of the material and mechanical properties of the LA wall. To overcome this issue, we propose an alternative approach to perform personalized blood flow analysis in the human LA by providing the 3-D LA endocardial surface motion derived from patient-specific cardiac CT images [7]. This approach allows personalized LA blood flow analysis which incorporates important patient-specific indices of LA structural remodeling that are associated with stroke. In this contribution, we applied this approach to patients with and without a prior history of stroke to evaluate the blood flow characteristics within the LA.

METHODS

The overall methodology of blood flow analysis in the human LA is described elsewhere [7]. Cardiac CT images of the 18 AF patients (Case=10, Control=8) were acquired during normal sinus rhythm using a 64-slice multi-detector CT scanner (Aquilion 64, Toshiba America Medical Systems, Inc. Tustin, CA) for a total of 20 phases during a cardiac cycle (0%RR, 5%RR, ..., 95%RR). The reconstructed image size was 512×512 with a pixel size of 0.5×0.5 mm^2. Slice number of images were 351 ± 55 (Case) and 320 ± 45 (Control) with the slice thickness of 0.5-1.0 mm. LA was segmented in the CT images at all the 20 phases using the cardiovascular segmentation tool of Mimics Medical 18.0 (Materialise, Inc. Plymouth, MI). Using the segmented CT images, LA endocardial surface mesh reconstruction and LV inner volume measurements were performed at all the phases. Representative geometry of LA in a patient with a prior history of stroke is shown in Fig. 1(a). The cycle length of the cardiac cycle was 0.80 ± 0.24 sec (Case) and 0.81 ± 0.15 sec (Control).

The patient-specific LA motion was obtained by using a non-rigid registration technique. The template surface mesh was constructed from the LA surface geometry at electrocardiographic ventricular end diastole using Pointwise V17.3R1 (Pointwise, Inc. Fort Worth, TX) and the motion estimation of the LA endocardial surface was performed in each phase. From the matched surface meshes in all phases, three-dimensional displacement vectors of all nodes constituting the LA endocardial surface mesh were calculated. These discrete displacement vectors given in 20 phases were interpolated to the trigonometric function given in arbitrary time t with using the discrete Fourier transform.

Tetrahedral meshes were constructed in the LA including the PVs using Pointwise for the blood flow analysis. Blood flow analysis in the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

LA was implemented in OpenFOAM 2.3.1. We assumed the blood as an incompressible fluid with density ρ of 1.05×10^3 kg/m^3 and the blood viscosity μ was assumed to be non-Newtonian fluid obeying the Carreau-Yasuda model with the same parameters of [8]. The flow in the LA was modelled with the incompressible Navier-Stokes equation and the equation of continuity given by

$$\rho\left(\frac{\partial \mathbf{v}}{\partial t}+\mathbf{v}\cdot\nabla\mathbf{v}\right)=-\nabla p+\mu\nabla^2\mathbf{v}\,, \quad (1)$$

$$\nabla\cdot\mathbf{v}=0\,, \quad (2)$$

where the **v** is the velocity vector and p is the pressure. These equations were solved with coupling using the Pressure Implicit with Splitting of Operations (PISO) algorism. The blood flow analysis in each case was performed with the time increment of 1×10^{-4} sec.

The boundary conditions of the CFD studies were as follows. The velocity vector at the wall boundary was determined by the wall motion in each time step and the zero gradient pressure was adopted. At the distal end of each PV, the velocity boundary condition was chosen to permit both inflow and outflow in the PVs that are observed during the cardiac cycle in human heart [9] and total pressure was constantly set to be zero. The boundary condition of the MV annulus during ventricular systole was treated as a wall boundary. During the ventricular diastole, patient-specific volume of blood ejected through the MV from LA to LV were assigned, in which the time cause of the blood volume was measured from the LV volume changes obtained by the CT images. The MV was considered to be closed during ventricular systole and open during ventricular diastole, and the time required for MV opening and closure was considered to be negligible. Ventricular systole and diastole were defined by the time course of LV volume.

For the evaluation of the flow characteristics in LA, a change of the shear flow field was investigated by introducing the shear rate defined by the $2\sqrt{II_{\mathbf{D}}}$, where $II_{\mathbf{D}}$ is the second invariant of the shear strain tensor **D** [8].

RESULTS

Figure 1(b)-(f) show representative snapshots of the iso-surface of the shear rate (=15 s^{-1}) during a cardiac cycle in patients with a prior history of stroke, whose LA had larger size and lower function. The shear rate was consistently low in LAA during a cardiac cycle. The shear rate was lower than 15 s^{-1} in LAA and some regions of LA during the ventricular systole (Fig. 1(b) and (c)). The regions with low shear rate (<15 s^{-1}) in the LA and LAA became smaller at the end of ventricular systole (Fig. 1(d)) and disappeared in LA during the ventricular diastole, whereas those in LAA persisted throughout the cardiac cycle (Fig. 1(e) and (f)). This pattern of time course of the shear flow was observed in all patients and spatiotemporal averaged shear rate in LAA was almost same in both case and control patients (30 s^{-1}). However, several case patients, whose LA had larger size or lower functions, had consistently low spatiotemporal averaged shear rate and larger volume of low shear rate (15 s^{-1}) in the LAA.

DISCUSSION

We find that the shear rate was consistently low (<15 s^{-1}) in LAA in patients with a prior history of stroke and LA structural remodeling. This finding is consistent with the fact that thrombus formation in the LAA is one of the main culprits of embolic stroke [10], and that the thrombus tends to form in the region with shear rate lower than 15 s^{-1} [11]. Our CFD results account for the hemodynamic effects of abnormal structural remodeling within LA associated with embolic stroke. Furthermore, our results also highlight the strength of our approach to understanding the risk of intracardiac thrombogenesis and embolic stroke.

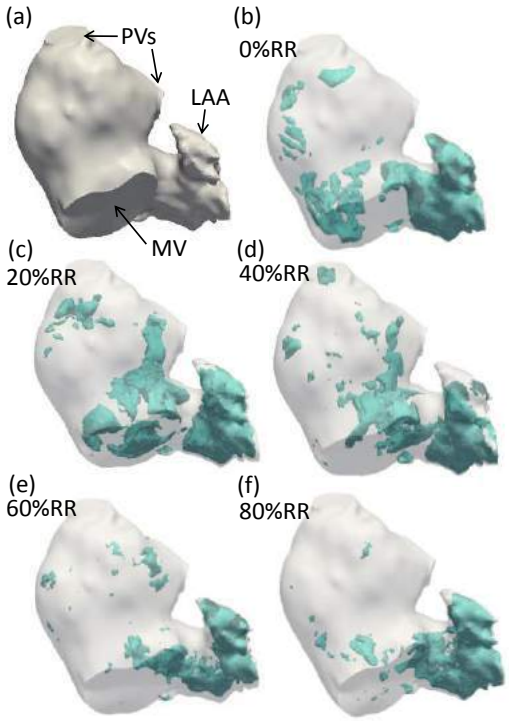

Figure 1: Representative LA geometry with prior history of stroke (a) and snapshots of the iso-surface of shear rate (=15 s^{-1}) during a representative cardiac cycle (b)-(f). RR indicates the interval between two consecutive electrocardiographic R waves and 0%RR indicates ventricular endo-diastole.

INTRODUCTION

Intracellular delivery of genes and macromolecules is an essential technique in biological research and clinical applications. Several methods including electroporation, sonoporation, microinjection, lipofection, and transfection mediated by a viral vector have been used to deliver impermeable molecules into cells. However, achieving high delivery efficiency and cell viability is difficult.

Under these circumstances, a unique method of intracellular delivery using the rapid squeezing of cells has been recently established [1][2]. Here, a cell suspension with delivery materials is passed into a narrow microchannel. Fluid shear stress and rapid compressive deformation of the cell membrane temporarily increases the permeability of the membrane and makes it possible to introduce various macromolecules into the cells. This method has the advantage of a high throughput and applicability to various cell types, while realizing both high delivery efficiency and viability. However, the mechanism behind membrane perforation is not well elucidated because the previous device was unsuitable for the observation of membrane deformation and repair process.

Therefore, this study aimed to reveal the contribution of compressive deformation to the intracellular delivery of macromolecules and the repair process of the cell membrane. We developed a new perfusion chamber system for microscopic observations of cells under compressive deformation. The kinetics of intracellular delivery and membrane repair were examined by circulating medium with four macromolecules at different time points after the application of compressive deformation.

METHODS

The setup of the perfusion chamber system is described in Fig. 1. The chamber was constructed between two glass plates, the top of which was connected to syringe pumps and a drain for perfusion and the bottom of which was placed on a clamp plate. A 5-μm thick double-coated adhesive film with a cutout measuring 40 mm long and 4 mm wide was sandwiched between the glass plates, thus producing a chamber.

Human prostate cancer cell line PC-3 was used for experiments. The cells were suspended at a density of 10^6 cells/ml in phenol-red free α-minimum essential medium (α-MEM) containing 20 mM HEPES. After dropping 0.76 μl of the cell suspension on the chamber, the upper slide glass and clamp plate were covered and screwed in firmly, causing the cells to be subjected to compressive deformation.

Immediately after the application of compressive deformation, phenol-red free α-MEM containing 20 mM HEPES was supplied from syringe pump 2 at a flow rate of 200 μl/min. By aspirating the medium using syringe pumps 3 and 4 at flow rates of 188 and 12 μl/min, respectively, the medium ran in the perfusion chamber at a flow rate of 12 μl/min. Syringe pump 1 was filled with the medium and delivery macromolecules: 2 mg/ml propidium iodide (PI, molecular weight (MW): 668), 1.25 mg/ml Cascade Blue dextran (MW: 3,000), Texas Red dextran (MW: 40,000), or FITC dextran (MW: 70,000). By

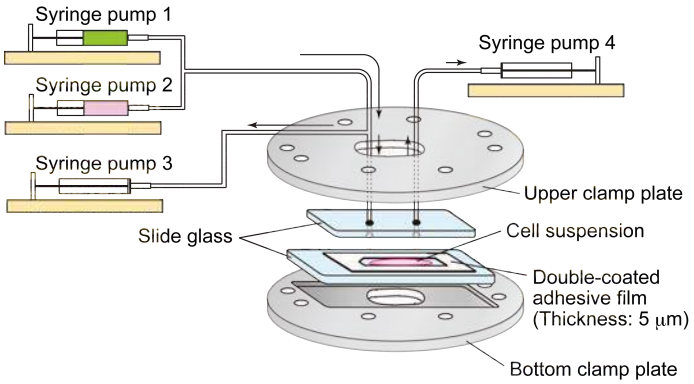

Figure 1: Schematic showing the structure of the perfusion chamber mounted on a microscope stage.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

switching the operation of syringe pump 2 to syringe pump 1, the medium with macromolecules was supplied to the perfusion chamber for only 1 min at 0.5, 5, 10, 12, 15, or 20 min after the application of compressive deformation.

Following the 1-min perfusion of macromolecules, the plain medium was supplied again until the medium with macromolecules was completely washed out from the chamber. Then, phase-contrast and fluorescent images observed using a fluorescent microscope (Eclipse E600FN, Nikon, Tokyo, Japan) with a 20× objective were captured using a digital microscope (VHX-1000, Keyence, Osaka, Japan).

RESULTS

Prior to the perfusion experiments, the diameters of PC-3 cells were microscopically measured before and after the application of compressive deformation. The average diameter of the cell contour in the top view increased from 18.4 ± 1.7 μm (mean ± standard deviation) to 22.7 ± 3.1 μm.

Figure 2 shows an example of phase-contrast and fluorescent images of cells exposed to the medium with PI at 0.5 and 15 min after the application of compressive deformation. At 0.5 min, most of the cells were stained by PI, emitting red fluorescence. The outlines of these cells were ruffled in the phase-contrast images. At 15 min, the cells almost completely excluded the intracellular delivery of PI. The ruffled outlines of the cells were recovered as sharp boundaries.

Figure 3 shows the percentage of dye-permeable cells as a function of the time spent under compression. The smallest molecular size PI permeated through the cell membrane for 10 min after the application of compressive deformation. The delivery efficiency reached 60%–80%. It suddenly decreased 12.5 min after compression, and dropped to approximately 10% at 15 min. Dextran with molecular weights of 3,000 and 40,000 were also diffused into cytoplasm for 10 min after the application of compressive deformation. The delivery efficiency decreased depending on the increased molecular weight. At 15 min after the application of compressive deformation, the delivery efficiency decreased below 10%. However, almost no cells received dextran with molecular weights of 70,000, which is comparable with the control without the application of compressive deformation.

DISCUSSION

In this study, the effects of the compressive deformation of the cell membrane on the intracellular delivery of macromolecules and repair process were examined using a perfusion chamber system. The exogenous macromolecules were introduced into the cells via the deformed cell membranes in a molecular weight-dependent manner. The state of high permeability of the cell membranes was maintained for 10 min after the application of compressive deformation. The damaged membranes were gradually repaired and finally recovered their integrity 15 min after compression. This finding shows that a resting period of at least 15 min after the application of compressive deformation is required for the identification of dead cells using PI staining since PI is permeable for 10 min regardless of whether the cells are alive or dead.

The cell strain was estimated with the assumption that a spherical cell is compressed by two parallel plates, as shown in Fig. 4. The area expansion ratio γ is calculated using the following equation by assuming that the cell volume is constant [3];

$$\gamma = \left(\frac{2}{3} - \frac{\pi^2}{16}\right)\left(\frac{h}{d_0}\right)^2 + \frac{1}{3}\left(\frac{d_0}{h}\right) + \frac{\pi}{4}\left(\frac{h}{d_0}\right)^2 \sqrt{\frac{\pi^2}{16} + \frac{2}{3}\left\{\left(\frac{d_0}{h}\right)^3 - 1\right\}} \qquad (1)$$

where d_0 is the diameter of a cell before deformation and h is the gap between the parallel plates. Considering that d_0 = 18.4 ± 1.7 μm and h = 5.9 μm based on microscopic measurements, γ is calculated to be 1.33–1.49. A biological cell membrane stretched to γ =1.51 forms small pores with diameters of approximately 4 nm [4]. The estimated pore size is sufficiently large to introduce Texas Red dextran (MW: 40,000), which has a diameter of approximately 3 nm, but not FITC dextran (MW: 70,000), which has a diameter of approximately 5 nm. This may be the reason for undelivered FITC dextran to the deformed cells.

INTRODUCTION

Ankle foot orthoses (AFOs) are external mechanical devices which are applied across the ankle joint encompassing the foot and calf so as to assist and improve the gait of patients with muscular and/or neurological problems affecting the leg. Their production is a time-consuming and manual process: the techniques involved are common and used for many years without significant innovation. Their performance are determined by the specific technical knowledge of the CPO (Certified Prosthetic Orthotist) and the manual skills of the technicians during production. However this way of manufacturing does not allow control of such AFO properties as thickness or stiffness. Perhaps using 3D printing, as process of production, would allow standardization and better control on the mechanical properties of these devices.

Different research projects have been reported on this topic, but few of them were focusing on the construction of finite element models of 3D printed ankle foot orthoses [1-2]. Probably this is due to the difficulty in finding materials, with the suitable flexibility and stiffness, that can be used in the application. Therefore this study is based on the creation of several finite element models of 3D printed ankle foot orthoses of different subjects and on the evaluation of their mechanical properties. The validation of these models will be made through the utilization of a dedicated experimental set-up.

METHODS

The starting point for this study was the utilization of stl files of AFOs, which are widely used for 3D printing. They only describe the surface geometry of a three-dimensional object, represented by a set of raw unstructured triangles. If directly used for finite element simulations, they may lead to inaccurate results because of the irregular shape of the triangles and also, the thickness of the device would not be taken into account. For solving these problems, an efficient approach was developed. By means of the open-source software pyFormex [3], an algorithm was created to allow the creation of a new regular mesh of the device with quadrilateral elements. The algorithm enables separate consideration of the internal and the external surfaces of the selected AFO and then slicing to obtain several polylines: a polyline is a set of points, where line segments are drawn between consecutive points. The next step was to reconnect all the polylines and obtain a regular representation of quadrilateral elements. This mesh is obtained by the average of the meshes of the new internal and the external surfaces. For the calculation of the thickness, which is not uniform along the device, the distance between the new mesh and the initial stl was considered. The effect of the algorithm is visible in Figure 1.

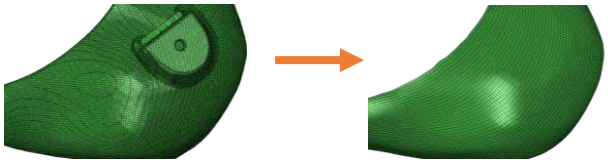

Figure 1: Effect of the algorithm on the mesh of the AFO.

The AFOs used for the study are mainly composed of two parts: the foot and the calf, which have been subjected to the procedure just described. The quadrilateral elements used for the new representation are S4R: shell elements with four nodes and reduced integration. This choice allows more flexible elements and less computational costs. The two parts are connected by beam elements, which represents the two rods of the device, and solid blocks, which are the connection parts between the rods and the foot/calf. In total 4 finite element models have been created,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

each of them for different AFO/people. The finite element analyses were performed using Abaqus/Standard 6.14 and consisted of two bending tests called dorsiflexion and plantarflexion. Dorsiflexion is defined as the movement of the AFO calf towards the foot section in the sagittal plane and plantarflexion by the reverse movement. In both cases an angle of 30 degrees is applied as maximal rotation. This rotation is applied through a point identified as the center of the ankle and allows the calculation of the moments acting on the device during the movement. In this way it is possible to define the AFO stiffness, which is the moment around the ankle joint exerted by the AFO per degree of joint rotation [4]. The effect of dorsiflexion and plantarflexion on the device at the maximal rotation of 30 degrees is visible in Figure 2.

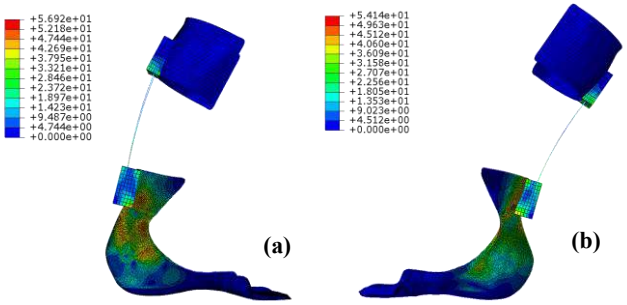

Figure 2: Dorsiflexion (a) and plantarflexion (b) on the device at the maximal rotation of 30 degrees.

The simulation strategy is based on applying the same boundary conditions that are going to be imposed in an experimental set-up, which is still under development. This has to facilitate the comparison between the results and predictions thus provide a means for model validation. The heel part and the zone in correspondence of the metatarsal-phalangeal (MTP) joint are kept fixed in all the directions. The internal surface of the calf part, instead, is constrained to move together with a point that represents the center of the leg. The rods are made of carbon and considered orthotropic. The foot, the calf and the solid blocks are realized in Polyamide 12 which has elasto-plastic properties: a Young's modulus of 1827 MPa and a Poisson's ratio of 0.41 are combined with experimental data provided by the Department of Materials Science and Engineering of Gent University. Moreover, the simulations aim to predict not only how the stiffness changes with the different shapes of the devices but also in relation to the diameter of the carbon rods: hence, tests were conducted with rod diameter of 8 mm and 6 mm.

RESULTS & DISCUSSION

The resulting stiffness values for the four AFOs models during plantarflexion and dorsiflexion are shown in Figure 3, 4, 5 and 6.

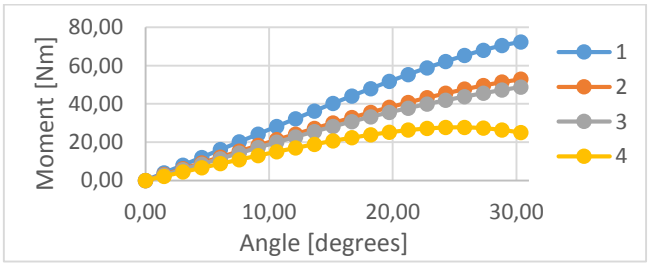

Figure 3: Stiffness during plantarflexion and 8 mm rod diameter

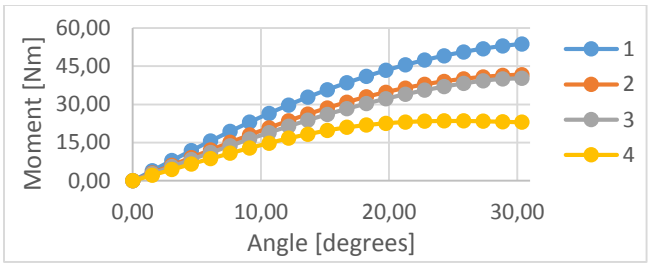

Figure 4: Stiffness during dorsiflexion and 8 mm rod diameter

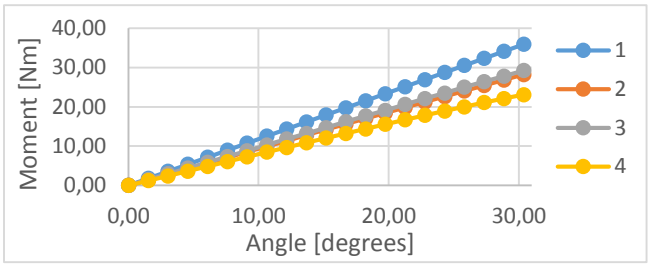

Figure 5: Stiffness during plantarflexion and 6 mm rod diameter

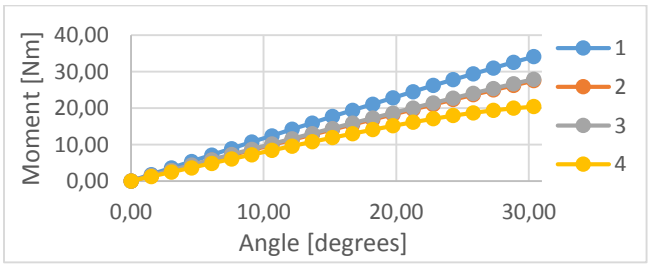

Figure 6: Stiffness during dorsiflexion and 6 mm rod diameter

The results show that the different shape of the devices has an impact on the stiffness, especially on subjects 1 and 4. The data related to subject 2 and 3, instead, have similar values. In general higher stiffness values are reached during the tests with carbon rods of 8 mm, but at the same time all these AFOs reach the plastic region. Further research is needed to investigate whether the AFOs with a rod diameter of 8 mm are also plastically deformed in real life.

CONCLUSION

Using pyFormex, a powerful tool was developed to convert stl files of 3D printed AFOs to high quality finite element models. From the finite element analysis it can be concluded that the different shape and the diameter of the carbon rods influence the stiffness of the devices. Therefore the use of advanced computer modelling algorithms with 3D printing techniques is a strong combination that is acting to revolutionize the manufacturing process of AFOs and to offer several benefits such as the decrease of the production costs, time and errors.

A NOVEL TECHNIQUE FOR ASSESSMENT OF MECHANICAL PROPERTIES OF VASCULAR TISSUE

Biomedical Engineering
Eindhoven University of Technology
Eindhoven, The Netherlands

INTRODUCTION

Rupture of atherosclerotic plaques in the carotid artery is a major cause for stroke. Rupture is a dangerous event, since it causes total vessel obstruction through thrombosis, and as such may be a lethal condition. Currently, the level of lumen occlusion caused by the stenosis is used to estimate the risk of plaque rupture. However, plaque rupture occurs when the mechanical stresses in the cap of the plaque exceed the local tissue strength, not necessarily when the luminal occlusion exceeds a certain level. Therefore, a biomechanical model of the plaque and its mechanical properties may help to better assess rupture risk.

To determine the risk of rupture, mechanical properties of plaque components and cap strength are measured in 2D inflation experiments and inverse numerical modelling. Since plaque material is highly inhomogeneous, tests on complete, intact vessels only elucidate global properties of the vessel. To make a distinction between individual constituents of a diseased vessel, tests on small samples in which each of the material components can be visualized, are required.

METHODS

In this study, we develop a method to assess material properties of (diseased) vascular tissue in a quasi-2D setting. Thin slices of material were cut and slightly compressed between two glass plates. Fluid was injected into the lumen, through a hole in the bottom plate, to inflate the sample (figures 1, 2). A pressure sensor monitored the intraluminal pressure, while a high speed camera recorded the displacement of the sample. The lumen diameter was calculated from these images. The experiments were modelled in the FEBio finite element package (v2.3.1) to assess material properties during pressure increase [1].

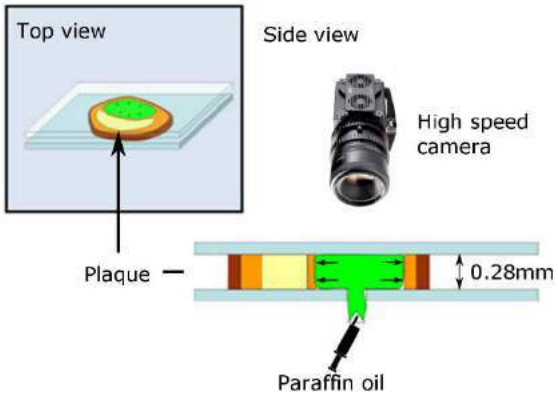

Figure 1: Schematic overview of the experiment.

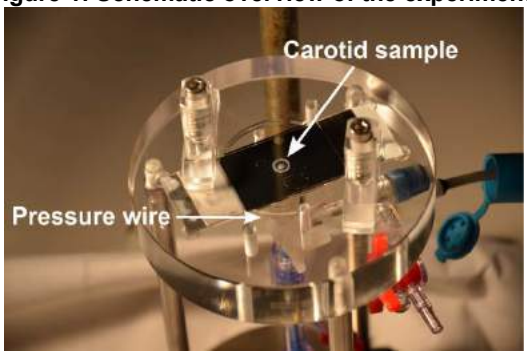

Figure 2: Experimental setup.

For validation purposes, thin rings of silicone rubber (Wacker elastosil M 4601 A/B), with known material properties, were inflated in the experiments (n = 7). The obtained material properties, using a Neo-Hookean model, were compared to the properties calculated from tensile tests on rectangular samples (n = 12) of the same material.

Next, for validation with fresh carotid tissue, ultrasound measurements have been performed on 3 healthy porcine carotid arteries [2]. Thin slices (0.3mm of thickness) were cut from these arteries and measured in the inflation experiment. The Gasser-Ogden-Holzapfel material model [3] was used in both the ultrasound as inflation experiment to obtain matrix stiffness, collagen fiber stiffness and the fiber stiffening parameter, c, k_1 and k_2, respectively. The collagen fiber angle, γ, was set at 31° in the stress-free state [4], fiber dispersion was not taken into account.

RESULTS

The inflation experiment using silicone rubber rings, showed typical Neo-Hookean behaviour (figure 3).

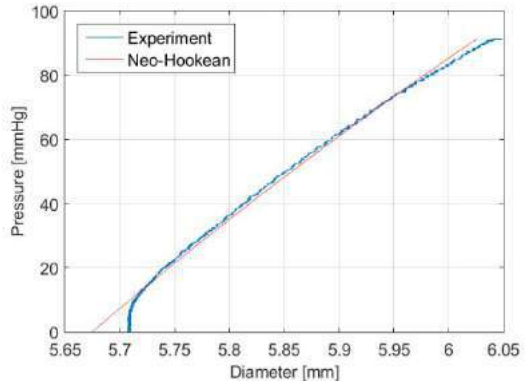

Figure 3: Comparison between inflation experiment and model for silicone rubber rings.

Similar E-moduli are calculated in the inflation experiment and tensile test (figure 4). The mean of both groups are not significantly different (Student's t-test, $p = 0.2 > 0.05$).

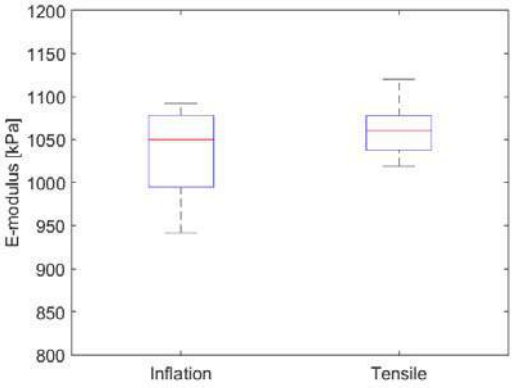

Figure 4: Figure 4: Boxplot of the E-moduli obtained from the inflation experiment and tensile tests.

Strain stiffening was observed at higher pressures in the carotid inflation experiments (figure 5).

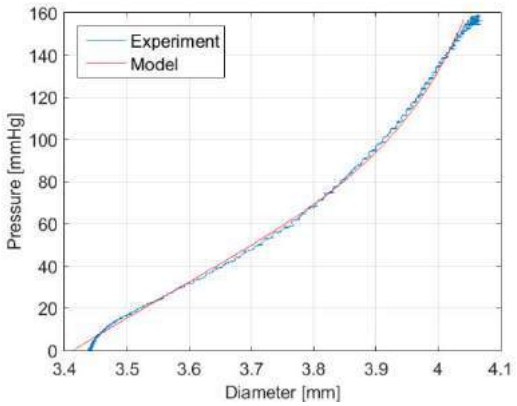

Figure 5: Comparison between inflation experiment and model for carotid tissue

A similar matrix stiffness is found in the inflation and ultrasound experiment (Table 1). The collagen fiber parameters show more variation between the two methods.

	Inflation experiment			Ultrasound experiment		
Sample	c [kPa]	k_1 [kPa]	k_2 [-]	c [kPa]	k_1 [kPa]	k_2 [-]
1	56	10	23	55	5	34
2	68	5	39	65	5	48
3	40	7	27	38	11	11

Table 1: Gasser-Ogden-Holzapfel model parameters obtained from the inflation and ultrasound experiments.

DISCUSSION

The results reveal a good agreement between properties found by classic tensile tests and our new method, for the silicone rubber rings. Increasing the number of inflation measurements could possibly further increase the p-value. A good agreement was found between whole-vessel inflation tests and our method. The fiber stiffness parameters are sensitive to small errors in the measurements, leading to a larger variation when comparing both experiments. Matrix stiffness, however, was similar in the inflation and ultrasound measurements.

The results so far hint towards a method that may successfully be applied for assessment of vascular properties, in a quasi 2D experiment. In future applications, heterogeneous properties, like in atherosclerotic plaque material, may be assessed as well, using vital staining techniques to distinguish different tissue components without affecting their mechanical behaviour.

INTRODUCTION

Retinal detachment (RD) is a serious condition and one of the most frequent causes of blindness in Western countries, affecting approximately 10 out of 100,000 people [1]. The most common type of RD is the rhegmatogenous retinal detachment (RRD), which occurs when liquefied vitreous enters the subretinal space through a retinal tear. Retinal tears are most often generated as a consequence of vitreoretinal tractions. With ageing the vitreous humor undergoes degeneration processes such that the vitreous gel liquefies in certain regions and progressively shrinks (vitreous syneresis). This typically leads to a posterior vitreous detachment (PVD), i.e. a detachment of the jelly vitreous from the retinal in the posterior region of the eye, where vitreoretinal adhesions are normally weaker than in the front. PVD is normally harmful but can lead to strong tractions on the retina if there are regions of vitreous tightly attached to the retina. Such tractions are the most common cause of non-traumatic tearing of the retina [2].

Vitreoretinal tractions generated in the presence of PVD can have both a static or dynamic nature. Dynamic mechanical stimuli on the retina are due to eye rotations that produce oscillations of the detached vitreous and, consequently, tractions on the retina, particularly at the attachment points of the gel-like vitreous to the retina [3]. Static forces on the retina are induced by the quasi-static shrinking of the vitreous humor produced by vitreous syneresis. Both types of forces are thought to have the potential to lead to retinal breaks. In the present work we propose a mathematical model of the quasi-static generation of tractions on the retina produced by syneresis of the vitreous humor.

METHODS

We consider a solid that initially has a spherical shape and represents the healthy vitreous humor within the vitreous chamber.

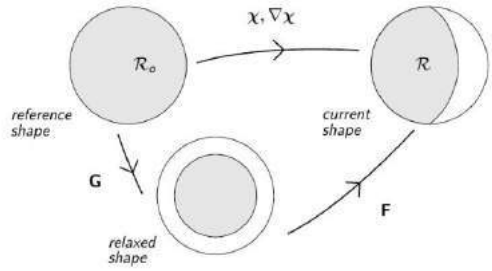

Figure 1: Schematic sketch of the modeling of the contraction and deformation processes.

We model the process of vitreous contraction (syneresis) assuming that the vitreous body progressively shrinks in time. Mathematically, we consider the following decomposition of the deformation gradient

$$\nabla\chi = FG, \tag{1}$$

where G denotes the distortion due to the contraction of the vitreous and F the elastic distortion. We model the contraction process as homogeneous and isotropic and thus we write $G = \gamma I$, with I the identity tensor and γ a positive scalar quantity decreasing in time from an initial value $\gamma(0) = 1$. This implies that, starting from an initially spherical shape and in the absence of any external forces or constraints, the body would shrink maintaining a spherical shape and without generating stresses. The meaning of equation (1) is pictured in Figure 1. In the figure the configuration R_0 represents the reference shape of the body. By looking at the decomposition (1), the deformation χ, which maps this configuration into the current

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

configuration ($\chi: R_0 \to R$) can be seen as made up, at least locally, of two steps: first G applies the contraction, then F applies an additional elastic distortion, which the body needs to reach the current shape while fulfilling the boundary conditions and preserving the material continuity.

The evolution of the system is governed by the following principle, written as a power balance on the reference configuration

$$\int_{\partial R_0} t_0 \cdot u dA - \int_{R_0} S_0 \cdot \nabla u dV - \int_{\partial R_0} \tilde{S}_0 \cdot \tilde{\nabla} u dA = 0 \quad \forall u. \quad (2)$$

In the above equation t_0 represents the external traction acting on the bounding surface of the body R_0, S_0 is the Piola stress and u a test velocity field. The last term in the balance principle accounts for the presence of a skin wrapping the body, so that $\tilde{S}_0$ represents a surface stress and $\tilde{\nabla} u$ denotes the restriction of ∇u to the boundary R_0. This is consistent with our basic kinematic assumption: the skin deformation is the restriction to the boundary of the bulk deformation, $\tilde{\chi} = \chi|_{\partial R_0}$, which implies that the skin deformation gradient is the restriction of the bulk deformation gradient $\tilde{\nabla} \chi = \nabla \chi|_{\partial R_0}$. The skin models the presence of the vitreous cortex, which is the outermost layer of the vitreous and is stiffer than the bulk vitreous. The vitreous cortex is also assumed to progressively contract in time, so that after introducing the skin deformation gradient decomposition, $\tilde{\nabla} \chi = \tilde{F} \tilde{G}$, we get

$$\tilde{F} \tilde{G} = (FG)|_{\partial R_0}, \quad (3)$$

with $\tilde{G} = \tilde{\gamma} I$ and $G = \gamma I$. If the skin contracts in the same way as the bulk body ($\tilde{G} = G|_{\partial R_0}$) then $\tilde{F} = F|_{\partial R_0}$. If the skin and the bulk body are subject to different contraction laws, the elastic distortions will be related to one another by the compatibility condition (3).

The material characterization of the vitreous body and the vitreous cortex is modeled through the response functions, $S_0 = \gamma^2 \Gamma(F)$ and $\tilde{S}_0 = \tilde{\gamma} \tilde{\Gamma}(\tilde{F})$. It is worth noting that we can set different elastic properties for the bulk material and the skin. We model both the bulk vitreous and the vitreous cortex as incompressible Neo-Hookean materials. This means that the strain energy function depends linearly on the first invariant of the right Cauchy-Green tensor, through the shear modulus, which we denote by k_b for the bulk solid and k_s for the skin.

At the boundary ∂R_0 we assume that the contact between the vitreous and the retina is described by a traction field made up of two contributions: an adhesive attractive force per unit area and a repulsive force per unit area. Both are assumed to be zero on the reference shape. The magnitude of the adhesive force depends locally on the distance between the current position of a material point on the boundary and its reference position. It is characterized by a limit value K_{ad}, corresponding to the onset of vitreous detachment. The magnitude of the repulsive force depends on the distance d from the inner wall of the vitreous chamber, which we can therefore think of as a rigid container. It grows very rapidly as d approaches zero and effectively keeps the vitreous body confined. Together with these two contributions we consider a viscous adhesive traction that avoids a sudden detachment of the body from the wall that would lead to numerical issues.

In the simulations we impose a limit value K_{ad} for the adhesion force per unit area that varies spatially along the surface of the wall. A very high value for K_{ad} in a small region will denote a focal adhesion, while a very low value will trigger the initial detachment. We also assume that K_{ad} grows from the back to the front of the vitreous chamber, consistently with clinical observations.

RESULTS

All simulations started with the vitreous body completely filling the vitreous chamber. We then observed the evolution of the shape of the detached vitreous during the contraction process and the consequent generation of stresses on the boundary and within the vitreous.

In Figure 2a,b we show two examples of three-dimensional configurations of the vitreous attained during the progression of the PVD process. In the first case (Figure 2a) we show a "complete vitreous detachment". In this case we assume that K_{ad} grows from the back (right in the plot) to the front (left in the plot) of the vitreous chamber. Thus the vitreous detaches first on the back of the vitreous chamber and then the detachment proceeds evenly towards the front.

In this Figure 2b we show the case of a PVD in the presence of a focal vitreoretinal adhesion at the back of the vitreous chamber. This case is known to be potentially dangerous in terms of tractions on the retina. In this case the model predicts that the vitreous deforms substantially during the contraction process, thus also generating large stresses. Both configurations reported in Figure 2 are very similar to configurations of PVDs that can be observed in reality. This suggests that the model retains the most important ingredients of the contraction process of the vitreous body.

In can be shown that, for a given spatial variation of the adhesive traction on the boundary, the shape of the detaching vitreous is completely determined once two dimensionless parameters are fixed: the ratio between the elastic moduli of the bulk solid and the skin (k_b/k_s) and the ratio between the elastic modulus of the solid and the limiting adhesive traction (k_b/K_{ad}).

The model can be used to identify shapes of the detaching vitreous that are likely to be associated with large tractions on the retina and to the existence of particularly strong focal adhesions on the retina, which are risk factors for the generation of retinal tears.

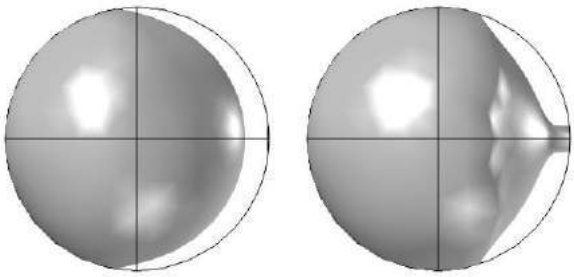

Figure 2: Twos examples of the shape taken by the contracting vitreous during PVD, as predicted by the model. (a) Complete PVD, (b) case in which there is a focal adhesion region at the back of the vitreous chamber.

THE RESPONSE TO STRESS DEPRIVATION DIFFERS BETWEEN THE INTERFASCICULAR AND FASCICULAR MATRIX OF TENDON

INTRODUCTION

Stress deprivation in tendon leads to reduced tendon strength as well as gene expression regulation similar to that seen in tendinopathy. It has been suggested that localized stress deprivation may be a mechanism involved in tendinopathy [1]. Tenocytes express primary cilia, which elongate when tendon is stress deprived [1]. With cilia length previously shown to regulate cell signalling, alterations to cilia length could have implications in tendon healing and tendinopathy [2].

Tendon is made up of strong elastic collagen fascicles bound together with a highly hydrated matrix called the inter-fascicular matrix (IFM). Previous work indicates differences in the morphology and metabolism of the tenocytes resident in the tendon fascicular matrix (FM) and the IFM, as well as differing cellular responses to mechanical overload [3]. This study tests the hypothesis that primary cilia of the cells in these two regions also respond differently to stress deprivation, and that this is associated with differences in the biomechanical degradation of tendon FM and IFM.

METHODS

Dissected rat tail tendons were either tested immediately (fresh), or maintained in media for 1 week, either stress deprived or at 4% static strain. Samples from each group were prepared for cilia imaging and mechanical testing.

In order to determine cilia length, fascicles and their surrounding IFM were fixed, stained and imaged (n = 80-120 cilia per group from 18 fascicles from 3 rats). An additional 30 fascicles from 1 rat were also dissected for a stress deprivation time course, fixing samples for imaging after 4, 6, 16, 24 and 168 hours of stress deprivation.

For mechanical testing, both fascicle and IFM samples were prepared from each test group (n = 6-8 per group per test). For FM testing, 20mm length fascicles were dissected, their diameter measured, and 10 cycles of 0-4% cyclic loading were applied followed by a quasi static pull to failure test. Testing was performed with an Instron (ElectroPuls1000, Canton, MA) mechanical testing machine. For IFM testing, two fascicles were dissected as a unit, and the opposing ends cut from the fascicles at a 20mm separation distance, to leave an isolated region of IFM for shear testing by pulling the fascicles apart along their long axis. The IFM was subjected to a quasi static pull to failure test.

RESULTS

Cilia length in the IFM & FM of fresh samples was not significantly different (fig1). However, cilia were significantly more aligned in FM than in IFM (fig1).

After 1 week of stress deprivation, the cilia significantly increased in length in both the IFM & FM, but the increase was significantly greater in the IFM (fig1). By contrast, when the tissue was maintained at 4% static strain, the cilia in both the IFM and FM regions were significantly shorter than those in stress deprived tissue, however they remained longer than those in fresh tissue (fig1). The time course clarified that while some of the lengthening occurred within the first four hours of stress deprivation, the majority of lengthening and the differential cilia response between the FM and IFM cells all occurred after 24 hours of stress deprivation.

Hashes (#) show significance between the two tendon regions for a given condition. */ˈ/#=p<0.05, **/ˈˈ/##=p<0.01, */ˈˈˈ/###=p<0.001. Error bars show ±1 standard deviation.**

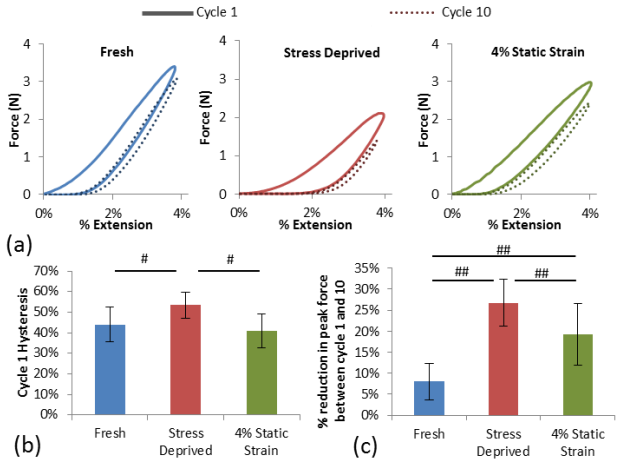

Figure 2: a) representative 4% preconditioning loops for each test group, comparing cycle 1 and 10. b) Average percentage hysteresis in the first preconditioning cycle. c) Percentage reduction in peak force over the 10 cycles. #=p<0.05, ##=p<0.01, ###=p<0.001. Error bars show ±1 standard deviation.

The tensile strength of fascicles was not significantly affected by either the stress deprivation or static strain conditions. However, the viscoelastic properties of the stress deprived fascicles were significantly reduced (fig2). Fascicles under static loading had some loss of viscoelastic properties but it was significantly less than the loss seen in the stress deprived fascicles (fig2). IFM shear force tests showed a dramatic and significant reduction in the quasi static mechanical properties of the IFM after stress deprivation, indicating large amounts of cell mediated degradation in this region (fig3).

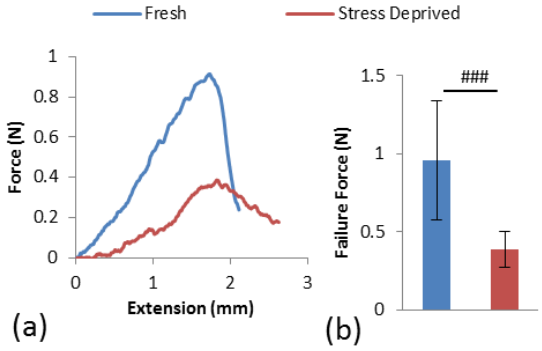

Figure 3: a) Representative force-extension curves to failure for the IFM in stress deprived and fresh samples, alongside b) mean IFM failure force data. ###=p<0.001. Error bars show ±1 standard deviation.

DISCUSSION

The different responses to stress deprivation in the two tendon regions imply a more pronounced cellular response in the IFM. The IFM has also been shown to have an increased response to overload [3], suggesting that cells in this region of the tendon may play a role in the aetiology of tendinopathy.

These data suggest that primary cilia elongation in tendon may be mediated by matrix degradation rather than the absence of strain, since elongation took in excess of 24 hours, and it has been previously established that cilia can respond to changes in strain within 3 hours [4]. The likely response of cilia specifically to matrix degradation may have important consequences for cilia signaling in tendon and in other connective tissues. The differential response of cilia to stress deprivation in the IFM and FM provides further indications that there are differences in the cell populations of these regions. Cilia are key regulators of cell signaling and differences in cell signaling between tendon regions will likely have multiple downstream effects.

INTRODUCTION

Many cell types exert contractile stresses onto their surroundings via actin stress fibers [1]. In order to obtain mechanically functioning engineered cardiovascular tissues it is important to understand and control the cell contractility, because it affects the tissue organization as well as the (apparent) mechanical properties. One technique to gain more insight into the cellular stress generation is the thin film method [2]. With this technique, the stress generated by a monolayer of cells attached to a thin silicon film can be determined via the deformation of this film by the cells. Current thin film studies have mainly focused on determining the contractile properties of perfectly aligned cells with the same orientation, such as in smooth, skeletal, and cardiac muscle tissue [3-5]. However, the cells in engineered cardiovascular tissues (e.g. heart valves) are in most cases not perfectly aligned in the same direction. It may be questioned whether the stress exerted by perfectly aligned monolayers represents the stress distribution inside these tissues. The aim of the present study is to determine the influence of the degree of cell alignment on the stress generation.

METHODS

To determine the influence of cell alignment on stress generation, fibronectin was micro-contact printed on thin film constructs [2,3] (figure 1). The fibronectin was either patterned as 10 µm wide lines parallel to the long axis of the film (0°) or as a fishnet pattern with 5 µm wide lines with an angle of ± 45° with respect to the long axis.

Subsequently, 80,000 human myofibroblasts were seeded onto each construct and cultured for two days at 37°C and 5% CO_2. After culture, the samples were fixed and stained with DAPI (nuclei) and phalloidin (actin fibers) for 1 hour and visualized with a fluorescent microscope to quantify the alignment of the cells and their actin cytoskeleton using Mathematica and Matlab.

In a separate experiment, after culture, the constructs were transferred to a Petri dish with preheated culture medium. Rectangular films were cut from the constructs (figure 2) and the medium was allowed to cool down below 32°C to dissolve the pIPAAm (poly-N-isopropylacrylamide). This enabled the myofibroblasts to deform the PDMS (polydimethylsiloxane) layer. A picture of the initial curvature (0 h) was taken using a stereomicroscope and the thin films were placed back at 37°C. After 1 hour, the contractile equilibrium was reached and another picture was taken. The curvature of the films was determined from the images using Matlab after which the cellular stress was estimated via finite element modeling in Abaqus. The model consisted of a layer with Neo-Hookean material properties (E=1.58 MPa, ν=0.49) representing PDMS, and a fiber-reinforced layer with an active stress component ($\boldsymbol{\sigma}_{ca}$) representing the cell sheet:

$$\boldsymbol{\sigma}_{ca} = \sum_{i=1}^{N} \varphi_{sf}\sigma_{max}\vec{e}_{sf}\vec{e}_{sf} \qquad (1)$$

where σ_{max} represents the maximum cell stress and φ_{sf} the (Gaussian)

actin stress fiber distribution:

$$\varphi_{sf}^{i} = Aexp\left(\frac{-(\gamma-\mu)^2}{2\sigma^2}\right) \quad (2)$$

with the main fiber direction (μ) in the long axis direction. The standard deviation (σ) was determined from the fiber distribution obtained from the fluorescent images.

Statistical differences ($p<0.05$) in curvature between groups were analyzed with SPSS using a Mann-Whitney U test. Differences over time were analyzed using a related samples Wilcoxon signed rank test.

RESULTS

In both groups the nuclear and actin fiber orientation coincide strongly. In the 0° samples the nuclei and actin fibers mainly align in the length direction of the film (σ=11°; figure 3a, c). In the 45° samples the cells adopt a random orientation (σ=360°; figure 3b, d).

Figure 4c shows that the median curvature increases over time from 0.28 mm^{-1} to 0.54 mm^{-1} in the 0° group while it stays the same in the 45° group (0.12 mm^{-1} and 0.13 mm^{-1}). The curvature of the films in the long axis direction of the 45° group is approximately two times lower than the initial curvature of the 0° group and approximately four times lower at equilibrium. The σ_{max} developed by the cells in the 45° group (1.24 kPa) is more than two times lower in the 0° group (2.91 kPa) at equilibrium while there is no difference initially (figure 4d).

DISCUSSION

In this study we investigated the influence of the degree of cell alignment on stress generation. When all cells are aligned in the same direction, σ_{max} at equilibrium is more than two times as high as when the cells are randomly distributed. These results therefore suggest that

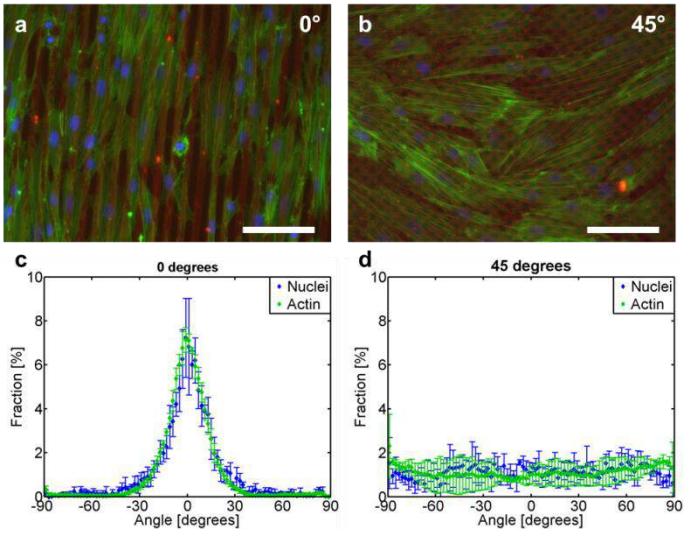

Figure 3: (a, b) Nuclei (blue) and actin fibers (green) of myofibroblasts on fibronectin (red) patterns; scale bar: 100 µm. (c,d) Histograms of the nuclear (blue) and actin fiber (green) orientation where the long axis of the construct is at 0° (n=5).

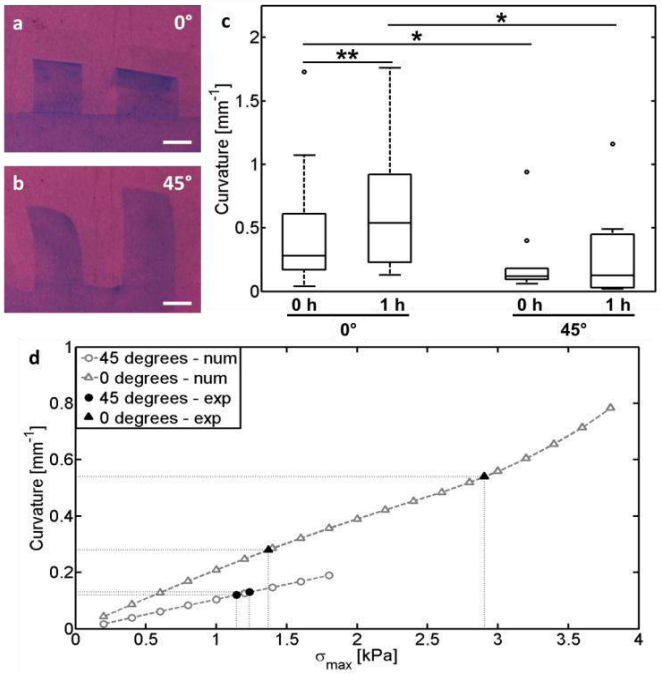

Figure 4: (a,b) Representative top view images of bend films at equilibrium; scale bar: 1 mm. (c) Boxplots of curvature (n=9-22), * p<0.05: Mann-Whitney U test; ** p=0.000: Wilcoxon signed rank test. (d) Numerically obtained relationship between σ_{max} and curvature and corresponding experimental median curvature.

the total active stress distribution cannot only be derived from the stress fiber organization, as the stress that each cell can exert (σ_{max}) apparently depends on the overall cellular organization. This study showed that the cellular orientation affects the stress distribution. In engineered cardiovascular tissues this will in turn influence the mechanical properties and thus the functionality of these tissues. [6,7].

It is hypothesized that the high variation in curvature is caused by the difference in cell density of each individual thin film. In previous experiments a large spread in cell density between individual thin films was observed, with differences up to two-fold (data not shown). In future studies, we aim to decrease this variation by correcting for the cell density of each thin film, which can be achieved by using a Hoechst staining of the cell nuclei. In addition, not only the extremes of alignment (perfect alignment and completely random) but also some in-between degrees of alignment will be investigated by printing fibronectin lines with different angles. This will give more insight into the stress development of e.g. tissue engineered heart valves as these degrees of alignment will be more representative for these tissues.

THE DYNAMICS OF PROTEOGLYCAN LOSS IN ARTICULAR CARTILAGE FOLLOWING MECHANICAL PERTURBATION.

Lorenza Henao Murillo, Keita Ito, Corrinus C. van Donkelaar

Orthopaedic Biomechanics, Department of Biomedical Engineering
Eindhoven University of Technology, Eindhoven, The Netherlands.

INTRODUCTION

It is commonly accepted that excessive mechanical loading may induce damage in articular cartilage. Given the poor repair capacity of the tissue, damage may accumulate, progressing to severe osteoarthritis when adverse mechanical conditions persist [1]. Unfortunately, the success of clinical treatment is also limited. This makes osteoarthritis one of the most frequent, painful and disabling diseases among people over 60 years of age.

The first signs of cartilage deterioration include surface roughening and proteoglycan (PG) loss [2]. This induces cartilage softening, which makes the tissue vulnerable to further damage. Both collagen damage and PG loss may occur following few excessive loading events, or they may develop after sustained or repetitive loading. Collagen damage has been hypothesized to occur as a result of excessive straining of the collagen fibrils [3]. This occurs during overloading, but not after the traumatic load has been released. In contrast, PG loss has been reported to occur in a delayed manner, extending up to 56 hours after excessive loading was applied and released [4]. We hypothesize that the mechanical conditions during this period, even when these conditions themselves would not be excessive, may have an effect on the PGs loss. This would then imply that PG loss may be modulated by changing the conditions during this post-loading period, which may be of clinical relevance.

The present study addresses the above hypothesis. More specific, the aim is to determine whether a period of moderate cyclic loading after excessive loading of articular cartilage, changes the loss of PGs from an osteochondral explant during the first 56-hours after the excessive loading was applied.

METHODS

Osteochondral explants were harvested from the metacarpal joint of 1-year old calves (obtained through a local abattoir). While keeping the tissue moist, 7.5 mm diameter plugs were drilled perpendicular to the surface using a diamond core drill. Plugs were shortened to 5-7 mm and stored at -20˚ C until further use.

For mechanical testing, samples were thawed in PBS during 24 hours and remain submerged in PBS while they were fixed into a custom-made chamber in a tensile tester (Zwick/Roell). Samples were subjected to loading with a 2 mm diameter stainless steel indenter. Six loading protocols were designed (n=4 per group), as explained in Figure 1. These included either a fast (F_x^{fast}), slow (F_x^{slow}), or no (F_x^{none}) excessive loading, with (F_{cycles}^{x}) or without (F_{rest}^{x}) subsequent cyclic compression during which 5 minutes of 0.1 N and 5 minutes of 5 N at 1 Hz is repeatedly applied with the same indenter.

Displacement and force were monitored over time throughout the experiment, and stored for later analysis of changes in tissue thickness and tissue properties (data not shown).

PBS was collected and refreshed at the end of the 24 hours equilibration period (t=0), after the cyclic loading (t=8 hours), and at the end of the experiment (t=56 hours; see Figure 1). Collected PBS was stored frozen (-20˚ C) until quantification of the released PG using a standard DMMB assay with shark chondroitin sulfate as standard.

At the end of the experiment, tissue was frozen for histology, including staining for PG content and immunohistochemical staining of collagen damage (data not shown).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

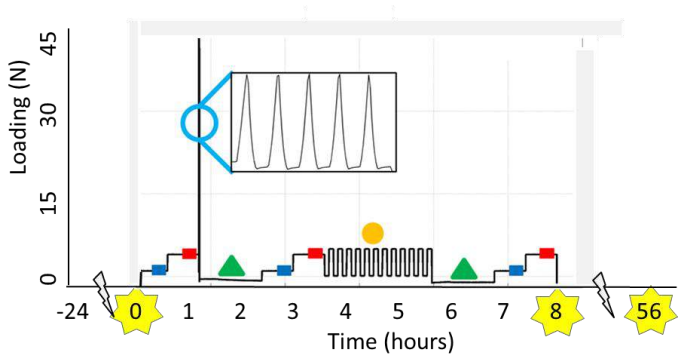

Figure 1: Total duration of the loading protocol was 8 hours (starting at t=0h). It was preceded by 24 hours equilibration time and followed by 56 hours of free swelling.
Colored areas in the figure represent: Green triangle: 70 min unloading; Blue and red bars: 35 min of 1N and 35 min of 4N constant load; Orange dot: 2 hours of cyclic loading (0.1-5N, 5 min on/off). Blue circle: five times 45N, applied at 5 mm/min (slow) or 120 mm/min (fast). Yellow stars: PBS was collected and refreshed. Flash-signs indicate jumps in time on the horizontal axis.

RESULTS

Total PG release into the PBS was measured at three time points, and presented as a release per hour in Figure 2 for the various loading cases.

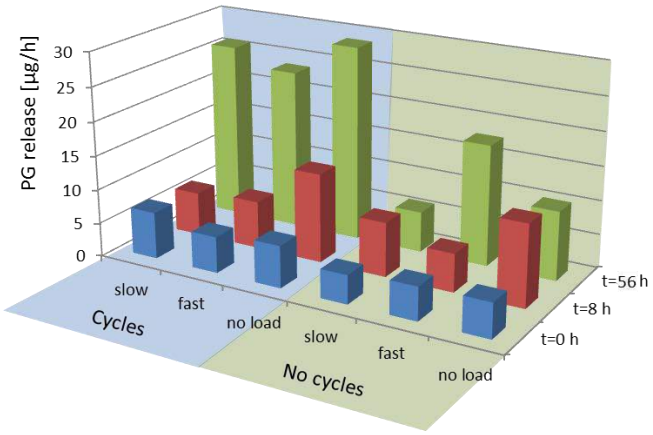

Figure 2: PG (PG) release into the PBS, calculated as the average release per hour over the relevant time period (Fig 1), plotted as a function of loading case and moment in time.
Blue: Release prior to loading. Red: Release between t=0h and t=8h. Green: Release between t=8 and t=45h.

Three things are important to observe. First, the blue bars are equal, demonstrating that there is no difference between groups prior to the experiment. Second, PG release after the cycles (t=8h) equals the release prior to loading for the groups that were loaded at t=0h, but is higher for the groups that did not receive the excessive loading. Third, after 56 hours, PG release in all groups which received cyclic loading is higher than in the groups that didn't.

DISCUSSION

This study shows that PG release into the bathing solution is dependent on the mechanical loading conditions. In agreement with our hypothesis, this release is delayed with increased release until 56 hours after loading, and it can significantly be modulated by a modest mechanical loading regime after an excessive loading event. Interestingly, the effect of the modest cyclic loading is more significant than the effect of the preceding five loads that had 9-fold larger magnitude.

The PG release after the 8 hours loading protocol was delayed. Within the 8 hours of loading, no enhanced PG release was observed, whereas release was elevated in most groups 56 hours after the first excessive loading. Such delayed response concurs with other studies, where enhanced PG loss was observed 56 hours after loading.

At 8 hours, surprisingly, the groups that did not receive the early five peaks of higher load, regardless of whether they received cyclic loading or not, showed more PG loss than the ones that were mechanically challenged. Assuming that the non-loaded samples represent the natural PG loss, apparently the ones that did receive the higher loads were protected against PG loss. An explanation of this phenomenon may be that the loaded samples were compacted by the loading, and that the denser matrix contained PG more than the non-compacted matrix in the other groups. This was confirmed by the measurements of tissue height (blue bars in Fig 1; data not shown).

At 56 hours, PG loss from all cyclically loaded groups was significantly enhanced compared to the groups without cycles and compared to the measurements after 0 and 8 hours. We hypothesize that the fluid flow that is induced in and out the matrix during the 5 minute loading cycles may drag PGs along. Thus, convective transport is added to the natural diffusion-driven PG release. Although this is a plausible hypothesis, it remains unclear why such convection would result in a delayed PG release, rather than an immediate PG loss.

In conclusion, the present study confirms the hypothesis that PG release from cartilage can be modulated by a mechanical loading regime, and that the consequent PG release is delayed. It is enhanced 56 hours after the mechanical perturbations stopped, but it was not yet enhanced within the 8 hour loading protocol, which contained the PG-release stimulating, cyclic loading protocol. Loading- and time-dependent PG kinetics such as those shown in the present study further our insight in the complexity of post-traumatic cartilage degradation. Ultimately, these insights may result in improved clinical treatment of cartilage defects or for guiding post-traumatic recovery.

INTRODUCTION

Atherosclerosis is the leading cause of death in the westernized societies and the primary cause of stroke. Atherosclerotic plaques can grow into the arterial lumen sufficiently to obstruct the blood flow. The local narrowing of the lumen, known as stenosis, leads to the occurrence of flow phenomena such as separation, recirculation and instabilities in the downstream region, in addition to larger velocity values as the flow accelerates through the throat of the stenosis. Flow bench studies on stenosed tubes embedded in tissue mimicking gels demonstrate that flow instabilities and pressure fluctuations induce mechanical waves that can be detected by means of accelerometers or laser Doppler vibrometry (LDV). As part of the H2020 project CARDIS, we are exploring the use of LDV as a non-invasive diagnostic tool for carotid stenosis via detection of stenosis induced vibrations at the level of the skin.

In addition to and complementing in-vivo and experimental studies, computational fluid dynamics may provide a better understanding of flow related phenomena leading to the generation of mechanical waves and their propagation through soft tissues. In this study, we present initial computational results obtained in two different settings: (i) flow in a simple tubular model with a 75% area stenosis (mainly for assessment of numerical parameter evaluation), (ii) a patient specific case, with a maximum area stenosis of 82%. The later stages of the study will involve the evaluation of the arterial wall movement generated by flow instabilities and the study of the propagation of the pressure waves from the arterial wall to the skin as compressional and shear waves.

METHODS

The geometry of the first model consists of an axisymmetric 75% area stenosis with length (L) equal to twice the tube diameter (D=6mm). The total length of the model corresponds to 5D and 10D for the upstream and the downstream side, respectively. Previous studies have shown that an upstream length of 2D is sufficient to obtain results independent of the position of the inflow boundary [1]. A Cooper-type meshing was performed in order to obtain a grid of 3251688 hexahedral elements with uniform spacing in the axial direction. Simulations were performed using Fluent (Ansys) with time-dependent 3D Large Eddy Simulations (LES) carried out with the Smagorinsky–Lilly constant C_s equal to zero in order to nullify the viscosity added by the model. Bounded schemes were used for the momentum and for the transient formulation. The time step was set to 1 millisecond. The constant inlet velocity value U corresponded to a volumetric flow rate (Q) of 1000 ml/min, leading to a Reynolds number (Re) based on the tube diameter of 1240. A zero pressure condition was set at the outflow boundary. For the patient-specific case, the geometry consists of a carotid bifurcation with a non-axisymmetric 82% area stenosis of the internal carotid artery (ICA). Initial simulations were carried out on a relatively coarse hexahedral grid (439680 elements) with the same settings as in the simplified model except for Q=250 and 500 ml/min, leading to Re=230 and 460, respectively. The outflow boundary was set as flow ratio of 32% for the ICA as defined by Harald et al.[2]. In both cases, simulations were performed for a total duration of 2 seconds with the last 500 milliseconds used for spectral analysis (FFT) to assess the frequency content of the signal. As this is an early stage of the study, in both models the arterial walls are supposed to be rigid.

RESULTS AND DISCUSSION

Although flow in a straight tube would not be transitional (since Re < 2300), in the 75% stenosis model pressure instabilities such as those depicted in Figure 1 are observed: the flow is not able to stay attached and vortices form downstream of the stenosis, as the flow

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

diverges and decelerates. The area-weighted average of velocity at the throat of the stenosis reached a value of 4*U*. The maximum amplitude of the observed pressure oscillations was 0.854 Pa. Frequency analysis of the pressure field showed the highest frequency peaks between 2D and 4D away from the stenosis throat and always in the frequency range of 10-450 Hz, consistent with experimental observations.

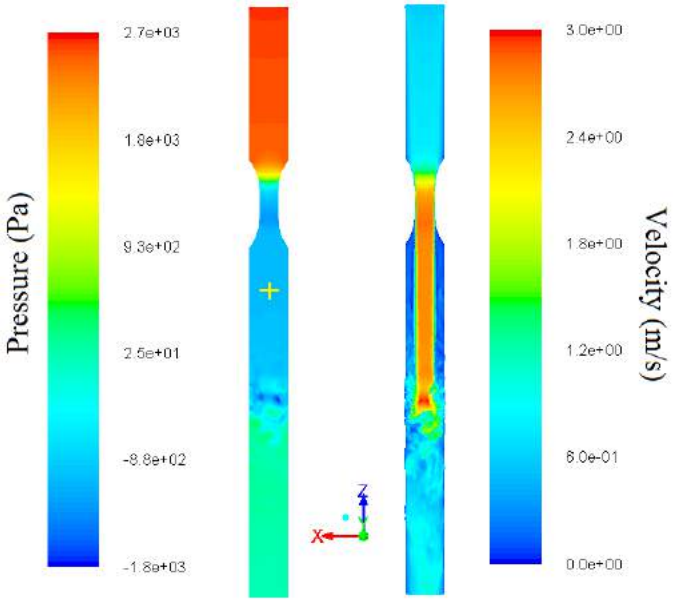

Figure 1: pressure and velocity instabilities at t=0.06s of the 75% simplified model. The yellow crosshair indicates the point where the frequency spectrum was calculated.

For the patient-specific case, only results for Re=460 will be shown. Instabilities are manifested by the swirling motion of the fluid in the post-stenotic region (Figure 2).

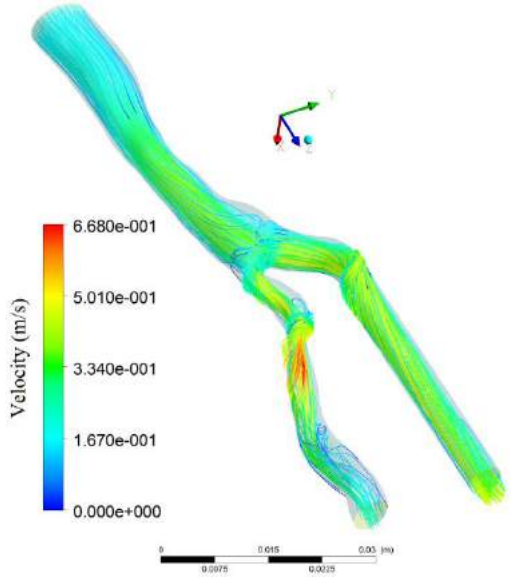

Figure 2: pressure for the patient specific case at t=2s for Re=460

The pressure and its frequency spectrum depicted in Figure 3 were calculated for a point located on the centerline of the ICA at a distance of 2.6 D from the stenosis center. The amplitude of pressure oscillations is in the order of 1.547 Pa. The FFT indicates peaks in the 10-450 Hz frequency band, with an intense low frequency peak. For Re=230 results are entirely different: the pressure does not show any peak at any location in the model. This is likely to be due to the low flow rate, which is insufficient to cause flow instabilities. Further analysis will be performed at different flow rates. The sensitivity of the results to the mesh density and to the time step will be further explored. We believe that the regularity of fluctuations in the patient-specific case, compared to the simple tube model, are likely to be induced by a relatively coarser mesh or low flow. Furthermore, the dependency of the pressure oscillations (and their frequency spectrum) on the shape and degree of stenosis will be assessed.

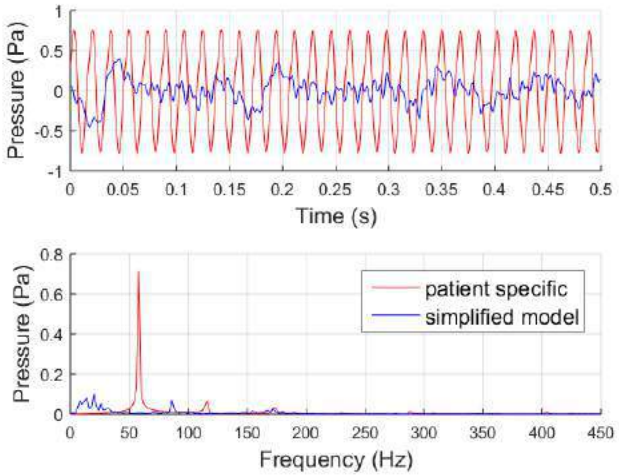

Figure 3: pressure and its frequency spectrum: comparison between the patient-specific model for Re=460 (red) and the simplified model (blue).

CONCLUSIONS

These initial CFD results are in line with previous studies with similar models [3] and our own experimental observations, and indicate that the stenosis-induced flow instabilities for the tested settings give rise to pressure fluctuations in the frequency range of 10-450 Hz.

The 3D printed phantom of the patient-specific model studied in this abstract will be the subject of future experimental studies. The integrated experimental-computational approach will provide further details on fluid dynamics and mechanical phenomena, and give more insights into the sensitivity and specificity of the use of LDV to detect carotid stenosis, providing subsequently guidance for studies on patients.

FATIGUE TESTING OF A COMPOSITE MENISCUS IMPLANT – WHAT ARE THE LIMITS?

INTRODUCTION

Long-term fatigue remains the main obstacle in the introduction of a synthetic total meniscus implant. Different materials have been proposed for this application, but none remained undamaged when tested in pre-clinical studies. For example, Kelly et al. (2007) chose to use a hydrogel material to create a meniscal implant, which was tested in an ovine model. Significant cartilage degeneration and implant failures occurred after 1 year. In another canine study by Hannink et al., (2011) a porous poly-caprolactone polyurethane meniscus implant experienced rapid degradation and subsequent loss of mechanical properties occurred after 2 years.

In recent years, the concept of composite design has emerged as a means to improve function and long-term stability of orthopedic devices. The first meniscus implant concept to have reached the clinical study phase (Figure 1) was developed by our group. It is constructed from a polycarbonate-urethane matrix that is reinforced with ultrahigh molecular weight polyethylene (UHMWPE) fibers. While preliminary results of this concept in an ovine model seem promising (Zur et al. 2010), its expected service-life has not yet been established. Furthermore, there is also need to characterize potential failure modes of such device. Controlled long-term fatigue experiments are a useful tool that can be used to evaluate the potential life-span of any orthopedic implant, yet no such study has been reported for the meniscus. In this study, fatigue testing was conducted up to 25 million loading cycles, to evaluate the polycarbonate-urethane meniscus implant.

METHODS

The fatigue resistance of the meniscus implant was characterized by means of S-N curve. The pattern of the cyclic load applied in the study was based on the vertical loading component of ISO-14243-3 (Wear of total knee-joint prostheses), which was scaled as follows: The minimum in the series of 5 loading conditions was that of normal gait (2500N peak load, ~ 3 times body weight, Figure. 1). Four additional loading conditions were created by rescaling the force curve so that the maximum peak load increased to 3000N, 3500N, 4000N and 4500N. The last three loads, 3500-4500N, represent approximately 5 to 6-times body weight – the typical load in the knee during higher impact activities such as running. Each test was performed on n=5 sterile implants. Each new meniscus specimen was placed between rigid UHMWPE surfaces that simulate the geometry of the articulating surfaces of the tibial plateau and femoral condyle in the medial compartment.

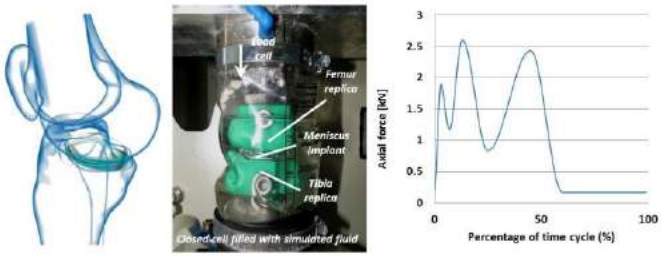

Figure 1. Illustration of the knee joint with the meniscus implant, the corresponding testing apparatus replicating the femur and tibia surfaces, and loading cycle of the medial compartment.

The testing cell was then sealed and filled with heated distilled water (37°C) and loaded axially at an accelerated rate (2 Hz) until failure was detected. Failure was defined as tear of either one of the composite material's components (PCU or UHMWPE fibers), which

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

could potentially lead to device failure and require an additional surgical intervention. If failure did not occur up to 25 Mc, the test was discontinued. The implants were evaluated macroscopically after 0.2, 0.5, 1 Mc and at 1 Mc intervals until reaching 25 Mc or failure.
Upon completion of the fatigue testing, the implants were imaged with FEI Quanta 200 FEG ESEM (environmental scanning electron microscope) under low vacuum conditions. The analysis of implants after failure was focused on the area of failure, and the damaged areas of the articulating surfaces, if not.

RESULTS

For the minimum in the series of loads (that of ISO-14243-3), all five implants reached 25 Mc without failing. The UHMWPE fibers remained intact, embedded within their designated tunnels in the PCU matrix. Mild deformation of the PCU material was noted mainly in the central region of the implant. When the peak load was increased to 3000N, the implants did not reach the ultimate goal (25 Mc), but still had a very long service-life of 15±3.1 Mc. The predominant mode of failure in the majority of specimens (4/5) was thinning of the PCU material in the central region of the implant due to creep, which then developed into a localized tear. The results under higher loading conditions (3500N, 4000N and 4500N) demonstrated a similar mode of failure, but shorter failure times, as shown in Figure 2. Specifically, under maximal loads of 3500N, 4000N and 4500N the average time to failure obtained was 5.2±1.3 Mc, 3.0±0.8 Mc and 2.1±0.9 Mc, respectively.

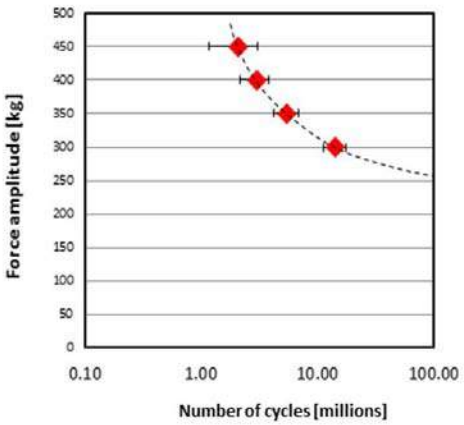

Figure 2. S-N curve of the NUsurface(R) Meniscus Implant.

Microscopic evaluation of the samples by ESEM showed that the surface prior to simulation was relatively smooth. Following the simulation, it became dominated by depressions and protrusions that occurred mainly in the middle portion of the superior articulating surface of the implant (Figure 3). The depressions varied in size and shape from small and round to broad and diffused. The inferior surface showed a much lower damage level compared to the superior surface, consisting of shallow pits that appeared infrequently on the surface. The deformation was not found to be homogenous over the surface. Specifically, the deformation inside the main axial load center tended to show no specific orientation while outside the main axial load center, a radial orientation of deformation was observed as well as tear generation. The tear damage that developed during the simulation demonstrated features distinctive of fatigue damage. Typically, the edges of the tear were uneven, likely because of gradual propagation of the tear. Characterization of the surface morphology (in the tear's inner walls) showed a rough and non-homogenous texture.

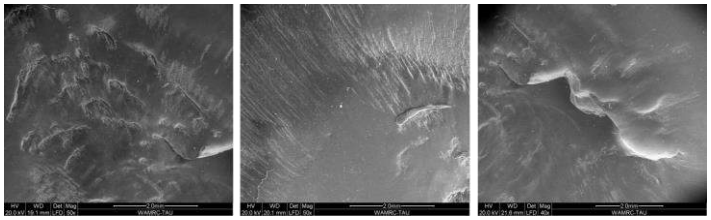

Figure 3. Surface characterization of the superior articulating surface showing the deformation at the main axial load center (Left), outside the center (Center) and the development of the tear damage (Right)

DISCUSSION

Uniaxial fatigue testing of a novel composite PCU/UHMWPE medial meniscus implant was performed. The S-N curve results show that under forces representing the expected activities of implanted patients (3 to 4 times body weight), the resistance of the device is at least 15 Mc.

The ISO-14243-3 standard is currently the most widely used standard for long-term fatigue of total knee replacement devices, and with the absence of any standard for meniscus implants, it serves as the best reference for their testing. Employing this standard also adds robustness by the introduction of an additional safety factor: the knee loads that fall on the medial knee compartment comprise roughly only 60-70% of the total knee load.

While in theory, this endurance limit represents a stress level below which the material does not fail and can be cycled infinitely, additional factors such as wear, weren't simulated in this study, and can contribute to earlier failure of the implant. Notwithstanding this, the meniscus implant has proven to be particularly resilient to fatigue, even at loads higher than those dictated by ISO-14243-3, which is a significant improvement compared to other materials that have been tested as meniscus replacement materials.

MILD TRAUMATIC BRAIN INJURY RESULTED IN INCREASED AQUAPORIN-4 EXPRESSION – RELEVANCE TO POST INJURY EDEMA

INTRODUCTION

Traumatic brain injury (TBI) is characterized by damage to the brain caused by an external force such as a blow or jolt to the head. Mild TBI (mTBI), as opposed to moderate or severe TBI, is the most common type seen in both civilian and military settings [1]. Most studies on mTBI are focused on how initial cell and tissue-level deformation alters overall neuronal and glial function [2].

Cerebral edema is one of the major factors that leads to high mortality and morbidity in TBI patients. Unfortunately, the mechanisms for immediate cell swelling and potential preventative treatments are not well studied. The discovery of aquaporins provides a basis for the understanding of water transport in the brain and could lead to the development of new treatment methods for injury-induced edema.

Aquaporin-4 (AQP4) is a highly permeable water channel largely expressed in astrocytes of mammalian brains [3,4]. These water channels play a critical role in the water uptake of astrocytes following injury. Since its initial detection in the brain, various studies have shown an upregulation of AQP4 following brain injury, however, the mechanistic link between the regulation of AQP4 and cytotoxic edema has been poorly researched. [5,6]. To better understand this link we have engineered a three-dimensional astrocyte-construct that can be subjected to a high-speed mechanical stretch. This construct provided a platform to investigate the effect of a mTBI on astrocyte vitality and swelling. We hypothesized that TBI-mediated cerebral edema occurs via an aquaporin-4 (AQP4)-mediated mechanism leading to increased intracellular volume and subsequent cell death.

Acetazolamide (AZA) is an antiepileptic drug that has been proven to inhibit AQP4 [7] as well as reduce injury-induced brain edema and neuronal death in vivo [8]. The most significant increase in cell vitality was seen when AZA was added 15 minutes before stretch of the construct. Following the vitality assay, we investigated the effect stretch and AQP4 inhibition had on cell swelling. To our knowledge, our study is the first time AZA has been used to mitigate the effects of TBI injury in vitro.

METHODS

Fabrication of a 3D strain model. A cell stretching device was designed and machined to have control over the stretch and stretch rate. There were two main components to this setup: the cell chamber and the cell stretching device/control system (Fig. 1A). A stretchable cell chamber was made by mounting a 10 mm tall piece of silicon tubing on top of an 8cm x 7cm, 0.010" polydimethylsiloxane (PDMS)-membrane.).

Cell Culture and mTBI Stretch. Preliminary culture of C8D1A mouse-derived astrocyte cells (ATCC® CRL2541™) was done in

Figure 1. (a) Top and (b) side view of an elastic chamber mounted on top of the high speed stretcher device (c) Representative SEM image of tissue-engineered astrocyte construct.

standard feed media (Dulbecco's Modified Eagle Medium (DMEM) and 10% fetal bovine serum (FBS)) at 37°C and 5% CO_2. To prepare samples for mTBI stretch, a layer of Corning Matrigel Basement Membrane Matrix was evenly spread within the stretchable chamber and set in the 37°C incubator for 20 minutes to polymerize. 350,000 – 500,000 cells were then removed from preliminary culture, resuspended in feed media/2.5% Matrigel and seeded on top of the polymerized layer of Matrigel to create a three-dimensional culture. The tissue-engineered astrocyte construct was incubate at 37°C for 24 hours to allow proper time for cell attachment to the Matrigel before being subjected to 10% stretch. After stretch, the astrocytes were isolated from the Matrigel using Corning Cell Recovery Solution before performing proteomic analysis.

AQP4 Inhibition. AQP4 expression was inhibited with 20 μM Acetazolamide (AZA) (Sigma-Aldrich, St. Louis, MO). AZA was put into contact with the cells (via feed media) at the time of seeding, 15 minutes before stretch, or immediately after stretch.

Cell Vitality. Astrocyte vitality following a mTBI was assessed using a commercially available cytotoxicity assay (LIVE/DEAD Cell Vitality Assay Kit, C12-Resazurin/SYTOX Green; Molecular Probes, Eugene OR) and flow cytometry. Twenty-four hours following deformation the tissue-engineered construct was rinsed 3 times with cold PBS. The cells were then isolated from the Matrigel with the use of Corning Cell Recovery Solution. After isolation from the Matrigel, astrocytes were resuspended in PBS and incubated with 50 μM C12-resazurin 1 μM SYTOX Green for 30 minutes at 37°C. Stained samples were then analyzed via flow cytometry. The percentage of live, injured, and dead cells present following a mTBI were normalized to the control (0% stretch, No AZA) and presented.

S100B and AQP4 Immunostaining. Astrocyte/Matrigel samples were immunostained with antibodies against DAPI, AQP4 and GAPDH. Briefly, twenty-four hours after injury, the samples were rinsed with 1X PBS and fixed in 4% paraformaldehyde. 20% goat serum was then pipetted onto the cells, for blocking, and incubated at 37°C for 1 hour. Next, anti-AQP4 antibody and anti-S100B antibody (abcam, ab52642) supplemented with 2% goat serum, were pipetted

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

onto the gels and allowed to sit overnight in 4°C. Secondary antibody solution comprised of DAPI, donkey anti-rabbit 594 and donkey anti-mouse 488. Secondary stain was left on and protected from light for 1-2 hours. The cells were imaged using a Nikon Eclipse epifluorescent microscopy at a 20X magnification. Fluorescent images were analyzed semi-quantitatively with the use of ImageJ. Results were presented as a ratio of the number of nuclei to the antibodies coverage area.

Western Blotting of AQP4. After isolation from Matrigel, the cells were lysed, centrifuged at max speed 4°C and cell debris was withdrawn. A BCA protein assay was done on the supernatant. 40 µg/lane of protein was loaded onto a TGX gel and subsequently transferred onto PVDF (polyvinyl difluoride) membrane. The membrane was probed with Rabbit anti-AQP4 antibody (abcam, ab46182) and Mouse anti-GAPDH (abcam, ab8245) and visualized with a Li-Cor scanner. GAPDH was used as the gel loading control.

Calcein Imaging. While still attached to the Matrigel, the cells were washed with PBS and stained with Calcein for 45 minutes. The cells were then incubated with Tyrode's buffer and stretched. Immediately after stretch, the cells were analyzed under a multi-photon microscope. A 40x (0.80 NA) water immersion lens with a 2x additional zoom was used to image the astrocytes. Excitation wavelength was 980 nm and emission was collected at 525/50 nm. Z-stack images with 1 µm z-height were acquired every 10 minutes for 1 hour for volumetric analysis. Cell volumes were assessed by importing a z-stack into a custom MATLAB script.

Statistical Analysis. Data was first tested for normality using the Shapiro-Wilk test. Statistical analysis was carried out by two-way analysis of variance (ANOVA) for normal data. Non-parametric analysis was used for data that was not normally distributed. SigmaPlot software was used for the statistical analysis. Values were expressed as mean ± standard error (SEM). A p value less than 0.05 was considered significant

RESULTS

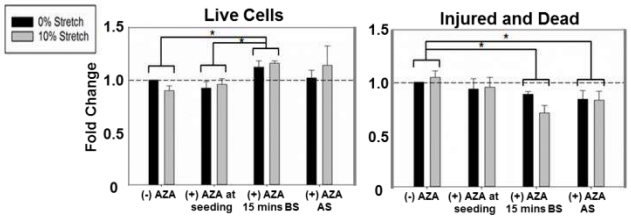

Figure 2. Cell Viability. Fold change in percentage of (a) live cells and (b) injured/dead

The tissue-engineered astrocyte construct was subjected to a mild TBI as described in the experimental section of this paper. The cell viability assay was aimed at finding the most effective time to add AZA to the tissue-engineered construct to best mitigate the effects of a mTBI. The key findings were that: (1) the 10% stretch did not have a significant effect on cell viability, (2) the addition of AZA increased the number of live cells and decreased the number of injured and dead cells in all conditions except the control, and (3) adding AZA 15 minutes before stretch resulted in the highest average number of live cells and lowest number of injured and dead cells.

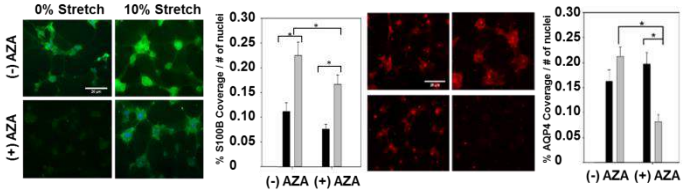

Figure 3. (a) S100B and (b) AQP4 immunofluorescent images and semi-quantification

Immunocytochemistry (ICC) was done on the tissue-engineered constructs to detect the presence of S100B, a marker for cell injury and AQP4 (Fig. 3). Semi-quantitative analysis of the ICC images showed that subjecting the cells to a mTBI significantly increased the expression of S100B and AQP4 following a 10 percent stretch, and a reduction of this expression when AZA was added. AQP4 western blots also showed that TBI resulted in a significant increase of expression.

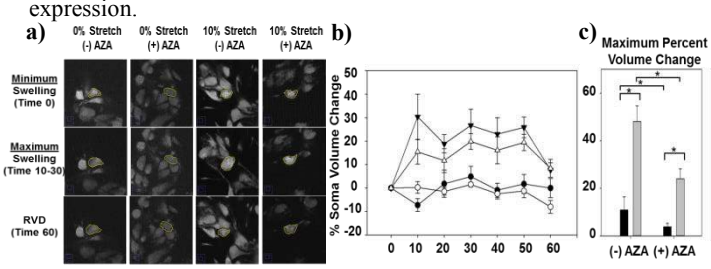

Figure 4. (a) Multi-photon images (b) Percent Soma Volume Change in the 60 minutes following stretch, and (c) Maximum Percent Volume Increase achieved by the cell.

A z stack of the cells were taken once every ten minutes for one hour to calculate the cells volume. Figure 4b shows the percent the soma volume changed from time 0. Key findings include: The percent volume change remained higher for cells that were injured, compared to cells that were not injured, for the entire hour following the stretch; adding AZA to the cells 15 minutes before they were stretched decreased the average volume increase from time 0 at every time point except at the 60 minute mark; and 60 minutes after stretch, the cells showed a drastic decrease in cell volume from the previous time point, this shrinkage reflects the cells regulatory volume decrease. Because the time point at which maximum swelling was observed could have been altered due to the amount of time it took to load the sample onto the microscope stage, we also reported the maximum cell volume increase for each condition, regardless of the time it was observed, to clearly see how stretch and the addition of AZA effected cell swelling.

Figure 4c shows the average maximum percent volume increase among cells in each condition. Cells that were stretched had a significantly higher maximum volume increase than cells that were not stretched (about 5 times higher) and the addition of AZA to the construct significantly decreased the percentage cells increased in size approximately in half.

DISCUSSION

The goal of this study was to better understand the link between the regulation of AQP4 and TBI-induced cytotoxic edema. Several studies have concluded that AQP4 expression increases following a TBI and/or observed decreased cellular edema and reduced mortality in AQP4-deficient mice. Our study presents an in vitro brain tissue model in which we (a) observed an increased expression in AQP4 following a mTBI, (b) observed an increase in astrocyte soma volume following the mTBI, and (c) administered the AQP4 inhibitory drug, AZA, prior to a mTBI and observed a less significant cell volume increase following the injury. Because this drug proved to be effective in pre-TBI administration, there is a possibility we can administer it to military personnel prior to combat and immediately attack the secondary injuries caused by the TBI. To our knowledge, our study is the first to observe astrocyte swelling in vitro following a mechanically induced TBI via imaging.

INTRODUCTION

Osteoarthritis (OA) is one of the most common musculoskeletal diseases, characterized by joint pain and swelling, lack of mobility and resultant loss of life quality. Strong motivations to study the mechanics of human articular cartilage include the lack of understanding of the early stages of OA and the limited viable treatment options for those affected by the disease. OA appears to be a mechanically driven process that occurs over a relatively long period of time. Understanding the transition from normal function to mechanical fatigue may provide insight into when cartilage is no longer functionally stable, what activities may result in higher incidences of damage and if mechanical fatigue serves as a precursor for OA.

In daily living articular cartilage sustains a variety of loading magnitudes and frequencies depending on the activity performed and joints involved. Healthy joints during light activities typically undergo loadings resulting in stresses ranging from 1 to 6 MPa [1]. Light activities are typically more frequent than high impact activities, but some common tasks can generate significant loads on cartilage. For example, non-uniform contact stresses reached up to 18 MPa in an instrumented hip while an individual simply rose to stand from a seated position in a standard chair [2].

In this study, we seek to probe the transition from normal mechanical compaction to functional deterioration (fatigue) during a range of physiologically motivated loadings. We hypothesize that with both increased loading magnitude and number of loading cycles, cartilage will mechanically soften during loading and will reach hydrostatic equilibrium faster (during creep displacement under constant load) due to fatigue.

METHODS

We prepared cartilage samples (3 mm Ø, full thickness) from the knees of six male donors from 22 to 34 years of age (M=27.7) from the Musculoskeletal Transplant Foundation. We tested location-matched samples in unconfined compression (Bose LM1, Eden Prairie, MN with a Futek load cell, Irvine, CA) under a range of loading conditions motivated by those seen *in vivo* and beyond (Table 1). Load magnitudes approximated walking, extreme weightlifting, and injury, while frequencies approximated walking and running (six total combinations, C1-C6). We tested samples from each donor and each combination of magnitude and frequency (36 total tests) with the following protocol, repeated three times after preconditioning: recovery for 2k sec, force ramp to peak force, creep displacement for 3.6k sec, recovery for 2k sec, and force controlled cyclic loading for 12k cycles. We measured sample thickness prior to loading and after every 12k cycles of loading. Throughout testing samples were bathed in PBS (0.01 M, pH 7.4) with protease inhibitors at 37°C.

Table 1: Test conditions C1-C6.

		1.44 Hz	2.88 Hz
Walking	**20 N (2.83 MPa)**	C1	C2
Weightlifting	**120 N (17.0 MPa)**	C3	C4
Injury	**200 N (28.3 MPa)**	C5	C6

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

We plotted first Piola-Kirchhoff vs. stretch (during load ramp to creep test) and creep displacement vs. time, both as a function of cyclic loading, for each test condition using MATLAB (The MathWorks, Natick, MA). Additionally we calculated effective stiffness (force/displacement near peak load), time to equilibrium during creep and sample thickness, all as a function of cyclic loading. To determine the significance of test conditions on mechanical responses, we conducted a repeated measures ANOVA (IBM SPSS Statistics 23). To probe the mechanisms underlying changes in the mechanical response, we studied images from histology and confocal microscopy via Second Harmonic Generation (SHG).

RESULTS

Under low load magnitudes the tissues generally stiffened with increasing cycles while at relatively high loads the tissues softened. Figure 1 shows representative creep and stress-stretch responses for Donor 1 under C1 loading conditions.

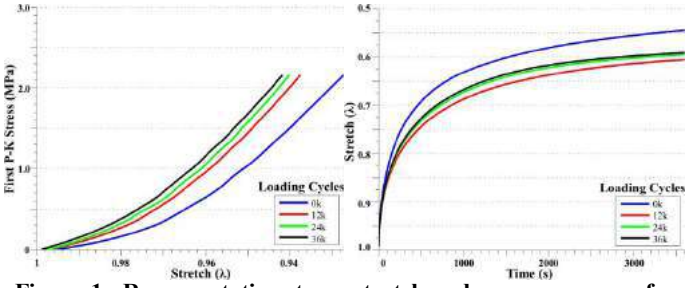

Figure 1: Representative stress-stretch and creep responses for Donor 1 under C1 loading (20 N force at 1.44 Hz).

Table 2, results from the repeated measures ANOVA, shows significant changes in effective stiffness and sample thicknesses among loading magnitudes but not frequencies.

Table 2: *p*-values (* $p<0.05$) from repeated measures ANOVA.

	Cycles	Force (N)	Freq. (Hz)
Change in Effective Stiffness	**0 – 12k**	0.000*	0.464
	0 – 24k	0.000*	0.707
	0 – 36k	0.000*	0.459
Change in Time to Equilibrium	**0 – 12k**	0.360	0.084
	0 – 24k	0.236	0.130
	0 – 36k	0.818	0.535
Change in Sample Thickness	**0 – 12k**	0.000*	0.951
	0 – 24k	0.000*	0.606
	0 – 36k	0.000*	0.894

There were statistically significant correlations between the magnitude of loading and all changes in effective stiffness and additionally the changes in sample thicknesses. Additionally there was a significant difference between loading with the low force magnitude (walking) and both of the larger applied forces (weightlifting and injury) for all changes in stiffness. There was no statistically significant correlation between the loading frequencies and changes to any of our mechanical metrics. Time to equilibrium is longest with the lowest force magnitude and decreases with larger forces. All samples' thicknesses decreased with increased number of loading cycles and a greater percentage of the initial height is recovered under loading with the lowest force. SHG images showed that the collagen network of cartilage cracks and rearranges under loading approximating weightlifting and injury. Frequency of loading has no visible effect on the collagen network.

DISCUSSION

Compressive stiffness has been correlated with the concentration of chemical constituents of cartilage, particularly glycosaminoglycans (GAGs) [3]. When cartilage is compressed, negatively charged proteoglycans (PG), held in place by a network of collagen, are pushed together, thus increasing repulsive forces resulting in greater stiffness. Stiffness generally increased with increasing cycles of loading, significantly after the first stage and more slowly with each increasing stage, cf. Fig. 1. Softening did occur in some test conditions. We attribute loss of mechanical function under cyclic loading to disruption in the collagen network as a result of mechanical fatigue. This softening of cartilage could be the first detectable sign of cartilage degradation [4].

Time to equilibrium during creep testing can be used to understand the mechanical integrity of the tissue. The tissue will reach thermomechanical equilibrium once all the unbound water is pressed out. The time to equilibrium is not affected by the loading conditions but the total stretch at equilibrium generally reduces after each sequence of 12k loading cycles, cf. Fig. 1, due either to compaction (less initial fluid retained) or fatigue (disruption of extra cellular matrix).

To investigate the mechanisms of (recoverable) mechanical compaction versus detrimental fatigue, we measured the changes in tissue thickness during testing and once again after 24 hrs of recovery in the PBS solution at 37°C. We attributed changes in sample thickness after 24 hrs of recovery to fatigue effects and not compaction. In every loading condition, some fatigue appeared to have been present.

We propose that cyclic loading up to 36k cycles disrupts the collagen network but does not allow sufficient time for the PG content to be diminished. In this scenario the permeability of the tissue is relatively unchanged (same total PG content) while the compressibility is altered (disrupted interaction between PG and collagen). These effects may not be as dramatic *in vivo* in light of the supporting subchondral bone and attached cartilage. In the future we aim to apply such results to better understand the mechanisms of cartilage degeneration and to inform computational models of tissue remodeling or damage, eg. [5].

INTRODUCTION

Approximately 1 in 2000 children born in the United States has only one functioning ventricle. Surgical intervention is needed within several days of birth for survival. The Fontan procedure is a multi-step surgical operation that reconnects the systemic and pulmonary circulations to restore a series circulation using the patient's single working ventricle. However, due to increased load on the single ventricle, some patients require bridge-to-recovery or bridge-to-transplant ventricular support. Therefore, ventricular assist devices (VAD) have been used as a means of artificial, mechanical support for single ventricle patients.

Nonetheless, survival rates of VAD patients with congenital heart defects has been observed to be significantly lower than patients without. Major physiological differences can also exist between pulsatile and continuous flow VAD support for single ventricle patients. This research aims to understand the physiological response of pulmonary shunted single ventricle patients to VAD treatment and identify major resulting physiological differences between the use of pulsatile and continuous flow VADs.

METHODS

A lumped-parameter model (LPM) based on previous work [1] was used to computationally model the cardiovascular system. To simulate a ventricular assist scenario, the VAD inflow and outflow cannulas were connected to the ventricle and aorta respectively. A pulmonary shunt was represented by a connection between the aorta and pulmonary arteries. The pressure drop across the shunt was calculated using a model by Migliavacca et al. [2]. To accurately simulate ventricular pressures during suction, a passive pressure-volume relationship for the negative pressure region was created using results from Nikolić et al. [3].

Clinical data from six pulmonary shunted single ventricle patients ($BSA \sim 0.3$) was obtained from the Great Ormond Street Hospital, Medical University of South Carolina, and University of Michigan. For the LPM simulations to accurately replicate each patient's physiology uniquely, the LPM element values were tuned for each patient separately with the goal of achieving pre-VAD simulation results within ±10% of the patient's clinical measurements. Once tuning was complete, ventricular contractility was set to zero to simulate heart failure.

Mathematical models were created to represent VADs being used in the simulations. These models were created from either experimental data or manufacturer specifications. The pulsatile flow VAD model describes the Berlin Heart, which is pneumatically driven by an external air compressor to create a pressure waveform. Berlin Heart sizes of 10, 25, and 50 mL were considered in this study. The continuous flow VADs used quadratic and linear trendlines to relate pressure and volumetric flowrate data for the HeartWare (centrifugal) and HeartMate II (axial) VADs respectively.

Since a VAD may induce suction on the ventricle, a model was needed to simulate the effective resistance, R_{SUC} (mmHg•s/mL), resulting from ventricular suction effects. Several existing models were tested but the accuracy of each was insufficient. We developed a new model using experimental ventricular suction data extracted from several prior studies. The new model is linearly related to ventricular pressure, P_{SV}, and uses 0 mmHg as the threshold pressure, P_{TH}. This new model is:

$$R_{SUC} = \begin{cases} 0 & if\ P_{SV} \geq P_{TH} \\ -0.01885(P_{SV} - P_{TH}) & if\ P_{SV} < P_{TH} \end{cases} \quad (1)$$

All simulations were run with a fourth order Runge-Kutta algorithm using FORTRAN, and data were analyzed using MATLAB.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Data from the last cardiac cycle (where the simulation has reached periodicity) were used in the analyses.

Two sets of simulations were done. One set used 6 mm inner diameter (ID) cannulas, and the second used 12 mm ID. The 6 mm ID is considered age appropriate for small children. For the Berlin Heart, variable inputs were the device's "heart rate" and size. For continuous flow VADs, the only variable input was motor RPM. The simulations were intended to emulate clinical use of VADs in pulmonary shunted single ventricle patients. Therefore, the simulation settings used for the VADs reflect this as much as possible. This included the peak VAD ejection pressure (desired mean aortic pressure + 100 mmHg), filling pressure (-40 mmHg), and diastolic filling ratio (60%).

RESULTS & DISCUSSION

The pre-VAD LPM results matched all clinical data to within 10% in all six patients except for atrial pressure (up to ±30%) in three patients and pulmonary flow (up to ±20%) in two patients.

For a pulsatile flow VAD, the ideal theoretical cardiac output (CO) is VAD stroke volume (SV) times VAD heart rate (HR). The ideal CO was achieved for the 10 mL Berlin Heart in all simulations. However, a reduction in CO occurred at higher heart rates for the 25 mL and 50 mL Berlin Heart (Figure 1).

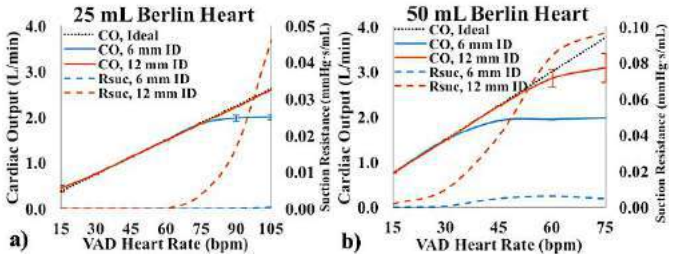

Figure 1: Cohort mean cardiac output and suction resistance vs heart rate for the a) 25 mL and b) 50 mL Berlin Heart.

For both the 25 and 50 mL Berlin Heart, the 12 mm ID cannula resulted in greater CO than the 6 mm ID at higher heart rates. The 12 mm ID resulted in the ideal CO at all heart rates for the 25 mL size. Since doubling the diameter decreased the resistance by approximately a factor of 32 as $R \propto ID^{-4}$, the higher CO for the 12 mm ID cannula may be attributed to its lower resistance, which allows more flow.

The departure in CO from ideal levels in the 25 and 50 mL size Berlin Heart can be examined more closely by looking at the filling and ejection of blood. To attain ideal CO, the Berlin Heart must both fill and eject blood completely in each cardiac cycle. In other words, ideal CO for a 50 mL size would occur only when minimum and maximum volumes are 0 and 50 mL respectively. The minimum and maximum volumes of blood in the 50 mL size for both cannula IDs is shown in Figure 2.

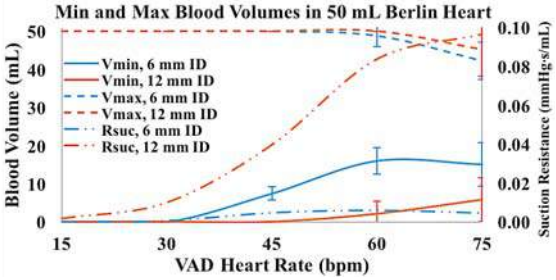

Figure 2: Cohort mean minimum and maximum volumes and suction resistance for the 50 mL Berlin Heart.

A minimum blood volume greater than 0 mL represents incomplete ejection of blood. This reduces stroke volume of the VAD and consequently CO. Figure 2 shows that incomplete ejection increased with heart rate for both cannulas. However, since incomplete ejection occurred with the 6 mm ID cannula earlier than with the 12 mm ID, this explains why the 6 mm ID produced a drop in CO at a lower heart rate (Figure 1). Note that incomplete ejection occurred before incomplete filling for both cannulas. Interestingly, ventricular suction did not have a major impact on filling. The maximum volume decreased from 50 mL to only 42.2 and 45.2 mL for the 6 and 12 mm ID cannulas respectively at the highest heart rate. The cause of incomplete filling may be a combination of ventricular suction effects and reduced VAD diastolic time. This may justify clinical use of the 50 mL size only up to 60 bpm.

For a continuous flow VAD, CO is a function of motor RPM only. The CO for both VADs increases steadily as motor RPM increases (Figure 3).

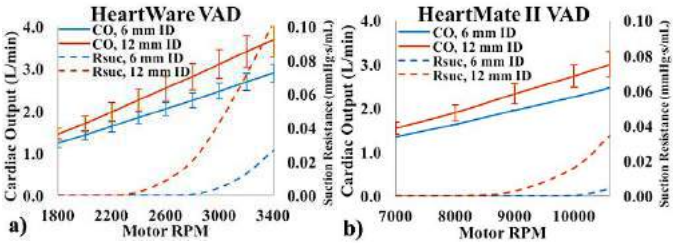

Figure 3: Cohort mean cardiac outputs vs motor RPM for a) HeartWare and b) HeartMate II VADs.

Since current clinical practice desires to avoid ventricular suction lest heart tissue be damaged, the actual "clinical" CO that could be practically achieved (scenarios with zero R_{SUC}, Figures 1 & 3) is lower than the maximum CO possible. With this constraint, the "clinical" mean CO for the 6 mm ID cannula were 1.85, 2.05, and 1.95 L/min for the Berlin Heart, HeartWare, and HeartMate II VADs respectively. For the 12 mm ID, the mean CO were 1.49, 1.97, and 1.90 L/min for the Berlin Heart, HeartWare, and HeartMate II VADs respectively. For both cannula IDs, the continuous flow VADs enabled greater CO than the pulsatile flow VAD, which is consistent with clinical observations. Ventricular suction began at lower heart rates or motor RPMs with the larger 12 mm ID (Figures 1 & 3). The larger ID cannula with the lower cannula resistance allows the VAD to more quickly draw blood from the ventricle to the point of creating suction.

There remains a need for future work on models for ventricular suction resistance and the negative pressure-volume passive curve. The majority of existing work focuses on animal experiments, from which it is unknown how well these translate to humans. In summary, our results reveal several underlying mechanisms affecting VAD output in a mechanically assisted, pulmonary shunted single ventricle circulation and that continuous flow VADs produce higher CO (both with and without a suction constraint) than pulsatile flow VADs, which corroborates clinical observations.

ACKNOWLEDGEMENTS

This work was supported by the Leducq Foundation as part of the Transatlantic Network of Excellence for Cardiovascular Research. We would like to thank the Department of Mechanical Engineering at Clemson University for funding support and Fei He for preliminary work on the ventricular suction model.

INTRODUCTION

Today's biomedical engineers are at the forefront of innovative technological solutions to global health problems. The National Institute for Biomedical Imaging and Bioengineering supports the adoption of interdisciplinary, team-based approaches to STEM education that are attentive to the practical value of new knowledge and focus on innovative technologies [1]. To maintain America's position as a world leader in the education of emerging engineers, universities must promote multi-disciplinary teamwork among students in order to produce higher quality results and added value through collaboration and new opportunities [2].

Since 1998, the lead author has received support through the NSF Research to Aid Persons with Disabilities (RAPD) program (now GARDE) to fund undergraduate senior design projects in the area of assistive technologies. Teams of students work with clinicians, therapists, and disabled individuals from special care facilities such as the United Cerebral Palsy of Greater Birmingham and the Bell Center of Homewood. Over the years, students have designed, constructed and delivered various prototype devices that meet the special needs of children and adults with disabilities. While none of these projects led to commercialized products, the efforts have benefited both the students and the disabled community, as observed by others [3].

With the receipt of an NIH R25 award in 2013, a working partnership was formed with the UAB Collat School of Business to bring engineering and business undergraduates together to foster commercialization strategies around new medical device designs. Project scopes were also expanded to include other medical device needs from pediatric neurosurgery, medical simulation, and orthopedic surgery, among others. These capstone projects produced numerous intellectual property (IP) disclosures, four provisional patents and one Patent Cooperation Treaty (PCT) filing. Unfortunately, lack of a viable environment to continue research and development of these projects beyond the end of the capstone activities has hindered commercialization.

The UAB Master of Engineering (MEng) in Design and Commercialization, launched in Fall 2015, provides an opportunity to address these needs. Multi-disciplinary teams of engineering and business graduate students and faculty engage in Innovation-Commercialization (IC) projects and course work that take promising innovative ideas through the R&D process to create marketable devices and start new businesses. The current manuscript describes the curriculum, which includes engineering and business courses, along with overviews of some new courses specifically developed for the MEng program. The purpose of this curriculum is to empower our students to work well in multi-disciplinary teams while shaping them to be successful innovators.

METHODS

In the MEng, engineering students engage in Innovation-Commercialization (IC) projects and take structured coursework designed to take innovative ideas through the research and development (R&D) process to create marketable devices. The curriculum (Fig. 1) contains 24 credit hours in engineering and 12 credit hours in the Master of Business Administration (MBA) program, which earn students the MEng degree as well as a Graduate Certificate in Technology Commercialization and Entrepreneurship from the UAB Collat School of Business.

New courses developed specifically for the MEng program include BME 630, Engineering Design and Commercialization, and EGR 693/694/695, Innovation-Commercialization Project I/II/III. In BME

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

630, engineering students select their IC projects and begin the R&D processes with client meetings to review the problem and need statement. They perform "deep dives" into the project background, market research, and explore the intellectual property/patent landscape in their design space. The students are incorporated together as "engineers" in a "virtual company" and deliver weekly memos and prototypes reflecting progress. The students receive prompt feedback from the course instructor, or "CEO", for rapid implementation. IC projects adopted this year include a recumbent patient weighing device and a hemostasis tool, two past capstone projects, as well as two projects from external sources. Formal presentations are held periodically for faculty in engineering and business, as well as patent attorneys in UAB's Institute for Innovation and Entrepreneurship (IIE), to offer feedback throughout the development and commercialization processes.

EGR 693 focuses on hands-on "maker activities" that allow students to build competency in prototyping. Students review Computer Aided Drawing (CAD) and are tasked to model a beam with a through-hole in the shape of any card suit (heart, spade, diamond, or club). Students first make their "beam with a hole" by hand machining. As the card suits contain sharp internal corners, students experience the limitations of manual approaches. Next, they create their beam designs using 3D printers as well as Computer Numerical Control (CNC) machining, where they are introduced to G-code and CNC mills. Students gain experience with contemporary electronics by integrating breadboards Arduino (Arduino, LLC, Cambridge, MA) and Raspberry Pi (Adafruit, New York, NY), as well as soldering printed circuit boards (PCBs). Students are provided with equipment to encourage further investigations outside of class. By course end, the student engineers know how to prototype and recognize which advanced methods are required during the process.

ME 677, Systems Engineering (taken in the fall), covers project life cycles, system hierarchy, risk and cost analyses, engineering alternatives and systems processes. Through the spring and summer project courses, EGR 694/695, the MEng students will implement the tools gained from EGR 693 to develop a series of improved prototypes. EE 605, Embedded Systems (spring), focuses on embedded electrical systems design and rapid prototyping. MSE 610, Advanced Materials and Manufacturing (summer), introduces students to modern manufacturing with application to their projects. MEng students are also required to take two graduate level engineering electives, which may include internships with partner organizations.

In the fall semester, the MEng students join with MBA students in MBA 681, Idea to IPO, which addresses how to take a device from the benchtop to the marketplace. MBA 690, Leading Innovation (fall), introduces Lean Startup principles, building mission and vision, and understanding business pivot points. MBA 673, Technology-based Venture Planning (spring), educates students on business plans, capital raising, and competitive analysis. In MBA 691, i2i Entrepreneur Accelerator, teams will be coached through SPARK, a mentoring program organized by the Birmingham Business Alliance to help start-ups succeed at pitching their companies at the Alabama Launchpad business plan competition. Winners gain financial support to launch a start-up company at Innovation Depot, the largest and most successful business technology incubator in the Southeast. As such, we have created an ecosystem that may allow student teams to successfully take their technologies to commercial viability (Fig. 2).

RESULTS AND DISCUSSION

The MEng is new and the first cohort of students is currently enrolled; therefore, no assessment data yet exists regarding student or program success. Targeted program outcomes include the number and quality of products completed, as well as the progress made towards commercialization, such as IP disclosures and patents filed. An important expected outcome is that upon program completion, students will gain competitive positions in industry, launch new start-ups, or be accepted into other graduate programs focusing on innovation and entrepreneurship. One promising early outcome: co-author Ophelia Johnson won a Marshall Scholarship to pursue a graduate

Figure 1: MEng curriculum

Figure 2. Flowchart of MEng activities towards commercialization

degree in medical device design and entrepreneurship at Imperial College London, which suggests our MEng graduates will be competitive at an international level.

As recommended by the National Research Council [4], the MEng program helps students learn through cohesive and engaging clinical and industrial experiences. These experiential/case-centered learning activities teach critical thinking and integrate new knowledge with prior learning. These activities also facilitate development of metacognitive skills, including planning the approach, monitoring comprehension, and evaluating progress towards completion [5].

In the MEng, students engage with professional engineers led by the senior author. The goal is to inspire and encourage the students, so they will gain confidence and develop skills necessary to provide innovative solutions to engineering problems. Our goals are consistent with Ramirez [6], who reports that successful mentoring ensures that students are content with their majors and reach their academic potential, leading them to pursue career paths and advanced study that they may not have otherwise contemplated pursuing.

UNINJURED SUPRASPINATUS TENDONS IN RODENTS DO NOT EXHIBIT DIFFERENT MATERIAL PROPERTIES ACROSS SEX

Kelsey A. Robinson, Adam M. Pardes, Benjamin R. Freedman, Louis J. Soslowsky

McKay Orthopaedic Research Laboratory
University of Pennsylvania
Philadelphia, PA, USA

INTRODUCTION

Injuries to the rotator cuff are common causes of disability among otherwise healthy individuals, especially in an aging population [1]. Although the exact prevalence of rotator cuff tears has not been established, known risk factors include increasing age [2], hypercholesterolemia [3], smoking [4], and family history [5]. While the relationship between sex and rotator cuff tears is debated [6, 7, 8, 9], gender is known to be a risk factor for other soft tissue injuries. For example, 84% of Achilles ruptures occur in men [10], while ACL injuries are more common in women [11]. Previously, we demonstrated that uninjured male and female Achilles tendons in rodents have different mechanical properties, which may partially explain the disproportionate clinical incidence of spontaneous Achilles ruptures in men [12]. Unfortunately, this mechanical property information has yet to be established for the supraspinatus tendon. Therefore, the objective of this study was to determine the mechanical properties of uninjured supraspinatus tendons in male, female, and ovariectomized (OVX) rats. OVX rats were used to mimic females with attenuated sex hormone levels. We hypothesized that the supraspinatus tendon of female and OVX rats would exhibit decreased cross-sectional area but equal mechanical properties to male supraspinatus tendons.

METHODS

Shoulders were randomized and harvested from 36 age-matched adult male (n=12), female (n=12), and OVX (6-weeks after OVX) (n=12) Sprague-Dawley rats. The supraspinatus tendon and humerus were fine dissected and Verhoeff's stain lines were placed at the bony insertion site and 8 mm proximally. Tendon cross-sectional area was measured with a custom laser device [13]. Humeri were then potted in PMMA, and cyanoacrylate was used to secure the tendon between two pieces of sandpaper leaving an 8mm gage length. A custom fixture was used to secure the potted samples in an Instron ElectroPuls E3000 affixed with a 250 N load cell. Tendons were submerged in a 1x 37°C PBS bath and underwent ramp to failure testing at 0.1% strain/sec. Using the captured load-displacement data, quasi-static mechanical properties were computed. A bilinear fit was applied to the force-displacement curve to delineate between toe and linear regions of the loading response. Researchers were blinded to animal groups during mechanical testing and data analysis. Comparisons between groups were made with one-way ANOVAs and significant relationships were evaluated with post-hoc t-tests with Bonferroni corrections (α=0.05/3).

RESULTS

The cross-sectional area of male supraspinatus tendons was significantly larger (30%) than female and OVX tendons (Figure 1). The maximum loads of male tendons were significantly larger (50%) than female and OVX tendons (Figure 2A). Stiffness in the linear region of the load-displacement curve was significantly larger (40%) in male tendons compared to female and OVX tendons (Figure 2C). The modulus of the toe region of the stress-strain curve was significantly smaller (30%) in male tendons compared to female and OVX tendons (Figure 2D). While changes in cross-sectional area and maximum loads were dramatic and expected, there were no significant differences in maximum stress, linear modulus, toe stiffness or transitional strain among groups (Figures 2B-E).

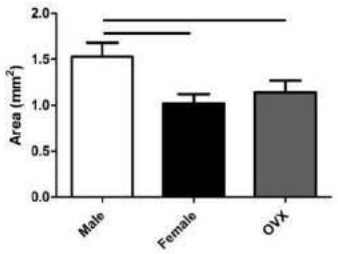

Figure 1: Cross-sectional area of male supraspinatus tendons is greater than that of female or OVX tendons. Data represented as mean and standard deviation. Significance bars indicate p<0.017.

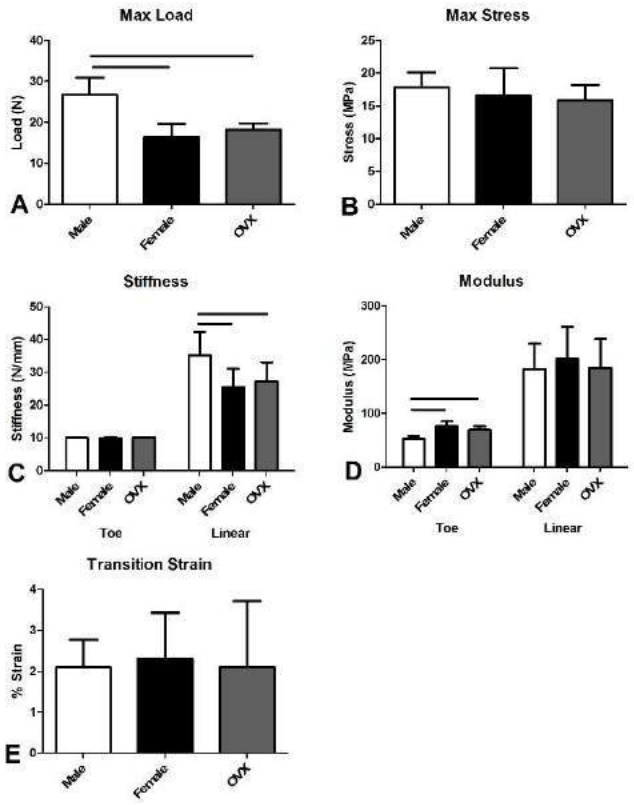

Figure 2: Mechanical properties of supraspinatus tendons. A. maximum load, B. maximum stress, C. stiffness, D. modulus, E. transition strain (between toe and linear regions of the force-displacement curve). Maximum load and stiffness in the linear region of the force displacement curve were significantly greater in male tendons, while toe modulus was significantly smaller than female and OVX tendons. Data represented as mean and standard deviation. Significance bars indicate p<0.017.

DISCUSSION

The objective of this study was to evaluate differences in the mechanical properties of supraspinatus tendons in male, female, and ovariectomized rats. In accordance with our first hypothesis, male tendons had increased cross-sectional area compared to female and OVX tendons. This increased cross-sectional area likely contributed to the greater maximum load in the male supraspinatus tendons. The increased linear stiffness in male tendons was also expected given the increased size of these tendons and maximum load. These results are in contrast to findings in the Achilles tendon, where there was no difference in linear stiffness across sex (Figure 3). The greater modulus of the toe region, but not the linear region, of female supraspinatus tendons suggests that sex may impact collagen fibril uncrimping [14]. Interestingly, this data is also in contrast to our previous results in the Achilles tendon, where the modulus of both the toe and linear regions of female tendons were greater than in male tendons (Figure 3). This Achilles tendon finding suggests that the protection from injury may, in part, be due to differences in the quality of this tendon tissue. The similar maximum stress, transitional strain, and linear modulus of the supraspinatus tendon among groups suggests that the mechanical properties of male tendons are generally similar to that of female and OVX tendons.

Unlike the Achilles tendon, which ruptures spontaneously clinically, supraspinatus injuries are typically degenerative [14, 15]. Therefore, it is possible that the similar supraspinatus tendon mechanical properties observed between sexes may result in degeneration occurring at a similar rate regardless of sex. This would support the lack of a clear relationship between gender and incidence of tears reported in the literature. One potential limitation of this study is the age of the animals, as differences in mechanical properties may be more prominent in aged animals, given that rotator cuff tears are most common in older adults.

Future work will investigate dynamic properties and histologic features of the supraspinatus tendon and muscle in order to further compare and contrast the mechanisms underlying tissue-specific sex differences.

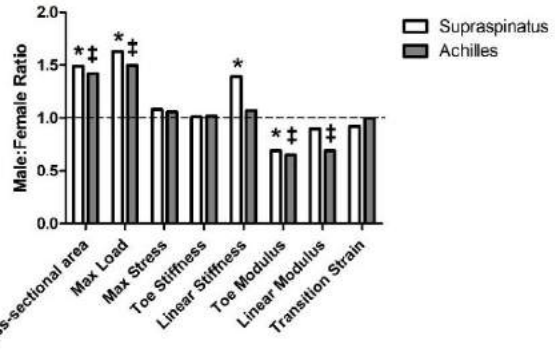

Figure 3: Tendon-specific sex differences in mechanical properties for supraspinatus and Achilles. Ratio of male to female means were taken for each parameter. Data that is significantly different between male and female supraspinatus or Achilles tendons are indicated by * and ‡, respectively. There were significant sex differences in cross-sectional area, maximum load, and toe modulus in both supraspinatus and Achilles tendons. Male supraspinatus tendons had increased linear stiffness and male Achilles tendons had decreased linear modulus compared to female tendons. No direct comparisons were made between supraspinatus and Achilles tendon property male:female ratio. Dotted line represents a ratio of 1.0.

INTRODUCTION

Important factors in the pathophysiology of the ascending thoracic aorta (ATA) are the biomechanical properties of the wall. Current literature has modeled the tissue with structurally motivated constitutive models that include fiber orientation and tortuosity. While an improvement over purely phenomenological material models, they are unable to consider the local effect of the collagen network on the non-collagenous matrix. Local variations in the collagen network can give rise to heterogeneity in the stress-state in the surrounding tissue which may influence structural and functional remodeling of the extracellular matrix through mechanosensitive pathways in the vascular smooth muscle cells (VSMCs). With this purpose, we have developed a micro-structural finite element model of ATA wall tissue including an experimentally derived collagen network embedded within the non-collagenous matrix. The fidelity of the model is shown by comparison to experimental uniaxial stress-strain data. Additionally, it is shown that the tissue stress, initially homogeneous, become heterogeneous due to collagen fiber recruitment. Finally, we show that the realignment of the network during loading creates "stress paths" which our model revealed to be the primary load bearing mechanism at high applied stretch.

METHODS

The ATA media is composed of repeating lamellar units (LU). Each LU is composed of an interlaminar space containing VSMCs and collagen networks surrounded by elastin lamellae (Fig. 1a). We modeled a single LU for the simulation of biomechanical response of the media to stretch. The symmetry in the radial (RAD) direction was utilized to create a representative volume element (RVE) modeling half of the LU. A custom nonlinear finite element code was utilized to simulate the mechanical response of the model. The collagen fibers were modeled with 1D bar elements embedded within the solid 3D elements representing the interlaminar space and elastic lamellae. For finite element mesh convergence, the RVE required 22,500 8-noded hexahedral elements (Fig. 1b). The collagen network was constructed with an isotropic voronoi tessellation. The initial network was then modified through a combination of affine transformation, fiber addition, and fiber deletion to yield a final network that was statistically matched with the experimentally measured network parameters[1] (two-sample chi-squared test $p \leq 0.05$ for fiber orientation distribution (OD)). Network parameters were areal density, fiber length, intersection density, and OD. The final network matches the experimental OD (Fig. 1c) and was composed of 860 fiber segments (Fig. 1d)

Collagen fibers were modeled using a bilinear constitutive response

$$\sigma = \begin{cases} 0 & \text{if } \lambda < \lambda_r \\ E_f(\lambda - \lambda_r) & \text{if } \lambda \geq \lambda_r \end{cases} \quad (1)$$

where λ is the fiber stretch, λ_r is the recruitment stretch of the fiber, and E_f the elastic modulus of the fiber. All fibers were modeled with the diameter of 3μm. The non-collagenous component of the model was composed of two constituents: the elastin lamellae and the interlaminar space. Both were modeled as one parameter isotropic incompressible neo-Hookean materials with the strain energy function

$$\Psi = \frac{\mu}{2}(I_1 - 3) \quad (2)$$

with μ the shear modulus and I_1 the first invariant of the right Cauchy-Green deformation tensor. The shear modulus of the EL was taken as 1000 kPa. The shear modulus of the IL (μ_{IL}), E_f, and λ_r were determined through regression against the experimental data.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The RVE was loaded to $\lambda = 1.5$ in the circumferential (CIRC) direction to simulate uniaxial test. The LONG faces and symmetry plane were on rollers. Stretch was applied over 400 load steps. Convergence studies were performed to ensure convergence in both mesh and loading. The CIRC component of the stress in the IL near the collagen network was gathered at each loadstep.

RESULTS

Regression against prior experimental data[2] provided the material parameters $\mu_{IL} = 170$ kPa, $E_f = 80$ MPa, and $\lambda_r = 1.25$. These parameters fall within experimentally reported ranges in the literature[2, 3]. The fit between the experimental and simulated stress-strain response was $R^2 = 0.996$ (Fig 1e).

The stress-state in the IL was homogenous under low stretches (less than λ_r) and heterogeneous at strains above the fiber recruitment stretch (Fig 2a,b). The coefficient of variance in the IL element stresses at $\lambda = 1.1$ was 0.1 while at $\lambda = 1.5$ was 1.25. Levene's test showed no difference in the standard deviation of the stress below $\lambda = 1.25$ but a significant difference above $\lambda = 1.25$ ($p < 0.01$). Fibers gradually began to bear load starting at $\lambda = 1.25$, with 90% of the total fibers bearing load at the end of the simulation.

The fibers in the networks reoriented under the applied stretch (Fig 2c,d) with most of the reorientation occurring in fibers initially oriented within 30° of the CIRC direction. Fibers orthogonal to the loading direction (±15° to the LONG direction) changed orientation by less than 1% over the course of the simulation. Low stretches (less than λ_r) yielded no fiber stress while high stresses revealed significant fiber stress. The fiber stress was not homogenous. Fibers aligned in the CIRC direction experienced the maximum stress while fibers orthogonal to the loading direction were unloaded over the course of the simulation. Continuous "stress paths" spanned the domain and were a result of the initial network architecture and gradual reorientation of the network over the course of the analysis. Disruptions in the fiber network such as loss of connectivity and areas of decreased fiber density were found to be colocalized with stress concentrations in the IL stress (white arrows in Fig 2).

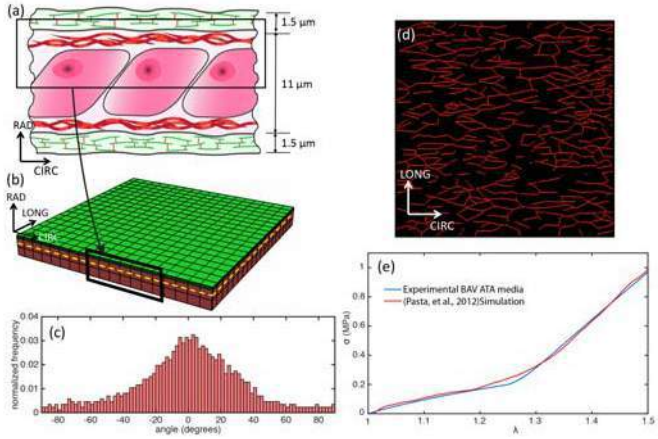

Figure 1: (a) The lamellar unit is composed of an interlaminar space surrounded by elastin lamellae. VSMCs and collagen networks reside within the IL. Half of the LU is taken as the RVE. (b) The RVE ($250\ \mu m \times 250\ \mu m \times 6.25\ \mu m$) was modeled hexahedral elements. The EL is shown in green and the IL in red. The fiber network (yellow) is situated directly below the elastin. A $75\ \mu m \times 75\ \mu m \times 6.25\ \mu m$ section of the mesh is shown. (c) the OD of the fiber network matches the experimental[1]. (d) The final network is composed of 860 fiber segments. (e) Fit between the simulated (blue) and experimental (red)[2] stress-stretch data.

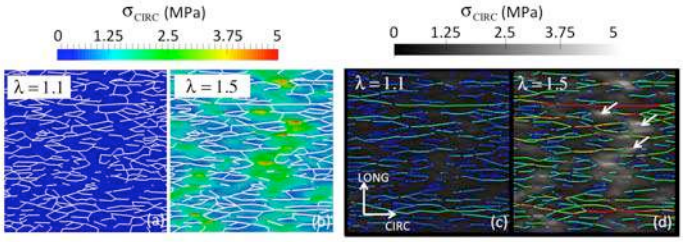

Figure 2: Local variation in the CIRC component of the IL stress in the deformed configuration at (a) $\lambda = 1.1$ and (b) $\lambda = 1.5$. The fibers are represented by white lines. Fiber stresses are shown in the same locations at (c) $\lambda = 1.1$ and (d) $\lambda = 1.5$. IL stress is shown in greyscale for comparison. The white arrows show regions of network disruption. These disruptions cause stress concentrations in the IL stress.

DISCUSSION

With a combination of a one parameter incompressible neo-Hookean solid and linear elastic fiber material model, the complex stiffening behavior of aortic tissue was captured. This was possible due to the novel fiber embedded finite element method utilized in this work. In contrast to previous work with embedded fibers, this method allows for arbitrary placement of fibers within the volumetric domain instead of along the edges of the volumetric elements. This capability drastically simplifies both volumetric element and fiber network design.

Fiber recruitment not only gave rise to the stiffening response of the stress-stretch curve, but yielded the heterogeneous stress-state in the IL tissue. Below the recruitment stretch of the fibers, the stress was homogenous, with the standard deviation in the stress increasing rapidly at high stretches.

The collagen fibers effectively shielded the surrounding matrix from stress. Thus, matrix stress along the "stress paths" was relatively low. In regions where there was disruption in the fiber network however, there was focal stress in the matrix. As VSMCs are mechanosensitive, this degradation could therefore induce local ECM remodeling.

This work has some limitations. An isotropic solid was assumed for the IL whereas VSMCs reside in this tissue in vivo. An additional source of material heterogeneity as well as the contractile nature of VSMCs are thus neglected. Failure is not included in this model. High stress regions of the domain could experience failure which would alter the stress state. Finally, we have modeled only a uniaxial tensile loading case. Future work will explore more physiological loading conditions.

INTRODUCTION

Coronary heart disease (CHD) is a chronic inflammatory process that manifests as atherosclerotic plaques composed of lipids and immune cells within the intima of coronary arteries. CHD is associated with a dysfunctional endothelium that is characterized by a pro-inflammatory phenotype [1]. Although numerous systemic factors contribute to this phenotypic modulation of the endothelial cell, the local mechanical environment plays a central role. Towards this end, most studies have focused on hemodynamics and atherosclerotic plaques have been shown to localize to regions of specific flow profiles typically described as disturbed or atherogenic [2]. However, few studies have examined altered vessel wall mechanics in the development of atherosclerosis and no study has examined an atherogenic stretch regimen that is analogous to atherogenic flow.

Herein, we built a custom cell stretching device with four independently controlled motors to mimic the stretch environment of the vascular endothelial cell *in vivo*, including: normal cyclical stretch, a reduced magnitude of cyclical stretch, which occurs with aging and development of arteriosclerosis, and a varied stretch condition that represents an idealized pro-inflammatory endothelial cell stretch stimulus. Cellular response to these different stretch conditions was gauged by the degree of nuclear expression of NF-κB, a known pro-inflammatory and atherogenic transcription factor [3].

METHODS

Cell Culture. The EA.hy926 endothelial cell line was used for all experiments. Cells were maintained in culture medium within a humidified incubator at 37ºC and 5% CO_2. Prior to stretching experiments, an elastic silicon membrane was covalently coated with 0.1% gelatin from bovine skin to facilitate cell adherence [4] and attached to four polycarbonate legs of the stretching device. Cells were seeded on each membrane in up to four separate quadrants using cloning rings and incubated for 2 days before starting the experiment.

Cell Stretching Device. We built a custom cell stretching device that allowed independent control over four high torque stepper motors in terms of displacement magnitude, direction, frequency, and variations in these parameters over time. Each motor of the device was attached via a stainless steel rod to one polycarbonate leg, to which the cell seeded membrane was attached. Membranes were calibrated to determine membrane stretch versus rod displacement and verify homogeneity of the imposed stretch across the cell-seeded portion of the membrane. The motors were controlled by a high speed microcontroller and motor drivers, all located on a separate custom-made printed circuit board. Three experimental conditions were considered: normal cyclical stretch in one direction (representing the circumferential direction of the vessel) of 1.08 [5] with an additional pre-stretch of 1.06 in the circumferential direction and 1.12 in the orthogonal (representative axial) direction [5], reduced uniaxial cyclical stretch of 1.02 with the same biaxial pre-stretch, and varied cyclical stretch magnitude (either normal or reduced) and direction (either circumferential or axial) every 30 minutes with no pre-stretch. For all conditions, the frequency of stretch was 1 Hz and the duration of each experiment was 6 hours.

NF-κB Staining, Imaging, and Analysis. At the end of each stretching experiment, media was drawn out of the stretching device chamber and replaced with 4% paraformaldehyde in PBS while continuing to stretch for another 5 min. The membrane was then removed from the device and the four quadrants (given by the four cloning rings used during seeding), each representing a separate cell monolayer, were immunostained with an antibody targeting the p65 domain of NF-κB, cell nuclei were counter-stained with DAPI, and both stains were imaged with a Zeiss PALM laser capture fluorescent

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

microscope at 20X magnification. A custom Matlab program was used to segment the cells within each image and compute the nuclear to cytoplasmic ratio of NF-κB, which accounted for possible variations in stain intensity between different staining sessions and was the primary readout of the study. The mean of this metric over all cells segmented from a monolayer was then computed, giving one value per monolayer. The mean of this ratio over all monolayers of a given experimental condition is reported, scaled by the mean of the cell monolayers exposed to normal stretch.

Statistical Analysis. Data are reported as mean±SD. A one-way ANOVA was used to evaluate statistical differences in nuclear to cytoplasmic expression of NF-κB between stretch conditions and a posthoc multiple comparisons test was employed with a Bonferonni correction to explore the significance of individual comparisons. P<0.05 was used as the threshold for statistical significance.

RESULTS

To test whether stretch could induce an atheroprone endothelial cell phenotype, we examined cell nuclear expression of NF-κB in three different stretch conditions: normal (physiological) cyclical stretch, reduced (pathological) cyclical stretch, and an idealized varied (pathological) cyclical stretch condition with changes in stretch magnitude and direction over time (Figure 1).

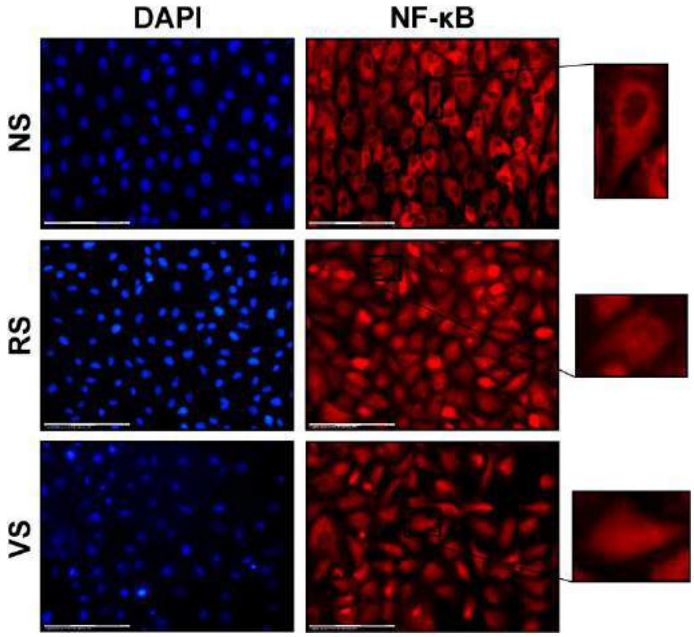

Figure 1: DAPI and NF-κB stains in cells exposed to normal (NS), reduced (RS), or varied (VS) stretch. Inset shows NF-κB in a representative cell for each stretch condition, demonstrating increased nuclear expression in those cells exposed to pathological stretch.

Cells experiencing the normal stretch condition exhibited the lowest expression of nuclear NF-κB of 1.0±0.1 (n=8 monolayers). Nuclear NF-κB levels were increased to 1.3±0.3 in the reduced stretch condition (n=10) compared to the normal condition (p=0.068). More strikingly, cells exposed to the varied stretch condition exhibited a much larger increase in nuclear NF-κB expression of 1.7±0.1 (n=7), which was statistically higher than both the normal (p<0.001) and reduced stretch conditions (p<0.01; Figure 2).

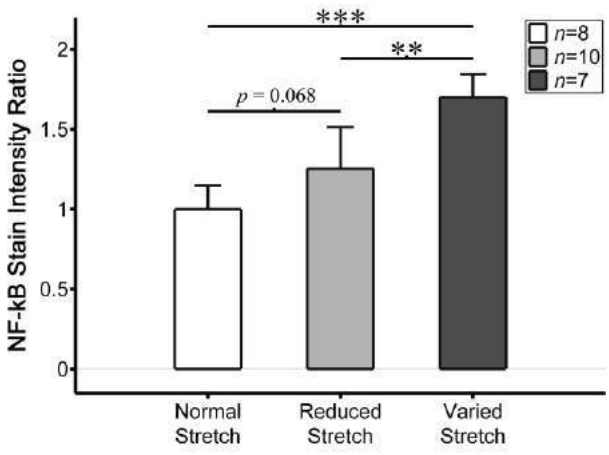

Figure 2: Nuclear to cytoplasmic NF-κB stain intensity ratio in cells exposed to normal, reduced, or varied stretch. Number of cell monolayers per condition is given by *n*. Asterisks indicate **p<0.01 and ***p<0.001. Bars are mean±SD.

DISCUSSION

Numerous studies have demonstrated that specific atherogenic flow profiles promote expression of pro-inflammatory signaling molecules in endothelial cells and localize to regions of the vasculature containing atherosclerotic plaques [2, 6]. Given that vessel wall mechanics is also an important part of the tissue mechanical environment of the endothelial cell and solid wall stress is several orders of magnitude larger than shear stress, it is likely that solid wall mechanics also influences endothelial cell behaviors and deviations from normal may promote a pro-atherogenic phenotype. Although previous studies have partially addressed this postulate by examining endothelial cell function under physiological levels of stretch [7], very little has been done to examine atherogenic stretch conditions. Herein, we developed a custom stretching device that allowed control over stretch magnitude and direction to examine the effects of two pathological stretch conditions on endothelial cell function. Each of these stretch conditions was motivated by an analogous atherogenic flow profile, reduced stretch comparable to reduced flow and varied stretch comparable to multidirectional or oscillatory flow. Both of these pathological stretch conditions were shown to up-regulate the pro-atherogenic transcription factor NF-κB compared to the normal stretch condition, which suggests that stretch can be atherogenic similar to flow. These findings motivate inclusion of vessel wall mechanics, in addition to hemodynamics, in mechanobiological studies of atherosclerosis.

INTRODUCTION

Infertility affects a large number of people worldwide; in [1] it was reported that approximately 10% of the world's population suffers from infertility. A progressively increasing number of people resort to in vitro fertilization techniques (IVF) to treat infertility. In IVF units embryos are normally cultured in micro droplets in static conditions and at 37 °C. Dynamic culture in microfluidic systems has been proposed in recent years as a viable approach to improve the rate of embryo implantation after IVF, which is still relatively low.

One of the key parameters to be accounted for in the design of a microfluidic device is the wall shear stress (WSS) experienced by the embryo during its development and this, obviously, depends on the rheological properties of the culture liquid.

In this work we characterize the rheology of a liquid used as medium for embryo culture (G-1 PLUS, Vitrolife) and find that it has non-Newtonian properties. We show with three-dimensional numerical simulations that fluid properties significantly affect the stress acting on the embryo.

RHEOLOGICAL TESTS

Rheological measurements have been performed using a rotational viscometer (Physica Anton Paar MCR 301) with a torque resolution of 0.1 nN·m, in the range between 0.05 μN·m and 200 mN·m. The measurement chamber was kept at a controlled temperature of 37°C. In order to obtain a constant shear rate throughout the sample a cone-plate configuration was adopted, with a conical rotor of 50 mm in diameter and an angle of 2°. The sample is placed in a 0.21 mm gap between the two plates.

We performed both tests at a constant rotational velocity, which allowed us to determine the stress-shear rate curve, and also oscillatory tests, from which we estimated the complex modulus of the liquid.

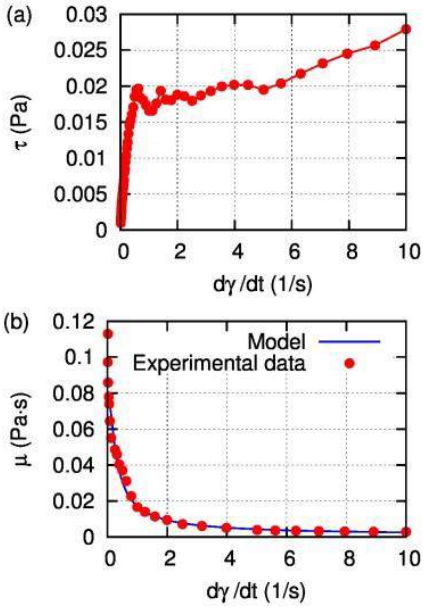

Figure 1: (a) Stress (τ) versus shear rate ($d\gamma/dt$). (b) Effective viscosity, defined as $\mu_e = \tau/(d\gamma/dt)$.

The results show that the behaviour of the fluid is highly non-Newtonian at low values of the shear rate, which are typical in microfluidic devices. This is shown in Figure 1a, where we report the stress (τ)-shear rate ($d\gamma/dt$) curve. In particular, the fluid

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

approximately behaves according to the Bingham model: for small values of shear rate the effective viscosity grows to very large values and it becomes constant for large enough values of the shear rate. In Figure 1b we show the effective viscosity μ_e, defined as the ratio between the stress and the shear rate at each point of the curve in Figure 1a.

The oscillatory tests provided the elastic and viscous responses of the fluid, quantified by its storage G' and loss modulus G''. At very low values of the stress ($\tau \lesssim 10^{-3}$ Pa), we find that G' becomes comparable to G'' ($G'' > G'$ for larger values of the stress), which implies that the sample presents characteristics analogous to those of a solid in this region.

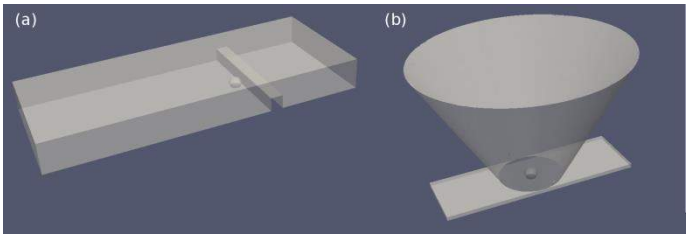

Figure 2: Sketch of the geometries considered in the numerical simulations. (a) microchannel, (b) microfunnel.

NUMERICAL SIMULATIONS

Various authors have studied the characteristics of microfluidic devices by performing numerical simulations of fluid flow [2, 3]. In all works we are aware of the mechanical properties of water have been adopted for the culture liquid. In order to assess the importance of the real rheological properties of the fluid on flow characteristics and, in particular, on the wall shear stress experienced by the embryo we performed numerical simulations adopting the two different geometries shown in Figure 2 and also considered by previous authors [2]. For each geometry we run two series of simulations: i) in the first we considered the rheological properties of the fluid as measured in the present work, in the second series we run the same simulations adopting the viscosity of water for comparison. In order to model the non-Newtonian properties of the fluid and avoid the numerical complications arising from the use of a constitutive law with a yield stress, we modelled the liquid adopting the Carreau-Bird law [4]. This implies that effective viscosity of the fluid is assumed to decrease with the rate of strain from a maximum value μ_0 to a minimum asymptotic value μ_∞. The curve resulting from fitting the four parameters of model with the experimental results is shown in Figure 1b in blue. We verified that changes in the value of μ_0 do not affect significantly the numerical results, which indicates that the use of the Carreau-Bird constitutive equation is appropriate for the present purposes. The numerical simulations are carried out using the open source software OpenFOAM [5], which is based on the finite volume method.

In Figure 3 we show the velocity magnitude on a longitudinal cross-section of the microchannel as predicted by the numerical simulations. In Figure 4 we report the ratio between the maximum wall shear stress on the embryo in the case of the Carreau-Bird model and in the case of a Newtonian fluid with the same properties as water as a function of the inlet velocity. The results suggest that the WSS predicted in the case of a non-Newtonian fluid is much higher than that obtained in the case of water, especially at low values of the velocity and consequently of the shear rate. For the smallest value of the velocity (which is consistent with real microfluidic devices) the stress is predicted to be almost 40 times higher when the real properties of the culture liquid are accounted for. Similar results are obtained in the case of the microfunnel geometry.

DISCUSSION

In this paper we have characterized the rheology of an embryo culture liquid (G-1 PLUS, Vitrolife). Various different culture fluids are available on the market, however most of them have similar constituents. Thus, we expect that tests performed on other brand fluids would lead to qualitatively similar results.

We showed that the fluid has non-Newtonian properties and this is particularly relevant at low values of the rate of strain $d\gamma/dt$. We note that in real microfluidic devices the values of the shear rate reached on the embryos are expected to be small enough for variation of the effective viscosity to be very significant.

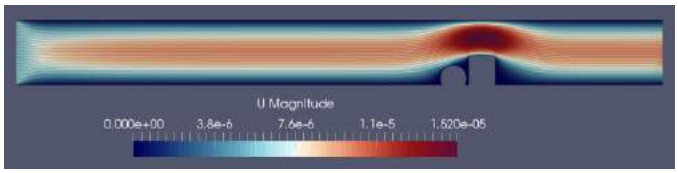

Figure 3: Velocity magnitude on a longitudinal cross-section of the microchannel.

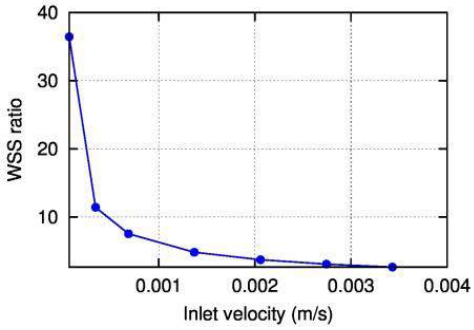

Figure 4: Ratio between the maximum wall shear stress on the embryo in the case of the Carreau-Bird model and in the case of a Newtonian fluid with the same properties as water. The geometry considered is the microchannel (Figure 2a).

The only feasible way of assessing the amount of stress that a laminar flow exerts on an embryo in a microfluidic device is to resort to numerical simulations of fluid flow, owing to the difficulty of performing direct measurements. The present work stresses the importance of measuring the rheological properties of culture liquid, the knowledge of which is a prerequisite for running feasible numerical simulations of fluid flow.

INTRODUCTION

To perform functions such as proliferation (1), differentiation (2) and locomotion (3), living cells establish stable attachments to the extracellular matrix (ECM) via the formation of specialized receptor mediated contact foci, referred to as focal adhesions (FAs). Accumulating evidence has demonstrated that, besides biochemical factors, the formation and function of FAs is tightly regulated by mechanical cues (4, 5). Theoretically, various FA models have been proposed (6–8) to test theories regarding the physics of FA formation. Despite these aforementioned efforts, several important issues remain unsettled: in most existing models, the size of the adhesion plaque has often been taken as a constant (6) or did not enter the formulation at all (7, 8); additionally, the impact of extracellular matrix structure and stiffness on FA assembly has also been reported (9); finally, recent observations also suggest that the physical properties of cell nucleus (10) can influence the size of FAs, however, to the best of our knowledge, no theoretical explanation has been provided. Aiming to address these problems, we developed a chemo-mechanical model to describe the growth dynamics of adhesion plaques as a function of substrate and nuclear stiffness. In particular, we will demonstrate the existence of a critical nucleation size for nascent patches to evolve into mature ones, and the extent to which stable plaque size is influenced by both the substrate and the nuclear rigidity.

METHODS

As described in the literature, a focal adhesion (FA) consists of a cluster of proteins (including individual integrin molecules that bind to ECM), that is then connected to the cell nucleus via the actomyosin stress fibers (Fig. 1a). A schematic of our proposed structural model describing the full mechanical feedback loop regulating FAs, the cytoskeleton and the nucleus is shown in Fig. 1b. The FA and ECM complex are treated as a spring (green box in Fig. 1b) whose stiffness is dependent on the FA structure and ECM mechanical properties. The actomyosin responsible for contractile force generation is illustrated in the blue box, and the nucleus is modeled as an elastic component to capture nuclear deformability (yellow box, Fig. 1b). The structure of the FA-ECM complex allows for sensing of ECM mechanical properties through force dependent assembly or disassembly of adhesions. Since cells have been shown to sense the ECM as fibers or non-fibers depending on ECM structure, we considered both fibrous and non-fibrous ECM types. If the ECM protein tethering spacing were larger than the FA size, a cell would sense the material as fibrous (Fig. 1c). However, if the ECM protein tethering spacing were smaller than the FA size, a cell would sense the ECM as a continuous elastic material (Fig. 1d). The model was combined with energy criteria for FA plaque recruitment to study the FA size dependence on the model parameters.

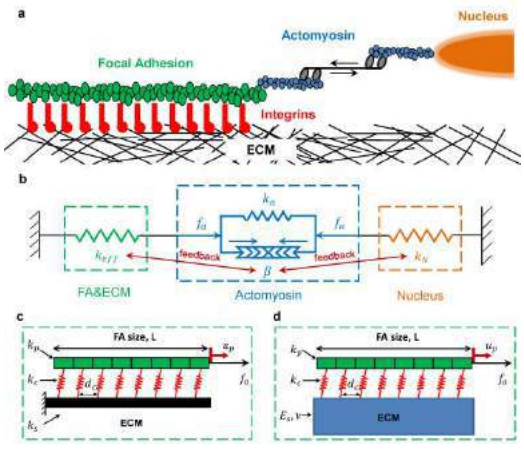

Figure 1: Illustration of cell-ECM adhesion (a). Schematic of model (b) and structures of FA-ECM complex on different kinds of ECM, fibrous (c) and continuous elastic (d).

RESULTS

The stiffness a cell senses increases first and then decreases as FA becomes larger

As discussed above, the FA effective stiffness (k_{eff}) can be determined by solving the mechanical governing equations. This physical parameter indicates the actual mechanical stiffness of the extracellular environment that the cell senses. This k_{eff} is plotted as a function of both the FA size and ECM rigidity in Fig. 2a and 2b for ECMs treated as fibrous or continuous elastic materials respectively. Interestingly, as FA size (L) increases, k_{eff} first climbs to a maximum before undergoing a monotonic decrease for both ECM types. The difference between the two models is that for gels there is a saturated effective stiffness, which is related to gel modulus: the stiffer the gel, the higher the effective stiffness. In conclusion, the effective stiffness of the extracellular environment that cells sense, first increases and then decreases as FAs becomes larger for both fibrous and non-fibrous ECMs.

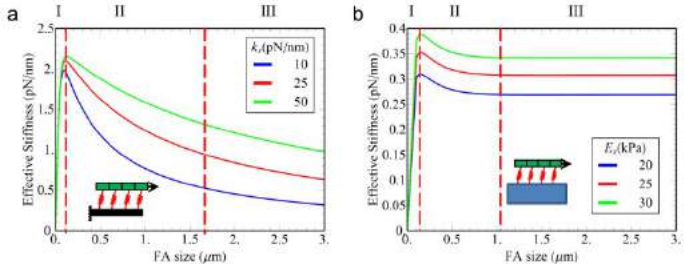

Figure 2: Effective stiffness of FA (k_{eff}) with respect to FA size (L) on different fibers with stiffness k_s (a) or on non-fibrous elastic materials with modulus E_s (b).

FA plaque recruitment is divided into three regimes by two important sizes: nucleation size and stable size.

Both models show the generic shape of the plaque recruitment flux J, as a function of FA size as shown in Fig. 3a. An immediate observation is that the value of J is positive only when $L_{nu} < L < L_{st}$ where L_{st} stands for the stable size of the plaque while L_{nu} can be considered the critical size a nascent plaque must overcome in order to grow and become fully developed. As such, the plaque dynamics can be divided into three regimes as depicted in Fig. 3a. Newly nucleated FAs with sizes smaller than L_{nu} will dissemble and eventually disappear. In comparison, a nascent FA will develop into a stable one once its size stochastically reaches this critical value. Larger FAs ($L > L_{st}$) are expected to shrink until reaching the predicted stable size. Fig. 3b shows the extent to which ECM rigidity influences the growth rate of FAs. Our results suggest that the stable size increases monotonically as the substrate becomes more rigid.

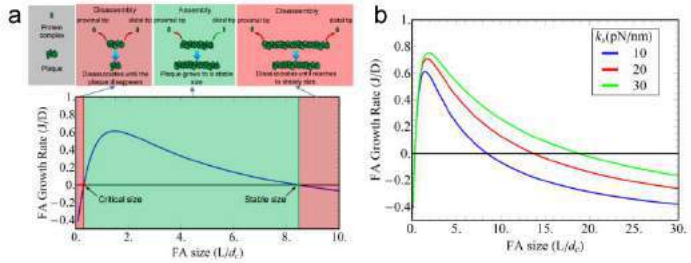

Figure 3: Two essential sizes for a FA plaque: critical size and stable size are predicted by the model (a). FA growth rate for different substrate stiffnesses (b) indicates stable FA size is larger on stiffer substrate.

Cells with stiffer nuclei have a lower barrier to form FAs and would assemble larger FAs, while higher contractility leads to a small drop in the FA nucleation barrier and a significant increase in stable FA size.

Our model predicts the dependence of FA size on nuclear stiffness. As shown in Fig. 4a, cells with stiffer nucleus would have a smaller critical FA recruitment size, which means the FA recruitment barrier is lower for these cells. Meanwhile, the model predicts that stiffer nuclei would also lead to a larger FA stable size, allowing for more and larger FAs to form.

Cell contractility is essential for FA formation and regulates FA size. Our model predicts the extent to which contractility regulates FA growth. For lower levels of cell contractility (20% lower actin pulling force) our model predicts that the FA nucleation barrier is larger and the stable size is smaller (Fig. 4b).

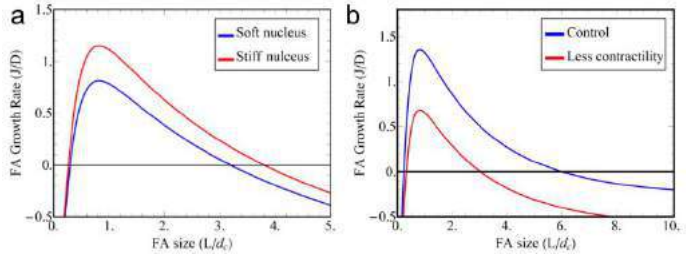

Figure 4: Effect of nuclear stiffness on FA recruitment (a). Stronger feedback effects with increased contractility result in larger stable FA and smaller FA nucleation barrier (b).

DISCUSSION

In this study, a chemo-mechanical model was developed to predict the growth of focal adhesion plaques, a process heavily influenced by the assembly of adhesion proteins as well as the stress build-up in the plaque itself (induced by actomyosin contractility). Main findings obtained here are summarized as follows:

- Two quantities of key interest, i.e. the stable size of adhesion plaques and the critical size for newly nucleated plaques to grow into mature ones, have been identified.
- A stiffer substrate/nucleus will lead to larger plaques. The prediction is consistent with experimental findings that large focal adhesions are formed on rigid surface (5).
- Interestingly, it was also found that the mechanosensitivity of the plaque is significantly influenced by contractility. Specifically, high levels of contractility will lead to bigger plaques.

We believe that the present model can also be used in studying phenomena such as cell locomotion and stretch-induced cell reorientation where contractile forces are generated inside the cell and the turnover of FAs play pivotal roles, indeed efforts along these lines are currently underway.

INTRODUCTION

Atherosclerotic plaque localized at the carotid artery bifurcation remains one of the most difficult regions of the human vasculature to treat using endovascular device based intervention. The treatment has been associated with a high rate of peri-procedural complications and the lesion has a higher predisposition to develop restenosis. Several studies have indicated that cutting balloon angioplasty (CBA) can achieve a large acute lumen gain through the use of force focused fractures controlled by longitudinal incisions in a plaque. The blade incisions created by CBA dilatation relieve the hoop stress of the plaque by disrupting and fragmenting the calcific deposits embedded in the stenosis [1] facilitating lumen expansion. However, vascular calcification is diverse in both its origin and manifestation and has material moduli ranging from 10-25GPa [2]. The ubiquitous use of CBA to treat calcified carotid plaques is partially impeded by the paucity of biomechanical data indicating the material properties of the plaque and its resistance to blade penetration.

In this regard the characterization of toughness, a mechanical parameter which determines the plaques resistance to crack propagation, can assist in quantifying the necessary cutting forces to propagate a crack in the mineralized structures. This study characterizes the toughness properties of carotid bifurcation plaque stenosis that is compounded with a number of pathological components using a custom designed guillotine-cutting tester in order to develop a longitudinal profile of the toughness properties across the length of the bifurcated vessel incorporating the three anatomical regions namely the internal, bifurcation and common carotid artery. Additionally, the fractured surfaces were structurally examined in order to better understand the unique mechanisms of plaque dissection.

METHODS

Sample Acquisition: Human carotid plaque samples were obtained from twenty-one endarterectomy patients in the University Hospital Limerick in a manner that conformed to the declaration of Helsinki and was approved by the hospital's Ethical Research Committee. Toughness values of the internal, bifurcation and common carotid artery plaque were measured. Each carotid plaque sample was segmented in 7mm intervals isolating a total of 62 rectangular sections of carotid plaque (common; CCA=17, bifurcation; BIF=21 and internal; ICA=24).

Mechanical Testing: The toughness of the carotid plaques was tested using a custom designed guillotine-cutting tester [3, 4] which characterized the mechanical work done to pass a surgical blade through the longitudinal axis of plaque measuring the resistance of the plaque to blade penetration across a unit length [4]. The applied work done (W, Joules) by the blade in cutting two new surfaces in the carotid plaque segment was calculated as follows;

$$W = \int F\, dx \tag{1}$$

The toughness (R, J/m^2) a measure of the energy provided by the system to grow the crack in the plaque segment was calculated by;

$$R = \frac{\mathrm{W_{cutting}} - \mathrm{W_{friction}}}{\mathrm{Area}} \tag{2}$$

The area was calculated using the sample thickness (t) and cutting length (L) and accounting for two new surface areas created.

Biological and Structural Characterization: The biochemical composition of each segment was acquired from Fourier transform infrared (FTIR) spectroscopy using an attenuated total reflectance probe across the fractured luminal surface at 4 separate points (total spectra 248). The analysis identified the biochemical composition of the plaques lipid, calcification and collagen which were related to toughness defining a toughness-composition relationship. Scanning electron microscopy (Hitachi SU-70) was coupled with an energy

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

dispersive x-ray spectroscope (EDX) and used to examine the fractured surfaces. Calcification was confirmed by identifying the presence of Ca and P.

RESULTS

Location specific toughness: The mechanical tests identified a significant difference in plaque toughness at each of the three anatomical locations examined. The bifurcation and internal regions of the carotid artery are both significantly tougher than the common carotid region ($p=0.004$ and $p=0.0005$) respectively as illustrated in figure 1A. Boxplots also indicated a considerable overlap with the toughness of common segments. All segments were subsequently divided into two toughness groups classified as low (0-364J/m^2) and high (>365J/m^2) based on reference toughness ranges of aortic tissue (250±110J/m^2) [4] and bone (365-7960J/m^2) [5] respectively. Of the internal carotid segments examined, 62.5% fell into the low toughness group while 50% of the bifurcation segments fell into the high toughness group displaying the toughest properties overall.

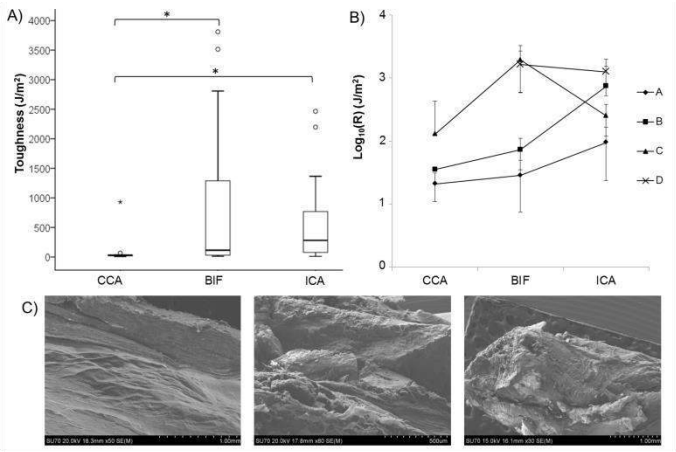

Figure 1: A) Box-plot of toughness properties for each location B) Log-linear plot of longitudinal toughness profile of each plaque type and C) corresponding electron micrographs of fractured surfaces.

Plaque specific toughness: Figure 1B illustrates the four unique longitudinal profile types of the toughness properties distributed across the length of the bifurcated vessel. Type A (38%) demonstrated low toughness properties in all three regions. Type B and C (47%) demonstrated high toughness properties in the internal or bifurcation and type D (14%) demonstrated high toughness properties in both. A non-significant difference was found at the transition between bifurcation and internal for type B ($p=0.383$) as a result of the high degree of heterogeneity contained within the stenosis. A significant toughness difference was identified at the transition between the common and bifurcation and bifurcation and internal for type C ($p<0.05$).

Structural characterization: Electron microscopy further rationalized the range of toughness values identified within the plaque segments. The failure analysis exposed the internal morphology of carotid calcification deposits and the array of different fractured calcified surfaces within the plaques cross sectional thickness indicating a number of distinct fracture mechanisms (Figure 1C). The material composition varied considerably across the length of the plaque. A clear distinction between the layers of fibrous tissue in the common segments (low toughness) was observed by the thickened fatty layer and thin outer plaque medial layer in comparison with the large calcification deposits located in the bifurcation and internal segments (high toughness).

DISCUSSION

This study identified the toughness of carotid artery plaques and distinguished the severely heterogeneous composition through determining the toughness properties at each anatomical location defining both the upper and lower scale toughness limits of necrotic plaque tissue. The mechanical tests determined the necessary cutting forces required for successful fragmentation and disruption of severely toughened plaque segments containing high calcific portions while additionally, characterizing fracture mechanisms of calcification.

A significant difference in toughness properties exists at each anatomical location of the carotid vasculature. The proximal end of the carotid artery contained distinct longitudinal sections of mismatching material properties demonstrating dissimilar toughness properties. The bifurcation segments demonstrated the toughest properties suggesting the calcification in this region to be far more advanced than the calcification development in the internal core region. Examination of the fracture sites indicates the crystallographic imperfections and the distorted crystal structure in the mineral deposits. High forces were required for propagating a crack in the calcified material. A force focused crack was propagated in the calcific deposit and complete fracture was achieved denoted by a reduction of force. A possible explanation for the variation in toughness properties of the calcified deposits could be related to the varying degree of maturity and crystallinity which evolve separately and have been shown to affect the calcification's characteristics and also have different implications on the biomechanical properties [6].

This study identifies four unique toughness profiles that incorporate the three anatomical regions of the carotid artery and are characteristic of localized calcifications. The clinical implications of the variation in toughness properties distributed along the length of the lesion are a possible explanation for the high restenotic response endured from the procedure. This advocates the need for a device that targets the specific high tough regions while conserves the lower scale soft tissue to prevent vessel perforation. It is important to distinguish the material properties between the different regions in the plaque, as stress is not uniformly distributed across the lesion during stenting and the internal region is more stressed than the common branch [7].

The experimental toughness values reported in this study are to serve as a fundamental basis for future studies to numerically simulate the concentration of the stresses observed around the cutting blade penetrating the severely toughened plaque segments and also to determine the mechanism of dilating the calcification component.

INTRODUCTION

Chronic Obstructive Pulmonary Disease (COPD) is the leading cause of chronic respiratory disease mortality. Morbidity rates due to COPD are rising faster than any other of the major causes of death. Pathological challenges associated with COPD increase the barriers for treatment efficacy. Major physiological changes include increased mucus production, alveolar deterioration, and airway lumen narrowing. The lungs are difficult to target via intravascular (IV) or ingestion routes due to first pass metabolism, proteolytic activity, and translocation into other organs. Inhaled nanoparticles can achieve 50% alveolar deposition, over twice the deposition compared to other inhaled therapeutics. Engineered nanoparticles designed for therapeutic drug delivery offer many enhancements. Engineering nanoparticles can achieve specific attributes such as size, surface charge, density, solubility, and hydrophobicity. Increased drug localization enables improved therapeutic effects and reduced side effects.

Numerous materials have been used to form nanoparticles each with adverse attributes. Long-term safety of polymers inhaled into the lungs is questionable [1]. Inhaled liposomes are considered safe, but undergo reduction or hydrolysis reactions causing cellular toxicity [2]. Tissue derived proteins have predictable degradation products making them the best suited for the treatment of chronic lung diseases. The objective of this study was to establish a novel drug delivery system and evaluate the cytotoxicity in vitro. This carrier is comprised of nanoparticles formed from natural lung-derived, extracellular matrix components.

METHODS

ECM Powder: Extracellular matrix powder was produced by decellurizing porcine lung tissue using aorta and tracheal perfusion of Triton-x and SDS for 3 days. After decellularization, the remaining tissue was lyophilized and cryomilled to form powder.

Electrospray deposition: The ECM powder was digested in various commonly used solvents at 5mg/ml for 4 hours with 0.5% $CaCl_2$. Solvents used include distilled water, Acetone with DMSO, ethanol with water and acetic acid. All of which are commonly used solvents for electrospray [3]. The solution was drawn into a syringe pump. Aluminum foil was placed 10cm away, perpendicular to the target. A voltage difference of 25 kV was applied between the nozzle (22 gauge, 0.403mm inner diameter) and the aluminum foil. At a flow rate of 0.2ml/hr the solvent evaporated before reaching the foil, leaving only the solid particles attached to foil. Nanoparticles were sterilized in ethanol after electrospray deposition. Lyophilization to remove the ethanol was performed.

Nanoparticle determination: Dynamic light scattering (DLS) and image analysis of SEM images were used to determine particle sizes after electrospraying. 1 mg/ml of lyophilized particulate was placed in 1 ml of filtered ultrapure water and added to a disposable cuvette (Malvern). The cuvette was placed in the Zetasizer and DLS was performed.

Hitachi SU-70 SEM images were taken and quantified using ImageJ to determine the average particle diameter [4], and to ensure the resulting ESD products met nanoparticle criteria of at least 1% of diameter sizes between the range of 1 nm to 100 nm.

Zeta Potential: Zeta potential is a measure of the surface charge of nanoparticles. Zeta potential was measured before and after electrospraying using a Zetasizer ZS90 (Malvern). 900 µl of solution was placed in a quartz cuvette (Malvern) and measured on a Zetasizer.

Cell proliferation and Cytotoxicity: The human alveolar epithelial-like cell line, A549s (ATCC) were cultured in tissue culture dishes (25,000 cells/cm^2) to achieve 80% confluence after 24 hours

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

with RPMI media supplemented with 10% FBS (Gibco). After 24 hours, the media was removed and replaced with nanoparticles in media. Various concentrations of sterile nanoparticles were added to media to determine cytotoxic effects of nanoparticle. Live/Dead staining (Invitrogen) and MTT metabolic assays (Roche) were used to quantify cytotoxicity and proliferation of nanoparticles.

RESULTS

Solvent selection: Acetic acid was chosen because the protein remained in the suspension for over 24 hours imaging showed the most consistent spheroid particles.

Electrospray deposition: Before acid digestion the majority of particles are about 0.3 µm, followed by 1.7 µm. After acid digestion the particle size peaks were found at 1.1 µm, 200 nm and 30 nm with the Zetasizer (Malvern).

Zeta potential: The most neutral zeta potential was found to be 2 mV in the 50% acetic acid solution with 0.5% $CaCl_2$ (Table 1). Of the solvents tested Acetic Acid retained protein in solution and had the lowest zeta potential magnitude ($p<0.05$). The addition of calcium chloride salt significantly decreased the zeta potential of the resulting nanoparticles ($p<0.05$).

Table 1. Characterization of nanoparticles after sterilization.

Electrospray solvent	DLS Measured radius of nanoparticles (nm)	Z eta Potential (mV)	St. Dev.
50% Acetic Acid (AA)	492	3.6	1.963
50% AA w/ 0.5% CaCl	124	-13.2	1.436

Nanoparticle determination: Scanning Electron Microscopy images were taken of the electrosprayed nanoparticles (Figure 1). Then using ImageJ 50 random particles from 3 different batches were measured. Average size was determined to be 277 nm (range 50-1500 nm) with 34% of measured particles smaller than 100 nm. The Zetasizer size determination was 492 nm average. Both of these ranges are sizes produced without filtering the nanoparticles after sterilization.

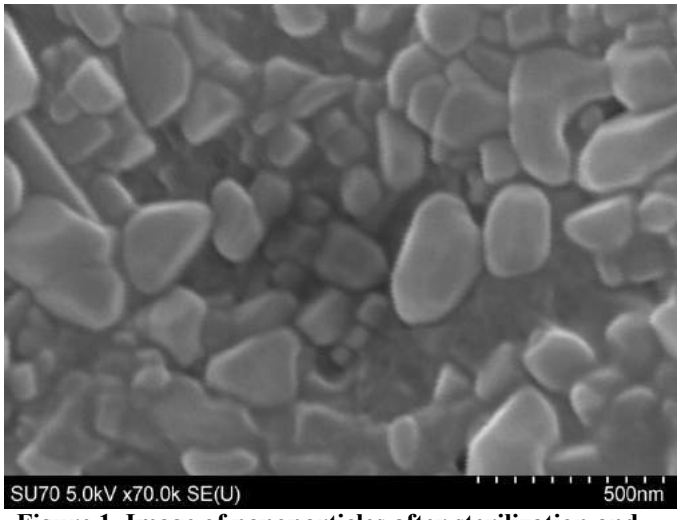

Figure 1. Image of nanoparticles after sterilization and lyophilization.

Cytotoxicity: Preliminary cytotoxicity results demonstrate increased cell proliferation with protein nanoparticle addition. A dose of 2 mg of nanoparticles added to 1 ml of growth media increases cell proliferation by almost 25% over controls according to MTT results. Live/Dead Staining shows increases in number of live cells but similar quantities of dead cells when 2 mg/ml nanoparticles are compared to control group (Figure 2).

DISCUSSION

Nanoparticles were formed through electrospray deposition of ECM components. Acid digestion resulted in a separation of components. Salt addition reduced the zeta potential, and decreased the success of electrospray deposition. Increased magnitude of zeta potential reduces particle agglomeration but increases cytotoxicity [5]. The formed particles demonstrated increased cell proliferation and metabolism compared to control groups. Hyperbranched PAMAM of equivalent size decreases proliferation by 15% in HEK293 and COS7 cells [6]. Equivalently sized chitosan particles at similar concentrations decreased A549 proliferation by 80% [7].

Future work will continue assessing solvents as well as minor protocol changes such as speed, use of antisolvents. examine stabilizer addition to improve long-term storage stability of nanoparticles. Macrophage activation and endocytosis will be investigated. Additionally, mucus penetration and and drug encapsulation will be determined.

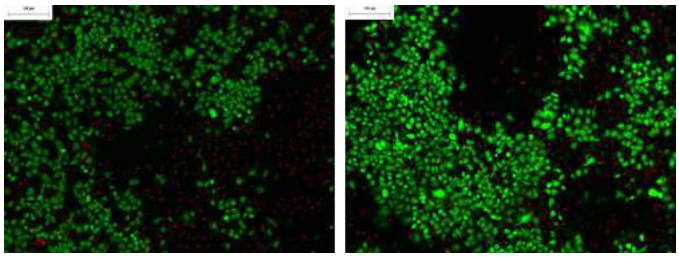

Figure 2. Image of Live (Green)/Dead(Red) staining of A549 cells after incubation. A) control cells wit no nanoparticles added. B) Cells plated with 2 mg of nanoparticle per ml of media for 48 hours. Scale bar 200 µm

ACKNOWLEDGEMENTS

Special thanks to the VCU Nanotechnology Core Characterization Facility (NCC) for SEM imaging. These investigations would not have been possible without the use of the electrosprayer and Zetasizer performed in Dr. Hu Yang's lab. Lastly, we thank Smithfield Farms for providing the porcine lung. Funding for this study was provided by the Commonwealth Health Research Board and NSF CAREER Award CMMI 1351162

INTRODUCTION

Dissection of the descending aorta, a potentially fatal condition of the aortic wall, occurs as a tear in the intimal leads to blood flow in between medial layers. This leads to diversion of blood flow from the original, true lumen into the intra-medial space, known as the false lumen. As a result, aortic branch vessels may be compromised, leading to visceral ischemia. Patients with such complications are treated with endovascular intervention in addition to the standard medical therapy initiated in all patients presenting with aortic dissection. However, in the absence of overt complications, the evidence is less clear [1]. Endovascular intervention has not been shown to be superior to optimal medical therapy in this sizable patient population [2].

Outcomes in these patients have been linked to the presence of false lumen thrombosis [3] as well as the diameter of the descending aorta [4]. The latter is a measure of aneurysmal degeneration of the aorta, a later stage complication that prompts endovascular intervention. Previous work has demonstrated a relationship between these pathologic processes and aortic hemodynamics that can arise from flow separation, reversal, and recirculation. In particular, altered wall shear stress and shear rate may lead to thrombosis [5] and correspond to locations atherogenesis [6] and aneurysm [7]. Additionally, outcomes have been correlated with different tear configurations in the aorta [8].

Previous investigation into the fluid dynamics of aortic dissection has relied on both computational [9] and experimental [10,11] models. These studies, however assumed either rigid geometries or non-anatomic aortae, respectively. The reported experimental model possesses anatomic geometry as well as compliant vessel walls and dissection flap, which are critical to modeling the fluid mechanics of the dissected aorta [11]. We hypothesize that flap motion will decrease with increased number of reentry tears. Thus, more tears are expected to decrease flow reversal observed in both the true and false dissection lumina.

METHODS

Silicone models of aortic dissection were fabricated as previously described [12]. Model flaps were incised at the level of the flexure of the lesser curvature and at dissection exit, in order to create entry and exit tears, respectively. In addition to these primary entry and exit tears at the extents of the dissection (Figure 1A), secondary tears were introduced at 50% (Figure 1B) and 75% (Figure 1C) along the length of the dissection distal to the entry tear. These tears extended along the circumferential extent of the false lumen.

The models were connected to a flow loop consisting of medical-grade PVC tubing, which was subsequently filled with water and purged of air. Physiologic flow was developed via a custom-built positive displacement pump. Pressure was measured using a pressure transducer (Harvard Apparatus, Holliston, MA) connected to a multipurpose access (MPA) catheter advanced to the proximal ascending aorta in an antegrade fashion. A flow probe (Transonic, Ithaca, NY) was connected inline with the flow loop. Flow rates of 4 L/min were maintained at physiologic (Figure 2) and pathologic pressures. A 33 mm aortic balloon catheter (B. Braun, Bethlehem, PA) was introduced into the model and inflated to distend the false lumen.

Models were imaged in a 3 Tesla Prisma magnetic resonance imaging (MRI) scanner (Siemens, Erlangen, Germany). Anatomic images were acquired using 2D ciné sequences, whereas flow images were acquired using both 2D and 4D phase contrast magnetic resonance (PCMR) protocols. Electrocardiogram (EKG) gating was triggered using the pulsatile pump output.

Image and data analysis were performed in custom software written in Matlab (The Mathworks, Natick, MA). Qualitative analysis

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

of velocity profiles was performed with vector plots and color Doppler overlays of through-plane 2D PCMR images. Bulk flow rates were calculated via integration of through-plane velocity profiles over cross-sections obtained normal to the aortic wall. Luminal areas were calculated over the course of the cardiac cycle. In addition, flap displacement was measured over time. Four-dimensional PCMR data were used to visualize flows across the whole aorta.

RESULTS

PCMR-derived bulk flow rate across the luminal flow divider was conserved and matched flow rates measured inline with the flow meter. However, flow division was modulated in time as a result of dissection flap motion.

In the absence of secondary tears, the whole of the dissection flap was observed to oscillate in conjunction with the cardiac cycle. While the false lumen was distended, its cross-section varied in shape and area along the dissection. Thus, in certain locations, the false lumen was the larger of the two lumina ("false-dominant"), compressing the true lumen, whereas in other locations the contrary was true ("true-dominant"). Relative true lumen area was calculated as 55% +/- 3 at the level of the entry tear, 36% +/- 7 at the middle of the dissection, and 91% +/- 3 at the exit tear, each being significantly different from the other in pairwise comparisons ($p<0.0001$). Flow reversal was observed in certain planes within the dominant lumen (Figure 1D). This phenomenon was initiated during the systolic deceleration phase, continuing through diastole.

Dissections with secondary tears exhibited similar oscillatory behavior. However, in these models, each segment of the dissection flap was observed to move independently of the others. Each inter-flap segment was able to assume an independent conformation, such as a widely-distended (Figure 1B, middle segment), tapered (Figure 1B, lower segment), or closed false lumen (Figure 1C, lower segments).

Flow reversal was still seen in the false lumen at mid-dissection level in the case of a single secondary tear (Figure 1E). This effect was however attenuated relative to the reversal seen without secondary tears (% forward flow in diastole: 2 tears – 40%, 3 tears – 93%, 4 tears – 100%). Furthermore, flow reversal was also present in the true lumen in this situation. Alternatively, in the case of multiple secondary tears, more distal segments remained collapsed, allowing for the mid-dissection tear to act as an exit tear. In this case, all false lumen flow was forward, with flow reversal occurring in the true lumen (Figure 1F). Flow separation and reversal in all cases is observed during systolic deceleration and diastole, as the dominant lumen expands in size.

DISCUSSION

We demonstrate that the number of reentry tears has an effect on the mobility of the dissection flap, which in turn influences aortic hemodynamics in an *in vitro* model of aortic dissection. As hypothesized, dissections with increased numbers of reentry tears exhibit less flap motion, and less flow reversal, than those containing only primary entry and exit tears. These phenomena have not been reported previously in controlled investigation.

Additionally, the presence of flow reversal, as well as a possible mechanism for its cause is demonstrated. As blood flow decelerates in late systole, the dominant false lumen at a given location is observed to expand. This may be a result of increased pressure as flow velocity decreases. With deceleration and expansion, an adverse pressure gradient may be created, leading to reversal of flow in the false, expanded lumen.

These results may provide insight into the natural history of clinical disease. Sustained flap motion and flow reversal may lead to aneurysmal degeneration of the aorta, which would require endovascular intervention. Thus, patients that possess these hemodynamic effects may be selected for earlier intervention to prevent formation of aneurysm. Alternately, areas of recirculating, low shear flow may be subjected to some level of thrombosis. In this case, close followup in these patients may be necessary to determine the extent of thrombosis and the need for intervention. Future work aims to relate these phenomena to patient anatomies and hemodynamics for improved patient selection.

UTILIZING PROBLEM-BASED LEARNING TO TEACH BIOMEDICAL ENGINEERING AS A CHEMICAL ENGINEERING ELECTIVE

Victor K. Lai (1)

(1) Department of Chemical Engineering
University of Minnesota – Duluth
Duluth, MN, USA

INTRODUCTION

The chemical engineering program at the University of Minnesota – Duluth is primarily a teaching-focused program, with a total undergraduate enrollment of about 250 students. In Fall 2014, I was asked to create a new graduate-level elective class in Biomedical Engineering for the program. In that first year, with 6 students in the class, I employed largely a traditional classroom approach: lectures on anatomy and physiology, biomechanics, biomaterials and tissue engineering, and biotransport were coupled with two teaching assignments on special topics (bioinstrumentation, bioelectricity, bioimaging), where students were expected to conduct independent research on their assigned topic and teach the material to the class. Based on end-of-semester evaluations, this approach to teach this class yielded mixed results: some students found the material too difficult, and others did not enjoy the special topics assigned to them.

After attending the education workshop on problem-based learning at SB3C2015, I decided to replace the teaching assignments with two research projects, the first related to biomechanics, and the second related to tissue engineering and biotransport. With only 4 students in Fall 2015, these projects were attempted in two groups of 2 students each. These projects started after the necessary content has been covered in lectures.

METHODS

Each project was divided into three sections, and every group was required to make an oral presentation for each section. The two projects are detailed below.

(1) Biomechanics: The first project involved the study of prosthetics used by two different celebrities (Amy Purdy, Noah Galloway) in "Dancing With the Stars":

Section 1: Students researched on their assigned celebrity – why were they famous, how they lost a part of their limbs and require prosthetics, and pick a (quasi)static pose/move during one of their dances on the show.

Section 2: Based on their selected pose/move, students performed a statics analysis to determine the forces and moments exerted on the prosthetic. Student were also required to evaluate qualitatively the effects of the prosthetic on joint reaction forces, compared to a person with a normal limb.

Section 3: Students applied their knowledge of material properties and deformable body mechanics to analyze the amount of deformation (compression/elongation, deflection) on the prosthetic due to the forces and moments exerted during the pose, and accessed critically the material used to design the prosthetic.

(2) Tissue Engineering and Biotransport: This project involved the study of a bioengineered tissue from a research paper of the students' choice, and setting up a mass transfer problem to analyze the culture conditions described in the paper:

Section 1: Students picked a research paper on a bioengineered tissue of their choice and summarized the paper, emphasizing concepts taught in class (e.g., describing and characterizing the biomaterials used, identifying components of the tissue engineering triad, etc.).

Section 2: Based on the geometry of the tissue, as well as the culture media and conditions, students were required to set up a mass transfer problem analyzing the concentration profile of a certain nutrient (e.g., oxygen, glucose) through the tissue.

Section 3: Students looked up another article by a different research group on the same bioengineered tissue, and compared and contrasted the methods used to engineer and test the tissue (materials used, culture conditions, testing methods, etc.).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

While the official end-of-year evaluations have not been made available, anecdotal information from conversations with the students suggests they enjoyed and appreciated this format of teaching. Specifically, students demonstrated the ability to apply lecture concepts to more open-ended problems:

(1) With the biomechanics problem, students applied successfully concepts from the statics and deformable body mechanics lectures to simplify their dance pose into a free-body diagram, identify correctly the forces and moments on the limb or prosthetic, and estimate the amount of deformation placed on the prosthetic during the pose. Figure 1 shows an example of the pose chosen by the students (A), and the free-body diagram (B). More importantly, they gained an appreciation of the assumptions that were made in their analysis, ranging from the use of general anthropometric data, to the geometry and homogeneity of the limb or prosthetic.

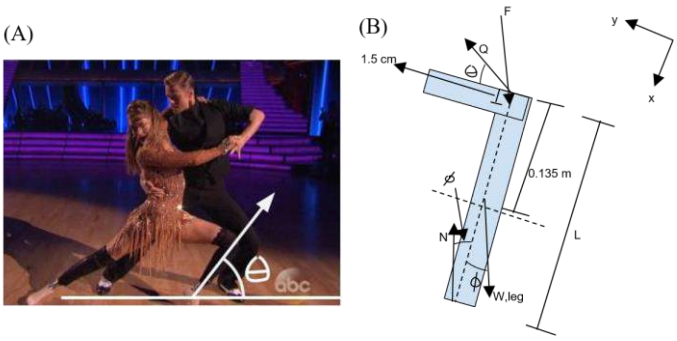

Figure 1: (A) One of the dance poses chosen by the students assigned Amy Purdy as their celebrity. (B) Free-body diagram generated by the students to analyze the forces and moments exerted on the prosthetic leg.

(2) The tissue engineering / biotransport problem was a more abstract exercise. Specific learning outcomes of this project include (a) students would be able to read and summarize a journal article related to tissue engineering, and (b) apply concepts of biotransport to set up fully (but not solve) a mass transfer problem related to the culture conditions listed in the article. This project yielded mixed results. One group was able to dig deep into their problem to set up complex differential equations with appropriate boundary conditions to govern the nutrient concentration in their bioengineered tissue, using histological images in the article to estimate dimensions of different layers. The second group, however, came up with an over-simplified solution to their problem, neglecting many assumptions regarding the geometry of their tissue, as well as the different layers present.

DISCUSSION

The primary goal of adopting problem-based learning in this class last Fall is to try out a different active-learning approach in teaching Biomedical Engineering. Previously, in using the teaching assignments to cultivate independent learning in students, I found that (a) the topics were too broad, such that students lacked direction in how much they should learn and cover in their presentations, and (b) expecting undergraduate students to read, understand, and teach on a topic that was had not been covered in class was not realistic, even though this was a graduate level class taken by juniors or seniors. This problem-based approach still achieved my desired goal of encouraging independent learning (and teaching, through presentations), but also provided a more structured framework for students to apply prior knowledge from lecture material.

One of the main difficulties of teaching an elective class in a broad field such as Biomedical Engineering is juggling breadth with depth. In my first year, I opted to go for both, going in depth in topics such as Biomechanics, Biomaterials, and Biotransport, but still "covering" other topics by making students learn the material independently and teach them to the other students. In my opinion, sacrificing breadth for depth last Fall was more ideal. While the students were made aware of these other topics that are also important to Biomedical Engineering, the above-mentioned topics covered in-depth were more in-line with the interests of my Chemical Engineering students, and were related to several other core chemical engineering classes (Properties of Engineering Materials, Heat and Mass Transfer, Fluid Dynamics, etc.). In addition, problem-based learning to apply lecture concepts enhanced significantly their understanding of the lecture material, and gave them a greater appreciation of the assumptions associated with the analysis.

ACKNOWLEDGEMENTS

Anecdotal feedback was provided by the students in this elective class in Fall 2015 (Jordan Remme, Andrew Commers, Jason Burns-Gausman, Erik Keeler). Material taken from students' work were reproduced with permission from the respective students.

FOOTWEAR AFFECTS MUSCLE ACTIVITY DURING RAMP WALKING

INTRODUCTION

Habitual footwear use has been reported to influence foot structure with an acute exposure being shown to alter foot position and mechanics [1]. The foot is highly specialized thus these changes in structure and position could influence functionality [2,3]. Numerous studies have been conducted to investigate the effects of footwear on gait, specifically focusing on assessment of kinematics, kinetics, and muscle activity between walking barefoot and in common footwear. Few studies, however, have yet investigated how footwear affects gait and foot/leg functionality while walking on a ramp.

The random nature of outdoor terrain makes controlled studies of outdoor footwear biomechanics extremely challenging. As a result, a solid, general understanding of such involvement in foot biomechanics does not exist. The purpose of the current study, which was our first step in an attempt to simulate various outdoor terrains in a laboratory setting, was to build an instrumented ramp with adjustable incline/decline angles and utilize it to investigate leg muscle activity during ramp walking in various footwear designs and barefoot condition. The hypothesis was that differences in muscle activity due to various footwear and barefoot conditions, even subtle changes that would not normally be measured during level walking, could be detected while walking on a ramp.

METHODS

Three male subjects were tested with ages ranging from 21 to 36, mean height of 173.5 ± 5.0 cm, and mean weight of 70.5 ± 6.8 kg. Prior to the tests written, informed consent was received from each subject, and approval of the study was obtained from the Michigan State University Institutional Review Board. Subjects were interviewed to ensure they were healthy with no known pathology or major lower body injuries within the past ten years.

A 16 feet long, 0-20 degree adjustable ramp was developed and used for level and angled walking trials. An AMTI force plate (Advanced Mechanical Technology Inc., Watertown, MA, USA) was embedded in the center of the ramp walkway, flush with the walking surface. The force plate data were not shown in the current abstract. A textured paint was applied to the surface of the ramp and force plate to increase traction and create a non-slip condition that was required at augmented angles. A platform which remained level at each angle was attached to the top of the ramp, and railings were added to the platform and sides of the walkway for safety purposes.

Figure 1: From left to right: Chameleon Low, Chameleon Medium, and Mattertal High.

Three pairs of Merrell footwear were used in the study (Figure 1). Surface electromyography (EMG) data were collected at a sampling rate of 2000 Hz from each subject performing three walking trials while wearing these footwear designs and in the barefoot condition at five different ramp angles, i.e. 0, ±10, and ±20 degrees (zero represents level, and plus and minus represent incline and decline, respectively). EMG sensors were attached to four leg muscles on the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

right limb, i.e. the tibialis anterior (TA), the medial gastrocnemius (MG), the rectus femoris (RF), and the biceps femoris (BF).

After a short practice walking on the ramp and prior to data collection, maximal voluntary contraction (MVC) was performed for each of the four leg muscles, according to Preston et al. [4], while the corresponding EMG data were collected to normalize EMG data collected while walking. During a single trial of ramp walking five or six steps were recorded from each subject and data from the third, fourth, and fifth steps were used in the post analyses. Raw EMG data were bandpass-filtered (20-500 Hz), rectified, and then low-pass-filtered with a cut-off frequency of 6 Hz to obtain a linear envelope for each muscle. Mean peak amplitude, averaged across three steps and three trials for each subject and reported in % of MVC, was used as a measure of muscle activity. Data from the three subjects were then averaged and compared between the barefoot condition and while wearing the three footwear designs between level and angled walking.

Two-way ANOVA and Student-Newman-Keuls post hoc tests were used to determine differences in EMG measures between the barefoot and various footwear conditions (factor one) for different ramp angles (factor two). Significance was indicated for $p < 0.05$.

RESULTS

In the MG, RF, and BF muscles significant differences were observed between level walking (0 degree) and angled walking ($p < 0.001$), with greater muscle activity being generated during angled walking (Figure 2). For the TA muscle there were significant differences between level walking and 10 and 20 degrees of incline walking ($p < 0.001$), but not between level and decline walking.

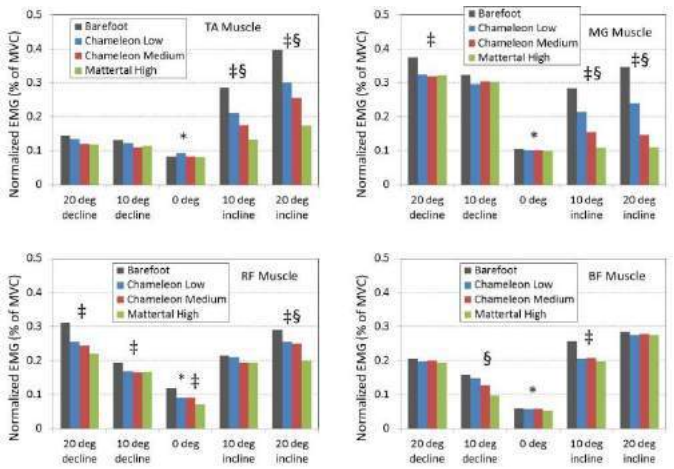

Figure 2: Normalized muscle activity (mean peak amplitude) in different leg muscles during ramp walking with barefoot and in various footwear designs. * indicates significant differences between level and angled walking. ‡ indicates significant differences between barefoot and footwear conditions. § indicates significant differences between footwear designs. For clarity, standard deviations across subjects were not shown in these plots.

In general, walking barefoot generated greater leg muscle activity than walking in footwear (Figure 2). This fact was especially true during incline walking versus decline walking. Specifically, during 10 and 20 degrees of incline walking significantly greater muscle activity was observed walking barefoot than in footwear for the TA and MG muscles ($p < 0.001$). The MG muscle also showed greater activity during 20 degree of decline walking ($p < 0.001$). For the RF muscle statistically significant difference between barefoot and footwear walking was found during 20 degree of incline walking ($p = 0.021$), level walking ($p = 0.001$), 10 degree of decline walking ($p = 0.030$), and 20 degree of decline walking ($p < 0.001$). For the BF muscle, however, significant difference between barefoot and footwear walking was only observed during 10 degree of incline walking ($p < 0.001$).

In addition, walking in different footwear designs generated significantly different muscle activity, with a trend for the Mattertal High to be the lowest, especially during incline walking and in lower leg muscles (Figure 2). Walking in the Chameleon Low generated the highest muscle activity while walking in the Mattertal High generated the lowest activity in the TA muscle for 10 ($p = 0.037$) and 20 ($p = 0.018$) degrees of incline walking and in the MG muscle for 10 ($p = 0.025$) and 20 ($p = 0.020$) degrees of incline walking. For the RF muscle different footwear designs generated statistically different muscle activity during 20 degree of incline walking ($p = 0.041$), while for the BF muscle footwear differences led to variations in muscle activity during 10 degree of decline walking ($p = 0.045$).

DISCUSSION

The current study, even with a limited number of subjects, was able to show significant differences in leg muscle activity between barefoot and footwear walking, and between walking in various footwear designs. As a result it was able to support the hypothesis that footwear effects on muscles, even subtle influences that would not normally be measured during level walking, can be detected while walking on a ramp.

Several studies in the literature use EMG measures to determine differences in muscle activity patterns while walking shod and barefoot, partially supporting the results of the current study. Scott et al. [5] demonstrate that the TA displays significantly reduced mean peak amplitudes from barefoot to shoes ($p < 0.001$), but the MG shows no difference. In addition to findings of differences between barefoot and shoes, our study may serve as a significant contribution to the literature by exposing the important role that ramp walking may play in amplifying the effects of footwear on leg muscle activity during walking.

The results of the current study may also suggest that footwear with higher and potentially stiffer uppers, such as the Mattertal High boots used in the current study, may have provided more ankle/lower leg support so as to require less muscle activity during angled walking. With more subjects being recruited into this ongoing study, more and greater effects of footwear are expected. The current study represents our first step in an attempt to simulate outdoor environments in a lab setting, potentially contributing to a scientific base on which new footwear can be designed for various terrains that might help limit muscle overuse-caused conditions, such as fatigue.

ACKNOWLEDGEMENTS

The authors would like to thank Mr. Clifford Beckett and Mr. Jerrod Braman for their technical support in this study. The authors would also like to thank Wolverine WorldWide, Inc. for a financial gift to help support our laboratories.

INTRODUCTION

Abnormal hemodynamics experienced by the heart valve cells are associated with valvulopathy. This altered mechanical environment also leads to modulation in valve cellular shape and architecture. Significant prior work has focused on t he role of the mechanical environment in potentiating cellular alterations and subsequent progression toward disease.[1-3] However, the role of cellular shape and architecture in regulating or predicting the overall balance between health and disease in the context of the valve is not well understood.

We hypothesized that by engineering the shape of single VICs to acquire the AR of cells seen in normal and pathological conditions, we could induce changes in cell architecture, subsequently potentiating acute alterations in cell function, specifically cell contractility and metabolism. Our objectives include 1) quantify and correlate the cell cytoskeletal and nuclear architecture with contractility measured via traction force microscopy 2) assess cell metabolism by us ing endogenous FAD/NADH metabolic redox ratio imaging.

METHODS

1. Microcontact printing and cell culture

50μg/mL Fibronectin was put onto the PDMS stamps with 3 different aspect ratios (AR) features and incubated for 1 hour at room temperature. 3 ARs were 1:3, 1:5 and 1:7 corresponded to 3 different cellular states: non stretched, normal stretched and elevated stretched.[4] The stamp was then placed in contact with PDMS-coated coverslips for 5 minutes, thereby transferring the pattern. VICs were seeded at 1000 cells/cm^2 and cultured at 37°C, 5% CO_2.

2. Fluorescent staining of actin and cell nucleus

After 48 hour s of culture, cells were fixed with 4% paraformaldehyde (PFA) and stained for F-actin using Alexa Fluor 488 phalloidin and for nuclei using 25μg/mL 4',6-diamidino-2-phenylindole (DAPI) for 1 h our at room temperature. Samples were then mounted onto a glass slide, allowed to dry overnight and imaged using a custom-built resonant-scanning multiphoton microscopy. Actin alignment was quantified using a custom-written MATLAB script. Nuclear shape was analyzed by fitting an ellipse to each nucleus using ImageJ. Nuclear chromatin density was calculated using images of the nucleus at the mid-point of each cell.

3. Traction force microscopy

VICs were seeded on 9kPa polyacrylamide gels for traction force microscopy (TFM) using methods published by others.[5] Fluorescent images of the beads immediately beneath the patterned cells were recorded using our two-photon microscope with a 960nm excitation wavelength and a 525nm/45nm emission filter. The change in the position of the fluorescent beads was quantified using a MATLAB script. Cell contractility was quantified by VIC response to 50nM ET-1 (Sigma) after 5 minutes. VIC basal tone was quantified by VIC response to a 100μM saturating dose of the rho-activated kinase inhibitor and vasodilator HA-1077 after 5 minutes.

4. Two-photon redox imaging

VIC samples were placed in heated imaging chambers and imaged using the same two-photon microscopy system described earlier. The laser excitation source was tuned to 755nm (NADH fluorescence) or 860nm (FAD fluorescence) and images were acquired via a 466nm/40nm (NADH) or 525nm/45nm (FAD) bandpass filters, respectively. Images were analyzed using a cu stom MATLAB script and redox ratio was calculated using the following equation on a per pixel basis.

RESULTS

1. Actin and nuclear architecture and orientation varied as a function of cellular shape

Phalloidin staining of F-actin, showed that the filaments became more prominent and aligned along the longitudinal direction of the cell as AR increased (Fig. 1A). Nuclear staining using DAPI revealed increased nuclear elongation as cell AR increased (Fig. 1B). Quantification of actin alignment using a previously developed technique revealed actin alignment to be statistically higher ($p<0.05$) at a stretch ratio of 1:7 compared to 1:5 and 1:3 (Fig. 1C) Quantification of the nuclear eccentricity from the DAPI stains indeed did indicate significantly increasing eccentricity increased with increasing cellular AR (Fig. 1D). The nucleus did not elongate to the same extent as the cell, probably due its higher mechanical rigidity. Analysis of chromatin density from the DAPI stains revealed significantly higher intensity in the 1:5 AR sample compared to 1:3 or 1:7 AR samples (Fig. 1E). There was no statistical difference in nuclear area at different ARs (Fig. 1F).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

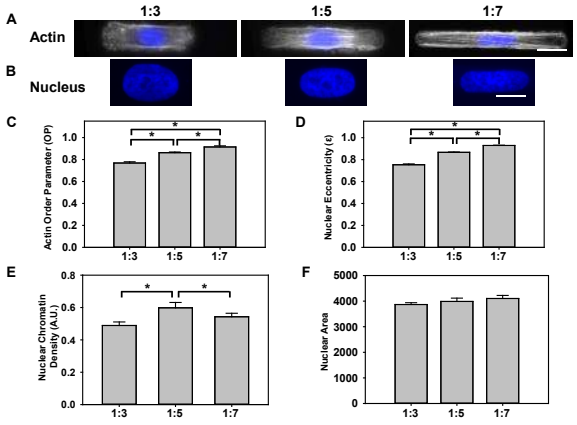

Figure 1: Actin orientation and nuclear morphology analysis of single cells

2. Elongated VICs generated greater contractile traction

VIC contractile strength, as computed by the traction stress applied by the cell on i ts substrate due to ET-1, significantly increased with increasing cellular elongation (Fig. 2A, C). Basal tone, as quantified from the response to HA-1077, was low at 1:3 AR and significantly higher at 1:5 AR (Fig. 2B, D). However there was no s ignificant difference in basal tone between 1:5 and 1:7 ARs.'

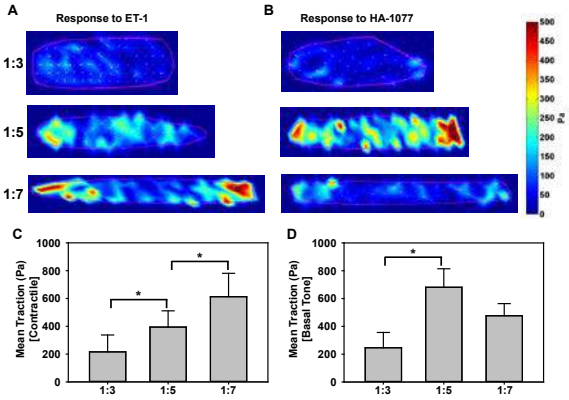

Figure 2: Traction force microscopy data

3. Elongated VICs exhibited reduced FAD/NADH redox ratio

We asked if the ratio of FAD to NADH fluorescence, termed the metabolic redox ratio, was altered as a function of cellular AR elongation. Our results show that as cellular AR increased, there was a significant increase in NADH intensity (Fig. 3A,B). FAD intensity also increased with increasing cellular AR, but there were only significant differences between the 1:3 and 1:7 AR (Fig. 3B). The above resulted in overall decrease in redox ratio (Fig. 3C). A previous study reported that a decrease in redox ratio was inversely proportional to cellular metabolic activity.[6]

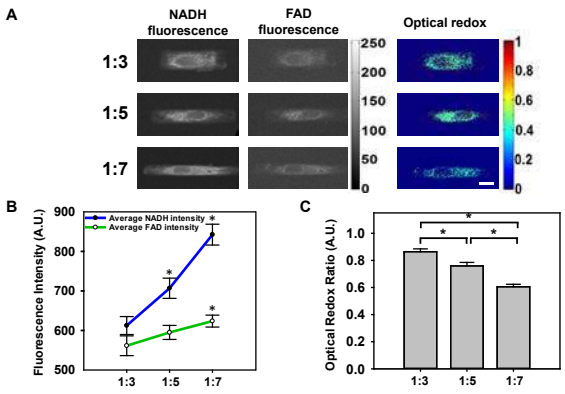

Figure 3: Redox imaging of single cells

DISCUSSION

We demonstrate the strong correlation between VIC shape and its contractile and metabolic function using single cell VIC model. VIC shape change could be thus seen as an indication of potential changes in the cell activity and vice versa. We also proposed the possibility of using redox ratio as one of the tools for early detection pathological state of VICs.

INTRODUCTION

Understanding mechanical properties of brain tissue is essential to the understanding of traumatic brain injury (TBI). Researchers have studied the mechanical properties of soft tissues, both *in vivo* and *ex vivo*, using magnetic resonance elastography (MRE) [1], ultrasound elastography [2] and direct tests [3,4]. Brain tissue has been studied *ex vivo* using ultrasound elastography [5], MRE and dynamic shear testing (DST) [6], and *in vivo* using MRE [7,8,9]. However, estimates of brain shear modulus *in vivo* by MRE are higher than estimates from DST *ex vivo*. It is not clear how much of these differences are due to methodology (MRE vs DST), the frequencies studied in each test, or to true differences between the properties of live and dead tissue. MRE studies of brain tissue *ex vivo* are needed for direct comparison to *ex vivo* DST and *in vivo* MRE. Directional differences in stiffness are also important and may be detected by MRE [1]. The aim of this study is to improve the understanding of brain material properties as well as the relationship between MRE and direct tests of brain tissue.

METHODS

Brains were obtained from two pigs (13 weeks; 38.5kg, 44.5 kg). In each brain, a disk-shaped sample (48 mm dia; ~8 mm thick) of mainly white matter (WM) was dissected from the corpus callosum and surrounding areas (Fig. 1(a)). Samples were embedded in food grade gelatin (Knox, 4% wgt/vol in 50% pre-buffered saline / 50% glycerol solution) within a 48mm ID cylinder. A 3-mm diameter Delrin rod provided axial (z) excitation at 200 and 300 Hz, leading to shear waves with radial propagation direction ($\boldsymbol{n} \approx \boldsymbol{e_R}$, Figure 1b). To confirm axon orientation in white matter, diffusion tensor imaging (DTI) was performed (30 directions, b=2000 s/mm^2). Time from animal sacrifice to DTI/MRE experiment was ~5.5 and 7.5 hours for samples #1 and #2.

To estimate material properties, shear wave images were analyzed using 3D local frequency estimation (LFE) [10]. In uniform media, shear modulus may be estimated directly from wavelength. Since the sample is heterogeneous, MRE results were compared to finite element simulations of the experiment to estimate shear modulus. A finite element (COMSOL^{TM} Multiphysics 5.1) model [11] was created of an 8 mm layer of brain tissue (shear modulus μ, loss factor η, density ρ) between two 20 mm gelatin layers (μ=1000 Pa, η=0.1, ρ=1000 kg/m^3). The boundary conditions (BCs) are: 20 μm axial harmonic excitation at 200 Hz on the inner radius (1.5 mm); 2.5 μm axial excitation at 200 Hz on the outer radius (24 mm); and free top and bottom faces (Fig. 2). A quarter wedge was simulated with symmetrical BCs on the *xz* and *yz* planes; the full field size of 50x50x48 mm^3 was created by interpolation.

RESULTS

Figure 1 panels (c-e, d-f) highlight the difference in both wavelength and dissipation between *ex vivo* brain tissue and gelatin. Average wavelengths were longer in brain tissue than in gelatin (Figure 3(a,c,d)). Shear waves were found to dissipate at a much greater rate within brain tissue when compared to gelatin. Shear wave fronts emanating from the center of the sample were found to be slightly elliptical in Sample #1 but similar elliptical behavior was not found in Sample #2. Figure 3c shows the wavelengths found, by slice, for Sample #1. Slices with predominantly *ex vivo* brain tissue and gelatin are highlighted. Figure 3d shows wavelengths found, by slice, for the simulation shown in Fig. 2. Radially propagating wave fronts were fit to ellipses, and the ratio of the major semi-axes and minor semi-axes were found for the different materials (Fig. 3b).

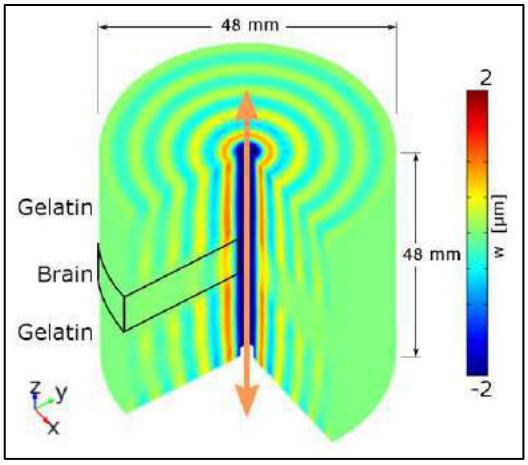

Figure 2: Finite element simulation model of an 8mm stiff layer ("brain", shear modulus μ = 2.5 kPa, loss factor η=0.5, and density ρ=1000 kg/m^3) sandwiched between two large (20 mm) soft layers ("gelatin", μ = 1.0 kPa). The center of the cylinder is excited in the z-direction producing shear waves in the xy plane.

DISCUSSION

Preliminary MRE results are consistent with white matter in the brain being stiffer (μ ~ 2.5 kPa) and more dissipative (η~0.5) at 200 Hz than surrounding gelatin. Slightly elliptical wavefronts suggest mild anisotropy. For comparison, a semi-axis ratio significantly greater than 1 was previously found in other transversely isotropic tissues [1].

Limitations of this study currently include the time from sacrifice to experiment and the composition of the surrounding gelatin. Current inversion and analysis methods must be adapted for thin tissue samples of non-uniform thickness and composition. The current comparison method with FE models serves to obtain rough estimates; however, automated methods are needed. The current FE model does not account for anisotropy due to axonal fibers, the difference between gray and white matter, or slip between tissue and gelatin. Reducing the shear stiffness of the surrounding gelatin may reduce its influence on shear waves in the brain tissue. While axonal orientation within the white matter may affect wave propagation, as in studies of other fibrous soft biological tissue [1], the fiber orientation within these brain tissue samples was not as consistent as the orientation of samples used in prior studies (aligned fibrin gel or ex vivo turkey breast). This heterogeneity complicates the interpretation of these wavefronts.

This present study provides new data on MRE of *ex vivo* white matter/brain tissue. Clear differences in shear wave wavelength and dissipative properties were found between slices containing predominantly brain tissue and gelatin. Future work will focus on developing automated analysis methods for thin, heterogeneous embedded samples and interpreting shear wave data with respect to the geometry and fiber directions in the sample. This study should advance the understanding of brain material properties *in vivo* and *ex vivo* as well as the relationship between MRE and direct tests of brain tissue *ex vivo*.

INTRODUCTION

According to the Strategic Plan of 2012-2016 [1], the National Institute for Biomedical Imaging and Bioengineering (NIBIB) supports a global shift to adopt an interdisciplinary approach to STEM education that is attentive to the practical value of new knowledge with a focus on innovative technologies. To ensure America's position as a world leader in the education of engineering talent, curricula are needed that teach students how to apply their knowledge using hands-on approaches. There is growing recognition of the potential for the "maker movement" to transform how and what people learn in STEM disciplines. According to President Obama and the Educate to Innovate campaign, makers "see the promise of being the makers of things, and not just the consumers of things" [2].

The Master of Engineering (MEng) in Design and Commercialization program at the University of Alabama at Birmingham (UAB) was designed to support the principles of hands-on learning in interdisciplinary teams and innovative environments. Teams comprised of engineering and business graduate students engage in hands-on design and prototyping of Innovation-Commercialization (IC) projects that take promising new ideas through the R&D process to create marketable products. This year's team has adopted projects with clients and faculty mentors from UAB Hospital and Children's Hospital of Alabama, among others. These partners, as well as participating local companies, share clinical, technological and business know-how with the students as the projects develop, and provide for experiential learning opportunities such as internships.

The curriculum for engineering students in the MEng consists of 24 credit hours in engineering and 12 credit hours in the MBA program, which earn students the MEng degree as well as a Graduate Certificate in Technology Commercialization and Entrepreneurship from the UAB Collat School of Business. The course sequence was coordinated to parallel the IC project development. The MEng students join with MBA students to form teams in the fall business course, MBA 681 Idea to IPO. Concurrent enrollment in the year-long MBA 691 course, i2i Entrepreneur Accelerator Independent Study, provides mentoring for commercialization that will culminate with students pitching their start-up companies at the Alabama Launchpad business plan competition, with the opportunity of gaining financial support to incubate a new business in the Innovation Depot.

The present manuscript documents the development of a new course, EGR 693 Innovation-Commercialization Project I, which focuses on hands-on training of "maker activities," including computer aided drawing (CAD), machining, and electronics, which allow students to build their competency in prototyping. The goal of the course is to provide students with the hands-on skills necessary for the development of innovative solutions to real-world problems, with the potential for commercialization.

METHODS

In EGR 693, students first review Computer Aided Drawing (CAD), a natural precursor to fabrication, using Creo software (PTC, Needham, MA). Students are tasked to model a beam with a through-hole in the shape of any suit from a deck of cards (heart, spade, diamond, or club). Students are then required to make their "beam with a hole" by hand-machining. The beam example extends to Computer Numeric Control (CNC) machining, where they are introduced to G-code and CNC mills. Next, they learn to 3D print their beams, with lectures on printing materials and hobbyist machines versus professional industrial printers. At the conclusion of the beam example, students are able to

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

compare each machining method and determine which method(s) would best suit their needs when prototyping.

In addition, the students explore contemporary electronics through hands-on activities using breadboards in conjunction with Arduino (Arduino, LLC, Cambridge, MA) and Raspberry Pi (Adafruit, New York, NY). Students are provided with kits to work on coding examples during class and to encourage further investigations outside of class. Finally, students receive instruction and lab experience on soldering printed circuit boards (PCBs). The end result of this course are students who have gained an invaluable set of engineering skills and capabilities for prototyping and applying advanced methods when developing complex projects.

The primary learning outcome for the EGR 693 course is that students will demonstrate proficiency in the maker skills to which they were introduced. To examine the levels of student proficiency, an assessment survey was given to each student to score their perceived levels of competency in each maker activity reviewed.

RESULTS

All students in the program (n = 11) successfully completed each module related to the "beam with a hole" exercise, which included CAD drawings, hand-machining, 3D printing and CNC machining (Fig. 1). Approximately 80% of students in the MEng program had previous experience with using the Creo CAD software; thus, they were able to quickly demonstrate proficiency in this activity. During the hand-machining activity, students experienced the limitations of hand-machining through difficulties creating profiles of card suits, which contain several sharp internal corners. Students found that CNC and 3D printing yielded higher levels of precision in comparison to the hand-machined parts. Students also noted the increased efficiency in the time, cost and labor required to machine parts using CNC machines and 3D printers.

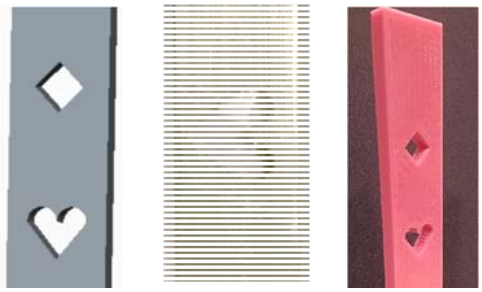

Figure 1: Example CAD drawings, hand machined, and 3D printed versions of the "beam with a hole."

Using a Sparkfun RedBoard and the Arduino IDE software, students programmed a variety of codes with circuits they built to apply integration techniques. Figure 2 illustrates an example completed by a student in which she integrated breadboards, programming and the microcontroller in order to control a multi-LED circuit.

The results of the student surveys indicate substantial increases in the perceived levels of competency among the various maker activities upon completion of the course (Fig. 3). In addition, the students' knowledge, retention, and personal investment have been seen to improve based on increased interest outside the classroom. For example, some students have invested in 3D printing for personal work outside of the course requirements. Similarly the same involvement beyond the classroom can be seen in their use of Raspberry Pi and embedded Linux systems. These investments by the students point to the intrinsic motivation inspired by the class. Student comments indicated that they feel more employable as a direct result of this course. Through the pursuit of commercialization and product development, each student has built up a work portfolio. Such example work greatly improves the resume of each student, which supports one of the desired program outcomes of aiding students in gaining competitive career placements.

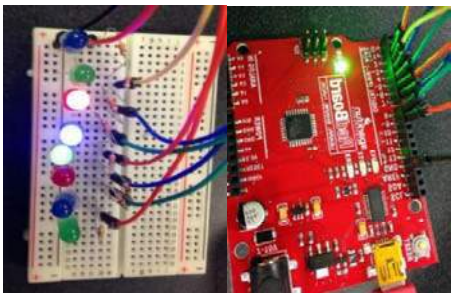

Figure 2: The assembled Multi-LED circuit and Arduino

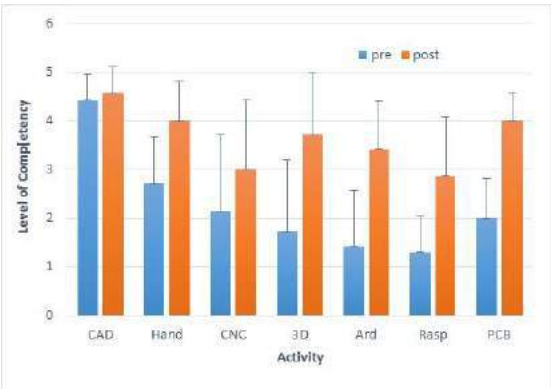

Figure 3: Perceived competency levels (mean + st. dev.) as reported by the students

DISCUSSION

The new EGR 693 course was successfully developed and led to increasing student competency in methods used in prototyping innovative technologies. Students now have firsthand experience in many manufacturing methods with "maker activities" serving as the vehicle for education. As the program has not yet graduated its first engineers, expected outcomes include improved employment opportunities for graduates; e.g., students will gain competitive positions in industry, launch new start-ups, or be accepted into PhD programs. Other desired outcomes include intellectual property gained by the university, and increased program funding with reviews and completed projects serving as evidence of the quality of the MEng in Design and Commercialization at UAB.

ACKNOWLEDGEMENTS

TSAI-HILL MAXIMUM-WORK THEORY AS A FAILURE CRITERION FOR FIBROUS BIOLOGICAL TISSUES

Christopher E. Korenczuk (1), Victor H. Barocas (1)

(1) Department of Biomedical Engineering
University of Minnesota – Twin Cities
Minneapolis, MN, USA

INTRODUCTION

Showing the von Mises stress in computer simulations of a tissue at risk of failure has become a routine practice (e.g., [1, 2, 3]). While its ease of calculation and its availability as a standard output in most finite-element software make the von Mises stress attractive, its use is accompanied by the implicit assumption that the von Mises failure criterion is applicable to the tissue in question. The von Mises criterion, however, is inherently isotropic and thus may make poor predictions in anisotropic tissues. In order to predict failure of such tissues accurately, one must use a failure criterion that can account for the anisotropy.

Extensive work has been done to analyze the failure behavior of non-biological fiber composites [4]. The Tsai-Hill theory [5,6] has been derived as a maximum-work theory to characterize the failure of anisotropic materials. The theory provides a single scalar failure criterion based on the principal material direction strengths and the shear strength. Thus, it provides a potential platform to analyze how off-axis loading affects an anisotropic fibrous material.

Arteries are anisotropic tissues that contain an underlying fiber laminate structure comprised mainly of collagen and elastin. The collagen fibers exhibit a strong preferential alignment in the circumferential direction, along with a weaker, but still significant preference for the axial direction, making these two fiber alignments the assumed principal material directions. Thus, the arterial wall provides an excellent representative system on which to study the efficacy of the von Mises and Tsai-Hill failure criteria. In this work, we studied porcine aortic tissue.

METHODS

Cadaveric porcine abdominal aortas were cut into uniaxial dog-bone-shaped samples with fiber angles ranging from 0° to 90° in increments of 15° (Fig. 1). Fiber angle was randomized along the length of the vessel to account for any regional heterogeneity (samples were not cut sequentially as shown). Samples were imaged before testing, and morphological measurements were computed with ImageJ. Samples were subjected to uniaxial tensile loading tests (Instron 8800 Microtester) at 10 mm/min until failure. Each sample was speckled with Verhoeff's stain in order to produce a distinct surface texture for full field strain tracking analysis via digital image correlation.

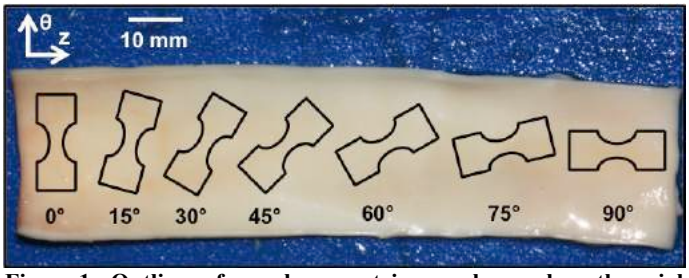

Figure 1: Outlines of sample geometries are shown along the axial length of the vessel. Angles were taken to be relative to the circumferential orientation (0°). Scale bar shown in white at top.

Failure stresses and stretches of each sample were analyzed in MATLAB. 1st Piola-Kirchhoff stresses were computed based on initial sample geometry and were converted to Cauchy stresses assuming tissue incompressibility. Statistical analysis was performed using GraphPad Prism 6.

The Tsai-Hill model for a uniaxial test takes the form [4]

$$\frac{\cos^4\theta}{\sigma_{LU}^2} - \frac{\cos^2\theta\sin^2\theta}{\sigma_{LU}^2} + \frac{\sin^4\theta}{\sigma_{TU}^2} + \frac{\sin^2\theta\cos^2\theta}{\tau_{LTU}^2} < \frac{1}{\sigma_x^2} \qquad (1)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

where σ_{LU}, σ_{TU}, and τ_{LTU} are constants representing the material behavior. For our system, the preferred principal material direction is assumed to be the circumferential alignment, and the transverse direction would then follow as the axial alignment. Therefore, θ is the counterclockwise fiber angle relative to the circumferential direction, σ_{LU} is the circumferential (0°) failure stress, σ_{TU} is the longitudinal (90°) failure stress, τ_{LTU} is the shear stress, and σ_x is the failure stress in uniaxial extension at a given fiber angle. The three constants σ_{LU}, σ_{TU}, and τ_{LTU} were fit to the experimental data. Curve fitting was performed in MATLAB.

RESULTS

Experimental testing (n>5 for each angle) showed that the largest failure stress occurred in the circumferentially aligned tests (0°) at 2.97 ± 0.66 MPa (mean ± 95% CI). A decrease in failure stress was seen with an increase in fiber angle to the fully axially aligned case (90°) at 1.15 ± 0.64 MPa (Fig. 2). The smallest failure stress was seen in the 75° case at 0.96 ± 0.30 MPa. A one-way ANOVA showed that the effect of fiber angle change on the failure stress was highly significant ($p < 0.0001$), and a Tukey-HSD comparison showed a significant difference between the 0° and 90° alignment cases ($p = 0.0001$). These results indicate that an isotropic failure criterion, such as the von Mises criterion, is not acceptable.

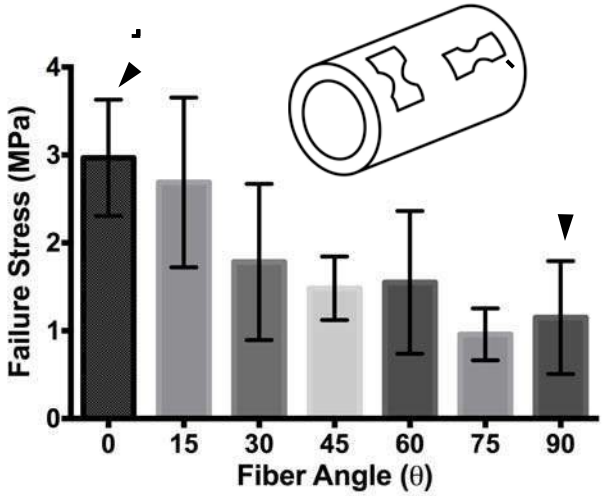

Figure 2: Failure stresses at each fiber angle. ANOVA showed that change in fiber angle is statistically significant ($p < 0.0001$). Error bars show 95% CI's. Note: the 60° case had two outliers removed due to high residual stresses affecting failure stress.

The Tsai-Hill maximum-work theory model (Eq. 1) showed a very good fit to the experimental data ($R^2 = 0.96$) (Fig. 3). Fitting the model provided a σ_{LU} value of 3.01 ± 0.51 MPa, a σ_{TU} value of 1.12 ± 0.34 MPa, and a τ_{LTU} value of 1.02 ± 0.35 MPa.

DISCUSSION

Uniaxial testing of porcine aorta confirmed previous work showing a higher circumferential failure stress compared to the axial alignment [7]. An increase in fiber angle to produce off-axis stresses resulted in decreased failure stress. These results show that failure stress is dependent upon fiber angle, a consideration not accounted for by the von Mises failure criterion. For a uniaxial test, the von Mises failure criterion reduces to a single, direction-independent tensile stress at failure, not accounting for the anisotropy of the tissue.

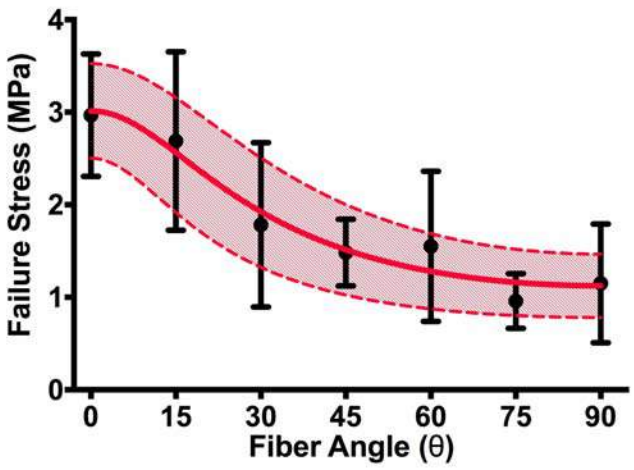

Figure 3: Experiment (points) and Tsai-Hill maximum-work theory model (solid line). Black error bars show 95% CI's on experimental points. The shaded region indicates the 95% CI on the fitted model.

The Tsai-Hill maximum-work theory provides a single scalar function incorporating both the fiber orientation and the directional strength interaction (longitudinal, transverse, and shear strengths). It is a more robust and physiologically relevant failure criterion, considering many tissues, such as arteries, contain anisotropic fibrous networks. Our results show its potential as a tool to predict failure in anisotropic tissues, including the porcine abdominal aorta studied here.

In our experiments, the minimum failure stress occurred at an angle of 75° from the preferred direction, but that failure stress was not significantly different from the failure stress at 90° ($p = 0.9987$). The Tsai-Hill criterion can support a non-monotonic failure-angle relation, as is often seen in synthetic fiber composites [4]. Whether the minimum at 75° was real or noise, and whether other tissues do or do not observe a local minimum in failure stress, are questions that merit further exploration.

Though the Tsai-Hill maximum-work theory model accounts for fiber anisotropy, it is possible that a different criterion may work better. Different tissues, for example, may exhibit regional heterogeneity and fiber anisotropy, in which case a modified approach must be used. Also note that the Tsai-Hill maximum-work theory only accounts for two fiber families, but arteries and other fibrous tissues have been characterized by four or more fiber families [8], so a more extensive model can also be explored.

INTRODUCTION

The coagulation cascade of blood may be initiated by shear-induced platelet activation, which prompts clot formation in prosthetic cardiovascular devices. Upon activation, platelets undergo complex morphological changes. Activated platelets polymerize fibrinogen into a fibrin network that enmeshes red blood cells. Continuum methods fail to capture the molecular mechanisms such as filopodia formation during platelet activation, while utilizing molecular dynamics is computationally prohibitive. A multiscale approach offers a means to bridge the gap between macroscopic flow and the cellular scales

We are developing a predictive multiscale numerical method that combines a Dissipative Particle Dynamics (DPD) model of viscous blood flow interfaced with a Coarse Grained Molecular Dynamics (CGMD) model of mechanobiology-based platelets, to simulate their activation via mechanotransduction pathways. This model bridges the gap between macroscopic transport flow-induced platelet activation scales and the ensuing molecular events. Platelets dynamically change their shapes in viscous shear flows and synergistically activate by a biomechanical transductive linkage chain. The CGMD platelet model is embedded in the DPD blood flow model, with macroscopic dynamic stresses interactively transferred to the platelet model. Hemodynamic stresses that lead to platelet activation and filopodial formation are mapped on membrane and simultaneously transmitted to cytoskeleton. Upon activation, platelets with intracellular constituents evolve as they lose their quiescent discoid shape and form filopodia. Actin filaments that are exposed to the highest stresses undergo filopodial formation. Model predictions are correlated with in vitro results.

METHODS

Our multiple spatial-temporal methods employ DPD to describe viscous blood flow and CGMD to model the intra-platelet constituents. Spatially, the DPD-CGMD interface was established by imposing a hybrid force field [1]. A 4-level multiple time-stepping (MTS) scheme was used [2] as an efficient numeric solver.

In the microscale, we improved the DPD formula by adding a Morse-based repulsive term for favorably producing Poiseuille flow of an incompressible fluid through a stenosis where the compressibility becomes a problem for DPD. We conducted a comparative study to investigate the fluid flow properties of DPD-Morse and DPD fluids through a 67% stenotic microchannel. Our DPD-Morse can extend the conventional DPD to sustain large compression caused by a stenosis.

In nanoscale, we built a mechanobiology-based platelet model by describing key constituents and biophysical properties. We modeled a bilayer membrane, ellipsoid shape, rigid filamentous core, gel-like cytoplasm using Morse potential [3], and filamentous actin. An α-helix structure was used to mimic a protrusible actin filament.

We validated our numerical method by correlating numerical simulations and model predictions with in vitro platelet activation experiments. Purified platelets [4] were prepared from whole blood obtained from consenting healthy donors of both genders. Platelets were exposed in a Hemodynamic Shearing Device to different shear stress-exposure time combinations up to 50 dyne/cm^2 and 4 min, respectively. Platelet samples were fixed with 2% glutaraldehyde, mounted on glass slides, and dehydrated through an ethanol series prior to imaging with scanning electron microscopy. We particularly examined the average number of visible filopods per platelet, circularity of activated platelets, and the position of filopods.

RESULTS

Our multiscale model describes the biophysical properties for platelets down to the nanoscales (Fig. 1). Membrane Young's modulus is 31.2 μN/m and shear elastic modulus is 33.0±9.0 μN/m. Cytoplasm viscosity is 4.1 mPa·s. Actin filament stiffness is 56.3±1.0 pN/nm.

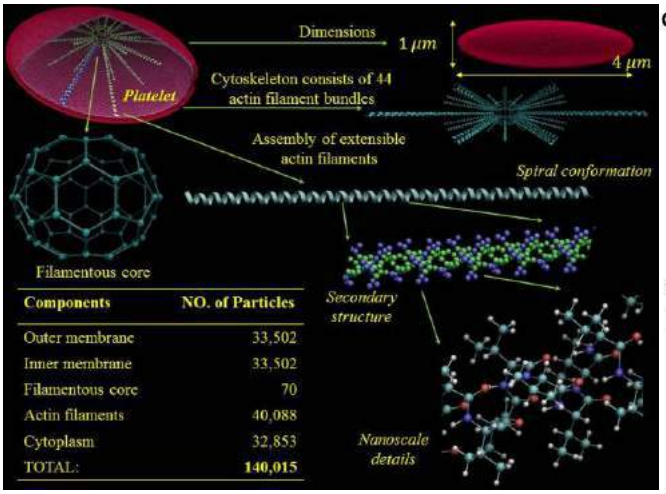

Figure 1: The nanoscale platelet model and its constituents

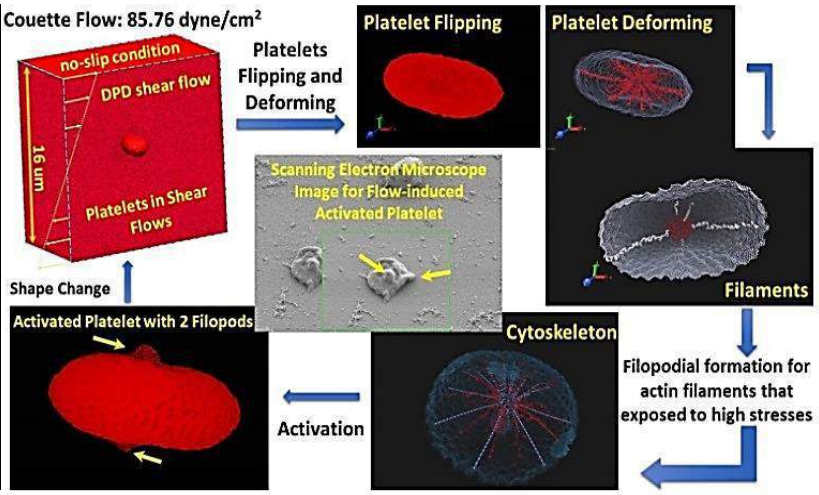

Figure 2: Mechanotransduction of the hemodynamic stresses and filopodial formation (two filopodia for activated platelet)

Using this model, we simulated the flow-induced platelet activation (Fig. 2). We assessed shear stress accumulation for flowing platelets in a flipping period. When platelets were flipping in the viscous flow, dynamic stresses were mapped on the cytoskeleton, with simultaneous accumulation of the mapped stresses over the period. This emulated the effect of mechanotransduction process of dynamics stresses in platelets. Filopodial formation is applied to actin filaments that are exposed to the highest stresses.

We correlated the morphological changes for activated platelets between numerical simulations (*A*) and in vitro results (*B-D*) (Fig. 3). (*A*) is morphological detail of our platelet model. (*B*) is a SEM image for cytoskeleton reorganization. (*C*) is the surface of activated platelets; (*D*) is the rendered view of a tomographic volume for a filopodium.

We correlated our numerical results for flow-induced platelet shape change with in vitro results. We counted the average number of visible filopods per platelet, the circularity of activated platelets, and the position of filopods of varying lengths. The in vitro results show that the average number of visible filopods is 2-3 per platelet, and their lengths ranged between 0.5~1.0 μm. The long filopods grew mostly on the edge of a platelet, while the filopods on the center were short. The majority of activated platelets preserved their ellipsoid shape and their circularity had no significant change. Our model assembled 44 actin filaments so it was capable of imitating enough visible filopods. In addition, our model also agreed with the preservation of the ellipsoid shape and reflected the position of the short and long filopods.

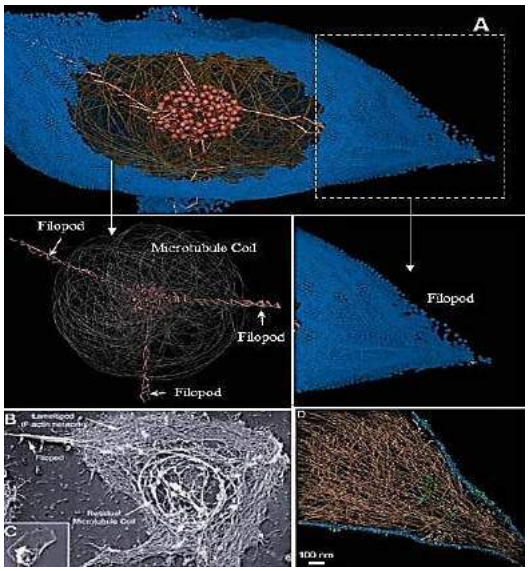

Figure 3: Morphological comparison between numerical model (A) and in vitro results (*B-D*). Credits: (*B*) and (*C*) are from J. H. Hartwig's book chapter [5]. (*D*) is from S. Sorrentino's work [6].

DISCUSSION

Our simulations do not only agree with the in vitro results but also suggest new testable predictions. Our results reveal that (1) decreasing membrane stiffness plays an essential role in promoting the formation of long filopods. In addition, (2) increasing numbers of longer filopods, for highly activated platelets, strongly correlates with microstructural rearrangement and mechanical properties. We show that a platelet needs to sustainably increase its protrusive force to grow a longer filopod and requires a stronger cytoskeleton to support more filopods growing radially outward. In this regard, a stronger structural arrangement and a stiffer mechanical property are supportive.

Our approach is the first computationally affordable numerical method for simulating the platelet activation by highly resolved mapping of mechanical stresses on the cytoskeleton in dynamic flow. Biophysical properties of a platelet are accurately described down to nm-length and ps-time scales. The viscous flows are described at μm-length and ns-time scales. Phenomena of filopodia formation are mimicked and correlate well with in vitro results. This model can be further employed to model the initiation of thrombosis in blood flow and study the effects of modulating platelet properties to enhance their shear resistance via mechanotransduction pathways.

INTRODUCTION

Injury to the growth plate is associated with growth disturbances, including premature cessation of growth and angular deformities (*1, 2*). Developing successful, less invasive treatments for growth plate injury has been impeded by incomplete understanding of the features of the injury response that cause these growth problems. Radiographic evidence indicates that the growth disturbances are associated with formation of bony bridges at the injury site (*3*); however, conflicting reports exists as to whether these bridges form via intramembranous or endochondral ossification (*4,5*). Histological evidence has revealed disorganized chondrocyte columns and increased growth plate thickness in the region of the growth plate adjacent to the injury site, suggesting that local changes in cellular activity may contribute to angular deformities (*6-8*). Using contrast-enhanced micro-computed tomography (CECT) for cartilage imaging (*9*), local changes in the cartilaginous and osseous tissues in the healing growth plate can be robustly examined with quantitative, three-dimensional measurement.

The goal of this study was to quantify spatial changes in the morphology and composition of the growth plate following injury. The specific objectives were: 1) to quantify local and global changes in growth plate thickness and CECT attenuation (indicative of glycosaminonglycan (GAG) content); 2) to quantify the amount of bone formed within the growth plate following injury.

METHODS

Animal model: All animal experiments were conducted according to a protocol approved by an Institutional Animal Care and Use Committee (IACUC). A 0.51mm-diameter pin was used to make a hole defect in the distal femoral growth plates of 39 four-week-old, male, C57BL/6 mice. Mice were sacrificed one, three, or six weeks following injury. Injured and contralateral femora were collected and stored at -80°C.

Micro-computed tomography (μCT): Femora were imaged using μCT (μCT40, Scanco Medical, Brüttisellen, Switzerland) at a nominal resolution of 6 μm/voxel, before and after incubation CA4+, a cationic contrast agent, for 14 hours (Figure 1A). Pre- and post-incubation images were aligned using rigid-body registration and then subtracted from one another (Amira 5.2.2, Visage Imaging, Andover, MA). Cartilage was identified in the subtracted image by applying a threshold based on a four-part Gaussian fit of the intensity of the subtracted image (*10*). Thickness of the growth plate was calculated using distance-transformation methods (Scanco Medical). The average thickness and CECT attenuation of the growth plate were measured within a 1mm-diameter volume of interest (VOI) centered at the injury site ("near"; Figure 2B inset) and within the rest of the growth plate ("far"). For comparison purposes, near and far VOIs were defined at matched sites in the growth plate of the contralateral bone. For assessing bony bridges, the bone volume fraction (BV/TV) and tissue mineral density (TMD) of bone within the entire growth plate were measured in the pre-incubation scan (Figure 1B). For injured growth plates, BV/TV and TMD were also calculated near (within 0.75mm of the injury site) and far from the injury site.

Histology: Decalcified, paraffin-embedded sections of the distal femur were stained with hematoxylin and eosin, safranin O, and fast green.

Statistical Analysis: Growth plate thickness, growth plate CECT attenuation, BV/TV, and TMD were each compared between injured and contralateral sides, between near and far VOIs, and among time points using a repeated-measures ANOVA (JMP 11, SAS Institute Inc., Cary, NC). When indicated by the ANOVA result, pairwise *post hoc* tests using the Bonferroni correction were carried out.

RESULTS

Growth plate thickness and CECT attenuation varied spatially

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

within the growth plate and over time, and were affected by injury (Figure 2A). Although thickness decreased over time ($p<0.0001$), this decrease was least pronounced at the injury site: thickness in the near VOI of the injured growth plate was higher than those in the far VOI ($p<0.0001$) and in the near VOI of the contralateral growth plate ($p<0.0001$; Figure 2B). Similarly, injury slowed the temporal decrease in CECT attenuation: whereas attenuation progressively decreased from day 7 to 21 and 42 in the contralateral VOIs ($p<0.0001$), no temporal changes were seen in the injured near VOI ($p=0.12$). In the injured far VOI, attenuation did not differ between days 7 and 21 ($p=0.65$), but was lower at day 42 vs. days 7 and 21 ($p<0.0001$).

Bony bridges were evident by histological analysis in most samples by day 7 and in all samples at later time-points (Figure 3A,B). While BV/TV and TMD increased over time within both injured and contralateral growth plates ($p<0.0001$), these changes were most pronounced at the injury site (Figure 3C). At day 21, BV/TV and TMD were higher near the injury site compared to far from the injury site and to the entire contralateral growth plate ($p<0.01$). At all three time points, BV/TV was higher in the contralateral growth plate than in the injured growth plate far from the injury site ($p<0.01$).

In day-7 samples with no evident bony bridging, CECT indicated a lack of cartilage at the injury site. Histological analysis confirmed the presence of loose connective tissue at this site. At later time points, some samples showed safranin O staining at the injury site, and CECT showed the presence of mineralized tissue. Disorganized chondrocyte columns were observed adjacent to the injury site at all time points, and the presence of large, round, hypertrophic chondrocytes was seen at days 7 and 21 (Figure 3B).

DISCUSSION

These results demonstrate that growth plate injury leads to localized changes in cartilage and bone. Injury resulted in reduced age-related thinning of the growth plate near the injury and slower loss of CECT attenuation, a measure of GAG, across the entire growth plate. These results, together with the disruption of the typical columnar organization of proliferating chondrocytes and the advent of many hypertrophic chondrocytes adjacent to the injury site, suggest that the healing response following injury involves local dysregulation of the normal endochondral process responsible for longitudinal growth.

Consistent with previous studies, injury resulted in the formation of bony bridges at the injury site (*3*). Use of CECT allowed identification of a defect in the cartilage preceding formation of bony bridges. Safranin O staining seen subsequently at the injury site, paired with CECT evidence of mineralized tissue at this site, supports the hypothesis that endochondral ossification contributes to bony bridge formation (*4,11*). However, increased TMD at the injury site compared to in the contralateral growth plate suggests that the bony bridges induced by injury are compositionally different from those formed during the normal aging process in mice. Surprisingly, while BV/TV was highest at the injury site, BV/TV was higher in the contralateral growth plate than in the injured far VOI. This relative paucity of bone away from the injury site combined with the high BV/TV at the injury site is further indicative of endochondral dysregulation and may contribute to angular deformities. Ongoing immunohistochemistry analyses are focused on identifying cellular and molecular mechanisms underlying this dysregulation.

INTRODUCTION

The vitreous humor is a substance that consists mainly of water, hyaluronan, collagen and additional molecular components. In youth, the vitreous is tightly adherent to the retina. With advancing age, changes in vitreous macromolecular interactions result in the formation of a liquefied vitreous that consists primarily of hyaluronan and water. Moreover, with aging the vitreous cortex (the outermost layer of the vitreous body) gets thinner, leading to the formation of small pockets of liquefied vitreous humor. These pockets slowly move through the thin cortex layer and settle between the cortex and the retina. These two processes, vitreous liquefaction and cortex thinning, normally occur simultaneously and result, in the majority of cases, in a posterior vitreous detachment (PVD) [1]. The effect of PVD may vary from negligible to significant, depending on the conditions of the vitreoretinal interface [2].

A split in the vitreous cortex, known as vitreoschisis, is a consequence of anomalous PVD (see Figure 1). It may result in different pathologies, including macular holes, macular puckers and retinal detachment. It is believed that the point where the two layers of the vitreous cortex re-join into a full-thickness layer is often site of significant tractions upon the retina [3]. In this work we study how the stresses exerted on the retina are spatially distributed in the presence of vitreoschisis and seek a mathematical explanation of the possible generation of strong retinal tractions.

METHODS

We study the generation of tractions on the retina during eye movements. In particular, we consider small-amplitude harmonic torsional oscillations of the eye. We model the vitreous chamber as a sphere and the vitreous body as a homogeneous viscoelastic fluid, with properties taken from [4]. The assumption of small-amplitude eye rotations allows us to linearize the governing equations. It is known from clinical observations [1, 2, 3] that the split in the vitreous is very thin with respect to the size of the domain. Based on this observation, we neglect the thickness of the split and model the vitreoschisis as a region of the eye wall on which the no-slip condition is partially relaxed. In particular, we assume that the velocity of the vitreous humor over the split is slightly smaller with respect to the velocity of the fluid attached to the normal vitreous cortex, where the usual no-slip boundary condition is imposed. Thus, we write that the normalized azimuthal velocity at the wall U reads

$$U = \left(1 - \varepsilon f(\theta, \phi)\right) \sin(\theta) \sin(t), \qquad (1)$$

where θ and ϕ are the zenithal and azimuthal angles and t is time. Moreover, $f(\theta, \phi)$ is the function describing the spatial variation of the slip: this is zero everywhere apart from in correspondence of the vitreoschisis where it attains positive values. Finally ε is a constant. In order to face the problem analytically we assume that $\varepsilon \ll 1$ and adopt a perturbation approach. This means that we consider a basic flow (the flow of a viscoelastic fluid in a harmonically rotating sphere [4]) and a perturbation, which accounts for the presence of the vitreoschisis. We find the solution using an expansion in vector spherical harmonics of the unknowns.

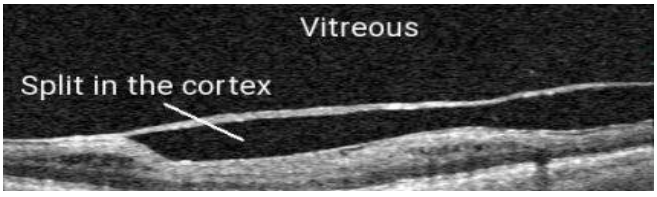

Figure 1: Clinical image of a vitreoschisis (modified from [1]).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

In Figure 2 we show the boundary condition at the wall, described by equation (1). The vitreoschisis is located on the equatorial plane and has a round shape. Note that in Figure 2 we have assumed ε large enough for the spatial variation of the velocity imposed at the wall to be visible in the plot. In Figure 3 we plot the total wall shear stress (WSS) maximized over the time. The figure shows that in correspondence of the vitreoschisis the WSS decreases with respect to the normal case. However, in the region where the split closes, the model predicts the generation of peaks of the WSS (dark red regions along the equatorial plane in Figure 3). The total stress is normalized with the maximum value of the WSS for the basic flow.

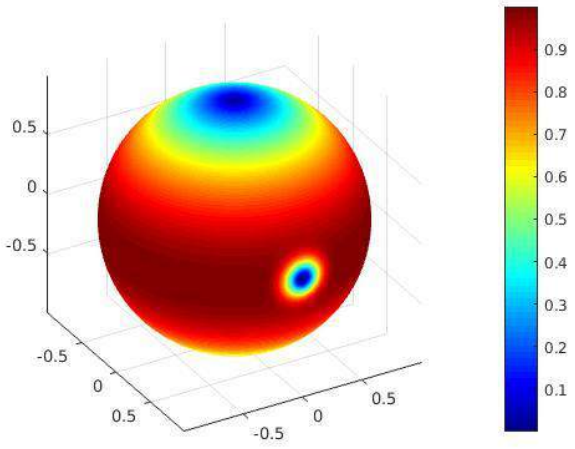

Figure 2: Normalized velocity imposed at the wall at time t = π/2. The blue spot on the equatorial plane is where the no slip condition is relaxed (vitreoschisis).

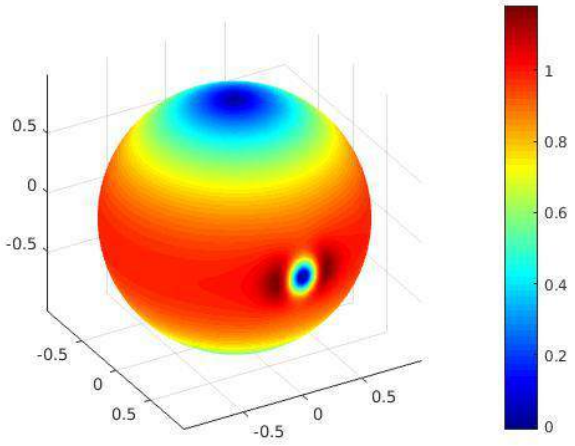

Figure 3: Map of the dimensionless WSS for the perturbation at the time instant t=π/2. The stress is normalized with $A\rho\omega^2R^2$, where A is the small amplitude of oscillations, ρ fluid density, ω the frequency of oscillations and R the radius of the sphere. ω=10 rad/s and ε=0.02.

In Figure 4 we plot the maximum total WSS (in time) along the equatorial plane. The WSS is normalized with the corresponding values in the absence of vitreoschisis (blue line). The red lines indicate the re-joining points of the split. Again, it appears that in these regions the WSS peaks, whereas it has a minimum in the middle of the vitreoschisis.

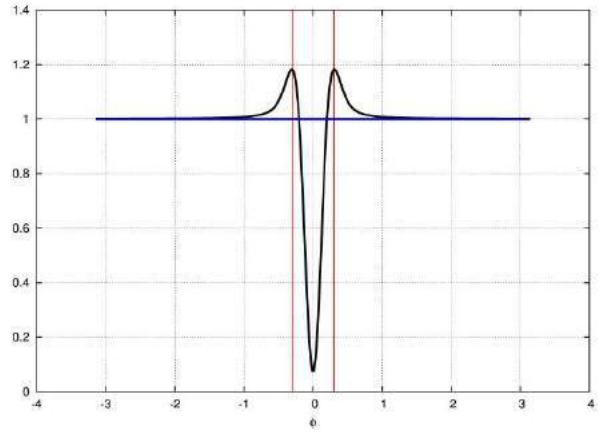

Figure 4: Maximum (in time) wall shear stress along the equatorial plane (θ = π/2). The stress is normalized with the maximum value of the wall shear stress of the basic flow (solid blue line). The red lines mark the points where the split re-joins. The frequency of oscillations is equal to $\omega = 10$ rad/s and $\varepsilon = 0.02$.

We also have studied how the effect of the vitreoschisis on the WSS depends on the mechanical properties of the fluid, finding that this grows both with the viscosity and the elasticity of the fluid.

DISCUSSION

In this work we have presented a mathematical model of vitreoschisis, i.e. a split in vitreous cortex, which is found in approximately half patients with macular holes and macular puckers. It is believed that the WSS in the region where the vitreous cortex split closes is larger than normal. The results of the model confirm that, during eye rotations, the WSS on the retina in presence of vitreoschisis experiences large peaks in the region where the vitreoschisis split re-joins. This provides a sound mechanical basis for the clinical observation that these regions are site of significant retinal tractions.

INTRODUCTION

With recent increases in youth sports involvement, the incidence rates of many musculoskeletal injuries in pediatric patients have been rapidly rising. For example, the incidence of anterior cruciate ligament (ACL) injuries of the knee joint have grown by as much as 11% per year in pediatric populations [1]. These injuries can lead to meniscal tears, chondral damage, and an increased risk for early-onset osteoarthritis [2].

In order to develop diagnostic tools and treatment algorithms and approaches specific to this growing patient population, it is important to understand the changes, and mechanisms of change, occurring in the knee joint during skeletal growth. Specifically, the nature and timing of tissue growth within and between tissues is not well understood, which in turn may have an impact on their relative function. As such, the objective of the current research was to characterize and compare volumetric size changes in the ACL, posterior cruciate ligament (PCL), medial meniscus, and lateral meniscus at several stages throughout skeletal growth in a large animal model. We hypothesized that the sizes of the tissues would scale similarly at all ages.

METHODS

For this study, hind limbs were collected from female Yorkshire pigs at ages of 1.5 months (n=6), 3 months (n=6), 6 months (n=6) and 18 months (n=5). These age groups are equivalent to juvenile (1.5 and 3 months), early adolescent (6 months), and late adolescent (18 months) age groups in humans. The stifle (knee) joints were isolated and stored at -20°C between experimental procedures.

The joints were imaged near full extension (approximately 30° flexion in the pig) using a 7.0 Tesla Magnetic Resonance Imaging (MRI) system (Siemens Magnetom) at the Biomedical Research Imaging Center at the University of North Carolina – Chapel Hill. Imaging scans were performed with a double echo steady state scan sequence (DESS, flip angle: 25°, TR: 17 ms, TE: 6 ms) with a voxel size of 0.42x0.42x0.4 mm and no gap between slices. Image series were analyzed using a commercial software package (Simpleware). Image segmentation and analysis was performed to collect the cross sectional area for each tissue in individual slices. Tools within Simpleware were then utilized to create and smooth 3D models for all knees (Fig. 1) and collect the volume of each tissue. Tissue dimensions were normalized as a percentage of their average late adolescent values in order to facilitate comparative analysis. Statistical tests included two-way analysis of variance with age and tissue type as factors followed by Bonferroni post hoc tests. Significance was set as $p<0.05$.

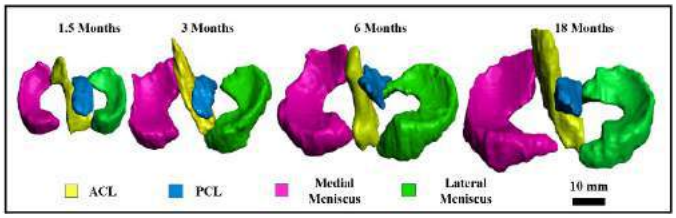

Figure 1: Models of porcine soft tissues at 1.5, 3, 6 and 18 months resulting from MR imaging and 3D reconstruction.

RESULTS

Two-way ANOVA testing of the normalized tissue volumes revealed age as a significant factor ($p=0.000$) and a significant interaction factor between age and tissue type ($p=0.032$), indicating a need to investigate individual groups using post-hoc tests.

Figure 2 shows the normalized volume of each tissue at 1.5, 3, 6, and 18 months of age. Statistical testing revealed that the PCL, medial meniscus, and lateral meniscus experienced similar and significant increases in normalized volume between 1.5 and 3 months ($p<0.05$) and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

3 to 6 months ($p<0.05$), with little change afterwards ($p>0.05$). Dissimilarly, the ACL experienced statistically significant growth between 1.5 and 3 months ($p<0.05$), but there was no significant change between either 3 and 6 or 6 and 18 months ($p>0.05$).

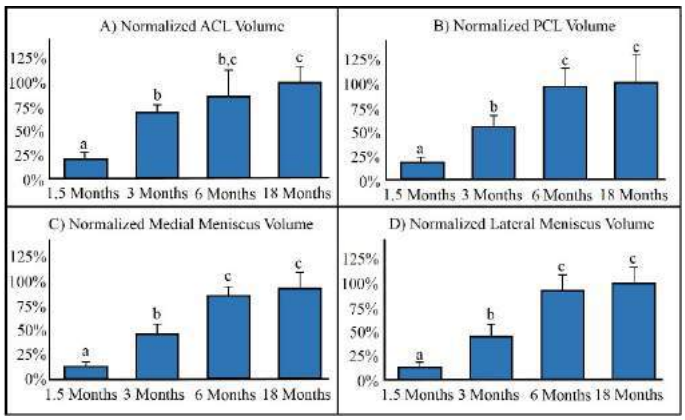

Figure 2: Normalized tissue volume (relative to the 18 month group) with respect to age in the A) ACL, B) PCL, C) medial meniscus, and D) lateral meniscus. Different letters represent statistically significant differences ($p<0.05$).

Figure 3 shows the normalized volume of all tissues at each age group. At 1.5 months of age, the ACL and PCL are approximately a fifth of their final size (20% and 18%) while the medial and lateral menisci are an average of 13% and 12% of their final size. Significant differences were found between the lateral meniscus and both the ACL and the PCL ($p<0.05$). By three months of age, the volume of the ACL increases to an average of 69% final size, while normalized volume of the PCL, medial meniscus, and lateral meniscus are 55%, 49%, and 46%, respectively. At this age, values for the ACL are significantly different than those for both the lateral and medial menisci ($p<0.05$). In both the 6 and 18 month age groups, normalized volumes were not significantly different between any of the tissue types ($p>0.05$).

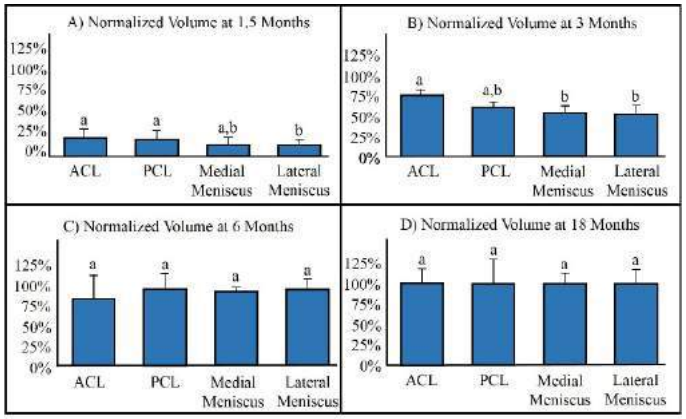

Figure 3: Normalized tissue volumes (relative to the 18 month age group) at A) 1.5 months, B) 3 months, C) 6 months, and D) 18 months of age. Different letters represent statistically significant differences ($p<0.05$).

Figure 4 illustrates the mean change in normalized volume between each age group (as a percentage of total per month, or "growth rate") for all four soft tissues. Between 1.5 and 3 months, the volume of the PCL, medial meniscus, and lateral meniscus grew at average rates of 24%, 23%, and 25% per month, while the volumes for the ACL increased at a higher rate of 32% final volume per month. Conversely, from 3 to 6 months, the average volumes of the PCL, medial meniscus, and lateral meniscus grew at rates of 14%, 16%, and 15% of the final volume each month while the values for the ACL increased more slowly, increasing by only 5% of its final volume per month. Growth slowed to under 2% per month in all groups from 6 to 18 months.

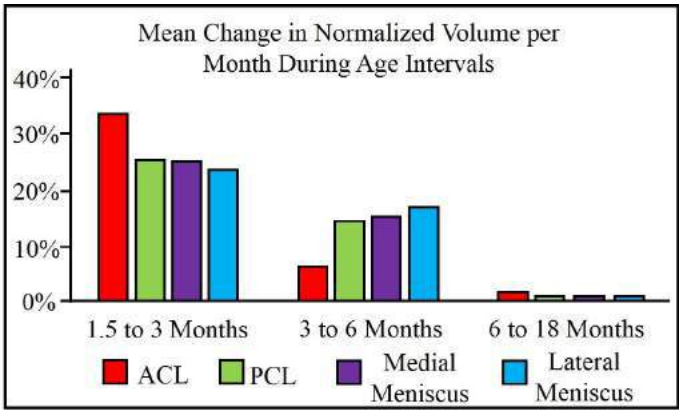

Figure 4: Volumetric changes for each tissue represented as the percentage increase in total volume per month.

DISCUSSION

This study provides a comparison of the volumetric changes in four soft tissues of the porcine stifle joint during skeletal growth. Contrary to our hypothesis, the ACL, PCL, medial meniscus, and lateral meniscus do not maintain a consistent scale during growth. Similar trends were found in the PCL, medial meniscus, and lateral meniscus, with steady increase in volume on average occurring up to 6 months of age (early adolescence) and more limited changes thereafter. However, the ACL experienced rapid increases in volume (49% of the final volume) between 1.5 and 3 months, with less drastic increases occurring during each age interval afterwards. Future studies examining the impact of these varying relative sizes with respect to relative tissue function throughout skeletal growth are warranted. A limitation of this study is the use of a porcine model. Although this model is commonly accepted as an analog for the human knee, key anatomical differences do exist [4], and further study of the human knee joint throughout skeletal growth is needed. Nevertheless, this model provides a valuable tool to compare a large number of samples at well-defined ages. An additional limitation is that only four tissues were studied. Inclusion of other tissues, such as the medial collateral ligament, lateral collateral ligament, cartilage, and epiphyseal bone, may reveal further insight into musculoskeletal growth. Nevertheless, these initial findings provide insight into the nature of tissue growth in the knee, and reveal a need for further investigation into the function of musculoskeletal soft tissues in skeletally immature joints.

DETERMINING THE EFFECT OF ELASTIN DIGESTION ON THE REGIONAL BIAXIAL MECHANICAL PROPERTIES OF THE MURINE CERVIX

INTRODUCTION

Preterm birth affects 12.7% of all pregnancies and is a significant cause of infant morbidity and mortality [1]. During pregnancy, microstructural and compositional alterations lead to drastic changes in mechanical properties and structural integrity [2]. The cervix must remain closed to maintain the growing fetus and then open sufficiently to allow passage at term. Incompetence of the cervix is a highly misdiagnosed form of preterm birth and leads to the rapid expulsion and often death of the fetus [3]. While the etiology of incompetence remains unknown, it has been suggested that decreased elastin content may contribute to cervical dilation and loss of mechanical integrity [3]. The role of elastin in normal cervical mechanical function, however, remains unknown. Further, while the cervix has been mechanically characterized in uniaxial tensile or compression [c.f., 4], the biaxial mechanical behavior of the cervix has not been evaluated. The cervix experiences multiaxial loading within the body, hence biaxial tests may provide additional insight into the physiologic mechanical state of the cervix and the contribution of each load-bearing constituent. Therefore, the objectives of this study are to: 1) Determine the regional passive biaxial mechanical properties of the murine cervix at estrus and to 2) Delineate the contribution of elastin to cervical mechanical properties. We hypothesize that: 1) The external os of the cervix will demonstrate a larger linear modulus compared to the internal os; and 2) Regardless of the region, the cervix will demonstrate a larger linear modulus following elastase digestion.

METHODS

Cervical complexes from female C57/BL/6 mice at 4-6 months of age (IACUC approved, n=8 at estrus) were dissected out and mounted within a custom biaxial testing system and the contralateral uterine horn was ligated with 6-0 silk suture. **MECHANICAL TESTING.** All specimens were subjected to pressure-diameter tests ($P = 0$ to 200 mmHg) at three different axial extensions around the estimated *in vivo* axial stretch and to axial force-length tests at three different pressures (67, 133, 200 mmHg) [5]. The outer diameter was tracked optically at both the internal and external os. For three samples, following mechanical testing, the specimens were intraluminally exposed to 1mL of pancreatic elastase at a concentration of 3.75 U/mL for 15 minutes while the cervix was subject to 0 mmHg pressure at the estimated *in vivo* axial extension. Following treatment, the cervix was rinsed with Hank's solution and allowed to equilibrate before the mechanical tests were repeated. Following mechanical testing, opening angle experiments were performed via isolating 0.5mm rings from the internal and external os. **DATA ANALYSIS.** A bilinear curve fit was applied to the local stress-strain data to quantify the moduli in the toe- and linear-regions for each mechanical test [6]. Opening angles were measured from the midpoint of the inner wall to the tips of the outer wall of the opened sections [7]. **STATISTICAL ANALYSIS.** 2-way ANOVAs (elastase treatment, region) with Bonferroni corrections were used if the interaction was significant. Following the ANOVAs, paired post-hoc t-tests were performed when appropriate. Data is presented as mean + SEM.

RESULTS

The 2-way ANOVA (regional location and elastase at estrus) identified that both location and elastase digestion had a significant effect on the toe- and linear-region moduli as well as the transition stress. Regional location had a significant effect on the transition strain. Additionally, elastase digestion was identified to have a significant effect on the *in vivo* axial stretch, unloaded length, thickness, and opening angle. No significant interactions between regional location and elastase treatment were identified.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The external os demonstrated a higher toe- and linear-region modulus, compared to the internal os for both the control and elastase test. Additionally, the external os demonstrated a higher transition strain and stress compared to the internal os for both tests.

Following elastase digestions, the linear modulus increased following elastase digestion at both the internal and external os, while the toe-region moduli increased at the external os. Transition stress was significantly increased following elastase digestion at the external os. A significant increase in the *in vivo* axial stretch and a corresponding decrease in the unloaded length were identified following elastase digestion. Additionally, the wall thickness decreased and the opening angle increased at both locations.

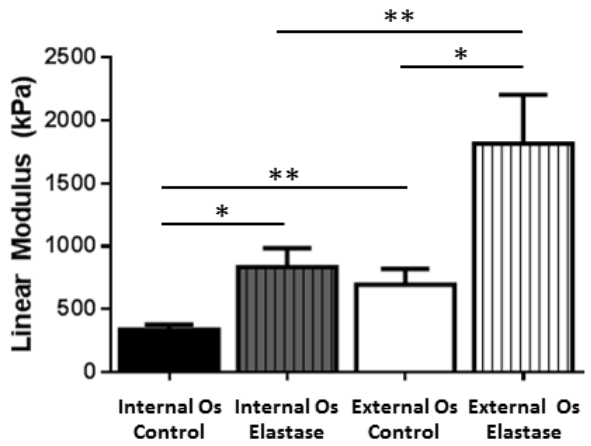

Figure 1: Linear-region moduli were significant higher at the external os compared to the internal os before and following elastase digestion (; p<0.05). Additionally, moduli values increased following elastase digestion at both locations (*; p<0.05).**

DISCUSSION

The current study demonstrates that the mechanical properties of the murine cervix vary with regional location, where the external os demonstrated larger toe- and linear-region moduli compared to the internal os (Figure 1). Previous studies have reported an increase in collagen content and a corresponding decrease in smooth muscle near the external os of the cervix in comparison to the internal os [8]. Hence, the higher collagen content at the external os may contribute to the larger moduli identified in this study. A higher transition strain and stress was also identified at the external os, which may suggest that the undulation of collagen fibers vary with regional location [9]. Further, it suggests that additional structural and compositional features (such as collagen cross-links and proteoglycan composition) may vary by location and influence local mechanical properties [10,11]. Future work, however, is needed to locally quantify local microstructural parameters and to elucidate their correlation to murine local cervical mechanical behavior.

In this study, cyclic pressure-diameter tests and associated Cauchy stress-strain curves confirm a large increase in stiffness and loss of distensibility at both the internal (Figure 2A) and external os (Figure 2B) of the murine cervix following exposure to elastase. These results, in addition to the increased linear modulus identified at both locations (Figure 1), suggest that elastic fibers contribute to the mechanical properties of the murine cervix and may interact with collagen fibers to prescribe cervical mechanical function. A prior study in carotid arteries noted a similar loss of distensibility following elastase digestion [12]. Future work, however, is necessary to quantify the microstructural orientation of elastic fibers in the cervix and their potential role in collagen fiber recruitment.

Further, this study reports a decrease in the unloaded length and increase in the *in vivo* axial stretch following elastase digestion in cervical tissue. Ferruzzi et al. demonstrated an increased unloaded length and decreased *in vivo* axial stretch for carotid arteries subsequent to elastase digestion in a preceding study. Herein, the cervical tissue displayed opposite behavior to what was observed in the carotid artery, despite a similar circumferential mechanical response [12]. Hence, the mechanical contribution of elastin in the tissue may be anisotropic. Consequently, there is a pressing need for additional information on the underlying microstructure, deposition, and turnover of elastin within the murine cervix.

NOVEL INSTRUMENTED MOUTHGUARD DESIGNS TO ACCURATELY MEASURE HEAD KINEMATICS FOR TRAUMATIC BRAIN INJURY

INTRODUCTION

Wearable head motion sensors are designed to provide quantitative measurements of rapid head kinematics for traumatic brain injury (TBI) research and diagnosis [1]. However, most sensors used either commercially or in research suffer from a lack of sufficient coupling to the skull. Clothing/equipment sensors can move with respect to the skull during impact and skin-mounted sensors are prone to errors resulting from soft tissue motion [2]. Errors in kinematic measurements have led to inconclusive findings on the mechanisms underlying TBI and could result in improper diagnosis on the field. Thus, there is a pressing need to develop accurate sensors to advance our understanding of TBI and properly diagnose its occurrence.

The instrumented mouthguard was thought to provide accurate head kinematic measurements because it has superior coupling to the skull through the upper dentition – an exposed hard surface attached to the skull via stiff ligaments. However, three previous laboratory validations of mouthguard accuracy yielded varying results [3,4,5]. In linear impact tests on anthropomorphic test dummies (ATD), Bartsch et al and Camarillo et al both showed the mouthguard had excellent kinematic accuracy [3,4] while Siegmund et al showed the mouthguard overestimated head kinematics in certain impact conditions [5].

In a series of free drop ATD and post mortem human subject (PMHS) tests, we found that perturbations from the mandible were the likely cause for the discrepancy in previous validation results and a major source of kinematic measurement error in the mouthguard [6]. We identified a mechanism underlying the mandible and mouthguard interaction responsible for kinematic measurement errors. We modeled the mandible and mouthguard as a mass-spring system with the mandible representing the mass and the mouthguard ethylene vinyl acetate (EVA) material representing the spring. The modeled characteristic frequency closely matched observed error frequencies in ATD and PMHS testing.

Because current mouthguard designs may suffer from kinematic measurement errors as a result of our identified mandible-mouthguard interaction, new mouthguard designs must be developed and evaluated before they can be used to collect reliable head impact kinematics for TBI research and diagnosis. Thus, the goal of this work is to evaluate three novel mouthguard designs that mitigate mandible perturbances.

METHODS

In our previous work to identify the mandible-mouthguard interaction, we used a mouthguard with a kinematic sensor located at the rear molars encased between two layers of 3mm thick EVA (original design) [6]. The actual thickness of the mouthguard was near 2mm because the mouthguard formation process melts and stretches the EVA material around subject specific dentitions. The kinematic sensor included a tri-axial accelerometer and a tri-axial gyroscope measuring kinematics at 1000Hz over 100ms (Figure 1).

We designed three mouthguards to mitigate potential mandible perturbances. We used the same kinematic sensor as the original design to ensure it was not a confounding factor. Our first design encased the kinematic sensor at the rear molars between two layers of 1mm EVA, resulting in a mouthguard thickness of less than 1mm (thin design). The second design encased the kinematic sensor at the rear molars between three layers of 3mm EVA (one layer between the teeth and sensor and two layers over the sensor), resulting in a thickness of approximately 3.5mm (thick design). These varying thickness designs were chosen to explore the effect of adjusting the EVA spring stiffness in our representative mass-spring mandible-mouthguard model.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The final design placed the kinematic sensor in front of the incisors and encased them between two layers of 3mm EVA (incisor design). In addition, material was removed from the bite plane at the incisors (Figure 1).

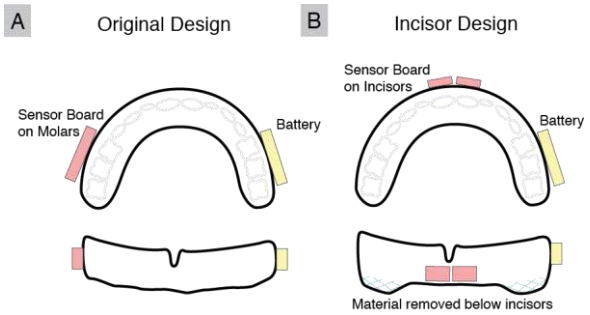

Figure 1: Mouthguard Designs. (A) Original design with the kinematic sensor at the rear molars. (B) Incisor design with the kinematic sensor at the incisors and additional material removed.

For each design, we evaluated its kinematic measurement accuracy performance using free drop impacts on a football helmeted ATD. We performed free drops at three drop heights: 10cm, 60cm, and 100cm, over 6 impact locations: vertex, frontal, facemask, frontal oblique, parietal, and occipital. These drops explored the range of impact conditions commonly observed in football [1]. The ATD mandible was left free to articulate to exercise the new designs in the scenario with the highest errors identified in our previous work (Figure 2).

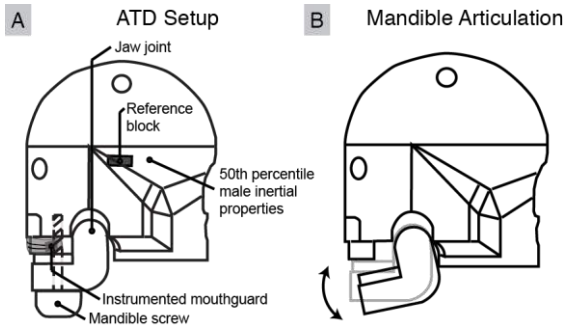

Figure 2: ATD Testing. (A) ATD test setup with mouthguard and reference sensors. (B) Mandible dynamics during an impact.

To assess mouthguard accuracy, we compared mouthguard kinematics against kinematics from a high rate reference sensor affixed to the center of mass of the ATD (Figure 2). This reference sensor consisted of a tri-axial accelerometer and a tri-axial gyroscope measuring kinematics at 10kHz over one second.

Linear acceleration and angular velocity data was collected from both the mouthguard and reference sensors. Angular acceleration was computed by performing a 5-point stencil differentiation on the angular velocity signal. We then performed a linear regression with forced zero intercept on the aggregated peak angular acceleration magnitudes and peak linear acceleration magnitudes from all free drops. A perfectly accurate sensor would have a linear regression m=1.0 and R^2=1.0.

RESULTS

Our results show that the thin and thick designs still had significant overestimation in kinematic measurements, while the incisor design showed improved accuracy (Figure 3). In both peak angular acceleration magnitude and peak linear acceleration magnitude regressions, the thin design had the highest overestimation error (angular m=2.4, R^2=0.4 and linear m=2.0, R^2=0.2), while the incisor design had the best accuracy (angular m=0.8 and R^2=0.9, linear m=1.0, R^2=0.9). The incisor design did underestimate peak angular acceleration magnitudes; however this was consistent with previous findings [4].

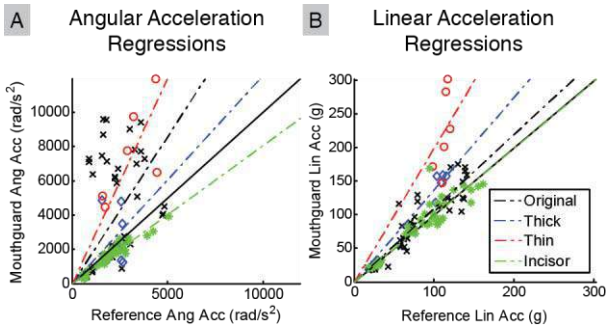

Figure 3: Regression Results: (A) Angular acceleration magnitude regressions for the original and three novel mouthguard designs. (B) Linear acceleration magnitude regressions.

DISCUSSION

In this study, we evaluated the kinematic measurement accuracy of three novel mouthguards that were designed to mitigate errors from mandible dynamics. We found that the incisor design effectively mitigated errors from mandible dynamics, while the remainder had overestimations in both angular and linear acceleration. Overestimation in angular acceleration magnitude correlated with thinner mouthguards. This indicates that thicker EVA material may dampen the magnitude of mandible perturbations. However, at 3.5mm, the mouthguard still overestimated kinematic values and even thicker mouthguards may be impractical for field deployment. Future work will refine and evaluate the performance of these new designs in more bio-fidelic PMHS tests.

The incisor design had the best accuracy because it isolated mandible perturbations at the rear molars from the kinematic measurement sensor at the incisors. This design demonstrates that while mandible perturbations can affect mouthguard accuracy, they can be mitigated with proper design of the mouthguard and placement of instrumentation. Our novel incisor design represents a new trend in head kinematic measurement device development that accounts for known sources of error and provides superior measurement accuracy. This design may fill the pressing need for an accurate head kinematic sensor in TBI research and, as we learn more about the mechanism of TBI, has the potential to translate towards real-time injury screening of athletes, military personnel, and other high-risk populations.

INTRODUCTION

Cervical spondolytic myelopathy (CSM) is the most common form of spinal cord injury with approximately 19,000 surgical cases annually in the USA[1]. It is caused by chronic, dynamic compression of the spinal cord by either osteophytes, herniated intervertebral discs, or ossified ligaments. The symptoms are often debilitating, presenting as loss of upper extremity function, gait disturbances, and most severe, quadriplegia. Treatment usually entails surgical intervention with the aim being to reduce the impingement of the spinal cord and stabilize the spine.

While treatment of CSM is based on intuition of the spinal cord mechanics little is actually understood regarding the changes in spinal cord stress and strain during motion. Since measuring *in vivo* cord mechanics on human subjects is infeasible, finite element (FE) modeling can be used to investigate cord stress distributions[2,3]. Currently published models have provided insight into cord dynamics but are primitive in anatomic and material property assumptions. It was therefore the goal of our study to create an FE model incorporating all major musculoskeletal and neurologic anatomy of the normal C2-T1 spine to predict cord mechanics during flexion and extension.

METHODS

A 3D FE model of the cervical spine (C2-T1) was previously developed and validated[4]. A CAD model of the cervical spinal cord was created based on histologic sections from levels C3, C5, C8 and scaled to fit the geometry of the aforementioned C2-T1 model. IA-FEMesh was used to create a hexahedral mesh of the cord, from which quadrilateral elements were extracted to define the pia. In a similar manner, a quadrilateral mesh of the dura was generated. A convergence study was performed to ensure solution stability. The resulting cord, including the pia and dura, is defined by 42,239 elements. Once introduced into the C2-T1, the entire model consisted of 229,649 elements. Dentate and mengiovertebral ligaments were modeled as compression free truss elements. Placement of the dentate and mengiovertebral ligaments was based on anatomical reports[5]. The dura, pia, and cord were modeled as hyperplastic Mooney-Rivlin and material constants were calculated based on published in vitro tissue testing[6]. The dentate and mengiovertebral ligaments were modeled as linear elastic. The cerebral spinal fluid (CSF) was modeled as a fluid cavity enclosed by the dura and pia, while the pressure in the extradural and intradual space was based on published data[7]. General contact was used to define contact between all surfaces.

The inferior endplate of the T1 vertebra was fixed in all directions as were the inferior most nodes of the spinal cord, pia, and dura. Using Abaqus 6.13-1/Standard a quasi-static rotation of 28° in flexion and 25° in extension was applied to the most superior portion of C2. This rotation corresponded to the average flexion and extension achieved by healthy controls during flexion and extension MRIs. To model the attachment of the spinal cord to the brain, a follower load was applied to the superior end of the spinal cord, dura and pia. During flexion 7.70N of tension and during extension 1.61N of compression was applied. These loads correspond to the force needed to achieve physiologic axial cord root displacement. Axial stretch between cord root entries (cord stretch) were obtained as were the von Mises stresses and logarithmic strains throughout the cord.

RESULTS

In extension, cord stretch between the root entries in the axial direction ranged from -6.34 mm at C2-C3 to 0.00 mm at C6-C7, average -2.15 ± 2.74 mm. At full extension von Mises stress on the anterior cord ranged from 0.008-0.081 MPa and 0.008-0.034 MPa on the posterior

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

cord. Interestingly, even with normal anatomy, anterior bony impingement occurred during extension causing a maximum stress of 0.081 MPa at the C56 level (Fig1). Locations of max principle logarithmic strain mirrored those of stress ranging from 0.80-14.8% with the maximum occurring at the C56 level of impingement (Fig2)

In flexion, cord stretch between the root entries in the axial direction ranged from 1.84 mm at C2-C3 to -0.71 mm at C4-C5, average 0.14 ± 1.02 mm. At full flexion von Mises stress on the anterior cord ranged from 0.001-0.009 MPa and 0.0017-0.033 MPa on the posterior cord (Fig1). Compressive stress was present anteriorly and tensile stress posteriorly. No bony impingement occurred. Max principle logarithmic strain ranged from 1.00-6.50% with highest strains occurring posteriorly.

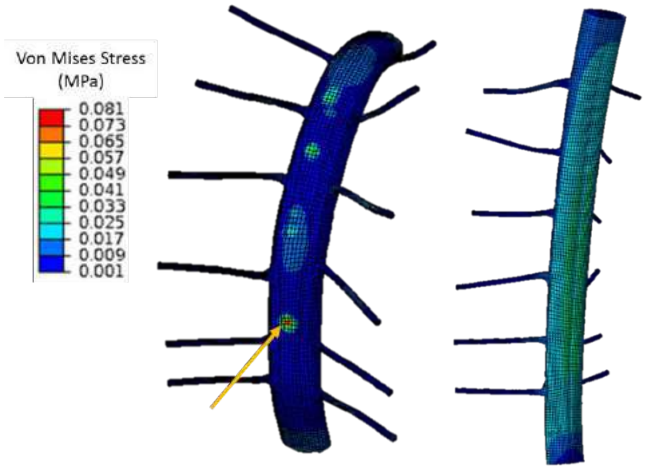

Figure 1: Spinal cord in extension (left) and flexion (right). Arrow highlights bony impingement on anterior surface. Tension stresses can be seen on the posterior surface of flexed cord.

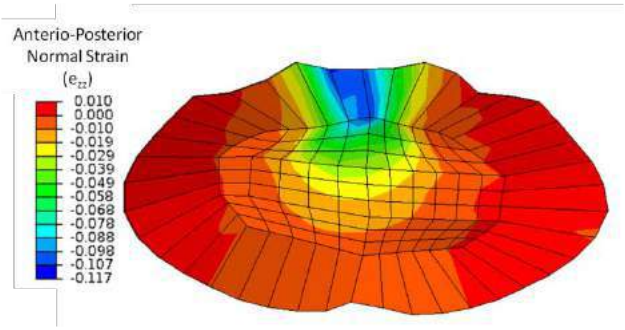

Figure 2: Axial cross section of C56 bony impingement during extension. Compressive strains (blue) can be seen below area of impingement where tensile strains (red) occur at the surface.

DISCUSSION

In this study we developed a model of the C2-T1 cervical spinal cord including the pia, dura, CSF, dentate and mengiovertebral ligaments and incorporated it into our pre-existing cervical spine model. We utilized this model to determine cord stretch, stress, and strain of the cord during physiologic motion. As with all FE models, our model has certain intrinsic limitations such as using a single anatomic model as a global representation and simplified material properties for biologic tissues. However we have aimed to minimize these limitations by incorporating all major spinal anatomy and using hyper-elastic material properties for the spinal cord.

Extension and flexion axial cord stretch between the root entries of our FE model were comparable, but on average are slightly larger, than those we obtained from control patient MR images which range from -0.57 to 8.83 mm in extension and -4.11 to 7.86 mm in flexion. This discrepancy is most likely due to differences in bony anatomy between patients as parametrically changing the force applied to the spinal cord in the FE model did not significantly alter cord stretch. This finding is particularly interesting when considering CSM is caused by altered musculoskeletal anatomy, suggesting that differences in the anatomy of cord compression may significantly affect cord mechanics.

The range of von Mises stress occurring in our model is comparable to previously published CSM FE models. Kim *et al* reported stresses ranging from 0.005 to 2.70 MPa depending on amount of cord compression and Ichihara *et al* reported 0.03 MPa.[3,8] Our model, with maximum von Mises Stress of 0.081 MPa in extension, overlaps the lower end of this spectrum which is to be expected as it is a model of normal anatomy and not CSM.

Unexpectedly, mild cord compression due to bony impingement occurred even in this normal disease free model. This unintended bony impingement shows the propensity of this model to accurately model CSM in the future. Firstly, the location of greatest compression occurred at the C56 level which is the most common level for occurrence of CSM[9]. Secondly the patterns of logarithmic strain caused by this compression closely match those reported by Bhatnagar *et al* in their *in vitro* MRI strain analysis of contused rat spinal cords[10]. Our magnitude of strains is much less than that of Bhatnagar et al as our model does not include such severe contusion. However, the fact that the FE spinal cord is behaving similarly to *in vitro* data is promising. Obviously, human and rat cord mechanics are not identical. In order to ensure that our model truly behaves as the human spinal cord, our goal is to validate our model with patient strain data calculated from mapping flexion and extension MR images to their respective neutral MR image.

Overall we have developed a model of the cervical spine and spinal cord which allows us to predict cord stresses and strain during dynamic motion of the neck. This will, in the future, help us to better understand the progression of cervical myelopathy specifically by incorporating anatomic abnormalities such as osteophytes which lead to stenosis. Finally we aim to model surgical treatments of stenosis to investigate which surgical interventions most effectively relieve spinal cord stress and strain.

SURFACE PROTRUSION OF HUMAN ENDOTHELIAL CELLS: EXPERIMENT AND MODEL

Jin-Yu Shao, Jin Hao, Yong Chen

Department of Biomedical Engineering
Washington University in Saint Louis
Saint Louis, MO, USA

INTRODUCTION

At sites of infection, injury, or atherosclerotic lesions, human leukocytes first roll on the endothelium, then become activated and firmly-adherent, and finally migrate out of blood vessels. One the one hand, unstable rolling impairs effective neutrophil and lymphocyte recruitment to infected tissues and renders human beings defenseless against invading microorganisms, resulting in immunological diseases such as leukocyte adhesion deficiency syndrome. On the other hand, stable rolling is essential for monocyte infiltration into the aortic intima that initiates and exacerbates cardiovascular diseases like atherosclerosis [1, 2]. Elucidating the mechanisms that underlie leukocyte rolling can pave the way toward therapeutic amelioration of such pathologies.

The rolling of leukocytes is a complex dynamic process that is mediated concertedly by adhesive receptor-ligand bonds between leukocytes and endothelial cells (ECs), shear stress due to blood flow, and cellular mechanical properties such as membrane surface protrusion and tether extraction. Surface protrusion is a solid-like behavior of cell membrane when it is subjected to a point force, whereas tether extraction is a fluid-like behavior of cell membrane that follows surface protrusion when the pulling force is large enough. Due to its important role in stabilizing leukocyte rolling, tether extraction of leukocytes and ECs has been extensively characterized [3, 4] and its features, including shear thinning, non-zero threshold force, and possible negative velocity, can be described by the following equation [5],

$$F = \alpha(U_t - U_0)^{\beta}, \quad (1)$$

where F is the pulling force, U_t is the tether velocity, U_0 is the tether velocity when $F = 0$, and α and β are constants. Although surface protrusion of leukocytes has been well-studied [6-8] and it is known that it can be simulated by the three-parameter solid model (a spring element connected in series with a Kevin element), surface protrusion of ECs remains poorly-understood. Recently, using the micropipette aspiration technique (MAT), Chen et al. found that both the protrusional stiffness and the crossover force (at which cellular deformation will make the transition from surface protrusion to tether extraction) increased when human umbilical vein endothelial cells (HUVECs) were pulled with forces at increasing loading rates from ~10 to 3000 pN/s [9]. However, reliable model parameters are still lacking even if we assume EC surface protrusion can be simulated by the three-parameter solid model. In this work, we report our measurement of the protrusional stiffness of HUVECs at near zero force loading rates and our simulation of HUVEC surface protrusion with the three-parameter solid model. This model is the last piece of the puzzle in regard to incorporating cellular mechanical behaviors into modeling leukocyte rolling systematically.

METHODS

Experiment

HUVEC culture and preparation, bead and micropipette preparation and diameter measurement, the micropipette manipulation system and its data analysis procedures can be found in the literature [10-12]. Figure 1 shows how a HUVEC can be pulled with the MAT. A latex bead that was coated with antibodies against CD31 was placed inside a micropipette. The bead fitted snugly inside the micropipette with only a very small gap between them so that the bead could move freely inside the micropipette. The pressure in the micropipette can be precisely controlled by a manometer. The bead was first driven by a positive pressure to contact the cell on the left. Then a negative suction pressure was applied so that the cell would be pulled if molecular bonds had formed during the contact. The antibody concentration on the bead was reduced until infrequent adhesion (frequency < 25%) occurred between the bead and cell. With this low adhesion frequency, the adhesion

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

between the bead and cell was very likely mediated by a single bond [13, 14]. Thus, the cell would be pulled through a single receptor, equivalent to being pulled by a point force. Four different suction pressures were used in our experiments: 0.25, 0.375, 0.5, 0.625 pN/μm^2.

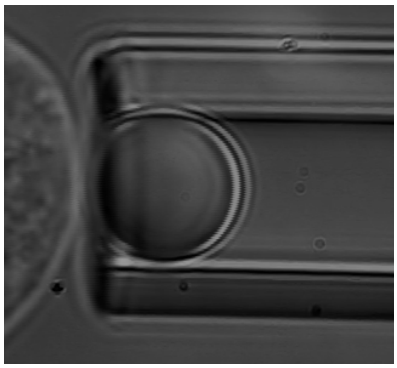

Figure 1. A video micrograph showing how a HUVEC was pulled by a point force with the MAT. The cell on the left was held by another micropipette, which was invisible on the left.

Model

Our viscoelastic model for HUVEC surface protrusion studied with the MAT consists of the three-parameter solid model connected in parallel with a dashpot. The additional dashpot here represents the damping of the surrounding medium imposed on the bead and its drag coefficient (η_{drag}) can be calculated from the bead free motion velocity under a suction pressure. In the three-parameter solid model, k_i (spring element) represents the initial elastic response, and k_d and η_d (Kelvin element) represent the slow elongation response. Under a pulling force with constant loading rate (τ_0), the force imposed on the cell (f) and the length of surface protrusion (ΔL) can be calculated from

$$f = \tau_0 t + \frac{\eta_{drag}\tau_0}{Q_2}[A_1 + A_2], \tag{2}$$

$$\Delta L = \frac{\tau_0 A_1}{\lambda_1 Q_2}\left[\frac{t\lambda_1}{1 - e^{\lambda_1 t}} - 1\right] + \frac{\tau_0 A_2}{\lambda_2 Q_2}\left[\frac{t\lambda_2}{1 - e^{\lambda_2 t}} - 1\right], \tag{3}$$

where

$$A_1 = \frac{k_i + k_d + \eta_d\lambda_1}{\lambda_1(\lambda_1 - \lambda_2)(k_i + k_d)}\left(1 - e^{\lambda_1 t}\right), \tag{4}$$

$$A_2 = \frac{k_i + k_d + \eta_d\lambda_2}{\lambda_2(\lambda_2 - \lambda_1)(k_i + k_d)}\left(1 - e^{\lambda_2 t}\right). \tag{5}$$

$$\lambda_1 = \frac{-Q_1 + \sqrt{Q_1^2 - 4Q_0Q_2}}{2Q_2}, \tag{6}$$

$$\lambda_2 = \frac{-Q_1 - \sqrt{Q_1^2 - 4Q_0Q_2}}{2Q_2}, \tag{7}$$

$$Q_0 = \frac{k_i k_d}{k_i + k_d}, \tag{8}$$

$$Q_1 = \frac{k_i\eta_d + k_i\eta_{drag} + k_d\eta_{drag}}{k_i + k_d}, \tag{9}$$

$$Q_2 = \frac{\eta_d\eta_{drag}}{k_i + k_d}, \tag{10}$$

RESULTS

Figure 2 shows a typical case of a HUVEC pulled under a constant suction pressure of 0.5 pN/μm^2. The cellular deformation (L) was fitted to the following equation

$$L = L_\infty\left(1 - e^{-t/t_c}\right), \tag{11}$$

where L_∞ is the asymptotic value when time t approaches infinity and t_c is the characteristic time. Converting the pressure to the corresponding pulling force and dividing the force by L_∞ yields the protrusional stiffness at near zero force loading rates, which can be inferred from Fig. 2. With all the suction pressures used, we obtained an average protrusional stiffness value of 55.0 ± 0.7 pN/μm. With this stiffness as the constraint for k_i and k_d , we fitted Eqs. 2 and 3 to all the protrusional stiffness data by Chen et al. [9] and obtained the following parameters for HUVEC surface protrusion: $k_i = 592$ pN/μm, $k_d = 60$ pN/μm, and $\eta_d = 108$ pN·s/μm.

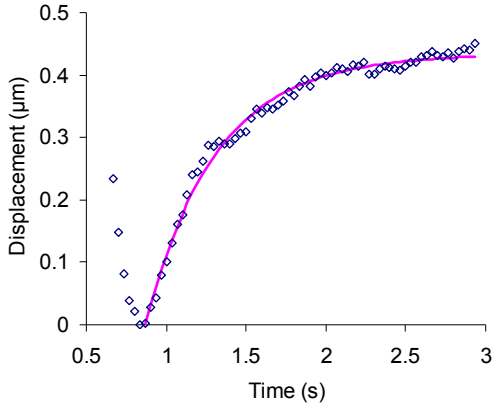

Figure 2. The displacement of an anti-CD31-coated bead before and after it adhered to an attached HUVEC under a constant suction pressure of 0.5 pN/μm^2. The solid line represents the fitting of Eq. 11 to the data.

DISCUSSION

EC surface protrusion has been largely overlooked in modeling and understanding leukocyte rolling. However, it is a critical precursor for tether extraction. Here, we have identified all the parameters that are needed for simulating EC surface protrusion during leukocyte rolling. Combining them with our previous findings on tether extraction, we can illustrate a complete picture of how ECs deform during leukocyte rolling. More importantly, we can now study how ECs influence leukocyte rolling stability with systematic simulation of leukocyte rolling. We can now also reliably predict how ECs will respond to point forces in other situations like creep, relaxation, and hysteresis.

INTRODUCTION

Glaucoma a leading cause of blindness worldwide, and elevated intraocular pressure (IOP) is the main risk factor for the development and progression of vision loss.[1] While much attention has been given to the mechanical insult and risk of vision loss associated with elevated IOP,[2] the role of intracranial pressure (ICP) is rarely considered. Recent epidemiological evidence suggests that ICP may have an important influence on the susceptibility to glaucoma. [3] This is thought to involve pressure-related insult of the lamina cribrosa, a structure in the posterior pole where retinal ganglion cell axons exit the eye, and where neural tissue damage initiates. [1,3]

Our goal was to measure and map with high detail in a primate model the in-vivo biomechanical insult to the lamina cribrosa caused by acute changes in intraocular and/or intracranial pressures Specifically, we determined the lamina cribrosa anterior-posterior displacements, stretch and compression under controlled levels of IOP and ICP.

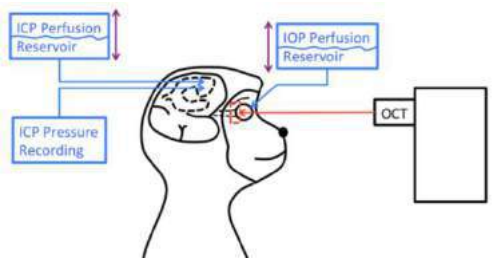

Figure 1: We imaged in-vivo the posterior pole of the monkey eye using optical coherence tomography while controlling intraocular and intracranial pressures (IOP and ICP).

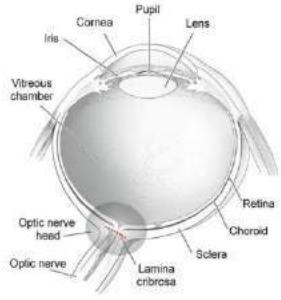
METHODS

Four eyes of 3 macaque monkeys were imaged in-vivo with spectral domain optical coherence tomography (Bioptigen, Durham, NC), while IOP and ICP were controlled through cannulas in the anterior chamber and lateral ventricle, respectively (Figure 1). Pressures were set to all combinations of the following levels (mmHg): for IOP 15 (baseline), 5, 30 and 50, and for ICP 10 (baseline), 5, 25 and 40. To allow viscoelastic effects to dissipate, images used were acquired 10 minutes after a pressure change..

The anterior lamina cribrosa (ALC) and scleral canal opening at Bruch membrane (BMO) were manually marked in 18 radial virtual B-scans per scan. Custom code was used to reconstruct 3D ALC surfaces and register BMOs. ALC depths were computed relative to the BMO best-fit plane within regions visible in all scans of an eye, and normalized to baseline in each monkey.



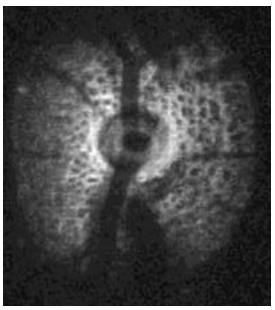


Figure 2: (Left) Eye diagram [4] and (right) example coronal view of the lamina cribrosa of Monkey 2 (red dotted line on left) at the baseline pressures: IOP=15 mmHg and ICP=10 mmHg. Note that this is a single 2D view through a 3D scan.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

A recently developed tracking algorithm based on image registration [4] was adapted to OCT and used to extract the pressure-induced tissue displacements, and from these to compute the stretch and compression.

RESULTS

IOP and ICP had nonlinear effects on the median ALC depth (Figure 3). There were strong interactions between the pressure effects, meaning that the effects of one pressure depended strongly on the other pressure. Pressure effects were non-monotonic. For example, in eye 3R at 20mmHg ICP, the ALC displaced anteriorly when IOP increased from 8 to 15 mmHg, and posteriorly for IOP from 15 to 30mmHg. In all 4 eyes, the most anteriorly ALCs occurred with IOPs below baseline (15mmHg) and very high ICP (20-45mmHg).

Pressure variations from the baseline caused substantial lamina cribrosa stretch and compression, sometimes exceeding 30% (Figure 4). Effects differed between lamina regions and animals, and depended on whether the pressures were increased or decreased.

DISCUSSION

The in-vivo effects of IOP and ICP on the lamina cribrosa are substantial, highly nonlinear and interact strongly. Deformations were larger than predictions with generic homogenized numerical models [2,4], but consistent with ex-vivo experiments [5], and recent micro-structure aware models [6]. The complex nonlinear effects indicate that the translaminar pressure difference (IOP – ICP) is too simplistic a parameter to describe lamina cribrosa mechanics. Our methods open a new way to investigate the interplay between IOP and ICP. The longer term effects of variations in IOP and ICP remain to be determined.

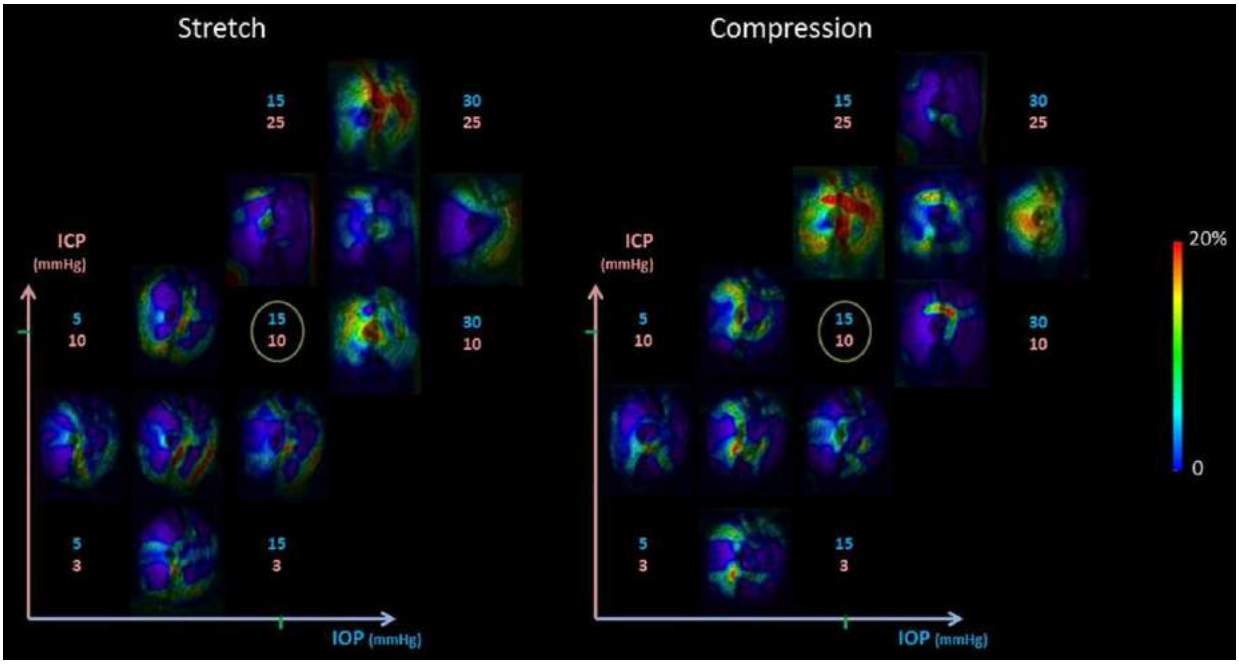

Figure 4: Coronal views through the lamina cribrosa of Monkey 2 color-coded by stretch and compression (1st and 3rd principal strains) resulting from acute pressure changes from the baseline (green circle). In this eye, increases in IOP caused lamina stretch, larger at elevated ICP. Increases in ICP caused lamina compression, larger at baseline IOP. Decreases in IOP or ICP caused less lamina stretch and compression. Simultaneous changes in IOP and ICP produced smaller, but still significant deformations, even if translaminar pressure was maintained at the baseline level.

INTRODUCTION

Moderate to severe mitral valve regurgitation (MR) has an occurrence rate of 1.7% among the adult US population [1]. In MR, the mitral valve (MV) leaflets do not completely coapt, leading to backward flow of blood from the ventricle to the atrium. In categorizing MR there are two classifications: (1) degenerative and (2) functional [2]. Although the MV is structurally normal in functional MR, the complexity of the valvular anatomy and the multitude of repair and replacement techniques makes using *in vivo* models difficult. In using *in vitro* models for functional MR, where a healthy MV can be used, the structural and fluid mechanics of the MV as well as surgical techniques are able to be studied in a more controlled environment.

In current *in vitro* models, the structural complexity of the excised MV is preserved and can be studied [3]. However, these models rely on certain simplifications, one being that the MV is mounted to a static, rigid annulus (leaflet attachment to the myocardium). This simplification of the annulus is justified when looking to control factors that are separate from a study's interest, e.g. investigating chordal forces. However, in order to study, for example, how current *in vivo* MR quantification techniques account for a moving leak in the valve (MR jet orifice), a more physiological model with dynamic contraction to move the jet orifice is needed. Motivated by this need, the work of this study provides the novel design and development of a dynamically contracting MV annulus within an *in vitro* left heart simulator.

METHODS

Mitral Valve Annulus Plate Design and Development

Designed to fit within the existing modular Georgia Tech Left Heart Simulator, it was critical to maintain the imaging capabilities of the previous version of the simulator [4]. First, a spring was embedded within a Dacron cuff which makes up the MV annulus. Then a wire was fed through the center of the spring. Finally, the wire was attached to the piston heads of two linear actuators (HAD2-2, RobotZone, Winfield, KS) (Figure 1).

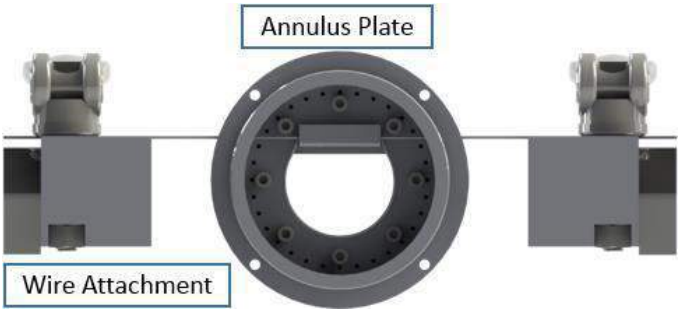

Figure 1. Simplified diagram of the dynamically contracting annulus setup with the annulus plate centered between the wire attachments at the ends of the linear actuators.

The linear actuators were displacement driven and controlled individually using PID and H-bridge controllers (DeviceCraft, Fitchburg, MA). The input displacement array consisted of healthy, ovine MV annular perimeter derived from prior *in vivo* work [5].

Experimental Setup

A healthy mitral valve was excised from a fresh ovine heart (Superior Farms, Denver, CO). During excision, the annulus and subvalvular structures (i.e. chordae tendineae and papillary muscles) were preserved. The valve was then mounted into the left heart chamber

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

with the MV annulus sutured to the annulus cuff and the papillary muscles (PM) attached to the PM rods for proper positioning (Figure 2).

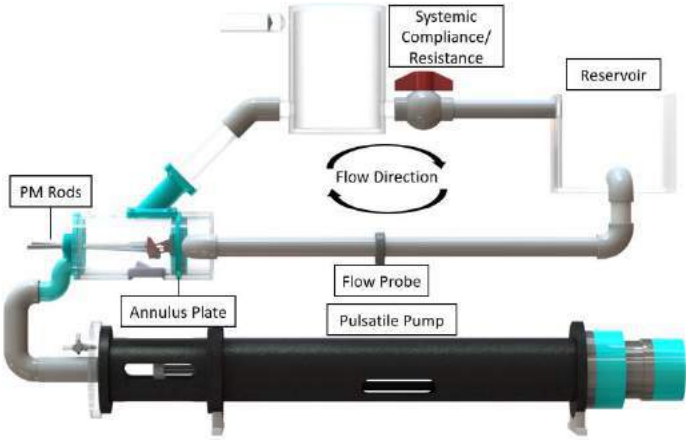

Figure 2. Overview of left heart simulator flow loop with the pulsatile pump.

A ratio of 35% systole and 65% diastole was utilized at 70 beats/min, and systemic resistance and compliance were tuned to reach a cardiac output of 5 L/min and a peak systolic pressure of 120 mmHg. In order to control the pulsatile pump (Vivitro Labs, Victoria, BC, CA) and the linear actuators, and record flow loop hemodynamics, custom codes were written in LabVIEW (2015, National Instruments, Austin, TX).

For MV visualization, 3D echocardiography via ie33 xMatrix ultrasound system and x7-2 probe (Philips Healthcare, Andover, MA) was performed. The motor position was measured using the built-in potentiometers of the linear actuators and compared to the desired displacement using LabVIEW.

RESULTS

Using the newly designed annulus plate, the hemodynamic criteria of the methods were all met. From the resultant images (Figure 3), the annular area was measured to be 4.84 cm^2 at peak diastole and 4.03 cm^2 at peak systole (-16.73% change). This result is similar to prior *in vivo* work (-19.02±4.94%) [5].

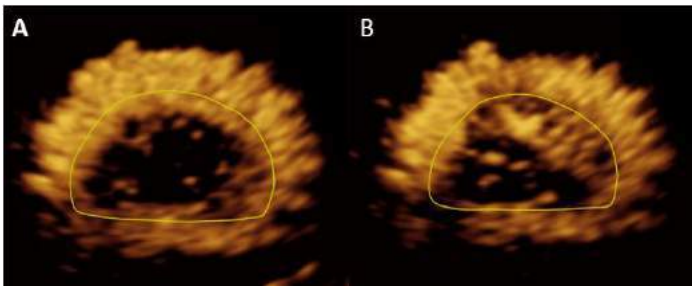

Figure 3. Acquired echocardiography of the mitral valve using the dynamically contracting annulus at peak (A) diastole and (B) systole. Annular area: A = 4.84 cm^2 and B = 4.03 cm^2.

In addition, annular perimeter, as measured by actuator piston position (Figure 4), showed strong agreement with the target waveform (RMSE = 8.69 µm, R^2 = 0.99).

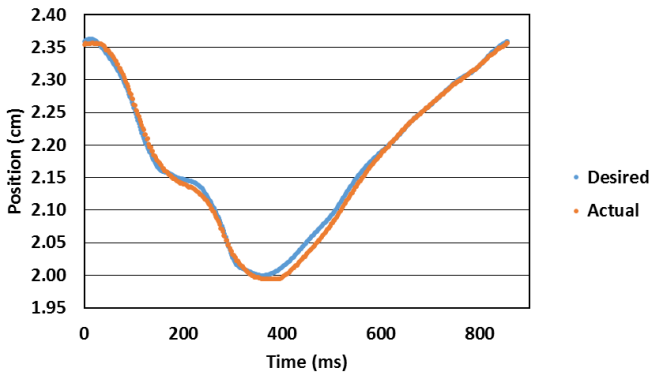

Figure 4. Comparison of desired and actual displacements of the linear actuators. RMSE = 8.69 µm and R^2 = 0.99.

DISCUSSION

This work provides the first *in vitro* MV simulator with a dynamically contracting annulus. The *in vitro* setup was tested at physiological conditions (i.e. flow rates and pressures) and maintained the size and shape of previous setups. In addition, the linear actuators were able to provide MV annular contraction, and reproduce the annulus perimeter motion and area change of previous *in vivo* studies.

The main limitation of this new annular design is that the annulus is flat and its contraction is limited to 2-D, planar motion. Physiologically, the MV annulus has a 3-D contractile motion over the cardiac cycle, changing between a saddle-shape and a more flat-shape. This out-of-plane shape change could play additional roles in leaflet billowing and tissue stresses [6].

The dynamically contracting annulus addition to the MV *in vitro* model enables another level of detail needed to advance mechanical understanding of the MV through experimental work, as well as computational modeling and quantification. Future work will focus on, but will not be limited to the following: (1) further validation of healthy and diseased annular motion, (2) comparison of physiological and pathophysiological MV mechanics of static vs dynamic annulus, (3) removing static assumptions from MR quantification, e.g. a nonmoving regurgitant orifice for proximal isovelocity surface area of MR, and (4) enhancing MV computational simulations using *in vitro* validation.

EFFECT OF ELASTIN DIGESTION ON THE BIAXIAL MECHANICAL RESPONSE OF THE MURINE VAGINA

Katy M. Robison (1), Derek J. Bivona (1), Kristin S. Miller (1)

(1) Biomedical Engineering
Tulane University
New Orleans, LA, US

INTRODUCTION

Pelvic Organ Prolapse (POP) is a global health concern, affecting over 41% of women [1]. POP is characterized by the atrophy of the vaginal wall and the prolapse of the pelvic organs which leads to both physical and emotional health consequences. Little is known about the underlying pathology of POP; however, dysfunction of the elastin metabolism within the vaginal extracellular matrix has been implicated [2-4]. Compromised elastin integrity may lead to an increase in matrix-metalloprotease activity within the vaginal extracellular matrix, which may increase the degradation of collagen fibers and compromise vaginal mechanical integrity [3]. In addition to the aforementioned biochemical role, elastin may also contribute to vaginal mechanical integrity by providing tissue resilience. Hence, the combined effect of elastin alteration and collagen turnover may affect the biomechanical properties of the vagina and contribute to the development of POP [3]. The role of elastin in normal vaginal mechanical function, however, is not fully understood [2-4]. Therefore, the objective of this study is to quantify the biaxial mechanical properties of the murine vagina before and after elastase digestion to determine the contribution of elastin to vaginal mechanical function. We hypothesize that the depletion of elastin will result in higher transition stress and strain (right-ward shift in the stress-strain curve) and an increased linear modulus.

METHODS

Five female C57/BL/6 mice (IACUC approved) were euthanized at 4-6 months of age while in estrus. After one freeze/thaw cycle, the reproductive tract was excised, and the vagina was isolated from the surrounding tissue. **MECHANICAL TESTING.** Samples were mounted onto metal cannulas within a pressure-myograph. Following preconditioning and equilibration, specimens underwent pressure-diameter tests ($P = 0$ to 25 mmHg) at three different axial extensions around the estimated *in vivo* axial stretch λ_z^{iv}, followed by axial force-length tests at four different pressures (2, 8, 17, 25 mmHg) [5]. After mechanical testing, specimens were intraluminally exposed to 1 mL of porcine pancreatic elastase at 15 U/mL for 45 minutes at the *in vivo* configuration [6]. The vagina was re-equilibrated in Hank's solution and the mechanical tests repeated. Following testing, a ring (~0.5 mm thick) was cut transversely in the center of the vagina, at the location at which the tissue diameter was tracked during the mechanical testing. The ring then was placed in Hank's solution, and following a 30-minute equilibration period, rings were imaged. The anterior section of the ring was cut radially, and the near zero-stress state was imaged 30 minutes later. **DATA ANALYSIS.** A bilinear curve fit was applied to the local stress-strain data to quantify the moduli in the toe- and linear-regions [7]. The opening angle was measured from the midpoint of the inner wall to the tips of the outer wall of the opening sections [8]. **STATISTICAL ANALYSIS.** Differences between the unloaded geometry, opening angle, toe- and linear-region moduli, and transition stress and deformation at the intersection of the toe- and linear-regions between the pre- and post-elastase digestion groups were analyzed using a paired two-tailed student's t-test, with $p < 0.05$ considered significant. Data is presented as mean ± SEM.

RESULTS

Intraluminal exposure to elastase for 45 minutes induced marked changes in the vaginal biaxial mechanical response (Figure 1). Both cyclic pressure-diameter (not shown) and corresponding circumferential Cauchy stress-strain curves (Figure 1) demonstrated the marked shift of the mechanical response following digestion. Bilinear curve fits demonstrated that the stress at the transition point between the toe- and linear-regions of the stress-strain curve

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

significantly increased following elastase digestion and that the linear modulus increased (Figure 1). Further, a decrease in the unloaded thickness and a significant increase in the opening angle were determined following elastase digestion.

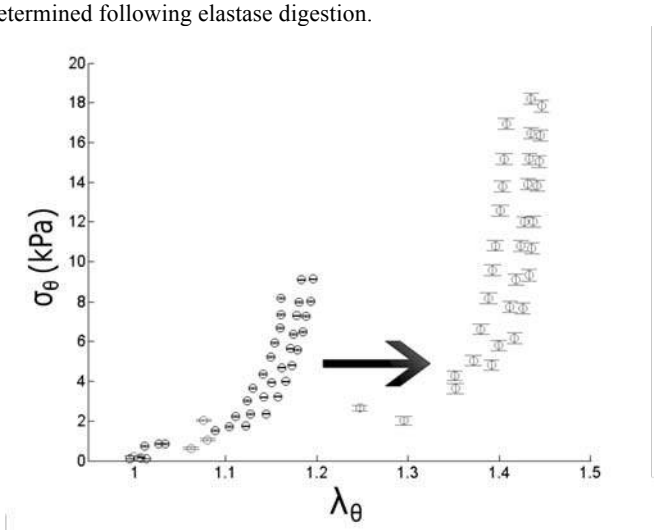

Figure 1: Circumferential Cauchy stress-strain curves for the vagina before (black) and after elastase digestion (grey) at 3 different axial extensions around the estimated *in vivo* axial stretch λ_z^{iv}. The dark arrow demonstrates the extended toe-region of the stress-strain curve following elastase digestion.

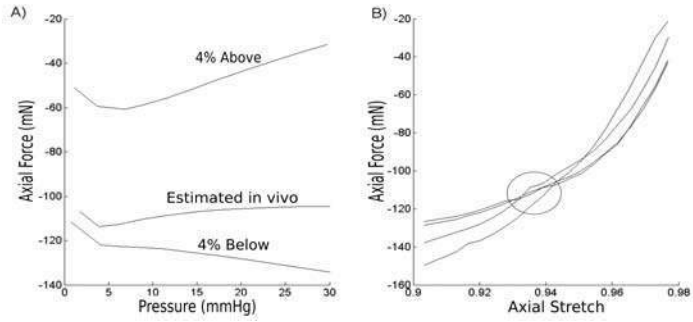

Figure 2: The estimation of the *in vivo* axial stretch ratio based on the near constancy of the transducer-measured force-pressure response during the cyclic pressure-diameter testing (Panel A), and typical force-length responses for which the intersection in the force-λ_z data, denoted by the circle, reveals the *in vivo* axial stretch (Panel B).

The values of *in vivo* axial stretch λ_z^{iv} (0.96±0.008 vs. 0.96±0.002) were not statistically different following elastase digestion. The vagina, however, demonstrated a similar behavior to that of arteries, wherein the measured axial force remained nearly constant in response to changes in luminal pressure at the estimated *in vivo* axial stretch (Figure 2A) [5]. The values of λ_z^{iv} were confirmed as the value of axial stretch where the $f - \lambda_z$ responses overlapped for multiple luminal pressures (Figure 2B). The transition strain, unloaded outer diameter, unloaded length, and toe-region modulus were not shown to be statistically different.

DISCUSSION

In this study, intraluminal exposure to elastase for 45 minutes induced significant changes in the nonlinear mechanical behavior of the murine vagina. The cyclic pressure-diameter tests (not shown) and associated Cauchy stress-strain plots (Figure 1) suggest that elastin may contribute to the mechanical response of the vagina in the low-strain regime. A reduction of tissue stress in the toe-region of the stress-strain curve following elastase digestion has also been observed in ligaments [9]. In this study, digestion of elastin resulted in a higher value of stress at the toe- to linear-region transition and a rightward shift of the associated stress-strain curve (Figure 1). The opposite trend, however, has been observed in the external os of the cervix (unpublished pilot study) and in carotid arteries wherein tissues demonstrated a marked loss of distensibility following digestion in the low-strain regime [6, 10]. Further, Ferruzzi et al. identified a significant loss of collagen fiber undulation following the removal of elastin, consistent with the marked increase in stiffness [6]. Hence, the rightward shift of the stress-strain curve observed in this study may indicate that the collagen undulation has increased following elastase digestion, resulting in a rightward shift of the stress-strain curve. These results may also be explained, in part, by the compressive λ_z^{iv} identified in the vagina in contrast to the axial prestretch observed in vasculature and the murine cervix (Figure 2B). These findings suggest, however, that both the mechanical contribution of elastin and the potential microstructural interactions of elastin and collagen within vaginal tissue may differ from cervical tissue and vasculature. Hence, future work is needed to rigorously quantify the microstructure of the vagina, including potential elastin-collagen interactions.

Further, in this study an increase in the opening angle was observed following elastase digestion, and as expected from the previous results, studies in vasculature report the opposite: a dramatic decrease in the residual-stress related opening angle [6,10]. Opening angles are thought to arise, in part, from the deposition of stable elastin during development and the continual turnover of collagen and smooth muscle at consistent preferred stretches within the ground matrix [11]. The stability and turnover of elastin within the vagina is currently unknown. Hence, there is a pressing need to determine the prestretch of elastin and the deposition timecourse within the vagina, as well as to ascertain how its deposition characteristics may affect collagen undulation and organization.

Our results presented herein differ from the findings of Rahn et al.; however, this may be due to differences in testing methods as well as elastin isolation. Rahn et al. conducted uniaxial tests consisting of rings of vaginal tissue mounted between stainless steel wires, whereas we performed biaxial tests with simultaneous axial extension [3]. Additionally, the use of a genetically-compromised mouse model of elastin compared to an elastase digestion in healthy tissues may contribute to variations in mechanical response. As demonstrated in both studies, however, a loss of elastin integrity clearly changes the mechanical response of the vagina, which may thus alter the environment for the cells residing in the extant matrix and subsequently disrupt vaginal homeostasis (e.g., lead to alteration in smooth muscle phenotype from contractile to synthetic). Hence, we submit there is a pressing need to further delineate the contribution of elastin to vaginal homeostasis and the potential development and progression of vaginal prolapse.

INTRODUCTION

The cartilage endplate (CEP) is a thin layer that separates the intervertebral disc from the adjacent vertebral endplate and vertebral body. The geometry of the CEP is critical to its functions of load bearing and transport. The CEP must be thick enough to transmit loads across the disc-bone interface, and thin enough to minimize the distance solutes must travel to reach disc cells. These functions may be affected by degeneration. With degeneration, CEP permeability decreases [1], its tensile modulus decreases [2], and it may become calcified or damaged [3]. While these biochemical and mechanical changes are known, the effect of disc degeneration on CEP geometry remains unknown.

Magnetic resonance imaging (MRI) is a non-invasive technique to assess tissue structure, but unfortunately, current clinical MRI sequences cannot distinguish the CEP from surrounding tissues. Recent advances in MRI have utilized two sequences, ultrashort time-to-echo (UTE) [4] and fast low-angle shot (FLASH) [5], that have enhanced the contrast between the CEP and the surrounding tissues. In the present study, we apply the FLASH sequence because it is readily available on clinical scanners and usually requires shorter scan times for the same field of view and resolution [5].

The objective of this study was to quantify 3D CEP geometry using a FLASH MRI sequence to evaluate relationships between CEP geometry and age, degeneration, spine level, and disc geometry. Additionally, we assessed the accuracy and repeatability of the MR-based measurements compared to morphological images.

METHODS

Human male lumbar motion segments (n = 22) from 9 cadavers (age 60.9 ± 10.2 yrs; range 42-75 yrs) were imaged using a Siemens 7T magnet. Disc degeneration was assessed by the Pfirrmann grading system and by T2 mapping and average T2* in the central nucleus pulposus [1]. Enhancement of CEP contrast was achieved using a 3D MRI FLASH sequence [5]. Imaging parameters were TR = 9 ms, TE = 3.7 ms, flip angle = 20°, 0.2 mm isotropic resolution [5].

Mid-sagittal and Axial Geometry

CEP thickness, anterior-posterior (A-P) width, lateral width, and axial area were measured. Thickness was measured in mid-sagittal plane images (Fig. 1A). Thickness was calculated for 5 evenly spaced regions across the CEP. Within a given region, the CEP was outlined using the polygon selection tool in ImageJ and converted to a binary mask. Thickness was calculated as the mask area divided by the mask width. A-P width, lateral width, and axial area were measure in the axial plane using OsiriX. Due to the curvature of the disc-bone interface, MR images were post-processed into thick mean intensity slabs of 1.5 mm.

Statistics

Many factors may affect CEP geometry including age, T2* value, Pfirrmann grade, spine level, disc height, and disc axial geometry. Therefore, multiple regression was performed using R software to identify the effect of each factor on each CEP geometry parameter.

Assessment of Accuracy and Repeatability

Two discs imaged with MRI were also processed for morphology analysis. Each disc was fixed in 10% formalin for 1 week and decalcified for 2 weeks with Formical-2000, refreshing the solution every 2-3 days. Discs were bisected along their mid-sagittal plane and

Figure 1: MR (A) and morphology (B) images were overlaid (C)

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

imaged.

The mid-sagittal morphology image (Fig. 1B) was paired with the corresponding mid-sagittal plane MRI image and overlaid using OsiriX software (Fig. 1C). Each image pair was evaluated for CEP thickness by 2 raters, who each independently measured CEP thickness on the MR image and the morphology image on 4 separate days. Accuracy was evaluated by correlating the MRI measurements with the paired morphology measurements. Residuals were calculated as the vertical distance between the MRI-morphology pairing and a 1:1 line. Repeatability was evaluated by calculating the coefficient of variation (CV) for each location and each rater. CV is defined as the ratio of the standard deviation to the mean. The average CV for each user was then compared.

RESULTS

Accuracy and Repeatability

MRI measurements were accurate compared to the paired morphology measurements (slope = 1.005) with an average residual of 0.02 ± 0.14 mm. The standard deviation of the residual (0.14) was less than the MRI resolution 0.2 mm. The method was also repeatable as the coefficients of variation were 13.6% and 14.5% for rater 1 and 2, respectively. For a CEP thickness of 0.5 mm these repeatability measures equate to 0.068 mm and 0.073 mm, respectively, both of which are below the MRI resolution.

CEP Geometry

CEP thickness was greater in anterior and posterior locations than in the center of the disc (Fig. 2A). Therefore, three thickness parameters were used in the multiple regression analysis: center thickness, anterior and posterior (A/P) average thickness, and average thickness for all 5 regions.

Several CEP geometry parameters correlated with age. Average thickness (r=-0.44, $p<0.01$, Fig. 2B), A-P thickness (r=-0.40, $p<0.01$), axial area (r=-0.37, $p<0.01$, Fig. 2C), and lateral width (r=-0.42, $p<0.01$) all decreased with age. Surprisingly, no CEP geometry parameter correlated with degeneration measured by T2* or Pfirrmann grade (Fig. 2D).

While no thickness parameter changed with disc level, some axial geometries did: CEP axial area was 35% greater in L3-L4 than in L5-S1 ($p<0.05$) and CEP A-P width was 20% greater in L3-L4 than L5-S1 ($p<0.05$).

No CEP geometry parameters correlated with disc height (Fig. 2E). However, some axial CEP geometry parameters correlated with disc axial geometry. CEP axial area correlated with disc axial area (r=0.47, $p<0.01$, Fig. 2F) and covers 31 ± 7% of the disc axial area. CEP A-P width correlated with disc A-P width (r=0.31, $p<0.05$) and covers 56 ± 8% of the disc A-P width. CEP lateral width correlated with disc lateral width (r=0.32, $p<0.05$) and covers 57 ± 8% of the lateral disc width.

DISCUSSION

This study quantified CEP geometry using MRI and evaluated potential relationships between CEP geometry and age, degeneration, spine level, and disc geometry.

We found that CEP thickness was greater at the anterior and posterior margins than in the center. This may be due to the anchoring of the inner annulus fibrosus through the CEP at those margins, which could require more material for mechanical support. CEP axial geometry correlated with disc axial geometry, and the CEP spans a larger area of the disc (30%) than just the NP (~25%). CEP thickness did not correlate with disc height, which may be valuable for the transport functions of the CEP. Larger disc heights are already burdened with a long diffusion distance from the solute supply to the cells in the center of the disc. If CEP thickness increased with disc height, this burden would only increase.

This study also assessed potential changes of CEP geometry with age and degeneration. Surprisingly, no g eometric parameters correlated with degeneration measured by either T2* or Pfirrmann grade. However, several properties (CEP axial area, lateral width, anterior and posterior thickness, average thickness) significantly decreased with age. The fact that CEP geometry changes with age and not with degeneration reinforces the notion that CEP degeneration may proceed differently than disc degeneration [1]. It is unclear what processes lead to a smaller CEP with aging. The CEP is prone to damage [2], herniation [6], and calcification [4] which may manifest in changes in CEP geometry.

We previously presented FLASH MRI as a tool to measure CEP geometry and demonstrated the potential clinical feasibility of the technique [5]. In the current study, we demonstrated outstanding accuracy and repeatability of the technique through paired MRI and morphology comparisons. Importantly the repeatability and inter-user error were both below the resolution of the MRI (< 0.2 mm). Moreover, the measurements of CEP thickness obtained from the MRI technique (0.3–1mm) were comparable to previous measurements using histology (0.4–0.8 mm) [3]. Thus the MRI technique, if modified for clinical feasibility, could be valuable for assessing CEP geometry in low back pain patients.

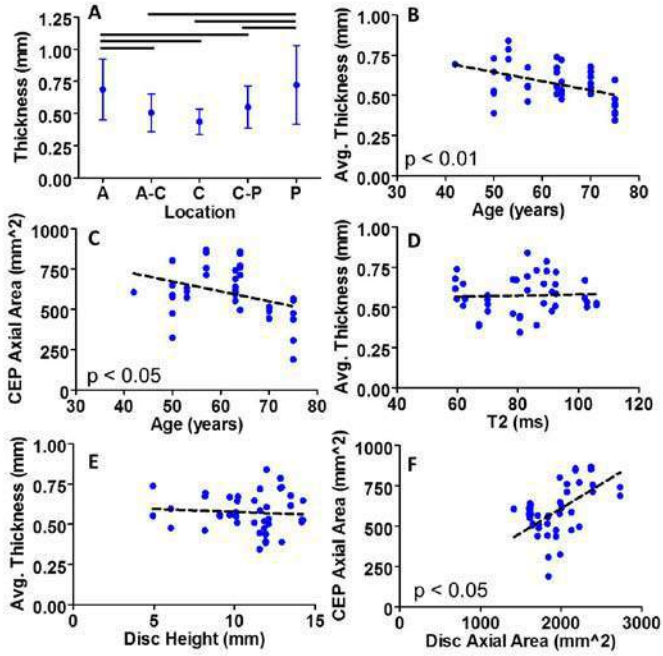

Figure 2: CEP was thickest at the periphery and thinnest in the center (A, p<0.01). Average thickness (B, p<0.01) and axial area (C, p<0.05) correlated with age. Average thickness did not correlate with T2* (D) or disc height (E). CEP axial area correlated with disc axial area (F, p<0.01).

INTRODUCTION

Three dimensional (3D) cell culture systems gain popularity due to its biomimicry in the anatomical architecture of a tissue [1]. A number of techniques have been developed for creating a range of 3D tissues where the spatial organization of scaffolds was constructed. Jiang et al. reported a modified gas foaming technique for expanding electrospun poly(ε-caprolactone) (PCL) nanofiber mats to a 3D scaffold with layered structure. However the detailed expanding process of nanofiber scaffolds, i.e., the gas bubble nucleation, growth, and coalescence is not well understood.

The goal of this work is to develop a numerical framework for capturing the expanding process of electrospun nanofiber membranes. A computational fluid dynamics (CFD) model was developed considering a gas-liquid two-phase flow to increase the gap distance between the adjacent layers of nanofiber scaffolds. A volume of fluid (VOF) method [2] was adopted to move the gas-liquid interface and thus track the fluid movement. The flow dynamics of the expanding process were systematically studied in order to optimize and control the spatial structure of 3D electrospun nanofiber scaffolds.

METHODS

The expanding process between two layers was considered using a VOF model in this work (Figure 1). Five inlets were constructed at the bottom layer to initiate the gas flow and mimic the gas bubble nucleation. The inlet velocity of gas was assumed as 2 m/s to simulate the bubble growth. The standard atmospheric pressure (1.013e5 Pa) was assigned at the outlet. The liquid with a density of 1000 kg/m³ and a dynamic viscosity 0.001 Pa·s was considered. The gas was taken as incompressible air with a density of 1.225 kg/m³ and a dynamic viscosity of 1.7894e-5 Pa·s. The surface tension is assumed as 0.07 N/m.

Flow dynamics of the gas and liquid was governed by the momentum and mass conservation equations:

$$\rho_f \Delta \cdot v = 0 \tag{1}$$

$$\rho_f \frac{\partial \boldsymbol{v}}{\partial t} + \rho_f ((\boldsymbol{v} - \boldsymbol{d}_f^{'}) \cdot \nabla)\mathbf{v} = \nabla \cdot \boldsymbol{\tau}_f + \boldsymbol{f}_f^B \tag{2}$$

where ρ_f is the fluid density, τ_f is the fluid stress tensor, f^B_f is the body forces per unit volume, υ is the fluid velocity vector, d'_f is the moving coordinate velocity and υ-d'_f is the relative velocity of the fluid with respect to the moving coordinate velocity.

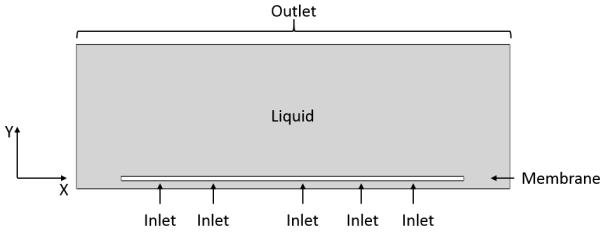

Figure 1: The CFD model of the electrospun nanofiber scaffold.

RESULTS

The volume fractions of the gas during the expanding process were described in the Figure 2. The VOF model tracked the volumes of gas in each numerical grid. Specifically, the blue region corresponds to near zero volume fraction of gas, indicating a liquid phase. The red region with a unity volume fraction indicated a gas phase. Here we tracked the gas-liquid interface based on a given volume fraction of 0.5, i.e., each grid that is half full with gas. It is clear that gas started to merge at t=0.0003s depending on the distance

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

between two nucleation sites. A short distance led to earlier gas bubble coalescence. The gas bubbles almost fully formed into one single large bubble after t=0.0011s. This process was also speculated in the work by Jiang et al. [1].

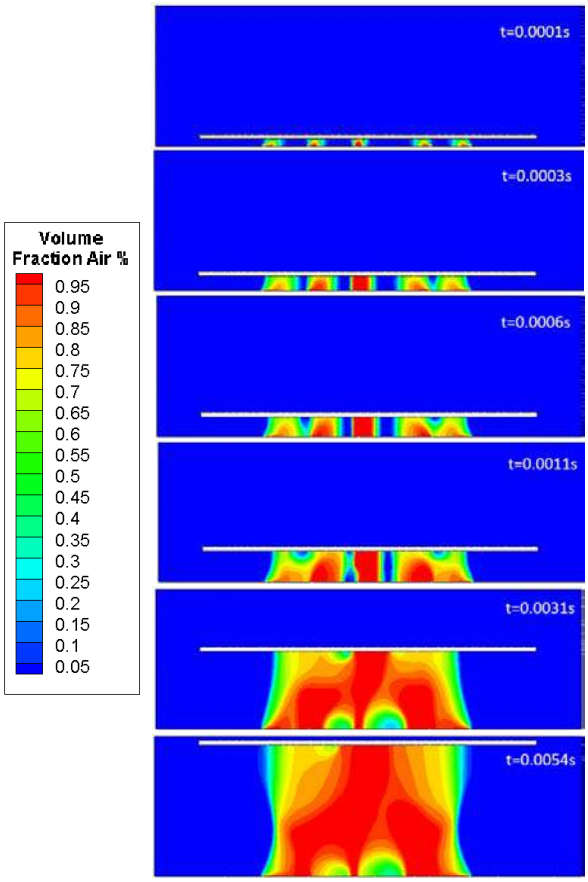

Figure 2: The expanding process of electrospun nanofiber membrane.

The streamline plots of the two phase flow during the expanding process of membranes were depicted in the Figure 3. The flow of gas phase was clearly observed between two membranes. The expansion process drove the growth of turbulence at both ends of membranes.

DISCUSSION

In this study, the gas foaming process for expanding electrospun nanofiber membranes in the third dimension was captured through a gas-liquid two-phase flow CFD model. The variations in the gas and liquid volume fraction shown in Fig. 2 illustrated the expanding process of scaffold, including the gas bubble nucleation, growth, and coalescence.

Theoretical models were proposed to address gas bubble issues during micro or nanoimprint lithography. Liang et. al. developed an analytical model to understand a single air bubble expansion and dissolution [3]. However the interaction between gas bubbles. i.e., bubble coalescence were not considered in their work. Reddy et al. also proposed a theoretical VOF model to study the bubble merging [4]. In this work, we combined these discrete theoretical bases and developed a VOF numerical model to capture the complete expanding process of gas bubbles in a liquid environment. The expansion speed of membranes was calculated based on the volume of incompressible liquid. Our results demonstrated that gas bubbles bridging two layers are noncircular, different with classical free-floating bubbles. This could be explained by the surface tension of bubble as well as the pressure gradient at both ends of the membrane. The observed turbulence intensity at both ends of membranes is related to the speed of gas growth. In the current model, the nanofibers between membranes was ignored which might alter the bubble expansion speed and disturb the bubble growth and merge. In summary, our preliminary model could capture the nanofiber membrane expanding process.

INTRODUCTION

An estimated 300,000 sports-related concussions occur in the United States annually [1]. A recent report from the Institute of Medicine and National Research Council of National Academies showed that male high school and collegiate football players reported higher rates of concussion compared to other contact sports [2]. Even though there has been a rise in the rate of sports-related concussion, the relationship between subconcussive head impacts and the onset of concussion remains unclear. Subconcussive impacts through routine participation in sports have been associated with structural and functional MRI changes, along with decreased cognitive abilities [3][4], even in the absence of concussive onset. Accordingly, it can be theorized that subconcussive impacts contribute to increased concussion susceptibility [5]. Therefore, it is important to characterize head impact history and determine whether that history differs between players that sustain concussion and those that do not. This study quantified head impact history during one athletic season using head impact sensors in college football athletes and compared subconcussive exposure between athletes that did or did not sustain concussion.

METHODS

The procedures described in this abstract were approved by the Institutional Review Board (IRB) at our Institution. Informed consent was obtained from all participants prior to data collection. One hundred and ninety-one athletes from four NCAA Division III football teams participated during the 2015 football season. Athletes were issued helmets containing the Head Impact Telemetry System (HITS) (Simbex, Lebanon, NH). Athletes wore the sensor during all uniformed activities (games, practices and scrimmages) throughout the season. Data collection and system maintenance were performed by study coordinators at each site.

The helmet-based HITS is an impact measurement sensor developed for use in football helmets. The sensor consists of 6 single-axis accelerometers mounted inside the helmet. The sensor starts data collection when a single accelerometer exceeds a pre-defined threshold. Once triggered, the sensor collects 40ms (8ms pre and 32ms post) of data at a sampling rate of 1,000Hz. The data are wirelessly transmitted to the sideline controller and downloaded to the computer for storage and processing. An algorithm is used to calculate head impact magnitude and location about the head center of gravity [6].

The sensors were mounted inside Riddell Speed Helmets (Des Plaines, IL). At the end of each activity, the data were downloaded from the sensor to the sideline controller for storage and processing. The system uses a proprietary algorithm to filter non-head impacts such as walking or running. HITS has been used in several studies for head impact measurement with extensive laboratory validation data available in the literature [7].

Head impact exposure data were compared between concussed and non-concussed players. Head impact history was compared between the groups by evaluating the magnitude and number of head impacts sustained by participants throughout the season. Resultant Peak Linear Acceleration (PLA) and Resultant Peak Rotational Acceleration (PRA) were compared between the groups. Data were also compared between concussed and non-concussed players based on player position.

RESULTS

Present results include data from 191 participants (182 non-concussed and 9 concussed) with a total of 77,140 recorded impacts during the 2015 football season. Head impact history was compared between concussed and non-concussed by evaluating the distribution of head impacts based on magnitude of peak linear acceleration (PLA) and peak rotational acceleration (PRA) (Figure 1).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

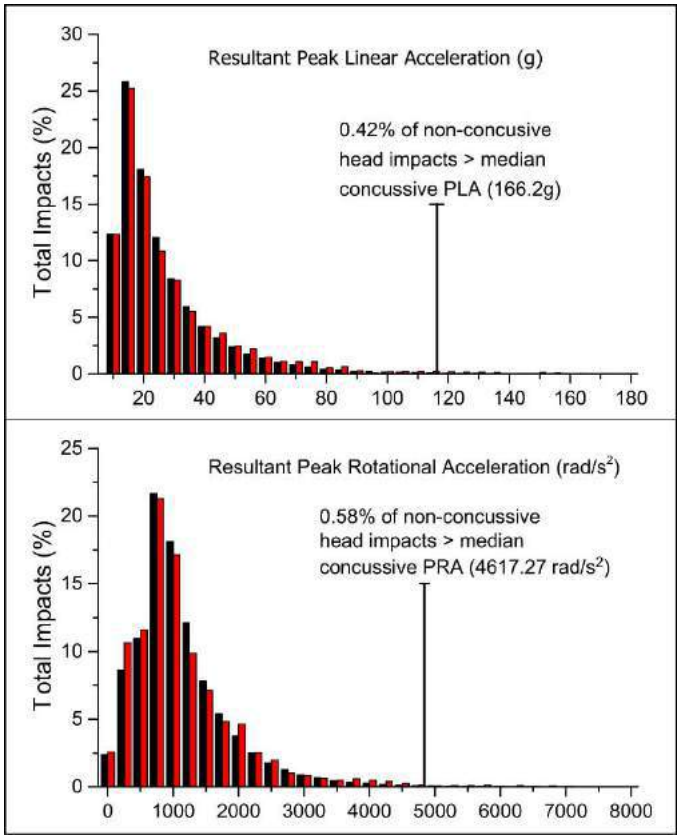

Figure 1: Distribution of peak linear and rotational accelerations between concussed(red) on non-concussed(black) players.

The mean PLA and PRA for all non-concussed players were 26.27g and 1134.05 rad/s^2 respectively. The mean PLA and PRA for all concussive impacts were 107.57g and 4840.05 rad/s^2 respectively.

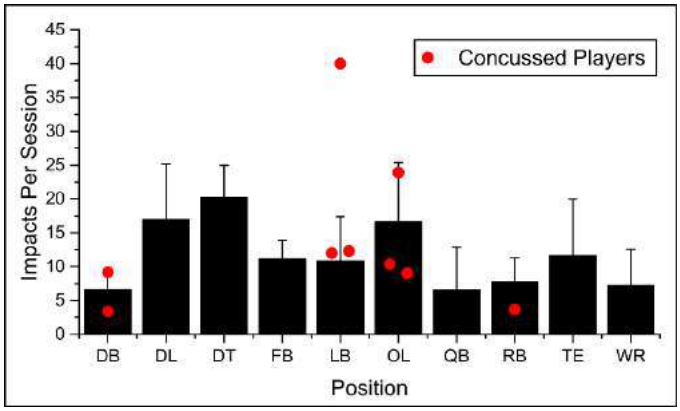

Figure 2: Number of impacts per session grouped by position. Position-matched data are provided for each concussed player.

Head impact history was also compared between position groups for non-concussed players by evaluating the average number of head impacts sustained by players per session (i.e., game, practice, or scrimmage). A one-way analysis of variance (ANOVA) of the average number of head impacts per session for non-concussed players was significantly different ($p < 0.05$) based on player's position. Bonferroni post-hoc analysis revealed that Defensive Back (DB) position had a significantly lower number of head impacts per session when compared to Defensive Line (DL), Defensive Tackle (DT) and Offensive Line (OL) positions. DL was also significantly different from Quarterback (QB), Running Back (RB) and Wide Receiver (WR). DT was significantly different from QB, RB and WR positions. OL was also significantly different from QB, WR positions.

Average PLA or PRA showed no significant differences between concussed and non-concussed players.

DISCUSSION

The goal of this study was to record and evaluate head impact history in collegiate football athletes over the course of a season. The frequency and magnitude of head impacts were compared between concussed and non-concussed players. Distribution of head impacts showed that concussed players sustained marginally more impacts at higher magnitudes for PLA and PRA compared to non-concussed players. Similar to other studies, the current study showed a significant difference in impacts per session based on player position. However, there were no significant differences in the magnitude of impacts between positions. A majority of concussed players had similar numbers of head impacts per session compared to non-concussed players, with the exception of two players that had remarkably more head impacts per session than their position-matched controls.

Data for current study show significantly different head impact history between football positions, with linemen generally sustaining more impacts per session. Comparison of concussed to non-concussed players shows somewhat of a shift toward higher magnitude impacts and primarily similar number of impacts per session, with two exceptions. This may point to a differing effect of head impact history on concussive onset, with some concussed players regularly sustaining higher magnitude head impacts and other concussed players sustaining a higher number of impacts. This important distinction will continue to be explored in this ongoing study.

INTRODUCTION

The increase use of explosive weaponry in military conflict and terrorist attack in recent years, has increased the number of combat related injuries sustained by soldiers and civilian induced by the blasts [1]. Ocular trauma is one of the most common types of combat injuries resulting from the interaction of military personnel with improvised explosive devices. Ocular blast injury mechanisms are complex, and trauma may occur through various injury mechanisms. However, the injury mechanism associated with the primary blast wave, which can result in significant damage to internal ocular tissues and visual impairment, is unknown. Recently, the use of computational models have been extended from modeling blunt object impact to understand the mechanism of the primary blast injuries of the eye, induced by blast overpressure [2, 3]. However, there is still a gap in the literature for a model which simulate the deformation of anatomically accurate eye model exposed to blast overpressure and calculate the corresponding risk of injuries.

An experimentally validated computational model which include the main internal ocular structures of the eye, spatially varying thickness of cornea-scleral shell and tissue properties, have been utilized to help us in understanding the mechanism of primary injuries and also provide a measurable estimation of risk of injuries by using the risk of injuries available in literature.

METHODS

In order to investigate the effect of the overpressure on human eye, a computational model which are composed of three dimensional deformable eye, rigid skull and fluid domain have been used. The flow field around the structure is compressible, and pressure fields on the structure are non-uniform and highly transient. The fluid-structure interaction (FSI) solver [3] that employ the following methods have been used:

- Finite difference compressible flow solver for the propagation of the blast wave.
- Finite element elastodynamic solver with finite deformation of the human eye.
- Sharp-interface immersed boundary method for fluid-structure interaction.

The model includes detailed descriptions of the facial features of an average 21 year old male [3], the internal ocular structures, spatially varying thickness and anisotropic properties of the cornea and sclera. The internal ocular which have been considered in our model is shown in Figure (1). The local thickness variations of important load-bearing ocular components (cornea and sclera) were obtained from published histological measurements. In addition, a distributed fiber model was applied to describe the anisotropic elastic behavior of the sclera and cornea. The model directly incorporated published wide-angle X-ray scattering measurements of the anisotropic collagen structure. Furthermore, the effect of the local thickness variations and anisotropy of the important load-bearing ocular components on the deformation and stress response of the intraocular components was investigated and the risk for injuries such as lens dislocation, retinal detachment, globe rupture, and hyphema was calculated based on experimental data for blunt impact available in the literature. In addition, a sensitivity analysis with using analysis of variance method was performed to determine the statistical significant of change in different ocular components material properties of isotropic model on the stress distribution.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

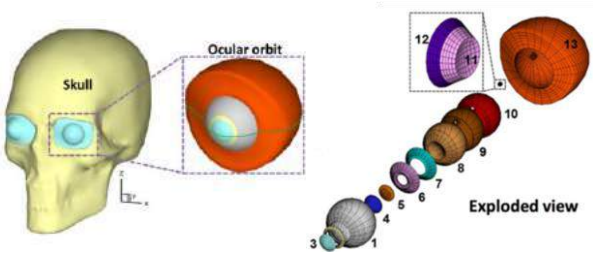

Figure 1: (onset) Assembled view of the eye depicting the extraocular tissues, sclera, limbus and cornea inside the skull. (inset) Ocular components in exploded view with associated zone numbers as follow (1) sclera,(2) limbus,(3) cornea,(4) aqueous, (5) lens (nucleus, cortex), (6) ciliary zonule, (7) ciliary muscle,(8) vitreous, (9) retina, (10) choroid, (11), Pre-laminar Neural Tissue (PLNT), (12) lamina cribrosa (LC), (13) extraocular tissue.

RESULTS

As it can be seen from Figure (2), the overall increase in maximum principal stress and IOP are due to the time-varying pressure loading boundary condition, and the periodic behavior of the stress and IOP for ocular components forming the posterior wall of the globe can be explained by the wave propagation inside the orbit. Ocular components forming the posterior wall of globe, experience higher oscillatory tensile and compressive stress (Figure 1-a) and ocular components forming the anterior structures of globe quickly reached their peak principal stress and quickly decayed (Figure 1-b). The von Mises stresses caused by tissue shear were largest in the scleral wall at the site of muscle attachments (Figure 1-c).

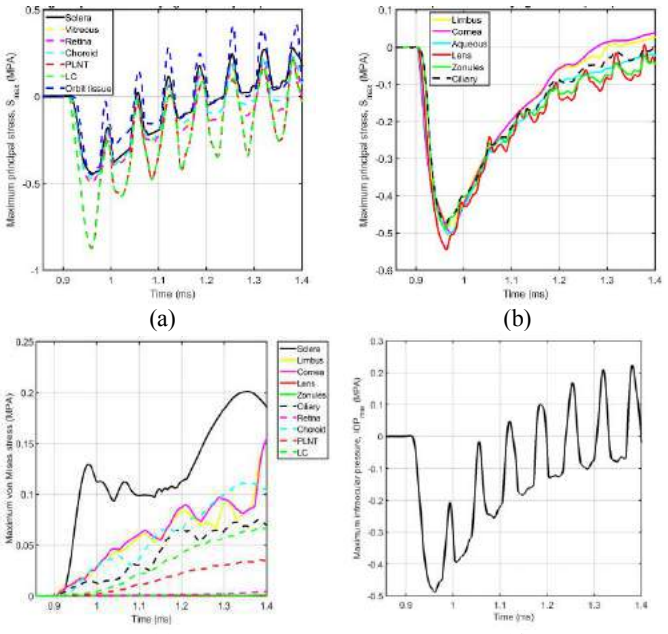

Figure 2: (a)High amplitude time varying maximum principal stress (b) Low amplitude time varying maximum principal stress (c) Time varying maximum von Mises stress (d) Time-varying maximum intraocular pressure (IOP)

In order to show the effect of considering an anisotropic material model to represent the cornea-scleral shell on the response of the structure, maximum principal stress (S_1) and maximum von Mises stress of the model with anisotropic material model ("anisotropic model") is compared to model with isotropic material properties with equivalent shear modulus for sclera and cornea to those in anisotropic model (Figure 3).

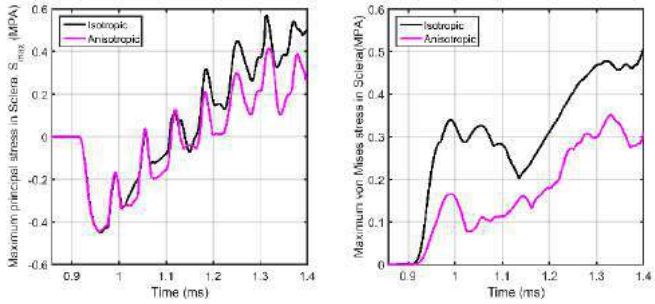

Figure 3: Comparison of anisotropic model and equivalent isotropic model (isotropic model) for cornea, limbus and sclera for time-varying (A) Maximum principal stress and (B) maximum Von Mises stress.

DISCUSSION

The stress analyses in our study correlate with the observed primary blast injuries in animal and cadaveric tissue studies, including retinal and scleral delamination, and lens detachment. Both trend of stress behavior agree with results reported by Rossi et al [4]. As shown in Figure 1-d, the maximum IOP inside the globe reached 0.22 MPa, corresponding to around 1650 mmHg, which is two orders of magnitude larger than the 15 mmHg physiologic IOP for a healthy eye. In addition, the maximum principal stress and maximum von Mises stress in sclera, choroid, retina, and ciliary zonlues showed the possibility of internal scleral delamination, chorioretinal detachments, and lens dislocation.

The blast wave loading may generated significant risk of corneal abrasions, hyphema injury. For a 2kg TNT blast at a standoff distance of, 2.5 meters we evaluated a 5% risk of Corneal Abrasions, 0.2% risk of hyphema and less than 0.01% risk of lens damage, retinal damage and globe rupture based on the maximum intraocular pressure. It should be noted that the injury risks were significantly reduced when calculated based on the maximum principal stress which show that, blast specific injury experiments are needed to more accurately evaluate the risk of injury. The anisotropic results shows that both isotropic and anistropic model have similar trends in stress. However, considering the isotropic material model can lead to overestimating both the von Mises and principal stress. Our sensitivity analysis for isotropic material model showed that the variation of the cornea-scleral shell have a significant effect on maximum principal stress of several main components of the eyes such as sclera, cornea, limbus, choroid, PLNT and LC.

INTRODUCTION

Rotator cuff tears are a significant clinical problem with an incidence rate over 30% in the general population [1]. Ultrasound (US) has become a common modality for detecting rotator cuff tears [2] and recently, quantitative ultrasound measures (QUS) have shown to be a reliable technique for quantifying tendon quality by analyzing ultrasound image grayscale values [3]. QUS has been established to quantify overall tendon quality [4], not the specific factors that can affect tendon quality such as by collagen fiber organization, tenocyte nuclei shape, tenocyte cell number, and lipoid degeneration. Histology has been used to investigate the specific factors responsible for tendon degeneration [5]. Therefore, the objective of this study is to assess the relationships between QUS of tendon quality and actual degeneration in tendons as quantified by histology. It is hypothesized that QUS will be correlated to structural parameters of the tendon such as collagen fiber organization.

METHODS

Four intact fresh-frozen cadaveric shoulders (55 ± 12 years) and four shoulders with a small supraspinatus tendon tear (71 ± 9 years) were used. Prior to dissection, US images were obtained in the transverse view of the widest part of the supraspinatus tendon near its insertion to the humerus, while using the cross-sectional view of the long head of biceps tendon (LHBT) as a consistent reference point between specimens [5]. Images were taken by an expert in musculoskeletal US for rotator cuff tear detection, using the same parameters for all images. A 1 cm wide region of interest (ROI) was measured 1 cm away from the posterior margin of the LHBT (Fig 1). Skewness, kurtosis, variance and mean echogenicity were calculated from a histogram that describes the grayscale value distribution, or echotexture, in the tendon ROI as a measure of tendon quality. Increased tendon degeneration has been reported to be associated with higher skewness and kurtosis as well as lower variance and echogenicity [3]. This type of quantitative analysis of regular US images provides different information than ultrasound elastography.

Following US imaging, all shoulders were dissected to isolate the supraspinatus tendon to obtain tissue biopsies (~2 x 4 mm) for histology. Biopsies were taken from each tendon near the myotendinous junction, mid-substance, and insertion site. All images were graded on four main parameters in a blinded fashion by two independent observers using a semi-quantitative scale (ICC = 0.89). The four parameters chosen to evaluate tendon degeneration were: collagen fiber organization, tenocyte nuclei shape, tenocyte cell number, and lipoid degeneration [4]. The grading scale was modified from Sano et al to create a 4-point scale of degeneration (0 = no change, 1 = slight localized change < 25% of tendon area, 2 = multifocal change 25-50% of tendon area, 3 = diffuse or global change > 50% of tendon area) [4]. For each parameter, the average grade between all three biopsy sites was used as a measure of the entire tendon. Total degeneration was determined as the summation of the score for all four parameters. QUS and histological findings were compared at the three biopsy sections and the entire tendon.

Pearson or Spearman's rho correlations were calculated between QUS and histological parameters with significance set at $p < 0.05$. Correlation strength was classified as negligible for r/rho = ±0.00-0.30, low for ±0.30-0.50, moderate for ±0.50-0.70, strong for ±0.70-0.90 and very strong for ±0.90-1.00 [6]. Independent samples t-tests or Mann Whitney U tests were conducted with significance set at $p < 0.05$ to compare QUS and histology grades between the intact and torn tendons.

RESULTS

A total of 3 significant correlations between QUS and histology grades were found. A strong correlation was found at the insertion site

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

between kurtosis and increased tenocyte cell number ($r = 0.724$, $p < 0.05$) (Fig 1). At the myotendinous junction, there was a strong inverse correlation between variance and lipoid degeneration ($rho = -0.843$, $p < 0.01$) (Fig 2). For the whole tendon, a strong inverse correlation was found between variance and lipoid degeneration ($rho = -0.826$, $p < 0.05$) (Fig 2). No significant differences of the QUS parameters were found between the intact and torn tendons ($p > 0.05$). For the histology grades, only a significant difference between the intact and torn tendons were found in lipoid degeneration at the midsubstance and the whole tendon ($p < 0.05$), and total degeneration for the whole tendon ($p < 0.05$).

DISCUSSION

All correlations found agree with prior studies that showed that increased kurtosis and decreased variance are associated with poor tendon health [4]. An increase in kurtosis implies that there was a sharp peak in the distribution of grayscale values of the ROI histogram, possibly resulting from the hypercellular regions found in the tendon. Variance measures the spread of the grayscale values, while lipoid degeneration indicates the amount of fatty infiltration. While the results did not support our hypothesis, our findings show that certain degenerative changes can be detected because of their effect on the echotexture of an image (eg. fatty infiltration due to lipoid degeneration will make the US image have hyperechoic regions). A limitation of this study is that the US image used for analysis corresponds most closely to the insertion site of the supraspinatus tendon. Interestingly, no significant differences of QUS and few significant histological differences were found between intact and torn tendons. This indicates that intact tendons show similar degenerative changes as the torn tendons and supports the reasoning that increased age increases the likelihood of a rotator cuff tear (Intact = 55, Torn = 71) [7]. However, a post-hoc power analysis for kurtosis showed only 4 additional samples in each group were needed to achieve a significant difference.

Overall, our results show that QUS can be used to assess some of the factors of tendon quality that can otherwise only be determined through histology in order to provide clinicians further insight on the degeneration of rotator cuff tendons and ultimately improve rotator cuff repair surgery. In the future, additional correlations will be performed using QUS and tendon tensile properties as determined from mechanical testing. This study provides information about how clinicians can use ultrasound as a diagnostic tool to non-invasively evaluate tendon degeneration.

CT-BASED ESTIMATION OF STRUCTURAL INTERACTIONS OF THE VESSEL WALL AND STENT GRAFT IN ENDOVASCULAR REPAIR OF ABDOMINAL AORTIC ANEURYSM

Ryan J. Pewowaruk (1), Victor H. Barocas (1)

(1) Biomedical Engineering
University of Minnesota – Twin Cities

INTRODUCTION

Abdominal aortic aneurysms (AAA, Figure 1A) are a pathological widening of the abdominal aorta, often treated by the placement of an endovascular stent graft (Figure 1B). The stent graft manages the blood flow, decreasing pressure in the aneurysm and in turn decreasing the likelihood of the rupture [1]. Aneurysms near the renal arteries present a challenge for the surgeon, as flow to the kidneys must not be obstructed [2]. This problem is solved by cutting holes in the side of the stent graft and then anchoring it to the renal arteries (Figure 1C). When the stent is deployed in the artery, however, it deforms the vessel wall. This deformation can change the location of the renal arteries, which means that the surgeon cannot know *a priori* which stent hole locations will be coincident with the renal arteries [3]. Aortic aneurysm deformation due to stent placement is not yet well understood, with both the irregular geometry of the aneurysm and the changing mechanical properties due to calcification and atherosclerotic plaques affecting the response [4, 5].

The goal of this project is to understand better how placing a stent in an AAA mechanically affects the vessel wall of the aorta and surrounding tissues. This was accomplished by calculating displacements and strains around the stent from before and after CT scans of a patient with an AAA.

METHODS

As part of standard care, a CT scan was taken of a patient with an AAA prior to treatment with a stent-graft. After the procedure was performed, another CT scan was taken using the same. A three-dimensional rendering of the aneurysm before and after stenting is shown in Figure 2 on the next page.

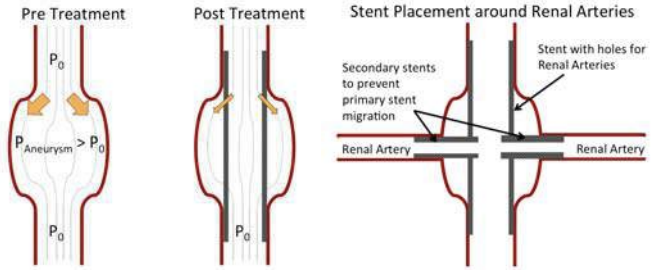

Figure 1: A. Abdominal aortic aneurysm. B. Endovascular stent graft, C. Modified stent graft to maintain renal blood flow

Matlab-based volume correlation software [6] was used to calculate the displacement field of the aorta and surrounding tissues as they deformed after the stent was placed. The software works by taking a volume of voxels from the first image stack and then iteratively finding the best match based on voxel intensities in the second stack of images, accounting for the fact that the volume can rotate, dilate, and shear. The displacement field was then numerically differentiated along each direction using a forward finite difference algorithm in MATLAB to obtain the deformation gradient at each point. From the deformation gradient at each point, the Green strain tensor was calculated using Equation 1, in which E_{ij} is the Green Strain tensor, F_{ij} is the deformation gradient tensor, and δ_{ij} is the Kronecker delta.

$$E_{ij} = \frac{1}{2}(F_{ki}F_{kj} - \delta_{ij}) \quad (1)$$

Figure 2: 3-D representation of stented aneurysm reconstructed from CT scans. Kidneys are shown in red.

RESULTS

A coronal cross-section of the aneurysm is shown in Figure 3. The arrows indicate the displacement of the aneurysm and surrounding tissue from before the stent was placed to after the stent was place. Throughout the middle of the aneurysm, the displacement vectors point to the left but at the distal end of the aneurysm, near the femoral bifurcation, the displacement vectors change direction and point the right. At the proximal end of the aneurysm, the vectors begin to point upwards and to the left.

Strain plots calculated in the same plane as the CT scan slice are also shown in Figure 3. In the anterior-posterior direction, peak in the tissue strain field is observed near the distal end of the aneurysm, with a Green Strain of 0.15 while surrounding tissues have strains in the range 0.05 to -0.05. An asymmetric effect is also seen at the proximal end of the aneurysm, near the junction with the renal arteries. To the left of the aorta, the tissue is in tension with Green strains ranging from 0.1 to 0.15, while tissue to the right of the aorta is unstrained.

In the left-right direction, the tissue on the right side of the patient's aneurysm is in tension while tissue on the left side of the patient's aneurysm is in compression. On the right side of the aneurysm, tensile strains in the left-right direction are highest near the renal arteries and lowest near the femoral bifurcation Green strains dropping from approximately 0.5 to 0.3. Conversely, on the left of the aneurysm, the compressive strains in the left-right direction are highest near the femoral bifurcation and lowest near the renal arteries with Green strains changing from approximately -0.25 to -0.1.

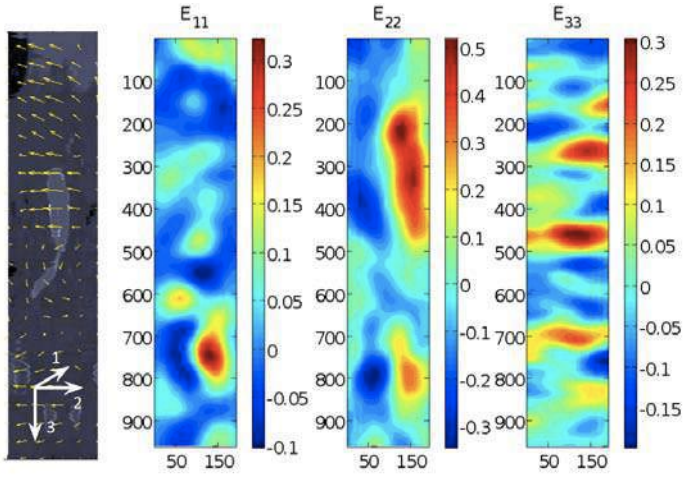

Figure 3: Coronal plane from CT image and strain plots. Aneurysm is in center above femoral bifurcation with arrows indicating displacements from pre to post operation (arrows not shown to scale). Directions are (1) anterior-posterior, (2) left-right, and (3) superior-inferior

Two peaks near the aneurysm appear on the strain plot showing strains in the superior-inferior direction. One peak is near the junction of the renal arteries, at the top of the stent at a vertical direction value of approximately 250. The second peak is at the distal end of the stent near the femoral bifurcation at a vertical direction value of approximately 500. At both peaks the maximum tensile strain in the vertical direction is approximately 0.25. In the areas immediately surrounding these peaks the Green Strain is closer to 0.1.

DISCUSSION

The calculated strains from before-and-after CT scans of a patient with an AAA provide two main insights into the mechanical interactions between the stent graft and the aortic wall and surrounding tissues. The first point is that the resulting deformation of the tissue is strongly dependent on aneurysm geometry. The original shape of the aneurysm is highly tortuous, and its mechanical properties likely vary with position. The tissue deforms when the straight cylindrical stent graft is deployed. The stent graft is rigid compared to the tissue, so the aneurysm must deform to accommodate it. This effect is clearly shown in the left-right direction strain plot, where tissue on the right side of the aneurysm is in tension and tissue of the left side of the aneurysm is in compression. This asymmetric effect is likely caused by the straight stent being expanded in the asymmetric aneurysm. A similar asymmetric effect is seen at the left side of the top of the aneurysm in the anterior-posterior direction strain plot.

The second trend observed in the strain plots is that strain is concentrated at the renal artery junction at the proximal end of the stent and also the femoral bifurcation at the distal end of the stent. In the superior-inferior direction strain (E_{33}) plot in Figure 3, peaks are seen at both ends of the aneurysm, where the stent begins and ends. Another peak in the strain field is seen at the femoral bifurcation in the anterior-posterior direction strain plot. It is important to recognize that the strains calculated in this work are based on the image stack and do not necessarily represent strain in the tissue proper.

By analyzing the strains calculated from before and after images of a patient treated with a stent graft for an AAA, it was determined that the strain varies spatially in the tissue around the aneurysm and that strain concentrations are present at the top and bottom of the aneurysm. It is speculated that asymmetries in the strain field are caused by the tortuous aneurysm conforming to the stent.

ACKNOWLEDGEMENTS

Thank you to Dr. Rumi Faizer of the University of Minnesota – Twin Cities for providing the clinical data presented in this abstract and his insight on endovascular repair. This work was supported with resources from the Minnesota Supercomputing Institute and by funding from the University of Minnesota Undergraduate Research Opportunities Program.

INTRODUCTION

Articular cartilage is a mechanically multiphase tissue consisting of fluid (water and dissolved ions) and solid (collagen, proteoglycans and chondrocytes) constituents. The interaction of water, proteoglycans and the collagen network creates the remarkable mechanical responses of cartilage under load. The principal alignment of collagen through the thickness is described by characteristic zones: superficial (SZ), middle (MZ) and deep (DZ). With respect to the articular surface, collagen fibers are principally orientated parallel in the SZ, random (isotropic) in the MZ and perpendicular in the DZ. In the SZ this orientation can easily be visualized as the so called split-line direction [1]. The mechanical properties of cartilage are strongly heterogeneous, varying both through the thickness and throughout the joint (e.g. load bearing vs. non load bearing regions) [2].

Cartilage experiences complex loading *in vivo*, combining compression, tension and shear. Relatively little is known about the shear response of cartilage although shear loads play a critical role in the development and progression of cartilage degeneration, e.g. Osteoarthritis (OA) [3]. Most studies on the shear properties of cartilage report torsion or simple shear tests under small strains and neglect the split-line direction, thus neglecting potential anisotropies.

In this study we seek to investigate the large shear strain response of human articular cartilage and its dependence on both the local split-line direction and location within the joint. Given the structure of the collagen network we hypothesize that the shear response of cartilage is strongly anisotropic. Toward this hypothesis we test location-matched human cartilage samples under multi-axial, large shear strains.

METHODS

We prepared samples from six human donors (30.2 ± 8 yrs old, mean ± std) from the Musculoskeletal Transplant Foundation. Using histology we verified the healthy condition of our samples [4]. We tested samples from both the lateral condyle and the patellar surface using seven representative locations within the joint (Fig. 1). We determined the split-line direction using India ink and extracted square samples (3x3 mm^2, full thickness) with one side parallel to the local split line. Using our triaxial shear testing device (Messphysik, Fuerstenfeld, AT) we completed large strain, simple shear tests at a quasi-static displacement rate (75 μm/min). First, we applied a pre-compression of 1% of the undeformed thickness and allowed the samples to equilibrate for 4000 sec. Next we applied cyclic simple-shear displacements parallel and perpendicular to the local split-line directions (six cycles per direction) at magnitudes ±5, ±10, ±15 and ±20% (with respect to the undeformed thickness) and measured the corresponding forces. When switching displacement directions we allowed the sample to equilibrate for 3000 sec. We completed all tests in a PBS bath at 37°C including antibiotics (100 U/ml penicillin and 100 μg/ml streptomycin) and protease inhibitor (Sigma Aldrich).

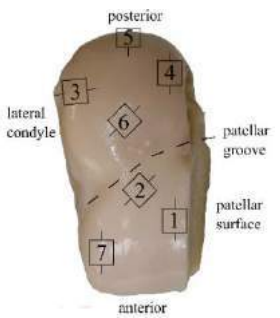

Figure 1: Locations within the femoral condyle where lines indicate the typical local split-line direction.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

We calculated the peak-to-peak Cauchy stress and the strain-energy dissipation density at each applied strain considering only the last three applied cycles (to avoid preconditioning effects) using MATLAB (The MathWorks Inc., Natick, MA). To determine inter- and intra-patient variability we conducted a one-factor analysis of variance (ANOVA), with patient number (1-6) and location (1-7) as variables, followed by post-hoc tests using Tukey's Honest Significant Difference (HSD) to test for significance of relations. We used a paired *t*-test to compare the mechanical responses parallel and perpendicular to the split-line direction. Finally, we assessed the influence of age and thickness using Pearson's correlation coefficient. We completed all statistical analyses using SAS 9.4 (SAS Institute Inc., Cary, NC) with a significance level of 0.05.

RESULTS

The mechanical responses of all cartilage samples in shear were nonlinear and showed distinct hysteresis. Figure 2 shows representative stress-strain responses for donor 3, location 7.

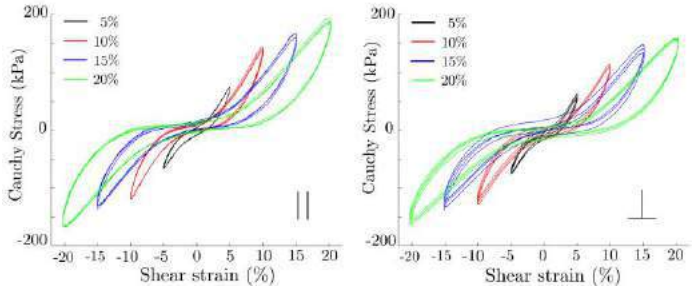

Figure 2: Representative stress-strain responses parallel (‖) and perpendicular (⊥) to the split-line direction (donor 3, location 7).

Table 1 shows the mean values and standard deviations for both the Cauchy stresses and energy dissipations (as a function of applied strain) summarizing all patients and locations. We report the strain-energy (density) dissipation in units of kPa, equivalent to $\mu J/mm^3$.

Table 1: Peak-to-peak Cauchy stresses and energy dissipations for all patients (mean ± std).

Strain (%)	Stress (kPa)		Energy dissipation (kPa)	
	‖	⊥	‖	⊥
5	107 ± 35	102 ± 35	1.56 ± 0.44	1.53 ± 0.46
10	216 ± 63	200 ± 57	5.86 ± 1.7	5.62 ± 1.7
15	302 ± 81	275 ± 71	12.8 ± 3.6	12.1± 3.6
20	355 ± 99	318 ± 93	21.9 ± 6.6	20.5 ± 6.3

There was no significant directional dependence for stresses at small strains (5%) but there was pronounced anisotropic behavior at larger strains, with the split-line direction being stiffer. Energy dissipation showed the same trend but initiated at larger strains, between 10-15%. Table 2 shows the mean difference δ between stresses and energies parallel and perpendicular to the split line, and the corresponding *p*-values from a paired *t*-test. A positive δ suggests that the split-line direction was stiffer and dissipated more energy.

Joint location did not significantly correlate with peak-to-peak stresses at 5% and 10% strain parallel to the split line. Location 6 was stiffest at 15% applied strain both parallel and perpendicular to the split line. Correspondingly, the most energy was dissipated at location 6 at all applied strains and in both directions. Donor age and sample thickness did not correlate significantly with the mechanical responses.

Table 2: Mean differences (δ) in peak-to-peak Cauchy stresses and energy dissipations between ‖ and ⊥ direction (* indicates $p<0.05$).

Strain (%)	Stress		Energy dissipation	
	δ (kPa)	*p*	δ (kPa)	*p*
5	4.8	0.1134	0.03	0.5696
10	16.0	0.0023*	0.24	0.1319
15	27.6	< 0.0001*	0.71	0.0150*
20	11.5	0.0013*	1.59	0.0060*

DISCUSSION

Our results showed a nonlinear stress-strain relation for large strains consistent with the nonlinear stiffening of collagen fibers, the main active load bearing component [5]. Tissue stiffening was more pronounced at 5% and 10% applied strain than at higher strains. This may suggest that the solid matrix adapts to external loads by rearranging the collagen fibers, or collagen-collagen and collagen-proteoglycan cross-links, within the matrix. It could also indicate that irreversible damage was induced. Equilibrating the specimen prior to each cycling of applied displacements eliminated reversible effects.

Our results showed pronounced anisotropy at strains larger than 5% for both stresses and energy dissipated. Dissipation effects due to fluid flow can be neglected due to our quasi-static loading, and thus the energy dissipation reported was due to the intrinsic viscoelastic response of the collagen and proteoglycan constituents. The correlation with direction, visualizable in the directionality of the SZ, may be a result of long-term adaptation of the tissues' load bearing components, mainly the collagen network, to *in vivo* loading.

Tissue from location 6, which dissipated the most energy at all strain levels, corresponds to the location with the highest loading *in vivo* [6]. The same location was only stiffest at 15% strain. Nine tests provided insufficient results at 20% applied strain (currently being retested) and were thus excluded in the statistical analyses. This may explain why the stresses at 20% applied strain did not follow the same trend. The relatively narrow age range of our donor group and the healthy state of the cartilage tested explain the lack of correlation among age and mechanical responses. Only tissue samples with an OARSI score of 0 (healthy tissues) were considered for this study [4]. Our finding that sample thickness did not correlate with peak-to-peak stress nor energy dissipation highlights the importance of structural integrity of the collagen network to the mechanical response [7].

Investigations on the mechanical response of cartilage to small shear deformations typically show linear, isotropic behavior, consistent with our study. To the best of our knowledge no study has previously shown the mechanical responses of cartilage under multi-axial, large-shear deformations. Interestingly, mechanical anisotropy only becomes apparent at large shear strains. In the future we aim to investigate the role of cartilage's zonal architecture on large shear response. We further aim to apply such results to mechanistically understand the mechanical behavior of cartilage and to inform computational models of the tissue's mechanics.

INTRODUCTION

Glaucoma, one of the leading causes of blindness worldwide, is characterized by gradual and progressive damage to the optic nerve [1]. Although elevated intraocular pressure (IOP) is widely accepted as an important risk factor for glaucoma, recent studies have demonstrated that an elevated IOP does not necessarily cause the development of this disease [2, 3]. The optic nerve head (ONH), which is the portion of the optic nerve clinically visible on examination, is exposed not only to the IOP within the eye, but also to the intracranial pressure (ICP), as it is surrounded by the cerebrospinal fluid in the retro-orbital subarachnoid space. These pressure regions are separated by the laminar cribrosa (LC) and thus influence the LC behaviors. Recent experimental data derived by using a postmortem, 3D histomorphometric technique show that the LC could move either posteriorly or anteriorly after acute IOP elevation (from 10 to 30 or 45 mmHg) in six adult normal monkeys [4]. It is speculated that the anterior movement of the LC is caused by the IOP, and its posterior movement is linked to the ICP. Mechanical strains in the ONH subjected to IOP have been well characterized [5]. However, the influence of ICP is lacking and needs to be elucidated for better detection and management of glaucoma.

In this work, the influence of ICP on the biomechanical responses of the ONH was systematically investigated. Specifically, a finite element (FE) model of the ONH with anatomical details was developed to elucidate how incorporation of the ICP would alter the strain distributions in the LC and post-laminar neural tissue (PLNT).

METHODS

An axially symmetric FE model of the ONH (Figure 1) was constructed with geometric dimensions estimated from histologic sections [5]. All tissues were assumed as isotropic, linear elastic, and incompressible materials with a Poisson's ratio $\upsilon = 0.49$. The Young's modulus for each tissue was adopted from the literatures [6-8], i.e., 3 MPa for sclera, 0.03 MPa for both pre and post-laminar neural tissues, 0.3 MPa for LC, 3 MPa for pia mater, and 9 MPa for dura mater. An ICP of 12 mmHg was applied to the subarachnoid space, representing the normal ICP measured in adults [9]. An IOP of 15 mmHg was applied on the interior of the eye, i.e., pre-laminar neural tissue [10]. A constant arterial pressure of 55 mmHg was considered [11]. The ONH model was meshed using 4-node bilinear axisymmetric quadrilateral shell elements with reduced integration and hourglass control (CAX4R). A mesh convergence test was conducted and the minimum mesh size of 20 μm was chosen. The model consisted of a total of 57,757 nodes and 56,673 elements. All simulations were carried out using ABAQUS/Standard 6.13 (Simulia, Providence, RI, USA).

RESULTS

The role of ICP in ONH biomechanics was estimated by comparing cases with/out the enforcement of the ICP. The contour plots of maximum principal strain (MPS) in the LC and PLNT were compared in Figure 2. It is clear that incorporation of the ICP did not alter the strain patterns much in the LC, i.e., the peak strains were located at the regions interfacing with the central retinal artery, and gradually decreased towards the LC edges. Moreover, the ICP relieved the strains sustained by the LC. The strain distributions in the PLNT were more sensitive to the ICP. For the case without considering the ICP, the peak strains were mainly concentrated at the top region of the PLNT. After considering the ICP at a magnitude of 12 mmHg, the peak strains shifted towards the bottom region in the PLNT.

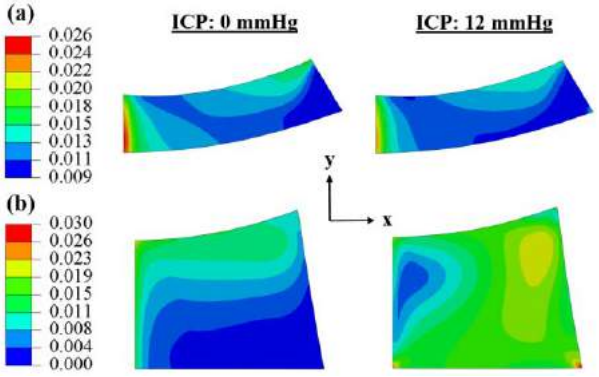

Figure 2: Contour plots of maximum principal strain in (a) lamina cribrosa and (b) post-laminar neural tissue.

The probability distributions of MPS in both LC and PLNT were further depicted in Figure 3. It is observed that the probability curves for both cases were almost overlapped in the LC. However, there was a profound right-shift for the PLNT after considering the ICP at the physiological level of 12 mmHg. For better characterization, the peak MPS was calculated as the average value in area sustained above 95% of the highest strain. After considering the ICP, the peak MPS in the LC decreased by 9.5% and the average MPS in the LC decreased by 5.7%. For PLNT, the peak MPS increased by 58.3% and the average one increased by 145.9%.

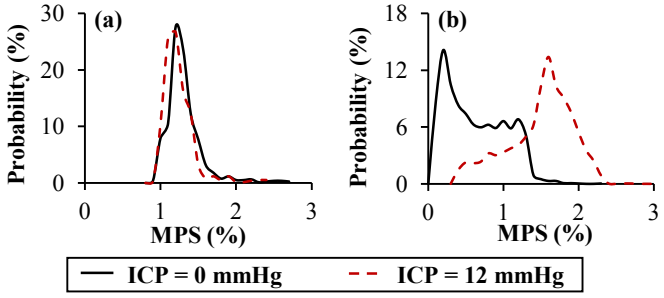

Figure 3: Probability distributions of maximum principal strain in (a) lamina cribrosa and (b) post-laminar neural tissue.

DISCUSSION

In this work, the influence of ICP on ONH biomechanics was investigated through a numerical model of the ONH. The MPS was chosen as the outcome measurement since strains have been speculated to correlate with ONH damages [12]. Our results showed that incorporation of the ICP in the retro-orbital subarachnoid space had less effect on strain distributions in the LC than those in the PLNT. The consideration of ICP altered peak strain locations in the PLNT from the upper region to the bottom region (Figure 2(b)). This could be explained by the enforcement of the ICP resulted in the deformation of the pia mater. To monitor the pia mater deformation, the x-displacement for the inner surface of the pia mater at the ICP levels of 0 and 12 mmHg was extracted (Figure 4). We found that the displacement at the top and bottom ends of the pia mater were along opposite directions. The top end displacement could be attributed to the domination of the IOP at 15 mmHg, and the bottom end displacement was most influenced by the ICP. As ICP varied from 0 to 12 mmHg, the displacement at the bottom end increased. The displacement of the pia mater would squeeze its adjacent PLNT, and has minimal impact on the LC since LC located above the pia mater.

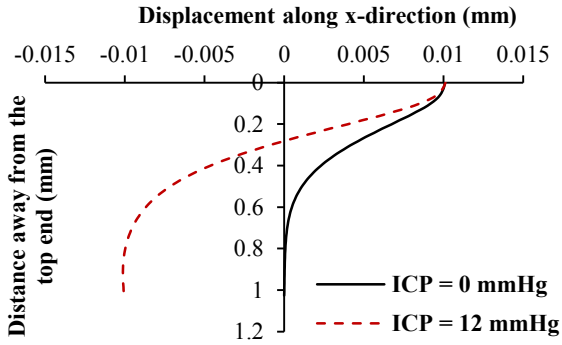

Figure 4: Displacement of the pia mater at different intracranial pressure levels.

This work could be enhanced by considering individual-specific models that could reproduce detailed anatomy of human ONH tissues. In addition, tissue properties were assumed as linear, isotropic, and homogeneous solids due to limited data in the literature. The viscoelastic nature of ocular tissues [13] will be considered in the future work through in-house characterizations.

In summary, we used numerical techniques to inspect the influence of ICP on the biomechanical responses of the ONH. Our results showed that incorporation of the ICP altered strain distributions in the PLNT, and this alternation was less in the LC. This work is clinically important since accurate characterization of the biomechanical environment within the ONH could be coupled to studies of the cellular and molecular responses to mechanical insults in glaucomatous eyes.

INTRODUCTION

The plasma membrane is segregated into lipid rafts, which are dynamic, heterogeneous regions, rich in gangliosides, cholesterol and glycosphingolipids. Lipid rafts regulate a variety of cellular processes such as protein trafficking and signal transduction [1]. Cholesterol is a major constituent of the lipid rafts and is vital in maintaining their integrity[2]. The effect of cholesterol content has been studied in a variety of cell types such as neutrophils[3], fibroblasts[4] and erythrocytes[5], among others. The impact of cholesterol on monocyte biomechanics remains understudied despite the well-established link between both cholesterol and monocytes/macrophages in atherosclerosis and other diseases. We modified the cellular cholesterol content and tested for differences in monocyte biophysical response. We altered the baseline cholesterol and studied the differences in the rolling and adhesion properties of monocytes on e-selectin, and observed significant changes in the instantaneous and short term response. As a causative agent for the observed changes, we investigated the changes in membrane lipid rift distribution and expression levels, and also changes in the membrane fluidity due to changes in the cholesterol content. We also studied the consequential distribution and expression of the receptors to e-selectin present on monocytes. Apart from this, we examined changes in cellular deformability as a possible contributing factor to the changes in the rolling and adhesion dynamics.

METHODS

Cell Culture. Primary human monocytes were isolated from buffy coat using monocyte isolation kit II by indirect magnetic labeling, and the purity of the monocytes was determined by flow cytometry using FITC-conjugated anti-CD14 antibody and a suitable isotype control. The monocytes were resuspended in RPMI 1640 with 10% FBS at required concentration depending on the assay.

Cholesterol treatment. Cholesterol depletion was performed using 10 mM Methyl-β-cyclodextrin (MβCD). For cholesterol enrichment, 0.5 mM MβCD –cholesterol complex was used with cholesterol concentration of 40mg/gm. In both cases, the cells were incubated for 30 mins. at 37° C and 5% CO_2. Cholesterol content was measured using Amplex Red Cholesterol Assay Kit, as per the manufacturer's protocol.

Fabrication of custom microfluidic platform. A silicon mold was made using standard photolithographic techniques. These silicon molds wre used as a master to make polymeric micro-channels in polydimethylsiloxane (PDMS), and final devices were assembled by bonding with clean glass slides using oxygen plasma treatment.

Lipid raft and receptor distribution and expression levels. Lipid rafts and e-selectin receptors were studied for their expression levels and distribution patterns using multispectral imaging flow cytometry.

Membrane fluidity. Membrane fluidity was assessed using pyrenedecanoic acid fluorescence intensity measurements.

Perfusion studies. For rolling and adhesion analysis, the micro-channel slide was coated with e-selectin assembled on top of an inverted microscope attached to a time-lapse digital camera A monocyte suspension was then perfused through the micro-channels using a syringe pump at a constant flow rate corresponding to a wall shear stress of 1 dyn/cm^2. Videos were captured at 20X magnification, followed by subsequent image analysis. For deformability studies, the microfluidic device was assembled on top of an inverted microscope attached to a high speed camera. We used a custom nitrogen based cell delivery system to deliver the cell suspension at a pressure of 2 psi. The videos were taken at a magnification of 20X using the proprietary software for the camera, followed by subsequent image analysis.

Statistics. All experiments were performed in triplicate, and each experiment was repeated at least thrice under independent conditions. The results are represented as mean ± SEM from one representative experiment. Statistical differences between treatments were evaluated using one way ANOVA with Tukey's post-hoc test, and significance was reported at α=0.05. * and ϕ represent

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

significance as compared to cholesterol depleted and untreated monocytes. Consistent for all experiments (unless otherwise mentioned).

RESULTS

Changes in rolling and adhesion behavior due to cholesterol content. Alteration of cellular cholesterol significantly impacted the rolling and adhesion behavior of monocytes. Cholesterol depletion led to more cells rolling on the e-selectin coated surface (Fig. 1 a). However, only a small fraction was able to convert the transient rolling into sustained adhesion, as compared to cholesterol enrichment and untreated controls (Fig. 1 b). It also led to longer pause time and shorter rolling duration in cells. Cholesterol depletion led to the cells rolling in a faster (Fig. 1 c) and more erratic fashion (Fig. 1 d). Enrichment led to antithetical effects.

Changes in membrane properties. In order to have a better understanding of the changes in the rolling behavior, we investigated changes in lipid raft expression and distribution as a consequence of cholesterol treatment. We observed that cholesterol depletion results in decreased expression and a more uniform distribution. We probed into the changes in membrane fluidity due to cholesterol treatment. Cholesterol depletion significantly enhanced the plasma membrane fluidity (Fig. 2). We also observed significant changes in the expression levels of receptors of e-selectin on monocytes (CD44 and CD15) due to cholesterol treatment.

Changes in cellular deformability. We probed the changes in cellular deformability as a function of cholesterol load and also to understand possible links with the changes in rolling and adhesion dynamics. Cholesterol depletion was observed to decrease the cellular deformability (Fig. 3).

DISCUSSION

This work establishes a link between cellular cholesterol load and biophysical response in monocytes. We observed significant changes in rolling and adhesion behavior of monocytes due to altered cholesterol loads. And as probable reasons for the observed changes in rolling and adhesion dynamics, we investigated the changes in membrane properties and cellular deformability.

Since cholesterol is responsible in maintaining the integrity of the plasma membrane, disturbance in its natural balance alters the membrane fluidity and the lipid raft distribution and expression. Consequently, the receptors on the membrane also show altered expression levels and distribution. These can greatly influence the rolling and adhesion behavior of monocytes.

There is evidence linking cellular deformability to rolling, with stiffer cells having higher velocities[6]. The changes observed in rolling can hence partly be considered as an effect of the change in deformability.

It has been shown that monocytes in circulation can be considered as suitable representatives of cholesterol loaded macrophages[7]. Hence, our results can provide the foundation for an enhanced understanding of mechanistic features of diseases like atherosclerosis.

CONTINUOUS ON-CHIP HUMAN CELL SEPARATION BASED ON CONDUCTIVITY-INDUCED DIELECTROPHORESIS WITH SELF-ASSEMBLED IONIC LIQUID ELECTRODES

INTRODUCTION

Cell separation is widely used in water analysis and diagnosis and treatment of diseases. [1, 2] Dielectrophoresis (DEP) is an attractive separation technique, which is capable to separate cells with low damage, no label, and high efficiency. [3, 4] There are various DEP devices, which can be divided into DC DEP devices and AC DEP devices, depending on the electric field used. The DC DEP devices can separate cells based on their conductivity and size. The electric gradient is generated by the patterns in the channels, and no deposition of metal electrodes is required. [5, 6] However, the DC DEP devices only can separate cells using negative DEP force, due to the lower conductivity of cells compared to the DEP buffer, which impedes the optimization of the separation. The AC DEP devices have the ability to separation cells based on the conductivity and size, as well as the permittivity and inner structures. [3, 4, 7] However, typically, the AC DEP devices need deposited metal electrodes. Moreover, even though the frequency can be adjusted, continuous positive DEP separation is also difficult to be achieved, because the positive DEP force attracts the cells towards the stronger electric field, where typically is close to the electrodes, which makes the cells attach to the electrodes. Besides, high voltage is required by the continuous DEP separation without solid electrodes. [8]

In this study, a continuous positive DEP separation is conducted using 3D self-assembled ionic liquid electrodes. The ionic liquid with higher conductivity than DEP buffer can form stable interface with the DEP buffer in the electrode regions. In addition, two types of DEP buffers with different conductivities were used to generate the electric field gradient in the electrode regions. In this study, the DEP device was used to separate live and dead PC-3 cells, and human ADSCs and MDA-MB-231 cancer cells.

METHODS

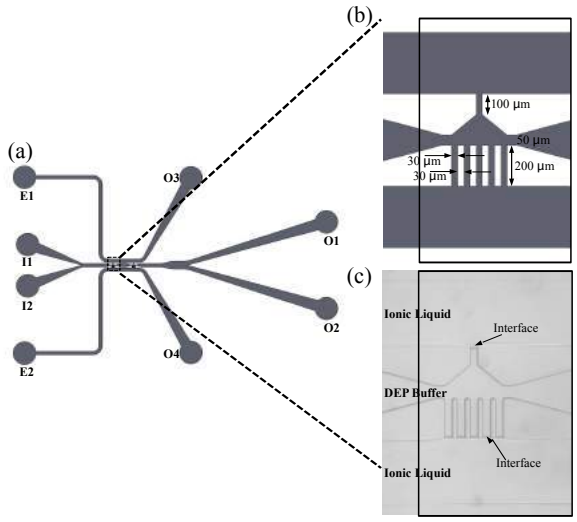

Figure 1: The structures of the DEP device and ionic liquid electrodes.

The DEP device was fabricated using the soft lithograph method and was made of PDMS. As shown in Figure 1, the modified DEP buffer (10% (w/v) sucrose, 0.3% (w/v) glucose, and 0.8% (v/v) cell culture medium in deionized water) with cells was introduced from I1 (100 μL/hr), and the original DEP buffer (10% (w/v) sucrose, 0.3% (w/v) glucose in deionized water) was introduced from I2 (400 μL/hr). The ionic liquid, [BMIM][PF_6], was used as the electrodes, and introduced from E1 and E2 (15 μL/hr). The samples after separation were collected from O1 and O2.

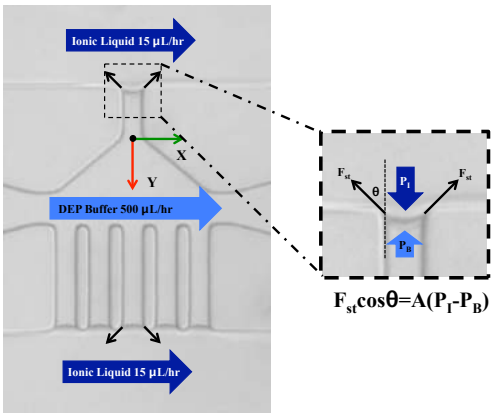

Figure 2: The formation of the stable interface between the ionic liquid electrodes and DEP buffer.

The interface between ionic liquid and DEP buffer experiences three forces: the pressure force from the ionic liquid, the pressure force from the DEP buffer, and the surface tension force (Figure 2). When three forces reach a balance, the stable interface forms.

In this study, the DEP device was used to separate live and dead PC-3 human prostate cancer cells, and human adipose-derived stem cells (ADSC) and MDA-MB-231 human breast cancer cells. Before separation, the cells were suspended in modified DEP buffer.

RESULTS

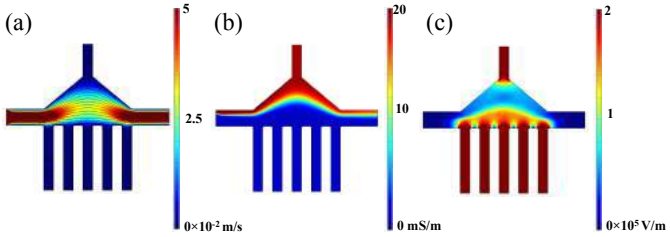

Figure 3: The simulated distributions of (a) velocity field, (b) conductivity field and (c) electric field in the electrode regions.

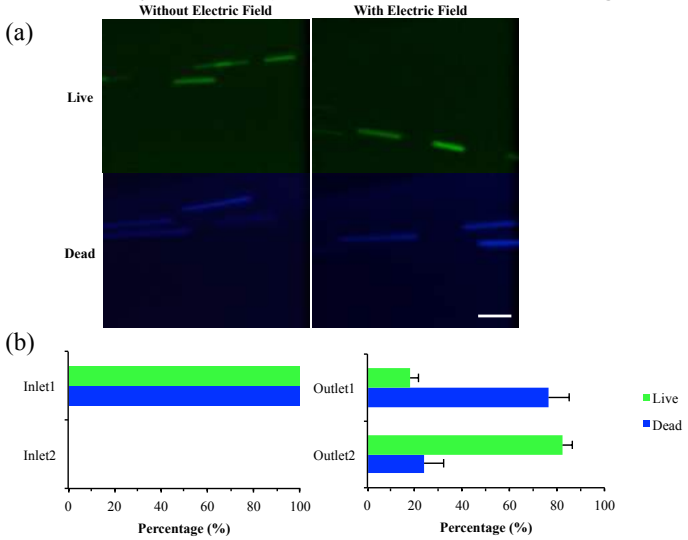

Figure 4: The separation of live and dead PC-3 cells. The error bars represent SD. Scale bar: 100 µm.

The distributions of velocity field, conductivity, and electric field were simulated using COMSOL Multiphysics (version 5.1), as shown in Figure 3. The conductivities of the modified DEP buffer and original DEP buffer are about 18 mS/m and 1 mS/m, respectively. Because the diffusion of the electrolytes between the modified DEP buffer and original DEP buffer, the gradual gradient of the conductivity is generated in the electrode regions. As a result, the gradient of electric field is induced by the gradient of the conductivity. In the frequency range used in this study, the cells experience positive DEP force, and are repelled towards the stronger electric field region.

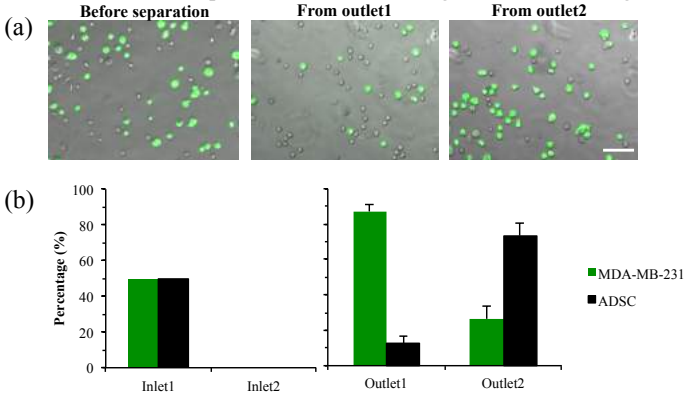

Figure 5: The separation of ADSC and MDA-MB-231 cells. The error bars represent SD. Scale bar: 100 µm.

As shown in Figure 4, the separation of live (green fluorescence) and dead (blue fluorescence) PC-3 cells was conducted. The live cells experience strong positive DEP force (83% deflected), and are defected more than the dead cells (23% deflected), when 150 Vpp at 100 kHz is applied to the electrodes. The separation of ADSC (green fluorescence) and MDA-MB-231 cells was also achieved (Figure 5). The ADSC experience stronger positive DEP force, and the purity of ADSC in the collection is about 74% and the purity of MDA-MB-231 is about 88%, when 75 Vpp at 50 kHz was applied to the electrodes.

DISCUSSION

In the separation of live and dead PC-3 cells, compared to the dead cells, the live cells have a lower conductivity and a higher permittivity of the membrane, and a higher conductivity of the cytoplasm, which lead to a stronger positive DEP response of the live cells than the dead cells. [9, 10] In the separation of ADSC and MDA-MB-231 cells, the ADSC, which are stem cells, have different electric properties from the cancer cells, MDA-MB-231. [4, 11] Moreover, the average size of the ADSC is larger than that of the MDA-MB-231 cells. Therefore, the DEP response of the ADSC is different from that of MDA-MB-231 cells.

INTRODUCTION

Endovascular coil embolization is the most popular minimally invasive treatment option for treating intracranial aneurysms (IAs). Despite the wide adoption of this treatment, up to 30% of cases experience poor outcome. Since coils induce thrombotic occlusion by modifying aneurysmal hemodynamics, treatment outcome was thought to depend on these blood flow modifications. Treatment simulations prior to actual treatments could help identify possible outcomes for patient-specific aneurysms. However such simulations require accurate and efficient model for simulating coil deployment. We present a novel algorithm that utilizes a coil's tendency to restore its pre-shaped geometry to simulate deployment of coils inside IAs. We represent a coil as a set of discrete ordered points that seek to assume its reference positions, based on geometric constraints that are modelled as spring forces. We validated this algorithm by comparing simulation results against physical experiments of coil deployment and found excellent agreement. In the future, this method, combined with CFD, could be used in a real-time clinical setting to assess the potential hemodynamic impact of coil embolization prior to treatment.

METHODS

We model the mechanics of the coil points as a discrete, pseudo-structural system based on the equation of motion. The dynamics of the system is simplified, we assume coil deployments to be a quasi-static process, and the damping constant is equal to 1. We use finite differencing to discretize the equation of motion:

$$p^{k+1} = p^k + (F_e - F_i) \quad (1)$$

where p is the position coil point.

In general, the progression of coil points inside an IA geometry can be interpreted as the interaction difference between the sum of all the internal forces (F_i) and the external force (F_e) acting on the coil nodes when the coil is fully deployed. The internal forces are modeled using spring forces, which drive the motion of points seeking to restore the pre-shape, whereas the restriction due to the collision with the IA vessel wall and other coils is modeled by the external force.

As input to our algorithm, we used previously-derived 3D parametric equations to describe the centerline of a pre-shaped, tubular, coil geometry with a fixed length [1]. We discretized this coil centerline from end-to-end with a set of equidistant, ordered points.

Internal Forces To ensure that the final deployed coil geometry resembles the manufacturer's specifications of coil shape, size, and length, we imposed three geometric constraints which the coil points were required to adhere to during deployment. $\boldsymbol{f_{restore}}$, $\boldsymbol{f_{length}}$, and $\boldsymbol{f_{smooth}}$. The rationale for these geometric constraints is described as follows:

1. **"Free" state configuration:** When deployed released from the catheter inside an IA sac, coils attempt to recapture recover their pre-shaped configuration. This behavior is imposed by a restoration force, or $\boldsymbol{f_{restore}}$. In our algorithm, the user defined pre- shaped input coil geometry serves as the resting configuration of the coil.

   $$\boldsymbol{f_{restore}} = k_{restore}(r_i - \boldsymbol{p_i}^{\boldsymbol{k+1}}) \quad (2)$$

   Here, r_i is the coil point's position in the reference configuration, p_i is the point's current position, and $k_{restore}$ is the stiffness constant of the spring which connects the current coil point to its reference position in the "free" state geometry, which is computed as:

   $$k_{restore} = \frac{AE}{r_i} \quad (3)$$

   Here, A is the circular cross-sectional area of the coil and E is the Young's modulus of the spring. For the purposes of testing our

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

algorithm, we chose E to be 0.5 N/m^2 for each spring, as defined previously [2].

2. **Coil length:** The total length of the virtual coil should not deviate from its actual physical length. This is imposed by a spring along the length of the coil. The stiffness of each spring, $\boldsymbol{k_{length}}$, is defined to be inversely proportional to the distance between the two points it connected as follows:

$$\boldsymbol{f}_{length} = \begin{cases} -k_{length}(p_i - p_{i-1}), & \Delta l > \epsilon \\ k_{length}(p_i - p_{i-1}), & \Delta l < \epsilon \end{cases} \quad (4)$$

where,

$$\Delta l = p_i - p_{i-1} \quad (5)$$

Here, Δl is the Euclidean distance between two points in the current coil configuration.

3. **Coil bending:** To not produce any unrealistic final coil configuration which is unphysical a smoothing force is applied. This constraint is imposed by a smoothing force, $\boldsymbol{f_{smooth}}$, which is implemented by moving averages.

Together, these three constraints are imposed as internal forces onto all coil points to drive its deployment. The combined internal force is denoted by Thus the sum of all internal forces F_i becomes:

$$F_i = (\boldsymbol{f_{length}} + \boldsymbol{f_{length}} + \boldsymbol{f_{smooth}}) \quad (6)$$

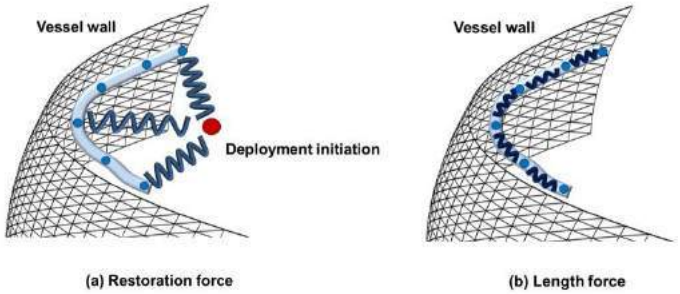

FIGURE 1: ILLUSTRATION OF INTERNAL SPRING FORCES USED IN OUR ALGORITHM.

External Forces During coil deployment, the patient-specific IA sac and the coils themselves act as external restrictions to the above-mentioned internal forces. To models these external force, coil points are deployed until they encountered the IA wall and/or other coil points, which act as external force.

Thus, the evolution of coil points is described by:

$$p^{k+1} = p^k + (\boldsymbol{F_e} - \boldsymbol{f}_{restore}(p^k) - \boldsymbol{f}_{length}(p^k) - \boldsymbol{f}_{smooth}(p^k)), \quad (7)$$

Where p^{k+1} describes the position of p node in the $k+1$ iteration. This equation is iterated across the coil mesh until the RHS of Equation (7) becomes equal to LHS.

RESULTS

We applied our algorithm to simulating coil deployment in internal carotid artery (ICA) sidewall patient-specific aneurysm geometry. To test our method, the aneurysm model was virtually coiled with 1-8 coils deployed sequentially to achieve 3.8%-29% packing density (PD, defined as the percentage of space occupied by coils in an IA). At 8 coils the IA approaches 30% which is the clinical goal. The entire simulation required 67-74 sec to deploy each coil, running on our workstation.

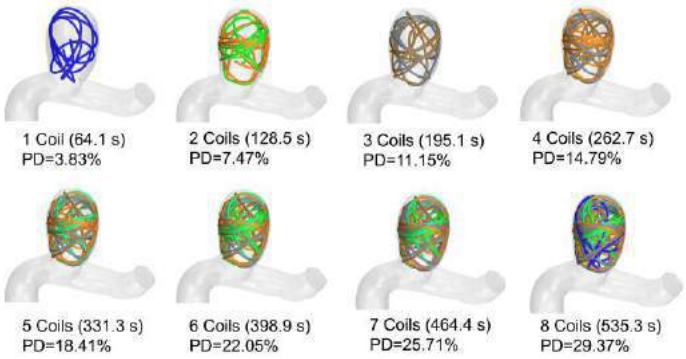

FIGURE 1: VIRTUAL COIL DEPLOYMENT IN A PATIENT SPECIFIC ANEURYSM USING OUR ALGORITHM.

In Vitro Validation: In a series of *in vitro* experiments we deployed a real 5 mm x 15 cm complex-shaped coil (Axium™ Detachable Coil, Medtronic, Dublin, Ireland) into an optically-transparent 8 mm x 8 mm x 3 mm hexahedron phantom. The deployments demonstrated that the simulated (Figure 2B) and experimentally deployed coils (Figure 2A) shared three key features. In both groups, the corners of the hexahedron geometry remained void of any coils, the center of the geometry contained a mass of coils, and the coils made large loops opposing to the walls of the models.

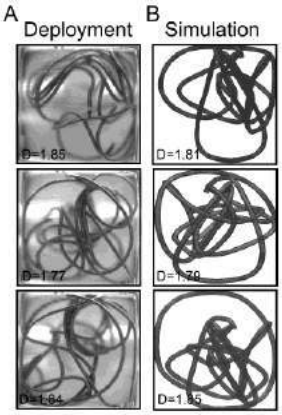

FIGURE 2: COMPARISON OF SIMULATED AND IN VITRO COIL DEPLOYMENTS IN PATIENT SPECIFIC ANEURYSM.

CONCLUSION

We developed a novel algorithm for virtually deploying endovascular coils in patient-specific aneurysms using a spring-based geometric constraint model.. Our validation studies demonstrate that this computational method closely matches with coils deployed experimentally *in vitro*. The accuracy and efficiency of our technique highlights its potential for implementation into a real-time clinical setting as a tool to investigate specific coil treatments prior to actual IA intervention.

INTRODUCTION

More than 65% of all adults over 60 years of age are affected by spinal deformity [1]. These deformities are most common in the thoracic region of the spine and can result in pain, poor balance, and reduced spinal mobility, the most common biomechanical measure presented in cadaveric and *in vivo* studies [2]. Corrective surgeries utilizing multilevel fusion systems are often recommended to alleviate patients' symptoms and regain spinal function.

In order to retain the most spinal mobility, the benefit of maximizing the number of unfused motion segments in the spine has been recognized [3]. However, it is difficult to quantify how much each individual motion unit contributes to *in vivo* spinal mobility because motion data is typically presented in segments comprised of multiple individual motion units due to anatomical constraints. These constraints are not present in cadaveric mobility studies resulting in the ability to present spinal mobility in terms of individual motion units [4], [5]. This inconsistency makes it difficult to compare data between these two models. The ability to compare cadaveric and *in vivo* motion is extremely beneficial for the clinical community because it allows for improved surgical planning.

The objective of this study is to develop a method that allows researchers to investigate the contribution of individual motion units to *in vivo* motion and frame it in a way that is more meaningful to surgeons. This method will allow for the comparison of individual thoracic and lumbar motion units in different physiological models and will be validated by comparing the calculated motion to different spinal mobility studies presented in the literature. With this new methodology, differences in percent contribution of individual motion units in various bending tasks and differences based on their location in the spine can both be investigated. The impact that individual motion units have on spinal mobility may aid clinicians in critical surgical planning decisions when using multilevel fusion systems.

METHODS

Spinal range of motion (ROM) in eighteen older adults, 70.0 ± 8.3 years (55-81 years), was measured using a TrakSTAR electromagnetic motion monitoring system (Ascension Technologies, Burlington, VT, USA) with sensors placed at the manubrium, at the spinous processes of T1, T3, T6, T10, L1, L3, and at the sacrum. After completing ten iterations of three trunk stretches, subjects performed a series of six bending tasks starting from a defined neutral standing position going to each subject's voluntary maximally bent position: flexion, extension, right and left lateral bending, right and left 45° anterior-lateral flexion. The order of the bending tasks was randomized for each subject and each task was repeated for five consecutive trials. Tasks with at least three acceptable trials were approved for analysis and the last acceptable trial was used for analysis.

Mean angular ROM was calculated for five segments: upper thoracic (T1-T3), middle thoracic (T3-T6), lower thoracic (T6-T10), thoracolumbar (T10-L1), and upper lumbar (L1-L3). Normalized ROM (nROM) was calculated by dividing the segmental ROM by the number of motion units in each segment. Percent contribution ROM (%ROM) was calculated by dividing each nROM value by the total ROM from T1-L3. Both nROM and %ROM represent the average motion and contribution of a single motion unit within a given segment, respectively. The first set of comparisons investigated the %ROM for all six bending tasks in a single normalized segment. The second set of comparisons investigated the %ROM for all five normalized segments in a single bending task. ANOVAs ($\alpha = 0.05$) were used followed by a Tukey-Kramer post hoc test to determine which combinations had significance.

All participants signed consent forms and this study was approved by the Institutional Review Board at the University of Kansas.

RESULTS

The nROM values calculated in this study were compared to *in vivo* and cadaveric studies found in literature. One *in vivo* study defined segments at different vertebrae than the current study [5]. To assess data for each motion unit, the same normalization methods were implemented on the data from this previous study. Another *in vivo* study used a Spinal Mouse system to measure ROM for each motion unit [6]. The motion unit data from all three studies indicated that ROM remains relatively constant through the thoracic spine and that there is a significant increase in ROM in the lumbar spine. The same trends were also present in cadaveric thoracolumbar mobility studies [4].

Based on the ANOVA results from the first set of comparisons, the percent contribution for all normalized spinal segments remained consistent, regardless of the bending task (Figure 1). The only significant difference in %ROM for a segment across bending modes was an increase in middle thoracic segment %ROM between right lateral bending and extension ($p < 0.01$).

Based on the ANOVA results from the second set of comparisons, the percent contribution of each sub-segmental region within a single bending mode was seen as consistent across the thoracic spine. The %ROM in the upper thoracic, middle thoracic, lower thoracic, and thoracolumbar segments were all statistically similar in flexion, extension, right lateral bending, and right and left 45° anterior-lateral flexion. However, for each given bending task, the upper lumbar %ROM was significantly greater than the %ROM in every other segment ($p < 0.02$).

DISCUSSION

Individual motion units are difficult to measure using traditional *in vivo* spinal mobility methods due to limited space between spinous processes and limitations in the resolution of external measures of the spine. This study developed a method to investigate the contribution of representative motion units within spinal segments during *in vivo* bending tasks.

The results from the first ANOVA set indicated motion contributed by a representative motion unit is independent of the bending task being performed. The second ANOVA set indicated the motion contributed by a representative upper lumbar motion unit is larger than its superior units and is also independent of the bending task being performed. The large nROM from the upper lumbar segment is supported by previous studies, signifying that the majority of total thoracolumbar spinal mobility originates in the lumbar spine. While results from this study indicate thoracic segments do not contribute as much to total thoracolumbar motion as lumbar segments, the upper, middle, and lower thoracic segments each contribute nearly 10% to overall trunk motion.

As with all *in vivo* data collected using motion sensors, soft-tissue artifact of the skin's movement over the spinous process during bending cannot be avoided. However, this artifact is less in the spine than in other areas of the body due to the firm attachment of the fascia to the spinous processes [7]. Limitations in analysis methods to transform position data into angular ROM prevented the ability to calculate ROM for the lower lumbar segment, L3-sacrum. Additionally, the developed method assumes that the contribution across a segment is equal for each motion unit.

The method presented is beneficial because it allows for an improved comparison of spinal mobility between different physiological models. It also provides surgeons with specific biomechanical information regarding the movement of motion units in the living spine. This information may become an important surgical tool for the planning of where spinal fusion constructs begin and end for patients with adult deformities. Understanding how much each motion unit contributes in a living spine can only help to better inform surgeons and spinal device designers.

CONFORMAL NANOENCAPSULATION OF ALLOGENEIC T CELLS MITIGATE GRAFT-VERSUS-HOST DISEASE BUT RETAIN GRAFT-VERSUS-LEUKEMIA ACTIVITY

INTRODUCTION

Due to a graft-versus-leukemia (GVL) effect, allogeneic hematopoietic stem cell transplantation (HSCT) is an effective adoptive immunotherapy with cure potential. However, GVL is typically accompanied with graft-versus-host disease (GVHD), one of major complications of allogeneic HSCT that can lead to patient death [1]. GVHD can be divided into acute GVHD (aGVHD) and chronic GVHD (cGVHD). aGVHD occurs within 100 days of transplantation and aGVHD generally affects the skin, liver and intestinal tract of patients, leading to severe complications.

Activation of donor T cells and recipient antigen-presenting cells (APCs) plays critical roles in the aGVHD initiation [2]. Activation of APCs occurs in the first phase of pathophysiology of aGVHD, in which tissue damage is induced by chemotherapy preceding HSCT. Recently studies indicated that prior to HSCT, irradiation and/or chemotherapy damage the epithelia that line the mucosal barriers of skin and gastrointestinal tract. Disrupted barrier function leads to translocation of commensal microbiotas present on the skin and in the gastrointestinal tract, which fuels continuous activation of innate immune cells, creating and maintaining an inflammatory milieu permissive for subsequent activation of deleterious adaptive immunity. This allows microbial products, such as lipopolysaccharide, to translocate to the circulation, which stimulates the secretion of pro-inflammatory cytokines, such as interleukin (IL)-1 and tumor-necrosis factor (TNF). These pro-inflammatory cytokines stimulate the activation of host APCs, and then host APCs present antigens via MHC class II to CD4 T cells, resulting in activation, proliferation, and differentiation of donor T cells. Additionally, donor CD8+ T cells are also potent for inducing aGVHD. Donor CD8+ T cells preferentially damage recipient medullary thymic epithelial cells and impair negative selection, resulting in production of autoreactive CD4+ T cells that perpetuated damage to the thymus and augmented the development of aGVHD. Therefore, blockade of donor T cell activation is a common approach to suppress or prevent aGVHD.

While there are no reports regarding use of encapsulation in the setting of GVHD, this technology is promising in other applications through encapsulating grafted cells, islets, and tissue in biomaterials. Biocompatible biomaterials are used to form a micro or nano-scale semi-permeable membrane that conformally cover cells, allowing free transportation of oxygen, nutrients, and metabolic wastes, while limiting direct contact between grafted cells and host cells including immune cells [3]. Specifically, nanomaterial encapsulation via layer-by-layer deposition of cationic and anionic biomaterials is attractive because it can generate a multi-layer membrane on the surface of cells that potentially block direct contact between host antigen-presenting cells (APCs) and donor T cells in the setting of allogeneic transplantation with no change of the size, which may prevent the activation of donor T cells and in turn to reduce GVHD severity.

METHODS

In this study, we designed a layer-by-layer nano scale-coating on T cells. The cationic chitosan was deposited on the negatively charged cell membrane, forming a uniform nano-scale layer. Subsequently, negatively charged alginate was then coated on chitosan layer based on electrostatic deposition. Overall, the coating repeats one time, to achieve a four-layer coating on the surface of T cells. To assess successful coating, alginate labeled with fluoresceinamine was used to show the deposition of layer-by-layer coating and encapsulated cells showed strong green fluorescence on the surface. In addition, scanning electron microscope (SEM) was utilized to further visualize the cell morphology before and after encapsulation. There were many microvillies on the surface of non- encapsulated T cell, while the surface of encapsulated T cell became relatively smooth with porous structure.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The encapsulation efficiency was further evaluated by the population of fluoresceinamine-FITC-positive cells assessed by flow cytometry, indicating that 85.7% cells were encapsulated. Since the cationic and anionic polysaccharides could alter the surface charges, we also measured the cell surface zeta potential during the coating process. The zeta potential was about -19.5 mV before coating, while after first chitosan layer, the zeta potential shifted to -0.3 mV, indicating the successful deposition of cationic chitosan on the cell membrane. The following coating step of alginate on chitosan layer gave the overall surface zeta potential back to -24.6 mV. Then the third layer of chitosan and the fourth layer of alginate changed the zeta potential to 27.4 mV and -26.9 mV, respectively.

After the encapsulation, donor T cells were characterized in vitro, and their ability to inhibit GVHD and retain GVL was determined in vivo after being transplanted together with non-encapsulated donor bone marrow (BM) cells in a C57BL/6 → BALB/c HSCT mouse model.

RESULTS

After encapsulation, we investigated T cell proliferation in vitro by observing the growth curves after 48 h, 72 h, 96 h, and 120 h culture, and the results showed the similar proliferation rate between control and encapsulated T cells. In addition, we tested the ability of those encapsulated cells binding to CD3, a typical T cell marker, and we found that there is no evident difference before and after encapsulation.

To examine the cytotoxicity of encapsulated T cells against tumor cells, effector encapsulated T cells were induced under the stimulation of CD3-CD28 beads and were incubated with A20 or P815 tumor cells. Encapsulated T cells were able to lyse A20 and P815 tumor cells. No significant difference was observed between encapsulated T cells and non-encapsulated T cells. IL-2 secretion was moderately decreased at 48 hours after stimulation with CD3-CD28 beads, but no significant difference was observed at 96 hrs, indicating the coating was gradually degraded over time.

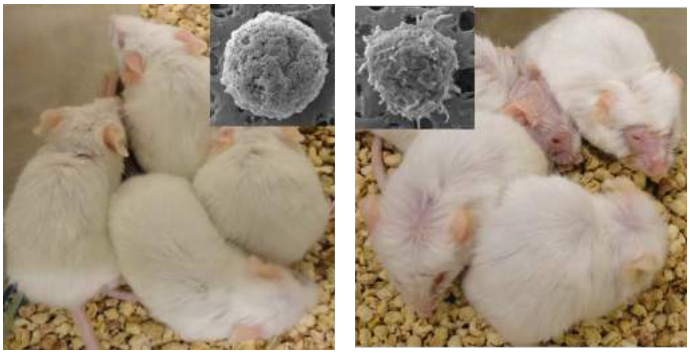

Figure 1: SEM images showing donor T cell after encapsulation has a smooth and porous surface (left inset) when comparing with non-coated one with microvilli (right inset). After transplantation, mice injected with encapsulated T cells have significantly less hair loss, weight loss and eye infection due to GVHD (left) than those injected with non-encapsulated ones (right).

To evaluate the potential of this encapsulation reducing GVHD, we transplanted encapsulated donor T cells into recipient mice. Compared to mice transplanted with allogeneic encapsulated T cells, the mice transplanted with control (non-encapsulated) cells developed more severe GVHD characterized by weight loss, hunching, reduced activity, ruffled fur and fur lost, and diarrhea. From day 21 to day 50, the clinical symptom scores of mice transplanted with encapsulated T cell group were significantly lower than those of mice in the non-encapsulated T cell group. Transplantation with encapsulated T cell significantly prolonged the survival of mice when compared with control donor T cells. A lymphoma A20 model were used to compare GVL effects of encapsulated and non-encapsulated T cells. Obvious tumor growth was observed in the mice engrafted with tumor cells alone 2 weeks post transplantation, while no tumor cells grew in the mice engrafted with BM cells together with either encapsulated T cells or non- encapsulated T cells throughout the 70-day observation period, demonstrating that the GVL effect of encapsulated T cells was not compromised. Consistent with these data, flow cytometric analyses indicated that there was no evidence of lymphoma in the spleen tissue in mice engrafted with encapsulated T cells or non-encapsulated T cell mice together with BM, but a tumor population were detected in mice transplanted with BM alone. In this model with both GVL and GVHD, transplantation with encapsulated T cell significantly prolonged the animal survival (63% at day 70, p = 0 .05 compared with T cell controls).

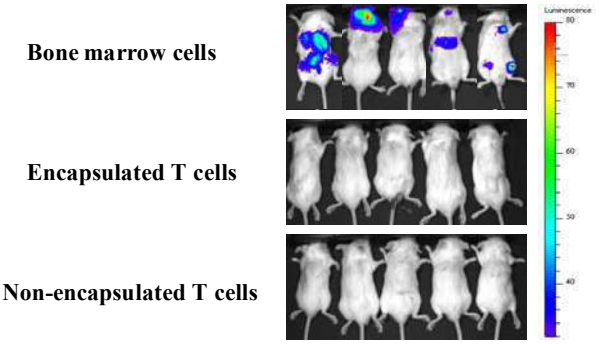

Figure 2: GVL activity was detected by biolumniscence imaging. Both encapsulated and non-encapsulated T cells treated mice had no evidence of lymphoma throughout the 70-day observation period, comparing with mice injected with bone marrow cells only.

DISCUSSION

In this study, we firstly adopted a nanomaterial encapsulation technology using chitosan and alginate to form multilayer semi-permeable membrane on the surface of T cells, which could contribute to the similar proliferation, secretion and cytotoxicity in vitro after encapsulation, which suggest that the function of T cell do not change after encapsulation. In addition, Encapsulated T cells reduce GVHD severity and prolong survival of mice with GVHD and retains the GVL activity of T cells. Therefore, we believe that the nano-encapsulated T cell in chitosan and alginate could attenuate GVHD through reducing the direct contact between donor T cells and host APCs, leading to inhibition of T cell activation by host APCs. These results indicated that nano-scale biomaterials could be used to encapsulate transplant cells aiming to reduce immune response while no significant increase of the size of cell itself.

INTRODUCTION

To treat deep seated brain lesions, a current neuroendoscopy procedure typically inserts rigid tubular retractors into patient's brain to create clear passages. Although most literature reported positive results with the tubular retractor systems, such devices still have two inherent drawbacks. Firstly, because of the rigidity and relative large size of such retractors, they pose potential risks to surrounding healthy brain tissue. White matter damage along the surgical trajectory[1] and cytotoxic edema and cellular damage[2] have all been reported. Secondly, the long and thin cylindrical corridor created by the rigid retractor obstructs endoscope and surgical knife's movements.

In light of existing inadequacies, we propose a novel self-expandable retractor system that not only minimizes tissue injury but also improves surgery capacity. Inspired by self-expanding stent graft concepts[3], the retractor is made of Z-shaped Nitinol (NiTi) rings and a layer of Dacron fabric. As illustrated in Fig.1, the retractor would be first compressed and confined in a rigid outer sheath, and then inserted into the brain as its dilator penetrates. When inside the brain, the outer sheath would be extracted, deploying the retractor and allowing it to expand. Once the retractor fully self-expands to a desirable diameter, the dilator is also extracted, creating a clear corridor to the lesion site.

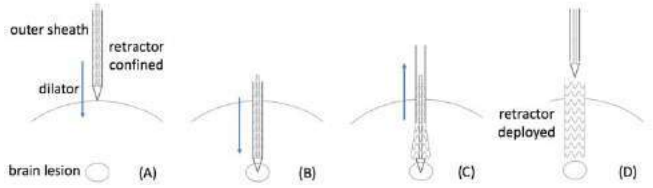

Figure 1 – Schematic drawing of self-expandable retractor deployment into brain tissue

The main objective of this paper is to find a functional design capable of self-expanding to a desired diameter when inside brain tissue.

METHODS

To develop such a self-expandable retractor, computational models have been made in ABAQUS/Explicit and finite element analysis has been conducted to study its mechanical behaviors and deployment inside brain tissue phantom. Then, based on the results of numerical design, prototypes have been made and experiments have been conducted to deploy the retractor in porcine brain *in vitro*.

In the finite element model, as an initial design, the self-expandable retractor has original diameter of 18mm and length of 30mm. It composes of 2 Z-shaped NiTi rings and a layer of Dacron fabric. It would be crimped and confined into an outer sheath of diameter 7mm before deployment. After being deployed inside brain tissue, it aims to self-expand to a minimum diameter of 16mm. The geometry of NiTi ring is first written in a Python script and imported into ABAQUS. Dacron fabric is fixed to NiTi rings using tie constraints. Rings with different geometries are modelled and flat plat compression tests are conducted to analyze their stiffness in order to find a functional design. Then, Coupled Eulerian Lagrangian method is used to model deployment of self-expandable retractor in brain tissue phantom, with brain tissue as Eulerian and retractor as Lagrangian. General contact is used in this model, frictions between parts are assumed to have coefficient of 0.1. Material properties for NiTi, Dacron and brain tissue are all taken from literature.

Based on our computational model, prototypes have been made using NiTi wires and Dacron fabrics. A set of jigs are custom made in order to heat treat NiTi wires to form the rings. The two free ends of the wire are connected using a thin stainless steel tube. Flat plate compression tests are also conducted experimentally. NiTi rings are

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

then stitched onto Dacron fabrics to form the retractors. A set of delivery device is also designed and 3D printed (Fig.2). To prepare for an experimental deployment of the retractor, porcine brains are obtained 6 hours post mortem and placed in a small container with open top. The retractor is then deployed and X-Ray images are taken.

Figure 2 - (left) A sample NiTi ring, (middle) some sample retractors and (right) a set of delivery device.

RESULTS

The deployment of retractor in brain tissue phantom is illustrated in Fig.3. Contour of strains on brain tissue is also shown. With an original diameter of 18mm, the retractor self-expands to a diameter of 15.9mm at the end of simulation. Current design features two rings with diameters of 18mm, heights of 12mm, wire diameters of 0.28mm and 5 crowns. Dacron fabric has thickness of 0.1mm. The retractor is 30mm in length, with 2mm space between each ring and 1mm at each end.

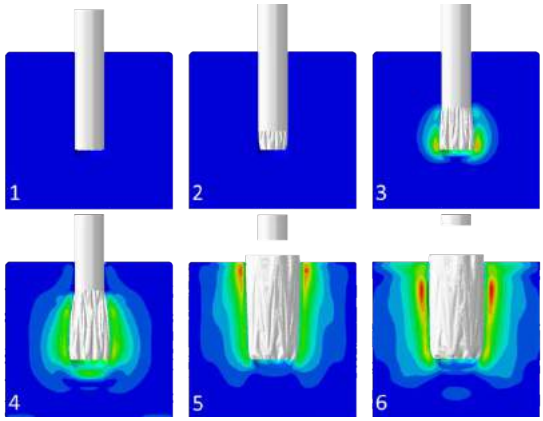

Figure 3 - FE simulation of a self-expandable retractor being deployed in brain tissue phantom.

Prototype with same parameters as the above mentioned numerical design is made and deployed into porcine brain *in vitro*. As revealed in the X-Ray image, the retractor self expands to a diameter of 16.2mm after deployment, which agrees well with the computational model.

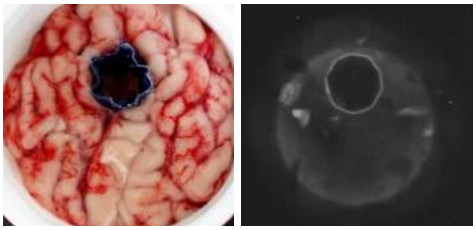

Figure 4 – (left) Experimental deployment in porcine brain *in vitro.* (right) X-Ray image of a deployed retractor

In both numerical analysis and experimental study, the current design proves to be functional as it successfully self-expands to desired diameter after deployment and creates a viable corridor for subsequent neuroendoscopy surgery. The concept of this novel retractor has been proved.

Flat plate compression test results further prove that the agreement in numerical and experimental deployments is not a coincidence. As shown in Fig.5, for NiTi rings with different geometries, experimental and numerical force vs compression distance results agree well.

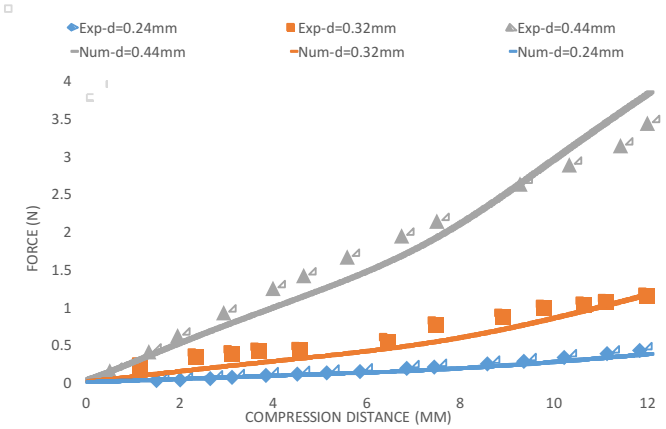

Figure 5 –Experimental and numerical results of flat plate compression of NiTi rings with different geometries.

DISCUSSION

A novel self-expandable retractor to assist treating deep brain lesion during neuroendoscopy has been presented. A coupled Eulerian Lagrangian model has been made and finite element analyses have been conducted to investigate interactions between brain tissue and surgical tools. The model is capable of simulating extreme deformations and thus is a sufficient tool to further develop this retractor. Prototypes of proposed retractor have also been made. The mechanical behaviours of the retractor in numerical and experimental analysis agree well. The concept of this novel self-expandable retractor has been proved.

However, the design of this novel retractor is still at its early stage. Current design is functional, but yet optimal. This study focused on mechanical behaviours of the retractor so that it is capable of self expanding to a desired diameter. The brain tissue is treated as a continuum solid at the moment. Though the computational model is capable of outputting stress/strain inside the phantom, it is unable to predict how much injury might occur in brain tissue.

Future work on this novel retractor will be dedicated to finding an optimal design that further minimizes brain tissue injury. More retractor designs will be explored, with different geometries and cover layer material choices. Biased stiffness[4] of NiTi rings will be considered so that the outward force acting on brain tissue is reduced, while the retractor is still capable of expanding to target diameter. Furthermore, an injury criteria of brain tissue will be added so that the finite element model becomes a comprehensive tool for designing, modelling, evaluating, and improving this novel retractor.

ELECTROMECHANICAL COUPLING BEHAVIOR OF AXON MICROTUBULES

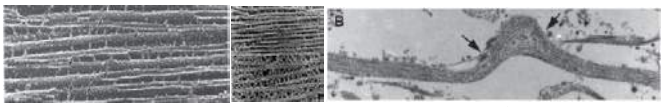
INTRODUCTION

The axon is composed of both long and short Microtubules (MTs), the largest and stiffest component of the axon that form the internal cytoskeleton, and allow the axon to stretch in response to tensile and/or compressive strains. These MTs can be stretched and shrunk through regulation of tau proteins. Tau proteins are the connective parts that bind the MTs in the axon using an electrostatic zipper bond as shown in Figure 1. [1]



(a) (b)

Figure 1: (a) Electron microscopy image of porcine brain MTs with tau protein connections [1] (b) Experimental results for injury of cultured 2-mm-long axons [1,2]

Specifically, the proline-rich region of a tau protein forms this bond with the negatively charged N-terminus of another tau protein. Because of their viscoelastic behavior, tau proteins dynamically bind and unbind with each other when exposed to a tensile strain. Inside of the axon is a gel-like fluid called axoplasm, composed of molecules that conduct electrical neural impulses. This conductive fluidic substance has an electrical resistance that can affect the travel rate of any applied electric field across the axon. Recent numerical studies developed a computational model of MTs to examine a rate-dependent behavior of the MTs relative to their dynamic interactions and the tau protein under different strains as well as strain rates. In a study conducted by Ahmadzadeh et al. [1], the breaking of the tau connections and microtubules during axonal stretch injury was examined using a COMSOL model. Tau proteins act as an electrostatic zipper bond, which can reform after breaking. The proportion of free to connected tau proteins in strain-rate dependent breaking was analyzed to determine the effects of fast loading on the permanence of axonal deformation. It was observed that fast loading rates contributed to the breaking of tau proteins observed in traumatic brain injury, and the rupturing of microtubules that deforms the axon. Dynamic strain rates of 1-50 sec^{-1} damaged the axon at very small strains. [3] This study proposes that by applying an electric field to the Axon, when tau connections are fully disconnected, the axoplasm fluid will be stiffer, thereby the damaged axon as well as disconnected tau connections can be reformed faster. This process is behaving like a cast in order to hold the broken tau connection which would make the process of improving the axon, MTs and their connections faster.

METHODS

Using a localized model, we performed unit cell simulations, where a unit-cell contains three microtubules connected with two tau proteins. When an electric field is applied to a specific region across an axon, a bulk fluid motion is observed. In this case, the velocity of this motion is linearly proportional to the intensity of the applied electric field and it is dependent on both the material used to construct the axon as well as the solution in contact with the channel wall. This flow in the channel is called an Electroosmotic Flow. The simulated model and the geometry used in this study are depicted in Figure 2 in order for better understanding on what is going on the present study.

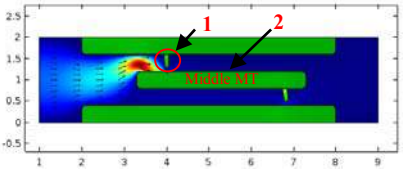


Figure 2: Geometry and simulation of the model, (1) the Upper tau connection (2) Middle short microtubule

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

While Ahmadzadeh et. al. [1], only focused on strain rate and therefore only required a mechanical model, we created a very first fluid structure interaction model of axon including MTs as well as tau connections and introduced the axoplasm as a fluid into the axon channel. First, by applying a velocity profile induced flow as an inlet, we measured flow and VonMises stress applied to the MTs without any applied electric field. The fluid flow is described by the incompressible Navier-Stokes equations for the velocity field, where $\mathbf{u} = (u, v)$, $\mathbf{u}_m = (u_m, v_m)$, and the pressure, p, in the spatial (deformed) moving coordinate system is stated in equations (1) and (2), respectively.

$$\rho\frac{\partial \mathbf{u}}{\partial t} - \nabla.[-p\mathbf{I} + \eta(\nabla\mathbf{u} + (\nabla\boldsymbol{u})^T)] + \rho\big((\mathbf{u} - \mathbf{u}_m).\nabla\big)\mathbf{u} = \mathbf{F} \quad (1)$$

$$-\nabla \cdot \mathbf{u} = 0 \quad (2)$$

Where, $\mathbf{I}$ denote the unit diagonal matrix and $\mathbf{F}$ is the volume force affecting the CSF flow. It is assumed that there is no gravitation or other volume forces affect the axoplasm, so that $\mathbf{F} = 0$.

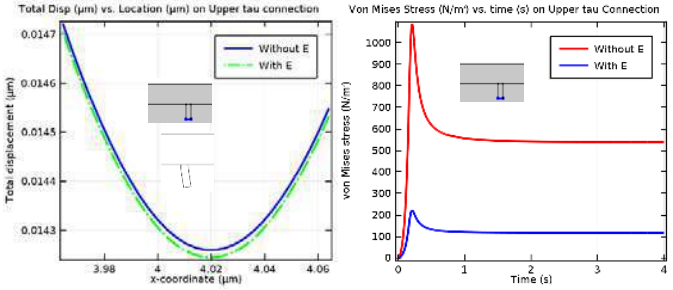
At the channel entrance on the left, the flow has fully developed laminar characteristics with a parabolic velocity profile but its amplitude changes with time. At first, flow increases rapidly, reaching its peak value at 0.215s; thereafter it gradually decreases to a steady-state value of 0.01cm/s as depicted in Figures 4 and 6. The velocity in the x direction, u_{in} with the steady-state amplitude U comes from the equation (3);

$$\boldsymbol{u}_{in} = \frac{U.t^2}{\sqrt{(0.04-t^2)^2+(0.1t)^2}} \quad (3)$$

Where, t is the time expressed in seconds and U is the mean velocity at steady state and is equal to 1[cm/s] due to a very small movement of the axoplasm in Axon. [2] Afterwards, we applied both electric field and the velocity profile induced flow as an inlet. An electroosmotic induced flow was simulated by using COMSOL Muliphysics 5.2 (Palo Alto, CA 94304 USA) Software. Therefore, a very first novel steady state electro-Fluid-Solid-Interaction (eFSI) numerical analysis performed in order to investigate the effects of the applied electric field on the axoplasm fluid and thereby the stress as well as FSI interactions between MTs and the tau connections. The geometry is meshed using extremely fine mesh for the fluid dynamics analysis and the process of simulation was done within 11min and 4 secs in order to get the final eFSI results. The dimensions of each part of the model is illustrated in Table 1 and the final results are depicted in Figures 3 to 6 to be discussed in the Results section.

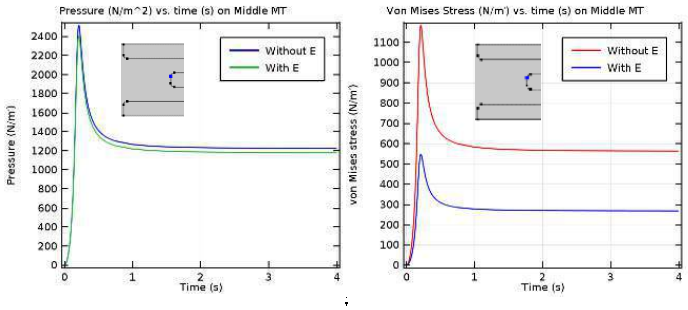
Dimension	Width (μm)	Height (μm)
Axon Channel	10	2
Upper Long MT	6	0.4
Lower Long MT	6	0.4
Middle short MT	4	0.4
Tau Proteins	0.1	0.4
Fillet Radius	r =0.1 (μm)	

Table 1: Information of the model [1,3]



(3) (4)

Figures 3 and 4: Displacement and Von Mises stress changes of the upper tau protein connection with and without E field.



(5) (6)

Figures 5 and 6: Pressure and Von Mises stress changes of the MTs with and without E field.

RESULTS

The results demonstrated that the applied electric field in conjunction with the induced velocity can reform the axon after the separation and broken connections of tau proteins with MTs in a traumatic brain injury. The results of this study reveal that the pressure and Von Mises stresses on the tau protein and MTs are reduced when the axon is subjected to an electric field. The analysis of this study was based on the coupling of electromechanical and FSI in conjunction with fluid mechanics' theories. Specifically, by looking at Figures 3 and 4, it can be found that the applied electric field decreased the amount of the total displacements on the upper tau protein while significantly reduces its Von Mises stress. Note that in Figure 3 there is not much difference between the cases with and without electric field until the simulation reaches its steady state position. Similarly, Figures 5 and 6 reveal that applied electric field decreased the amount of the total pressure on the MT while significantly reduces its Von Mises stress. Hence, it is concluded that the axoplasm fluid is influenced by the induced electric field and therefore it acts as a stiffer fluid that the axon's MTs as well as the broken tau protein connections can regain their original forms.

Finally, by looking at both MTs and the tau protein connections between them, this study showed that an applied Electric field can reduce the displacement and the von Mises stresses on the tau protein and MTs thereby leading to repairing a damaged axon where tau protein connection is broken, as shown in Figures 3 to 6. Therefore, it is hypothesized that by applying an electric field, a damaged axon can repair itself through regaining the original morphology of its tau proteins and MTs. Further 3-D studies of the axon and its tau protein and MTs are needed to quantify the effect of electric field on the damaged axon.

INTRODUCTION

Cell microencapsulation is a technique to use biocompatible polymer to encapsulate single cell or cell clusters, which is widely used in 3D cell culturing, stem cell therapy, cell cryopreservation, drug delivery, and tissue engineering. [1-4] The hydrogel microcapsules allow the essential metabolism substances to pass through the capsules, while they block the immune cells and antibodies, and protect the encapsulated cells. [5] Recently, microfluidics has been an attractive technique for microencapsulation, which is well controllable and does less damage to cells than other techniques, such as emulsification and electrospray. [6-8] However, one challenge of microfluidics is that the cell microcapsules usually form in oil phase, but need to be transferred to aqueous phase for further applications. The conventional transfer process based on centrifuge and washing is complex and may damage the cells [9]. In addition, prolonged exposure to the oil phase decreases the cell viability in microcapsules significantly. As a result, timely extraction from the oil phase to the aqueous phase is required to improve the cell microencapsulation applications. There are many methods used to extract microcapsules from the oil phase into the aqueous phase, such as interfacial tension methods. [9, 10] However, these methods depend on the strength of the microcapsules, and if the microcapsules are too soft, they can't work.

This study reports a stiffness-independent and dielectrophoresis (DEP)-based approach for on-chip extraction of hydrogel microcapsules. Liquid electrodes are used in the DEP device instead of metal electrodes. Hydrogel microcapsules are generated in oil emulsion using flow-focusing junction. When the microcapsules pass through the electrode regions, the DEP force can deflect them towards the aqueous phase regardless of their mechanical strength. Complete extraction can be achieved when the electric field is higher than 1700 V. Moreover, the DEP extraction does not compromise the viability of the microencapsulated cells.

METHODS

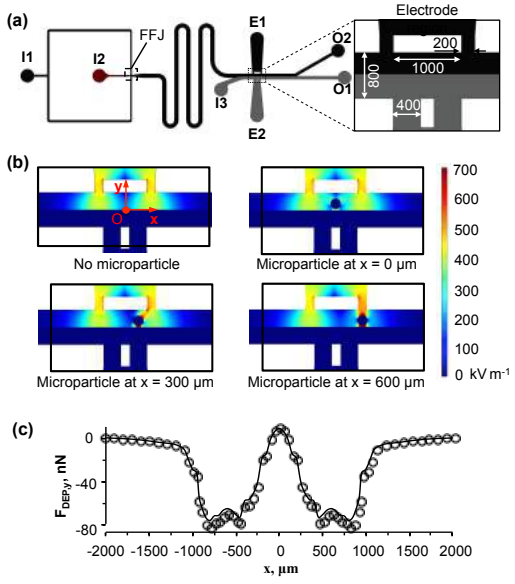

Figure 1: (a) The schematic figure of the DEP device. (b) The simulated electric field distribution in the electrode regions. (c) The calculated DEP force the microcapsules experience in the electrode regions.

As shown in Figure 1(a), the device was made of PDMS using soft lithograph. The alginate droplets, which were made of 0.5% or 2% (w/v) sodium alginate in saline without or with cells (introduced from I2, 100 µL/hr) were generated in the oil emulsion (introduced from I1, 5 mL/hr) at the flow-focusing junction (FFJ), and then formed hydrogel microcapsules in the microchannels. The oil emulsion was prepared by mixing mineral oil with $CaCl_2$ in deionized water using ultrasound. 1.3% (w/v) medium-viscosity carboxymethyl cellulose in saline was introduced via I3 (5 mL/hr). In the main extraction channel, a two-phase interface forms between the oil emulsion and cellulose solution. In addition, the electric field was applied to E1 and E2.

The electric field distributions in the electrode regions without and with microcapsule were simulated using COMSOL Multiphysics (version 4.3), as shown in Figure 1(b). The microcapsule affects the electric field distribution significantly in the electrode regions, and the electric field inside the microcapsule is much lower than that outside. In addition, the DEP force a microcapsule experiences at various locations in the electrode regions also was calculated. The results indicate that the DEP force is in the negative Y direction, and drives the microcapsules towards the aqueous phase.

Human C3H10T1/2 mesenchymal stem (C3) cells were suspended in 2% alginate in saline for cell viability study.

RESULTS

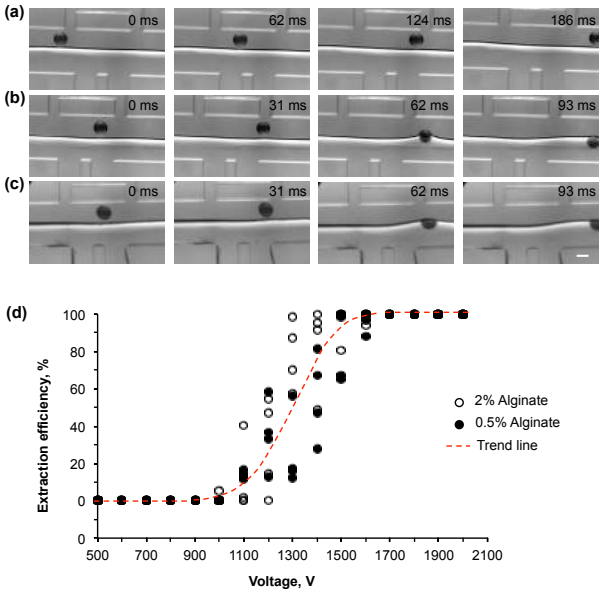

Figure 2: (a-c) Movement of hydrogel microcapsules in the electrode regions without and with electric field (moving from left to right). Scale bar: 200 µm. (d) The DEP extraction efficiency of alginate hydrogel microcapsules under various electric fields.

The behavior of an alginate (2%) hydrogel microcapsule in the electrode regions without electrical field is shown in Figure 2(a). The microcapsule moves without extraction. Figure 2(b) and (c) show the extraction of 2% and 0.5% alginate hydrogel microcapsules with electric field 1700 V, respectively. In the electrode regions, the DEP force drives the microcapsules towards the aqueous phase. Once the microcapsules touch the interface between the oil emulsion and aqueous solution, the microcapsules will be extracted by the surface tension force into the aqueous solution due to the hydrophilic property of the microcapsules. Figure 2(d) shows the extraction efficiency of the microcapsules in various electric fields. When the applied voltage is above 1700 V, 100% extraction can be achieved.

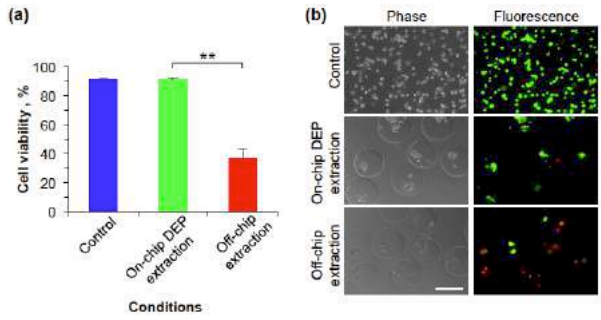

Figure 3: (a) The cell viability of the microencapsulated C3 cells in on-chip and off-chip extraction. (**): $p < 0.01$. The error bars represent SEM. (b) The phase and fluorescence images showing cell viability of different groups. Scale bar: 200 µm.

The cell viability results are shown in Figure 3. The cell viability of the on-chip DEP extraction (2000 V) group is 91.1%, which is similar with the control group (cells suspended in alginate solution without any treatment), while the cell viability of the off-chip extraction group (conventional centrifuge and washing method) is much lower (36.7%). These results indicate that the high electric field outside the microcapsule does no harm to the cells in the microcapsules when they pass through the electrode regions.

DISCUSSION

Based on the theory of dielectrophoresis, a microcapsule in a conductive medium can experience a DEP force in an electric field when the gradient of the electric field exists. In this study, as the size of the microcapsules is comparable to that of the microchannel, the microcapsules have a significant effect on the electrical field distribution in the electrode regions, as shown in Figure 1(b). Therefore, the microcapsules should be considered in the evaluation of the DEP force the microcapsules experience, which can be calculated using COMSOL Multiphysics based on the theory of the Maxwell stress tensor. As the DEP force depends on the electric properties of the microcapsules, but not the stiffness, the DEP device can achieve the stiffness-independent extraction of the microcapsules.

Due to the electrolyte (NaCl) in the microcapsules, the electric field intensity inside the microcapsules is much lower than that in the oil emulsion as a result of the Faraday cage effect. This can protect the cells in the microcapsules from the damage of the high electric field outside when the microcapsules move in the oil emulsion before extraction.

INTRODUCTION

Microdroplets and microcapsules have been widely produced using microfluidic flow-focusing junction for biomedical and chemical applications. However, the multiphase microfluidic flow at the flow-focusing junction has not been well investigated. In this study, the displacement of two (core and shell) aqueous fluids that disperse into droplets altogether in a carrier oil emulsion was investigated both numerically and experimentally. It was found that extensive displacement of the two aqueous fluids within the droplet during its formation could occur as a result of the shear effect of the carrier fluid and the capillary effect of interfacial tension. We further identified that the two mechanisms of fluid displacement can be evaluated by two dimensionless parameters. The quantitative relationship between the degree of fluid displacement and these two dimensionless parameters was determined experimentally. Finally, we demonstrated that the degree of fluid displacement could be controlled to generate hydrogel microparticles of different morphologies using planar or nonplanar flow-focusing junctions. These findings should provide useful guidance to the microfluidic production of microscale droplets or capsules for various biomedical and chemical applications.

METHODS

Numerical simulation: The numerical simulation of the flow in multiphase flow in microfluidics with flow focusing junction can be modelled by commercial software COMSOL Multiphysics 4.3 by combining two independent level set functions($\emptyset_1$ and $\emptyset_2$). It solves the partial differential equations via finite element method (FEM) and transforms them into their weak forms. The discretization type for velocity components, pressure field, Level Set variables are second-order, linear and quadratic elements, respectively. Both the streamline diffusion and crosswind diffusion are turned on for the Navier-Stokes equations and Level Set equations for consistent stabilization with tuning parameter $C_k = 0.5$. Considering the complexity of numerically solving equatio, backward differentiation formulas (BDF) has been used to discretize the time steps with maximum order being 2 to further stabilize the computation. The governing equation set is shown as follows:

$$
\begin{cases}
\nabla \cdot \vec{u} = 0 \\
\rho \dfrac{\partial \vec{u}}{\partial t} + \rho(\vec{u} \cdot \nabla)\vec{u} = \nabla \cdot [-p\boldsymbol{I} + \mu(\nabla\vec{u} + (\nabla\vec{u})^T)] + f_{it} \\
\dfrac{\partial \emptyset_1}{\partial t} + \vec{u} \cdot \nabla\emptyset_1 = \gamma_{ls}\nabla \cdot \left(\epsilon_{ls}\nabla\emptyset_1 - \emptyset_1(1-\emptyset_1)\dfrac{\nabla\emptyset_1}{|\nabla\emptyset_1|}\right) \\
f_{it} = \nabla \cdot \left(\gamma\left(\boldsymbol{I} - (\vec{n}\vec{n}^T)\right)\delta\right) \\
\vec{n} = \dfrac{\nabla\emptyset_1}{|\nabla\emptyset_1|} \\
\delta = 6|\nabla\emptyset_1||\emptyset_1(1-\emptyset_1)| \\
\dfrac{\partial \emptyset_2}{\partial t} + \vec{u} \cdot \nabla\emptyset_2 = \gamma_{ls}\nabla \cdot \left(\epsilon_{ls}\nabla\emptyset_2 - \emptyset_2(1-\emptyset_2)\dfrac{\nabla\emptyset_2}{|\nabla\emptyset_2|}\right) \\
\rho, \mu, \gamma = f(\emptyset_1, \emptyset_2)
\end{cases}
$$

Experimental setups: All the fluids were irrigated into BD syringes before being introduced into microchannels by syringe pumps (Harvard Apparatus). To check the trajectory and distribution of dispersed fluids within droplets, we took fluorescence rather than bright field time-lapse images of the shell fluid. This is because the refraction indices of the fluids and materials of channel walls are required to be matched for the bright field or phase images to accurately capture the flow within droplets near the liquid-liquid interface and near the channel walls. The fluorescence time-lapse images were taken by a Zeiss AxioCam HSm fast-speed CCD camera equipped on a Zeiss Axio Observer.Z1 microscope under a 2.5X objective. The image size was set as 462 × 346 pixels and the exposure time was 2 ms, resulting in imaging frequency ~ 64 Hz. On the other hand, static images of hydrogel particles were taken using a Zeiss

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

AxioCam MR3 CCD camera under phase contrast field of a 10X objective. The corresponding resolution was 1388 × 1040 pixels.

RESULTS

As shown in Figure 1, numerical simulation revealed two mechanisms of fluid displacement during droplet formation. During droplet growth stage, the dispersed fluids still attach to the inlets and the carrier fluid flows over the pendent droplet, which induces shear stress and two counter-rotating vortices (arrows in the velocity field) within the growing droplets. During droplet pinch-off stage, one of two the aqueous tails recoils back to the inlet from the pinching point with the capillary velocity. The other aqueous tail recoils forward in the droplet that has pinched off. The recoiling could cause redistribution of the dispersed fluids in both the droplet that has pinched off and the next droplet to form. Of note, as the pinched-off droplet moves downstream in the same direction as the recoiling velocity, it causes less fluid displacement within the pinched-off droplet than the pendent one.40 The counter-rotating vortices and the capillary recoil can significantly disturb and transfer the aqueous core and shell fluids in the droplets, which could displace them off their desired and ideal positions (the shell fluid locates on the peripheral and core fluid in the inner area of the droplets). This phenomenon was referred as fluid displacement in this study.

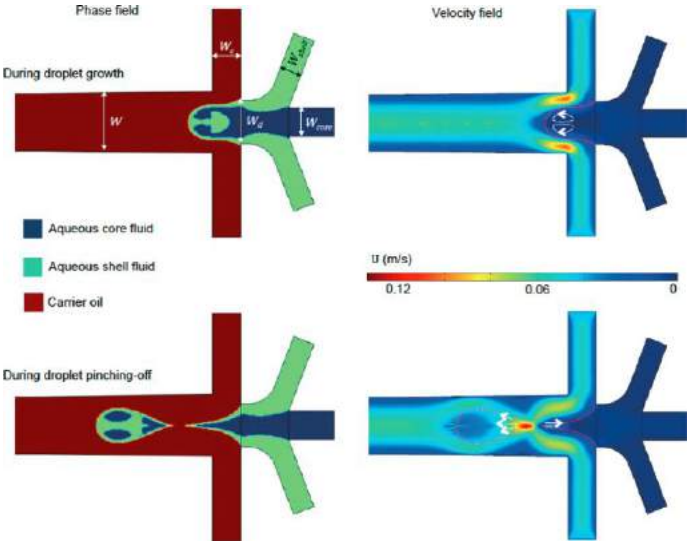

Figure 1: Numerical simulation of droplet formation at a planar flow-focusing junction for a typical flow condition. The arrows on the images of velocity field represent velocity vectors in the dispersed phase. Numerical settings: σ = 30 mN m^{-1}, $\mu_{core} = \mu_{shell}$ = 200 mPa s, μ_c = 30 mPa s, $q_{core} = q_{shell}$ = 0.4 ml hr^{-1}, and q_c = 10 ml hr^{-1}. Geometries: W = 400 µm, W_d = 300 µm, W_c = 200 µm, W_{shell} = 150 µm, and W_{core} = 200 µm.

The ratio I_{in}/I_{out} was used to evaluate the degree of fluid displacement within the droplets. A higher I_{in}/I_{out} suggests more shell fluid is displaced to the inner region. As shown in Figure 1, shear stress applied on the pendent droplet by the continuous carrier oil could induce vortices and fluid displacement during droplet formation, which however, could be balanced (with damping) by the viscous effect of the dispersed fluids. Therefore, a shear stress ratio ζ can be used to represent the shear effect on the fluid displacement within a droplet. On the other hand, the recoiling of the dispersed tail during and after droplet pinch-off is caused by interfacial tension between dispersed and carrier fluids. This deformation and the resultant displacement of dispersed fluids are also balanced (with damping) by viscous effect although the duration may not span over the whole droplet formation period. As a result, the capillary effect on fluid displacement can be evaluated by parameter λ.

As shown in the upper left inset of Figure 2, for constant λ, the slope between I_{in}/I_{out} and log10(ζ) is 0.55. While for constant ζ, the slope between I_{in}/I_{out} and log10(λ) is -0.82. As a result, the combined effect of these two mechanisms gives rise to the following relationship:

$$I_{in}/I_{out} = 0.55\log_{10}(\zeta) - 0.82\log_{10}(\lambda) = \log_{10}(\zeta^{0.55}/\lambda^{0.82})$$

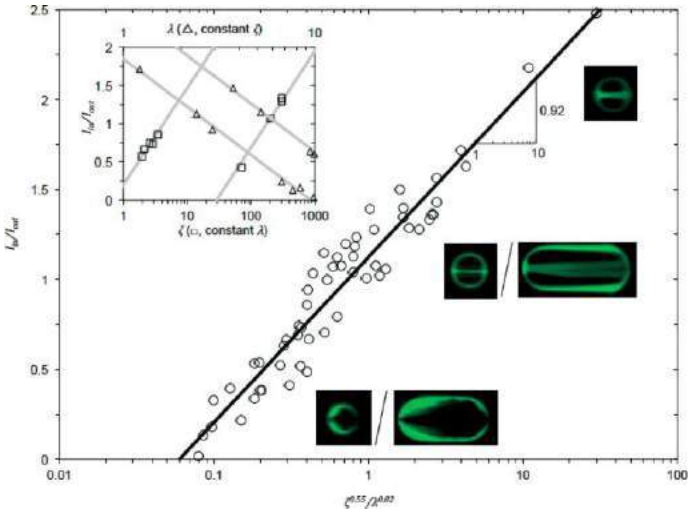

Figure 2: Experimental data showing the dependence of I_{in}/I_{out} on the two dimensionless parameters: shear stress ratio ζ and relative droplet size λ. The slope of the least square fitting line (black line) between I_{in}/I_{out} and $\log_{10}(\zeta^{0.55}/\lambda^{0.82})$ is 0.92. The ratio of q_{shell}/q_{core} = 0.2 for all experiments. Upper left inset: $I_{in}/I_{out} \sim 0.55\log_{10}(\zeta)$ for constant λ, $I_{in}/I_{out} \sim -0.82\log_{10}(\lambda)$ for constant ζ. Insets of fluorescence images: microdroplets generated with various combinations of ζ and λ.

The slope of the least square fitting line between I_{in}/I_{out} and $\log_{10}(\zeta_{0.55}/\lambda_{0.82})$ is 0.92, which is close to 1. The fitting goodness R^2 = 0.92. The insets of fluorescence micrographs show microdroplets of different I_{in}/I_{out} (i.e., different morphologies) for various combinations of ζ and λ.

ENHANCED MICROWAVE HYPERTHERMIA OF CANCER CELLS WITH FULLERENE

Mingrui Sun (1), Xiaoming He (1)

(1) Department of Biomedical Engineering
The Ohio State University
Columbus, OH, United States

INTRODUCTION

Hyperthermia is a widely used method for cancer treatment, which utilizes various energy sources, such as ultrasound, laser, or microwave to heat and damage the tumor. [1, 2] Among them, microwave hyperthermia has been commonly studied. The microwave field can be generated using antennas and heat the tumor effectively due to its high water content. However, only by designing the antennas to control the intensity distribution of the microwave field, the heating cannot be well targeted and the normal tissue adjacent to the tumor also may be damaged, [3-5] In order to improve the therapeutics and targeting property, nanoparticles are utilized as agents in the microwave hyperthermia. For instance, carbon nanotubes (CNTs) have been used to absorb the microwave energy and generate heat, enhancing the treatment of the tumors. [6, 7]

Fullerene (C60) is a carbon isotope with CNTs, and has been studied on its photodynamic effect. However, the poor water dissolvability limits its applications. Therefore, various methods have been developed to use chemical functionalization to improve the dissolvability of the fullerene. [8, 9] But the chemical modification may alter the properties and behaviors of the fullerene in the biological systems. [10-12] In addition, the fullerene has been demonstrated to absorb the microwave energy and generate heat, which makes it a promising agent in the microwave hyperthermia. [13]

In this study, a novel type of water-dissolvable nanoparticles, fullerene Pluronic F127-chitosan nanoparticles (C60-PCNPs), was synthesized by using Pluronic F127-chitosan nanocapsules (PCNPs) to encapsulate the free fullerene without any chemical modification, which can be utilized in microwave hyperthermia as the thermal agents. In addition, a microwave dish with an antenna was fabricated to heat the PC-3 cells with and without C60-PCNP treatment. The results demonstrate that the C60-PCNPs have great potential to enhance the cancer treatment by microwave hyperthermia.

METHODS

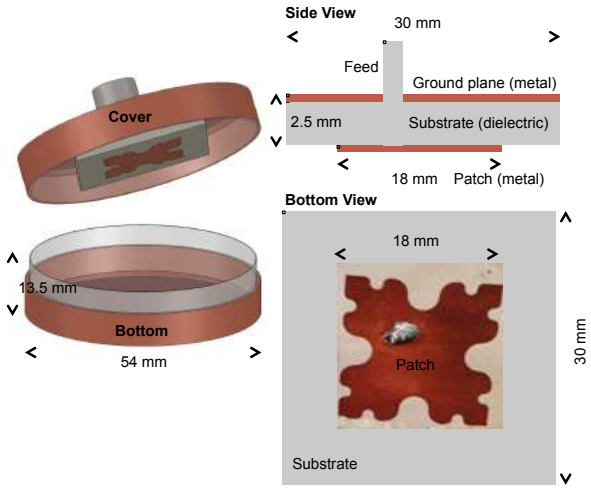

Figure 1: The structures of the microwave dish and antenna.

As shown in Figure 1, the microwave dish was fabricated by covering the 60 mm polystyrene petri dish using copper. The antenna was designed to heat 3 ml cell culture medium with cells in the microwave dish, and the frequency of microwave was about 2.4 GHz.

The PNCPs were synthesized as reported in the previous study, and then were used to encapsulate the fullerene to synthesize the C60-PCNPs. [14] Firstly, 5 mg PCNPs were dissolved in 2 ml DI water and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

1 mg fullerene was dissolved in 1 ml toluene. Two solutions were then mixed using Vortex mixer for 3 hours. The mixture was rotatory evaporated to remove the toluene, filtered using 450 nm filters and then freeze-dried overnight to gain the dry C60-PCNPs.

PC-3 human prostate cancer cells were used in this study. 6×10^4 PC-3 cells in 300 µl medium were cultured at the central region of the dish for 1 day. 3 mg/ml of C60-PCNPs in cell culture medium was used to treat the cells (if needed) for 2.5 hours at 37 °C. Before the heating, cells were washed using cell culture medium, and 3 ml cell culture medium was added into the dish with cells for heating.

In the microwave heating, the cell samples were heated by microwave and cooled down at room temperature, and then incubated for 48 hours at 37 °C before the cell viability measurement. In the water-bath heating, the cell samples in the dish were floated on DI water in a beaker and heated on a hot plate, and cooled down at room temperature, and then incubated for 48 hours at 37 °C before the cell viability measurement. The thermal history in the water-bath heating is controlled to be the same with that in the central region of the microwave dish in the microwave heating.

RESULTS

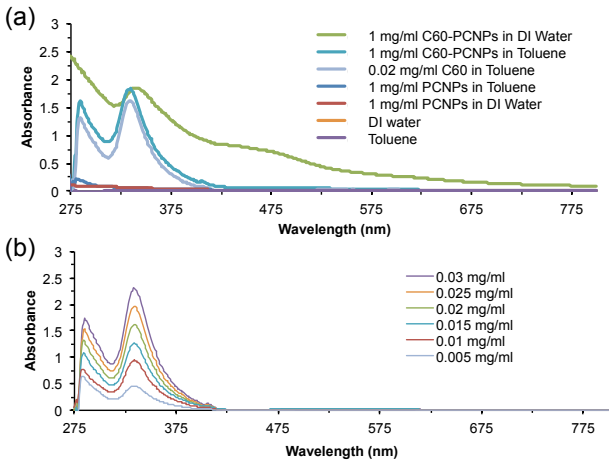

Figure 2: The absorbance spectra of various solutions.

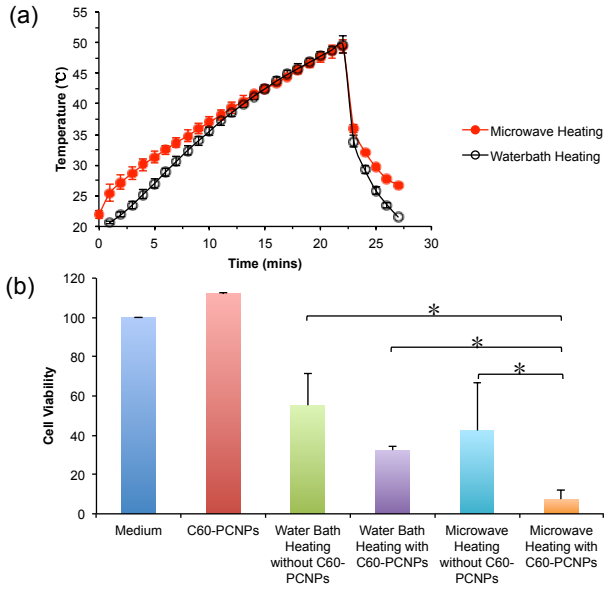

Figure 3: (a) The thermal process of the center of the dish with microwave heating and water bath heating. (b) PC-3 cell viability of different groups. (*): p<0.05..

As shown in Figure 2(a), the absorbance spectra of C60-PCNPs dissolved in DI water and toluene have a high peak at 334 nm, which is significant different with that of PCNPs in DI water and toluene. Additionally, the spectrum of C60-PCNPs in toluene has a similar profile with C60 in toluene. All these results indicate that the fullerene has been encapsulated into the nanocapsules in the C60-PCNPs. Moreover, as shown in Figure 2(b), the peak value at 334 nm is almost linearly related to the concentration of the fullerene in toluene. In addition, the diameter of the C60-PCNPs in DI water was measured around 340 nm at both 22 °C and 37 °C, while the diameter of the empty PCNPs is about 350 nm at 22 °C and 20 nm at 37 °C.

As shown in Figure 3, the thermal histories in the microwave heating and water-bath heating have no significant difference above 43 °C. The cell viability in C60-PCNPs group shows that the C60-PCNPs are not toxic to the PC-3 cells. The cell viability in the microwave heating with C60-PCNPs group is lower than that in any other groups, which indicates that the C60-PCNPs have the thermal effect (absorbing the microwave energy and generating heat in the microwave field) and can enhance the damage of the microwave to the PC-3 cells. Moreover, the viability in the microwave heating without C60-PCNPs group is similar with that in the water-bath heating without C60-PCNPs group, which shows that the damage of the microwave heating to the PC-3 cells mainly comes from the high temperature of the cell culture medium as the water-bath heating does.

DISCUSSION

The empty PCNPs can shrink when the temperature increases from 22 °C to 37 °C, but the diameter of the C60-PCNPs is not significant different in 22 °C with that in 37 °C, which indicates that the fullerene is encapsulated into the nanocapsules, and it is the fullerene inside the nanocapsules that impedes the shrinking of the C60-PCNPs. In addition, based on the linear relationship between the absorbance peak value at 334 nm and the concentration of the C60-PCNPs in toluene, and the peak values of the C60, PCNPs, and C60-PCNPs in toluene, the loading content of the C60 in the C60-PCNPs is calculated to be 23.0 ± 0.4 µg/mg.

INTRODUCTION

Cryopreservation of mammalian cells is an enabling technology in cell line maintenance, assisted reproduction1, regenerative medicine and tissue engineering. It is achieved by first cooling cells into deep sub-zero temperatures (e.g. -196 ºC), under which all the biophysical and biochemical activities are arrested in the state of suspended animation, followed by warming back to normal temperatures (e.g. 37 ºC) for future use at a desired time and place. Nevertheless, it induces substantial cellular damages through intracellular ice formation (IIF), unduly dehydration and/or osmotic shock (freezing concentration)2. To alleviate the cryoinjuries, two conventional approaches have been adopted with the assistance of penetrating cryoprotective agents (pCPA, such as dimethylsulfoxide (DMSO) and 1,2-propanediol (PROH)), slow freezing and vitrification. Slow freezing (usually requires 1.5 – 2 M pCPA) would progressively dehydrate cells due to exosmosis driven by elevated extracellular osmolality as the extracellular water gradually transform into ice during freezing at a slow cooling rate (typically < 5 ºC/min), which permits intracellular water to emigrate across plasma membrane before freezing3. On the other hand, vitrification (usually requires 6 – 8 M pCPA) can deliver samples into amorphous or vitreous state without ice formation with ultra-rapid cooling rate (typically > 10,000 ºC/min) so that water molecules do not have time to rearrange their positions and orientations for crystallization before the loss of translational and rotational degrees of freedom4.

METHODS

Cryomicroscopy: Cryomicroscopy were undertaken using a Linkam (Waterfi eld) FDCS196 freeze-drying stage mounted on an Olympus BX 51 microscope. Real-time images were recorded using a QImaging Retiga CCD color camera. In each experiment, 5 µL cell suspension was loaded into the sample crucible and sandwiched with a coverslip (9 mm in diameter) to obtain clear images during both cooling and warming. The samples were cooled to −80 ºC (or -130 ºC) at 60 ºC min−1, held for 2 min, and warmed back at 60 ºC min−1 to room temperature (22 ºC). For the scenarios with IS, the samples were cooled to -4 ^{0}C and held for 2 min, during which ice seeding was performed by touching a LN_2-cooled steel onto the periphery of the crucible. Ice crystal would nucleate around the deeply-cooled spot, then proliferate to occupy the whole sample in a flash of second.

IR assessment: To investigate the IR activity during warming phase of cryopreservation, cryomicroscopy studies were conducted to visualize the possible ice growth in annealing. 5 µl PBS (or including trehalose), with or without IS at -4 ^{0}C, was cooled to -80 ^{0}C, and then warmed to -6 ^{0}C. The warming and cooling rates are the same as cryomicropic study (60 ^{0}C min−1). The icy samples were held at -6 ^{0}C for 15 min for annealing, during which real-time polarized images were taken to track the crystalline changes of size, morphology and orientation. The information of ice crystals, such as area and circularity, were measured by ImageJ, and the average entropy of polarized images was calculated by MATLAB (MathWorks).

Pre-dehydration by trehalose: For 3T3 cells, 5 µl coverslip-sandwiched sample (cell suspension with or without trehalose pre-dehydration) was cooled -6 ^{0}C, followed by IS and holding for 5 mins before warming back to 22 ^{0}C. The choice of -6 ^{0}C as IS temperature is due to the fact that IS at -6 ^{0}C can achieve similar dehydration level for cells suspended in PBS as the pre-dehydration of 0.33 M trehalose at room temperature. Cell size and viability were recorded prior, during and post dehydration and/or cooling. 5-min holding is of similar icy period for the cells in cryomicroscopy. For hRBCs, 100 µl sample with or without 0.33 M trehalose pre-dehydration was cooled to -6 ^{0}C and seeded with ice crystals around the periphery of the crucible. After holding for 5 min, it was warmed back to 22 ^{0}C. Then it was centrifuged at 1000 g for 5 min before measuring hRBCs hemolysis and recovery rates.

RESULTS

Cryomicroscopic study was performed to mimic the cryopreservation procedures of 3T3s as illustrated in Figure 1. Being consistent with mouse embryonic stem cells (mESCs) and human adipose-derived stem cells (hADSCs) in previous study[11], 3T3s are subjected to extensive IR and concomitant IIF during warming, which is a lethal event for either slow freezing or vitrification. Without IS,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

ice crystals nucleate stochastically between -20 ^{0}C and -30 ^{0}C during cooling and propagate to occupy the whole sample instantaneously in this deeply metastable state (first three rows in Figure 1(A)). Only minority of suspended cells (< 30%) are captured by IIF during ice nucleation and further cooling to -80 ^{0}C (Figure 1(B)). However, all 3T3s experience intensive IIF during warming (darkening cells) and none of them can survive post thawing (Figure 1(C)). However, IS at -4 ^{0}C during cooling can dramatically eliminate IIF during warming (bright cells in last three rows of Figure 1(A)) and high cell viability ensues (Figure 1(C)), especially with 0.33 M trehalose predehydration at room temperature.

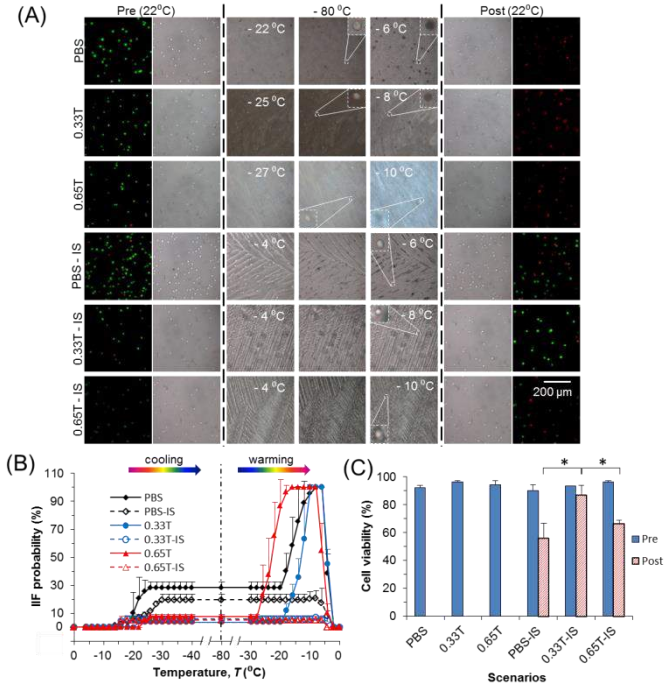

Figure 1: Intracellular Ice Formation (IIF) and viability of 3T3 cells during the cryopreservation. (A) Phase and fluorescence images of 3T3 cell in various scenarios. "PBS", "0.33T" and "0.65T" represent the cells are suspended in Phosphate-Buffered Saline (PBS), 0.33 M trehalose solution (dissolved in PBS) and 0.65 M trehalose solution (dissolved in PBS), respectively. IS stands for Ice Seeding. "Pre" and "Post" indicate the cases before and after cryopreservation. 5 μl samples were sandwiched by cover slip (diameter: 9 mm) in silicon crucible on the cryostage, and were cooled to -80 ^{0}C. Both cooling and warming rates were 60 ^{0}C/min. (B) IIF probabilities of 3T3 cells during cooling and warming phases in cryopreservation. (C) Vaiblities of 3T3 cells before and after cryopreservation. Each condition was performed by three independent runs. Error bar: standard deviation, *: $p < 0.05$.

The IRI mechanism of IS was investigated by polarized light cryomicroscopy. Without IS, the fine ice crystals nucleating between -20 ^{0}C and -30 ^{0}C during cooling undergo remarkable growth during warming through the reprecipitation of more stable crystals at the expense of the dissolution of unstable crystals and/or self-assembly-based aggregation and coalescence by oriented attachment. As a result, when the front of ice growth penetrates through the cell membrane, significant IIF is triggered to disrupt intracellular integrity as indicated by darkening region (Figure 2(A)).

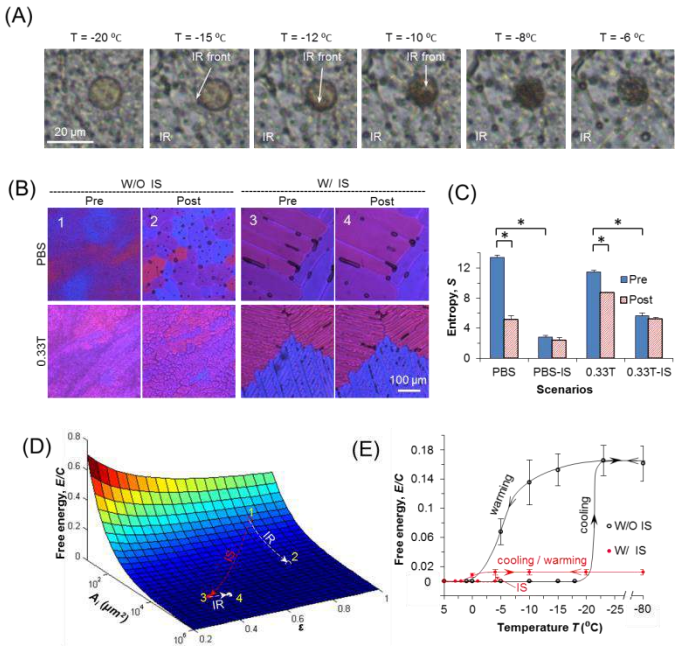

Figure 2: Inhibition of ice recrystallization (IR) and associated IIF by IS. (A) IIF induced by extracellular IR during warming phase. Significant IIF is triggered when the extracellular IR front penetrates the cell membrane, which precipitates the solutes and organelles from ice crystals and thus darkens the cells. (B) Polarized cryomicroscopic images of PBS solutions (with or without trehalose) before and after annealing at -6 ^{0}C for 15 min. (C) Entropies of polarized cryomicroscopic images before and after annealing. It shows that IS can dramatically decrease the entropy of overall icy samples and nearly eliminate IR in annealing. (D) Free energy of overall icy samples. A_i and ε are the area and circularity of ice crystals. Points 1, 2, 3 and 4 correspond to image 1, 2, 3 and 4 in (B), respectively. (E) Free energy of overall samples during cryopreservation. The free energy of isotropic solution at equilibrium state before and after ice melting is assume to be ground (zero). Error bar: standard deviation.

The polarized images during annealing at -6 ^{0}C are displayed by Figure 2(B). The IR can be illuminated by the entropy (S) change of these image of the sandwiched samples as IR would reorganize the orientations and positions of local crystals into a uniform pattern (Figure 2(C)), which implies IR during warming can be effectively prevented or even completely eliminated by IS during cooling. The corresponding free energy is plotted by Figure 2(D). While the overall energy change path is demonstrated by Figure 2(E), which shows a giant hysteresis loop of free energy with a precipitous rise and fall during freezing and thawing, respectively, when IS is absent, and marginal variation when IS present at -4 ^{0}C. In other words, IS at high subzero temperature can release the enormous free energy that otherwise would be engendered and stored in frozen samples during cooling and released to drive significant IR and IIF during warming

INTRODUCTION

Intracranial aneurysms (IAs) are pathological outpouchings of cerebral arteries, which, if ruptured, often lead to death or permanent disability. Rupture risk stratification is critical for treatment decision. As potential biomarkers for rupture risk, aneurysm hemodynamics has been explored, since patient-specific Computational Fluid Dynamics (CFD) simulations can be implemented based on routine clinical rotational angiography or CT Angiography (CTA). Past CFD studies have shown both low Wall Shear Stress (WSS) and high WSS being correlated with rupture [1-3]. Towards this controversy, we have proposed two different hemodynamic-biological pathways, mediated by inflammatory infiltrates and mural cells, respectively [4]. Furthermore, it has been speculated that these two pathways could lead to different aneurysm wall phenotypes, from translucent thin walls that are almost cell-free to thick walls with atherosclerosis and inflammatory cell infiltration [4].

In our study of 204 aneurysms at the Gates Vascular Institute in Buffalo, we have statistically found that low WSS and high Oscillatory Shear Index (OSI) predict rupture status, although some ruptured aneurysms had high WSS [3]. We wish to explore possible relationship between these hemodynamic stresses and IA wall by directly observing patient aneurysm images, provided that we could simultaneously obtain the aneurysm 3D geometry (and thus CFD) and the wall thickness distribution.

Recent advancement in high-resolution MRI image has made it possible to image aneurysm wall [5]. Thus the objective of this study is to test the feasibility of combining hemodynamics based on CTA (which provides the accurate geometry and thus CFD) with aneurysm wall thickness distribution derived from high-resolution MRI vessel wall imaging performed on the same patient. This will pave the way for future exploration of association between hemodynamics and aneurysm wall phenotypes, so as to improve aneurysm rupture risk prediction.

METHODS

We analyzed high-resolution (0.8 mm isotropic resolution) 7.0 Tesla MRI images and CT Angiography images of a 5 mm unruptured aneurysm located at the left middle cerebral artery of a 55-year-old female patient. The images were taken at University Medical Center Utrecht, for detailed methods of MR imaging, refer to Kleinloog et al. [5].

Image Processing

We reconstructed the 3D luminal geometry of the aneurysm from CTA and the 3D geometry of the aneurysm wall through high-resolution MRI images, as shown in Fig. 1, and spatially co-registered the two 3D images for comparison. The 3D geometry of the lumen was reconstructed from DICOM images using an open-source visualization tool, The Vascular Modeling Toolkit. This lumen surface (inner surface of vasculature) represents the domain of blood flow.

The 3D reconstruction of MRI images was more challenging, because of the low signal-to-noise ratio and the small thickness of the aneurysm wall, surrounded by brain tissue. In order to distinguish and separate the aneurysm wall from the surrounding brain tissue, we used the 3D geometry of the aneurysm obtained using CTA images to determine the location of the aneurysm wall in MRI images. In this approach, since the MRI images of the parent arteries had better definition than aneurysm sac, we reconstructed the parent arteries wall and mapped it on the parent arteries reconstructed from the CTA images, as shown in Fig 1.B. This method helped us to identify the aneurysm wall location in MRI images. The process of removing the tissue around the aneurysm was done under supervision of a clinician who is familiar with medical images. As previously shown [5], thin portions of the aneurysm wall yield insufficient MRI signal to be visible. Therefore, we selected the regions that where visible as thick wall regions, see Fig 1.B.

CFD simulation

We assumed incompressible and laminar flow and conducted pulsatile CFD simulation using ANSYS FLUENT package. Patient-specific velocity inlet waveform, zero pressure outlet and rigid wall assumptions were adopted for numerical simulation. Viscosity and density of blood were taken as 0.0035 *Pa.s* and 1056 kg/m^3, respectively. We performed a sensitivity study of the effects of different assumptions frequently used in vascular CFD, such as neglecting the wall compliance, different outlet boundary conditions, and non-Newtonian behavior of the fluid. We found that the general distribution of hemodynamic parameters such as WSS and OSI are insensitive to these different simulation assumptions [6].

RESULTS

Figure 2 shows results from both CFD (distributions of WSS and OSI) on the luminal surface and MRI (wall thickness). Distribution of the WSS (Fig. 2A) shows that most parts of the aneurysm were exposed to low WSS (less than 1 *Pa*), except for the regions subjected to an inflow jet coming from the parent artery. Figure 2.B shows the distribution of OSI. The flow was not highly oscillatory, and only two small regions (one on the aneurysm and one on parent artery) had OSI values more than 0.1. This was expected because of the saccular and smoothly rounded shape of the aneurysm. Figure 2.B also shows that the location of regions with highest OSI value were located within low WSS regions. Figure 2.C shows that the thick wall regions were co-localized with low WSS regions. Likewise, the thin walls regions (not visible on 7.0-Tesla MRI images), were co-localized with high WSS regions (WSS higher than 0.2 *Pa*).

Based on this preliminary analysis, we hypothesize that a thicker wall (which is more visible on the MRI images) correlates with low WSS and high OSI value.

DISCUSSION

In this study we have demonstrated the feasibility of combining CFD simulation with direct imaging of aneurysm wall to study the association of hemodynamics and aneurysm wall thickness. Our preliminary results show that the thick wall regions are co-localized with low WSS, high OSI regions. This finding is in agreement with a previously described view [4]: low WSS is known to increase the thickness of the aneurysm wall by increasing inflammatory cell infiltration, atherosclerotic plaque, and formation of luminal thrombus. However, our result is opposite to findings by Kadasi et al. [7], who observed a positive correlation between WSS and thickness of the wall. This difference could be attributed to the different hemodynamic-biological pathways to aneurysm growth and rupture [4].

Even though we have analyzed only one case at this point, our approach paves the way for a more comprehensive study with more IA cases. A more advanced and computerized method for distinguishing and separating the thick wall regions will be developed to reduce human errors.

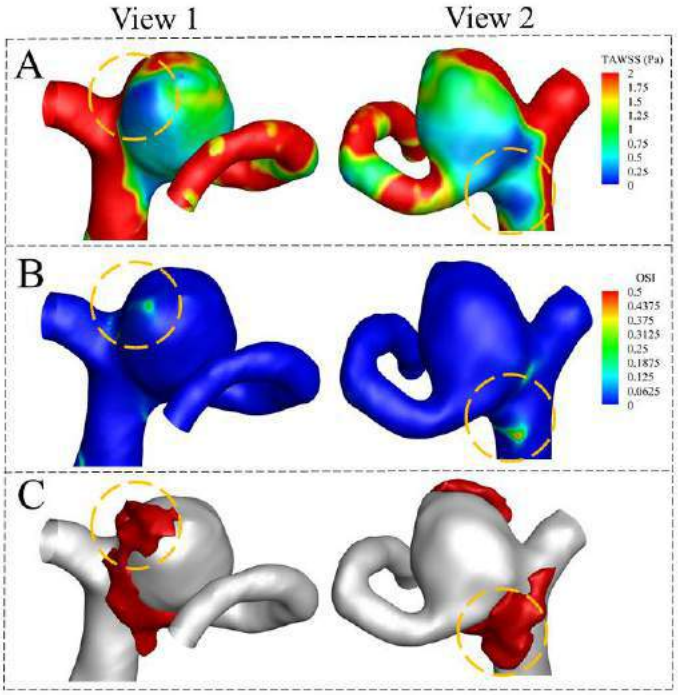

Figure 2: Distribution of: A) Wall Shear Stress B) Oscillatory Shear Index C) Thick-wall regions. Dashed-circles on the images indicate the approximate location of low WSS regions.

INTRODUCTION

Ligaments provide joint stability through a dense network of collagen fibers that align along the primary loading direction. When a ligament is torn, fibroblasts at the wound site repair the tissue by forming scar tissue, a disorganized or multiaxial network of collagen fibers. Over time, repaired tissue achieves only modest fiber realignment, and after one year its strength is less than half that of healthy tissue. This diminished strength can lead to recurrent ligament sprains, pain, and abnormal stress patterns on the articular surface that can trigger irreversible cartilage degeneration. In order to develop clinical techniques that improve the structural and functional restoration of torn ligament, the mechanical and chemical factors that stimulate matrix remodeling must be identified. A challenge to identifying these factors is the absence of an *in vitro* model for ligament wound healing. The development and validation of an *in vitro* model would enable the study of mechanical and chemical factors that instruct fibroblasts to align the disorganized scar tissue and strengthen the ligament.

Prior studies have used cross-shaped (cruciform) molds to develop fibroblastic collagen gels with variable collagen networks.[1, 2] Although the center of these cruciform gels has a multiaxial fibrillar microstructure similar to scar tissue, no study has measured the gene expression of these gels to determine if they are suitable as an *in vitro* wound healing model. The objective of this study is to determine if gels that exhibit a multiaxial fiber architecture will promote the expression of genes associated with healing ligament.

METHODS

Overview. Collagen gels seeded with murine fibroblasts were incubated for 1, 2 or 3 weeks under three loading conditions: stress-free, uniaxial, or biaxial. At each time point, five genes associated with ligament wound healing were measured. Confocal microscopy and imaging software measured fiber alignment. In total, 90 collagen gels were synthesized and tested.

Collagen Gels: Collagen gels were produced by adding Purecol (bovine type I collagen), 10x DMEM, and suspended NIH/3T3 mouse embryonic fibroblast cells in culture media. The collagen gel solution was then neutralized to physiological pH with 0.1 M NaOH and brought to a final volume with 1x PBS. This gave a final cell density of 0.83 x 10^6 cells/mL per gel and a final type 1 collagen density of 1.5 mg/mL.

Teflon cruciform molds were machined with a channel aspect ratio of 1:0.5 (Fig. 1A). The cruciform design generates stress in the gel by resisting gel contraction with fixed glass rods (Fig. 1B).[1, 2] The stress environment at the cruciform channel arms (uniaxial stress) differs from the cruciform center (biaxial

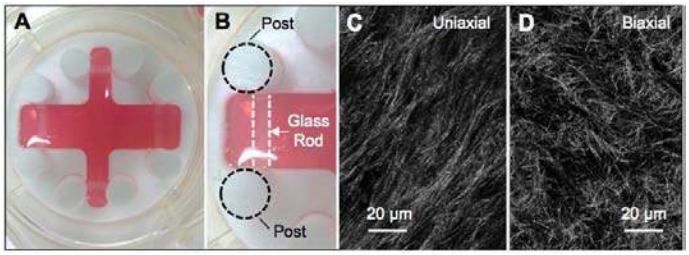

Figure 1: Collagen gels. A) Cruciform. B) Mechanical constraint, C) confocal image of cruciform center and D) cruciform arm.

stress). The gel solution was cast into the cruciform molds at 1.2 mL per mold, and at 2 mL per well in a six-well plate (stress-free). Cells were passaged at 60% confluency using trypsin/EDTA, and the collagen solution was allowed 120 minutes to gel at 37^{0}C. Cell culture media was exchanged every three days. 54 cruciform-shaped cellular gels and 36 stress-free discs were created to allow for a 1 week, 2 week and 3 week time course experiment.

Gene Expression. RNA was extracted from the molds via the TRIzol protocol [W.M. Keck Foundation, New Haven, CT], which required 16-18 cruciform gels to yield enough RNA for PCR analysis. The control specimens consisted of extracting RNA from NIH3T3 cells in a 2D tissue culture flask via the TRIzol method. RNA concentration was determined by measuring the absorbance at 260 nm. Messenger RNA (mRNA) was amplified by RT-PCR (40 cycles). Genes of interest were contained within the RT² Profiler™ PCR Array Mouse Extracellular Matrix & Adhesion Molecules. All results were normalized to GAPDH, and are expressed as positive fold-changes by comparing to results from the 2D tissue culture flask (data not shown).

The genes targeted for analysis include: collagen type I alpha I (Col1a1), collagen type III alpha I (Col3a1), collagen type V alpha I (Col5a1), integrin alpha 5 (Itga5), and tenascin-C (TnC). The rationale for selecting these genes is that previous animal studies on ligament wound healing found scar tissue at three weeks had a 2.6-fold increase in collagen I and a 1.9-fold increase in collagen III[3], and scar tissue at six weeks had a 4.2 fold increase in collagen V[4] and an increase in TnC[5]. In human ruptured ACL, Itga5 showed a 1.7 fold decrease[6].

Imaging. Confocal microscopy was used to evaluate the collagen fibril alignment in the stressed and stress-free gels at each time point. The collagen gels were auto-fluoresced at 63x using the 405 nm laser of a confocal microscope and ZEN imaging software (Fig 1C-D). FiberFit software was used to apply a fast-Fourier transform that measured fiber dispersion (fiber disorder) in the confocal images.[9] A trypan blue/calcein AM assay for live/dead cells was used to determine cell viability via the EVOS microscope's cell counting function.

RESULTS

A gradual increase in collagen was observed for all gels over time (Fig. 2). At three weeks, the stress-free gels had the greatest increase in Col1a1 expression (5.4 fold) and Col5a1 expression (4.8 fold), while the biaxial stressed gels had the greatest increase in Col5a1 expression (12.2 fold). The ratio of Col3a1 to Col1a1 had the greatest increase with time in the stress-free and biaxial gels (Fig. 2D). For all gels, only minor changes occurred over time in the ratio of Col5a1 to Col1a1 (Fig. 2D).

The increase in expression of Itga5 was lowest (2.7 fold) in the uniaxial stressed gels at two weeks and highest (4.2 fold) in stress-free gels at three weeks. The expression of TnC was greatest in the stress-free gels at week 2 (7.8 fold).

Image analysis found the uniaxial stressed gels had greater fibril alignment than the biaxial stressed gels (Fig. 1C-D; $p<0.001$). A significant interaction existed, where fibril alignment increased over time in the uniaxial gels and decreased over time in the biaxial gels ($P = 0.02$). Cell viability was a robust 100%.

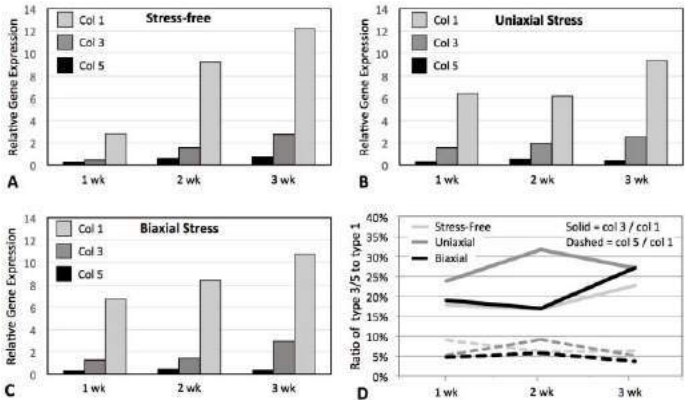

Figure 2: Gene expression when gels are exposed to A) stress-free, B) uniaxial and C) biaxial loads. D) Collagen ratios over time.

DISCUSSION

This study investigated whether growing NIH/3T3 cells in 3D bovine collagen gels could replicate the gene expression observed during ligament wound healing. Based on literature values[3, 4, 6, 7, 8], our results indicate that the stress-free gels have a gene expression profile most similar to healing ligament. For example, the stress free gels had gene expressions of Col1a1 and Col5a1 very near to *in vivo* studies. A close second to the healing ligament profile were the biaxial constructs based on the increase in expressions of the Col1a1, Col3a1, Itga5 genes and their disordered collagen fibril alignment. The uniaxial stressed constructs were least like the healing ligament gene profile and had the most aligned network of collagen fibrils.

Limitations of this work include an RNA sample size that precluded statistical analysis. Although eighteen gels were created for each loading group, all gels were required to extract sufficient RNA for analysis. Another limitation is that comparable animal studies use different molecular biology techniques. Also, the gel protein composition was not measured, but future work will characterize the molecular constituents using proteomics.

To our knowledge, this is the first study to focus on validating an *in vitro* model for ligament wound healing by examining mRNA expression and collagen fibril alignment in multiaxial collagen gels. Previous animal studies have compared differences in gene expression in fibroblasts from injured and healthy ligament *in vivo*. Also, studies have mechanically stressed cellular gel constructs but not with the aim of a healing ligament model. Once an *in vitro* healing ligament model has been validated, it can be used to test the effect of mechanical loading regimes and chemical stimuli on the remodeling and strengthening of the fiber network during healing. This could potentially aid in the development of clinical techniques that restore collagen organization and strengthen the healing ligament.

INTRODUCTION

The large elastic arteries provide reversible extensibility during the cardiac cycle and reduce the workload on the heart. This is made possible by the protein elastin, which is only present in the cardiovascular system of vertebrate animals [1]. Elastin is secreted from cells as the soluble protein tropoelastin, which is crosslinked by lysyl oxidase enzymes into insoluble elastic fibers [2]. In humans, lysyl oxidase (LOX) deficiency is associated with Ehlers-Danlos syndrome type IX and Menkes syndrome. LOX is an extracellular copper enzyme that initiates crosslinking of collagens and elastin by catalyzing oxidative deamination of the epsilon-amino group in certain lysine residues. Lox-knockout mice (Lox KO) die perinatally, exhibiting cardiovascular instability with abnormal lengthening and tortuosity of the descending aorta (DA), ruptured arterial aneurysms and diaphragmatic rupture [3]. Most aneurysms and vascular abnormalities occur in the DA. Therefore, Lox KO mice are a unique model to investigate locational differences in aneurysm susceptibility. We hypothesize that in Lox KO mice, mechanical properties, altered by deficient elastin crosslinking, and genetic signaling, are linked with DA aneurysms and tortuosity. To test our hypothesis we measured arterial mechanical behavior using a pressure myograph. Ongoing work includes imaging structural changes of the vascular wall using confocal microscopy and gene array analysis.

METHODS

To test vascular mechanics we isolated ascending aortas (AAs) and DAs from newborn wild type (WT) and Lox KO pups. The vessels were cannulated and pressurized in a pressure myograph (DMT) and subjected to a series of inflation and stretching protocols. The changes in outer diameter, pressure and axial force were recorded to determine the mechanical behavior of the WT and KO vessels (Figure 1).

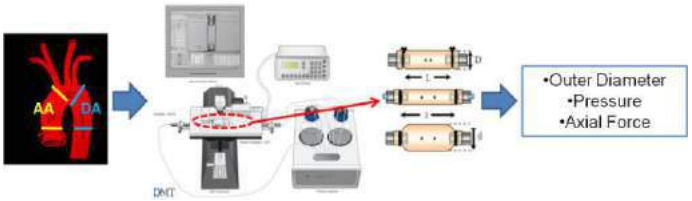

Figure 1. Schematic representation of the mechanical testing protocol.

For mechanical data analysis, we examined pressure–diameter and -compliance curves at the in vivo length. Compliance represents a structural property of the wall (depends on geometry and material). Diameter compliance (C) at each pressure (P_i) was calculated by,

$$C_{P_i} = \frac{\partial d_0}{\partial P}\Big|_{P=P_i} \quad (1)$$

where $d_0 = a_1 + a_2\left\{1 - exp\left(-\frac{P^{a_3}}{a_4}\right)\right\}$ (2)

is the outer diameter of the aorta [4], P is the lumen pressure, and a_i are constants determined by regression in Matlab (Mathworks). Material properties of the wall, such as stress, strain, and tangent modulus, under different loading conditions were also measured, but are not reported here.

To determine compositional and microstructural differences between Lox WT and KO vessels, images of pressurized arteries and arterial cross-sections were acquired with a Zeiss LSM 710 inverted confocal microscope. Imaging was performed with a Zeiss 20X air objective lens (NA 0.8) and a Zeiss 40X oil

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

immersion objective (NA 1.3). Prior to imaging, the vessels were stained with Alexa Fluor633 Hydrazide (elastin), Oregon Green488 conjugated CNA35 (collagen) and Hoescht 34580 (cell nuclei) for 20 – 30 min.

Microarray data will be obtained from an Affymetrix mouse Gene 2.0 array run by the Genome Technology Access Center at Washington University. We dissected the AA and DA from individual newborn pups. We pooled in groups of eight like-genotypes to obtain enough tissue for the array analysis. We currently have enough samples and are isolating the RNA.

RESULTS

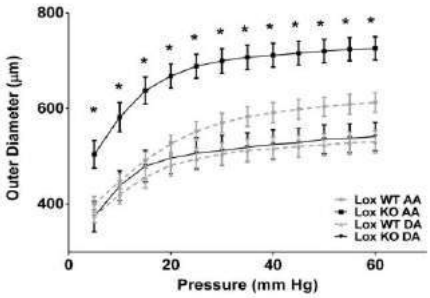

Figure 2. The arterial outer diameter increases nonlinearly with applied pressure in all groups. Lox KO AA (n=6) has a 20 – 25% larger outer diameter than Lox WT AA (n=8) at all pressures. However, in DAs from Lox KO (n=6) and Lox WT (n=6), the outer diameters are not significantly different. Data are means ± SEM. (*) P<0.05 (t-test, two tailed, equal variance) between Lox KO and WT AAs.

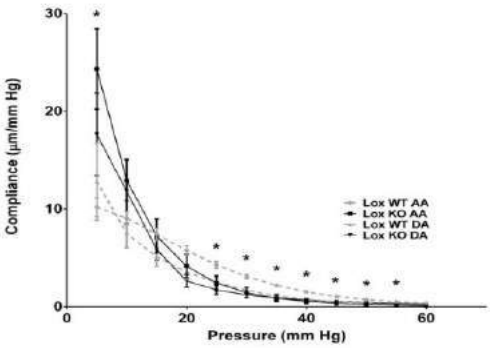

Figure 3. Compliance for both genotypes is high at low pressures, and very low at high pressures. Compared with WT AA (n=8), compliance is significantly higher in Lox KO at 5 mmHg (n=5), whereas between 25-55 mmHg the compliance is significantly lower. In DA, the compliance is not different between Lox KO (n=5) and WT (n=5). Data are means ± SEM. (*) P<0.05 (t-test, two tailed, equal variance) between Lox KO and WT AAs.

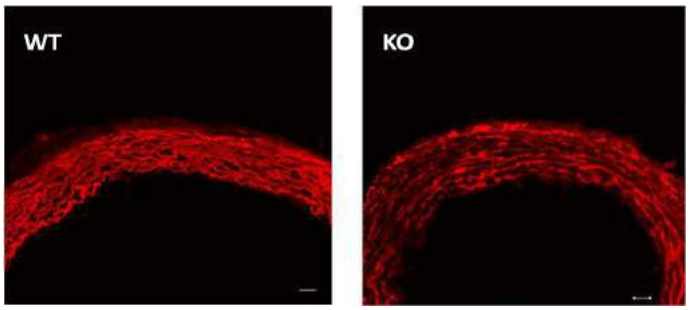

Figure 4. Cross-sections of AAs stained for elastin. Elastic lamellae in Lox WT AA are uninterrupted while in Lox KO the lamellae are discontinuous, revealing defects in elastin crosslinking. The scale bar is 10 μm.

DISCUSSION

Lox KO mice have thicker walls and fragmented elastic lamellae. Improper elastin fiber crosslinking due to Lox deficiency is probably the main cause of elastic lamellae fragmentation. AAs from Lox KO mice have larger outer diameters at all measured pressures. In contrast, DAs from Lox KO mice have similar outer diameters to WT mice. Despite the presence of aneurysms and tortuosity in the DA of Lox KO mice, the compliance is not significantly different from WT mice. However, the compliance is significantly lower in AA Lox KO mice between 25 and 55 mmHg. Our initial results do not explain the differences in the development of aneurysms and tortuosity mainly in the DA of Lox KO mice. Therefore, future research will concentrate on further characterizing wall material properties through stress/stain analysis under different loading conditions and examining genetic signaling through gene array analysis.

Our study of vascular mechanics and gene expression in a newborn Lox deficient mouse model is novel. There are currently no approved pharmaceutical treatments to prevent aneurysm growth. Large aneurysms can dissect and rupture, which is often fatal. Rupture and dissection depend on the mechanical properties of the aneurysmal wall. Thus, establishing a link between vascular mechanics and genetic signaling may lead to new therapeutic approaches to prevent aneurysm growth and rupture.

INTRODUCTION

Heart attack or myocardial infarction (MI) is the leading cause of death globally [1]. This is due in part to the facts that the human heart has a very limited capacity of self-repair and there is no effective treatment for the loss of cardiac tissue, particularly cardiomyocytes (CMs), following MI. SCT has been explored as a promising option for treating MI, for which various types of stem cells have been investigated with both pros and cons and pluripotent stem cells (PSCs) including embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) are well established to be capable of differentiating into functional CMs3-6. However, the delivery of stem cells needs significant further improvement regardless of which types of stem cells are used. The retention of single or individual stem cells in the infarct zone delivered in suspension has been dismal and most of the retained cells die due to the hostile inflammatory microenvironment of MI (that could be exacerbated by the implanted cells to trigger immune reaction), leading to often as low as 1% or less viable cells in the heart within a few hours to days post injection. Delivery of stem cells in tissue-engineered constructs in the form of macroscale (up to a few centimeters) hydrogel, porous scaffold, or cell sheet/patch has improved cell retention. However, because there is significant cell death inside the constructs due to the limited diffusion length (less than ~100 um) of oxygen in vivo, it may require multiple surgeries (for cell sheet/patch less than ~100 um thick as 1D microscale constructs) to overcome the diffusion limit of oxygen in vivo.

METHODS

Here we produced 3D microscale stem cell constructs that allow for implantation by injectable delivery. This is achieved by first microencapsulating single pluripotent mouse embryonic stem cells (ESCs) in microcapsules with a liquid core and a semipermeable alginate hydrogel shell for culture to obtain the ESC aggregates with high (>90%) cell viability using novel coaxial electrospray technology [2]. The core-shell architecture of the microcapsule mimics the physical configuration of pre-hatching embryos during early embryo development with a hydrogel-like shell known as the zona pellucida and a permissive core, where stem cells from the totipotent to pluripotent stage are grown in vivo. The one integrated ESC aggregate formed in each microcapsule on day 7 resembles the single integrated cell aggregate in each pre-hatching embryo at the morula stage. Probably because of the biomimetic nature, our previous studies show that miniaturized, semi-closed culture in the core-shell microcapsules is inductive to stemness of both pluripotent and multipotent stem cells compared to the conventional open bulk culture. To bypass teratoma formation18,19 associated with using PSCs in their pluripotent state for tissue regeneration, we pre-differentiated the aggregated ESCs before implantation for 3 days using BMP-4 and bFGF to direct them to the early cardiac lineage as confirmed by qRT-PCR data and flow cytometric data.

After pre-differentiation, we released the aggregates from the core-shell microcapsules using isotonic sodium citrate solution. Next, we re-encapsulated the released aggregates in an alginate-chitosan micromatrix (ACM) by soaking the aggregates first in chitosan (and then in a solution of oxidized alginate. Chitosan is a positively charged polymer that can be attracted to the cells in the aggregate because the cell plasma membrane is negatively charged. The same electrostatic interaction applies to the complexation of alginate with chitosan and vice versa (alginate is negatively charged). As shown in the first two columns of Fig. 1, individual cells on the surface of bare pre-differentiated aggregate (Bare-A, top) are clearly visible while the aggregate with ACM encapsulation (ACM-A, bottom) is covered with materials. Furthermore, the elastic modulus of ACM-A is significantly

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

higher than that of Bare-A determined by atomic force microscopy (AFM) nanoindentation.

To investigate the safety and efficacy of ACM-A as compared to Bare-A, saline, and materials only (i.e., ACM) for treating MI, we conducted intramyocardial injection of $2x10^5$ cells/animal in 20 ul saline into the peri-infarct zone at 3 different sites using a 28 gauge syringe needle. This was done immediately following permanent ligation of the LAD at its proximal location to create a large-area MI in 8-12 week old male C57Bl6/J mice that are either wild-type (WT) with a normal immune system or CARD9 knockout (KO) with deficient macrophage function. After 4 weeks, all the characterization of heart dunction and cardiac tissue regeneration were performed.

RESULTS

The treatment with Bare-A and bare single cells differentiates themselves from the others with the formation of a large mass of tissue that grows out of the heart. It was observed in 60% WT mice with the bare single cells treatment and 57% with Bare-A treatment while it was not detected in WT mice with any of the other treatments including 30 WT mice treated with ACM-A. Further microscopic examination of the gown-out tissue revealed that it is a typical granuloma that contains inflammatory cells (mainly macrophages) with a loose tissue matrix, indicating that the outgrowth results from inflammatory reaction. More importantly, the MI mice treated with Bare-A started to die at as early as 2 days post injection while mortality was not observed for the single cells, saline and materials only (ACM) treatments until 5 days and for the treatment of ACM-A until 7 days after injection. Nearly 40% of the MI mice treated with Bare-A died during the first 4 days, a known time frame of acute inflammatory reaction to implanted bare single cells. Interestingly, although WT mice treated with single cells have higher occurrence of granuloma, the overall size of granuloma is smaller, compared to those treated with Bare-A, which might result relatively alleviated mortality in early time frame.We therefore reason that the biodegradable ACM should temporarily isolate the aggregated cells from contacting the host cells including macrophages and possibly NK cells and T cells to achieve a temporary immunoisolation (or "local immunosuppression") effect, which contributes to the significantly higher survival (~80% after 15 days of injection) and elimination of granuloma in WT mice treated with ACM-A.

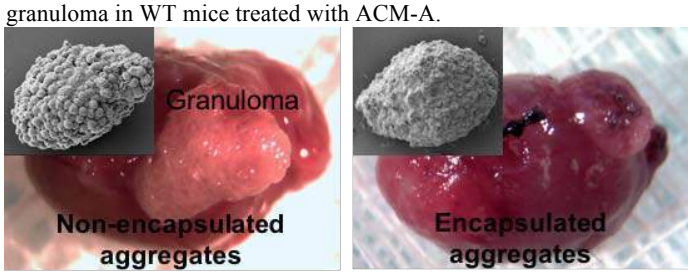

Figure 1: SEM images showing mESC aggregates after encapsulation has a smooth and porous surface (right inset) when comparing with non-coated one with visible single cells (left inset). After transplantation, the hearts of mice injected with Bare-A has large granulomas (left), but no for the ACM-A treated ones (right).

The ACM-A treatment also significantly improved heart function indicated by ejection fraction measured by PV-loops and ECG when compared to saline, Bare-A and ACM treatment. In addition, all cell treated groups (single cells, Bare-A and ACM-A) have partially restored the maximum and minimum rate of pressure change in left ventricle. ACM-A treatment significantly improved stroke volume and cardiac output compared to saline and ACM, and the time constant of isovolumic pressure relaxation (tau) when compared to saline treated ones, as well as the volume of left ventricle of LV end-systolic volume and end-diastolic volume compared to Bare-A and ACM. Noticeably, the measurements of those parameters indicated that ACM-A treated mice have more consistent recovery when comparing to those treated with single cells or Bare-A which have large variations, probably due to the existence of granuloma and resultant immune response in over half of the mice.

Furthermore, the ACM-A treatment significantly reduces fibrosis and inflammation compared to all other treatments 28 days after injection, which in turn should contribute to the high survival of WT MI mice with the ACM-A treatment. To find out if the significantly improved survival and the therapeutic benefit with the ACM-A treatment are partially a result of cardiac regeneration of the aggregated cells in situ, we injected the ACM encapsulated, pre-differentiated GFP-mESC aggregates into WT MI mice. Extensive fluorescence of GFP is evident in and beyond the whole MI zone 28 days post injection, suggesting the implanted cells survived, detached from the aggregates, and migrated throughout the MI zone and to proximal areas. By counting the GFP cells, it is determined that 47% of injected cells are retained in the heart 28 days post injection. This is much higher than single cells (7.3%) and Bare-A (17.6%) as well as that reported in previous studies5. Moreover, CM-like cells with green fluorescence are observed in the MI zone, indicating direct differentiation of the implanted cells into CMs. Furthermore, the green fluorescent CMs integrated with the neighboring non-fluorescent native CMs (Fig. 2), indicating the micromatrix was biodegraded allowing for timely integration of the implanted cell derived CMs and native ones. This is further supported by the expression of three typical markers of CMs including cTnI, connexin 43, and alpha-actinin in the green fluorescence CM-like cells derived from the implanted cells.

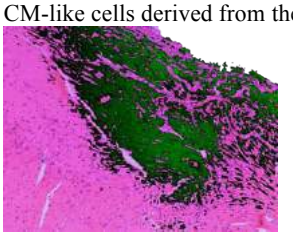

Figure 2: Low magnification GFP merged views of H&E stained tissue from left ventricle of MI heart of WT mice 28 days after treated with ACM aggregates, showing their integration with the neighboring non-fluorescent native host tissue.

DISCUSSION

ACM encapsulation of pre-differentiated microscale mESC aggregates improves the cell retention after intramyocardial injection and provides a temporary "local immunosuppression" for the aggregated cells to prevent early animal death due to acute inflammatory and immune reactions. The implanted cells have superb capability of regenerating cardiac tissue in situ via direct differentiation into not only CM- but also endothelial-like cells, to significantly reduce fibrosis and enhance cardiac function, which ultimately contributes to the significantly improved animal survival. Considering the proven biocompatibility of alginate and chitosan in the ACM, the micromatrix encapsulation technology may be valuable to facilitate clinical applications of SCT for treating MI and possibly many other diseases.

A NOVEL DISTRACTIVE AND MOBILITY-ENABLING LUMBAR SPINAL ORTHOSIS

Daniel C. Hillyard (1), Denis J. DiAngelo (1)

University of Tennessee Health Science Center
Memphis, TN, U.S.A.

INTRODUCTION

Low back pain (LBP) affects 60% to 90% of individuals at some point in their life[1], and as many as 5.4 million Americans are disabled annually as a result of LBP[2]. Most lumbar orthoses are marketed to treat LBP and provide amounts of immobilization, stabilization, or spinal decompression. Studies have suggested that with adequate frequency and duration of treatment, conservative treatments that decompress the spine and allow movement, such as water therapy, can be beneficial in the treatment of LBP[3-4]. More recently, dynamic orthoses that claim to axially decompress the spine have been introduced, but no supportive data exist. The objective of the study was to design a distractive mobility-enabling orthosis that applied a distractive load across the lumbar spine while allowing the user to move with minimal resistance.

METHODS

Distractive Mobility-Enabling Orthosis (DMO). The DMO (Fig. 1A) consisted of a distractive force component (DFC) and a mobility-enabling component (MEC). The DFC (Fig. 1B) was comprised of a flexible rod (anchored to the pelvic belt), a rod clamp, a non-deformable ring (attached to the upper torso glove), and a cable pulley array system. The cable system was connected between the lower part of the ring and the upper part of the flexible rod. As the user applied tension to the cable system the rod deformed downward creating an upward force on the ring. As cable tension increased more distractive force was applied between the the upper torso glove and the belt. The MEC (Fig. 1C) consisted of three tie rod ends attached to an interface plate mounted to the torso glove. The tie rod ends were guided by the ring to provide flexion and extension. The location of the ring was adjustable with the design goal of aligning the center of the ring with the center of rotation (CoR) of the lumbar spine.

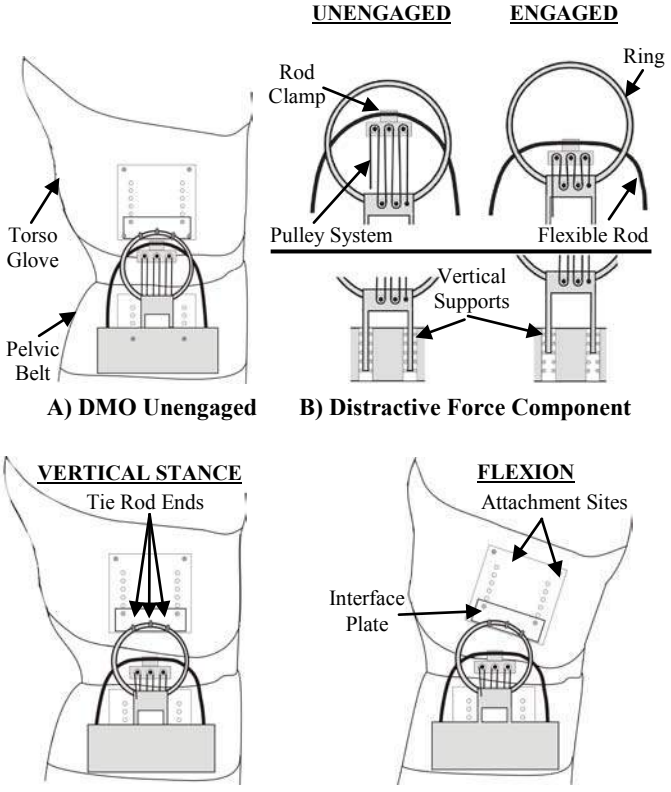

Figure 1: The Distractive Mobility-Enabling Orthosis.

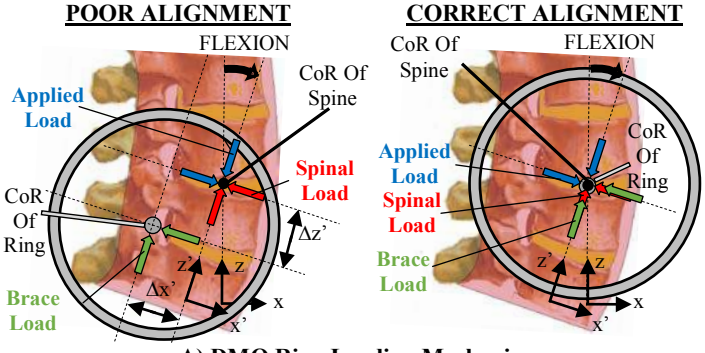
Robotic Testing Platform and the Human Mechanical Analog. A robotic testing platform[5] (RTP) was used that provided four programmable degrees of freedom and included two load cells: an upper load cell (ULC) and a bottom load cell (BLC). The ULC measured applied loads and moments and the BLC measured loads and moments transferred through the spine. A previously validated human mechanical analog of the upper torso, lumbar spine, and pelvic girdle was mounted in the RTP and used for simulation testing[5].

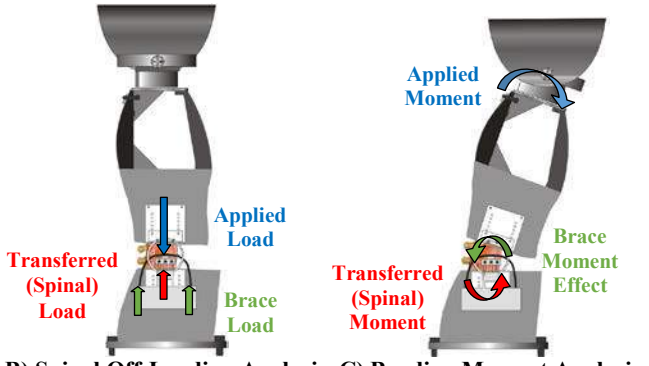
Testing Protocol and Force Analysis. The DMO was placed on the mechanical analog with the ring CoR aligned with the previously determined CoR of the lumbar spine[6]. This step minimized any off-axis loads from being applied to the orthosis (Fig. 2A). If the alignment of the ring is poor, the brace load will enduce additional resistance to bending (brace load force component multiplied by its respective distance from the CoR of the lumbar spine). Two test conditions were simulated: vertical stance and extended ranges of flexion (25deg) and extension (10deg). An upper torso load of 300 N was applied during both tests. The ULC and BLC loads and moments were transformed to the sacral disc plane. Differences between them represented the spinal off-loading (or brace load, Fig. 2B) and resistance to bending (brace moment effect, Fig. 2C) of the DMO.

RESULTS

The off-loading capacity of the DMO is shown in Fig. 3. The DMO supported 98%, 99%, and 102% of the 300N applied vertical torso load during vertical stance, at 25 degrees of flexion, and at 10 degrees of extension, respectively. The DMO contributed 6.6 Nm of the 21.7 Nm (about 30%) and 4.4 Nm of the 10.9 Nm (about 40%) of the bending moment required for 25 degrees of flexion and 10 degrees of extension, respectively (Fig. 4).



A) DMO Ring Loading Mechanics



B) Spinal Off-Loading Analysis C) Bending Moment Analysis

Figure 2: Force Analysis of the DMO

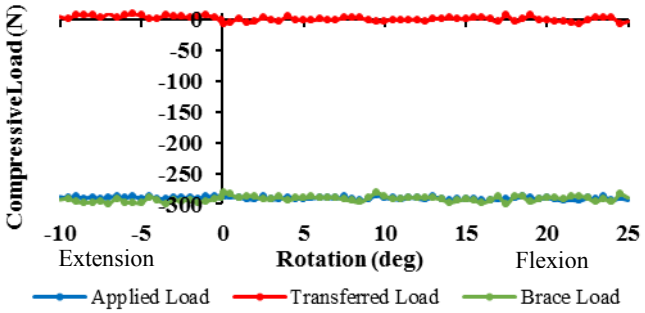


Figure 3: Spinal Off-Loading of the DMO.

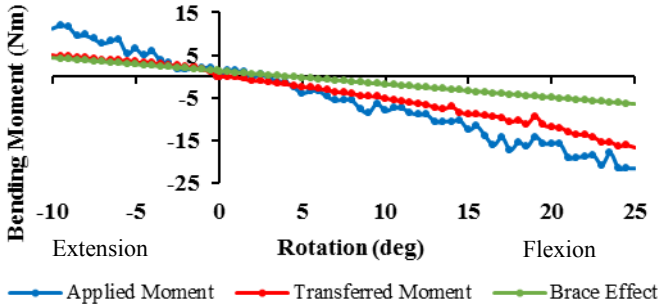

Figure 4: Resistance to Bending of the DMO.

DISCUSSION

The DMO reduced all spinal loading in upright stance and continued off-loading throughout extended ranges of flexion and extension with minimal brace bending resistance required. No literature has been found that contains laboratory data that demonstrates the efficacy of a dynamic lumbar orthosis. A 300 N torso load simulated an upper body weight of a 170lb person[7]. Aligning the center of the ring close with the CoR of the lumbar spine minimized additional bending moment required to move. The vertical torso load and the brace load act through approximately the same point of rotation minimizing the effect of off-axis force contribution to the effort required to bend. Lower brace effect moments compared to the moments transferred to the spine demonstrated that the DMO's resistance to bending was much lower than the spine's contribution; a desired outcome. Some limitations of the study were that the in vivo spinal bending moments were ignored, motion was limited to the sagittal plane, and flexion and extension ranges were limited by the physical size of the RTP.

ACKNOWLEDGEMENTS

John Simmons completed an initial DMO prototype and developed the testing protocol with assistance from Daniel Wido. Denis DiAngelo and John Simmons have a patent (U.S. Patent Application Serial No. 14/209,925) entitled "Lifting Distraction Back Support Device" on this device.

INTRODUCTION

Traumatic brain injury (TBI) is a devastating cause of death and disability. Although damage to brain tissue is the fundamental concern in TBI, nearly all significant traumatic brain injuries include some element of injury to the blood vessels [1, 2], and any injury or dysfunction of the vasculature puts neural tissue at risk. Cerebrovascular dysfunction is a common outcome of TBI and can occur even in the absence of brain hemorrhage. Much is unclear about the mechanisms behind vascular impairment; however, we hypothesize that it is in part due to subfailure damage of the vascular wall.

Little is known about the nature of damage that arteries incur as a result of overstretch. We recently presented the novel application of collagen mimetic peptide (CMP) to characterize collagen disruption in axially overstretched cerebral arteries [3]. Results showed that damage occurred primarily among the axially oriented fibers within the adventitia. Furthermore, we demonstrated that the strength of the CMP signal was correlated with overstretch magnitude.

The objective of the present study was to characterize the nature of collagen damage following overstretch in different directions. Isolated sheep cerebral arteries were subjected to circumferential overstretch. CMP was again used to identify mechanically disrupted collagen. Results were compared to the axial overstretch case.

METHODS

Dissection and Sample Prep: A sheep head was obtained from a collaborating lab on campus. Immediately after death, the brain was removed and middle cerebral arteries (MCA) were dissected from the brain. Straight lengths of the MCA were cut into 3-5 mm segments (n=2) and branches ligated with unwound 6-0 suture.

Mechanical Testing: Mechanical testing was performed with an apparatus and methods similar to those described previously [4]. Briefly, each segment was cannulated with hypodermic needles and secured with 6-0 suture and cyanoacrylate glue. Samples were preconditioned to determine the *in vivo* configuration through a series of pressure cycles at varying axial stretches. Segments were then removed from the needles and cut into rings approximately 1 mm long (n=14). Two 28 gauge hypodermic needles were fed through the lumen of each ring and separated to circumferentially distend it beyond *in vivo* diameter (strain rate ≈ 0.025/s). Five of the samples were stretched to failure. Control rings (n=4) were not overstretched.

Staining for Collagen Fiber Damage: Immediately after overstretch, samples were removed from the testing needles and incubated for 1 hr in a PBS solution containing 20 μM of CF-CMP (CMP with a carboxyfluorescein tag for visualization) at 4°C. Following incubation, samples were rinsed in PBS (3x, 10 min also at 4°C), cut open circumferentially, and laid flat on a glass slide for imaging.

Confocal Imaging and Analysis: Samples were imaged at 10x (512 x 512 pixels) using a laser scanning confocal microscope (Fluoview 1000; Olympus). Serial slices were taken through the vessel wall in 2 μm increments. Using a custom MATLAB script, adjacent stacks were stitched together to form a single montage covering the full circumference of the vessel.

The CMP signal was quantified by calculating the average pixel brightness of the tissue and normalizing it relative to its control. The local strain associated with each imaged region was calculated based on the motion of the microspheres enveloping it. In the case that a sample was stretched to failure, the CMP signal and maximum strain were quantified away from the failure site.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

CMP binding to mechanically damaged collagen: The CMP effectively bound to mechanically damaged collagen following circumferential overstretch. Figure 1 shows the strong fluorescent CMP signal in a sample stretched to failure compared to the negligible signal of a control.

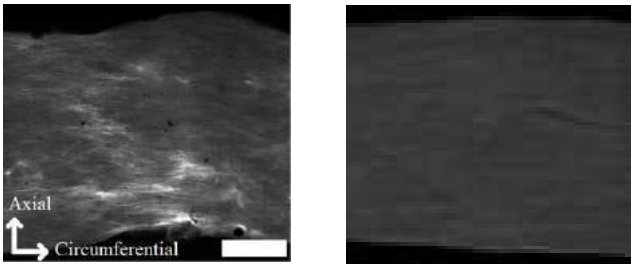

Figure 1: CMP fluorescence in the media of an artery stretched to failure (left) and control (right). Legend and scale bar (200 µm) apply to both images.

Location and Orientation of Damaged Fibers: In addition to increasing the fluorescence of damaged samples, the CMP signal localized the damaged fibers within the wall. The signal was found to primarily originate in the media and have a circumferential orientation (Fig 1).

Increased Signal with Overstretch Severity: The CMP signal was also found to increase with circumferential overstretch severity (Fig 2). The reported damage was calculated for a single slice within the media.

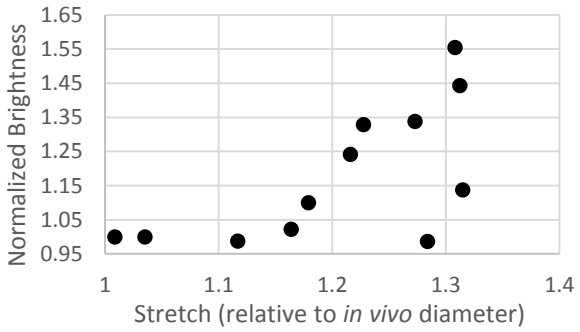

Figure 2: Normalized brightness of tissue within the media vs. stretch following circumferential loading.

DISCUSSION

Binding of CMP to mechanically damaged collagen in arteries is a novel discovery for the field of soft tissue biomechanics. CMP provides a non-destructive approach for localizing damaged collagen within the arterial wall. This is in contrast to SEM, TEM, and histological methods which require serial slicing to reveal subsurface damage. Furthermore, this approach effectively reveals the orientation and depth of the damaged fibers as well as strain-damage relationships.

First, the CMP bound along the length of the damaged fibers – revealing that the orientation of the damaged fibers aligned with the direction of loading. This was also true in our previous investigation of axial loading where the damage was found primarily among the axially oriented fibers. These finding are in agreement with the well-established role of collagen as the primary load bearing constituent in arteries [5].

Second, as in the previous study, the CMP bound in a depth-specific manner – revealing that circumferential loading primarily damages collagen within the media. In contrast, axial loading resulted in damage within the adventitia. Both of these findings are supported by the fact that longitudinally oriented collagen fibers are primarily found in the adventitia and that the media is rich with circumferentially oriented fibers [5].

Finally, the quantitative results in this study shed light on the threshold and distribution of collagen damage. Figure 2 shows that CMP intensity first rose above control values when stretched at least 15% beyond the in vivo diameter. Additional analysis needs to be done to understand the outliers in the graph as well as to compare this trend to that previously reported for axial loading.

These findings have significant implications for better understanding the nature of vascular damage in TBI. Vessels resected following TBI can be stained with CMP to characterize collagen damage and elucidate additional mechanisms at play in vascular dysfunction. Furthermore, the reported direction-dependent nature of vascular damage (and the CMP signal) may also increase understanding of the modes of vascular loading if observed following TBI.

INTRODUCTION

Characterizing the evolution of the structural and mechanical properties of cardiac tissue after myocardial infarction (MI) is critical toward understanding the disease and creating better treatment strategies. Comprehensive biomechanical models of the infarcted heart can improve virtual surgery technologies and medical device development, as well as provide quantitative risk stratification tools for these interventions. However, cardiac tissue is highly heterogeneous, containing a complex mixture of cellular and matrix components that span several length scales. Moreover, due to its fiber structure, myocardium is distinctly anisotropic and highly nonlinear, requiring the acquisition of three-dimensional stress-strain relations in order for its mechanical properties to be properly characterized. These factors make creating physiologically realistic models of the behavior of myocardium especially challenging. Existing models of myocardium are based on very limited sets of extant biomechanical data, most often obtained from biaxial testing. Many underlying assumptions are necessary for three-dimensional generalization due to the utter lack of three-dimensional data. In addition to rigorous characterization of the behavior of normal myocardium, there is also a need to optimize the deployment of MI treatments (e.g., degradable hydrogels injected into the infarct site). This is severely hindered by not only the shortcomings of current models, but also the lack of understanding of the evolving mechanical properties of the infarct region over time.

Herein we propose a unified framework that utilizes an integrated numerical-experimental approach to investigate changes in the mechanical behavior of infarcted ovine myocardium from early to fully developed states. This work serves as a basis to advance and motivate more realistic mechanical models of myocardium for effectively evaluating future treatment strategies after MI.

METHODS

Preparation of Infarcted Ovine Myocardium Samples

Three adult 40-kg Dorset sheep were subjected to coronary ligation of the left anterior descending and second diagonal coronary artery, causing infarctions located around the apex of the left ventricle [1]. The hearts were explanted at 2, 4, and 8 weeks after the initial infarction, one sheep per time point, and the size and location of the infarcts were assessed. A sheep with no induced infarct was used as a healthy negative control and considered as a 0 week time point.

Bulk fiber orientation was estimated throughout the infarct region, and adjacent ~1x1x1 cm cuboidal samples were cut out in which the bulk fiber orientation was orthogonal with a cube edge (Figure 1). Samples were sectioned for both structural measurements and testing for mechanical properties (see below).

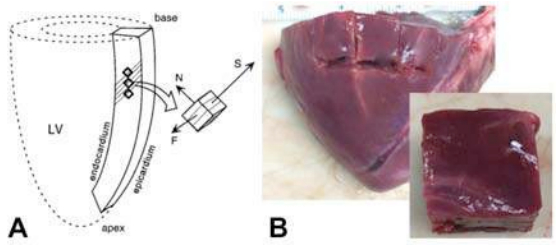

Figure 1: (A) Schematic of strategy for obtaining myocardium samples [2]**. (B) Sample collection (non-infarcted tissue shown).**

Three-Dimensional Mechanical Testing of Infarcted Myocardium

We have constructed a novel triaxial loading device (Triaxial EXperimental Analysis and Simulation, TEXAS) for acquiring the experimental data necessary to represent the three-dimensional mechanical properties of soft fibrous tissue (Figure 2A). The TEXAS

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

is capable of simultaneously applying a full range of three-dimensional deformation modes on cuboidal tissue samples, and it has been previously validated in determining the stiffness of synthetic gels in individual tensile, compressive, and simple shear.

The infarct samples were mounted using a nine pin attachment arrangement on each face of the cube (Figure 2B), and a set of tension, compression, and shear deformations was performed, both along the major axis direction of the tissue (aligned with the mean fiber direction) and along the two orthogonal cross-fiber directions. The data was then utilized to determine orthotropic constitutive relations of the infarct samples with an inverse modeling approach (see below).

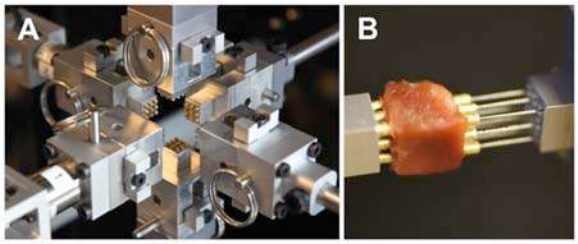

Figure 2: (A) Close-up of actuators and attachment pads of the TEXAS. (B) Myocardium sample attached.

Fiber Structure from Transmural Small Angle Light Scattering (SALS)

Transmural SALS employs a low power laser beam to raster scan planar sections of soft tissue [3], then computationally reconstructs the original three-dimensional tissue structure with unique rank tensors at each position that determine the overall directions of alignment for each plane, as well as boundaries of high-alignment regions [4].

Samples for structural characterization were first histologically analyzed. Subsequently, each cube was sectioned into ~40 planes along the transmural axis, approximately normal to the principal fiber planes. Using transmural SALS, we analyzed the samples with circumferentially varying fiber directions for each plane and compounded the three-dimensional local arrangement of the fibers to be utilized in our previously developed inverse modeling approach [5].

Inverse Modeling with Finite Element Simulations

The mechanical behavior of healthy and infarcted myocardium can be characterized by a stored energy density function $W(\mathbf{F})$, where $\mathbf{F}$ is the deformation gradient. The relation for the first Piola-Kirchhoff stress tensor $\mathbf{P}$ in terms of W is written as:

$$\mathbf{P} = \frac{\partial W}{\partial \mathbf{F}} - p\mathbf{F}^{-\mathrm{T}} \tag{1}$$

where p is the hydrostatic pressure. The orthotropic Fung-type material was employed:

$$W(\mathbf{E}) = \frac{1}{2}c_0\left[e^{Q(\mathbf{E})} - 1\right] \tag{2}$$

where $\mathbf{E} = (\mathbf{F}^{\mathrm{T}}\mathbf{F} - \boldsymbol{I})/2$, $\boldsymbol{I}$ is the identity tensor, c_0 is a positive constant, and Q is given by:

$$Q = c_1E_{11}^2 + c_2E_{22}^2 + c_3E_{33}^2 + 4c_7E_{12}^2 + 4c_8E_{13}^2 + 4c_9E_{23}^2 \tag{3}$$

Our inverse modeling approach is based on finite element (FE) simulations corresponding to the deformations performed in the TEXAS experiment. In the simulations, the stress-strain data collected from the TEXAS and the local fiber directions obtained from transmural SALS were incorporated into the inverse modeling FE problem and the mechanical properties of the infarct samples at the 0, 2, 4, and 8 week time points were determined through nonlinear least-squares regression (Figure 3).

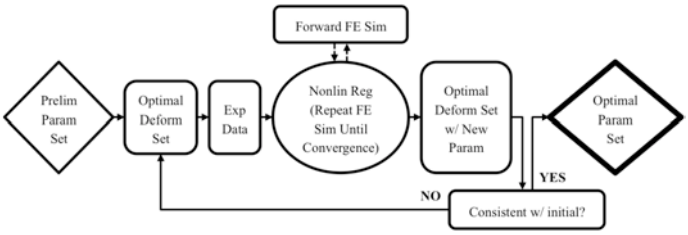

Figure 3: Overall combined numerical-experimental approach. FE simulations are repeated until convergence is reached.

RESULTS

Our inverse modeling analysis confirmed that the transient stiffness properties of the infarct samples increased nonlinearly over 8 weeks. Representative stress-strain plots for tension and shear also showed strongly nonlinear behavior (Figure 4A). From the local fiber orientation distribution functions, we obtained the planar fiber distributions (Figure 4B) to develop the FE simulations for our inverse model (Figure 4C).

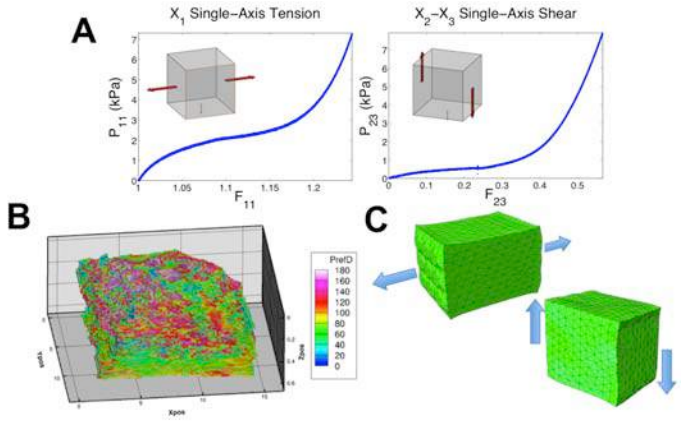

Figure 4: (A) Representative tension and shear stress-strain curves for healthy ovine myocardium. (B) Three-dimensional preferred fiber direction of collagen in an ovine infarct sample. (C) Corresponding FE simulations.

DISCUSSION

We have been able to successfully integrate structural and mechanical experimental components into a simple mechanical model for infarcted myocardium that shows the evolution in the mechanical properties of the infarct over time. Our next steps are to continue increasing the detail of our material modeling and expand the complexity of deformations performed in the TEXAS. This information will lead to more fully realistic models of healthy and infarcted myocardium to be incorporated in organ-level modeling of heart function and to aid in the *in silico* development and optimization of treatment interventions after heart attack.

INTRODUCTION

Glaucoma is a debilitating cause of vision loss affecting millions of people worldwide, and although treatments exist, they unfortunately do not work for all individuals. A large body of evidence suggests that ocular biomechanics is intimately involved in the development and progression of glaucoma, particularly evidenced by the causative risk factor of elevated intraocular pressure (IOP) [1]. All clinical treatments operate on the paradigm of lowering IOP, and there is presently no alternative when this approach fails.

Some have suggested [2] benefit in stiffening the sclera (the white outer coat of the eye) to help counteract the biomechanical consequences of elevated IOP. Animal models of glaucoma can be used to screen such an approach. One such model uses the rat, which has been extensively employed to study the pathogenesis of glaucoma [3]; however, the biomechanics of rat sclera has not been tested, nor has its response to stiffening agents. Here we used inflation testing of rat eyes treated with the stiffening agent glyceraldehyde [4] to study the effects of dose and age on the magnitude of scleral stiffening achieved. We hypothesized that glyceraldehyde would induce a dose-dependent stiffening of rat sclerae and that age would not significantly impact this effect in adult rats. Such characterization is important as we evaluate glyceraldehyde and other agents in modulating scleral biomechanics in the rat model of glaucoma.

METHODS

Eyes from freshly-euthanized Brown Norway rats were incubated overnight in either PBS or glyceraldehyde solution (either 0.25M or 0.125M, made in from a 0.5M solution in PBS diluted with deionized water to approximate physiological osmolarity in the final solution). Two different age groups of female, retired breeder rats purchased from Charles River were used in this study: Group A rats were 6-9 months old (exact ages unknown, as retired breeder dates of birth are not routinely transmitted upon purchase), and Group B rats were approximately 1.5 years old. Using 3D digital image correlation (DIC) techniques, we quantified the relative magnitude of stiffening by inflating whole eyes to simulate conditions of normal and elevated IOP. Eyes with sclera cleaned of all loose connective, fat, and muscle tissue were mounted on a custom-milled acrylic block that cradled the eye and incorporated an access channel for IOP modulation (Figure 1). We glued eyes cornea-side down using a thin coat of gel-style super glue and applied a speckle pattern of graphite powder to the exposed sclera using a fine mesh flour sifter and air brush. After waiting approximately 3 minutes for the eye to dry, it was rinsed in PBS to rehydrate and wash away excess graphite. Next, a 1mm diameter biopsy punch was inserted through the access channel to puncture the cornea. The biopsy punch was retracted and a Luer fitting was glued to the channel, which was purged of air by flushing with PBS. This mounting block was subsequently attached to a hydrostatic pressure reservoir set initially to 5 mmHg, and was immersed in a room temperature saline bath.

Using a pair of calibrated stereo cameras (AVT Stingray 504B) fitted with 50 mm lenses, we acquired 3D images of the surface of the posterior sclera over a period of 10 minutes per pressure step from 5 to 30 mmHg in increments of 5 mmHg. Images were correlated using Istra 4D 4.1.1 software (Dantec Dynamics), and first principal strain values were exported to Matlab R2016a for further processing. We computed the average strain magnitude of facets falling between the 25th and 75th percentiles to eliminate outliers, and we estimated the average stress in the posterior sclera using the assumption of a thin-walled spherical pressure vessel with a diameter of 6.5 mm and a thickness of 100 μm. Assuming transversely isotropic material properties with negligible radial stress and near incompressibility (ν=0.49), initial estimates of Young's modulus were obtained at 15 mmHg from the estimated

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

principal stresses (assuming first and second principal stresses are equal and third is negligible [5]) and the average first principal strain at this pressure for each eye, as:

$$E = (\frac{\sigma(1-\nu)}{\varepsilon_1}$$

This is a simplification of the material properties of this complex biological tissue but is sufficient for this initial comparative study investigating the relative magnitudes of stiffening.

One eye's strain decreased with increasing pressure (Group A, PBS) and was excluded as a technical failure. Finally, using R 3.2.2, we computed statistical likelihoods of differences using ANOVA. To differentiate between Young's modulus, we used a 3-factor split-plot model accounting for age, subject, control or treated eye, and dose. To differentiate between relative stiffening, we used a two-factor cross-factored model for both age and level of stiffening.

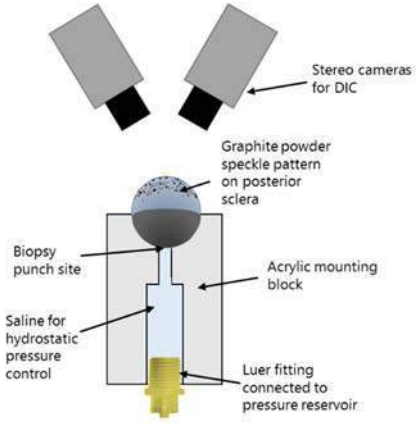

Figure 1: Rat eyes were mounted in an acrylic holder, corneas were punctured with a biopsy punch, and intraocular pressure was modulated with a hydrostatic pressure reservoir while stereo cameras imaged the posterior sclera.

RESULTS

Treating eyes overnight with glyceraldehyde significantly reduced mechanical strain at all pressure levels (Figure 2). At an inflation pressure of 15 mmHg, the estimated Young's modulus was increased by a factor of 2.24 ± 0.40 (mean ± SD) for 0.125M and 4.51 ± 2.49 for 0.25M when compared to PBS controls ($p = 0.011$) (Figure 3). When comparing relatively younger adult rats (Group A) to very old rats (Group B), we did not detect a significant difference between control eyes and eyes stiffened at 0.125M or eyes stiffened at 0.25M ($p = 0.26$).

DISCUSSION

Glyceraldehyde has a powerful stiffening effect on rat sclera, consistent with prior findings in mice [4], and even at moderate doses can more than double the relative stiffness of the sclera. This finding is important because high concentrations of stiffening agents could have off-target biological consequences if delivered clinically, while even relatively lower doses may have a strong stiffening effect. Further, we did not see a difference in either baseline stiffness or in susceptibility to glyceraldehyde stiffening between young adult rats and very old rats, increasing our flexibility for using this animal model of a disease strongly associated with advanced age in humans. Future steps to characterize the ocular biomechanics of the rat will include investigation of additional stiffening agents and concentrations as well as fitting the stress-strain relationship to nonlinear models of mechanical stiffness, as the modulus at a single magnitude of IOP provides only a limited description of rat ocular biomechanics.

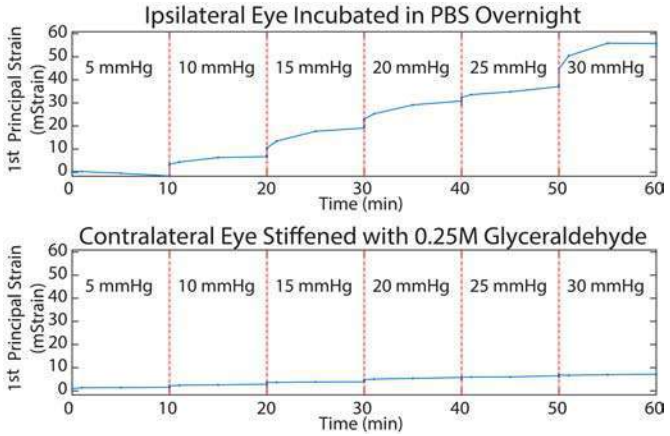

Figure 2: Representative strain vs. time at 6 pressure increments for a single rat from Group A. Scleral strain is much higher in the control eye than the contralateral stiffened eye, indicating that glyceraldehyde has a strong stiffening effect in the rat eye.

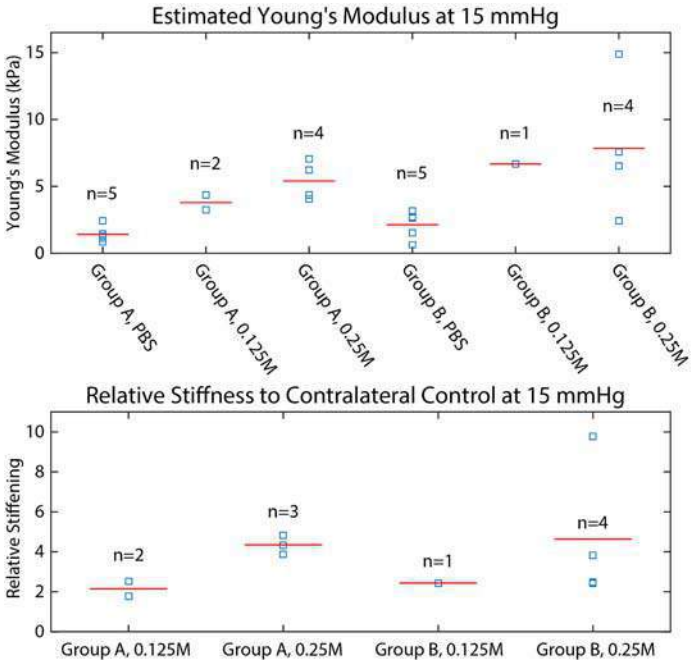

Figure 3: Glyceraldehyde increased the estimated Young's modulus at 15 mmHg in both ages of rats (Group A and Group B, top) relative to contralateral eyes incubated in PBS (bottom). Red lines are means for each group.

PHYSIOLOGICAL BASIS FOR RATIONAL CRYOTHERAPY PROTOCOL DESIGN

INTRODUCTION

Cryotherapy is used widely to manage the pain, swelling, and inflammation associated with soft tissue injury [1]. Many methods are based on the melting temperature of ice, either by direct application of an ice bag or by circulation of melted water from a cryotherapy unit (CTU) and do not accommodate protocol design based on a scientific understanding of the tissue response to low temperatures. A second major protocol parameter is the length of time and the frequency of application of cold to tissue. Cryotherapy practice varies dramatically among various practitioners [2], and may be recommended for use intermittently [3] or continuously [4], with each episode lasting for as briefly as 10 minutes to as long as multiple days. There are numerous publications that present anecdotal observations of the clinical benefits of cryotherapy as well as many reports on complications arising from its use [5–9]. The resulting injuries may range from nerve damage [9] to full thickness skin necrosis [5], typically as a consequence of the prolonged diminution of local blood flow in conjunction with the low temperature [10]. Most CTUs can and do produce temperatures far below the range for which significant diminution in blood flow occurs.

The surface application of cooling causes a reduction of skin temperature that gradually penetrates into the tissue. The extent to which the cooling penetrates depends on tissue type and its degree of perfusion and metabolism. This reduction in tissue temperature results in localized vasoconstriction and a profound reduction in perfusion to the area under treatment. Upon cessation of surface cooling, the skin temperature begins to increase while the deeper cold front is still propagating into the tissue. This increase in skin temperature does not directly translate into a rise in tissue perfusion. To clarify, the relationship between perfusion and tissue temperature shows a hysteresis effect such that the reduction in tissue temperature during surface cooling causes a direct decline in tissue perfusion, but the subsequent increase in temperature is not necessarily accompanied by an equivalent increase in perfusion [11]. This sustained vasoconstriction after removal of localized cooling can last for an extended period of time (hours), resulting in a reduced state of tissue perfusion at elevated tissue temperatures.

Cold-depressed skin perfusion can be enhanced by active surface heating. This understanding of the physiological response to localized heating or cooling may be applied to manipulate cryotherapy outcomes. Cold-induced vasoconstriction causes tissue starvation of nutrients and oxygen, plus a buildup of metabolic byproducts. Heat-induced vasodilation has the opposite effects. Therefore, inclusion of intermittent heating episodes during cryotherapy can be applied to modulate the time progression of blood flow to ensure adequate tissue nutrition. Accordingly, a cryotherapy protocol that includes intermittent cooling and warming episodes is anticipated to combine cooling therapy benefits with improved tissue healing.

METHODS

Experimental Procedure: Each subject was instrumented by applying multiple thermocouples, heat flux gauges (Omega) and Laser Doppler flowmetry probes (LDF, Moor Instruments) to his/her thigh. A flexible silicone heater (Chromalox) was used to allow active warming during the heating portion of the protocol. Heaters had built-in holes to allow application of perfusion probes through them during the experiment. The cryotherapy pad was applied at the treatment site such that it completely covered the heater in addition to a segment of the skin adjacent to the heater. This allowed for an area of the skin to be only cooled (control region) while another segment could be either cooled or heated (experimental region) based on the portion of the protocol. At each point of time during the active heating or cooling either the heater (heating) or CTU (cooling) was on. A perfusion probe

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

was applied to the region that only experienced active cooling (control probe) and two more probes were applied to the area that experienced both active heating and cooling (experimental probes). Data was collected using the National Instruments thermocouple (NI9213) and voltage (NI9215) modules, a data acquisition chassis (NI 9174) and a host computer and was analyzed using Matlab. Each experiment started with a baseline period where no water ran through the cooling pad followed by active cooling. The active cooling was intermittently interrupted by the inclusion of an active warming episode into the protocol.

Data Processing: Area under the curve was calculated for perfusion measured in both the experimental and control regions. This area was calculated in relation to an average baseline of zero and was considered to signify a deficit in perfusion in response to cooling and in respect to a continuation of baseline condition if cooling had not taken place. The total deficits were compared between the two regions (control and experimental). Additionally, recovery was defined as the area under the curve in respect to the minimum perfusion at the end of cooling for the active heating segment and compared to the deficit for the cooling episode prior to it.

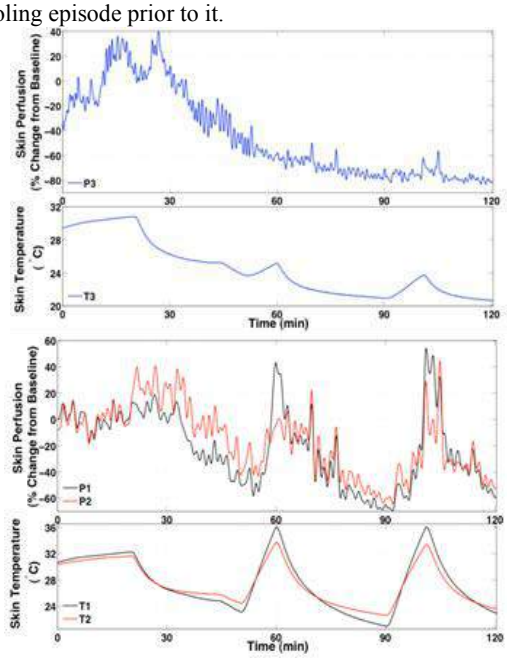

Figure 1: Plots of temperature and perfusion during cryotherapy trials. The upper data in blue show cooling interrupted for 10 min at 50 and 90 min with only passive rewarming. Lower plots in red and black substitute 10 min of active rewarming at 50 and 90 min.

RESULTS

Figure 1 illustrates surface skin temperature (bottom panels) and skin perfusion (top panels) from an exemplar experiment showing data from a perfusion probe in the control (top figure, blue) and experimental region (bottom figure, red and black). This experiment included a baseline, three cooling and two heating episodes. The first two cooling episodes lasted for 30 min each and the 3rd for 20 min while each heating episode was 10-min long. The control region, in the absence of active heating, experienced passive rewarming between each two consecutive cooling phases. As it can be seen with the control probe the skin temperature dropped considerably with active cooling and increased with its termination. As expected, the skin temperature increased more profusely with active heating in experimental region. During active cooling, perfusion encountered a significant reduction in both experimental and control regions while an increase in skin perfusion was only observed when active heating was present (experimental site). For this exemplar experiment, the total deficit was an order of magnitude higher for the control probe compared to the experimental probes. Additionally, the deficit and the recovery for the experimental probes were in the same order of magnitude. So even though the perfusion remained depressed during the duration of experiment, the inclusion of intermittent heating into the protocol allowed replenishment of oxygen and nutrients and removal of metabolic byproducts for brief time intervals.

DISCUSSION

There is now emerging a scientific basis for the rational design of cryotherapy protocols based on a coordinated manipulation of time and temperature of exposure. Although many variations are possible, the objective is to balance the benefits of low temperatures on reducing pain with the potential risk of inducing ischemic driven injury resulting from low temperature. The key to achieving an acceptable balance is intermittent rewarming at the treatment site. This type of protocol is difficult, although not impossible, to produce with a CTU that operates based on melting temperature of ice. An alternative that offers multiple advantages is to apply thermoelectric coolers (TEC) in the design of a CTU. TEC allows modulation of the active CTU temperature by regulating the magnitude and polarity of applied voltage. The result is the ability to change the therapeutic temperature continuously between values far below to far above the physiological range independently as a function of time and with a single CTU. When combined with a quantitative understanding of how blood flow can be manipulated by the applied temperature, the opportunity now exists for rationally designing and applying cryotherapy protocols to produce targeted therapeutic outcomes with minimized risk of ischemic injury side effects.

SUSTAINED PRESENTATION OF NEUROTROPHIC CUES FOLLOWING TRAUMATIC BRAIN INJURY THROUGH MATRIX IMMOBILIZED BDNF FRAGMENT PEPTIDES

Christopher J. Lowe (1), David I. Shreiber (1)

(1) Department of Biomedical Engineering
Rutgers, the State University of New Jersey
Piscataway, NJ, United States

INTRODUCTION

Traumatic Brain Injury (TBI) is a devastating condition that often has long-lasting and life-altering effects. The initial, physical, primary injury is followed by a persistent, inflammatory secondary injury cascade. Cellular damage and death from primary injury occur instantaneous to the injury, but secondary injury persists for weeks and months after the initial insult, offering a potential opportunity for treatment. An obstacle to treatment is the complex, hostile nature of the secondary injury environment, which includes oxidative stress from free radicals, glutamate induced excitotoxicity, mitochondrial dysfunction, and cell death. Delivery of neurotrophic factors to the site of TBI has shown some promise in alleviating these symptoms, particularly with brain derived neurotrophic factor (BDNF). BDNF is critical to neuronal development and survival, but is rapidly cleared in vivo and it is unable to cross the blood-brain barrier at a therapeutically relevant rate, which limits its therapeutic potential. Recently, Cardenas-Aguayo et al identified short peptide fragments derived from BDNF's sequence that mimicked the activity of the full length growth factor [1]. Our laboratory has routinely created functional biomaterials by covalently grafting peptides and small molecules to collagen [2,3]. In this report, we seek to enhance the efficacy of these BDNF fragment peptides by covalently immobilizing them to a polymer matrix for sustained presentation at the injury site.

METHODS

Peptide Grafting to Collagen

The BDNF fragment peptide, IKRG, was synthesized commercially by Genscript (Piscataway, NJ). Type-I bovine collagen (Elastin Products Company, Owensville, MO) was reconstituted in 0.02N acetic acid at 3mg/mL. Peptides were coupled to amines on lysine residues in the collagen backbone via a zero length crosslinker, 1-ethyl-3-(dimethylaminopropyl) carbodiimide. The resulting solution was dialyzed to remove un-grafted peptide, lyophilized, and reconstituted at 3mg/mL in 0.02N acetic acid [2].

Hydrogel Preparation

Buffered hydrogel solutions from native or IKRG-grafted collagen were prepared using the following ratios: 20µL HEPES:130µL 0.15N NaOH:100µL 10x MEM: 53µL M199: 10µL L-glutamine: 10µL penicillin/streptomycin: 677µL 3.0mg/mL collagen solution. Hydrogels with varied peptide concentration were created by admixing grafted and native collagen hydrogel suspensions at target ratios. Hydrogel suspensions were placed in multiwell plates and allowed to self-assemble at 37°C for one hour.

Cerebellar Neuron Culture

Cerebellar Granule Neurons (CGNs) were isolated from day 6 rat pups. For neurite outgrowth assays, cells were cultured on collagen hydrogels at ~50,000 cells/cm^2 for 7 DIV in Neurobasal Medium (Life Technologies) containing 0.5% L-glutamine, 1% penicillin/streptomycin, 2% B27 supplement, and 1% potassium chloride. Soluble IKRG and BDNF were included at 1µM and 20ng/mL, respectively in requisite controls. For cellular activity assays, CGNs were plated onto poly-L-lysine (PLL) coated tissue culture plastic at ~200,000 cells/cm^2 using the same media compositions and maintained in culture for 9 DIV.

Immunocytochemistry for Neurite Outgrowth

CGN cultures were fixed on DIV 7 and stained immunohistochemically for β-III tubulin (TUJ1) and DAPI before being observed with fluorescent microscopy. Neurite outgrowth of CGNs was quantified from TUJ1 images using ImageJ.

Glutamate Induced Excitotoxicity

Glutamate induced excitotoxicity was modeled in vitro by adding 300µM or 500µM glutamic acid to the culture media for 1 hour.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Glutamate containing media was then removed and replaced with fresh media containing recovery treatments. Recovery treatments included native and IKRG grafted collagen at 0.33mg/mL, soluble IKRG or BDNF, as well as a no treatment control (media only).

Free Radical Induced Injury

Free radical injury was modeled via addition of rotenone, an inhibitor of the electron transport chain, which causes mitochondrial dysfunction and production of free radicals in a physiologically relevant way. 10µM rotenone was added to CGN cultures for 1 hour, and then replaced with fresh media containing recovery treatments described in the glutamate excitotoxicity studies.

Cellular Activity

Cellular activity for both glutamate and free radical studies was examined via Vybrant MTT Cell Proliferation Assay (ThermoFisher) using the manufacturer's instructions.

RESULTS

Neurite Outgrowth Assay

Neurites extending from CGNs cultured on IKRG-grafted hydrogel conditions tended to grow longer than those on native collagen (NC) (Figure 1). Increasing concentrations of grafted peptide corresponded to longer neurite outgrowth. CGNs cultured on IKRG-100 hydrogels, the highest peptide concentration tested, compared well with outgrowth from controls with soluble BDNF or IKRG.

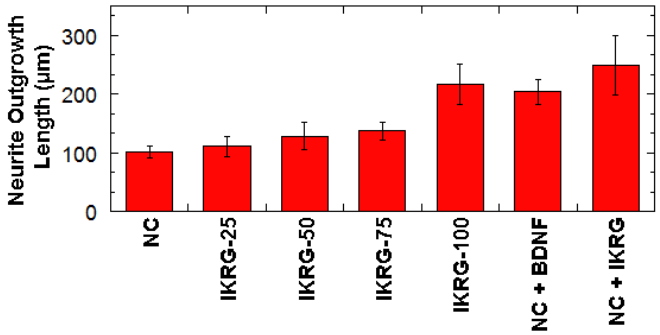

Figure 1: CGN Neurite Outgrowth on IKRG Grafted and Native Collagen (NC) Hydrogels

Glutamate Induced Excitotoxicity

CGN cultures demonstrated ~60% reduction in cellular activity following injury with glutamate. CGN cultures treated with native collagen (NC) following injury experienced a further reduction in cellular activity. CGN cultures treated with 100% IKRG grafted collagen following injury saw a twofold increase in cellular activity as compared to native collagen treated cultures, but the increase over untreated conditions was minimal (Figure 2).

Free-Radical Induced Injury

CGN cultures injured with rotenone exhibited a ~80% reduction in cellular activity. CGN cultures treated with native collagen following rotenone induced injury showed a greater than twofold increase in cellular activity. All IKRG grafted conditions showed a similar increase in cellular activity following injury as the native collagen condition. Soluble IKRG peptide induced the greatest recovery, a greater than three-fold increase in average cellular activity (Figure 2).

DISCUSSION

IKRG grafted collagen induced an observable increase in neurite outgrowth in CGN cultures. This confirms that IKRG was successfully grafted to the collagen backbone, and that the IKRG peptides retain their bioactivity following covalent coupling to collagen.

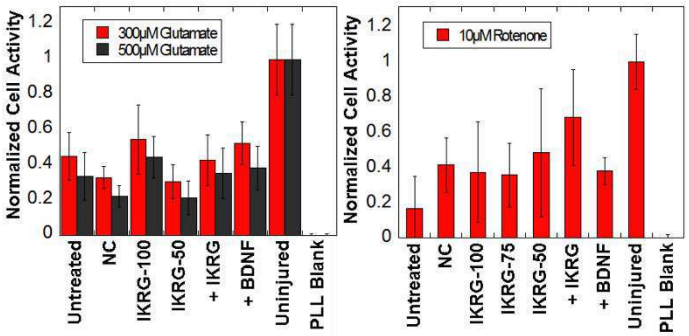

Figure 2: CGN Viability Following Glutamate Injury (Left) and Free-Radical Injury (Right) with Subsequent Recovery Treatments

Cells subjected to secondary injury were treated with native or grafted collagens at 0.33mg/mL in culture media. This concentration is too low for the collagen to self-assemble into a fully formed hydrogel network, however individual collagen molecules will partially self-assemble to generate higher molecular weight fibers. These fibers aggregate at the bottom of the culture well forming a viscous slurry, thereby presenting the grafted peptide cues in close proximity to the CGNs in a sustained manner.

Preliminary studies of glutamate-induced excitotoxicity revealed that treatment with collagen seems detrimental to CGN activity, as native collagen treatment further exacerbated the effects of the glutamate injury. IKRG grafted collagen at the highest concentrations showed a substantial increase in cellular activity as compared to native collagen, but the gains were minimal when compared to the untreated condition. This suggests that the negative effects collagen seems to be inducing in the CGNs are masking the full benefit of the grafted IKRG peptide to combat glutamate induced excitotoxicity.

Preliminary studies with free-radical injury induced by rotenone seemed to respond in an opposite manner. CGN cultures treated with native collagen following injury showed a strong improvement in cellular activity. It is possible that the collagen is serving as a sink for free radicals generated by the rotenone, sequestering the radical species away from the cells reducing the potential for further injury. No increase was observed in cellular activity as a result of incorporating the grafted IKRG peptides as compared to the native collagen conditions, indicating that the immobilized peptides may not be influencing CGN activity. The soluble IKRG peptide induced a very large recovery in cell viability following rotenone injury.

Secondary injury following TBI is inherently complex, which is highlighted by the injury-dependent responses of the CGNs to collagen treatment. Despite this, benefits to delivering IKRG were observed in both studies. Ongoing studies are examining the potential for a bio-inert matrix to serve as a carrier for the IKRG peptides, possibly eliminating the negative effects of collagen observed in glutamate studies.

NEAR-WALL STAGNATION IN LARGE ARTERIES: IS WALL SHEAR STRESS MAGNITUDE SUFFICIENT?

INTRODUCTION

Wall shear stress (WSS) is the most common parameter used to correlate blood flow with cardiovascular disease. WSS quantifies the frictional drag force on the vessel wall, and WSS vectors provide insight on near-wall transport, with the latter influencing key process including atherosclerosis and thrombosis. Likewise, near-wall stagnation is an important measure of hemodynamics, and relative residence time (RRT), defined as the inverse of time-average WSS (TAWSS) vector magnitude, is the traditional measure used to quantify near-wall stagnation. Due to the high Schmidt number in intravascular transport problems, there often exists thin concentration boundary layers next to the vessel wall and the WSS vector field can be scaled to obtain an accurate estimate of the flow velocity in these boundary layers. Using this approach, we recently introduced Lagrangian WSS structures as the organizing structures of near-wall transport and WSS exposure time (WSSET) [1]. This study investigates and compares RRT, surface concentration, WSSET, and Lagrangian WSS structures in different vascular pathologies to determine how to best quantify near-wall hemodynamics.

METHODS

WSS data were obtained from patient specific computational fluid dynamics simulations in abdominal aortic aneurysms (AAA), coronary artery aneurysms (CAA), and carotid arteries (CA). Briefly, Linear tetrahedral elements with a next to wall edge size of 200 μm (50 μ m) were used, and the time step divided the cardiac cycle into 1000 (5000) time steps in the AAA (carotid artery) models. The CAA data were used from a previous study [2] and obtained from vascularmodel.org. All the simulations were done in the open source SimVascular software (simvascular.org), based on a stabilized finite element method.

Next, near-wall transport measures were computed. RRT is computed as

$$\mathrm{RRT} = \frac{1}{\|\frac{1}{T}\int_0^T \tau dt\|}\ , \tag{1}$$

where τ is the WSS vector and T is the cardiac cycle duration. Lagrangian particle tracking of surface-bound tracers were used to generate WSS pathlines, using the near-wall velocity $\boldsymbol{u}_\pi = \frac{\boldsymbol{\tau}\delta n}{\mu} + O(\delta n^2)$, where δn is a small normal to wall distance chosen inside the concentration boundary layer and μ is the dynamic viscosity. Subsequently, WSSET was computed for each surface element as the accumulated amount of time that all the WSS trajectories spend inside the element

$$\mathrm{WSSET}(e) = \tfrac{1}{\mathcal{T}}\sqrt{\tfrac{A_m}{A_e}}\sum_{p=1}^{N_t}\int_0^{\mathcal{T}} H_e(p,t)\ \mathrm{d}t \tag{2}$$

$$H_e = \begin{cases} 1 \text{ if } \boldsymbol{x}_p(t) \in e \\ 0 \text{ if } \boldsymbol{x}_p(t) \notin e \end{cases}\ ,$$

where A_e is the area of the surface element, A_m is the average surface element area, $\mathbf{x}_p(t)$ is the position of the WSS trajectory, N_t is the total number of trajectories released, and $\mathcal{T}$ is the integration time. The WSS Lagrangian coherent structures (WSS LCS) [1] were also computed to provide insight on the near-wall flow topology. In this study, invoking the quasi-steady nature of near-wall transport the WSS LCS were directly computed from the saddle type fixed points of the time-average WSS vector field. Figure (1) depicts the procedure used in the computation of WSSET and WSS LCS.

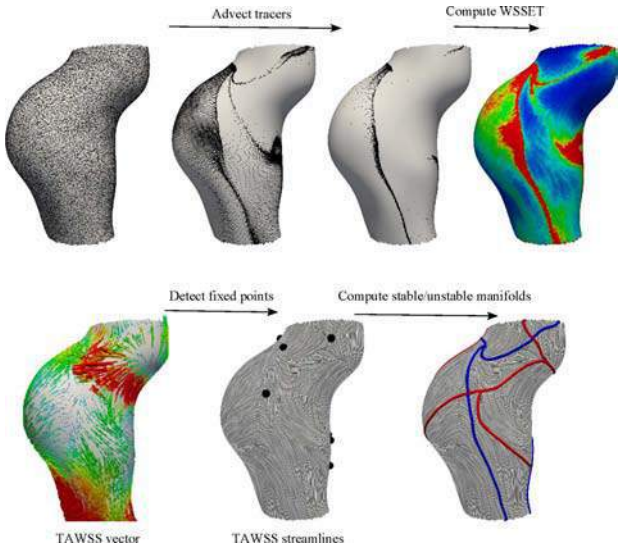

FIGURE 1: THE LAGRANGIAN APPROACHES USED TO COMPUTE WSSET (TOP) AND WSS LCS (BOTTOM).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Surface concentration was computed from the solution of 3D Eulerian advection-diffusion equation

$$\frac{\partial c}{\partial t} + \boldsymbol{u} \cdot \nabla c = D \nabla^2 c \,, \tag{3}$$

where c is a non-dimensional concentration, $\boldsymbol{u}$ is the velocity, and $D = 1 \times 10^{-5} \frac{cm^2}{s}$ is mass diffusivity. A constant Neumann boundary condition was prescribed at the vessel wall representing a uniform flux of concentration into the lumen. Zero Dirichlet boundary conditions were used for inlet and outlets with the outlets extended. The equation was solved using a finite element method with second order tetrahedral elements and boundary layer meshing implemented in FEniCS software.

RESULTS

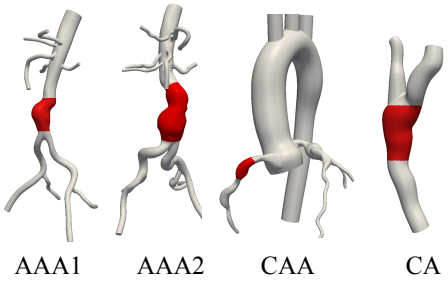

FIGURE 2: TWO ABDOMINAL AORTIC ANEURYSM (AAA1 AND AAA2), CORONARY ARTERY ANEURYSM (CAA), AND CAROTID ARTERY (CA) MODELS .

Representative results are presented in this section. Figure (2) shows the patient-specific models where the highlighted region shows the region where near-wall transport was studied. Figure (3) compares RRT, WSSET, Eulerian surface concentration, and WSS LCS. Comparison of RRT and WSSET to surface concentration reveals that WSSET has a higher correlation to surface concentration. This improvement is more pronounced in complex flows such as AAAs. RRT only considers the magnitude of the average near-wall velocity (a scale of TAWSS vector), whereas WSSET takes into account the complete tangential convective nature of near-wall transport.

The WSS LCS provides a template for near-wall transport and could be used to predict the regions where high concentration and stagnation occur. The attracting WSS LCS show the regions where near-wall tracers accumulate leading to high stagnation and concentration. The repelling WSS LCS mark the boundaries for the basins of attraction. Therefore, the repelling WSS LCS could be used to qualitatively infer how much an attracting WSS LCS will lead to high concentration. Moreover, the repelling WSS LCS partition the near-wall transport and provide transport barriers to convective transport [1].

DISCUSSION

Near-wall transport is an important aspect of cardiovascular mass transfer problems. This is manifested in the transport of thrombogenic, atherogenic, and atheroprotective biochemicals near the arterial wall. Moreover, near-wall transport of certain biochemicals influences endothelial cells mechanotransduction. Near-wall stagnation and concentration are both essential for these processes to be effective. For instance, it has been demonstrated that monocyte adhesion to endothelial cells occurs in regions of high concentration and stagnation [3]. In this study we compared RRT and recently proposed Lagrangian WSS metrics to surface concentration. WSSET demonstrated superior correlation with surface concentration. RRT only quantifies near-wall stagnation while WSSET quantifies near-wall stagnation, concentration, and takes into account the origin of the near-wall trajectories. The WSS LCS computed from the stable and unstable manifolds of TAWSS vector field provided a framework for studying the topology of near-wall transport and explaining the surface concentration results. Our results demonstrate that as the flow topology becomes more complex, the importance of considering the near-wall flow induced by the WSS vector fields in quantification of near-wall stagnation becomes more significant. Future work includes extending these comparisons to more aortic pathologies such as cerebral aneurysms.

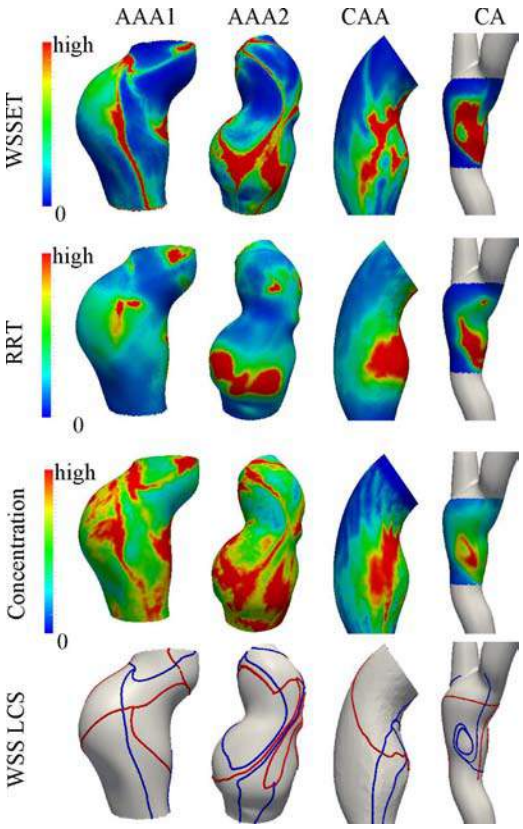

FIGURE 3: COMPARISON OF RRT, WSSET, SURFACE CONCENTRATION AND WSS LCS. THE UNSTABLE MANIFOLDS (ATTRACTING WSS LCS) AND THE STABLE MANIFOLDS (REPELLING WSS LCS) ARE SHOWN WITH BLUE AND RED LINES, RESPECTIVELY.

INTRODUCTION

Metastatic cancers account for approximately 90% of cancer-related deaths[1]. Certain metastatic cells undergo dormancy, a stage in tumor progression when cancer cells cease proliferating but remain alive in a quiescent state as a result of delayed adaptation to the new microenvironment. Recent studies suggest that metastasis-initiating cells enter into dormancy in response to signals within their new microenvironment and can remain dormant for years to decades, after which they regain a tumorigenic phenotype due to various not well understood reasons[1]. Therapeutic targeting of dormant cancer cells is difficult because the majority of cancer treatments target only rapidly proliferating cells. Therefore, understanding the microenvironmental niches that lead to dormant cell deactivation and reawakening is crucial in developing therapeutics to kill dormant cells, awaken in a controlled fashion so that they can be targeted by chemotherapeutic agents, or sustain dormancy to convert cancer into a manageable chronic disease.

Current methods to induce cancer cell lines into dormancy include serum starvation in 2D cell cultures and *in vivo* injections with cancer cell lines that exhibit dormant behavior. Several studies have shown that 2D cell culture does not recapitulate 3D *in vivo* cell behavior. In fact, it had been shown that serum starvation of 2D cell culture does not differentiate between cancer cell lines that have been shown to undergo dormancy in vivo (dormancy-capable) vs. those that do not (dormancy-incapable)[2]. *In vivo* models are problematic due to low dormant cell recovery for downstream processing, *in vivo* therapeutic experimentation and expense of animal studies. More recently, 3D *in vitro* encapsulation within a basement membrane extract system was proposed in order to drive cells into dormancy[2]. This was a successful model in differentiating dormancy-capable cell and dormancy-incapable cell lines. However, biological-based hydrogels such as basement membrane extract present challenges due to the presence of bioactive molecules such as fibrin, which has been shown to awaken dormant cells. Additionally, animal-derived products have an inherent batch-to-batch variability, leading to reproducibility challenges.

Recently, there has been an interest in encapsulating mammalian cells in silica hydrogels due to their biocompatibility, mechanical properties fine tuning and high permeability[3]. Controlling stiffness in particular allows production of gels where proliferation is controlled. Additionally, silica being a synthetic material ensures no unintended microenvironment-induced cell signaling cascades that occur in other 3D platforms such as basement membrane extract hydrogels.

We have developed stiff but reversible, highly permeable silica-PEG hydrogels where stiffness can be manipulated to control cell migration and proliferation. Reversibility of these hydrogels allows high cell recovery for downstream processing and analysis. We hypothesize that the stiffness of our hydrogel platform creates a biphasic, stress-inducing stimulus where dormancy-capable cancer cell lines can enter quiescence meanwhile highly invasive, dormancy-incapable cells become frustrated, enter senescence and eventually apoptosis. To our knowledge, we are the first group to use physical proliferation inhibition as a means to induce cancer cell dormancy.

METHODS

Gel synthesis: Tetraethylorthosilicate (TEOS) was hydrolyzed in 0.5 M acetic acid (AA) at a ratio of 1:9 for 30 min. 10 wt. % fumed silica (FS) was mixed separately with 4-arm PEG. TEOS-AA and FS-PEG solutions were then mixed at a ratio of 3:5. pH was then neutralized using 0.5 M ammonium hydroxide and gels are aged for 72 hrs. Gels were then particulated via sonication, washed with media 3 times and centrifuged at 1500 RPM for 5 min.

Cell encapsulation: Gel aliquots were vortexed, cells were added to the liquid gel at a concentration of $2x10^5$ cells/mL of gel and transferred into a well. After 5 min, culture media was added to the well.

Scanning Electron Microscopy: SEM conducted with a Hitachi S-900 FESEM. FIJI was used to measure pore size from images.

Live/dead staining: Calcein AM and propidium iodide were used as a live/dead kit, respectively, at optimized concentrations.

Alamar blue metabolic assay: 10 µL of Alamar Blue solution was added to 100 µL of gel and media. Abs_{570} and Abs_{600} were measured 12 hrs. later. Live, 2D cultured cells were used as positive controls and dead encapsulated and 2D cultured cells as negative controls.

Ki-67 staining and counting: Cells were fixed and permeabilized with 4% paraformaldehyde and 0.3% triton x-100, respectively. Encapsulated cells (for 30 min. and 2 days) were stained for proliferating marker Ki-67. Nuclei were counterstained with DAPI. 2D cultured serum-fed and serum-starved cells were used as a positive and negative controls, respectively.

RESULTS

Scanning Electron Microscopy: Fig. 1 shows a highly porous hydrogel structure with 1-5 µm size pores.

Live/Dead staining: A high number of encapsulated cells remained alive past 5 days of encapsulation as seen in **Fig. 2 (a) & (b)**, with very few staining dead.

Metabolic Activity: Metabolic activity data showed a clear distinction in cell viability between dormancy-capable cell lines (DCIS.COM, LNCaP, and MCF-7) from dormancy-incapable cell lines (OVCar-5 MDA-MB-468, and SKOV-3) with results summarized in **Table 1**. Dormancy-capable cell lines

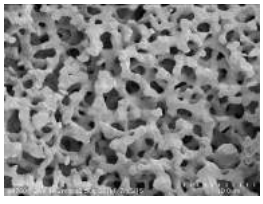

Figure 1. Silica-PEG hydrogel

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

had a $t_{50\%}$ and $t_{0\%}$ (time to 50% and 0% metabolic activity, respectively) of 7 and 21 days, respectively. On the other hand, nontumorigenic cell lines had a $t_{50\%}$ and $t_{0\%}$ of 1-4 and 3-7 days, respectively. **Fig. 3** shows this difference between dormancy-capable (MCF-7) and dormancy-incapable (MDA-MB-468), where the former has a slight decrease in metabolic activity meanwhile the latter has a sharp drop over 7 days of encapsulation.

Table 1. Cell lines encapsulated and their $t_{50\%}^{*}$ and $t_{0\%}^{**}$.

Cell Line	Time to 50% MA (days)*	Time to 0% MA (days)**
Human Ovarian Epithelial Cells (OVCar-5)	4.0	7.0
Human Mammary Gland Epithelial Cell (MDA MB-468)	<1	1
Human Ovarian Epithelial Cells (SKOV-3)	1.0	3.0
Human Mammary Gland Epithelial Cell (DCIS.COM)	>7	>21
Human Prostate Epithelial Cells (LNCaP)	>7	>21
Human Mammary Gland Epithelial Cells (MCF-7)	>7	>21

* and ** Time for in-gel metabolic activity of the encapsulated cells to drop down to 50% of its initial (day 0) value and zero, respectively.

Ki-67 expression: Immunofluorescent staining (**Fig. 1 (c)-(f)**) showed MCF-7 cells encapsulated for 5 days and serum-starved cells had a similar decrease in Ki-67 expression when compared to cells encapsulated for 30 min and serum-fed cells, respectively.

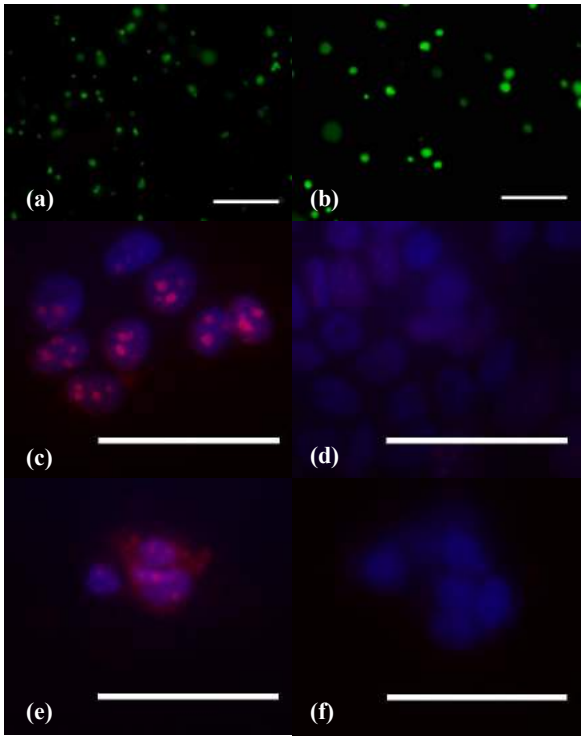

Figure 2. Live/Dead staining of MCF-7 cells encapsulated for **(a)** 30 min and **(b)** 5 days; scale bar = 200 µm. Ki-67 and DAPI staining of 2D cultured **(c)** serum-fed cells, **(d)** serum-starved cells, **(e)** cells ecapsulated for 30 min and **(f)** 5 days; scale bar = 100 µm.

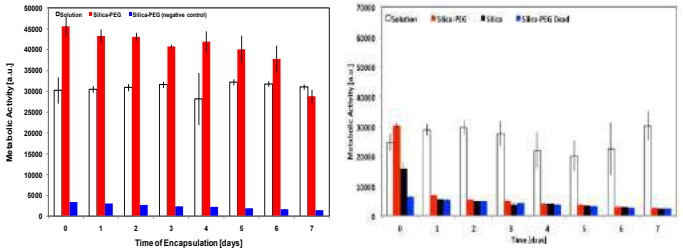

Figure 3. Metabolic activity data for dormancy-capable MCF-7 (left) cell line and dormancy-incapable MDA MB 468 (right).

DISCUSSION

SEM images show a highly porous structure with pores small enough to prevent cell migration and proliferation but large enough to allow nutrient and gas diffusion required for cellular metabolism.

Live/Dead staining and metabolic activity assay confirmed that MCF-7 cells remain alive and metabolically active when encapsulated for extended periods of time. Furthermore, metabolic activity data showed a stark contrast between dormancy-capable and dormancy-incapable cell lines. MDA-MB468, a highly-invasive, dormancy-incapable cell line had the sharpest decline in metabolic activity when encapsulated, with a $t_{50\%}$ and $t_{0\%}$ of <1 and 1 days, respectively. Conversely, MCF-7 cells only saw a modest drop in metabolic activity over 7 days. A sharp decrease in metabolic activity was attributed to cell death meanwhile a modest drop in metabolic activity was attributed to cells entering quiescence. During quiescence, metabolic activity is lowered given cells are not proliferative active and metabolic pathways are downregulated[1]. This biphasic response between MCF-7 and MDA-MB-468 can be credited to the physical constrains of our encapsulation platform, where cell migration and proliferation are inhibited, leading to cellular frustration and arrest (G0 phase of the cell cycle). In response to this stimulus, we believe if a cell cannot enter quiescence, it is forced into senescence and eventually apoptosis. Our platform differs from other dormancy-inducing methods such as serum-starvation because it contains an inherent specificity for dormancy-capable cells.

Ki-67, a cellular marker indicative of proliferation, was used to assess if encapsulated MCF-7 cells are in a quiescent state (G0). A similar decrease in Ki-67 expression can be seen between serum-fed **(c)** and serum-starved **(d)** cells and cells encapsulated for 30 min **(e)** and 5 days **(f)**. This concludes that encapsulated cells have indeed entered quiescence and are no longer proliferative active in a similar fashion as 2D serum-starved cells, the predominant method of inducing cell dormancy.

These findings conclude that this platform successfully and specifically drives dormancy-capable cell lines into quiescence. The platform's biocompatibility, high permeability to nutrients, and specificity for dormancy-capable cell lines make it an improved method to induce cancer cell dormancy compared to current approaches. Further studies will focus on the clinical applications of this platform to study cancer cell dormancy and potential treatments.

SMOKING AND SMOKING CESSATION: IMPLICATIONS ON THE DEGENERATION OF THE INTERVERTEBRAL DISC

INTRODUCTION

Tobacco smoking is still a popular habit in the United States, interestingly, 20% of the adult population smoke tobacco [1]. Epidemiological studies demonstrated an association between smoking and low back pain, a pathological condition strongly linked to the degeneration of the intervertebral disc (IVD) [2]. It is hypothesized that tobacco-smoking affects IVD health via two distinct mechanisms: (1) through nicotine, which reduces cell proliferation and biosynthesis of extracellular matrix (ECM) components; and (2) through constriction of the capillaries surrounding the IVD, thus hindering nutrient transport to the disc.

Disc homeostasis is complex and involves a series of intertwined metabolic processes which are difficult to control and study during *in vivo* experimental investigations. Hence, in this study, a computational model describing the homeostasis of IVD is used for quantifying how tobacco-smoking affects disc health, and for determining if and to which extent the process of disc degeneration due to tobacco-smoking can be reverted by cessation of smoking.

METHODS

The computational framework used in this analysis describes IVD homeostasis *via* the diffusive-reactive transport of nutrients, metabolites and growth factors [3, 4], see Figure 1. The effect of smoking on IVD homeostasis is accounted for in this model in two ways: (1) nicotine diffusing in IVD from the surrounding vascular network reduces the rate of glycosaminoglycan (GAG) production and cell proliferation in a dose-dependent manner [5, 6]; and (2) smoking impairs transvascular transport of solutes, thus reducing nutrient supply to IVD [7]. Based on the amount of nicotine delivered to the disc and the extent of nutrient deprivation, 'light smoking' and 'heavy smoking' scenarios were simulated, and the results were compared to a 'non-smoking' scenario.

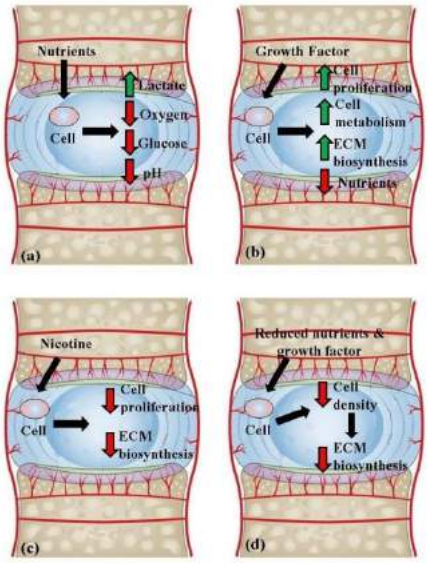

Figure 1: (a) Nutrients regulate cell metabolism. (b) Growth factor up-regulates IVD anabolism. (c) Nicotine down-regulates IVD anabolism. (d) Vasoconstriction deems IVD cell metabolism and anabolism

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Due to smoking, cell density in the annulus fibrosus (AF) and nucleus pulposus (NP) decreased to 82% and 72% ('light smoking' scenario) and 58% and 43% ('heavy smoking' scenario) of normal levels, while no changes were observed at the cartilage endplate (CEP). Levels of GAGs decreased in all disc regions, with the largest reductions observed at the NP approaching 72% ('light smoking' scenario) and 38% ('heavy smoking' scenario) of that attained in a 'non-smoking' scenario, see Figure 2.

Smoking cessation was simulated by restoring the normal physiological supply of solutes and by eliminating nicotine delivery to a disc degenerated by tobacco-smoking. Changes in cell density and GAG levels in the IVD were observed over the time frame of one year, and it was discovered that GAG levels suddenly increased in all disc regions within a few days after quitting smoking. However, at the end of the year, cell density in the AF and the NP only attained 87% and 74% (light smoking), and 70% and 55% (heavy smoking) of the values corresponding to normal physiological conditions. Similar recovery patterns were observed for GAG levels, see Figure 3.

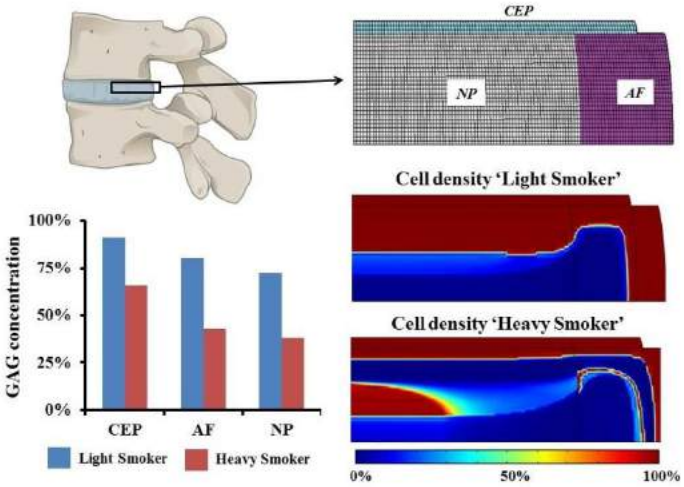

Figure 2: Effect of smoking on IVD homeostasis. The computational domain is shown together with cell density distribution and GAG levels in the disc. Data are normalized with respect to the 'non-smoking' scenario.

DISCUSSION

Depletion of GAG content across all disc regions, and reduction of cell density in both AF and NP found in this analysis are consistent with experimental studies reporting signs of disc degeneration at the NP, and at the inner and intermediate AF of rats and rabbits [8, 9].

In agreement with previous studies [9], our model shows that the benefits to disc health associated with cessation of smoking are limited. Quitting smoking has been associated with mitigation of low back pain [10]. Hence, it may be plausible that the inflammatory cytokines produced by disc cells upon exposure to nicotine would migrate outside the disc and interact with nociceptors responsible for low back pain [11]. Hence, upon cessation of smoking, also the nicotine-mediated expression of inflammatory cytokines would stop, and low back pain could be attenuated despite the fact that the disc is still degenerated.

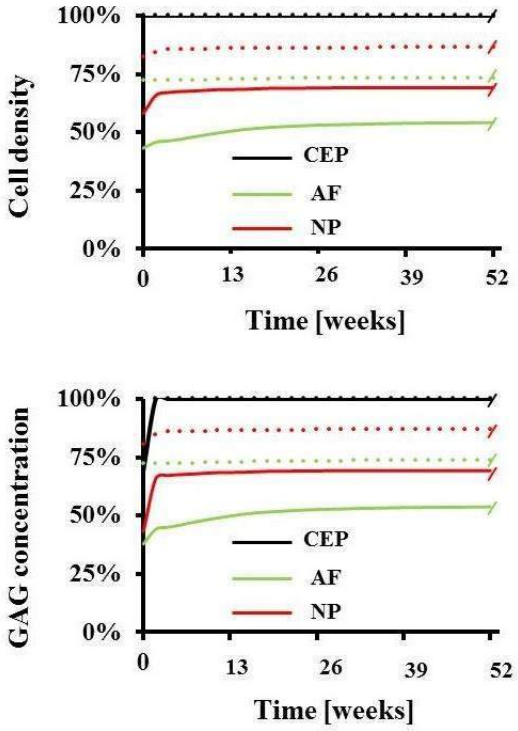

Figure 3: Effect of cessation of smoking. Both 'light smoking' (dotted lines) and 'heavy smoking' (solid lines) scenarios are reported. Data are normalized with respect to the 'non-smoking scenario'.

INTRODUCTION

We have numerically investigated the marginations of leukocyte and circulating tumor cell (CTC). Here, we review our recent works [1-2]. Leukocyte/CTC has to marginate to establish the adhesion to endothelial cells by the interaction with red blood cells (RBCs). Leukocyte/CTC has different physical properties, particularly in size, where a leukocyte is around 8 μm in diameter and a CTC is around 12-16 μm in diameter [3-4]. Despite previous experimental and numerical attempts [5-7], the interaction behavior between leukocyte/CTC and RBCs has not been yet understood in detail. The behaviors of leukocytes/CTCs are of fundamental importance in design of microfluidic devices, which help us to diagnose the progress of disease and to evaluate the efficacy of anticancer drugs. Hence, understanding the flow modes of leukocytes/CTCs in microvessels, including the cell velocities, is helpful in the design of novel microfluidic devices. The objective of this study, therefore, is clarifying the detailed interaction between single leukocyte/CTC and RBCs in microvessels, and also identifying the similarities and differences between flow mode of leukocyte and CTC.

We found that the flow mode of the leukocyte/CTC with RBCs underwent a transition from train formation to margination as the diameter of the vessel increased, although the motion of RBCs differed. We also found that both leukocytes and CTCs flowed faster than the mean blood velocity.

METHODS

Consider a cellular flow consisting of plasma, RBCs, and a leukocyte or CTC in a microvessel, which was modeled as a cylindrical channel of radius R. The periodic boundary conditions were employed. The plasma was assumed to be a Newtonian fluid with a viscosity of $\mu^P = 1.2 \times 10^{-3}$ Pa·s. The RBCs were modeled as biconcave capsules with a radius of $a^R = 4$ μm and a thickness of $t^R = 2$ μm, filled with a Newtonian fluid of viscosity $\mu^R = 6 \times 10^{-3}$ Pa·s, and enclosed by a hyperelastic membrane. The membrane was assumed to follow the constitutive law proposed by Skalak et al. (1973)[8], i.e.,

$$w = (I_1^2 + 2I_1 - 2I_2 + C\,I_2^2)(G/2) \qquad (1)$$

where w is the strain energy density function, G is the surface shear elastic modulus, C is the coefficient of the area dilation modulus, and I_1 and I_2 are the invariants of the strain tensor.

The leukocyte and CTC were modeled as spherical capsules with a radius of $a = 4$ μm for leukocyte, and $a = 8$ μm for CTC [3-4]. Because of cytoskeleton networks, the leukocyte/CTC are known to be less deformable than the RBCs, and hence we set to be $R_G = G/G^R = 10^2$. The other parameters remained the same (i.e., $C = C^R$ and $\mu = \mu^R$). The problem was characterized by the capillary number $Ca = \mu^P \dot{\gamma} a^R / G^R$, where $\dot{\gamma} = U_m/2R$ is the mean shear rate and U_m is the mean velocity. A fixed capillary number of $Ca = 0.2$ was used to mimic microcirculation. All data was for 20% volume fraction of RBCs (i.e., $Hct = 0.2$).

The finite-element method for the membrane mechanics and the lattice-Boltzmann method for the fluid mechanics were coupled by an immersed-boundary method. All procedures were implemented on a graphics processing unit (GPU) to accelerate the numerical simulation. The precise description of numerical method was documented in our previous works [1-2].

RESULTS AND DISCUSSION

Figure 1 shows snapshots of typical numerical results for different vessel sizes, where the channel size relative to the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

leukocyte/CTC is normalized by the thickness of RBC, i.e., $(R - a)/t^R$. In the smallest vessel, $(R - a)/t^R = 0.5$, the leukocyte/CTC and RBCs formed train formation, where the leukocyte and RBCs exhibited single-file flow (Fig.1A1), while the CTC and RBCs exhibited a recirculating motion, whereby as an RBC approached the CTC in the center of the vessel, it retuned to the wall (Fig.1A2). When the vessel size was increased to $(R - a)/t^R = 1.5$, the leukocyte/CTC began to marginate by passing motion of RBCs, where the leukocyte was overtaken by RBCs (Fig.1B1), while the CTC overtook the RBCs (Fig.1B2). As the vessel size was further increased to $(R - a)/t^R = 2.5$, the passing motion of RBCs continuously occurred, and hence the leukocyte/CTC remained to be marginated. Although the CTC was faster than most RBCs, some RBCs passed forward (Fig.1C2).

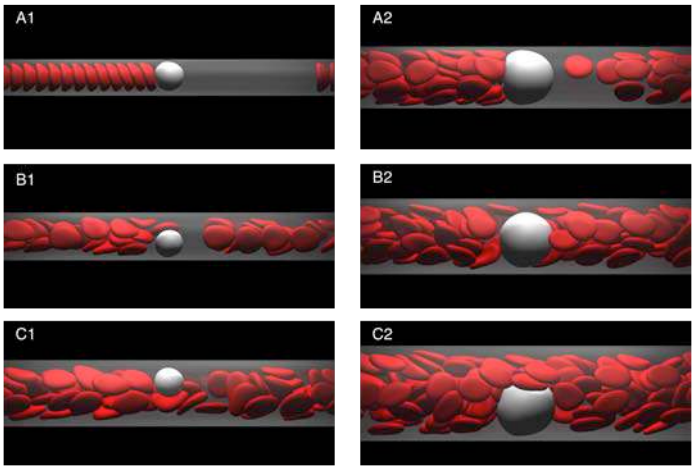

Figure 1: (A1, A2) Train motion of a leukocyte (a = 4 μm) and CTC (a = 8 μm) with RBCs (a^R = 4 μm, t^R = 2 μm) for $(R - a)/t^R$ = 0.5. (B1, B2) margination of leukocyte/CTC for $(R - a)/t^R$ = 1.5. (C1, C2) Margination of leukocyte/CTC for $(R - a)/t^R$ = 2.5.

We examined velocities of three different sized cells (a = 4, 6 and 8 μm). Figure 2 shows the numerical results of cell velocity together with an analytical result of rigid spheres with $R/a \approx 1$ [9], where the cell velocity V_C was normalized to the average blood velocity V_B. As shown in Fig.2, $V_C/V_B > 1$ for all values of R/a. With train formation, for small R/a values, the normalized cell velocity was similar to the analytical result for all cell sizes. When the cell marginated, the cell velocity diverged from the analytical result, but it remained higher than the average blood velocity.

To describe the flow modes of the leukocyte and CTCs quantitatively, we plotted a diagram showing the flow modes, which indicates the cell velocity relative to the average velocity of the RBCs, i.e., $(V_B - V_R)/V_B$ (Fig. 3). When a cell forms a train with the RBCs, the relative velocity should be almost zero. When the leukocyte is marginated and is overtaken by RBCs, the relative velocity is negative; when the CTC overtakes the RBCs, the relative velocity is positive. The relative velocity during train formation was assumed to be negligibly small, $|V_B - V_R|/V_B < 0.005$. The small CTC (a = 6 μm) first overtook the RBCs and was then overtaken by the RBCs over the range of vessel sizes investigated. Figure 3 also shows that the CTCs flowed faster than the RBCs; in constant, the velocity of the leukocyte was always smaller than the average RBC velocity.

In conclusion, we found that the flow mode of a CTC with RBCs in microvessels was similar to that of a leukocyte with RBCs. A transition from train formation to margination occurred at $(R - a)/t^R \approx 1$. The cell velocities of CTCs and leukocytes were larger than the average blood velocity, even when they were marginated. Moreover, only CTCs moved faster than RBCs.

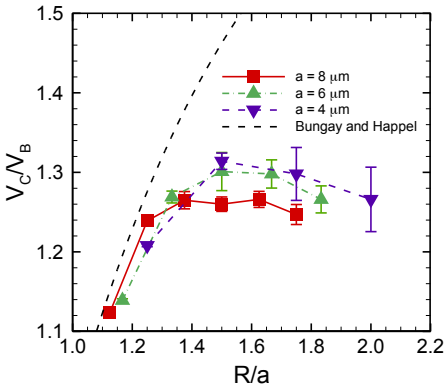

Figure 2: Ratio of cell velocity to the average blood velocity for various diameter microvessels. Analytical solutions are also shown using the expression reported by Bungay and Brenner [9], with $R/a \approx 1$.

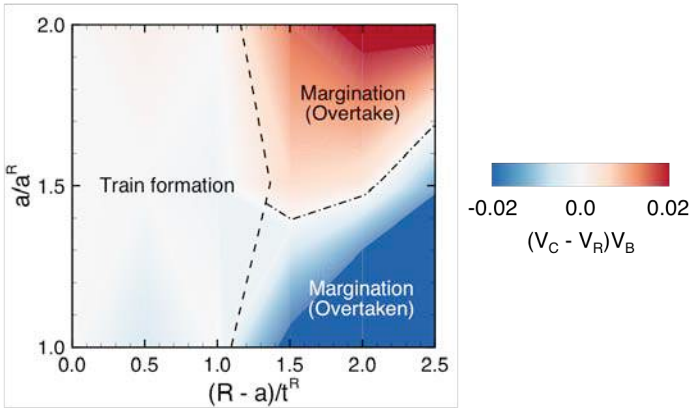

Figure 3: Comparison of flow modes. The flow modes as functions of $(R - a)/t^R$, and a/a^R. The color contours represent the cell velocity relative to the average velocity of the RBCs (i.e., $(V_C - V_R)/V_B$), and dashed lines show $|V_C - V_R|/V_B < 0.005$, and the dash-dot lines show $(V_C - V_R)/V_B < 0$.

INTRODUCTION

Traumatic brain injury (TBI) is prevalent in both the civilian and military populations [1]. Although it is clear that non-penetrating forms of TBI results from rapid forces or accelerations applied to the head, the factors that contribute to the mid- to long-term repercussions of TBI have yet to be fully elucidated. Recent work has implicated metabolic changes in even sub-concussive events of the brain [2], substantiating the need for further research in the brain's response to various levels of trauma.

Since the mechanics of TBI can not be studied *in vivo* in humans, computational models may lead to improved understanding of this process. However, experimental data of human brain mechanics remain required for model validation. Understanding how brain biomechanics may differ with demographic factors like race, age, and sex also informs the design of appropriate computational models.

Previous work by our group to assess brain biomechanics in living subjects has shown that accelerations of the living brain at sub-injury levels can be measured reliably with tagged magnetic resonance imaging (MRI) [3]. In this study, we acquired tagged MRI data in healthy volunteers to assess whether there is a sex-linked difference in the shear response of the brain to mild angular acceleration.

METHODS

Twenty healthy adult subjects (10 females, 10 males) were consented under an IRB-approved protocol and enrolled in this study. Subjects lay with their heads secured within an MRI-compatible head support [4] and voluntarily released a latch that permitted a head rotation of ~32° about the inferior-superior axis toward the left shoulder, aided by a counterweight and generating a rapid deceleration of the head when it rotates into a padded stop. Multiple repetitions of the motion were required to reconstruct multiple image slices with tag lines in orthogonal directions.

MR images were acquired using a Siemens 3.0T mMR Biograph scanner (Siemens, Munich, Germany) with a tagged image sequence that has been previously validated with this head rotation device [3]. Briefly, a 1-1 SPAMM tagging pulse [5] was followed by a segmented cine gradient echo acquisition at 18.06 ms temporal resolution, 1.5 mm x 1.5 mm spatial resolution, and 8 mm slice thickness. A position-controlled double-trigger system permitted the application of tag lines after the initiation of the head rotation to ensure repeatable synchronization of the image acquisition [3]. Motion between tagged image frames was tracked using harmonic phase (HARP) analysis [6] with the shortest-path HARP refinement algorithm [7]. Displacement vectors were computed between each voxel center in the first image (reference) to their locations in subsequent image frames and permitted the calculation of 2D Lagrangian strains. Maximum shear strain, γ_{max}, was then computed from principal strains.

To compare between subjects, area fraction (AF) was defined as the proportion of voxels of interest in which the shear strain exceeded a specified threshold. Brain tissues were segmented from a 1-mm isotropic MPRAGE anatomical scan using the S3DL technique [8] and registered to the tagged images. AF was computed at γ_{max} thresholds of 1% to 6% in the whole brain, cortical gray matter (CGM), deep gray matter (DGM), and white matter (WM). Differences between male and female groups were tested at each strain cutoff and time point using a Wilcoxon rank sum test at a significance level of 0.05.

RESULTS

One female subject was excluded from analysis due to image artifacts that prevented reliable calculation of strains and AFs. The

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

remaining female (n = 9) and male (n =10) subjects did not vary significantly in age or estimated brain volume (Table 1).

	Age	Brain	CGM	DGM	WM
	[years]	Estimated tissue volume [cm^3]			
Females (n = 9)	28.44 ± 5.64	1127.5 ± 125.3	537.0 ± 51.2	54.7 ± 5.7	391.5 ± 57.7
Males (n = 10)	28.30 ± 5.36	1175.4 ± 100.6	576.7 ± 43.3	55.7 ± 4.3	418.3 ± 39.3
P =	0.96	0.40	0.10	0.69	0.28

Table 1: Age and brain tissue volumes (mean ± S.D.) did not differ (Student's *t* test) between female and male groups.

AFs were computed for strain cutoffs of 1% to 6% in all subjects for whole brain, CGM, DGM, and WM (Figure 1). AFs peaked at the cine frame acquired at 45 ms, around the time of initial impact. A smaller and longer peak occurred in most subjects after impact, although the amplitude and timing of that peak varied by individual (not shown) and accounted for the increased variation of AFs after the impact. Significant differences in γ_{max} AFs were found in the whole brain and CGM (Figure 2) but not DGM and WM (not shown) after impact. Female AFs were higher than male AFs at each strain cutoff and time point pair for which significant differences were detected.

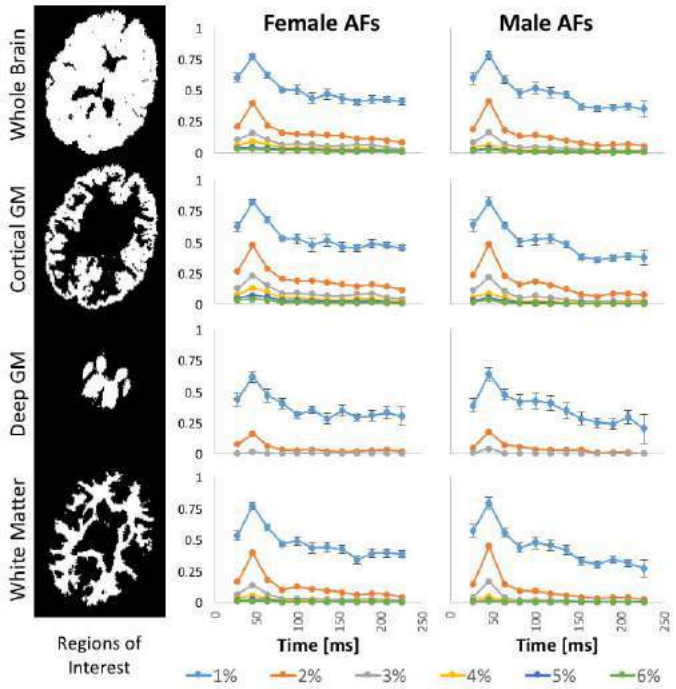

Figure 1: Segmented tissues of interest are shown through a single slice of the brain of a representative female subject. Median AFs are shown for each γ_{max} strain cutoff and time in tissues of interest, except where AFs are ~0 (i.e., DGM at 4%+). SEM is only shown for AFs at 1%, as they are larger than AFs at 2%+.

DISCUSSION

This study showed that shear strains were the highest at the initial impact (~45 ms), and that higher shear strains are more prevalent in the cortical gray matter than white and deep gray matter (Figure 1). However, no statistically significant differences were detected at the times that coincided with the height of the shear strain response. Comparisons at later time points show that there may be sex-linked differences in the shear strain within the cortical gray matter after the initial impact (Figure 2), with AFs at these times consistently greater in females than males. This difference may be the result of the inertial response of the brain after the skull has ceased motion, since sex-specific anatomic differences in overall head mass or size may affect the moment of inertia despite the similar brain size between males and females. These differences in the inertial response, which plays out across a longer time frame after impact, may also reflect sex-related differences in the dissipation of mechanical energy.

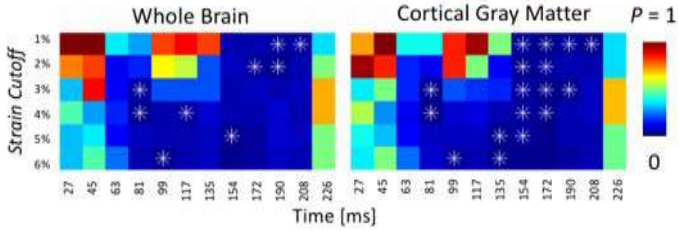

Figure 2: Differences in AFs between female and male groups were compared with a Wilcoxon rank sum test and P values are shown for each γ_{max} strain cutoff and time combination in whole brain and cortical gray matter (✳ $P < 0.05$).

Although this study compares males and females, it does not examine *why* this difference may be associated with sex, nor whether other factors – including subject compliance, age, or hormonal variations – may result in this difference. A major limitation of voluntary and subject-initiated motion is that subject compliance and consistency affect head accelerations, which in turn will influence image acquisitions that require at least 120 head rotations for multiple orthogonal slices through the whole brain. The sensitivity of such imaging measurements is dependent on multiple factors, and work is ongoing to quantify these effects *in vivo*. Future work will also include larger subject pools, allowing for an examination of the effect of age group, and a deeper examination of the various factors that effect the spatiotemporal response of the brain after impact.

Work to identify sex-linked differences in TBI remains unclear, with research showing that males have more severe disruption of the white matter and longer times to symptom resolution than females [9] but that females are more likely to report post-concussive symptoms [10] and show slower recovery of working memory [11]. This study represents a key step towards elucidating differences in brain biomechanics with sex and other demographic markers. Such work will enhance understanding of the factors that lead to brain injury and its costly long term effects and inform computational models of the brain that are applicable to a diverse civilian and military population.

AN ALTERNATIVE METHOD TO CHARACTERIZE THE QUASI-STATIC MATERIAL PROPERTIES OF MURINE ARTICULAR CARTILAGE

Alexander Kotelsky (1), Chandler Woo (1), Mark R. Buckley (1)

University of Rochester
Rochester, NY, USA

INTRODUCTION

Articular cartilage is a load bearing structure that transmits forces across diarthrodial joints. A key feature of osteoarthritis (OA) – the leading cause of disability in the United States [1] – is cartilage degeneration. In the mouse, OA is easily induced through genetic or surgical means. Thus, murine models provide a valuable, low-cost research platform to study the progression of articular cartilage degeneration in OA. However, alterations in the mechanical properties of murine articular cartilage are challenging to measure due to its small size (thickness ~ 50 microns). A few research groups have quantified the mechanical properties of murine cartilage through nano- and micro-indentation techniques [2, 3]. Though effective, these techniques are somewhat indirect, as they require assumptions regarding the 3D geometry of the tissue and how it deforms due to a prescribed indenter displacement. We propose an alternative, more direct method of measuring the mechanical properties (Young's modulus and Poisson's ratio) of intact murine cartilage through inverse finite element modeling and confocal microscope-based 3D strain mapping of intact specimens subjected to compression.

METHODS

Distal femurs with fully intact cartilage (n=3) from 8-10 weeks-old BALB/c female mice were carefully dissected immediately after sacrifice and stored at -20°C until testing. The cartilage covering the distal femoral condyles was tested mechanically. For every experimental test, the femurs, hydrated in phosphate buffer saline solution, were placed onto the glass slide of a custom microscope-mounted device and loaded with 0.07N on the anterior side (on top of the patellofemoral groove) such that cartilage on the posterior femoral condyles was compressed against a cover glass (Figure 1). The experiments were performed at room temperature.

Characterization of material properties (E, ν) involves multiple experimental and computational methods. These methods and their sequence are as follows: 1) confocal microscope-based mapping of compressive strains in 3D; 2) implementation of inverse finite element analysis (iFEA) based on experimentally measured specimen displacement and strain distribution for calculation of the Poisson's ratio; 3) characterization of the boundary forces exerted on articular cartilage on a single condyle; and 4) implementation of iFEA based on specimen displacement and condylar boundary forces to characterize Young's modulus at equilibrium (E). A schematic diagram of the methods is depicted in Figure 1.

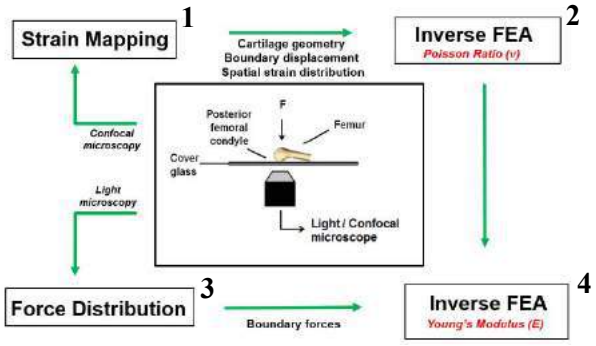

Figure 1. Schematic diagram of the experiments.

1. Strain mapping. Prior to testing, each specimen was fluorescently stained for 1h with 5-DTAF (10 µg/mL) (Sigma-Aldrich, Milwaukee, WI, USA) at room temperature to enable visualization of the extracellular matrix. Two femoral condyles in each of the stained murine cartilage samples were imaged with a 40X dry lens (LUCPLFLN, NA 0.6) on an Olympus FV1000 laser scanning confocal microscope (Olympus America, Center Valley, PA). 3D

image stacks were taken before compression and after the cartilage reached its post-compression equilibrium (i.e., 5 minutes after compression) (Figure 2 a-b). From the acquired image sets, spatially-varying compressive strain E_{33} (where E is the Green-Lagrange strain tensor) was quantified using custom MATLAB software (The MathWorks Inc., Natick, Massachusetts, USA) (Figure 2c).

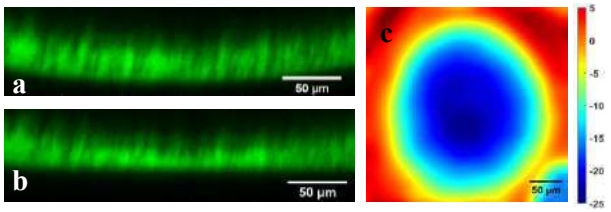

Figure 2. Representative confocal micrographs of murine articular cartilage in sagittal view (a) before and (b) after specimen compression; and (c) resultant compressive strain (E_{33}) map.

2. iFEA to determine Poisson's ratio. A 3D finite element model (FEM) of murine cartilage on a distal femoral condyle was created using FEBio software [4] (Figure 3a). The cartilage on a femoral condyle was approximated as an ideal hemispherical shell with outer radius of 826.5 ± 63.1 μm and a thickness of 45.9 ± 4.9 μm. The radius and thickness of each specific model was based on the 3D confocal micrograph used for step 1 (Figure 2a). The top surface (cartilage-bone interface) was constrained to be stationary, and a rigid wall contact was applied at the bottom surface and translated in the vertical direction with a prescribed displacement corresponding to the displacement measured in the strain mapping experiment. Although articular cartilage is a poroelastic/biphasic material, the cartilage was taken to be a neo-Hookean hyperelastic material, simulating the mechanical response of articular cartilage at equilibrium.

A FEM-based sensitivity study simulating the effect of Poisson's ratio ranging from 0 to 0.49 in increments of 0.025 on spatially-varying strain distribution was performed. Importantly, no effect on strain distribution was found for Young's moduli ranging from 1 to 14 MPa (data not shown). A Poisson's ratio was determined by matching spatially averaged strains in 4 regions along the radial direction between experiments and FE simulations (Figure 3b-e). The radial direction of a strain pattern was defined to originate from the maximum compressive strain observed. The Poisson's ratio was found by minimizing the root of sum of squared error (SSE) between compressive strains (E_{33}) obtained from the strain map experiment and FE simulations.

3. Measurement of boundary forces. Applying a force to the anterior side of the femur (Figure 1) produces three specimen-glass contact points: one cartilage contact on each distal femoral condyle and one bone-glass contact on the proximal end of a femur. Therefore, it is important to analyze the distribution of loading between two femoral condyles as a result of applied load of 0.07N on top of the patellofemoral groove of a specimen. The calculation of loading distribution on articular cartilage was performed by implementing principles of static mechanics. The approach includes identification of contact force locations on intact specimens through microscopic imaging and implementation of equilibrium moment balance in order to calculate the force distribution between femoral condyles.

4. Inverse finite element analysis to determine Young's modulus. The models from step 2 with pre-determined Poisson's ratios were used to estimate the Young's modulus of articular cartilage. An iterative optimization algorithm implemented in FEBio [4] was used to match boundary forces, which were determined from step 3.

Compressive stresses were obtained from forward FEA with pre-determined Poisson's ratio and Young's modulus from steps 2 and 4.

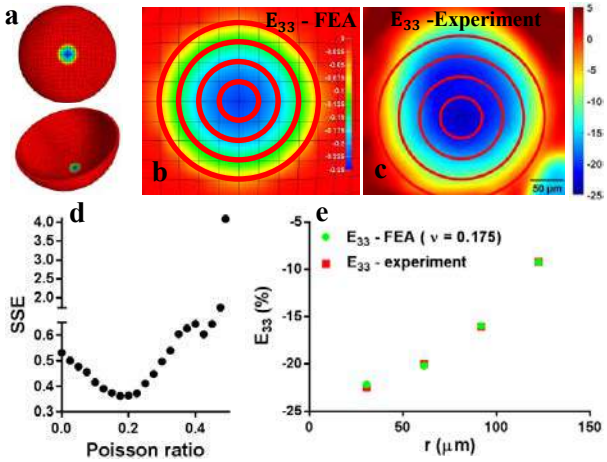

Figure 3. Representative (a,b) FEA of cartilage on murine femoral condyle, (c) strain map from step 1 with defined 4 regions, (d) SSE and (e) E_{33} comparison between FEM and experimental data.

RESULTS

Reaction forces (F), compressive strains (E_{33}), material properties (E, ν) and compressive stresses (σ) were calculated for the medial and lateral femoral condyles of all tested specimens using the methods described above. The mean Young's modulus across all medial and lateral specimens was 2.07 MPa, and the mean Poisson's ratio was 0.26.

Table 1: Parameters for murine cartilage on medial and lateral femoral condyles (mean ± standard deviation)

	F (mN)	E_{33} (%)	ν	E (MPa)	σ (MPa)
Medial	23.5 ± 1.5	-25.8 ± 2.3	0.28 ± 0.15	1.53 ± 0.94	-0.75 ± 0.08
Lateral	33.5 ± 3	-22.3 ± 1.1	0.24 ± 0.21	2.61 ± 1.16	-1.02 ± 0.11

DISCUSSION

In this study we developed an alternative method to quantify the material properties of murine articular cartilage at equilibrium. The method provides direct measurements of tissue deformation, and material properties are determined separately based on distinct measurement (strain distribution for Poisson's ratio and boundary force for Young's modulus). Mechanical properties found in this study are consistent with the values reported in the literature [2]. The applied compressive strains and stresses were below injurious levels [5, 6], such that material properties of articular cartilage were found without damaging the extracellular matrix during mechanical testing.

One limitation of the proposed study is that nonlinear material properties and biphasic material properties (e.g., hydraulic permeability) responsible for the transient deformation of articular cartilage were not assessed. Future studies will expand the proposed method to incorporate measurements of these parameters, and will apply this method to the assessment of material properties of murine cartilage at different stages of experimentally-induced OA.

INTRODUCTION

Plasmonic gold nanoparticles (GNP) have received broad interest in biomedical applications due to their unique optical and thermal properties [1]. Specifically, GNP can be designed to strongly absorb or scatter optical energy at different wavelengths of interest. The laser energy absorption can lead to significant temperature changes on the nanoparticle as well as the surrounding biological environment. Among the molecular components in the biological system, proteins are extremely thermally sensitive and play a critical rule in performing biological functions. The thermal effect on proteins are well understood in low temperatures (below 100˚C) and longer time scale (seconds to minutes) and the rate of protein thermal inactivation or denaturation is highly dependent on temperature. Several emerging applications (such as photoacoustics, nanophotothermolysis) involve laser heating of GNPs with ultra-short laser pulses (nanosecond to femtosecond) and the resulting temperature adjacent to GNP can be well above 100˚C without vaporization, for example up to 140 K overheating has been observed [2]. Although molecular dynamic simulations [3] and preliminary experiments [4] have shown protein inactivation, systematic investigation of the fate of proteins adjacent to GNPs under nanosecond laser heating is lacking.

In this research, we investigated on the effect of GNP heating on adjacent proteins in the nanosecond scale. Specifically, we experimentally measure protein inactivation as function of laser pulse energy, pulse number, and distance between the protein and GNP. Our research suggests a novel method to target and selective inactivate proteins of interest for biomedical applications.

METHODS

Protein conjugation to GNP: Protein inactivation was studied experimentally by conjugating an enzyme (α-chymotrypsin or α-CT) to 15nm GNP with a polyethylene glycol (PEG) spacer. Specifically, heterobifunctional PEG (Thiol-PEG-COOH with molecular weights 400, 600, 1000 and 3400Da) was first conjugated to GNP. Then we modified the carboxylic group by EDC and sulfo-NHS to replace the carboxylic group with sulfo-NHS ester intermediate which can react with amine groups in protein [5]. The reacted complex was then cleaned by centrifugation.

Protein inactivation by nanosecond laser: The prepared GNP-protein complex was then irradiated by an Nd:YAG nanosecond pulsed laser at 532nm (Quantel USA, 6 ns, beam diameter D = 9 mm), shown schematically in Figure 1A. The laser pulse energy is varied from 0 to 200mJ and the pulse number is from 1 to 20. The laser beam diameter is 9 mm. 40 μL sample was loaded in the cuvette and tested each time. The optical density (OD) of the sample was adjusted to be less than 0.1 in order to make sure that the sample was exposed to a uniform laser intensity.

Protein activity measurement: The protein inactivation was measured by a colorimetric enzyme assay. Specifically, α-chymotrypsin (α-CT) is a protein of molecular weight 24800 [6], and the a-chymotrypsin-catalyzed substrate hydrolysis is well known process. We used N-succinyl-L-alanyl-L-alanyl-L-prolyl-L-phenylalanine-4nitroanilide (Suc-Ala-Ala-Pro-Phe-pNA, Sigma-Aldrich) as the substrate, due to the high affinity (i.e. low K_m value) and high reactivity (i.e. high k_{cat}) [7-8]. The hydrolysis of Suc-Ala-Ala-Pro-Phe-pNA leads to a color change which can be monitored by the absorption value at 410nm (Figure 1 B&C). The enzymatic activity of α-CT was determined by measuring the rate of hydrolysis of the substrate Suc-Ala-Ala-Pro-Phe-pNA [9].

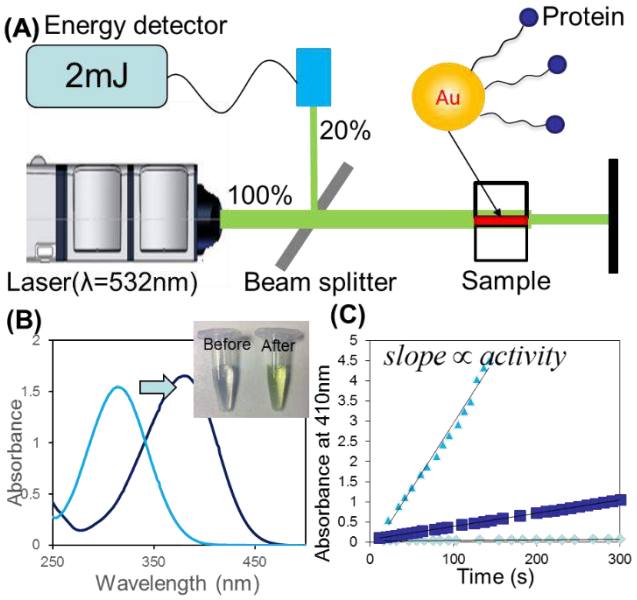

Figure 1: Schematic of experimental setup (A) and protein activity measurement using a colorimetric enzyme assay (B – C). B inset shows the color change after adding substrate to the enzyme.

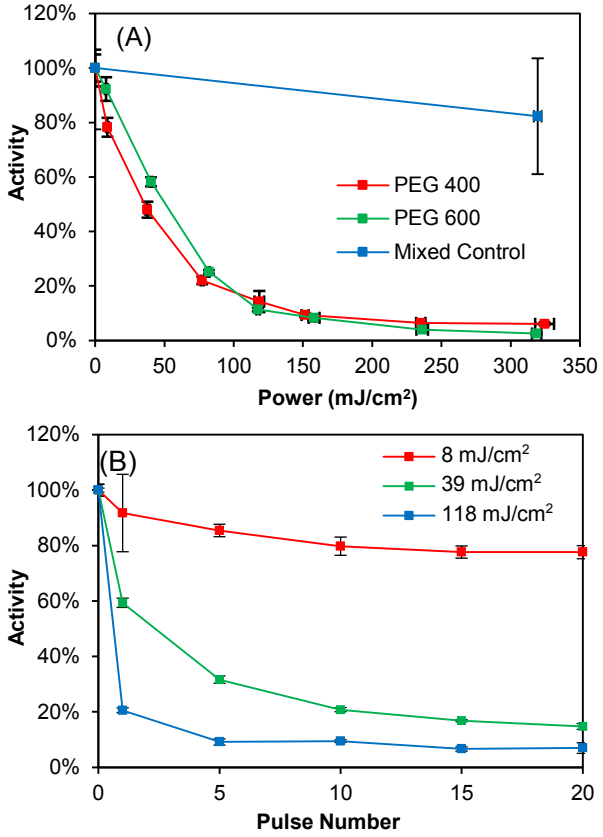

Figure 2: Preliminary experimental results of nanosecond protein inactivation. (a) Protein activity as a function of laser pulse energy (pulse width = 6 ns) for conjugated (PEG400 and 600) and free protein (Mixed control). PEG 400 refers to a 400 Da PEG spacer, mixed control refers to mixing PEG-coated GNP with α-CT directly without conjugation. (b) Effect of pulse number for PEG 600 sample.

RESULT

The experiment results are shown in Figure 2. The protein inactivation is dependent on laser pulse energy and complete inactivation (> 90%) is possible under one laser pulse with beam width of 6 ns (Figure 2A). Higher pulse energy leads to more reduction in protein activity. When pulse energy is higher than 116 mJ/cm^2, one pulse leads to more than 80% inactivation of α-CT. When the protein is not attached to the protein, shown as mixed control in Figure 2A, no obvious inactivation was observed, suggesting a highly selective and localized effect.

Further investigation is needed to determine the spatial extent of the protein inactivation. Preliminary results comparing PEG 400 and PEG 600 activity shows slight difference at low laser pulse energies, with PEG400 leading to more reduction in protein activity (Figure 2A). PEG spacers with higher molecular weight lead to longer distance between α-CT and GNP. As a result, the heating of protein is less intensive with longer PEG spacers.

The protein inactivation is strongly dependent on pulse number, shown in Figure 2B. The activity decreases dramatically in first five pulses and does not change significantly when further increasing the pulse number. After 5 laser pulses, the final activity is only strongly dependent on the laser pulse energy.

DISCUSSION

In summary, this study proves the selective protein inactivation adjacent to gold nanoparticles during nanosecond pulsed laser heating and establishes an experimental approach to investigate and understand this important phenomenon. The protein inactivation can be further controlled in the nanometer scale by laser energy, nanoparticle size, distance between protein and nanoparticle, and thermal interface resistance. Importantly, our study suggests a novel protein inactivation method with broad biomedical applications, such as investigating and designing novel nano-surgical tools to target and selectively inactive proteins of interest in living systems.

INTRODUCTION

Thoracolumbar fractures represent approximately 90% of fractures found at spine, and nearly 20% of such injuries are burst fractures [1]. Surgical correction with corpectomy and subsequent fusion of neighboring levels is a well-known treatment, which can be performed with different fixation techniques. The objective of fixation is to correct angular deformity, stabilize fracture, decompress neural elements, and restore vertebral body height [2]. The stiffness of the construct plays a key role in the success of achieving these goals by re-stabilizing the anterior and middle spinal column. Accordingly, several biomechanical studies have been performed to analyze the stiffness of the different fixation constructs at the thoracolumbar junctions [2, 3].

There are many procedures for burst fracture treatment, and they generally involve corpectomy, which consisted in the dissection of the affected vertebral body and the adjacent intervertebral discs (IVDs). Often, an expandable cage is placed between the superior and inferior vertebral bodies to stabilize the anterior column of the spine. However, expandable cages alone are not enough to fuse the junction. In some cases, pedicle screws and rods are implanted through posterior approach to increase the stiffness of the fusion [4, 5]. Alternatively, aiming to achieve less invasive type of procedure, a lateral (transverse) plate can be used as a hardware component to fix the segment through a posterolateral approach [6]. Whether one family of procedures is better than the other is yet to be determined.

In order to try to answer this question, we deployed a computational model for spine biomechanics to simulate the biomechanical behavior operated segments (T12-L2) under physiologically relevant mechanical loads. More specifically, we investigated the biomechanics of three different constructs using (1) pedicle screws and rods, (2) transversal plate, and (3) a hybrid construct including both screws and plate. The different constructs were compared in terms of their stiffness, which is considered a quantitative metric to measure the quality of a fixation construct.

METHODS

A 3D nonlinear finite element model of the thoracolumbar junction (T12-L2) was constructed from CT scan of a healthy male subject (Visible Human Project®) via commercially available image processing software (Mimics; Materialise, Louvain, Belgium). The model included the cortical and cancellous bones of T12 and L2, the posterior element of L1, facet joints, and the major spine ligaments except the anterior and posterior longitudinal ligaments. All material properties were taken from the literature [7, 8], and a gap of 0.4 mm was specified between cartilage layers with a sliding interface between the superior and inferior cartilage [9].

To obtain the constructs, complete corpectomy was performed at L1 level by removing L1 vertebral body and the adjacent IVDs. A total of three different fusion constructs at the thoracolumbar junction were investigated: (1) expandable cage with a transverse plate and one posterior pedicle screw (1RPC), (2) expandable cage with two posterior pedicle screws (2RC), and (3) expandable cage with transverse plate (PC), see Figure 1. All the hardware material was assumed to be of titanium with 110 GPa elastic modulus and 0.3 poisson's ratio [10]. Sliding interfaces were defined between the expandable cage and the surfaces of the vertebral bodies of T12 and L2, with friction coefficient of 0.8 to prevent the cage from slipping [11]. The pedicle screws were placed posteriorly and connected with

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

posterior rods by a tied contact. The transverse plate was connected via four lateral screws to T12 and L2 vertebral bodies, and a sliding contact with 0.1 friction coefficients was assumed between plate and vertebrae [12]. Four-node solid elements were used to discretize the model, and non-commercial software FEBio (FEBio 2.2.0, Musculoskeletal Research Laboratory, University of Utah, Salt Lake City, UT) was employed to solve the FE model.

For all the constructs, bending moments of 5 Nm were applied at T12 on the three major anatomical planes, to obtain loading conditions of Flexion-Extension, Lateral Bending, and Axial Rotation. The base of L2 was fixed. The stiffness (Nm/deg) for each loading condition was measured by dividing the applied moment by the amount of rotation of T12 relative to L2. Also, for each loading condition, we measured the coupled motion (i.e., rotation in the anatomical planes where the moment is not applied).

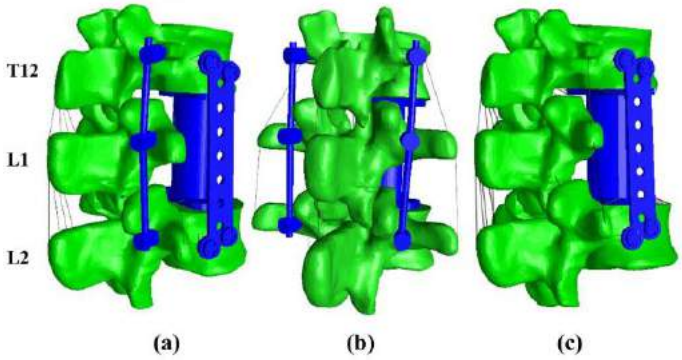

Figure 1: Thoracolumbar spine FE model with performed corpectomy at L1: (a) 1RPC construct, (b) 2RC construct, (c) PC construct

RESULTS

Stiffness values are reported in Figure 2. It is shown that the 1RPC construct was the stiffest, while the PC construct was the most compliant for all loading conditions. The only exception was for the case of left lateral bending, where the PC construct yielded higher stiffness than 2RC. Moreover, for all the constructs, the largest values of stiffness were attained during left lateral bending. In contrast, the lowest values were found during axial rotation. Table 1 shows the coupled motion for all the constructs. For almost all the cases investigated, the PC construct produced a coupled motion nearly one order of magnitude larger than that found in the other constructs. Also, 1RPC almost always generated the lowest coupled motion.

Table 1: Coupled motion during the six loading conditions for all constructs in degrees. Table abbreviations: Lateral Bending (LB); Flexion-Extension (FE); Axial Rotation (AR)

	Flexion		Extension		Right Lat. Bend.	
	LB	AR	LB	AR	FE	AR
1RPC	0.0868	0.0189	0.039	0.0387	0.1082	0.006
2RC	0.0127	0.015	0.0239	0.0167	0.124	0.0623
PC	0.598	0.278	0.19	0.086	0.484	0.045
	Left Lat. Bend.		Right Axial Rot		Left Axial Rot

1RPC	0.058	0.038	0.02	0.1	0.052	0.037
2RC	0.114	0.069	0.142	0.071	0.172	0.0793
PC	0.001	0.0251	0.096	0.208	0.062	0.721

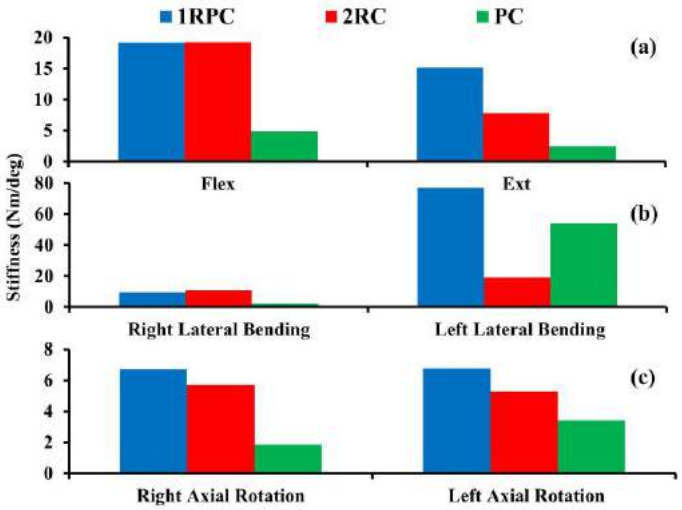

Figure 2: Stiffness of the three constructs for all the loading conditions: (a) Flexion-Extension, (b) Lateral Bending, (c) Axial rotation.

DISCUSSION

Several studies reported high failure rates of fusion techniques applied to treat burst fracture at the thoracolumbar junction due to poor anterior column support, and insufficient points of fixation [10, 11]. Hence, the choice of the fixation hardware is crucial to guarantee the success of such surgeries. In this study, three different short segment constructs were biomechanically compared to investigate their stiffness under different loading conditions. The results show that using pedicle screws increase the stiffness during flexion-extension moments when compared to lateral plate only, see Figure 2a. However, during left lateral bending, the main load was supported by the transverse plate. Accordingly, 1RPC and PC produced higher stiffness than 2RC. Consequently, the stiffness of 1RPC and PC reduced significantly at the right lateral bending, due to the lack of a transverse plate, see Figure 2b. These findings emphasize the non-symmetric behavior of the transverse plate in stiffening the junction when loaded in the coronal plane. These results were corroborated by the higher coupled motion for the PC construct in all loading condition, except for the case of left lateral bending. In conclusion, the results of this analysis suggest that pedicle screws are very important in supporting the spine during flexion, extension and axial rotation, and also suggest not using the transverse plate alone.

IN-SITU HEAD ACCELERATION MEASUREMENTS FOR PLAYGROUND IMPACTS RELATIVE TO HEAD INJURY METRICS

Eric A. Kennedy, Greg P. Danchik, Chris D. DiDomenico

Department of Biomedical Engineering
Bucknell University
Lewisburg, PA, USA

INTRODUCTION

Recent scientific efforts to better understand the risk of traumatic brain injury (TBI) – particularly as a result of head impact in sports and play [1, 2] – have led to increased societal awareness, changes in gameplay and practice rules, and new initiatives in the evaluation of helmets. Additionally, campaigns such as the federal government's "Let's Move" initiative encourage a rediscovery of physical activity, particularly for children. While the benefit of an active lifestyle is hardly disputed, the need for injury prevention strategies does increase.

Playground injuries account for 200,000 emergency room visits every year [3]. Approximately 70% of these injuries come from falls onto the surface [4], with the vast majority of injuries (75%) occurring on public playgrounds [5]. Of those emergency room visits, approximately 30% of those injuries were to the head and neck area [6]. This is critical as a childhood head injury can have a lasting impact throughout life. Head injuries have a variety of side effects; some of the most common side effects are headaches and behavioral changes [7, 8, 9] but head injuries have also been linked with educational lag and psycho-social challenges from one year after the injury to even two decades later in life [10, 11].

Little research exists regarding in-situ surface data and assessment of the variability of surface performance in different locations on the playground (swings, slides, etc.). The research that does exist supports that in-situ surface erosion caused by foot traffic and other factors, as well as the location within the playground, play a significant role in head injury potential [12]. It is evident that the locations within the playground that have the most amount of surface erosion pose the highest risk in general, but this risk is not yet quantified.

With that context, the purpose of this study was to perform on-site (in-situ) evaluation of playground surfacing – particularly high-maintenance surfaces, such as wood-chip mulch – to evaluate the impact attenuation characteristics between maintenance cycles. Additionally, in-situ results are compared to established limits for head injury, such as automotive head injury metrics and limits utilized by US federal regulations and the Insurance Institute for Highway Safety (IIHS).

METHODS

To assess various playground surfaces, a Playground Impactor Missile (PIM) and test protocol was developed in conformance with standard ASTM F1292-13 [13]. The PIM was instrumented with three accelerometers in a triaxial configuration located at the missile's center of gravity. The testing height from the bottom of the PIM to the playground surface for the tests was 1.50 ± 0.08 meters. Four playgrounds, municipal and private, with various ground covers (mulch, grass, unitary surface) served as the test sites. The locations that were assessed included the surface under the swings, slides, monkey bars, and on several low traffic areas (open, non-specific locations) with the appearance of high quality ground cover. The PIM was then dropped three times at each location. Thickness of the ground cover was determined by measuring the depth of the wood chips to the geotextile fabric beneath the surface after three tests were conducted at each location.

Head injury risk assessment was performed by calculating the Head Injury Criteria (HIC_{15}) for each test location and categorizing the risk level for an Abbreviated Injury Scale (AIS) level 2 ("moderate") head injury. AIS 2 was the head injury risk level chosen because the injuries classified as AIS 2 head injuries are most closely related to mild traumatic brain injury events, such as concussion. Similarly, the AIS 2 risk curve is also closely related to other biomechanical risk estimates for concussive injuries [14].

The risk levels were based on the severity of head injury risk and were divided into six different levels: *Risk Level 1* (<10% of AIS 2 head

Table 1: The average HIC_{15} scores, with associated AIS 2 head injury risk, and head accelerations for each surface type and depth.

Surface	Average HIC_{15}	Avg. Peak Accel. (g)	AIS 2 Injury Risk
Bare Soil	1612 ± 563	261 ± 59	99% (92% - 100%)
2.5 cm Mulch	679 ± 94	135 ± 13	62% (50% - 73%)
7.5 cm Mulch	346 ± 62	87 ± 10	20% (14% - 27%)
10.0 cm Mulch	283 ± 34	73 ± 5	14% (11% - 17%)
12.5 cm Mulch	236 ± 30	66 ± 5	10% (8% - 12%)
15.0 cm Mulch	178 ± 58	53 ± 12	6% (3% - 10%)
Grass	1238 ± 336	197 ± 34	97% (84% - 99%)
Unitrary Surface	567 ± 72	113 ± 12	47% (38% - 57%)

injury), *Risk Level 2* (10%-20%), *Risk Level 3* (20%-30%), *Risk Level 4* (30%-40%), *Risk Level 5* (40%-89%), and a *Critical Limit* risk level (89+%), which is the current threshold limit established by the ASTM (HIC_{15}<1000). Due to the non-linear relationship between HIC_{15} and predicted injury risk, the risk level divisions were determined by percentage of head injury risk rather than the calculated HIC_{15} value. The 40% risk threshold was chosen to serve as a cutoff for acceptable surfaces (*Risk Level 4* or below) versus poor performing or incompliant surfaces (*Risk Level 5* – *Critical Limit*). The *Critical Limit* was identified in accordance to ASTM's standard for impact attenuation on playground surfaces; if the HIC_{15} score exceeds 1000, the test exceeds the ASTM's critical limit [13].

RESULTS

The tests were performed at four different test sites, i.e. different playgrounds. The test locations (41) were selected from high and low traffic areas and were found to have surface types of 15 cm of mulch (10 locations), 12.5 cm (2 locations), 10 cm (3 locations), 7.5 cm (3 locations), 2.5 cm (1 location), grass (13 locations), unitary surface (5 locations) and bare soil (4 locations). The three HIC_{15} scores and g-max scores at each location were averaged together to determine the average HIC_{15} and g-max at each location (Table 1). The average HIC_{15} scores ranged from 178 with 15 cm of mulch and 1612 at bare soil, while average peak accelerations ranged from 53-261 g. The HIC_{15} scores were also plotted along the AIS 2 injury risk curve (Figure 1).

DISCUSSION

ASTM standard F1292-13 is the preeminent standard for impact attenuation on playgrounds. This study followed this standard with surface preparation, data analysis, and the identification of the critical limit (HIC_{15}<1000 and g-max<200). In ASTM F1292-13, the height at which the critical limit is reached is defined as the critical height. The critical height is then compared to the fall height of the equipment as determined by ASTM F1487-07 and is generally defined as the highest point at which a child could fall off that piece of equipment [16]. While determination of the critical height was not the focus of this study, the ASTM critical limit was exceeded on two surface types: bare soil and grass – both located directly underneath swings, one of the highest risk pieces of playground equipment. Based on current ASTM F1292-13 limits, all other surfaces remained below the ASTM critical limit (from a drop height of 1.5 m).

This study found that areas with decreased surface quality had a decrease in impact attenuation and an increase in head injury risk, which is consistent with other studies that have shown head injuries to occur most frequently around high-use playground equipment [4, 5, 12]. This

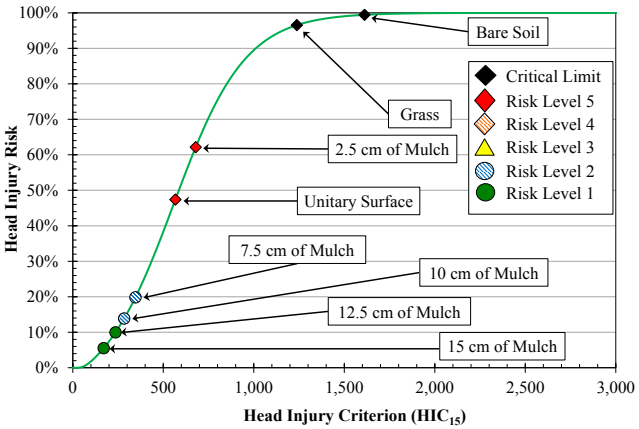

Figure 1: The average HIC_{15} scores of each surface depth and type are plotted on the AIS 2 head injury risk curve.

underscores the importance of regular maintenance, and the data particularly shows the benefits of strict adherence to a minimal mulch depth (7.5 cm or greater) as a potential maintenance guideline for loose fill surfaces.

It is interesting to note that the ASTM limit of HIC_{15}<1000 allows for a tolerable head injury risk (AIS 2) of <89%, while contemporary automotive crash test standards have evolved to lower injury metrics, with a HIC_{15} limit of 700 (<65%) for US crash test regulations [15] and HIC_{15} thresholds of 840 (<79%) for *Marginal-Poor*, 700 (<65%) for *Acceptable-Marginal*, and 560 (<46%) for *Good-Acceptable* performance classifications within the IIHS testing protocols [17]. While the ground covers were found to be compliant with current playground standards (outside of bare soil and grass), several passing surfaces would otherwise approach head impact performance thresholds for automotive safety testing. Due to the high observed risk of AIS 2 head injury and associated potential long-term consequences, it is suggested that current playground standards should be revisited in relation to standards in other industries, such as the automobile industry.

INTRODUCTION

Under body blast (UBB) events in theater are frequently the cause of injuries sustained by the modern warfighter. According to Owens et al., explosion-related injuries have increased from 7% to 81% from World War I to recent conflicts [1]. The U.S. Army Warrior Injury Assessment Manikin (WIAMan) program is seeking to mitigate injuries from UBB events through the development of a soldier-representative, biomechanically-validated anthropomorphic test device (ATD). The WIAMan ATD will be used to enhance human risk assessment in the UBB environment (e.g. live-fire test and evaluation) and to improve safety mitigation technology. This effort includes the development of a computational model of the pre-generation 1 design of the WIAMan ATD. The current study focuses on the head and neck of the computational model. The objective of this study is to use the model of the WIAMan head and neck to predict its response in two UBB-related simulations and to analyze geometrical sensitivity in this regime. This study leverages the strength of finite element models (FEMs) as a predictive tool to better inform the development of the physical ATD.

METHODS

The geometries used for this study were based on computer aided designs of the pre-generation 1 WIAMan head-form and neck. The molded head flesh and skull were tetrahedrally meshed and were modeled as Shore 55A PVC and Shore 75D polyurethane respectively. The molded neck was hexahedrally meshed and modeled as a Shore 75A rubber. Physical instrumentation and connection plates included in the designs of the pre-generation 1 ATD were also meshed and included in the model. The assembled head-form and neck can be seen in Figure 1.

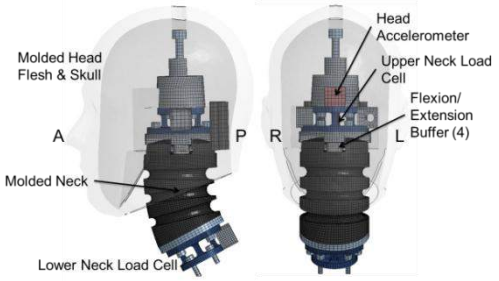

Figure 1. WIAMan Pre-Gen 1 ATD head and neck design.

For this study, two experimental loading conditions were simulated with the FEM. The first was based on a controlled vertical compression of the neck (MTS experiments performed by Bass et al. Duke University, Figure 2a). The second scenario simulated was based on a vertical acceleration of the head and neck components together (experiments performed by Pintar and Yoganandan et al., Medical College of Wisconsin, Figure 2b). In this simulation, the full head-neck was accelerated vertically towards a barrier representing a simplified vehicle roof. As in the experiments, the head of the model was also outfitted with a helmet. Each simulation was run at various speeds and all simulations were run using MPP LS-Dyna (v. 6.1.1, LSTC, Livermore, CA). Filtering was performed using SAE filters in LS-Prepost. Following simulation, model results were compared to physical tests and objectively evaluated using CORrelation and Analysis (CORA). For the neck-only compression tests, additional simulations were also performed to evaluate the sensitivity of the WIAMan neck to curvature changes, geometry modifications, and load cell alignment.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

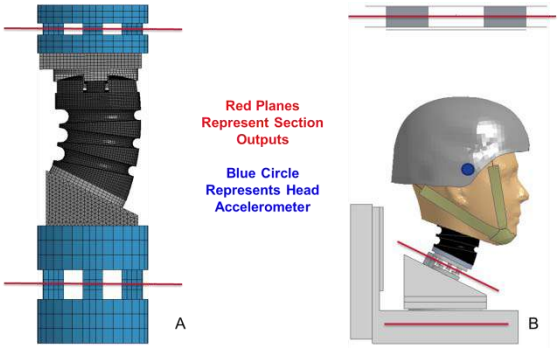

Figure 2. Primary test setups.

RESULTS

In the neck-only compression simulations, the molded neck had upper neck peak loads of 5.6 kN, 7.1 kN and 8.7 kN for compression velocities of 200 N/ms, 400 N/ms, and 600 N/ms respectively. CORA [2] scores comparing the simulated compression tests to the physical tests can be seen in Table 1. Additionally, the percent difference in peak load can also be found in Table 1. For both the CORA score and peak differences, the scores were weighted to emphasize the primary responses (compressive load and primary moment) over off-axis loading. Plots of two representative traces can be seen in Figure 3. These plots are representative of the upper load cell compressive load (Z Force) along the vertical axis and the primary moment at the upper load cell in the sagittal plane (Y Moment).

Table 1. CORA Scores

	200 N/ms	400 N/ms	600 N/ms
Weighted CORA Score	**0.82**	**0.81**	**0.81**
Weighted Peak Difference	**0.11**	**0.09**	**0.10**

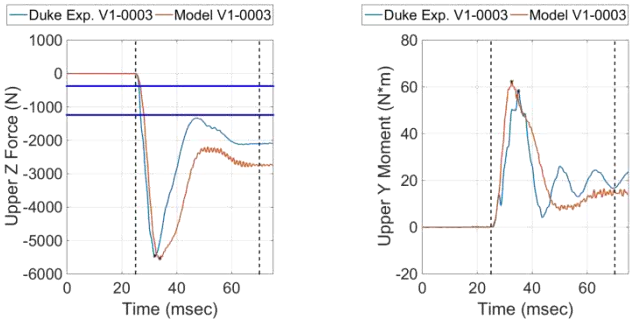

Figure 3. Primary responses at 200 N/ms. Data shown were measured at the upper load cell.

With regards to sensitivity analysis, the base of the molded neck was translated ± 15 mm in the anterior-posterior direction to evaluate the effect of neck curvature on the peak loads. From this, 15 mm of posterior translation was found to decrease the peak compressive load by 11% and increase the moment by 12%. Anterior shift had little effect on the compressive load, but reduced peak moment by 18%.

The effect of load cell alignment was evaluated by translating the upper load cell ± 5 mm in the anterior-posterior direction. Following these translations, the model was found to show no sensitivity in peak compressive load, but showed a 64% increase in moment for posterior shift and a 57% decrease in moment for anterior shift.

Lastly, the effects of volume change due to geometry modifications were evaluated. Based on these simulations, reductions in volume led to a linear decrease in compressive forces (Figure 4).

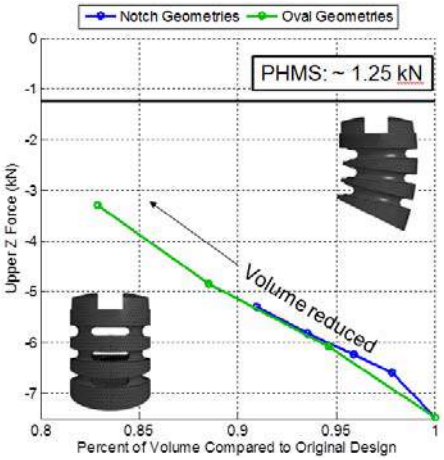

Figure 4: Sensitivity to design modifications. Typical notched and oval modifications shown. Plot shows typical peak value for PMHS testing.

The helmeted head-neck simulations were run at 3 speeds: 1m/s 2m/s and 3m/s. Of these, only the 3m/s simulation had head-to-roof contact. In this simulation, the peak roof contact force was 13.5 kN. In general moments were greater for the roof contact case than in the neck-only compression tests.

DISCUSSION

In this study, the pre-generation 1 design of the WIAMan neck was evaluated in two conditions. It has been validated in axial compression. Next steps will focus on continued validation in the roof impact scenario which are pending physical testing. It is known from the physical tests (and supported in virtual evaluation) that the neck is stiffer than cadaveric cervical spine tests conducted for the program. Therefore, the sensitivity analyses were run to evaluate where design modifications can have the most impact in aligning the ATD response to the PMHS tests. From these, the neck (particularly moment) was found to be most sensitive to load cell alignment and volume changes induced by removing material from the molded neck had the greatest effect on lower the force. Thus, Modeling and Simulation (M&S) activities are informing the design, evaluating design modifications and assessing strength of design for the WIAMan program.

INTRODUCTION

Circulating tumor cells (CTCs) have been recognized as the precursor to metastasis in many cancers. These cells are rare in the bloodstream, and, if isolated, can provide details on the diagnosis of non-hematologic and epithelial cancers, along with furthering the research on metastatic cancers and their origins. The ultimate goal in this field is to isolate CTCs from normal blood cells with a high efficiency, high purity and high viability [1]. Various technologies have been developed which fall into two main categories: physical property based and immuno-affinity based approaches. Due to the complexity of cell biology, there is currently no definite method,yet, to achieve the above-mentioned goal yet. Most of the methods on the separation of CTCs from whole blood require complex blood processing and complex approaches to detach captured CTCs, thus yielding a low viability. As a result, there is an urgent need to develop a technique to isolate CTCs from blood samples in a convenient and reliable manner.

In literature, it was found that E-selectin is present on endothelial cells when chemotaxis of leukocytes (leukocyte migration) occurs [2]. The ligand-receptor attraction allows for the rolling of leukocytes due to a relatively weak bond. A similar interaction is noted with tumor cells. Through their binding to E-selectin, tumor cells are able to travel along blood vessels to different organs and cause metastasis. In a previous study, CTC rolling on E-selectin was compared to white blood cells (WBCs). The WBCs exhibited a stronger interaction with stable, more numerous bonds. Conversely, CTCs maintained a weaker bond [3]. By taking advantage of this adhesion force difference, we aim to develop a novel microfluidic chip coated with E-selectin to isolate CTCs from normal blood cells.

In the following contents, the working mechanism of the device is first discussed. Then our preliminary experimental results are used to support the proposed idea.

METHODS

Working Mechanism

The overall strategy to isolate tumor cells from normal blood cells is described below. After designing an E-selectin coated microfluidic chip with inclined wavy patterns, blood samples spiked with tumor cells are injected through the chip. Different cells either flow or roll along different pathways, as sketched in Fig. 1(a) and explained in the following paragraphs The experimental test system is shown in Fig. 1(b). For the preliminary flow test, RBCs are lysed so that isolation of only WBCs and CTCs are tested.

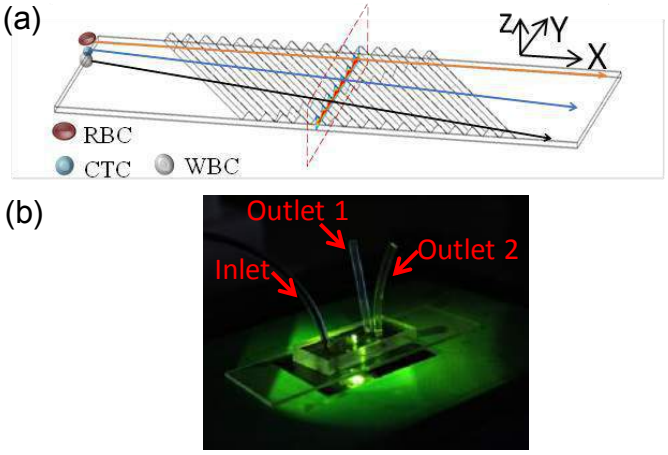

Fig. 1 (a) The proposed concept of different cells flowing or rolling along different pathways. (b) Experimental setup for the tumor cell isolation.

To achieve the cell adhesive rolling based cell isolation mentioned above, the device performance was evaluated from two aspects. First, with the inclined wavy pattern, the flow presents velocity components in the cross-section as shown in Fig. 2(a). Due to the fluid mass conservation and the inclined wavy direction, a large looped flow pattern with a clockwise direction is formulated as shown in Fig. 2(b). Regarding the forces, cells experience same gravity force and buoyant force everywhere while drag forces exhibit different directions in different locations. With Since the densities of both CTCs and WBCs are larger than that of the fluid medium, cells undergo an unstable force balance and shift following the flow loop pattern. They

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

finally focus at the interfaces where buoyant force and drag force balance with the gravity [4].

After the cells focus to one side of the channel, subsequent cell isolation is achieved based on different adhesive force for CTCs and normal blood cells. As shown in Fig. 2(c), it was found that RBCs have no interaction with the E-selectin coated surface, thus following the straight flow stream. Both CTCs and WBCs perform adhesive rolling on E-selectin while stronger adhesion force exists for WBCs. In combination with an inclined wavy pattern, which provides a guiding direction, it is expected that CTCs and WBCs will roll on the E-selectin coated surface following different pathways.

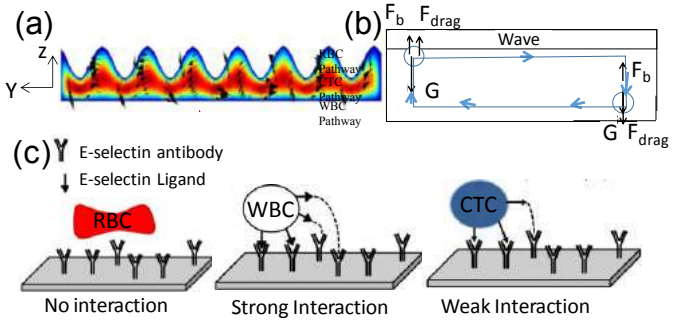

Fig. 2 (a) The velocity contour in the cross-section of Fig. 1(b). (b) A schematic image of the looped flow pattern and the forces acting on a flowing cell. (c) A schematic image indicates the interaction between cells and E-selectin coated surfaces.

Fabrication Approach

A reflow approach was used to fabricate the inclined wavy pattern. Briefly speaking, a traditional grooved pattern was first fabricated. After replicating an uncured photoresist mold by the nano-imprint approach, the photoresist was melted to form waves at 65 ^{o}C.

Cell Isolation Test

PC3 cells were cultured and used as a model CTC cell line. PC3 cells were pre-stained with cell-tracker and then spiked into human whole blood or RBC lysed blood. Cell solution was then injected into the E-selectin coated microfluidic chip. Regular and fluorescent microscopes were used to observe the cell rolling and isolation process. To quantify the cell rolling velocities, the cell rolling process was recorded and then analyzed by ImageJ.

RESULTS

To demonstrate the focusing effect brought by the inclined wavy pattern, we then performed a cell flowing test in a microfluidic chip with no E-selectin coating, as shown in Fig. 3. It was clearly observed that all cells are focused to the side channel with a narrow focusing band. This observation shows that all cells are first focused to one side, and are then isolated based on the adhesion force difference mentioned above.

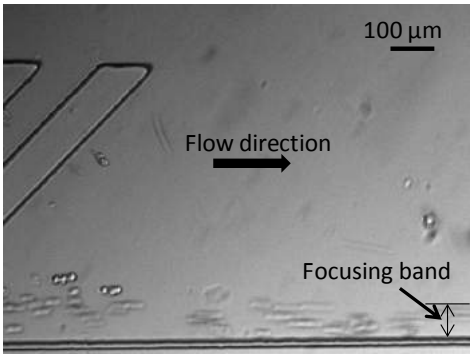

Fig. 3 Optical image indicates cell focusing effect in a microfluidic chip with inclined patterns.

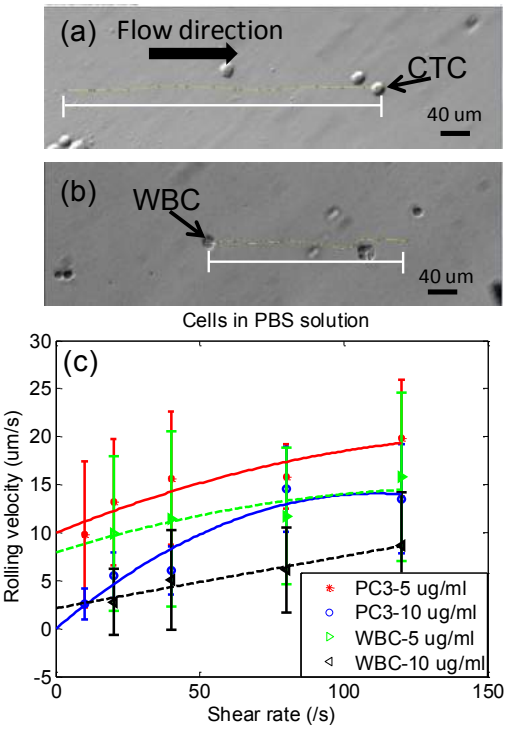

Fig. 4 Transient cell rolling image for (a) CTC and (b) WBC. (c) Rolling velocity for PC3 cells and WBCs under different shear rates and different E-selectin coating density.

To demonstrate the adhesion difference for CTCs and WBCs, Fig. 4(a) and (b) show time series of CTCs and WBCs rolling on an E-selectin coated flat surface. It indicates that CTCs roll faster than WBCs. Fig. 4(c) shows a further quantitative analysis of cell rolling velocities for CTCs and WBCs under different shear rates and different coating densities. In comparison to WBCs, the larger rolling velocity for CTCs suggests a smaller adhesion force between CTC and E-selectin. This supports our hypothesis that CTCs and WBCs will be geared towards different pathways, as sketched in Fig. 1(a).

DISCUSSION

Our preliminary results demonstrate the cell focusing effect and adhesive force difference in the proposed microfluidic chip coated with E-selectin. This suggests that the proposed cell adhesive rolling based approach for tumor cell isolation is feasible. This approach provides a convenient strategy to isolate tumor cells from whole blood without any blood processing and cell detachment operation, thus presenting a convenient platform which is essential for tumor cell profiling and genomic analysis. Future work will be performed to validate the full functionality of this device.

INTRODUCTION

Substrate properties, such as stiffness, control cell morphology, elongation, alignment (spatial orientation), and anisotropy of cell and nucleus shape, which partially direct the cell fate. Thus, it is of utmost importance to achieve elongated and aligned cellular organization *in vitro* for functional and hierarchical study of cell behavior. Even though methods exploiting substrate topography were previously utilized to achieve cellular alignment, they were limited to two dimensional (2D) planar substrates. In native tissues, extracellular matrix and other cells confine cells, which result in different morphology, adhesion, migration, and cytoskeletal arrangement in comparison to cells in 2D. Thus, there is a need for engineered 3D microenvironments with precise control over topography and stiffness.

Microengineered substrates allow simplification and decoupling of the complex in vivo 3D environment by mimicking key physical characteristics, such as stiffness and directionality. Micropillar arrays have been utilized as 2D semi-continuous substrates for studying the relationship between focal adhesion size and traction forces, and cell differentiation [1]. Micropillars can be used as 3D microenvironments with controlled mechanical, chemical, and biological features.

Here, we have designed and fabricated, anisotropically stiff micropillar array substrates to confine, align, and elongate single mesenchymal stem cells (MSCs) and cardiomyocytes in a 3D microenvironment (Fig. 1a-c). We present for the first time, to the best of our knowledge, control of cell elongation and alignment in a 3D microenvironment by systematically modulating the stiffness anisotropy of the microfabricated substrate. We discovered that anisotropically stiff micropillar substrates provide cellular confinement in 3D, aligning cells in the stiffer direction with extraordinary elongation of both MSCs (≈ 600 μm) and cardiomyocytes (≈ 500 μm).

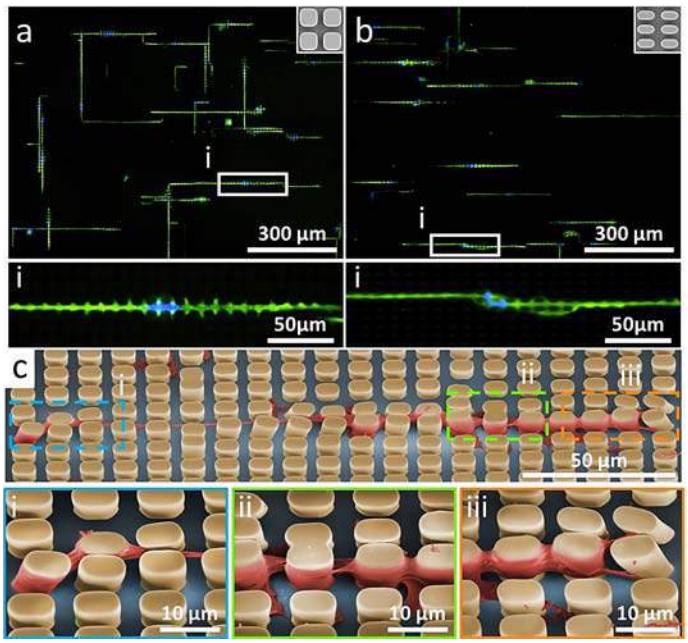

Figure 1. Unidirectional cell elongation in anisotropically stiff micropillar arrays. (a, b) Entrapped cells (F-actin, green) and their nuclei (DAPI, blue) display elongation in both **(a)** isotropic, and **(b)** anisotropic 3D micropillar environment. **(c)** Scanning electron microscope (SEM) image (pseudo-colored, cells: red, pillars: brown, substrate bottom surface: gray) of an elongated cell entrapped within an anisotropic inter-pillar space.

METHODS

Micropillar arrays were fabricated in both isotropic and anisotropic configurations with stiffness anisotropies (SA) ranging from 1 to 3.7 (Fig. 2a-d). Poly(dimethylsiloxane) (PDMS) replica-molding was used to fabricate negative template by casting PDMS over SU-8 micropillar master. After curing and peeling off, micropillar arrays were obtained by casting PDMS over the negative template. Afterwards, MSCs and cardiomyocytes were seeded on isotropic and anisotropic micropillar arrays. Overnight cultured cells were labeled with cytoskeletal F-Actin and nuclear staining to analyze cell alignment, elongation, and entrapment in 3D anisotropically stiff micropillar environment. A fluorescent cell tracking stain was used for time lapse live cell imaging.

RESULTS

Isotropic micropillar arrays showed random cell alignment in both horizontal and vertical directions, whereas cells in anisotropic micropillar arrays unidirectionally aligned in the stiffer (horizontal) direction. We observed higher degree of unidirectional cell alignment with increasing SA of the micropillar arrays both for MSCs and cardiomyocytes (Fig. 2d). In time lapse analysis, cells settled down and migrated into inter-pillar space within 0.6 hours and elongated in both directions within 5 hours (Fig. 3a-d). Cells were completely elongated and aligned in the stiffer direction within 15 hours (Fig. 3e).

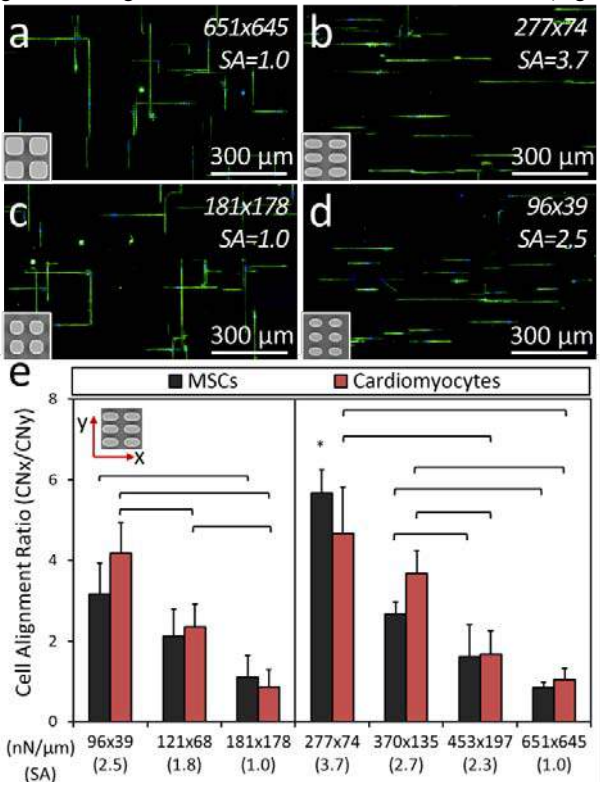

Figure 2. Functionalized anisotropic micropillar arrays control cell morphology and alignment. (a-d) Cell alignment in isotropic **(a)** and anisotropic **(b-d)** micropillar arrays was observed, indicated by cytoskeletal F-Actin staining. **(e)** Higher cell alignment ratios (CNx/CNy; number of cells aligned in x- direction, CNx, divided by number of cells in y- direction, CNy) were observed with increasing stiffness anisotropy of the micropillar arrays for both MSCs and cardiomyocytes. The horizontal lines between individual groups represent statistically significant difference based on one way ANOVA test ($p<0.05$).

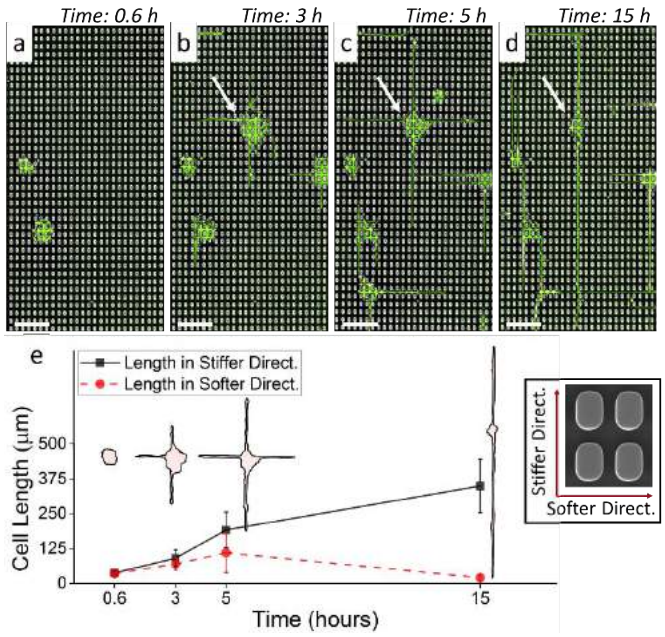

Figure 3. Time lapse analysis of cell entrapment and elongation in inter-pillar space. (a) Seeded MSCs settled down on anisotropically stiff micropillar arrays (SA=2.3) and started migrating into the inter-pillar space. **(b, c)** Cell elongation in inter-pillar space began within 3 to 5 hours after cell seeding. **(d)** Cells were fully elongated and aligned in the stiffer direction (vertical) within 15 hours after cell seeding. White arrows points to a typically elongated cell. Scale bars indicate 50 µm of length. **(e)** Cell length in softer direction increased within 0.6 hours to 5 hours, but decreased from 5 to 15 hours after seeding. On the other hand, cell length in stiffer direction displayed a continuous increase within 15 hours after seeding. Schematic of a typical cell morphology over time is displayed in the plot.

DISCUSSION

Here we present a new approach and platform that would allow the study of cell behavior in a precisely controlled 3D microenvironment. The described microfabricated pillar system can be utilized for the study of cell-ECM interactions and cell behavior in a mechanically controlled 3D environment. The micropillar platform allows precise control over substrate stiffness and stiffness anisotropy, which induces different degree of cell alignment and elongation. The presented microengineered approach induces cells to elongate and align along the stiffer axes of micropillars while confining cells in a 3D environment. Cultivation of highly elongated and aligned cardiomyocyte constructs can potentially lead to a highly organized and functional cardiac tissue. Furthermore, highly organized cell arrays can be utilized in other tissues with elongated cell phenotypes, such as nerves, tendons and ligaments.

INTRODUCTION

The cell nucleus is known to contain, maintain, and interpret the genomic information that forms the basis of every individual. In addition, it experiences an enormous amount of deformation in everyday tasks, especially in mechanically challenged tissues like the heart, muscles, skin and tendons. Elevated nuclear strain can lead to extensive DNA damage [1]. Genomic instability due to altered chromatin structuring factors is one of the suspected main mechanism for the accumulation of mutations necessary for cancer development [2]. Understanding how the nucleus reacts to high nuclear strains and protects the integrity of its genome can open new perspectives on diseases ranging from cancer to conditions with pathological stiffened tissues, e.g. in the heart due to aging, malnutrition or post-infarction.

In differentiated cells, chromatin shows a distinct architecture with areas of different chromatin densities. This structure is achieved through histones: DNA is wound around a histone core at regular intervals (200±40 bp) and histone modifications control chromatin density by changing DNA-histone and histone-histone interactions [3]. Functional evaluation of this architecture mostly focuses on transcriptional accessibility. However, it can also serve a physical purpose as shown for photoreceptor cells of nocturnal animals which utilize a centralized dense chromatin core to focus light into receptor areas like a lens [4]. Here we propose a similar role for the chromatin architecture of mechanically challenged cells in which areas of loose non-coding and/or inactive DNA could be used as a strain relief system to protect active genes and reduce DNA breakage.

To test for our hypothesis, we analyzed the relation between strain and architecture of cardiomyocyte (CM) nuclei during contraction. We utilized a novel algorithm that determines spatial strain maps from an undeformed and deformed image input [5] in combination with fluorescently-labeled histones to assess chromatin architecture (Figure 1b). Additionally, we took advantage of the observation that

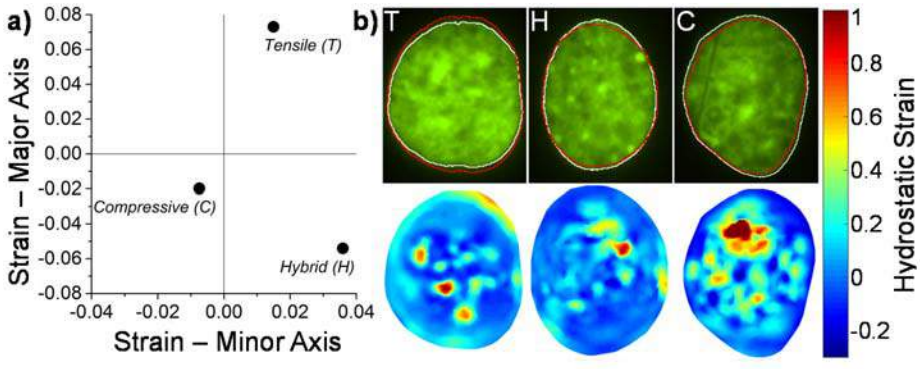

Figure 1. Nuclear loading modes of CM nuclei during contraction. Image stacks of nuclear deformation during CM contraction were recorded. **a)** Image stacks were reoriented along the major axis and the relative size difference (strain) before and after contraction was determined for each axis. Displayed are 3 nucleus that represent the 3 major loading modes: Tensile, Compressive and Hybrid. **b)** Upper panel: Chromatin intensity pictures (H2B-EGFP); nuclear borders, white: resting state, red: peak contraction. Lower panel: Spatial nuclear strain maps between resting state and peak contraction.

cultured CMs show different nuclear loading modes that range from biaxial tensile to biaxial compressive to hybrid modes with mixed tensile and compressive features along the main axis (Figure 1a). Comparing chromatin mechanics in different loading modes enabled us to identify consistent features that further supported our theory.

METHODS

Cardiomyocytes (CM) were derived from embryonic mice 16.5 days post conception which harbored an EGFP-tag at the H2B histone protein (JaxMice #006069). Isolated CMs were cultured on thin (500 µm) layers of polydimethylsiloxane (Sylgard® 527) with a stiffness of ~15 kPa and coated with Matrigel. 4 days after plating, image stacks of nuclear deformations during CM contractions were acquired using epi-fluorescence microscopy with a EMCCD camera at ~6.4 fps. Chromatin density was determined from EGFP-H2B fluorescence intensity pictures.

High resolution intra-nuclear strain fields were determined from an undeformed nuclear image during resting state and deformed image during peak contraction using a Hyperelastic Warping-based set of custom-written algorithms [5].

RESULTS

Chromatin intensity distributions followed the pattern of a multi-term Gaussian distribution with a distinct peak at mid-density chromatin (MDC) regions (Figure 2a). Notably, absolute strain values for all loading modes tended to decrease towards this peak. In the tensile loading mode strain values were highly tensile for low density chromatin (LDC), decreased towards the chromatin peak and become compressive towards high density chromatin (HDC). Interestingly, in the compressive case this observation was reversed. The hybrid loading mode in turn revealed an overlay of both before described cases with high tensile and compressive strains in both LDC and HDC and decreased strains at MDC where chromatin distribution is peaked. Analysis of 10 nuclei with mixed loading modes confirmed the trend of decreased absolute strains at MDC (Figure 2b). Segmenting the nuclei intensity pictures into LDC, MDC and HDC regions using the chromatin distributions, respectively, revealed a distinct pattern of a MDC core surrounded by LDC and MDC distributed throughout the interface of both (Figure 2c). Population analysis (n=10) confirmed that observation with LDC residing close the nuclear border, HDC close to the center and MDC being distributed in between (Figure 2d).

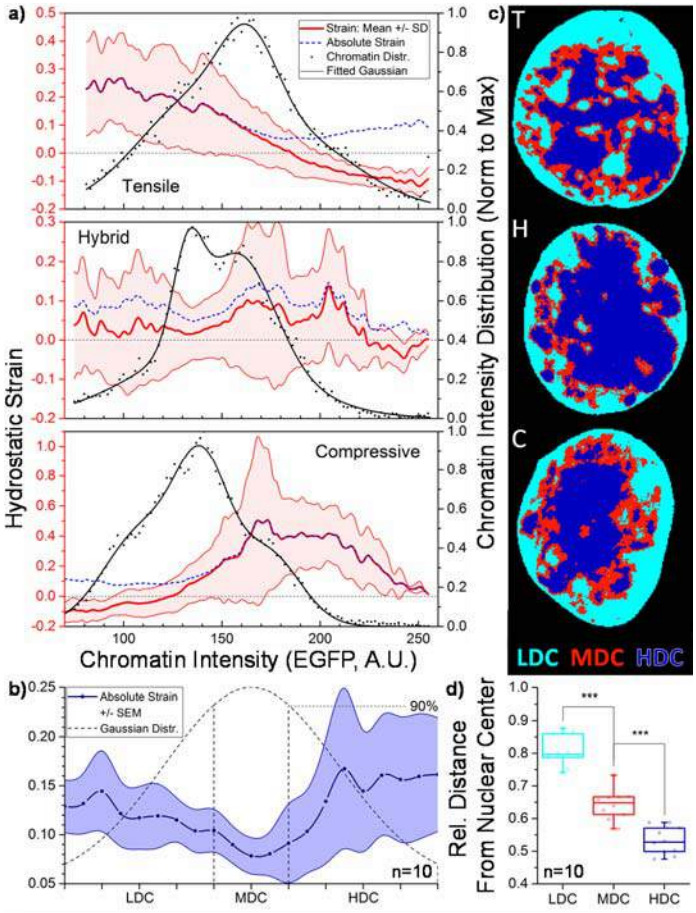

Figure 2. Relation between nuclear strain and architecture. Spatial relation of chromatin intensity images and strain maps shown in Figure 1 were analyze. **a)** *Left axis*: For each intensity value (grey values 0-255) the spatially correspondent strain values have been averaged. *Right axis*: Chromatin intensity histogram. The distribution followed a 3-term Gaussian distribution (R^2>0.98). **b)** Chromatin intensity values were normalized using Gaussian fits and absolute strain values were averaged. **c)** Intensity maps were segmented into LDC, MDC and HDC regions via histograms. **d)** Average relative distance [0-1] to nuclear center was determined for LDC, MDC and HDC regions for 10 nuclei; *** p<0.0001.

DISCUSSION

We hypothesized that chromatin architecture can serve a mechanical purpose in mechanically challenged cells to protect important genes from strain-induced damages. In such a system, soft LDC could act as an elastic element and cushion incoming strains. In accordance to that, strain values in LDC followed the main loading mode in all three nuclei, as would be expected from a spring-like element. Additionally, LDC was primarily found at the nuclear border which would be the best location to place a cushioning element. In contrast, ridged HDC was expected to display higher stiffness with only minor strains, however, absolute strain values where even higher than in LDC regions and showed a reversed relationship to the loading mode being tensile in the compressive case and compressive in the tensile case. One explanation could be, that HDC rather acts as a chromatin reservoir. During nuclear tension, chromatin would be withdrawn from HDC regions and the image-based algorithm would register the optical shrinking as compressive strains. Also during nuclear compression, more chromatin would be pressed into HDC regions during compressive loads. In accordance with our hypothesis, chromatin withdraw from this reservoir would also provide strain relief for adjacent MDC regions during tensile strains. We observed that absolute strain values are lowest for MDC where chromatin distribution peaked. It is reasonable to assume that such regions may also harbor most of the actively transcribed genes, though further investigation is needed to explore this.

In summary, using a novel imaging algorithm we provided first data that the distinct chromatin architecture of differentiated cells may provide a protective mechanism to maintain genomic integrity and enable proper gene transcription even under high nuclear strain burdens.

OBJECTIVE IDENTIFICATION OF THE YIELD POINT FROM TENSILE TESTING OF AORTIC TISSUES

Madhavan L. Raghavan, Timothy K. Chung, Chaid D. Schwarz

Biomedical Engineering
University of Iowa
Iowa City, IA, USA

INTRODUCTION

Identifying the yield point in the elastic curves from uniaxial extension failure testing of biological soft tissues is useful for two purposes – demarking the elastic region for determining elastic parameters and for determining the yield strength, a conceivable metric of the specimen's susceptibility to failure. Unlike ultimate point (the peak point in the curve), the identification of the yield point is not straightforward for biological soft tissues. For these tissues, the definition of the yield point itself is mixed, further aggravated by the nonlinear force-extension response, the micromechanics of gradual collagen recruitment, the not-so-uncommon presence of seemingly multiple yield points and the inevitable noise in acquired data. Due to these challenges, approaches for yield point identification in the elastic curves of classical structural materials are not applicable for soft tissues. In tissue biomechanics literature, the yield point is typically identified visually by subjective discretion. While expedient, subjective visual approaches to yield point identification, especially in the absence of precise *a priori* definitions, can adversely impact reliability of inferences drawn. The goal of this study was to develop an objective method for identifying the yield point from elastic curves generated from uniaxial testing of aortic wall tissue. Specifically, we sought to: 1) develop algorithms for determining yield point based on multiple definitions; 2) apply algorithm and determine yield points on a study population of force-extension curves obtained during uniaxial extension testing of aortic tissue samples from 100 study subjects; 3) Identify the optimum yield point identification method by comparing algorithm-based estimates of yield points with subjective adjudicated consensus of three human experts.

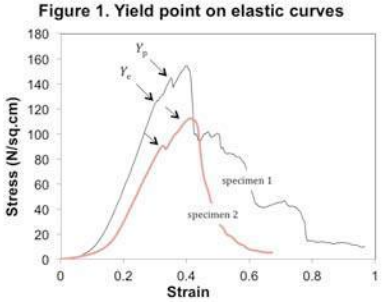
METHODS

The definition of yield point, unlike the ultimate point, requires nuanced consideration. The theoretical definition for classical structural materials – isotropic, following Hooke's law – is easy and straightforward enough. It is the point where the material starts to behave inelastically or undergoes irreversible deformation. In practice, for such materials, this coincides with the point where the linear stress-strain relationship is breached and the slope starts to decrease. But even here, the operational definition requires additional consideration such as an allowance for noise in measurements. How much decrease in slope is decrease enough such that the inevitable noise does not affect the determination? For isotropic Hooke's law materials, Christensen [1] defines the yield point as the point at which *the actual strain is 5% greater than that of the linear elastic projection* – presumably 5% is low enough not to adversely impact the theoretical definition while being high enough to ensure the yield point pick does not succumb to measurement noise. Even this operational definition is problematic for biological soft tissues mainly because the slope itself is changing incrementally (albeit increasing) prior to yield requiring us to further define, ad hoc, a predefined range of strain over which the incremental slope is determined resulting in a strong sensitivity to such choices. But a further complication is the not-so-uncommon presence of multiple local minimas in slope between the first occurrence of a yield point candidate and the ultimate point. For these reasons, slope calculations were unsuitable for our methods. Instead, we used the stress/strain ratio as its proxy. While the stress/strain ratio is certainly not the slope for nonlinear curves, because of the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

strain stiffening behavior of biological soft tissues, a drop in stress/strain ratio would reflect the beginning of the underlying structural damage that the yield point would signify. Because it is evaluated independently point-by-point, its calculation does not require a smooth curve. We evaluated two yield point definitions and identified the optimal definition by comparing against the consensus picks among three human users. The 'elastic yield point' (Y_e) was defined as the first instance where the stress/strain ratio drops by 3% (with additional criteria for filtering noise described subsequently). the peak yield point (Y_p) was defined as the point where the stress/strain ratio reaches its peak (with no noise filtering).

Figure 1. Yield point on elastic curves

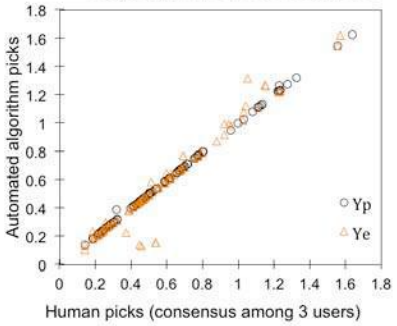


An algorithm was developed for identifying Y_e and Y_p based on the stress-strain curve in MATLAB. First, the stress/strain ratio (k), which is the slope of the line joining the origin to each datapoint prior to the ultimate point was calculated. To identify the local maxima of k without using derivatives (which are highly sensitive to noise), a two-pass filtering approach was taken: a coarse filtering approach to identify the neighborhood where a local maxima occurs and a fine filter to identify the precise point of the local maximum within that neighborhood. k at each point is first compared to that at its coarse neighbor before and after it. The coarse neighborhood around a point was defined as a window that is 3% of the ultimate strain for a specimen. The points whose k is larger than both its coarse neighbors on either side pass this filter. Next, k at the points that pass the coarse filter is compared to that at its immediately neighboring point. Again, only the points whose k is larger or equal to its neighbor on it left (lower strain) and larger to its neighbor on its right (higher strain) pass this filter and hence assigned as a yield point candidate. Among all the yield point candidates, the point corresponding to the lowest strain is designated as Y_e and that corresponding to the highest value of k is designated as Y_p. The algorithm was used to determine Y_e and Y_p in a study population of 100 elastic curves obtained from uniaxial testing of 100 aortic wall tissue specimens. These specimens were harvested from human cadavers and from patients ranging in ages from 30 through 70 years. The specimens were all cut into rectangular strips of approximately, 4 mm wide and 20 mm long. Upon measurement of its dimensions, the specimens were clamped and extended uniaxially at a constant strain rate until they tore and separated into two pieces. The recorded force and extension data was then used to calculate the incrementally varying stress and strain to obtain the elastic curves [2]. The stress-strain data was then analyzed by our developed algorithm without any human intervention to identify the Y_e and Y_p for each curve.

To assess the reliability of our algorithm, three human users who had prior experience with elastic curves of biological soft tissues were chosen. First, a training set of 10 randomly chosen curves were used to ensure the three users understand the yield point definitions. Subsequently, they individually visualized each of the remaining 90 curves and demarked manually their subjective picks for Y_e and Y_p per their respective definition. The three users picks were then compared to identify the curves where discrepancy in picks existed. These were then adjudicated and a consensus was reached. Thus, a single set of consensus yield point picks became available for the human users. These were then compared to the algorithm picks.

RESULTS

Figure 2. Yield strain estimates



The algorithm found the yield points for all the curves in the study population. The algorithm-estimated yield points matched quite well with the human consensus-based estimates with the r^2 values for stress (0.995) and strain (0.999) at Y_p being higher than the r^2 values for stress (0.930) and strain (0.927) at Y_e (Figure 2).

DISCUSSION

The elastic curve obtained during tensile testing of biological soft tissues is a window into its structural mechanical caliber. Traditionally, key inferences drawn from such curves tend to be the elastic parameters and the ultimate strength. The yield point is rarely focused on because of legitimate concerns about the consistency in its determination even though it may just signify a key milestone for failure, perhaps even more so than the ultimate point. We report here definitions for two yield point definitions, developed an algorithm to determine them objectively, used it to make picks in a large population of elastic curves for aortic wall tissue, and compared it to the gold standard of visual identification that had consensus of three users. An automated approach to yield point identification allows for analysis of large population of elastic curves rapidly while also being devoid of human subjectivity. But first, such an automated approach has to be shown to be reliable and consistent with a gold standard - human users consensus. By that yardstick, in our study, the algorithm picked peak yield point (Y_p) was the most reliable. When using the algorithm, we propose that Y_p be used as the yield point, while individualized attenstion be paid to cases where there is a large difference between Y_p and Y_e. One limitation of our approach is that the very notion that the curve would inflect when the elastic region is breached (revealing a yield point) remains unproven owing to a poor understanding of the failure mode of these tissues. Still, the first and final points of inflection in the pre-failure regions of the elastic curve (referred to here as yield points) likely signify breach of some micromechanical milestones under tension for these tissues and therefore, our proposed objective automated methodology can help improve inferences drawn from tensile testing of biological soft tissues.

EFFECT OF TRANSCATHETER AORTIC VALVE POSITIONING ON PARAVALVULAR LEAKAGE: A PATIENT-SPECIFIC NUMERICAL MODEL

Matteo Bianchi, Ram P. Ghosh, Gil Marom, Danny Bluestein

Department of Biomedical Engineering
Stony Brook University
Stony Brook, NY, USA

INTRODUCTION

Calcific aortic stenosis (CAS) is a formation of calcium deposits that thickens and stiffens the aortic valve's leaflets, thus causes a significant obstruction to blood flow during systole and limits the closure during diastole. Currently, replacement of the stenotic valve with a prosthetic valve is the only effective treatment. In recent years, a minimally invasive option of transcatheter aortic-valve replacement (TAVR) is available for high-operative-risk patients. The prosthetic valve is comprised of a bio-prosthetic leaflets mounted on a metal stent that is deployed on the diseased leaflets and therefore 'anchored' only by contact between the native root and the stent. A possible suboptimal deployment location can cause longitudinal shift of the prosthesis during the deployment [1] or post-procedural migration [2] as a result of paravalvular leakage (PVL). Currently, despite several modeling attempts to replicate the procedure, few studies investigated different stent positioning. However, these models employed either a not calcific aortic root (AR) geometry [3] thus neglecting the effect of the calcifications on the deployment outcome, or a self-expandable TAVR valve [4]. None of them modeled the influence on the PVL hemodynamics.

The aim of this work is to evaluate the effect of different TAVR deployment positions on the procedural outcome by specifically assessing risk for migration phenomena. As a first stage toward this goal, a finite element analysis (FEA) of Edwards SAPIEN valve crimping, with the prosthetic leaflets, was performed. Then, the crimped TAVR stent was deployed via balloon-inflation in a patient-specific calcified AR in three and in various locations. After a recoiling period, when the stents achieved their final position, the PVL will be evaluated by employing computational fluid dynamics (CFD) models of these configurations. Thrombogenic potential will be calculated from platelets particle flow through the paravalvular gaps.

METHODS

An 88-year-old male patient with annulus diameter of 23 mm was implanted with 26 mm Edward SAPIEN TAV in Stony Brook University Hospital. The valve was deployed via transfemoral approach and migration of the prosthesis into the LV cavity occurred after retrieval of the delivery system. The CTA scans of this case were collected after obtaining approval from IRB. The DICOM files were processed in the open source segmentation tool ITK-SNAP v3.2 to extract the blood lumen and the calcifications domains. The aortic vessel wall was extruded with a homogenous thickness while for the AV leaflets thickness varied proportionally to the radial location, resulting in thinner leaflets toward the free edge. The soft tissue thickness was then modified by to assure that the deposits are fully embedded in it. The shape and area of the AV opening were determined from the CT and echocardiography measurements.

The stent of the balloon-expandable Edwards SAPIEN is made of stainless steel (AISI 316 LVM) and was modeled as elastic material [5], whereas the bioprosthetic leaflets were modeled as hyperplastic [6]. The crimping process was simulated by radially displacing a cylindrical crimper in Abaqus Explicit 6.14 (SIMULIA, Dassault Systèmes, Providence, RI). The stent was meshed with 69,876 brick elements and the bioprosthetic leaflets with triangular-shell elements The stent was fully crimped to outer diameter of 8 mm. The balloon was meshed with 216,960 quadrilateral elements, its thickness was 0.06 mm, and its material was linear elastic [5]. The balloon deflation was modeled to fit inside the crimped stent.

The AR mesh was smoothed with ANSYS 15 Fluent Meshing obtaining a tetrahedrons-based mesh that can facilitate large deformations. The AR sinus, calcifications and each leaflet were modeled with independent material models. Three deployment configurations were simulated by placing the stent centroid in the AV

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

annulus plane, 30% shifted toward the aorta, and 30% shifted toward the left ventricle (LV) cavity and referred to as midway, distal and proximal, respectively (first row of Figure 1). In every model, the balloon was gradually inflated to a pressure of 1.38 atm and, once reached the full deployment, the stent was allowed to recoil.

The blood domain was extracted from each deployed configuration and the hemodynamics through the paravalvular gaps was investigated. Thrombogenicity is calculated from stress accumulation along the trajectories of platelets passing through these gaps. As a preliminary study, a novel TAVR valve's model was employed. The fluid domain geometry was obtained from the Living Heart Model (SIMULIA, Dassault Systèmes, Providence, RI), inclusive of a healthy AR, ascending aorta and aortic arch. The pressure and flow boundary conditions were obtained from Olufsen et al. [7] and the CFD simulations were carried out in ANSYS Fluent 16.2.

RESULTS

Similar stress distribution patterns and magnitudes were observed in the distal and the midway cases, where the maximum value were in the contact region (Figure 1). The embedded calcifications experience higher stresses than the surrounding soft tissue (for example, 3.4 MPa vs. 0.5 MPa), as a result of the stiffer material properties. The proximal deployment resulted in higher stress magnitudes at the middle of the deployment and in overall lower stresses at the end of the deployment.

The anchorage strength and the landing zone of the three configurations were quantitatively assessed based on the contact between the stent and the AR in the final recoiled configuration. Spatial maximum contact pressures at the end of the recoil were then calculated, with the distal deployment resulting in the highest magnitude of 10.38 MPa, compared to the midway and proximal cases (6.26 MPa and 3.84 MPa, respectively). In the first period of the deployment (until 80%), the inflated balloon develops the characteristic "dog-bone" configuration and then it expanded rapidly. It can be seen from the quick increase in the area. At the beginning of the recoil, when the contact with the balloon stopped, a sudden drop of the contact area can be seen. The proximal deployment experienced a loss of almost 75% of the contact area at the end of the recoil when the stent dislocated to the LV (Figure 2).

The preliminary CFD analysis demonstrates that the strong systolic jet leads to a maximum wall shear stress on the aortic wall in front of the valve (Figure 3). The ascending aorta creates a right-handed helical flow. The wall shear stress magnitude on the aortic side of prosthetic leaflets was found to be the highest on the valve surface (90 Pa). Based on the final deployed configurations in the patient-specific AR, the diastolic flow in the distal and midway positions is being evaluated. Regurgitations through the paravalvular gaps appear to be more pronounced in the midway configuration. Higher thrombogenic potential is expected to be found in the gaps with higher flow rate.

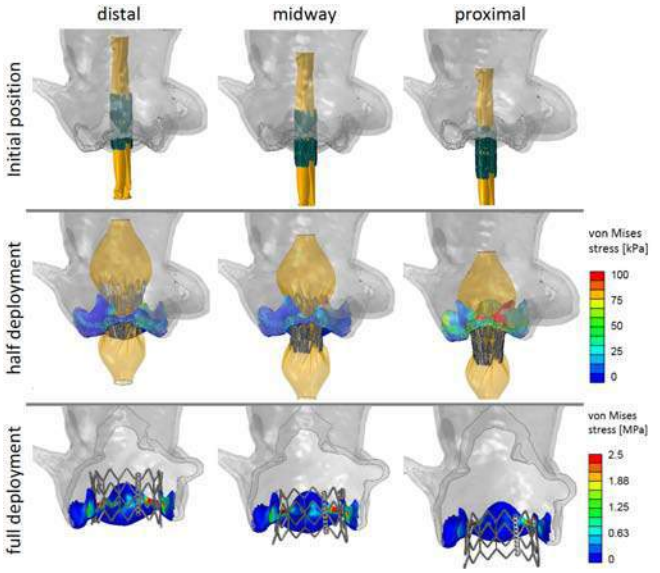

Figure 1: Various stages of the stent deployment in the three deployment locations with von Mises contours plots.

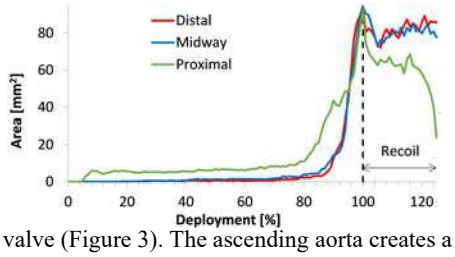

Figure 2: Total contact area in the deployment and recoil phases.

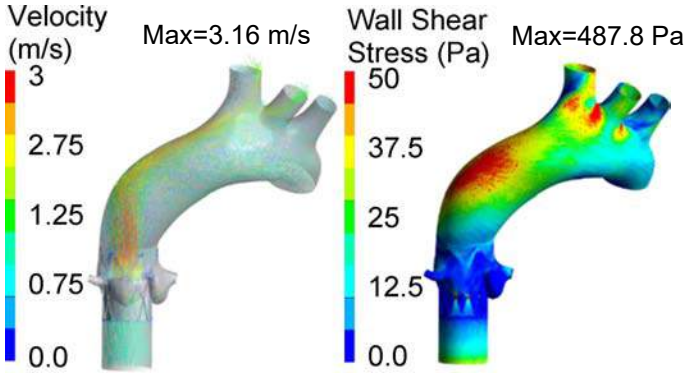

Figure 3: Flow velocity field in the TAVR valve and the aortic arch (left) and wall shear distribution on the vessel wall (right).

DISCUSSION

This study investigated the impact of TAVR deployment position on the procedural success with a focus on the risk of device migration. The comparison of the three positions showed that proximal deployment could lead to migration into the LV. This case resulted in lower contact area, which led to higher localized contact pressure and higher stress levels in the native tissue. The distal and midway configurations had comparable outcomes that would probably lead to similar performance. The influence of the TAVR valve on the hemodynamics in the anatomical aortic arch was numerically modeled for the first time. We plan to model the flow through the paravalvular gaps with fluid-structure interaction and estimate the thrombogenicity of the various configurations. After further validation of the current methods, the proposed approach might be used as a predictive tool for procedural planning in order to ultimately prevent prosthesis migration. In addition, the calculated thrombogenic potential may help design better procedure, by reducing the risk for thrombus formation and stroke events.

EFFECT OF HYDRATION ON INTERVERTEBRAL DISC RECOVERY

Semih E. Bezci, Grace D. O'Connell

Department of Mechanical Engineering
University of California, Berkeley
Berkeley, CA, USA

INTRODUCTION

Intervertebral disc mechanics are largely dependent on its structure and biochemical composition. The disc consists of a collagen-rich annulus fibrosus (AF), which surrounds a gel-like core, the nucleus pulposus (NP). The high water content of these subcomponents (NP: 80-85%, AF: 70-80%) allows the disc to resist large compressive loads while maintaining spinal flexibility and mobility [1,2]. External loads induce fluid flow out of the disc while negatively charged proteoglycans attract water during bed-rest recovery. Previous studies, including work from our own laboratory, have used osmotic loading to evaluate the effect of tissue hydration (i.e. water absorption) on mechanical function. Recently, we demonstrated that an increase in disc hydration decreases disc joint compressive stiffness [3]. This previous study only considered disc mechanics once a steady-state condition was achieved; therefore, the time-dependent response to achieve a steady-state condition under osmotic loading is not well understood.

Water re-absorption into the disc increases internal pressure; however, water flow into the disc is not trivial, due to porosity differences in the NP, AF, and endplate [4]. The first objective of this study was to analyze the time-dependent response of disc components (i.e., NP, AF and whole disc) under free-swelling conditions. Swelling response of the NP and AF were evaluated as tissue samples and under in situ conditions to account for differences in tissue swelling behavior and boundary conditions. The second objective of this study was to evaluate time-dependent recovery behavior under osmotic loading.

METHODS

Skeletally mature bovine spine sections were acquired from the local abattoir (n = 14 spines, age = ~18 months). Bone-disc-bone segments were prepared by removing the surrounding muscles and posterior elements for Studies 1 and 2 (n = 31). In Study 1, discs were dissected from the superior and inferior vertebral bodies using a scalpel to assess swelling behavior of the whole disc (n=10), NP (n=6) and AF (n=6). Whole disc or tissue samples were immersed in phosphate buffered saline (PBS) solution (0.15 M or 1.5 M PBS) until equilibrium swelling was attained, which was defined as a change in wet weight of less than 0.02 g/hr. The swelling ratio was calculated as the differences between pre- and post-swollen wet weights, normalized by the pre-swollen wet weight. A stretched exponential function was used to describe the swelling ratio as a function of time (Eq. 1), with model parameters to describe equilibrium swelling ratio (Q_∞), time constant (τ), and stretch parameter (β) where $0 < \beta \leq 1$. The stretch parameter, β, describes the rate of change of tissue-swelling with respect to an exponential curve, where the response is faster than an exponential description for $t < \tau$ and slower than exponential curve for $t > \tau$ [5]. A Student's t-test was performed to determine differences in swelling behavior of the 0.15 M and 1.5 M PBS groups.

$$Q(t) = Q_\infty \left(1 - e^{-(t/\tau)^\beta}\right) \quad (1)$$

In Study 2, unloaded recovery of bone-disc-bone motion segments was assessed with respect to osmotic loading. Motion segments were potted in bone cement to ensure parallel loading and hydrated in 0.15 M PBS solution prior to mechanical testing. A 300 N creep load was applied and held for two hours. At the end of the creep portion of the test, the water bath was replaced with fresh saline (0.015 M, 0.15 M, 0.75 M and 1.5 M PBS). Then, motion segments were allowed to recover at a nominal load (20 N) to ensure the platen was in contact with the sample during recovery (12 hours). Each sample was re-hydrated between tests and tested in a random order. Force and displacement were measured. The displacement during recovery was

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

curve fit to a 5-parameter rheological model (lsqcurvefit function, Matlab Inc.) shown in Eq. 2 [6].

$$d = \mathrm{L}\left[\frac{1}{S_1}\left(1 - e^{-(t/\tau_1)}\right) + \frac{1}{S_2}\left(1 - e^{-(t/\tau_2)}\right) + \frac{1}{S_E}\right] \quad (2)$$

The model is composed of two Voigt solids with a spring in series and allows for the characterization of the fast response (S_1 and τ_1), the slow response (S_2 and τ_2), and the elastic response (S_E). To simplify the model, the elastic response (S_E) was set as the instantaneous displacement during recovery. The model also provided parameters for equilibrium distance (d_{eq}) and equilibrium time (t_{eq}). To validate the equilibrium time predicted by the model, additional samples were loaded under the same conditions and allowed to recover for 48 hours (n = 5). A one-way ANOVA with Tukey post-hoc test was used to determine the effect of bath osmolality on recovery properties. The 0.15 M PBS group served as the control. Significance was assumed at $p \leq 0.05$.

RESULTS

The stretched exponential function described the swelling ratio well for all groups (Fig. 1; $R^2 > 0.98$). Equilibrium swelling ratio of whole discs hydrated in 0.15 M PBS was 18% greater than the 1.5 M PBS group (Fig. 2 – '*'; $p < 0.015$). There was no difference in the time constant and the stretch parameter (Fig. 2; $p > 0.07$). Tissue swelling of the NP and AF separately (0.15 M PBS only) resulted in a significant difference in swelling ratio and the stretch parameter, as expected (Fig. 2 – '^'; $p < 0.02$).

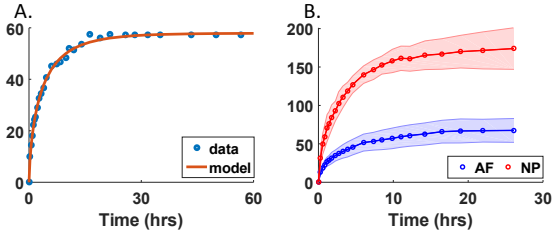

Figure 1: A) A representative AF sample showing the swelling ratio, Q (%), with model fit and B) swelling ratio for NP and AF - whole disc data not shown. Circles indicate the experimental data.

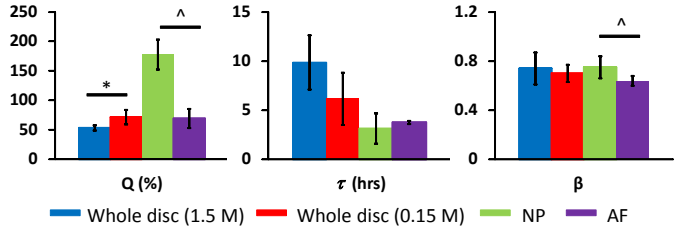

Figure 2: The parameters for the stretched exponential function.

Full recovery was not observed within 12 hours for any group, but there was a decrease in recovery with osmotic loading ($p < 0.001$; Fig. 3A). Recovery in a hyperosmotic saline (≥ 1.5 M PBS) demonstrated a reverse trend in disc height after ~3 hours, such that the disc exhibited features of loading rather than recovery (Fig. 3A – purple line). The 5-parameter model fit well to the experimental data (Fig. 3B, $R^2 > 0.99$) except in 1.5 M due to the decrease in disc height during recovery. The instantaneous displacement (elastic response) during recovery was 0.52 ± 0.12 mm (pooled average across all osmotic loading conditions). The equilibrium displacement predicted by the model agreed well with the results obtained from samples tested for 48h (Fig. 3B). The fast response behavior (S_1 and τ_1) was altered with osmotic loading ($p < 0.05$), while the slow response behavior (S_2 and τ_2) was not dependent on the osmotic loading condition (Fig. 4, S_2 = 1620 ± 422 N/mm and τ_2 = 26.7 ± 8.76 min, pooled average across all osmotic loading conditions).

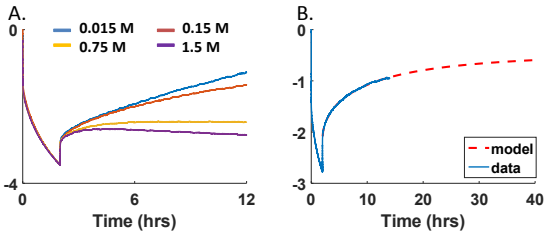

Figure 3: A) Disc height recovery for each osmotic loading group (PBS solution). B) A representative sample of data and model fit.

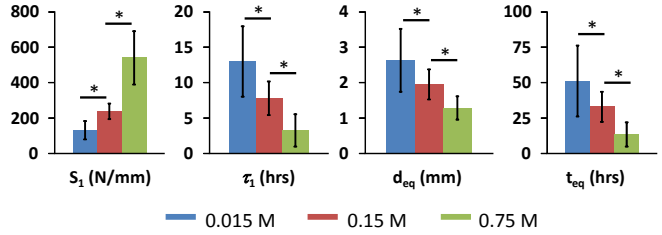

Figure 4: The results obtained from the 5-parameter model. Only statistically significant results are shown.

DISCUSSION

The disc needs to maintain adequate hydration in order to preserve flexibility, mobility, and resistance to external loads. This study evaluated the effect of osmotic loading on disc recovery behavior. In Study 1, swelling ratios of NP and AF tissue structures were evaluated separately and as a composite material (i.e. whole disc). The swelling ratio of excised discs decreased with hyperosmotic loading, which agreed well with disc joint recovery measured in Study 2. As expected, swelling behavior was greatly altered by the boundary conditions. The swelling ratio of the whole disc was closer to the AF swelling ratio, even when accounting for differences in the initial volume of each subcomponent (Fig. 2; NP volume ≅ 30% of disc volume) [7].

In hyperosmotic saline (≥ 1.5 M PBS), disc height recovery did not follow the expected behavior. After approximately 3 hours of recovery, disc height recovery reversed, suggesting a shift between recovery from mechanical loading and loading from the osmotic environment. To estimate the balance between mechanical loading and osmotic loading, the displacement at 12 hours (d_t=12hrs) was compared to the elastic displacement (S_E). The findings reported here suggest that the disc is in osmotic equilibrium in a saline bath with a concentration of ~1.0 M.

The intervertebral disc loses a significant amount of water during diurnal loading. Rehydration plays a crucial role in the disc mechanics and tissue maintenance. In conclusion, changes in the disc's external osmotic environment greatly alters disc recovery following mechanical loading, which may result in long-term degenerative like changes in composition and mechanical function.

DETAILED FINITE ELEMENT MODELING OF FIBER-REINFORCED TISSUES

Bo Yang, Minhao Zhou, Grace D. O'Connell

Mechanical Engineering
University of California, Berkeley
Berkeley, CA, United States

INTRODUCTION

Fiber-reinforced tissues, including tendons, ligaments, and the annulus fibrosus (AF) of the intervertebral disc, sustain large tensile stresses during physiological loading. These materials consist of collagen fibers embedded within a proteoglycan rich matrix, and previous constitutive models have shown that fiber-matrix interactions may play an important role in stress distribution; however, these properties are difficult to measure experimentally [1, 2].

Finite element modeling (FEM) is widely used as a complementary approach to experiments. FEMs provide detailed information of stress strain distributions that are difficult to measure directly, including stress distributions and failure behavior throughout complex tissues [3, 4]. For fiber-reinforced biological tissues, most FEM methods describe the fibers and matrix components as either fibers fixed within a matrix [5, 6] or a homogenized volume [7, 8]. However, these two methods cannot provide information about the fiber-matrix interactions, which may be crucial for understanding failure mechanics [9]. Alternatively, a more intuitive and biomechanically correct method describes collagen fibers as a separate material from the extrafibrillar matrix. Separation of fibers and matrix materials has been rarely used, likely due to difficulties of fiber bundle modeling and computational time.

The objective of this study was to compare the mechanical behavior of AF tissue under uniaxial tension using the three FEM methods described above. We based the model architecture on the AF due to the complex fiber architecture, where collagen fibers are oriented at ±45-65º to the vertical axis of the spine (Fig. 1). However, the methods applied here are easily applicable to understanding fiber-matrix interactions of other fiber-reinforced tissues, such as tendons and ligaments.

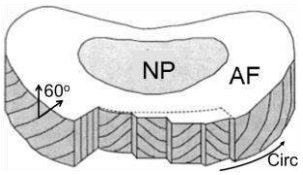

Fig. 1: Schematic of disc.

METHODS

Single lamella models were developed based on AF anatomy reported in Marchand *et al.* [10]. Specifically, each lamella is 0.2 mm thick with fibers described as cylinders through the length of the tissue (radius = 0.059 mm & 0.22 mm between fibers). Three FEM descriptions were assessed, including (1) embedded smeared (EMB), (2) homogenized hyper-elastic (HOM), and (3) fiber-matrix separated (SEP).

The solid matrix for all three models was described using a Mooney-Rivlin material description and all fibers were described as tension-only materials (Table 1). In the EMB model, the fibers were described as being an embedded rebar layer (material coefficients: E = 500 MPa, ν = 0.3, which was first reported in [5] and latter widely used in [6, 11, 12]). In the HOM and SEP models, an exponential-linear description was employed for the fibers, where the stress-stretch response increases exponentially at lower strains, then increases linearly past a defined strain threshold. Single lamellae tensile testing data in [13] was used to determine material coefficients for HOM and SEP models.

The EMB model was developed and solved by Abaqus (6.11) using model parameters reported in the literature for the AF [5]. The HOM model was developed using Preview. The SEP model was developed in SolidWorks (2015) and meshed by Abaqus and Ansa

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

(v16.0.0), and then imported into Preview. HOM and SEP models were evaluated using the FEBio solver.

	EMB(Matrix)	HOM	SEP(Matrix)	SEP(Fiber)
C_1 (MPa)	0.7	0.5	0.75	0.75
C_2 (MPa)	0.2	0.1	0.1	0.1
K (MPa)	N/A	50	50	50
D	~0	N/A		
C_3 (MPa)	N/A	0.05	N/A	0.21
C_4		78		98
C_5 (MPa)		70		380
λ		1.017		1.025

Table 1: Material parameters for FEM models.

Once material coefficients were determined, uniaxial tensile simulation results of double-layer models with fibers in ±65° orientation were compared to multi-layered uniaxial tensile data reported by Ebara *et al.* [14]. HOM and EMB double-layer models had ~20,000 elements, while SEP has ~2-3 x 10^6 elements. Finally, the SEP model was used to evaluate the effect of fiber orientation on tissue-level mechanics. Fiber bundles were arranged at ±45º, ±50º, ±55º, or ±60º, representing the change in fiber orientation from the inner to the outer AF.

RESULTS

Material properties for the HOM and SEP models were able to closely match single-lamella data (Fig. 2A) [13], while the linear description of fibers in the EMB model resulted in a poor fit to the data (Fig. 2 – green line). Model validation of the HOM and SEP models using a multi-layered description with alternating fiber orientation showed a close fit to experimental data (Fig. 2B; $R^2 = 0.64$ and 0.99, respectively) [14], and EMB almost had a linear behavior.

Once validated, the SEP model was used to describe uniaxial tensile with fiber orientation varying from ±45º to ±65º. A decrease in fiber orientation reduced tissue modulus by approximately 64% (Fig. 3A – slope of purple line *versus* blue line). Tensile stress resulted in fiber re-orientation along the direction of loading (Fig. 3B), which matched well with experimental data of fiber re-orientation [15].

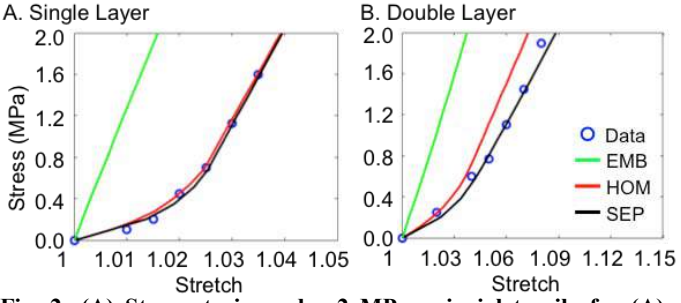

Fig. 2: (A) Stress-strain under 2 MPa uniaxial tensile for (A) single-lamella models and (B) double-lamella models (fiber orientation = ±65°).

DISCUSSION

In this study, we developed a separated fiber-matrix model description (SEP) and compared it to more commonly used FEM for fiber-reinforced tissues (EMB and HOM). Describing collagen fibers as a separate material from the extrafibrillar matrix is more consistent with the disc anatomy, but is rarely used due to computational requirements (run time: 2 minutes for HOM, 30 minutes for SEP). Recent work has demonstrated the importance of fiber-matrix interactions under physiological loading conditions [2, 16], and it is likely that these interactions play an important role in understanding the failure mechanics. SEP model demonstrated inhomogeneous stress distribution between the matrix and fibers, due to the large differences in material properties (Fig. 4)

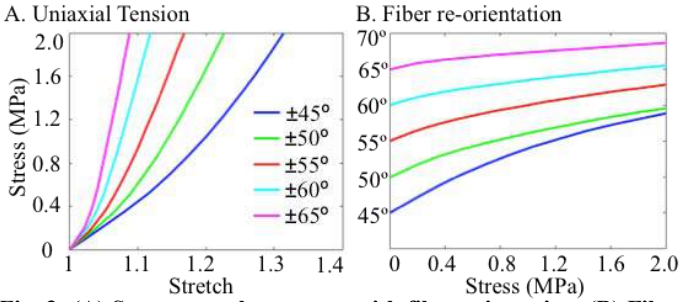

Fig. 3: (A) Stress-stretch response with fiber orientation. (B) Fiber re-orientation under tension.

The healthy AF is noted by transition of collagen fiber orientation and collagen composition (type I to II) from the outer AF to the inner AF. We used the SEP model to evaluate the effect of collagen fiber orientation while maintaining fiber strength. As expected, decreasing the fiber's initial orientation from ±65º (i.e. more aligned with the direction of loading) to ±45º resulted in a decrease in tissue stiffness. The decrease in Young's modulus from 21.8 MPa to 7.5 MPa in the inner AF follows a similar trend to experimental values (17.22 ± 7.69 MPa and 2.65 ± 1.03 MPa, respectively) [17]. However, the predicted Young's modulus of the inner annulus was 3X greater than reported values, which is likely due to the differences in collagen type.

Most embedded model descriptions for fiber-reinforced biological tissues use the linear elastic model description for collagen fibers (i.e. EMB model), with disc joint nonlinearity in compression provided by the disc geometry with fibers of various orientations [5]. However, both our single-lamella and double-layer embedded model showed an approximately linear behavior under a physiological level of strain (Fig. 2). This implies that geometric nonlinearity is not significant enough to cause stress-stretch nonlinearity in tension.

In conclusion, the findings of this study demonstrate that the SEP model has advantages over the EMB and HOM models and will be valuable for studying tissue failure. Future work will incorporate tissue-swelling behavior of the extrafibrillar matrix. Few FEMs of disc tissue include tissue swelling; however, it is likely that matrix swelling will allow for more homogenized stress distributions during loading [18].

HEMODYNAMIC REGULATION OF TIE1 IN AORTIC VALVE ENDOTHELIAL CELLS

Camryn L. Johnson (1) and W. David Merryman (1)

(1) Biomedical Engineering
Vanderbilt University
Nashville, Tennessee, U.S.

INTRODUCTION

Throughout each cardiac cycle, the aortic valve is subjected to a variety of mechanical forces. During systole, blood is ejected from the left ventricle through the aortic valve, exposing the ventricularis, the side of the valve facing the ventricle, to pulsatile flow with high magnitude shear stress (~20 dynes/cm^2). Following systole, the valve closes, and the fibrosa, the side of the valve facing the aorta, is exposed to recirculatory flow patterns with low magnitude shear stress (~2-5 dynes/cm^2). These two sides of the valve have different transcriptional profiles, indicating unique phenotypes. It is suspected that many of these differences arise from the distinct flow patterns to which each side is exposed [1].

Tie1 is an orphan tyrosine kinase receptor found almost exclusively in endothelial cells. Not much is known about its direct signaling, though Tie1 has been associated with several diseases, including atherosclerosis and rheumatoid arthritis [2]. Although there is no known ligand for Tie1, it has been shown to respond to mechanical stimuli and is expressed more highly in regions of disturbed flow. Tie1 is also frequently associated with Tie2, another tyrosine kinase receptor with key functions in endothelial cell survival and angiogenesis. Angiopoietin-1 (Ang1) is a known agonist of Tie2, although the association between Tie1 and Tie2 has been shown to mediate the response of Tie2 to ligand binding. While Tie1 is bound to Tie2, the extracellular domain of Tie2 is not available for binding to a ligand. In response to certain signals, including shear stress, Tie1 is cleaved into its ectodomain and endodomain, which contains the intracellular and transmembrane domains. Upon cleavage, the endodomain remains bound to Tie2, but frees the extracellular portion of Tie2 for ligand binding. Additionally, the endodomain of Tie1 can phosphorylate Tie2 independent of ligand, and Tie2 can phosphorylate the endodomain of Tie1 [3].

Although studies have previously demonstrated the effects of shear stress on the cleavage of Tie1, none have focused on the aortic valve endothelial cells. Though very similar in morphology to vascular endothelial cells, valve endothelial cells demonstrate distinct gene expression profiles. One important difference is that while aortic endothelial cells align parallel to flow, valvular endothelial cells align perpendicularly [1]. The change in expression of Tie1 in response to mechanical stimuli in the valve could reveal more phenotypic differences between vascular and valvular endothelial cells and could be crucial to understanding the effects of the distinct hemodynamic profiles on each side of the aortic valve.

METHODS

Porcine aortic valves were excised and digested in 600 U/mL collagenase for 10 minutes. The fibrosa and ventricularis were identified and endothelial cells were isolated from each. Populations of porcine aortic valvular endothelial cells (pAVECs) were purified using clonal expansion, with an initial concentration of 0.3 cells/well. Pure populations were combined following immunostaining for CD31 and aSMA to confirm that there was no fibroblast contamination.

Strain experiments were performed using the Flexcell FX-4000 Tension System. Cells were plated onto the flexible bottom of Flexcell plates coated with collagen IV. The plates were placed onto loading posts and a vacuum was applied, resulting in equibiaxial strain of the cells. In order to simultaneously apply shear stress and strain to the pAVECs, an insert for the Flexcell plates was designed and 3D printed. These inserts (**Figure 1A**) were placed into the Flexcell plate wells, replacing the cover. A barb on each side was attached to tubing, which was connected to a peristaltic pump programmed using an Arduino Uno microcontroller. Media flowed into the barb through the insert and out via a small notch (0.6 mm in height) at the base of the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

insert (**Figure 1B**). During pulsatile unidirectional flow, media entered the well through one side of the insert and exited through the other side. This repeated with a frequency of 0.5 Hz. During pulsatile bidirectional flow, the notches on each side of the insert alternated as the entrance and exit for media. The entire cycle repeated with a frequency 0.25 Hz (**Figure 1C**). This setup resulted in flow over the cells, and the applied shear stress was calculated using the flow rate from the pump. For combined strain and shear experiments, strain was applied during the periods without flow. Protein expression was quantified via Western blots.

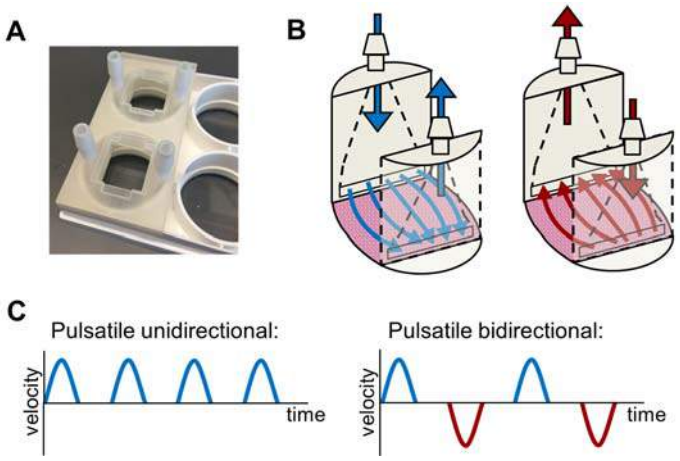

Figure 1. A) Flow insert placed into Flexcell plate. B) Illustration of the flow direction within the inserts. C) Velocity profiles for the two types of flow used.

RESULTS

Full length Tie1 protein expression in pAVECs decreased ~40% in response to 15% strain over 24 hours, while Tie1 endodomain levels increased (**Figure 2A**). Additionally, qPCR results showed that Tie1 mRNA levels did not decrease this dramatically, further indicating that Tie1 is cleaved in response to cyclic strain. Full length Tie1 protein expression in pAVECs also decreased ~60% in response to 7 hours of 10 dynes/cm^2 pulsatile bidirectional shear stress and decreased ~90% in response to 24 hours of 15% strain combined with 2 dynes/cm^2 pulsatile bidirectional shear stress (**Figure 2B and 2C**). Akt, a protein kinase downstream of Tie2 activation, shows increased phosphorylation after 15 minutes of strain (**Figure 2D**), demonstrating that Tie1 is being cleaved and activating Tie2.

DISCUSSION

These results demonstrate the importance of mechanical stimuli to Tie1 expression in the aortic valve. The finding that 15% strain decreases full length Tie1 expression contradicts studies in microvascular endothelial cells that indicate strain increases Tie1 expression [4]. Given the different flow patterns, gene expression profiles, and response to flow of valvular endothelial cells compared to vascular endothelial cells, it is important to better understand the signaling of this cell type and particularly the influence of mechanical stimuli. Despite an increasing understanding of Tie2 signaling, there is a lack of sufficient understanding of Tie1, and even less is known about its particular role in the aortic valve. The varying responses in Tie1 expression to different shear stresses and strains further demonstrate that mechanical regulation plays an important role in its signaling and warrants further investigation.

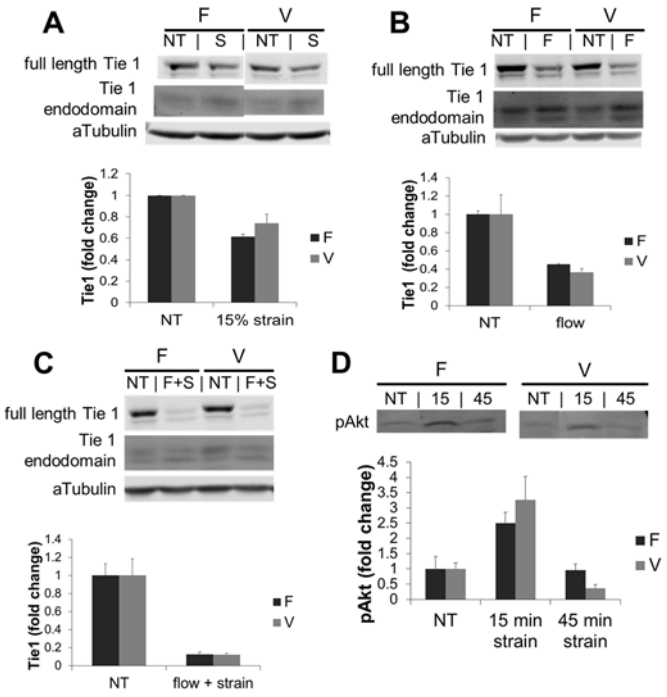

Figure 2. A) 24 hours of 15% cyclic strain (S) resulted in ~40% reduction in Tie1 expression in fibrosa (F) and ventricularis (V). B) 7 hours of 10 dynes/cm^2 shear stress with pulsatile bidirectional flow (F) resulted in ~60% reduction in Tie1 expression. C) 24 hours of 15% cyclic strain combined with 2 dynes/cm^2 shear stress with pulsatile bidirectional flow (F+S) resulted in ~90% reduction in Tie1 expression. D) 15 minutes of cyclic strain resulted in increased phosphorylation of Akt.

INTRODUCTION

Altered hemodynamics in total cavo-pulmonary connection (TCPC), a palliation of single ventricle defects, results in long-term complications, such as decreased exercise capacity, arrhythmia, and ventricular failure [1]. Patient-specific anatomy hinders a general solution for all patients. Although flow-sensitive magnetic resonance imaging (4D flow MRI) has been used to assess flow in TCPC *in vivo*, this approach is limited in its ability to predict flow behavior under extreme conditions or to evaluate effects of varying surgical procedures. Computational fluid dynamics (CFD) helps to understand hemodynamic phenomena and to virtually explore variations in physiological conditions, anatomy and tissue properties. Limitations due to simplifications and lack of validation have hindered clinical use of this potentially powerful tool [2]. The use of 3D printing to create patient-specific models is becoming more widely adopted, including complex congenital heart disease [3], as the technology becomes more ubiquitous and less expensive. There are now a variety of 3D printing techniques commercially available, including stereolithography (SLA), selective laser sintering (SLS), and fused deposition modeling (FDM) [4, 5]. There are substantial differences between each of these technologies with respect to their printing resolution, material properties, and costs. The impact of different printing resolutions and material properties on quantitative 4D flow MRI measurements in TCPC are unknown. In this study, we compared in vitro 4D flow MRI measurements in three models, each fabricated with a different 3D printing technique, to determine if there are any significant differences in hemodynamics due to manufacturing method.

METHODS

Patient-specific models: Three physical models of TCPC were created using 3D printing according to an IRB-approved and HIPAA-compliant protocol. The TCPC was segmented from images acquired as part of a clinical cardiac MRI study in MIMICs (Materialise, Leuven, Belgium) (Fig. 1A). The segmented TCPC volume was exported in STL format and printed using an SLA (Formlabs), an SLS (DTM Sinterstation 2500CI ATC), and an FDM (Makerbot Replicator) 3D printer (Fig. 1B). Internal support was removed from the SLA and FDM models. The FDM model was treated with acetone to remove remaining support material and smooth the internal surfaces.

In vitro MRI: Polyethylene tubing was attached to the inlets and outlets of the TCPC and then connected to a perfusion pump (Stockert SIII Heart-Lung Machine). MRI was performed on a clinical 3T scanner (GE Discovery MR 750, Waukesha, WI) with a 32-channel phase array body coil. 4D flow MRI was performed with a 5-pt radial-undersampled technique (PC-VIPR with following parameters: FOV = 32 x 32 x 32 cm^3, TR/TE = 5.5/2.3 ms, α = 15°, Venc = 150 cm/s, projection number ≈ 22000, 16 reconstructed cardiac time frames, scan time: 5 minutes 15 seconds. Each TCPC model was imaged separately while secured in agar, as water was pumped through the TCPC models at three different flow rates (1, 2, and 3 L/min).

Analysis: 4D flow MRI data sets were segmented, visualized and quantified in Ensight (CEI, Inc., Apex, NC). Velocity streamlines were generated to visualize flow trajectories (Fig. 1C). Flow (L/min), kinetic energy (mJ) and vorticity (s^{-1}) in the inferior vena cava (Fontan), superior vena cava (Glenn), left pulmonary artery (LPA), and right pulmonary artery (RPA) were quantified at each flow rate. Flow measurements were compared with flows experimentally measured using a clamp-on flow sensor (Transonic, Ithaca, NY). Flow values measured in each vessel were compared between different models using paired Student t-test. A p-value of 0.05 was chosen to indicate statistical significance. Finally, flow distributions (ratios) to the LPA and RPA were calculated.

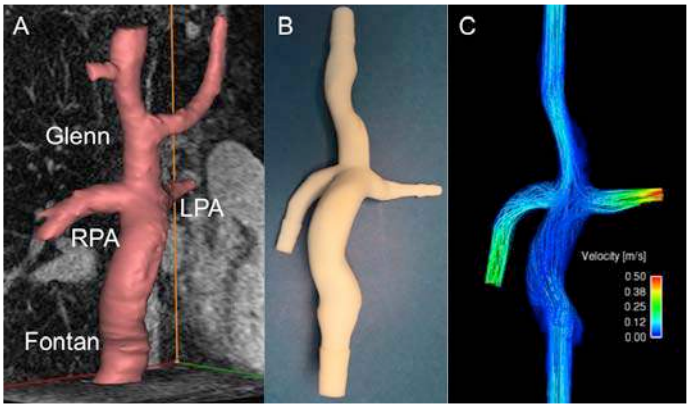

Figure 1: 3D patient-specific geometries generated from PC angiograms. A. Computational 3D model of extra-cardiac TCPC. B. TCPC model fabricated with SLS. C. Velocity streamlines.

RESULTS

4D flow MRI data was successfully acquired at each flow rate in all three models. Qualitative analysis of the velocity streamlines (Fig. 1C) revealed similar flow structures in the three models. Increase in flow rate did not substantially change the flow profiles and streamline distributions in any of the models. Excellent correlation between MRI and direct flow measurements was found (R^2 = 0.96) (Fig. 2). Differences in net flow measured with 4D flow MRI in the different models were not statistically significant ($p > 0.05$). Figure 3 shows vorticity and kinetic energy in the Fontan measured at the three different flow rates. Table 1 summarizes the flow distribution (%) to the LPA and RPA for the models at the three different flow rates.

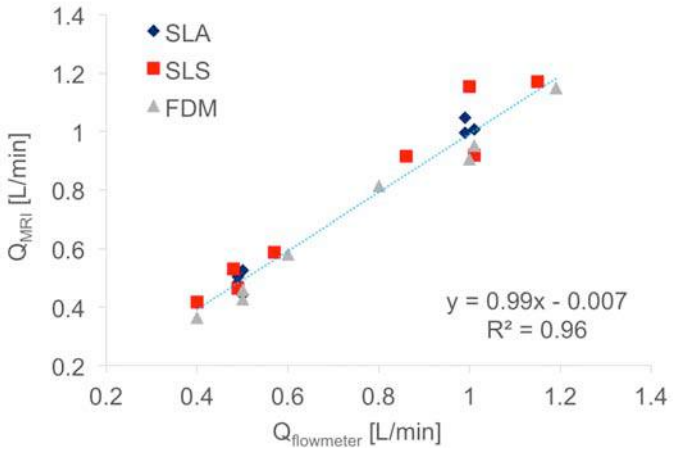

Figure 2: Linear correlation between MRI and direct flow measurements in TCPC in vitro models fabricated using SLA, SLS and FDM.

DISCUSSION

In-vitro systems, using SLA, SLS and FDM technologies, were developed using patient-specific models as a tool not only to control flow parameters but also to compare with CFD simulations. The three technologies showed similar flow measurements. Although not statistically significant, a trend can be noted at a flow of 3 L/min, where kinetic energy and vorticity show lower flow values for the FDM technique. Further analysis on surface roughness may add more insight into its effects on hemodynamics. Flow measurements performed with the flowmeter highly correlate with those done by 4D flow MRI, showing the accuracy of the latter as a technique to quantify flow. Using agar to fix the model substantially improved the signal-to-noise ratio in the MR images and significantly decreased motion artifacts when compared to the model submerged in water. The combination of additive manufacturing techniques and advanced MRI allows the in vitro hemodynamic assessment of highly complex anatomical variations in several cardiovascular pathologies.

INTRODUCTION

Tissue engineered heart valves (TEHVs) are an unmet medical need that have not been able to achieve long term viability post-implantation. Previous TEHV models using cell sources such as mesenchymal stem cells or arterial fibroblasts have failed due to valve calcification, stenosis, and fibrosis [1]. These outcomes suggest a failure of the cells to respond to the dynamic environment of the valve appropriately. Potentially, these problems may be addressed by using patient specific induced pluripotent stem cells (iPSCs) that are differentiated into endocardial cells and subsequently guided *in vitro* to the cell types of the mature cardiac valves.

Endocardial cells are a unique subtype of endothelial cells which line the chambers of the heart. During embryonic development, a select population of endocardial cells overlaying localized swellings in the primitive heart tube called endocardial cushions undergo endothelial to mesenchymal transformation (EMT) to become valve interstitial cells (VICs). These cells invade the cushion and remodel the extracellular matrix to form the atrioventricular valves. In mature valves, VICs function to maintain the structure and integrity of the valve, making them an ideal cell source for TEHVs. Unfortunately, these cells are often defective in patients needing valve replacements, and no stem cell based method to generate them currently exists.

Current biochemical strategies of stem cell differentiation use static culture, which does not represent the dynamic mechanical environment of the developing heart. Contraction of the myocardium and blood flow over the endocardium impart mechanical stretch and fluid shear respectively, which are known to affect endocardial EMT and valve development [2]. We hypothesize that incorporating these mechanical stimuli in the differentiation of endocardial cells will create a more physiologically relevant environment, enabling the generation of an alternative cell source for tissue engineered heart valves. Herein, we demonstrate that we can utilize mechanical stimulation to drive endothelial progenitor cells (CD34+) derived from human iPSCs down an endocardial lineage (Nfatc1+). These cells may be an essential cell source for patient-specific TEHVs.

METHODS

iPSCs were maintained on Matrigel in mTeSR, changed daily. Endothelial progenitors were generated following a previously published differentiation protocol [3]. iPSCs were dissociated to single cells and seeded at 50,000 cells/cm^2 onto Matrigel coated six-well culture dishes in mTeSR with 10 μM ROCK inhibitor (Y-27632) for 24 hours, after which they were cultured for an additional two days in mTeSR. After three days in culture, media was changed to a basal media consisting of Advanced DMEM/F12 with 2.5 mM Glutamax and 60 μg/mL ascorbic acid with 6 μM GSK3 inhibitor (CHIR99021). After two days in culture, media was replaced with basal media without additional CHIR and cells were cultured for an additional 3 days.

Endothelial progenitors were purified by MACS cell separation with a CD34 MicroBead kit (Mitenyi Biotec). Cells were immediately seeded onto collagen IV coated BioFlex culture plates (FlexCell) in EGM-2 MV (Lonza). Cells were allowed to adhere and grow to confluency (3-4 days). Confluent monolayers of endothelial progenitors were subjected to either equibiaxial strain using the FlexCell-4000 tension system or fluid shear using a custom built bioreactor (**Figure 1**). A strain regimen was created to approximate physiological values (10% strain, 1Hz) and carried out for 24 - 48 hours. Likewise, shear testing was performed at physiologically relevant values of 10-15 dyne/cm^2 in either pulsatile, unidirectional flow, or bidirectional flow. Following mechanical stimulation, cells were lysed for analysis. RNA was isolated from cell lysates using TRIzol and reverse transcribed to cDNA using a

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

SuperScript IV Reverse Transcriptase kit. qPCR was performed with an iQ SYBR Green kit and BioRad CFX96 themocycler.

RESULTS

Endothelial differentiation was demonstrated via qPCR throughout the differentiation protocol and CD31 immunostaining of differentiated cells following one week of culture in endothelial media. The results indicate successful generation and efficient purification of endothelial progenitors (CD34+) at day eight of the protocol (**Figure 2**). HUVECs were used as an endothelial control for comparison. Notably, expression of endocardial marker Nfatc1 was higher in the differentiated cells than in the HUVECs, indicating the presence of cells with an endocardial expression profile (**Figure 2D**).

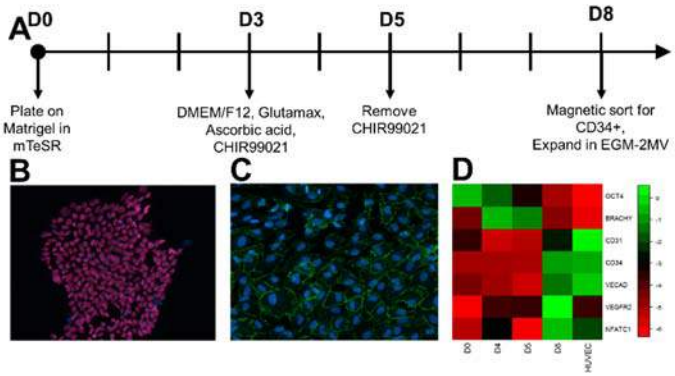

Figure 2: (A) Timeline of endothelial differentiation of iPSCs. (B-C) Immunostaining of D0 iPSCs (B. Oct4-red, DAPI-blue) and iPSC-endothelial cells (C. CD31-green, DAPI-blue). (D) Heatmap showing transition from pluripotency through mesoderm (Brachyury), to an endothelial precursor. Color bar in log10 scale.

Shear testing of the cells revealed differential gene expression response to unidirectional versus bidirectional flow (**Figure 3**). While uni-directional flow increased expression of Nfatc1, bidirectional flow caused a slight decrease. This decreasing Nfatc1 expression was accompanied by a dramatic increase in expression of Snai2, an EMT inducing transcription factor, and BMP2, an EMT associated protein known to be required for endocardial EMT [4]. These changes to EMT markers were not seen to nearly the same extent in cells sheared unidirectionally. Finally, cyclic strain was found to down-regulate both endocardial and EMT markers. Together, these data indicate a role of pulsatile unidirectional shear stress in maintaining an endocardial phenotype while bidirectional shear induces EMT.

DISCUSSION

This study shows fluid shear stress to be a potential regulator of endocardial cell phenotype and that the pattern of the shear stress may be a source of further control. Several genes were differentially regulated in unidirectional versus bidirectional shear stress, including endocardial marker Nfatc1 and EMT inducing transcription factors Snai2 and BMP2. The inverse effects of the two shear conditions could provide a tool with which to both maintain an endocardial population (uni-directional flow) and induce EMT to generate VICs (bidirectional flow). This type of control over cell fate would be extremely beneficial in creating a novel cell source for tissue engineered heart valves.

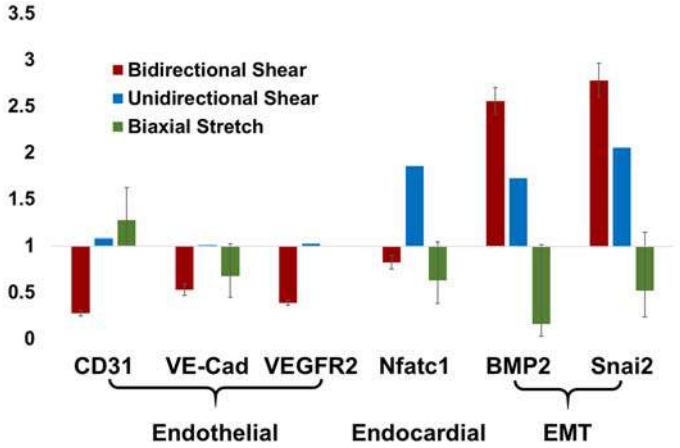

Figure 3: qPCR quantified expression of endocardial and EMT markers in endothelial progenitors exposed to unidirectional or bidirectional shear, or mechanical strain relative to endothelial progenitors in static culture.

DETERMINATION OF THE TENSILE MECHANICAL PROPERTIES OF THE SEGMENTED TRICUSPID VALVE ANNULUS

INTRODUCTION

The tricuspid valve apparatus consists of the tricuspid annulus, leaflets, and chordae. The valve is located between the right atrium and right ventricle of the heart and prevents the back flow (regurgitation) of blood into the right atrium. The tricuspid annulus (TA) is defined as the hinge point of the leaflets (Figure 1A); surgically it is identified as the apparent transition between the right atrial tissue and the tricuspid leaflet.

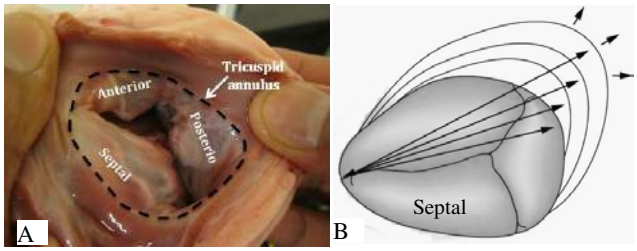

FIGURE 1 – (A) THE NATIVE TRICUSPID VALVE ANNULUS AND (B) TRICUSPID ANNULUS DILATION

Functional tricuspid regurgitation (FTR) is increasingly recognized as a source of morbidity in patients, particularly those with chronic mitral valve regurgitation [1]. Asymmetrical tricuspid annulus dilation (Figure 1B) is a major feature in FTR. The mechanism of this asymmetric dilation is not understood clearly. Tricuspid ring annuloplasty (TRA) is the most preferred surgical therapy to repair FTR. In TRA, a partial ring is sutured to the annulus, which cinches the dilated annulus and restores the native shape. However, the ring only partially covers the annulus, keeping the septal segment untouched due to the presence of the AV node. After TRA, instances of recurrent regurgitation, septal dilation, and ring separation have occurred [2]. Differing strengths between the free and septal annulus segments can contribute to the asymmetrical annulus dilation or to the septal dilation after TRA. The hypothesis is that the annulus segments may not have same mechanical properties. To date, there has been no quantification of the mechanical properties of the tricuspid valve annulus. This study aims to quantify the tensile mechanical properties of the segmented tricuspid annulus. The data collected will be used to identify the differences in the tensile mechanical properties between the septal and free wall regions across species. The findings of this study may potentially enhance our understanding of asymmetrical tricuspid annulus dilation and may contribute to the durability of the TRA technique.

METHODS

This method was modeled after a previous tensile test study of the mitral valve annulus [3]. Ovine and porcine hearts were collected from local slaughterhouses and transported in coolers. Hearts were cryopreserved until the day of the experiment upon which hearts were thawed in a saline bath at 37.5°C. To carry out the experiment, we used the UStretch Tissue Tensile Test system (Cellscale). The TA was cut into a free wall segment and a septal wall segment. The free wall segment consisted of the anterior and posterior sections. The tissues were then isolated and trimmed to an approximate length of 30.0 mm, width of 6.0 mm, and thickness of 1.2 mm. The tissues were then marked with 4 graphite markers placed in a square at the center of the tissue. We secured 6.0 to 7.0 mm of the tissue on both sides between two grips (Figure 2).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

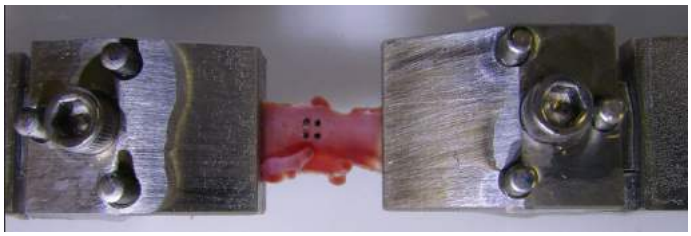

FIGURE 2 – TENSILE TEST SET-UP OF TRICUSPID ANNULUS SEGMENTS

The experiment was carried out at 37.5°C. Samples first underwent a preconditioning phase in which the tissues were stretched by 7.5 mm at a speed of 2.0 mm/min and then recovered to their original length. After the completion of the preconditioning phase, the tissues were stretched at a speed of 2.0 mm/min until they presented the first sign of failure, which was indicated by a drop in the magnitude of force required to stretch the tissue.

To calculate stress, the force was divided by the product of the thickness and width of the tissue. Stress was analyzed through a calculation of force divided by the product of tissue thickness and width. The percent strain was quantified using UStretch image analysis. As shown in Figure 3, the trackers were placed at the center of each marker, and the percent strain was measured for each movement between images as a 4-point average.

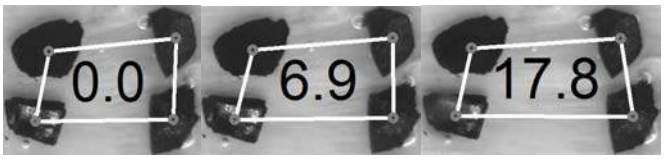

FIGURE 3 – CALCULATED PERCENT STRAIN USING POSITIONED TRACKERS

RESULTS

The results are based on two ovine hearts and two porcine hearts. In the preconditioning (Figure 4) and stretch to failure curves (Figure 5), we found that as the tissues were stretched, the stress and strain also both increased. Variation of mechanical properties between the septal and free wall regions was greater for the porcine hearts compared to the ovine hearts.

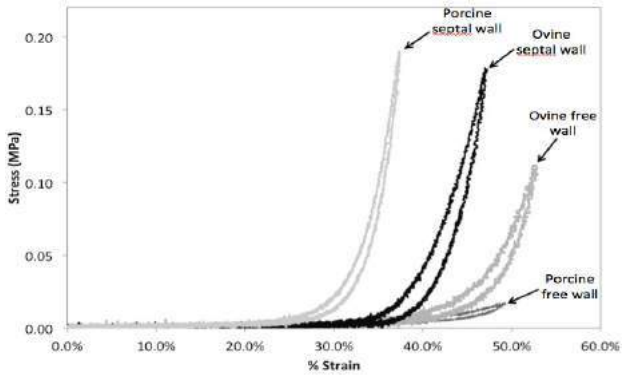

FIGURE 4 – PRE-CONDITIONING CURVES FOR OVINE AND PORCINE TRICUSPID ANNULUS SEGMENTS

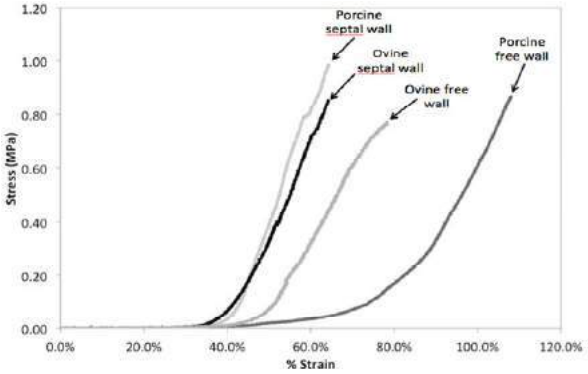

FIGURE 5 – STRETCH TO FAILURE CURVES FOR OVINE AND PORCINE TRICUSPID ANNULUS SEGMENTS

The porcine septal wall tissue samples had an average stress and strain of 0.983 MPa and 64.4%, respectively. The porcine free wall tissue samples experienced an average stress of 0.868 MPa and an average strain of 108.1% at the first sign of failure. The ovine septal wall tissue samples had an average stress and strain of 0.854 MPa and 64.2%, respectively. The ovine free wall tissue samples experienced an average stress of 0.771 MPa and an average strain of 78.4% at the first sign of failure.

DISCUSSION

The mechanical properties of the TA have not been investigated. The purpose of this study is to build a database for the mechanical properties of the TA. In both species, it appears that the septal wall can withstand a larger stress, but lower strain than the free wall before failing. We found that the septal walls of the porcine hearts could withstand a greater amount of stress and lower amount of strain than the ovine hearts before exhibiting the first sign of failure. The free wall tissues of the porcine hearts experienced lower stress and lower strain than the free wall tissues of the sheep hearts.

Although the stress increases with strain and strain and vice versa, their values at the first sign of failure for the porcine septal wall tissue were lower than the values shown at the first sign of failure for the septal tissue in the ovine hearts, indicating that the two species do not exhibit the same stress and strain over the same amount of tissue.

The preliminary experiment showed a difference in the mechanical properties between the septal and free wall regions of porcine and ovine TA. More experiments need to be done to validate these findings. The variation in mechanical properties across different segments of the TA and across the species may help us understand the mechanics of asymmetrical tricuspid annulus dilation. The results can also enhance our understanding of the cause of septal dilation following TRA. This can lead to a better ring design, increase the durability of TRA, or the development of a percutaneous TRA technique.

INTRODUCTION

The nucleus is the largest organelle in the cell and its primary functions are maintaining hereditary information and controlling cell activities. Alternations of nuclear functions and components thus have been implicated in disease pathogenesis. Recently, mechanical condition of the nucleus in a cell and its mechanical properties have also received increasing attention, because changes of nuclear mechanical properties are found as features of cancer cells and "laminopathies" patient cells, which are genetic disorders caused by mutations in genes encoding nuclear membrane proteins [1, 2].

Previous studies have shown that mechanical stimuli such as fluid shear stress and mechanical cyclic strain induce changes in mechanical properties of the nuclei of cells [3, 4]. Mechanical stimuli are now recognized as important cues for cell physiology and pathology, and known to cause morphological changes concomitant with actin cytoskeletal reorganization. Mechanical forces acting on the surface of a cell are transmitted through actin cytoskeletons to intracellular mechano-sensor regions such as focal adhesions and intercellular junctions where mechanical signals are sensed and transduced into biochemical signals. Since actin cytoskeletons are bound to the nucleus in the cell with LINC (linker of nucleoskeleton and cytoskeleton) complex, which is composed of nesprins and SUN proteins, and mechanical forces are also transmitted to the nucleus and believed to play important roles in cell morphology and functions. Indeed, previous studies reported that knockdown of nesprin-1, which is a component of LINC complex and directly bind to actin cytoskeletons in cells, causes suppression of the cell morphological responses to mechanical stimuli [5, 6]. However, the detailed relationship between the force transmission to the nucleus and nuclear mechanics are still unclear.

To address the underlying mechanisms, we explored the effect of knockdown of nesprin-1, a key component of LINC complex for the force transmission to nucleus, on nuclear mechanical properties of cells exposed to cyclic stretching.

METHODS

Cell culture and siRNA transfection

Human skin fibroblasts (Riken Bioresource Center, Japan) were used in the present study. For siRNA knockdown of nesprin-1, cells were transfected with 100 nM siRNA targeting human nesprin-1 (Dharmacon, USA) according to manufacturer's protocol. To confirm reduction of nesprin-1 expression, cells were fixed, stained with an antibody for nesprin-1 (Abcam) and Hoechst33342 (Life Technologies), and examined by fluorescence microscopy (Olympus).

Cyclic stretching experiment

Fibroblasts treated with siRNA were detached form a cell culture flask with tryspin-EDTA, seeded in a collagen-coated stretching chamber (Strex, Japan), and then subjected to 10 % uniaxial cyclic stretching at 1 Hz for 24 h.

AFM measurement

After the cyclic stretching experiment, atomic force microscopy (AFM) indentation (Olympus, Japan) was performed to assess the nuclear mechanical properties in cells. Force-indentation curves were captured at the center of single intact cell (i.e., over the nucleus). Curves obtained were then fitted to the Seddon model (eq. 1) to calculate apparent nuclear elastic moduli.

$$F = \frac{2E\tan\alpha}{\pi\left(1-\nu^2\right)}d^2 \quad , \qquad (1)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

where F is the loading force, E is the elastic modulus of the sample, d is the indentation depth, ν is the poisson ratio of the sample, and α is the half cone effective angle. It should be noted that in preliminary experiments (data not shown), we confirmed that changes of nuclear mechanical properties in intact cells can be assessed by this method.

RESULTS

Fluorescence microscopy showed that localization of nesprin-1 to the nuclear envelope observed in non-treated wild type cells (WT cells) was depleted in fibroblasts transfected with siRNA targeting nesprin-1 (siNes1 cells) (Fig. 1). This result indicates that the expression of nesprin-1 in fibroblasts was depleted by transfection of nesprin-1-specific siRNA.

Typical force-indentation curves are shown in Fig. 2. There is no obvious difference in curves for statically cultured WT cells and siNes1 cells. For the WT cells, similar force-indentation curves were obtained after exposure to cyclic stretching for 24 h. In contrast, curves for cyclic-stretched siNes1 cells have lower slope than those for static cells.

Fig. 3 indicates apparent elastic moduli of nuclei for WT and siNes1 cells. No significant differences in the elastic modulus of nuclei were found between static WT cells and static siNes cells. The elastic modulus for siNes1 cells exposed to cyclic stretching was significantly lower than those for static siNes1cells and cyclic-stretched WT cells.

DISCUSSION

The result of this study suggests that nesprin-1 plays an important role in maintenance of nuclear mechanical stiffness in cells under mechanical condition. Lamins, the major components of nuclear lamina, are known to provide mechanical stiffness of the nuclei, but nuclear lamin-associated proteins are also thought to contribute the nuclear mechanical properties. A recent study reported that a mechanical force applied via nesprin-1 caused an increase in phosphorylation of emerin, one of the lamin-associated proteins [2], which may lead structural reorganization of nuclear lamina. We need to investigate changes in protein expression and structures of nuclear lamina in cells exposed to cyclic stretching as a next step.

INTRODUCTION

The Intraocular pressure (IOP) is a mechanical property of the intraocular fluids in the eyeball. One of the main eye diseases that affect the IOP is the so called Glaucoma, it alters the intraocular aqueous humor balance, causing an elevation of the intraocular pressure, and therefore irreversible damage to the optic nerve terminal fibers. Currently, the IOP measurement is performed by using techniques based on the Imbert-Fick principle (Chihara 2008); which states that the pressure of a liquid inside a thin-walled sphere is proportional to the force required to flatten part of its surface, divided by the area of flattening. This type of measurement requires physical contact to directly induce a mechanical deformation of the human eyeball. Several ophthalmologist reports point out the fact that patient movements, blood pressure changes, and the cornea physical characteristics which are distinct person to person, directly affect the IOP measure accuracy and precision.

The study of the laser-induced cavitation phenomenon in biological media began with the use of Q- switched lasers in therapeutic applications in the mid 60's Lee &Gojani [1]. With the advent of lasers in medicine, it is possible to cut and remove material at a few microns scale; these new techniques were based on the mechanism of breaking of molecular bonds due to high energy lasers that provided UV ranges and high absorption of the tissue to such wavelengths Niemz [2].

Cavitation bubbles are well characterized through their maximum radius and collapse time; however them both are elaborated and expensive to determine. The traditional laser-photographic techniques require several laser shots and bubbles generated in order to recreate a whole bubble event and its dynamics Gregorčič[3], Evans [4]. An immediate disadvantage is the fact that even when the shot to shot energy per pulse does not fluctuate much, the stochastic nature of the laser-induced plasma produces a slightly different cavitation bubble from shot to shot making it somehow hard to fully recreate a single cavitation bubble event from a series of many laser shots. The use of high-speed cameras, say over 300.000 frames per second,is expensive and no matter this speed it still happens many times to miss either the maximum radius or the exact time collapse frames. This is a significant inconvenience since those data are quite important for the study and applications of the cavitation bubble phenomenon.

METHODS

The experimental part of this work is based on a recently reported cavitation characterization technique called Transmittance Spatial Modulation (TSM), Devia et Al. 2012 [5] , where the modulation of the spatial intensity profile of a probe CW beam is generated by the cavitation bubble itself. A HeNe laser (@632.8 nm) was used as probe beam, it passed co-linearly (see Figure 1) with the pump (@532nm) beam and then it is collimated throughout the sample. When the pump pulse arrives and the cavitation process starts, the bubble grows to its maximum size, and then it collapses to start it over again.

The bubble acts as a negative lens, therefore the (collimated probe) light incident onto the bubble is deflected or/and scattered sideways and the total amount of light detected is inversely proportional to the bubble size. All the transmitted light was collected through a lens onto a fast (1 ns rise time) photo diode, whose signal was visualized and recorded using an oscilloscope (1GHz, Tektronix DPO). Figure 2 shows a typical trace of the time evolution of the whole cavitation event. The collapse time for the first bubble depends

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

on both the pump pulse energy and on the actual liquid pressure. It is then possible, to infer the actual liquid pressure by just measuring the first collapse time for a given pump pulse energy.

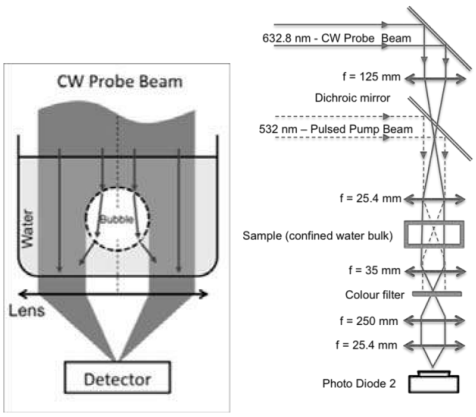

Figure 1.STM technique operation principle and experimental setup.

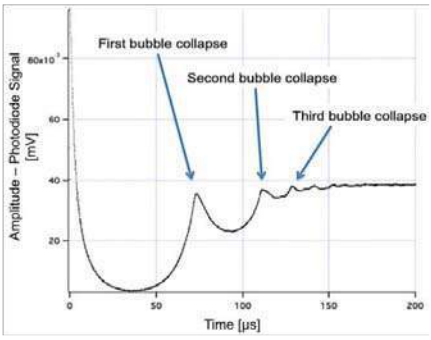

Figure 2. Trace from the transmitted light that propagates through the cavitation Bubble plane. The collapse times can be measured off from this trace with a high time resolution, since the trace is obtained by using a very fast photo diode.

RESULTS

The collapse time was measured under several liquid pressure values and pulse energy conditions. Parametric curves of the collapse time dependence on the liquid pressure were obtained and are shown in Figure 3.

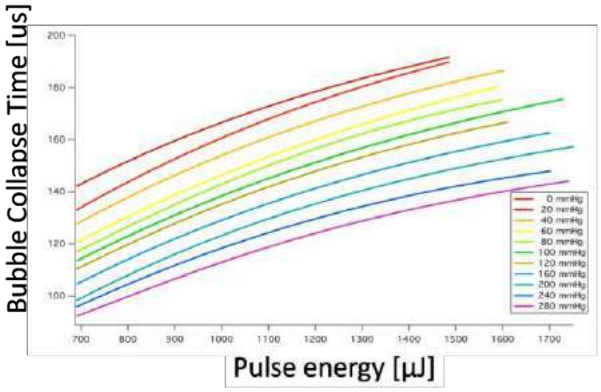

Figure 3. Cavitation bubble collapse time dependence on the liquid pressure and pump pulse energy.

DISCUSSION

The first collapse time in a laser-induced cavitation bubble event depends clearly on both the external liquid pressure and on the laser pulse energy. For well-known pulse energy, it is possible to infer the actual liquid pressure by precisely measuring the bubble collapse time. The presented STM technique seems to be a feasible way of implementing an IOP sensor. By using this technique the IOP measurement is expected to be more accurate than traditional tonometry measurements. Some advantages of the laser- induced cavitation and STM based sensor, among other,are that the in this case the IOP measurements would not depend on person to person factors as: patient age, gender, patient eye ball movements during measuring and/or corneal thickness. This is so due to the fact that the through the scheme proposed here the IOP measurement takes only a few tens of microseconds and the sensor measures the IOP directly inside the anterior chamber, avoiding all the above mentioned factor as sources of uncertainty on the measurements.

INTRODUCTION

Many diseases occurring within a lung are caused by deposition of inhaled particle. Therefore, predilection sites of lung diseases are closely related to airflow in lung. In development of drag delivery system for lung, drug accessibility has a close relation with airflow in a lung. Especially, as a pulmonary acinus is complex shape, airflow in a lung can be much influenced by the complex acinus shape.

Since airflow in a pulmonary acinus has low Reynolds number, it was considered that molecular diffusion contributes to substance transportation. However, recently, it is reported that complex flow induced by expansion and contraction of acinar associated with respiratory enhances gas transportation [1]. Moreover, according to a previous report, as a result of experimental visualization of mixing in rat lungs, stretch and folding mixing pattern was observed in the lung [2]. On the other hand, in numerical simulation, characteristic of chaos mixing was observed in pulmonary airway, nevertheless, that was not observed in bronchiole [3]. This difference can be closely related to complex geometry of pulmonary acinus. Although several studies about pulmonary acinus were reported, characteristic of mixing in pulmonary acinus and mixing mechanism is not clear.

The objective of this study is to evaluate characteristic of chaos mixing in a realistic pulmonary acinus model in terms of streamline, distribution of scalar concentration and lyapunov exponent.

METHODS

A realistic 3D model of pulmonary acinus was reconstructed from synchrotron radiation-CT images of a closed-chest mouse. Model construction method is as previously reported [4]. Figure 1 depicts the realistic pulmonary acinus model. The volume size was 893×727×930μm^3, and the inlet was of 79.7 μm diameter. The computational mesh was generated using enGrid (enGits GmbH) and Amira 5.4.0 (Visualization Science Group). An unconstructed mesh with tetrahedron was created for the whole. The mesh comprised 1,079,407 cells.

The working fluid was air (density: ρ=1.140 kg/m^3, kinematic viscosity: ν=1.713×10^{-5}m^2/s) under body temperature (310K). The flow in the model was assumed to be 3D, laminar, unsteady, and incompressible. The governing equations were expressed as

$$\frac{\partial u_i}{\partial x_i} = 0 \quad (1)$$

$$\frac{\partial u_i}{\partial t} + \left(u_j - u_{gj}\right)\frac{\partial u_i}{\partial x_j} = -\frac{1}{\rho}\frac{\partial p}{\partial x_i} + \nu\frac{\partial^2 u_i}{\partial x_j x_j} \quad (2)$$

$$\frac{\partial \theta}{\partial t} + u \cdot \nabla\theta = a\nabla^2\theta \quad (3)$$

Where, u_g is the moving grid velocity. These equations were solved using non-commercial CFD library (OpenFOAM 2.3.x, OpenFOAM Foundation), with flow solver based on the PIMPLE method.

The overall configuration of the model was assumed to remain self-similar throughout the expansion and contraction cycle. The volume change *V(t)* was taken as a moving boundary problem given by the sinusoidal function of Eq.(4). The dynamic mesh function of OpenFOAM software was used to model the expansion and construction, with all grid velocity (u_g v_g w_g) given by Eqs.(5)-(7) based on the coordinate system with its origin (x_0 y_0 z_0) at the cross-sectional center of the artificial inlet.

$$\mathrm{V(t)} = V_{FRC} + V_T\left(\frac{1-cos\omega t}{2}\right) \quad (4)$$

$$u_g(t) = \left(x_g - x_0\right)\left(\frac{\sqrt[3]{V_{ratio}}-1}{2}\right)\omega sin\omega t \quad (5)$$

$$v_g(t) = \left(y_g - y_0\right)\left(\frac{\sqrt[3]{V_{ratio}}-1}{2}\right)\omega sin\omega t \quad (6)$$

$$w_g(t) = \left(z_g - z_0\right)\left(\frac{\sqrt[3]{V_{ratio}}-1}{2}\right)\omega sin\omega t \quad (7)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Here, V_{FRC} is functional residual capacity, V_{TLC} is total lung capacity, $\omega = 2\pi/T$ is angular frequency, and x_g, y_g, z_g are grid coordinates at t = 0. In this study, we set V_{FRC} and V_{TLC} as 4.94×10^{-11} and 18.7×10^{-11} m^3 respectively. Breathing period T was 4.0s.

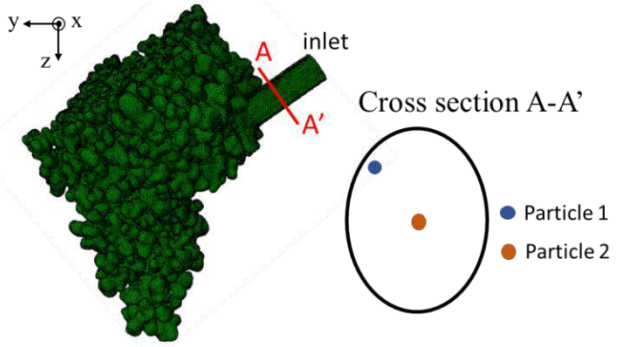

Figure 1: Pulmonary acinar model

The lyapunov exponent was calculated based on the particle tracking in order to judge the occurrence of the chaos [5]. Although the lyapunov exponent is strictly defined as a spectrum having dimensions of the phase space, practically the largest value among them is important. The largest lyapunov exponent λ is defined by the following Eq. (8).

$$\lambda = \lim_{t\to\infty}\left[\left(\frac{|dx(T)|}{|dx(0)|}\right)\right] \qquad (8)$$

Here $x(T)$ and $x(0)$ is the distance between two particles at time $t=T$ and t = 0, respectively. When λ is positive, the flow is chaotic. In the present study, λ was calculated from the distance between two neighboring particles during t/T = 0 - 7.0.

RESULTS

Figure 2 shows streamline in one of alveolus during one respiratory period at phase intervals of t/T= 0.25. The flow condition are Re_{max}=0.123 and Womersley number α=0.0129 in artificial inlet. The completion of inspiration at t/T=0.5 and the completion of respiration at t/T=1.0 correspond to the times of maximum and minimum volume, respectively. The phase of t/T=0.25 and the phase of t/T=0.75 correspond to the times of maximum and minimum grid velocity. A recirculating flow was observed at t/T=0.25, 0.75, however, a recirculating flow was not observed at t/T=0.5,1.0. Formation and elimination of vortex during one respiratory cycle was suggested.

The effect of the complicated flow on substance transportation was evaluated using advection-diffusion equation. We set thermal diffusion coefficient a as approximately zero to visualize scalar transportation lead to advection. Figure 3 (a) (b) shows distribution of scalar concentration in y-z plane passing the origin (x_0 y_0 z_0) at t/T=0, 2.0. The distribution at t/T=0 was totally different to the distribution at t/T=2.0. Especially, distribution of scalar concentration in alveolus was high.

Chaotic mixing was quantitatively evaluated using lyapunov exponent. Figure 3 shows lyapunov exponents in any two particles in a cross section A-A' (Figure 1). As a result, in seventh period, both of the lyapunov exponents show 0.14.

DISCUSSION

According to the previous report, in axial oscillatory flow through a furrowed channel, formation and elimination of unsteady vortex in furrowed part was observed [6], which was reported as chaotic mixing typical example [7]. It is presumed that a recirculating flow in this study was occurred owing to this phenomenon. This reason why distribution of scalar concentration in alveolus was high is that a fluid in an alveolus part was trapped by vortex.

Lyapunov exponent of Lorenz attractor and Rossler attractor, which was known for typical chaos example, was 0.1~1.5 [8]. Therefore, it is suggested that flow in a pulmonary acinus model has characteristic of chaotic mixing.

EFFECT OF DEFORMATION ON CEREBRAL ANEURYSM IN MIDDLE CEREBRAL ARTERY

S. Omachi (1), G. Tanaka (1), H. Liu (1), R. Yamaguchi (1)

INTRODUCTION

The middle cerebral artery MCA is one of predilection vessels of aneurysm in circle of Willis. In the present study, the flow model simulates an ideal aspherical aneurysm model located at the apex of bifurcation in middle cerebral artery (MCA: M1, M2 and M3). The effect of elasticity on flow pattern around aneurysm induced at the apex of middle cerebral artery was experimentally examined by particle image velocimetry *in vitro*. Flow structure was examined for elastic model 3 folds as large as real aneurysm size. The effect of wall deformation on flow structure was examined at several phases in pulsatile blood flow wave.

METHODS

In the present study, flow behavior inside aneurysm induced at the apex where middle cerebral artery MCA: M1 bifurcates to M2 and M3 was examined for both elastic and rigid models as shown in Figure 1 [1]. There is an aneurysm with width of N= 6 mm and depth of D= 12 mm (AR= D/N= 2.0). We experimentally examined the flow behavior inside aneurysm wall and wall deformation in PIV. Aneurysm wall is made from silicone resin with the wall thickness of 0.4 mm.

In PIV, the measurement conditions are interrogation window size 32 pixels× 32 pixels and 50% overlapping.

The working fluid is 51.5% aqueous glycerin with a refractive index of 1.41 identical to that of silicone resin (KE-1606, Shin-Etsu Chemical Ltd., Tokyo, Japan), a density of $\rho = 1.13$ g/cm^3, and a kinematic viscosity of $\nu = 6.33 \times 10^{-6}$ m^2/s at 293 K (26°C). The working fluid flows into the model through the 320-mm-long straight inlet tube. The working fluid flows through an ultrasonic flow meter (TS410, Transonic System Co. Ltd.).

As the boundary condition, the pulsatile blood flow wave which simulates that by Valen-Sendstad, et al [2] is assumed at inlet M1 as

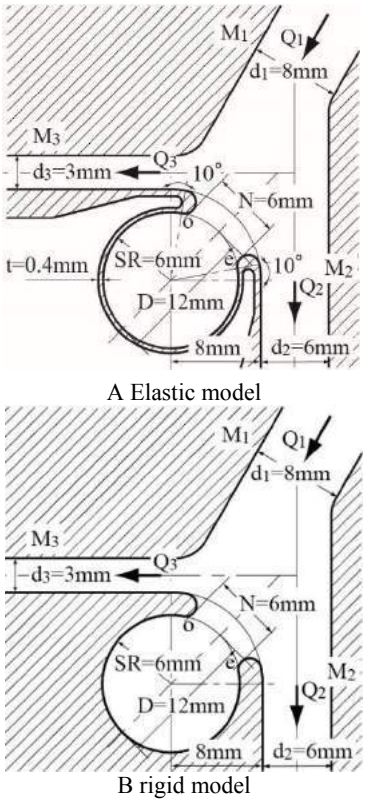

Figure 1: Patient-specific aneurysm model in MCA

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

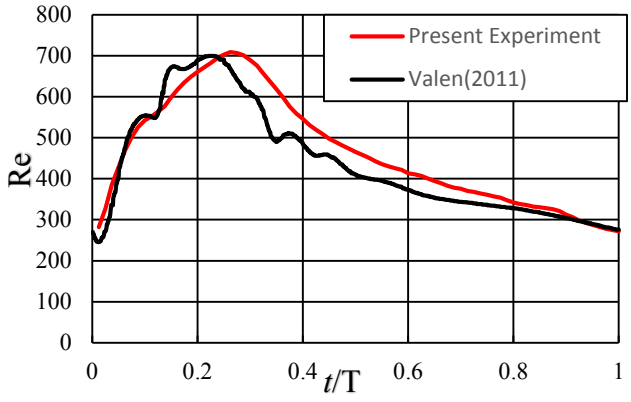

Figure 2: Pulsatile flow wave form by Reynolds number (α=1.41)

shown in Figure 2 and flow rate at both outlets is even.

The experiment was carried out in the laminar pulsatile blood flow wave form with a Womersley number of $\alpha = (d_0/2)\,(\omega/\nu)^{(1/2)} = 1.41$, a mean Reynolds number of $Re_m = d_1 U/\nu = 400$, where ω, d_1 and U are the pulsatile angular velocity, the diameter of MCA: M1 vessel and the mean velocity through it.

The light source was a 15 Hz dual-pulse YAG laser with 30 mJ output and a pulse interval ranging from 350–1600 μs. A cylindrical lens produces a laser sheet thickness of 0.3 mm that is irradiated parallel to the median plane of aneurysm model. The scatter material comprises fluorescent particles of 14 μm in diameter. Scattered radiation from tracer particles was recorded using the Image Intense CCD camera (1376 × 1040 pixels, GmbH) fitted with an AF NIKKOR lens (Nikon) positioned perpendicularly to the median plane of aneurysm. Digital images were processed using DaVis 7 software (LaVision, GmbH).

RESULTS

At three typical phases, i.e. early systole (t/T=0.125), peak systole (0.25) and mid-diastole (0.375), the velocity vector inside the aneurysm are shown in Figure 3, 4. In elastic model, as the flow rate increases, the inflow velocity along the aneurysm wall in M2 vessel side steeply increases as shown in Figure 3 at peak systolic phase. In rigid model, the inflow velocity is smaller than that in elastic model.

The deformation phase in elastic model is similar to that of pulsatile flow wave because the Womersley number is not so high (α=1.41). As shown in Figure 5, the deformation defined as the ratio of difference maximum and minimum to minimum diameter is comparable to 5.0% indicated by Weber [3].

The distribution of WSS along aneurysm wall at peak systolic phase as a typical result is shown in Figure 6. From θ=0 to 90, WSS in elastic model is smaller than that in rigid model. On the other hand, from θ= 90 WSS is a little larger than that in rigid model. This difference might be related to inertial flow of high penetrating velocity into elastic model.

INTRODUCTION

There is a renewed interest in the thermal properties of ferrofluids due to the biomedical application of heating effect of magnetic nanoparticles (mNPs) [1] and application of focused ultrasound therapy for ablation of malignant tumors [2]. The ultrasound based treatment is a non-invasive alternative to conventional surgical procedures. However, one of the major problem in the field has been controlling accurate delivery of heat (energy) to the disease site, while minimizing collateral damage to the surrounding healthy tissue. One of the most important requirement for ultrasound therapy for clinical planning is to determine heat generated in tissue due to acoustic energy transfer to heat energy. These lead us to investigate the reason of temperature rise in mNPs in presence of ultrasound. Although most of the experimental investigations have predicted that the main reason behind the temperature rise is ultrasonic attenuation [3-6], there is a lack of fundamental knowledge based on either experimental or theoretical investigation on the contribution of attenuation to temperature rise in media such as ferrofluids or mNPs infused tissue mimicking materials (TMM). Few theoretical investigations have been made based on fluid dynamics and "streaming theory" to study acoustic attenuation [6-9]. Following Ref. [10], we develop a simple model based on acoustic mean free path to calculate temperature rise due to ultrasound attenuation in ferrofluids. From this model it is possible to calculate contribution of different media on temperature rise by changing volume fraction (x) of nanoparticles, viscosity of ferrofluid medium, etc.

METHODS

Acoustic wave propagated in a medium interacts with the thermal phonons and as a result of this acoustic wave is absorbed [10]. Due to this absorption, the momentum of thermal phonons increase which tends to set up heat flow in the direction of ultrasound propagation and generates a temperature gradient. Following Ref. [10], the increase in temperature with time is given by,

$$\Delta T = \int_0^t \frac{3N\hbar\omega v_{nf}}{\lambda_{nf} C_{nf} V}\, dt \qquad (1)$$

where λ_{nf} is the acoustic mean free path for ferrofluids, C_{nf} is the heat capacity, v_{nf} is the velocity of ultrasound, V is the total volume of medium, N is the number of phonons in acoustic mode, $(N\hbar\omega/V)$ is the energy density in the medium which we can calculate from the power of ultrasound wave, $\hbar$ is the reduced Planck constant and ω is the ultrasound frequency.

Acoustic mean free path of the media is calculated from absorption coefficient, $\lambda_{nf} = (((\frac{x\alpha_{np}}{\rho_{np}} + \frac{(1-x)\alpha_f}{\rho_f})(\rho)^{-1}$ where ρ is the total density.

Absorption coefficient α_f of ultrasound for fluid is calculated using theory of Stokes [11]

$$\alpha_f = \frac{2\eta\omega^2}{3\rho_f v_f^3} \qquad (2)$$

Where η is the viscosity of base fluid, ρ_f is density of fluid, v_f is the speed of sound in base fluid

The absorption coefficient, α_{np} for nanoparticle can be written as, [12]

$$\alpha_{np} = 1.1\frac{\gamma^2\omega^2\tau C_{np}T}{v_{np}^3} \qquad (3)$$

C_{np} is the heat capacity of nanoparticle, v_{np} is the speed of ultrasound in nanoparticle, ρ_{np} is the density of nanoparticle at absolute temperature, γ is the Gruneisen parameter, τ is the phonon relaxation time which is calculated as, $\tau^{-1} = (\frac{1}{\tau_b} + \frac{1}{\tau_{np}}$. τ_b is the bulk phonon relaxation time, $\tau_b = \frac{3\kappa}{C_{np}\rho_{np}v_{np}^2}$, where κ is the heat conductivity and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$\tau_{np} = \frac{l}{v_{np}}$ is the relaxation time for boundary scattering, *l=10nm* is the nanoparticles diameter. The values of different physical parameters for Eqn. 1-3 are listed in Table. 1.

Table 1: List of physical parameter used in Eqn. 1-3.

	Water	**Fe_2O_3**
Specific Heat, C_p	4175 J/Kg-K [13]	650.6 J/Kg-K [14]

RESULTS

Fig. 1 represents the acoustic wave mean free path calculated for different volume fraction (x), and Fig. 2 represents the temperature rise due to ultrasound attenuation. Supplied power (P) to the ferrofluids medium is calculated from experimental temperature rise as,$P = \frac{dT}{dt} MC_{nf}$, where M is the total mass, $\frac{dT}{dt}$ is calculated from the linear region of experimental temperature rise(Fig.2). The calculated P for x values of 0.5%, 1% and 2 % is 1.8 J/s.

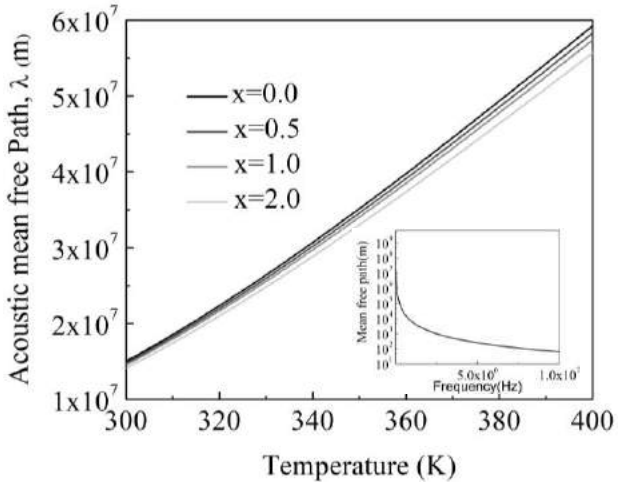

Figure 1: Acoustic mean free path for different volume fraction of ferrofluids for 20 KHz frequency. Here, *x* is the volume fraction of Fe_2O_3. (Inset) mean free path for different frequencies.

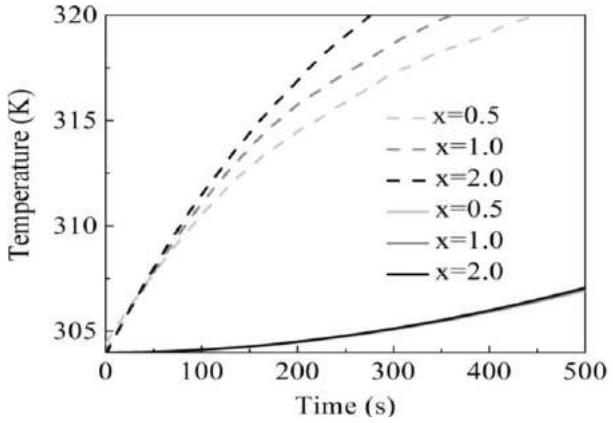

Figure 2: Temperature rise for ultrasound propagation time. Dashed lines are experimental values of total temperature rise for 20 KHz ultrasound frequency, solid lines are theoretical calculation for ultrasound attenuation. *'x'* is the volume fraction.

DISCUSSION

Here, we have shown that the theoretical temperature rise in ferrofluids due to purely ultrasound attenuation is very low (1.7 °C after 400s at x= 0.5%). However, for highly viscous medium the temperature rise is faster and higher compared to ferrofluids. Only by changing the viscosity of base fluid to 3.4 cp and 10 cp, we observed temperature rise of 3.6°C and 10.2°C respectively for x =1%, after 300s. It has been observed that change in acoustic mean free path in ferrofluids is smaller after 1.5MHz frequency, so the change in frequency will not have a dominant effect on temperature change at very high frequencies. This model can also be used for the temperature calculations in TMM and it can be further improved by incorporating other phenomena for temperature increase such as phonon-electron interaction in NPs, viscous heating and temperature rise due to fluid momentum.

INTRODUCTION

Prediction of temperature distribution in tissues and organs is important for treatments such as hyperthermia, radiofrequency ablation, high-frequency focused ultrasound and cryosurgery, which induce a change of temperature from their physiological state. Many types of models and equations have been therefore developed to take into account the effect of blood perfusion that often has a significant effect on the heat transport in tissues. However, they have introduced many parameters associated with blood perfusion and, in some cases, anatomical information, which are not available in many cases. In addition, from the practical point of view, the result of using complicated models was not significantly different from that of simple bioheat equation proposed by Pennes [1]. These were the reasons why the conventional Pennes bioheat equation has been used for many applications in spite that it has intrinsic problems. However, even in the case of using Pennes bioheat equation, the blood perfusion, which is defined by the rate of blood flow per unit volume of tissue, is not available in many cases particularly for human tissues and organs. This leads us to come up with a practical idea of using apparent thermophysical properties that include the effect of blood perfusion. The objective of this study is to examine the feasibility of introducing our idea to cryosurgery for predicting the size of ice ball.

METHODS

Simulation was carried out for cryosurgery operated with a 1.5-mm-dia. cryoprobe. We assumed that a single probe was placed in a uniform tissue. The bioheat equation that neglects the effect of metabolic heat generation and takes into account the freezing process as a source term is expressed by

$$\rho\left(c-L\frac{\partial g_s}{\partial T}\right)\frac{\partial T}{\partial t}=\frac{1}{r}\frac{\partial}{\partial r}\left(kr\frac{\partial T}{\partial r}\right)+\frac{\partial}{\partial z}\left(k\frac{\partial T}{\partial z}\right)+\rho_b c_b \omega_b (T_b-T) \qquad (1)$$

where T is the temperature, ρ is the density, c is the heat capacity, k *is* the thermal conductivity, L is the latent heat of freezing, g_s is the solid fraction, and ω is the blood perfusion rate. Subscript b stands for the blood. We assumed that the tissue is equivalent with a 0.9 % sodium chloride aqueous solution, and no blood flow takes place in the frozen region. The temperature at the probe surface of a Joule-Thomson cryoprobe measured by an experiment [2] was used as a boundary condition. The probe temperature decreased to ~–95 °C when the argon gas was supplied at 27.4 MPa, ~–85 °C at 25.2 MPa, and ~–75 °C at 22.4 MPa. It was assumed that the probe surface 32 mm from the tip was uniform but adiabatic at the rest.

Solutions of the bioheat equation and the normal heat conduction equation were compared with each other. The bioheat equation, Eq. (1), was solved for given values of thermal perfusion rate B (= $\rho_b c_b \omega_b$) as a parameter. The heat conduction equation that neglected the perfusion term in Eq. (1) was solved using apparent thermal conductivity k_{ap} as a parameter. We defined the enhancement factor ε by $k_{ap}=\varepsilon k$ to express the increase in apparent thermal conductivity due to blood perfusion. Based on the literature survey, we used B = 17 kW/(m^3·K) as a typical value for soft tissues [3], and examined the perfusion effect within the range of B < 50 kW/(m^3·K).

RESULTS

Figures 1 and 2 respectively show the effect of B and ε on the radial temperature distribution at 16 mm from the tip at 600 s after the start of cooling. The radius of ice ball, which is identified by the place where T = –0.5 °C, is smaller for larger B (Fig. 1) and larger ε (Fig. 2), while the temperature gradient at the unfrozen part near the ice front is larger for larger B but smaller for larger ε.

Since the effects of B and ε on the size of ice ball were qualitatively the same, we tried to determined ε that gave the same ice-ball size with that obtained for a given B. Figure 3 demonstrates that

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

the simulation with $\varepsilon = 1.9$ agrees well with that obtained for $B = 17$ kW/(m^3·K) not only in the size of ice ball but also in the temperature distribution inside the ice ball irrespective of the freezing time.

The value of ε determined for given B is shown as a function of B in Fig. 4. The ε value increases with B, which is reasonable from the physical point of view. In addition, the value determined for three different gas pressures, *i.e.* different probe temperatures, agreed well with one another, and overlapped in Fig. 4.

Figure 5 compares the growth of ice ball between $B = 17$ kW/(m^3·K) and $\varepsilon = 1.9$. They agree well with each other irrespective of time and the gas pressure.

DISCUSSION

Prior to the simulation of cryosurgery, we examined the effect of B and k_{ap} on the temperature distribution for a non-freezing case where the temperature at the probe surface was decreased to 7 °C. At a given time the temperature-changed area was smaller, *i.e.* the temperature gradient near the probe surface was larger, for larger B or smaller k_{ap}. This indicates that the increase of blood perfusion does not correspond to the increase of apparent thermal conductivity from a perspective of temperature distribution, which was also suggested by Figs. 1 and 2. Therefore, the apparent thermal conductivity does not work for predicting temperature distribution in tissues with blood perfusion.

However, the apparent thermal conductivity does work for predicting the size of ice ball during cryosurgery. We determined the apparent thermal conductivity for a given rate of blood perfusion. The enhancement factor ε, which expresses the increase of apparent thermal conductivity from the intrinsic value, was determined to give the same size of ice ball as that for a given perfusion rate. Thus determined ε was independent of cooling time and also the probe temperature that depends on the pressure of supplied gas. It was reasonable from the physical point of view that ε increased with the thermal perfusion rate B. The result shown by Fig. 4 demonstrates that freezing of tissue with blood perfusion of $B = 20$ kW/(m^3·K) is equivalent to freezing of material that has the thermal conductivity twice larger than the tissue. The fact that the temperature distribution inside the ice ball also agreed well indicates that using apparent thermal conductivity is also useful for predicting a safety margin of ice ball that should be made larger than a tumor to completely kill all cancer cells.

INTRODUCTION

High intensity focused ultrasound (HIFU) is a promising noninvasive treatment for tumor. Ultrasound energy is focused in a tiny region inside the body where the temperature can reach above 56 ℃ within several seconds, leading to thermal necrosis of the tumor tissue.

The acoustic droplets vaporization technique are shown to be able to greatly increase the lesion size and thus accelerate the treatment process [1]. During the treatment, the acoustic droplets instead of the bubbles are injected, only when they are exposed to the ultrasound of certain frequency and pressure, these droplets are vaporized into bubbles. Experiments have shown that the introduction of ADV droplets in HIFU would significantly shorten the treatment time [2].

Injected droplets accumulate at the periphery of the tumor where there are plenty of vessels. Usually the bottom of tumor would be treated first. HIFU lesions are created within tumor along the bottom face, while all the ADV droplets are vaporized in this region, forming a bubble wall along the tumor bottom edge. The existing bubble wall would greatly reshape the followed acoustic field and thus result in very different lesion shape for each focus used. However, this process is highly dynamic and it hard to image at the same time for a safe planning of the treatment. A simulation model which can precisely predict the influence of the bubble wall on the following evaporation of droplets is necessary for acoustic parameter selection and treatment pathway planning. Current models have successfully predicted the acoustic field and correspondent temperature distribution during HIFU treatment, but none of the models is suitable for this study.

In this paper, a model is proposed to mathematically describe the droplets evaporation conditions and correspondent acoustic field and bubble formation in ADV assisted HIFU treatment in the presence of preexisting bubble is studied numerically. The highest pressure in front of a plane wall or a curved wall as function of the location of the wall is obtained.

METHODS

Both plane wall and curved wall are employed in the simulation as shown in Fig.1

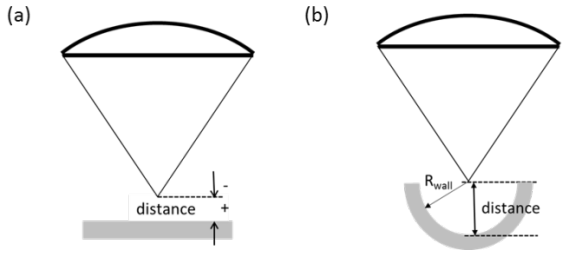

Figure 1: Geometry for simulation of the highest pressure in front of a plane wall (a) and a curved wall (b).

Acoustic field is calculated using linear sound propagation equation. It is solved in frequency domain by the following equations.

$$\nabla \cdot \frac{1}{\rho_c} \nabla p - \frac{k^2 p}{\rho_c} = 0 \tag{1}$$

$$k = \frac{\omega}{c} - i\alpha, c_c = \frac{\omega}{k}, \rho_c = \frac{\rho c^2}{c_c^2} \tag{2}$$

Where p is pressure, ρ is density, k is wave number, ω is angular frequency, and c is sound speed. Subscription c indicates the parameter is complex number. The presence of bubbles in the medium leads to the variation of parameters. Bubble void fraction is defined by f_G, on which density, sound speed and sound attenuation coefficient α

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

all depend. Subscription p and G refer to parameters of phantom and gas, respectively.

$$f_G = \begin{cases} 0 & \text{, no bubble} \\ \frac{4}{3}\pi n_G R_0^3 & \text{, with bubbles of number density } n_G \text{ in medium} \end{cases} \quad (3)$$

$$f_P = 1 - f_G \quad (4)$$

$$\rho = f_P \rho_P + f_G \rho_G \quad (5)$$

$$\frac{c_P^2}{c_c^2} = 1 + 4\pi c_P^2 \int_0^\infty \frac{R_0 n_G(R_0)\, dR_0}{\omega_0^2 - \omega^2 + i\frac{4\mu\omega}{\rho_P R_0^2}} \quad [3] \quad (6)$$

$$\omega_0^2 = \frac{1}{\rho_P R_0^2}\left(3\kappa P_0 - \frac{2\sigma}{R_0}\right) \quad [3] \quad (7)$$

$$c = \frac{c_P}{real\left(\frac{c_P}{c_c}\right)}, \quad \alpha = \frac{imag\left(-\frac{c_P}{c_c}\right)\omega}{c_P} \quad [3] \quad (8)$$

ADV droplets would be vaporized under certain conditions, which are related to ultrasound frequency, diameter of the droplets, super heat degree and total ultrasound 'on time'. The following assumptions are used to decide how much bubbles will form in certain acoustic field:

(i) Threshold for droplets in phantom gel exposed to 750 kHz ultrasound is found to be 7.4 MPa as was found in experiment [4].

(ii) The probability of droplets vaporized increases linearly with pressure in a range, which is defined as 1.6 MPa as found in one of the experiment [5].

(iii) The phase shifted threshold decreases as the total ultrasound 'on time' increases. The relationship between the threshold and the ultrasound 'on time' is obtained by averaging the findings from three different approaches [5].

(iv) The threshold is lowered when there are bubbles coexist as has been found experimentally [5].

RESULTS

The bubble area created in after 200 pulses with preexisting of a plane wall is shown in Figure 2. All the bubbles vaporized are in the proximal side of the bubble wall, which indicates the shielding effect of the wall. This character of bubble wall can be employed to protect normal tissue in distal area in practical. The shape and size of the created bubble area are similar to the one created in the experiment [4] which used the same parameters of ultrasound and droplets. Comparing to the bubble area formed when there is no preexisting bubble wall as also shown in Fig.2(b), the preexisting bubble have caused a lot more bubbles formation in the region close to the bubble wall, and the bubble area formed are shorter with a larger head.

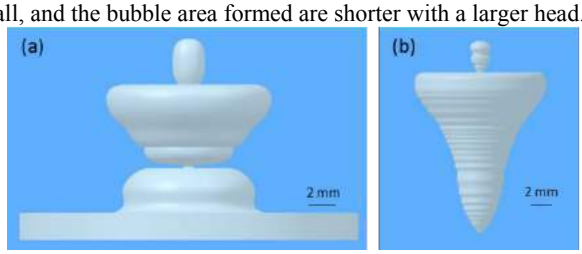

Figure 2: (a) Bubble area created in the presence of 2 mm bubble wall after 200 pulses (pulse duration 20 μs) of ultrasound exposure. The HIFU is focused on the upper surface of wall with focal pressure of 14.7 MPa. The frequency is 750 kHz. (b) Bubble area created without bubble wall for the same condition.

Fig. 3(a) and (c) are the pressure field and the relationship of the highest pressure achieved with the distance between the HIFU focus and the front surface of the plane bubble wall. Fig.3 (b) and (d) are the same results when the bubble wall is a curve. It is found that the pressure in front of a plane bubble wall can be as high as 6.66 dB. Almost all the highest pressure in front of the wall are higher than 0 dB in location range from -2.8 mm to 4.3 mm. The highest pressure achieved in front of a curved wall is 4.07 dB.

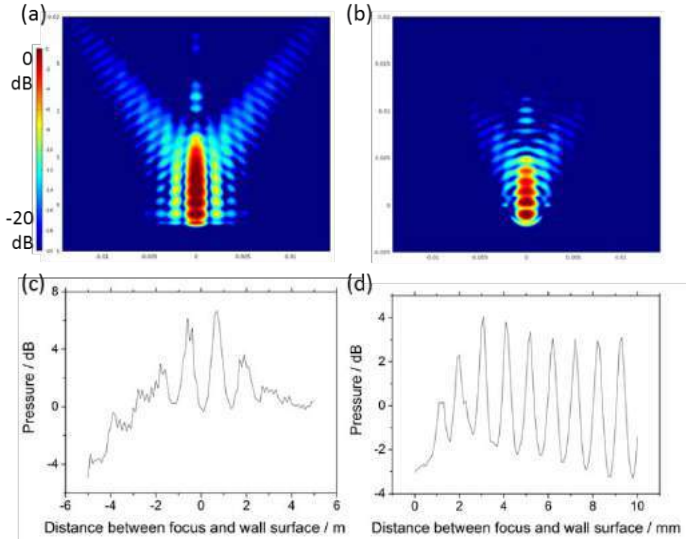

Figure 3: Pressure distribution in front of a plane wall (a) and a curved wall (b) when the front surface of the wall is at 2 mm. Highest pressure as function of wall location in front of a plane wall (c) and a curved wall (d). The frequency was 750 kHz, the focal pressure was 14.7 MPa.

DISCUSSION and CONCLUSION

By comparing to others experiment study, the current model could give a good prediction of bubble area in ADV droplets assisted HIFU therapy with the influence of the preexisting bubble wall being discussed. The model can be further used for study of irregular shape of the bubble wall as real tumor edge. In this study, a linear sound propagation equation has been used, which excludes the nonlinearity in the treating process and may have underestimated the size of the bubble area. Further work is needed to couple the heat transfer model with this proposed model to simulate the thermal lesion in this therapy, which may have greater potential to be used as a tool for design of path and parameters before treatment.

LONGITUDINAL STUDY OF WALL SHEAR STRESS OVER SURGICALLY-INDUCED ATHEROSCLEROTIC PLAQUES IN MICE

INTRODUCTION

Wall shear stress (WSS) is the frictional force that blood flow exerts on the endothelium of the vessel wall. It is known to initiate atherosclerotic plaque growth, which is the accumulation of lipids, fibrous tissue and inflammatory cells in the arterial wall.

As the disease advances, plaques can progress into two distinctive types: a stable or a vulnerable plaque. Vulnerable plaques are characterized by thin fibrous cap, large lipid pool and increased plaque inflammation. Rupture of a vulnerable plaque is the main cause of stroke and myocardial infarction. However, factors determining plaque progression and plaque vulnerability remain unclear.

We hypothesized that WSS plays a role in atherosclerotic plaque progression and plaque stability [1]. We want to study this hypothesis using a WSS-manipulated atherosclerotic mouse model, in which both a stable and a vulnerable plaque are present in the same vessel [2]. In this study, we demonstrate for the first time how WSS patterns change over time during plaque progression in this mouse model.

METHODS

A tapering cast was placed around the right common carotid artery (RCCA) of female ApoE$^{-/-}$ mice (n=7). The cast has a tapering lumen (diameter from 400 µm to 200 µm over 1.5 mm) which changed the blood flow in the RCCA. The cast induces a low WSS region upstream of the cast, high WSS in the cast, and oscillatory WSS area downstream of the cast. It was previsouly shown that vulnerable plaques develop in the region upstream of the cast [2]. We followed plaque progression over time at 5, 7, 9 weeks after cast placement. In order to calculate WSS, blood flow and detailed 3D geometry of the RCCA is required.

First, we measured the blood velocity and vessel diameter in the RCCA by Doppler Ultrasound (Vevo 2100). The two measurements were captured at the same location to determine the flow rate. Next, RCCA vessel geometry was obtained using the contrast-enhanced micro-CT imaging system (Quantum FX) with a resolution of 40 µm. RCCA vessel surface was then reconstructed using an in-house developed segmentation protocol. Finally, computational fluid dynamics (Fluent 14.5) was applied to compute the velocity field and WSS distribution in the RCCA at three time points during plaque progression. Quantitative analysis was performed using Matlab (Matlab 2011b).

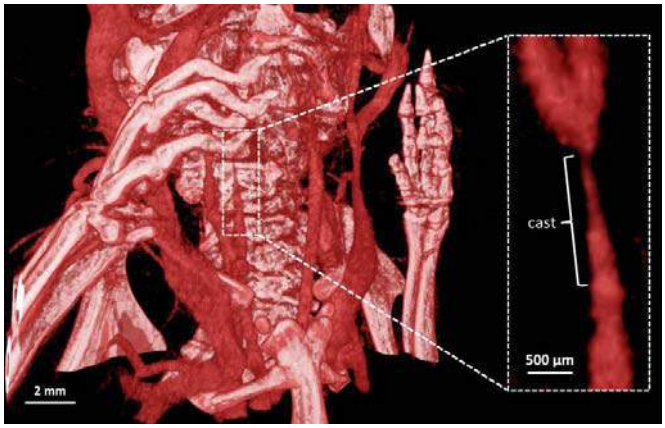

Figure 1: 3D volume rendering of the murine vascular network. The box shows the zoomed-in area of the narrowing carotid artery caused by the tapering

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

CT-imaging: A 3D volume rendering of the contrast enhancement vasculature is shown in Figure 1. Next to the arteries, bone tissues including vertebrae, sternum and ribs were also visualized. The common carotid arteries are located close to the vertebrae. They travel parallel along the vertebrae, at both sides of the neck. The narrowing of the RCCA caused by the tapering cast and the carotid bifurcation are clearly visible (Figure 1, zoomed-in box).

Flow data: Diameter and velocity measurements were performed in all mice successfully. The resulting flow data (figure 2), reveal an immediate reduction in the flow after cast placement of approximately 66%, followed by a further decrease to 20% at week 5. After that time point, the flow stabilized.

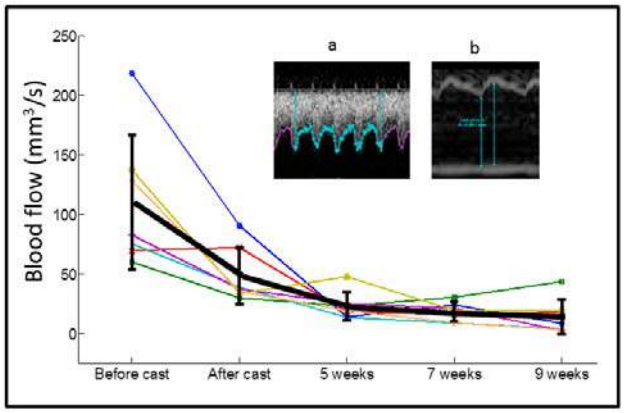

Figure 2: The blood flow at 5 different time points derived from (a) blood velocity measurements upstream to the cast using Doppler Ultrasound and (b) vessel diameter measurements using M-mode at the same location.

Geometrical data: The average diameter of the upstream part of the common carotid artery was 480±51 µm, 473±27 µm and 450±43 µm at week 5, 7 and 9 respectively. The minimum diameter decreased from 386±79 µm to 303±82 µm. The average area stenosis was 51±16%, 67±9% and 72±13%. Two examples of the reconstructed lumen for two different animals are shown in figure 3. They illustrate that significant differences can be found between individual animals.

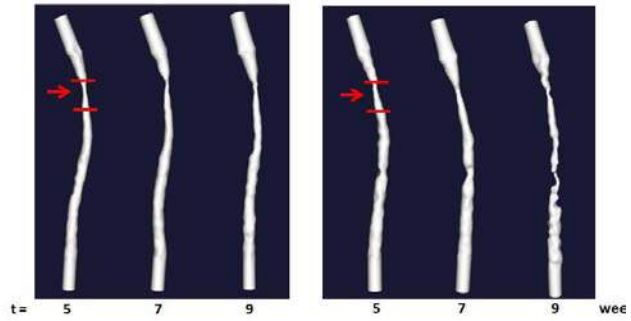

Figure 3: The reconstructed lumen from two animals at three different time points during plaque development. The cast region is indicated by the red lines. The differences between the animals are evident: while disease progression is slower for the mouse in the left panel, the carotid artery of the animal in the right panel shows severe plaque progression, leading to an irregular lumen narrowing.

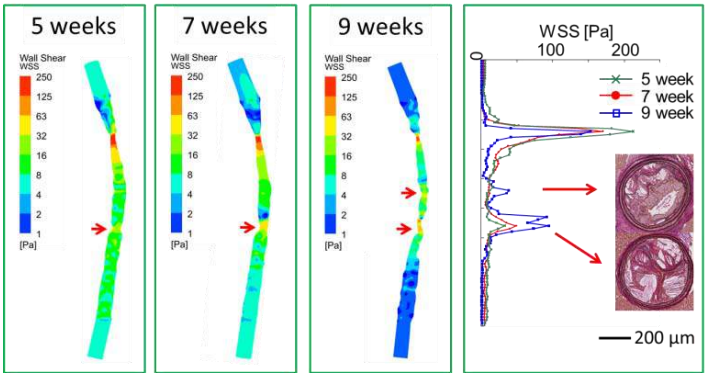

Figure 4: The WSS patterns at three different time points in a severly diseased animal. The appearance of heterogeneous WSS distributions due to lumen intruding plaques (red arrows) is obvious. After registration, averaged WSS patterns can be related to histology (right panel).

Shear stress data: An example of the time averaged WSS distribution in a severely diseased animal is shown in left three panels in figure 4. Five weeks after cast placement, WSS was low upstream of the cast, while maximum WSS was observed inside the cast region. Asymmetrical WSS patterns were present downstream of the cast. Seven weeks after cast placement, WSS slightly increased upstream of the cast while flow recirculation appeared downstream of the cast. A distinct stenosis with high WSS upstream and low WSS downstream developed upstream of the cast. An increasingly complex pattern with multiple focal lesions appeared at week 9. After averaging the WSS in the circumferential direction, the WSS data was co-registered with histology. The preliminary analyses show that plaque composition was different at the different location: a larger necrotic core was present at the upstream plaque, indicating a potential role of WSS.

DISCUSSION

Genetically modified mice are frequently used to study the initiation and progression of atherosclerosis. The relationship between atherosclerosis and WSS was hardly studied in mice before, mainly due to the size of the arteries. Imaging them with sufficient spatial resolution for WSS computations, especially in a longitudinal study design, is a real challenge. In this study, we used contrast-enhanced µCT to monitor WSS patterns in a diseased mouse carotid artery over time.

We analyzed the effect of plaque growth on WSS and we were able to demonstrate that there were significant variations in the rate of plaque progression, leading to significant differences between both geometry and flow ratess. Animal-specific measurements are therefore required to accurately assess WSS patterns in vivo. A second consequence of these data is that longitudinal studies within a single animal are required to establish causal relationships between biomechanical indices and plaque composition and progression.

Future work will focus on establishing causal relationship between (changes in) WSS and plaque composition.

MORPHOLOGICAL MEASUREMENT AND THE OXYGEN DIFFUSION ANALYSIS IN MOUSE ACINAR CLUSTER OBTAINED FROM MICRO-CT

INTRODUCTION

As the main site of gas exchange, pulmonary acini play an important role in respiratory functions. The acini consist of tree-like ducts and alveoli, which form highly fine and heterogeneous structure. An acinar cluster is a peripheral unit of the acini belong to the same terminal conducting airway. The oxygen in inhaled air has not been exchanged yet before it arrive to the entrance of the acinar cluster. To understand the effects of heterogeneity on respiratory functions, it is necessary to estimate the heterogeneous features of acini and subsequently to perform biomechanical analysis of gas exchange in a cluster. In this paper, we performed morphological measurements and the oxygen diffusion analysis with the measured data of the mouse acinar cluster.

METHODS

A semi-automatic segmentation method was used to collect mouse acinar clusters from synchrotron micro-CT images of the mouse lungs [1, 2]. The acinar volume and surface area of the segmented acini were estimated based on the voxel and surface meshes. The locational information of individual acini in the cluster was imparted by estimating the skeleton of each airway branch. 31 acini in three acinar clusters were analyzed.

To describe the oxygen transport in the acinar cluster, a three-compartment model (the airway side, the acinar wall tissue, and the blood side) was used with considering the conservation of oxygen flux between the compartments (Figure 1) [3].

The airway side includes the terminal conducting airway and the acinus. The averaged oxygen concentration C (dimensionless volume fraction) in the airway is considered by the diffusion equation for the one-dimension and the steady state. The oxygen flux J_{air} in the airways is

$$J_{air} = AD\frac{C_{in}-C_w}{L}, \quad (1)$$

where A is the apparent cross-sectional area of the airway to an acinus, D is the diffusion coefficient of oxygen in air, C_{in} is the constant concentration at the entrance of the terminal conducting airway, L is the averaged distance from the entrance to the acinar wall, and C_w is the averaged oxygen concentration at the wall.

The blood side includes blood capillaries. The oxygen concentration C in a capillary is considered by the advection equation for the one-dimension and the steady state. The oxygen flux J_{blood} in the blood capillary is

$$J_{blood} = Q_b\left(C_{b_{out}} - C_{b_{in}}\right), \quad (2)$$

where Q_b is the averaged blood flow in the capillary, C_{bout} is the averaged concentration at the capillary exit, and C_{bin} is the constant concentration at the capillary entrance.

In the airway, the oxygen concentration can be converted to the partial pressure by using Henry's law. In the blood capillary, the relationship between the oxygen partial pressure and the oxygen concentration can be written as the following set of equations [4];

$$\begin{gathered} C_b = S_{O_2}\cdot H_{max} + 3.0\times 10^{-5}\cdot P_b, \\ S_{O_2} = \frac{u}{u+1}, \\ u = 0.925v + 2.8v^2 + 30v^3, \text{ and} \\ v = \left(0.004273 + 0.04326\cdot {P_{b_{co_2}}}^{-0.535}\right)\cdot P_b, \end{gathered} \quad (3)$$

where S_{O_2} is the hemoglobin saturation that can be pre, H_{max} is the maximum amount of oxygen blood unit volume saturated with the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

oxygen, and $P_{b_{co_2}}$ is the partial pressure of carbon dioxide in blood. C_{bout} in Eq. (2) can be obtained from Eq. (3) by assuming $P_b = P_w$.

In this model, the morphological parameters, A, S, L, and Q_b were obtained from our experimental data. A is estimated by averaging the cross-sectional area of the terminal conducting airway from the entrance of the terminal conducting airway to the entrance of the individual acinus. S is the surface area of the individual acinus. L is estimated by the sum of L_{acinus} and L_{airway}, where L_{acinus} is the characteristic length of the individual acinus estimated by taking cubic root of the acinar volume, and L_{airway} is estimated based on the centerline of the terminal conducting airway. For each individual acinus, Q_b is estimated by volume-dependent scaling based on the pulmonary blood flow in healthy human lungs. Other constant parameters are obtained from the healthy human lung conditions e.g. Ref. [5, 6], and the value of the parameters are summarized in Table 1. The morphology-dependent C_w were determined self-consistently.

Table 1: Parameter settings of the three-compartment model.

Parameter	Value
D [mm^2/s]	20
C_{in} [-]	0.132
$P_{b_{co_2}}$ [mmHg]	40
$P_{b_{in}}$ [mmHg]	40
H_{max} [cm^3/cm^3]	0.197

RESULTS AND DISCUSSION

Figure 2 shows the relationship between the volume and the location of each acinus from the entrance of the terminal conducting airway. The location of each acinus was normalized using the overall length of the terminal conducting airway as a measure of scale. The mean acinar volume and surface area were 0.07 ± 0.05 mm^3 and 6.13 ± 3.78 mm^2 (mean ± standard deviation), respectively. The largest acinus of each cluster was found in the distal region of the terminal conducting airway.

In above three clusters, the oxygen concentrations at acinar wall of each acinus were analyzed using the self-consistent model described above. Figure 3 shows the relationship between the oxygen concentration at acinar wall and L, for C_{in} = 0.132 (corresponding to 100 mmHg). The acinus at the distal region in the cluster shows a lower oxygen concentration comparing with that of the closer acini, but it is still in a larger range (>90 mmHg).

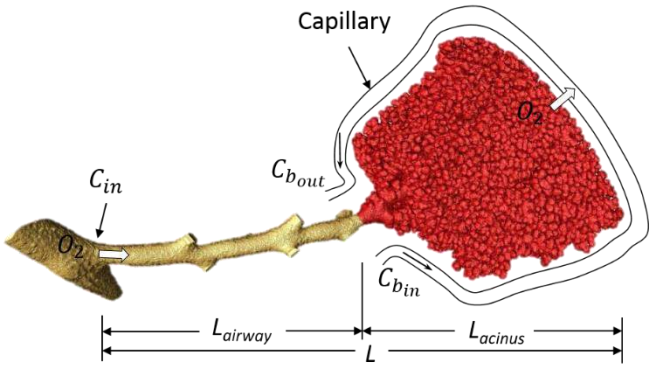

Figure 1: Model schematic of the oxygen transport for an individual acinus in an acinar cluster.

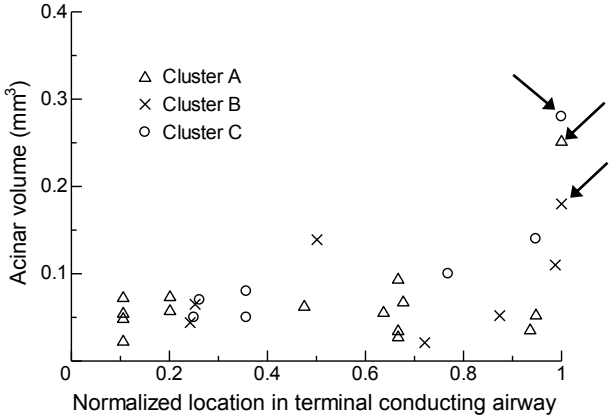

Figure 2: Acinar volume vs. location in the terminal conducting airway. Arrow indicates the largest acinus in each cluster.

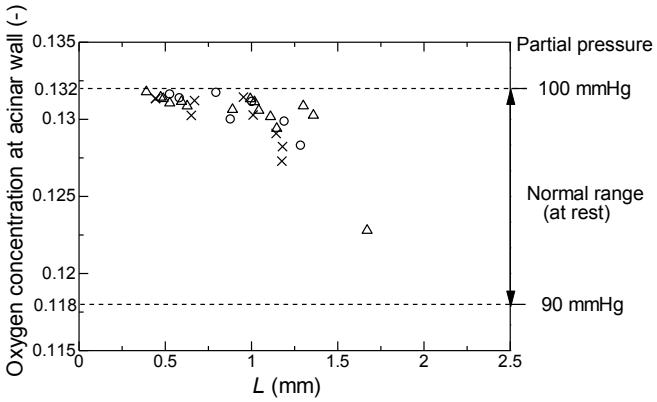

Figure 3: Oxygen concentration at acinar wall vs. distance from the entrance to the acinar wall (L).

SUMMARY

This study investigated the oxygen diffusion based on the acinar cluster morphology using a three-compartment model. Considering the gas transport at acinar cluster level, in spite of the large-volume acinus at distal region, the oxygen transport ability is enough to cover the large volume. In the future, the analysis with more sophisticated model should be conducted and it may be interesting to analyze the effects of the heterogeneity on respiratory functions for diseased lung conditions.

INTRODUCTION

Pancreatic cancer of all types was the 4th most common cause of cancer death in the United States in 2015 with few effective treatments available. Clearly, there is a need to find more effective approaches including possibly focal therapies that can be applied directly or under image guidance to treat this devastating disease.

One promising new focal therapy is irreversible electroporation (IRE) which has increased during the past decade due to many advantages over other focal therapies including being simple, fast and minimally invasive[1]. Compared to other thermal therapies, IRE has two important advantages if properly deployed: (1) reduction of collateral and thermal damage (e.g. over-treatment and thermal effects [2]) and (2) lack of dependence on blood perfusion (i.e. no blood sink or source thermal effects). The new application of IRE as an independent cancer therapy and its unique advantages has led to widespread interest from the scientific community [3-5].

This work presents preliminary data on the assessment of the impact of IRE on pancreatic cancer in *in vitro* and *in vivo* models. A series of IRE parameters (electric field and number of pules) were applied to cell suspensions in the *in vitro* model, and outcome is presented in terms of viability. Different treatment strategies with the same voltage, pulse number and pulse width but different in timing were applied to vivo tumor model, and the efficacy was evaluated by tumor growth delay after treatment.

METHODS

In Vitro Experiments:

In vitro experiments were performed with human adenocarcinoma cells (AsPC-1) and murine pancreatic ductal adenocarcinoma cells (KPC). For each *in vitro* electroporation test, 400 µl of the prepared cell suspension (0.5~0.6 million cells/ml) was pipetted into the electrode gap (2 mm) in an electroporation cuvette (FB102, Fisher Scientific), which was then placed in an external electric field created by an electric pulse generator (BTX ECM 830, Harvard Apparatus). The pulsing frequency was set to 10 Hz and the pulse duration was 50 µs. Cells were subjected to 10, 50, and 99 pulses at electric fields between 500, 750, 1000 and 1250 V/cm.

Viability after pulsing was evaluated using a Tetrazolium-based Cell Counting Kit-8 (CCK-8) assay. It is a metabolic-based assay that measures the dehydrogenase activity within cells. A clear, flat-bottomed 96-well plate was loaded with 100 µL of cell suspension and 10 µL of CCK-8 dye per well. The plate was then incubated at 37 degrees C and 5% CO_2 for 3 – 4 hours depending on the cell concentration. After incubation, the optical absorption of the samples was read in a spectrophotometer at a wavelength of 450 nm.

In Vivo Experiments:

In vivo tumors were grown using AsPC-1 cells grown in a nude mouse hind limb model. All animal usage and experimental procedure protocols were reviewed and approved by the Institutional Animal Care and Use Committee of the University of Minnesota. 100 µL of the suspension of 1 million cells was injected subcutaneously over hind limb of mice under general anesthesia.

Tumors were treated with IRE 15 days after implantation, with average size of 100 mm^3 (on average 9 mm by 7 mm). Treatments were delivered by a pair of customized needle electrodes connected to an electrical pulse generator (BTX ECM 830, Harvard Apparatus). The needles (OD = 0.7 mm) were fixed on a plastic block with a center-to-center distance of 4 mm. An insulating layer was coated outside each needle with heat shrink tubing leaving a 3 mm tip for treatment. The needle electrodes were inserted symmetrically to the center of the tumor through the skin. Effective treatment depth is determined by the exposed needle length (3 mm).

The animals were randomly divided into four group with each group receiving a different treatment plan. Group 1 received sham procedure without any electric pulses. Groups 2 and 3 were applied

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

with 51 IRE pulses at pulse strengths of 600 V (potential between two electrodes), durations of 50 µs and pulse repetition rates of 10 Hz. However, for group 3, the 51 pulses were delivered in three trains of 17 pulses with delays of 30 s in between trains. Group 4 have the same pulses as group 2, but the repetition rate was set to 1 Hz.

After IRE treatment, the mice were returned to their cages and monitored for any complications. Tumor growth measurements were taken twice a week using a caliper. The sizes of the major axis (L) and minor axis (S) of the tumors were measured and used to calculate tumor volumes (V) by using V=1/2*L*S^2. All tumors were monitored for at least 40 days after the IRE treatment.

RESULTS

The *in vitro* result of cell viability after IRE with different parameters are shown in Figure 1 (AsPC-1) and Figure 2 (KPC). The AsPC-1 cells can be seen to be more sensitive for the same IRE conditions than KPC. For instance, field strength (V/cm) had relatively little impact on AsPC-1 (all above 90%) at 10 pulse repetitions where KPC dropped to 85% and 64% at 750 and 1250 V/cm. Reductions were more dramatic at higher pulse numbers.

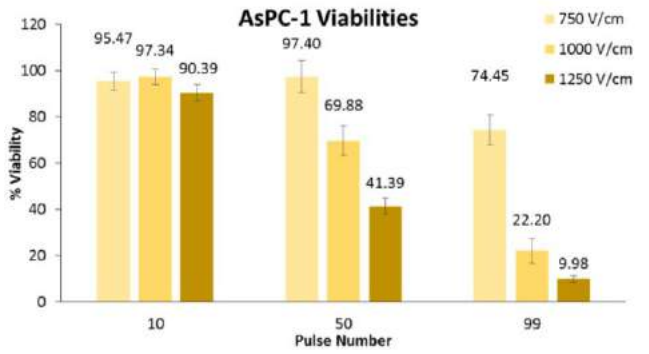

Figure 1: AsPC-1 viabilities after 10, 50, and 99 pulses and electric fields of, 750, 1000, and 1250 V/cm.

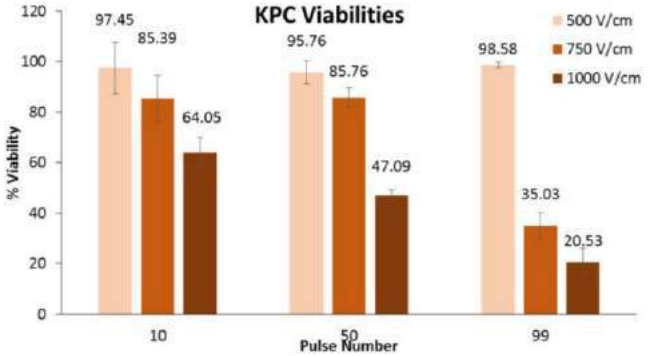

Figure 2: KPC cell viabilities after 10, 50, and 99 pulses and electric fields of 500, 750, and 1000 V/cm.

The *in vivo* tumor growth demonstrates that pulse timing can have a dramatic impact on tumor growth delay. The in vivo tumor growth is being collected as of the deadline of this abstract submission.

DISCUSSION

Our *in vitro* and *in vivo* data sets can help in protocol development for pancreatic and other cancer treatments by IRE. For instance, in vitro testing can demonstrate relative susceptibility of different cancer types to IRE. In the cell types tested were found that the human line (AsPC-1) was less susceptible for the same IRE

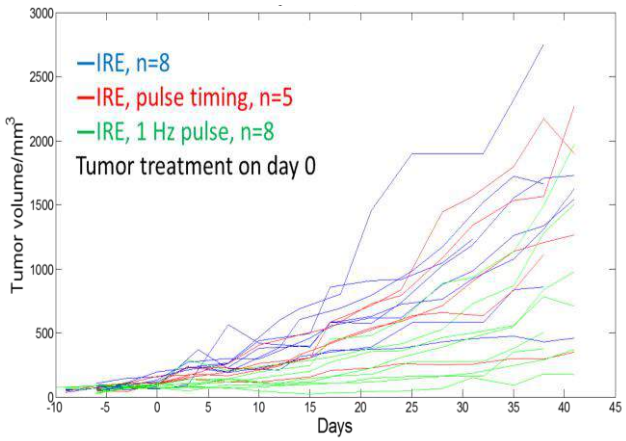

Figure 3: Partial results from *in vivo* IRE tumor ablation study.

conditions as the KPC (murine line). Further, we were able to define the conditions where viability dropped between 10% for the cell type. In the case of *in vivo* testing, the pulse timing and delivery methods were also explored to improve the destructive potential or IRE. In this case, for the same energy applied, waiting between pulses (Pulse timing group) improves outcomes over IRE pulsing at 10 Hz. This agrees with previous work on pulse timing presented both in vitro and *in vivo* in a prostate cancer model with IRE[5]. By extending this pulse timing out to as long as a second between pulses improves this result even further. It is not clear whether there is a limit to this effect in the pancreatic lines tested. The time frame of 1 second between pulses during timing is interesting because it suggests that IRE can be gated along with the heartbeat in the clinic. Together, these results suggest that further IRE protocol design and parameter setting exploration is warranted. In the future, this information can perhaps help in the effective design and translation of a clinical IRE device for the treatment of pancreatic cancer.

NUMERICAL MODELING OF FLOW DIVERTER STENT IN GIANT CEREBRAL ANEURYSM

A. F. Sanches (1), E. Gutheil (1)

(1) Interdisciplinary Center for Scientific Computing, University of Heidelberg, Heidelberg, Germany

INTRODUCTION

Cerebral aneurysm is a vascular disease characterized by the local dilatation of arterial walls in the intracranial space. The aneurysm may rupture and cause sub arachnoid hemorrhage, associated with high mortality and morbidity. Due to widely used imaging methods in clinical surgery, the detection of cerebral aneurysms that are not ruptured becomes more and more frequent. In order to reduce the risk of rupture and hemorrhage and to identify highly effective treatment options, the understanding of the hemodynamic mechanisms involved is of great importance [1-2] and numerical tools may provide excellent support of the medical treatment of cerebral aneurysms.

Endovascular intervention is one of the treatments of choice for cerebral aneurysms because of both its safety and efficacy. Large, giant, wide-necked, and fusiform aneurysms are considered more challenging and less tractable to traditional endovascular coil embolization. The flow diverter stent is a promising method of endovascular reconstruction for large and complex intracranial aneurysms, with an overall porosity metallic mesh placed in the parent artery to reduce blood flow in the aneurysm to the point of stagnation and gradual thrombosis [3].

Computational techniques offer new capabilities in the healthcare provision for intracranial aneurysms. The availability of a simulation tool for virtual flow diverter is extremely useful to support the decisions of treatment options by medical experts and to develop and optimize new implant designs [4-5]. In this project, the development of a computational tool for the modeling and simulation of the hemodynamic effects of the endovascular stents with different porosities are performed. A flow diverter and a regular stent are modeled and analyzed taking into account their design, porosity, and the flow reduction through the giant sidewall cerebral aneurysm is studied.

METHODS

An idealized giant sidewall cerebral aneurysm with a diameter of 33 mm is modeled based on a three-dimensional cerebral rotational angiography image provided by the Heidelberg Medical School. Two stents with regular meshes made of cylindrical wires are considered which fit the shape of the parent artery. Their geometrical properties are summarized in Table 1 in terms of a stent unit cell. The stent with a low metal coverage proportion is called regular stent (RS) and that with high metal coverage proportion is known as flow diverter (FD).

The computational grids for the simulations were generated using the software ICEM-CFD v.11 (Ansys Inc.). The laminar flow is described by three-dimensional incompressible equations, which are solved using the software platform OpenFoam v2.3. The non-Newtonian flow is modeled with Carreau-Yasuda's fluid model [6]. A uniform velocity profile of 0.14 m/s for the late diastole, and 0.56 m/s for the peak systole is prescribed at the inlet, and the pressure gradient at the outlet is zero. All the vascular walls are assumed rigid with a no-slip boundary condition. The elasticity of the stent is neglected.

Table 1: Geometrical dimensions of the assumed stent unit cell [5]

Unit cell	Dimension	RS	FD
	C (μm)	0.94	0.30
	L (mm)	60	42
	β	49°	55°
	ε (porosity)	0.88	0.73

RESULTS AND DISCUSSION

Figures 1 and 2 show a comparison of the velocity and its streamlines for the pure aneurysm, the regular stent, and the flow diverter during the systolic and diastolic cardiac flow, respectively.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

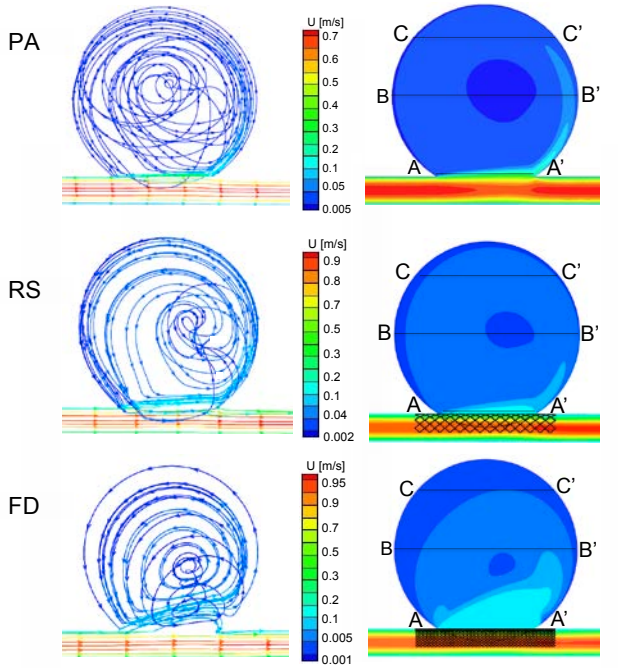

Figure 1: Velocity streamlines (left), velocity contour at the mid plane (right) for systolic cardiac flow, of pure aneurysm (PA), regular stent (RS), and flow diverter (FD)

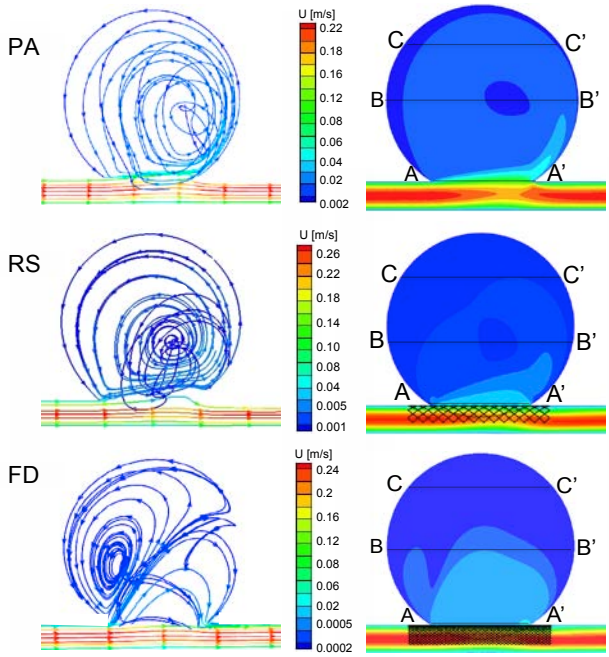

Figure 2:Velocity streamlines (left), velocity contour at the mid plane (right) for diastolic cardiac flow, of pure aneurysm (PA), regular stent (RS), and flow diverter (FD)

In the pure aneurysm and for the regular stent, the flow pattern at the aneurysm neck consists of a main clockwise distal inflow jet. A possible physical mechanism to describe this phenomenon involves both shear stress and pressure [5]. The shear stress transmitted at the cerebral aneurysm neck, induced by a strong velocity gradient in the parent artery, drives a counter-clockwise intra-aneurysmal flow. The use of the flow diverter causes the flow to transfer to a clockwise streamline from the proximal to distal side of the neck, driving a low motion swirl to the aneurysm's dome. The implantation of the FD impedes the flow at the aneurysm's neck, resulting in both a lower shear stress transmission and an increase of pressure gradient along the parent artery. The latter pushes the circulating fluid inward and outward the cerebral aneurysm at the proximal and distal sides of the neck, respectively. The magnitude of flow velocity inside the aneurysm is strongly reduced due to the use of the RS and even more due to the FD as shown in Fig. 1, note the different scales in the different parts of the figure.

The reduction of the aneurysm inflow and the flow activity after the implantation of a stent or flow diverter is a key factor for thrombus formation inside the aneurysm. As flow activities decrease, the turnover time increases in an inverse proportion, and therefore the chance of aneurysm thrombotic occlusion is likely to increase.

Tables 2 and 3 show the wall shear stress (WSS) for the PA, the RS, and the FD, for the systolic and diastolic cardiac flow, respectively. A strong reduction of the WSS for the different cross sections for both the regular stent and flow diverter is noted. However, the WSS reduction of the flow diverter during the peak systole is more significant, especially in the dome of the aneurysm.

CONCLUSIONS

The flow diverter effectively reduces the wall shear stress, the blood flow velocity and provides a structure to support endothelialization and reconstruction of the parent artery. This device also relocates the center of the vorticity in the intracranial aneurysm. The use of the flow diverter greatly improves the performance compared to the regular stent, and flow separation at the distal side of the neck is observed, promoting thrombosis.

Table 2: Wall shear stress for the systolic cardiac flow

	PA	RS	FD
A-A'	13.2 Pa	2.6 Pa (-80.3%)	1.3 Pa (-90.1%)
B-B'	0.45 Pa	0.066 Pa (-85.3%)	0.04 Pa (-91.1%)
C-C'	0.18 Pa	0.031 Pa (-82.7%)	0.0015 Pa (-99.2%)

Table 3: Wall shear stress for the diastolic cardiac flow

	PA	RS	FD
A-A'	1.6 Pa	0.88 Pa (-45%)	0.24 Pa (-85%)
B-B'	0.038 Pa	0.0043 Pa (-88.7%)	0.0043 Pa (-88.7%)
C-C'	0.013 Pa	0.0018 Pa (-86.1%)	0.0001 Pa (-99.2%)

ACUTE EFFECTS OF CELL FREE HEMOGLOBIN AND SICKLED RED BLOOD CELLS ON PULMONARY VASCULAR IMPEDANCE IN OTHERWISE HEALTHY MICE

INTRODUCTION

Patients with sickle cell disease (SCD)-related pulmonary hypertension (PH) have a substantially increased risk of sudden death compared to those with SCD alone, as high as a 50% within 2 years [1, 2]. The prevalence of PH in adults with SCD is high--about 30%, while the percentage of SCD patients with evidence of PH via lung histology at the time of death is even higher--75% [3-5]. SCD red blood cells (RBC) are more rigid, dense and frequently trapped in the microcirculation, thereby interrupting blood flow and causing ischemia, thrombotic events, increased oxidative stress, and reperfusion injury [6]. SCD RBCs also lyse easily, releasing cell-free hemoglobin, which itself causes depletion of nitric oxide, vasoconstriction and is a major contributor to endothelial cell dysfunction in SCD. All of these consequences of SCD can and often do have drastic effects on hemodynamics including increasing pulmonary vascular resistance (PVR) [6] and systemic arterial wave reflections [7].

In this study, we sought to investigate the impact of SCD RBCs and cell free hemoglobin, independent of other SCD-related abnormalities, on the hemodynamic changes that ultimately cause PH and increase mortality in SCD. We chose to use pulmonary vascular impedance (PVZ) to measure these changes as it provides a comprehensive view of the both static and dynamic components of right ventricular (RV) afterload in the pulmonary vasculature. That is, in addition to PVR, PVZ relays information about characteristic impedance and wave reflections, which are affected by changes in pulmonary arterial stiffness, which has been shown to be a predictor of morbidity and mortality in patients with pulmonary hypertension alone [8]. We hypothesized that SCD RBCs, especially when exposed to acute hypoxia (AH), and cell free hemoglobin will increase PVR and wave reflections in the pulmonary circulation in otherwise healthy lungs.

To test this hypothesis, we infused RBCs from control mice (cRBCs), RBCs from SCD mice (SCD RBCs), or cell free hemoglobin in solution into the jugular vein of mice. We measured PVZ in vivo at baseline, after each injection, and also after 5 minutes of 10% O2 ventilation, which has been shown to lower blood oxygen levels in mice [9]. Our results confirmed that cell free hemoglobin increases both PVR and wave reflections, with a further increase with exposure to AH, while SCD RBCs increase PVR and wave reflections only after exposure to AH, suggesting that increased cell free hemoglobin and lowered blood oxygen levels are key to poor outcomes in SCD-related PH.

METHODS

Whole blood was drawn from donor male SCD mice, or C57Bl6 mice (14 weeks-old) to obtain RBCs. Cell free hemoglobin was purchased commercially. Using established techniques from our lab [10-12], male C57BL6 (14-16 weeks old) mice underwent catheterization of the main pulmonary artery (PA) to obtain pressure with simultaneous echocardiography to obtain PA flow. Once baseline measurements were recorded, 200 uL of blood (Hct~45%) was drawn from each mouse and replaced with an equal volume of a 45%-by-volume suspension of SCD RBCs, cRBCs or cell free hemoglobin in physiological saline solution (200 μM). All pressure and flow measurements were repeated and the cycle was repeated 1 more time, thereby introducing a total of 400 uL of SCD RBCs, cRBCs or cell free hemoglobin in solution. After all transfusions were performed, the animal was exposed to 5 minutes of AH (10% O_2), and then pressure and flow measurements were repeated.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Simultaneously obtained pressure and flow waveforms were analyzed using both time and frequency domain techniques as each method can relay important information about the state of the pulmonary vasculature. Metrics of PVZ were calculated in the time domain using wave intensity analysis as previously described [13]. Total PVR (Z_0) is calculated as mPAP divided by Q averaged over the cardiac cycle. The pulmonary arterial pressure waveform is separated into forward (Pf) and backward (Pb) traveling components using the linear wave separation method [14]. The index of global wave reflections (RQ) is calculated as the ratio of the amplitude of Pb to Pf. The characteristic impedance (Z_C) is calculated as the derivative of pressure with respect to the flow at 95% max flow in early systole.

In the frequency domain, P and Q are decomposed into sinusoids at harmonics of the heart rate using a Fourier transform, which expresses the data as the sum of series of sine and cosine waves. Z_0 is obtained as the magnitude of PVZ (Z) at 0 Hz; characteristic impedance (Z_C) is obtained by averaging Z from the 4th to 10th harmonics.

RESULTS

Infusion of cell free hemoglobin (Hb+) did not affect mPAP but did increase PVR and wave reflections after the 2nd infusion. These increases were maintained with exposure to acute hypoxia (AH). Hb+ with or without acute hypoxia did not affect Z_C. Infusion SCD RBCs did not affect mPAP, PVR or wave reflections until the animals were also made acutely hypoxia. As with Hb+, SCD RBCs with or without acute hypoxia did not affect Z_C. Infusion of cRBCs did not alter mPAP, PVR, wave reflections or Z_C after either infusion with or without acute hypoxia.

Table 1. Hemodynamic values: mean pulmonary artery pressure (mPAP: mmHg), pulmonary vascular impedance (Z_0) and characteristic impedance (Z_C: mmHg*min/ml), and wave reflections RQ (dimensionless).

	mPAP	Z_0	RQ	Z_C
cRBCs	13.3±1.3	1.6±0.2	0.32±0.03	0.26±0.02
2nd	12.0±2.2	1.6±0.4	0.29±0.03	0.28±0.01
AH	10.3±2.5	1.5±0.3	0.32±0.04	0.30±0.05
Hb+	13.2±1.0	1.2±0.1	0.33±0.02	0.20±0.03
2nd	13.7±1.0	1.4±0.1*	0.38±0.03*	0.24±0.03
AH	13.2±1.3	1.5±0.1*	0.44±0.04*	0.20±0.02
SCD RBCs	15.5±0.6	1.3±0.1	0.31±0.04	0.21±0.02
2nd	14.2±0.4	1.6±0.1	0.32±0.02	0.21±0.01
AH	12.2±0.7*	1.9±0.2*	0.37±0.05*	0.21±0.02

Note: values are ±SE, n=4 for cRBCs (animals injected with control RBCs), n= 5 for Hb+ and SCD RBCs (animals injected with cell free hemoglobin or SCD RBCs). *P<0.05 versus baseline, represented by cRBCs, Hb+, and SCD RBCs.

DISCUSSION

Our results confirm that infusion of cell free hemoglobin and sickled SCD RBCs alter RV afterload and further suggest that release of cell free hemoglobin, as occurs in SCD due to hemolysis of fragile RBCs, increases wave reflections. Additionally, acute hypoxia, which has previously been shown to cause hypoxemia, increases wave reflections after multiple transfusions of SCD RBCs, suggesting that decreased oxygen levels in SCD increases wave reflections. The increases in pulmonary vascular resistance with no change in mPAP can be explained by significant decreases in cardiac output. Interestingly mPAP actually significantly decreased with transfusions of SCD RBCs after exposure to acute hypoxia. Since both heart rate and systemic pressure also decreased with exposure to AH in animals with SDC RBCs, it is possible the combination hampered the ability of the left ventricle to increase CO, which ultimately decreased pulmonary artery pressure. Additionally, endothelial cells in these otherwise healthy lungs could have released NO in response to SCD RBCs and AH, which would also explain the decreased mPAP. We also note that mPAP and Z_0 were not increased by AH as might be expected due to hypoxic pulmonary vasoconstriction. Since the lungs were healthy and hematocrit was normal, we anticipate release of NO from healthy endothelial cells counteracted any vasoconstriction induced by AH.

In conclusion, our results suggest that SCD increases both steady (Z_0) and unsteady (wave reflections) components of RV afterload. Further, release of cell free hemoglobin from lysed SCD RBCs may contribute to increased risk of sudden RV failure in SCD.

A COMPUTATIONAL INVESTIGATION OF THE POSITIONING OF TRANSCATHETER AORTIC HEART VALVES TO ENHANCE LONG TERM PERFORMANCE

McGee, O. M. (1), Gunning, P. S (1), McNamara L. M. (1)

(1) Biomedical Engineering,
College of Engineering and
Informatics, NUI Galway, Ireland

INTRODUCTION

Aortic Stenosis (AS) is an age related degenerative disease of the aortic valve that causes progressive narrowing of the valve and aortic regurgitation. The current gold standard of treatment requires open heart surgery to replace the stenotic valve with a surgically implanted prosthetic valve. However, approximately 30% of the patients are refused this highly invasive surgery because of the high preoperative mortality risk [1]. Transcatheter Aortic Valve Implantation (TAVI) is a minimally invasive alternative to open heart surgery. TAV's consist of an expandable metallic frame onto which animal derived tissue leaflets are attached, and then crimped onto a catheter for minimally invasive delivery to the site of the native stenotic valve. The valve stent is positioned at the site of the native valve using radiopaque markers under fluoroscopy and then expanded radially, using a balloon or by means of self-expanding stent material.

The first generation TAVR's in clinical use were the Edwards Sapien® Valve (a balloon expanding stent) and the Medtronic CoreValve® (a self-expanding Nitinol stent) [2]. For these valves, the final deployment position of TAVR's varies changing over time depending on operator experience [3]. Incorrect positioning of TAVR's, for example a valve extending excessively into the ventricle or the aorta, can cause adverse effects such as mitral insufficiency, arrhythmias or aortic injury [4]. Precise positioning of TAV's might overcome the need for revision surgery and enhance the long term mechanical performance. Second generation TAVR's have been developed to allow for repositioning of the TAV directly after deployment (TRINITY TA, Evolut R^{TM}, Lotus$^{TM)}$. However, it remains that optimal positioning of TAVR's has not been defined.

Finite element models have been applied to model the performance of TAV's in particular to understand the role of the interaction of the valve with the native anatomy in device performance [5-7]. However such methods have not been applied to predict the role of valve positioning. In this study finite element techniques will be used to compare a first generation self- expanding laser cut stent to a second generation self-expanding braided stent with a repositionable locking mechanism. This research will derive an understanding of the role of positioning on the mechanical performance on both TAV's.

METHODS

A patient specific aortic root geometry was generated from Multi-slice computed tomography (MSCT) images of an 89 year old male with a stenosed aortic valve. The images taken pre-TAVR at peak diastole (slice thickness = 0.625 mm, slice dimensions = 512 9 512 and pixel spacing = 0.5 mm) were manually thresholded between Hounsfield units of 250 to 700 using Mimics 14.1 Imaging Software (Materialise, Leuven, Belgium) [6]. This aortic root was meshed using 43296 shell elements (S4R), with reduced integration and hourglass control, and implemented into a finite element model created in ABAQUS. Crimping and deployment of two different self-expanding Nitinol TAV stents (a braided stent and a laser cut stent) into the aortic root was modelled. The braided stent was modelled using 3 node quadratic beam elements (B32). The laser cut stent was modelled using 8 noded linear brick elements (C3D8R) with reduced integration and hourglass control. Both stents were modelled using a self-expanding superelastic Nitinol inbuilt material model (VUMAT). The aortic root was modelled as isotropic hyperelastic. Before the valve stents were deployed they were reduced radially inward by 12 mm using a rigid cylindrical surface (crimper). Boundary conditions were placed on the rigid surface to reduce the diameter. Surface-to-surface contact with a coefficient of friction of 0.1 was implemented between the crimper (master) and stent (slave). The stents were deployed annularly such that the TAVR was positioned with an equal distribution of the TAVR

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

stent above and below the annulus using surface-to-surface contact between the stent (master) and aortic root (slave) with coefficient of friction of 0.1. A final locking step was applied to the braided stent to simulate locking, which is representative of commercial repositionable TAVI devices.
This approach was also undertaken for stents positioned 5mm above the annulus (supra-annular) and 5mm below the annulus (sub-annular).

RESULTS

Laser Cut Stent:
The 99th percentile maximum von Mises stresses in the aortic tissue were taken to eliminate possibly eschewed elements. Higher stresses were observed in the supra annular and annular positions with 99th percentile maximum von Mises stresses of 0.1254 MPa and 0.1136 MPa respectively. The lowest maximum stress of 0.1056 MPa was observed at the sub annular position. The stent experienced a maximum von Mises stress of 2409 MPa (Figure 1) when deployed at the aortic annulus. The maximum von Mises stresses of 909.3MPa and 710.72MPa were predicted for stents deployed at 5mm supra and sub annular positions.
Fig. 2 shows percentage volume vs. stress graph showing the percentage stress distribution in the aortic root for the laser cut stent. The supra annular position had larger percentages of the aortic root volume experiencing high stress, whereas at the sub annular position larger percentages of the tissue volume were at a low stress (MPa).

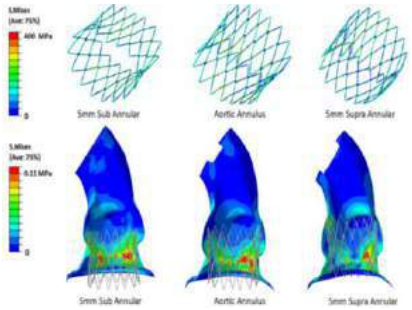

Figure 1: Contour plots of Von Mises stresses (MPa) in the aortic root and the laser cut stent in three different positions

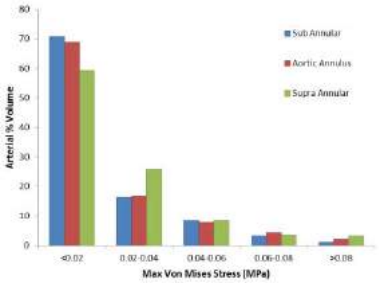

Figure 2: Percentage Volume plots of Von Mises stresses (MPa) in the aortic root deployment of laser cut stent.

Braided Stent:
Higher stresses were observed in the supra annular and sub annular positions with 99th percentile von Mises stresses of 0.8635 MPa and 0.8887 MPa respectively. The lowest stress of 0.7012 MPa was observed at the annular position. The stent experienced a maximum stress of 405.453 MPa (Figure 3) when deployed sub annularly. Stresses of 284.31 MPa and 261.29 MPa were predicted for stents deployed at the annular and 5mm supra annular positions.

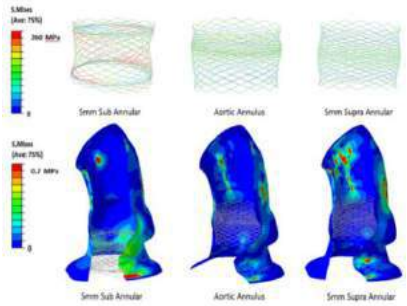

Figure 3: Contour plots of Von Mises stresses (MPa) in the aortic root and the braided stent in three different positions

Fig. 4 shows a percentage volume vs. stress graph showing the percentage stress distribution in the aortic root for the braided stent. There were larger percentages of the aortic root volume at high stress sub annularly, whereas at the sub annular and annular positions large percentages of the tissue volume were at a low stress (MPa).

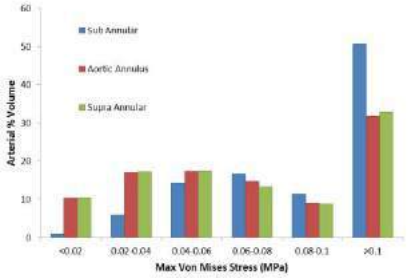

Figure 4: Percentage Volume plots of Von Mises stresses (MPa) in the aortic root after deployment of braided stent.

DISCUSSION

These results show that valve positioning influences the maximum stresses in the aortic tissue and in the valve stent. The results also suggest that the optimal position is dependent on valve design. Recommendations for the optimal positioning vary with the design of the valve [3]. However, this has never been investigated while examining the impact of stress. For the braided stent the optimal position appears to be between the aortic annulus and sub annular positions, as this is where the lowest aortic and stent stresses were seen. The maximum Von Mises stresses predicted for all three deployment positions for both the braided stent and the laser cut stent are well below the rupture stress of the aortic tissue (1.75MPa [8]). Although the lowest stresses for the braided stent were seen at the supra annular position, positioning of the valve stent too high can lead to obstruction of the coronary arteries [3]. The exclusion of the native leaflets and calcifications from the aortic root is a limitation of the study, but will be included in future work. Secondly, the laser cut stent design is not representative of any commercially available stent, but was used to develop the computational approach.

WINDKESSEL APPROACH FOR BLOOD FLOW RESPONSES: APPLICATION IN VENOUS ULCER RISK ASSESSMENT

W. Pan (1), S. Baek (1), TR. Bush (1)

(1) Mechanical Engineering
Michigan State University
East Lansing, MI, USA

INTRODUCTION

Venous ulcers, or stasis ulcers are severe skin wounds that make up 90% of all lower extremity ulcers [1]. Venous ulcers are a global problem affecting 2.5 million people in the US, 6 million in Brazil, and approximately 14 million in Europe [2], [3]. A venous ulcer is usually caused by chronic venous insufficiency which results in an inability to effectively move the blood back to the heart [1]. These ulcers are painful and can become infected and result in amputation. Therefore, it is important to understand the blood flow in the lower leg and to be able to identify populations at risk of developing venous ulcers prior to their formation.

One of the classical models for studying blood flow is the "Windkessel" method, in which the hemodynamic characteristics of cardiovascular blood flow are modeled using electrical circuit elements [4]. The blood pressure and flow are equalized with circuit voltage and current, while the vessel resistance and compliance are represented with resistors and capacitors. However, none of the Windkessel-based models have considered the effects of external loads on perfusion, nor have they addressed patient-specific parameters for the potential of risk assessment.

The goal of this study was to develop a model that represents the blood flow responses of locally-induced loading and to compare model parameters across samples of healthy individuals and those with venous ulcers.

METHODS

Experimental data were collected by performing a perfusion test among eighteen participants with venous ulcers on one or both of their legs and twenty healthy participants. In the perfusion test, external normal (perpendicular to skin) load and combined normal and shear (parallel to skin) load were applied on the lateral side of the participants' lower legs (Figure 1) [5]. Each test started with a one minute baseline (no loading); then one minute of either normal or combined loading; followed by a recovery period after the load was removed. Every leg of every participant was tested with the two different loading conditions and the skin perfusion was monitored continuously.

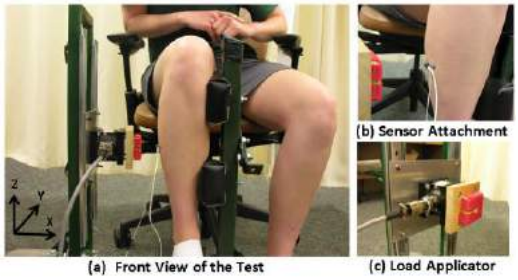

Figure 1: Leg perfusion test set up (a) front view of the test (b) perfusion sensor attachment (c) load applicator with load cell implemented

The magnitude of the load was measured with a 6 axis load cell (AMTI, USA) and the regional blood perfusion was recorded with a non-invasive Laser Doppler Perfusion sensor (Perimed, Sweden).

Meanwhile, a circuit model based on the Windkessel approach was developed. The proposed model consisted of two resistors (where R_1 represented the global vascular resistance and R_2 represented the local vascular resistance), one capacitor (C) that represented the capillary compliance and two voltage sources V_{ext} that represented the external pressure and V_0 represented the hydrostatic pressure (Fig 2). The voltage source V_{ext} was placed in series with R_2 to represent the external pressure applied locally by the loading on the participants'

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

legs. The voltage source V_0 represented the hydrostatic pressure at the testing site on the lower leg, which was determined by the pressure at the heart and the vertical distance between the heart and the test site.

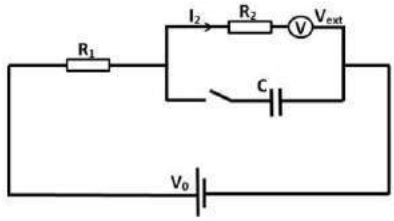

Figure 2: Model to simulate the blood flow of lower leg under normal and shear external loadings

A switch was added in series with the capacitor so that the effect of the capacitor could be controlled to be open during the reperfusion period (after load removal). This feature was designed based on the capacitor's time-history characteristic during discharging. The model was then built in Simulink (MATLAB, USA) and simulation output was brought into MATLAB for comparison with the experimental data.

During the iteration process, R_1, R_2 and C values (RCR values) were adjusted so that the model output fit the experimental data. Two individual observers performed the model iterations for all trials. The subject-specific RCR values for both observers were then analyzed statistically within each observer.

RESULTS

The legs from test participants were categorized into three groups: legs with open ulcers ("wounded"), legs without ulcers but from the same patients who had an ulcer ("non-wounded"), and legs from healthy participants ("healthy"). This categorization resulted in 20 wounded legs, 15 non-wounded legs (some participants had wounds on both legs or only on one leg) and 40 healthy legs.

Figure 3 displays an example of the comparison between the model output and experimental data for one participant. The initial spike in the plot was an experimental artifact caused by the contact of the load cell with the perfusion sensor as load was applied.

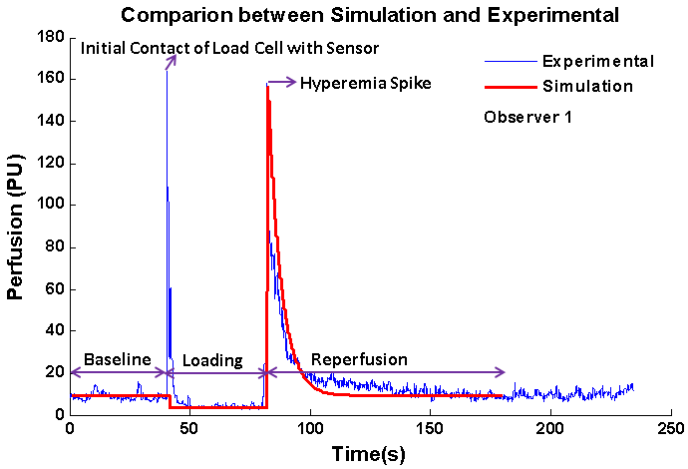

Figure 3: Comparison between model simulation output and experimental data. The experimental artifact was due to the contact of the load cell with the perfusion sensor during initiation of force application

The parameters of R_1, R_2 and C values from the model simulation are listed in Table 1.

Table 1: R_1, R_2 and C values from two individual observers that yielded model outputs representing each patient's experimental data set.

	Observer 1	Observer 2
R1		
Wounded	8.85 ± 4.56	5.02 ± 3.46
Non-Wounded	9.25 ± 4.93	6.91 ± 4.65
Healthy	9.21 ± 4.36	6.36 ± 3.93
R2		
Wounded	2.05 ± 3.21	4.97 ± 3.61
Non-Wounded	2.61 ± 3.25	4.14 ± 3.70
Healthy	3.64 ± 1.58	6.24 ± 2.59
C		
Wounded	26.76 ± 46.59	11.65 ± 27.51
Non-Wounded	6.86 ± 8.15	5.49 ± 9.70
Healthy	7.30 ± 10.30	4.28 ± 4.85

Note: Data refer to average of all subjects ± standard deviations

A one-way ANOVA showed that significant differences existed in R_2 ($p=0.0033$ for Observer 1 and $p=0.0044$ for Observer 2) and C ($p=0.00027$ for Observer 1 and $p=0.044$ for Observer 2) between the three groups. However no significant differences were found by either observer for R_1. These results indicate that the global vessel resistance did not differ between the three groups; however, the localized resistance and compliance were significantly different between wounded legs and healthy legs.

DISCUSSION

The model demonstrated its capability for replicating the blood perfusion during a loading and unloading process, as well as the reperfusion period; further we were also able to use it to identify patient-specific RCR parameters. Of particular interest is that smaller R_2 values were found for individuals with wounds, regardless of whether a wound had formed or if was on the leg without a wound. Further, the C value was much higher for those who already had a wound. This suggests that there are thresholds for these values which could be identified and used to determine when a person moves to a high risk category for wound formation. If this threshold could be established then a "just-in-time" prevention strategy could be utilized. Such a strategy would be a vast improvement from the current state, where treatment occurs *after* the wound is present. This approach would be to *prevent* the wound all together.

Future work will be to increase the sample size so that ranges of RCR values can be identified for patient sub-groups and these thresholds for the parameters can be developed to determine when a person is at high risk for developing a venous ulcer.

The modeling of skin perfusion will help us better understand the blood flow behavior pre- and post- venous ulcers, advancing our biomechanics knowledge on wound formation.

HOW MUCH ADDITIONAL MATERNAL SPATIAL CAPACITY DO FORCEPS REQUIRE WHEN DELIVERING THE FETAL HEAD DURING VAGINAL BIRTH?

INTRODUCTION

Approximately 11% of U.S. women undergo surgery for pelvic organ prolapse or fecal and urinary incontinence [1]. Injury that occurs during vaginal birth is the leading risk factor for causing these pelvic floor disorders [2]. Pelvic organ prolapse is found most often in women who sustain levator ani muscle injuries during delivery. Indeed, ~13% of women delivering vaginally for the first time sustain these injuries [3]. A (maternal) geometric capacity – (fetal head) demand model was developed to examine these issues [4]. The model was used to examine the role of four potential risk factors for levator ani muscle injury during a typical occiput-anterior vaginal delivery: the subpubic arch-angle, levator hiatus length, levator origin location on the pelvis, and fetal head size. The model allows one to estimate the degree of cephalo-levator disproportion, represented by the variable *g*, the ratio of maternal capacity divided by fetal head demand, which indicates the risk for levator injury.

During difficult vaginal deliveries when labor is obstructed, it is sometimes necessary to deliver the fetal head by attaching obstetrical forceps on either side of the head and pulling. The risk is that, even though the fetal head is delivered safely, up to 49% of forceps-assisted deliveries are associated with maternal levator muscle injuries [5]. Two hypotheses have been proposed to explain this injury: 1) the space occupied by the forceps themselves causes increased maternal levator muscle stretch, and 2) excessive traction force on the forceps and too little time to allow for levator tissue stress relaxation [5].

The purpose of this analysis was to test the first hypothesis.

METHODS

Sequential 2 mm thick MRI scans were acquired of a 50th percentile female pelvis in the axial, sagittal, and coronal planes. These images were imported into 3D Slicer (Brigham and Women's Hospital, Boston, MA, USA), and 3D models were generated using the segmentation editor tool. These models included the pelvis, the internal anal sphincter, the perineal membrane, and the puborectal and pubococcygeal portions of the levator ani muscles.

From this model, the length of the soft tissue loop that forms the maternal birth canal was determined. Maternal capacity, C_M, was then calculated as the sum of the soft tissue loop length, SL, and the arch length of the portion of the fetal head not in contact with the soft tissue loop (D_{head} = diameter of fetal head), less the portion of the soft tissue loop not in contact with the fetal head, L_{wrap} (Eqn. 1, Fig. 1). Here, maternal capacity refers to the largest diameter spherical head the pelvic floor can accommodate without injury. Soft tissue loop length reflected a 1.6x striated muscle stretch ratio prior to injury as well as 1.37x muscle fiber lengthening reported to occur during pregnancy [6].

$$C_M = SL + \pi * D_{head} * \left(\frac{180-\theta}{360}\right) - L_{wrap,left} - L_{wrap,right} \quad (1)$$

Here, we modify our previous assumption [4] that the presenting fetal head cross section is circular so that we may also include the cross-section of both forceps blades in the birth canal. The cross-section of the blades is actually rather small compared to that of the fetal head. For example, in the case of the Simpson forceps, which have open spoon-shaped steel frames, we measured the total cross-section of the blades frames to be 1.2 cm^2 compared to the 62 cm^2 of a 50 percentile male fetal head. Hence the cross-sectional area occupied by the forceps is less than 2% of that of the fetal head.

Clinically, it has been observed that use of Simpson forceps results in noticeable indentations on the sides of the fetal head

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

following delivery. So, we calculated the fetal head demand for three cases (Fig. 1). Case 1, in which no forceps are applied (the control case). Case 2, in which the forceps blades' frames have just been placed with the blades standing proud of the fetal skin surface, the maternal levator muscles is stretched across them, yet no indentation of the skin by the forceps has occurred. Case 3, in which pressure has been applied to grip the head and the forceps have fully indented the fetal head skin. We then calculated *g*, the ratio of maternal capacity divided by fetal head demand, for the three cases.

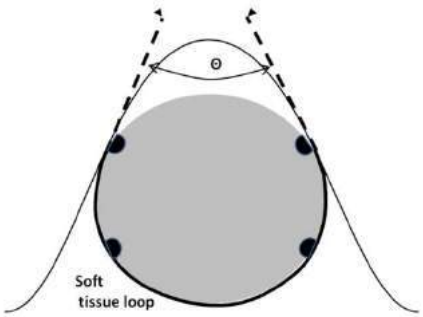

Figure 1: Caudal view of anterior pelvis with variables used in the maternal capacity calculations. The soft tissue loop originates high on the pelvis (filled arrow heads) and wraps around the fetal head (grey circular structure). The portion of the soft tissue loop in contact with the fetal head is represented by the thick black band, while the portion not in contact with the fetal head is represented by the dashed lines. Θ = subpubic arch angle. The left and right pairs of small filled black semicircular shapes represent the cross-section of the open frame spoon-shaped forceps blade fully indenting each side of the head (Case 3).

RESULTS

In Case 2, the attachment of Simpson forceps with zero indentation, resulted in increases in fetal demand of 1.7% compared to the 'no forceps' case across all combinations of fetal head circumference and maternal capacity (Case 1). However, in Case 3, when forceps fully indented the fetal head, this increase in fetal demand was reduced to 0.8 – 1.1%.

The application of Simpson forceps was sufficient to cause a decrease in the predicted value of *g (*cephalolevator disproportion) from ≥1 (no injury predicted) to <1 (injury predicted) in 2.5% of maternal-fetal pairings for the no indentation (Case 2), and 1.2% of maternal-fetal pairings for the full indentation (Case 3).

DISCUSSION

The application of Simpson forceps was found to change the predicted levator injury outcome by no more than 3% in the at-risk maternal population, a value much less than the 49% increase in the rate of levator ani injury reported when forceps are used (see Introduction). Hence, we reject the hypothesis that it is the space taken up by the forceps in the birth canal that is the primary factor that causes maternal levator injury. Instead, the alternative hypothesis, excessive traction force, would seem to be a more tenable argument [5]. Since the smallest women with the largest babies will require Caesarian (C) section, it is the smaller women with larger babies not requiring C section who are at greatest risk for forceps-related injuries.

INTRODUCTION

Conventional ultrasound techniques for evaluating left ventricular (LV) health are dependent on geometric assumptions from 2D images.[1] These assumptions often yield inaccurate measurements with large variability, especially in patients with remodeled hearts or cardiac deformities.[2] Recently, there is also a growing interest in characterizing 3D myocardial strain to study regional myocardial function, dyssynchrony, and cardiac remodeling.[3] However, to evaluate 3D myocardial strain, we need a 4D imaging technique that captures a pulsating 3D structure with high spatiotemporal resolution. The purpose of this study was to develop a cardiac and respiratory-gated volumetric (4D) ultrasound technique that can reconstruct exact 3D geometries of a mouse's LV throughout the cardiac cycle.

METHODS

Animal Preparation: We used 51.6 ± 22.3 weeks old, wild-type, C57BL/6 mice (n=5) for this experiment. The mice were anesthetized with 2-3% isoflurane and medical grade air at 1.5 L/min. We removed hair from the left ventral thorax of each mouse using a depilatory cream and secured its paws to gold-plated ECG and respiratory leads while lying supine on a heat-modulated stage. Throughout image acquisition, isoflurane levels were adjusted to maintain a stable heart rate and respiration rate.

Image Acquisition: We acquired cardiac datasets using the small animal Vevo2100 ultrasound system (FUJIFILM, VisualSonics Inc.) with a MS550D probe (40 MHz central frequency) attached to a linearly translating 3D motor. All datasets were obtained at 1000 frames-per-second using the VisualSonics ECG-gated kilohertz visualization (EKV) module, which collects a series of images taken at consecutive time points across the cardiac cycle **(Figure 1, Step 1)**. The ultrasound probe was positioned on the left ventral thorax to acquire cross-sectional cine loops of the left ventricle, and the probe was translated from the apex to the base of the left ventricle with step sizes ranging from 80 to 200 μm **(Figure 1, Step 2)**.

Data Reconstruction: Using MATLAB (MathWorks), spatially adjacent EKV cine loops were concatenated and temporally matched to reconstruct a volume representing one synchronized time-point in the cardiac cycle **(Figure 1, Step 3)**. The series of time-dependent volumetric datasets were then temporally merged to create a 4D dataset **(Figure 1, Step 4)**. Gaussian smoothing was implemented temporally and spatially to remove speckle artifacts.

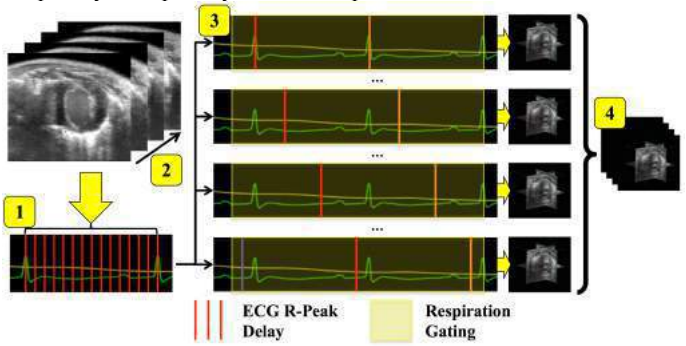

Figure 1: A schematic of the 4D imaging technique from image acquisition to volumetric rendering.

Data Analysis: The data were resampled to isotropic voxels and were exported to FSL, a functional MRI software, to nonlinearly register successive temporal volumes together.[4,5] Nonlinear transformations **(Equation 1)** were calculated in FSL using a sum-of-

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

squared, intensity-based, residuals cost function **(Equation 2)** to optimize a 3D warping field represented by cubic B-spline functions.[6]

$$\begin{bmatrix} x' \\ y' \\ z' \\ 1 \end{bmatrix} = A \begin{bmatrix} x \\ y \\ z \\ 1 \end{bmatrix} + \begin{bmatrix} d_x(x,y,z) \\ d_y(x,y,z) \\ d_z(x,y,z) \\ 0 \end{bmatrix} \quad (1)$$

$$O(w) = \sum_{i=1}^{N} \left(g\left(x_i'(x_i, w)\right) - f(x_i) \right)^2 \quad (2)$$

In **Equation 1**, $(x', y', z', 1)$ is the nonlinear transformation, A is a 4x4 transformation matrix, and $d_i(x,y,z)$ is the warping field represented by cubic B-splines. In **Equation 2**, $O(w)$ represents the optimization function, g denotes the image we want to warp to, and f denotes the reference image. Once the nonlinear transformations between successive time points have been calculated, they are applied to the manually segmented binary masks of the LV endocardial and epicardial walls to deform the masks and track their motion across the cardiac cycle. Volume quantifications of the binary masks at each time point were used to evaluate LV function **(Table 1)**.

RESULTS

The proposed ultrasound technique can be used to capture the geometries of a beating mouse left ventricle, independent of geometric assumptions. **Figure 2** and **Figure 3** demonstrate the changing left ventricular geometries during end-diastole and peak-systole in 2D and 3D, respectively. To obtain true measurements of LV lumen volumes, the papillary muscles were excluded from the quantification of chamber volumes. Although a significant decrease in end-diastolic volume (EDV) and peak-systolic volume (PSV) was observed (EDV=41±9 µL vs. PSV=13±4 µL; $p<0.01$), myocardial wall volumes remained relatively constant with a slight increase (2.5%) from 118±7 mm^3 during end-diastole to 121±14 mm^3 during peak-systole. **Table 1** summarizes the different cardiac parameters that we calculated to evaluate left ventricular function.

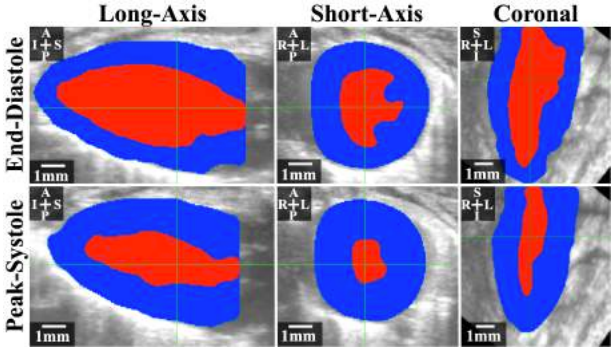

Figure 2: Three axis views of a representative mouse LV at both end-diastole and peak-systole. Masks of the LV lumen (red) and myocardial wall (blue) are shown overlaid to the ultrasound data.

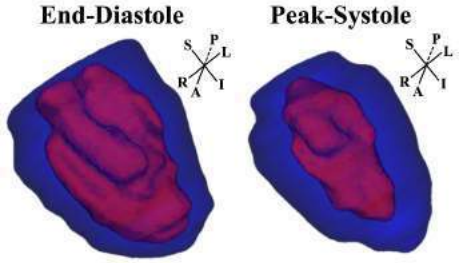

Figure 3: 3D representations of a mouse LV lumen (red) and myocardial wall (blue) at end-diastole and peak-systole (right).

Table 1: Comparisons of LV function measurements acquired from the reconstructed 4D data and those reported from literature. Data are shown as mean ± standard error.

Table 1. Evaluation of LV Function		
Parameter	**Measured**	**Literature**
EDV (µL)	41 ± 9	50 ± 8 [7]
PSV (µL)	13 ± 4	20 ± 6 [7]
SV (µL)	28 ± 7	30 ± 6 [7]
EF (%)	68 ± 6	60 ± 9 [7]
HR (bpm)	526 ± 47	331 ± 35 [7]
CO (mL/min)	14 ± 3	10 ± 2 [7]
LV mass (mg)	126 ± 12	122 ± 6 [8]
LV Mass/BW (mg/g)	3.0 ± 0.5	3.4 ± 0.1 [9]

DISCUSSION

The results of this study show that our ultrasound technique is capable of acquiring evolving 3D geometries with high temporal resolution. When applied to the LV, we can quantify its motion across the cardiac cycle and evaluate cardiac health more accurately, independent of geometrical assumptions. As seen in **Table 1**, our measured end-diastolic and peak-systolic volumes were smaller than previously reported values because we excluded the papillary muscles from the measurements of LV lumen volumes. Despite these differences, our measured stroke volumes of 28±7 µL and ejection fractions of 68±6 % were very similar to those reported in literature.[7] Furthermore, similar to results depicted in literature, the measured LV myocardial wall volume is for the most part constant throughout the cardiac cycle.[10] The slight increase (2.5%) in myocardial wall volume during peak-systole may be attributed to LV wall thickening during contraction.

The application of the proposed 4D ultrasound technique goes beyond the evaluation of cardiac function. Since we can accurately extract 3D LV geometries with high temporal resolution (1 ms), the proposed technique is capable of capturing both three-dimensional global and regional wall motion and contractility of the LV to study myocardial wall dynamics. This technique is particularly useful in studying the dynamics of diseased or remodeled hearts, as the geometric assumption that the left ventricle can be modeled as a stack of elliptical discs is often incorrect. Future work will focus on utilizing the proposed 4D ultrasound technique to study how 3D myocardial strain evolves throughout cardiac remodeling.

INTRODUCTION

Today, sent deployment is the most common treatment for symptomatic atherosclerosis. Bioresorbable stents (BRS), the latest concept in stents, are based on the premise that a stent is needed only until arterial wound healing occurs after which it would be desirable for the stent to degrade so that the arterial wall recovers its natural compliance. Deployment of a stent profoundly alters the mechanical environment in the arterial wall, and these alterations play an important role in regulating the incidence of complications such as restenosis and neointimal hyperplasia [1]. In the case of a BRS, the mechanical stresses in both the stent and the arterial wall evolve as the stent degrades. Furthermore, the hydrolysis-driven degradation of the stent can be accelerated by mechanical stresses in the stent, an additional coupling that needs to be taken into account. We are interested in determining the evolution of stresses in both the stent and the arterial wall during the stent degradation process and in elucidating the effect of these stresses on remodeling processes in the wall. To this end, we have developed a 3D finite element model of the deployment and degradation of a polylactic acid (PLA) BRS that integrates the coupling between the stent and the artery.

METHODS

A two-step model of stent deployment and degradation was developed using the commercial finite element multi-physics code COMSOL 5.1. A 3D model of a 160 µm-thick BRS with a closed-cell design is first subjected to pressure-driven deployment within an artery. The deployment is arrested when the average internal radius of the stent attains a desired value. The stent remains open after expansion due to plastic deformation. Residual stresses in the stent are computed and used as initial conditions for the degradation step. Both artery and stent are modeled as hyperelastic materials. Parameters for the incompressible artery are taken from literature. The stent is assumed to be nearly incompressible, and we model its hyperelastic behavior using a neo-Hookean strain energy density function W given by:

$$W = \mu(t).(I_1 - 3) \tag{1}$$

where µ is the shear modulus and I_1 is the first invariant of the right Cauchy-Green deformation tensor. Hydrolysis-driven stent degradation is modeled through the time evolution of mechanical properties as:

$$\mu(t) = \frac{1}{2}\mu_0 e^{-k_h t} \tag{2}$$

where $1/k_h$ is a degradation characteristic time [2,3] and μ_0 is the initial value of the shear modulus, considered to a first approximation equal to one third of the Young's modulus of PLA. Literature values for PLA Young's modulus are 3-5 GPa; however, due to computational issues in limiting the recoil of the stent post deployment, we used a value of 20 GPa. Water diffusion is considered instantaneous; thus, water concentration is uniform in the stent and hydrolysis-driven degradation is spatially homogeneous. In light of evidence that PLA mechanical properties and molar mass evolve in a similar manner [2], k_h can be deduced from the evolution of molar mass. Because mechanical loading – in this case both residual loads and loads induced by the artery – accelerate the degradation of polymers, we added load-induced degradation to the model. Thus, the overall mechanical behavior of the stent is described as:

$$\mu(t) = \frac{1}{2}\mu_0 e^{-(k_h + k_l(load)).t} \tag{3}$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

with k_l(load) a stepwise function of the load, taken as the von Mises stress within the stent. The function is assumed to evolve linearly with load up to a prescribed threshold beyond which it saturates.

The finite element model yields the evolution of stresses in the stent and the artery as well as information on the evolution of stent mechanical characteristics. In future work, the stresses in the arterial wall will be combined with a model of wall remodeling to gain insight into the biological ramifications of the altered mechanical stress field.

RESULTS

Figure 1 depicts the time evolution of the internal radius of the stent (Fig. 1a) and the average von Mises stresses in both the stent and the arterial wall (Fig. 1b) during stent degradation (t=0 denotes the end of stent deployment). As can be seen from the stent radius data (Fig. 1a), the stent undergoes rapid recoil immediately after deployment. In this simulation, the recoil is 7.9% of the maximum radius reached during deployment, comparable to reported recoil of BRS in vivo (vascular surgeons; personal communication). During the degradation phase, the stent radius decreases progressively; the decrease is ~2% of the post-recoil radius at t=100. The average von Mises stresses in the stent and in the arterial wall exhibit largely similar time evolution: they increase with deployment and reach a peak at the end of it (not shown), decrease sharply with the plastic recoil, and then decrease more slowly during degradation (Fig. 1b). Between the beginning and end of degradation, the average von Mises stresses in the present simulation are reduced by a factor of 3.7 and 4.8 for the artery and the stent, respectively, and the maximal von Mises stresses are reduced by a factor of 1.9 and 1.03. Not surprisingly, the decrease in stent radius and in the stresses within both the stent and the arterial wall are larger when the degradation is both hydrolysis- and load-driven compared to when it is solely hydrolysis-driven. The magnitude of the difference between the two scenarios naturally depends on the saturation threshold chosen for the k_l(load) function.

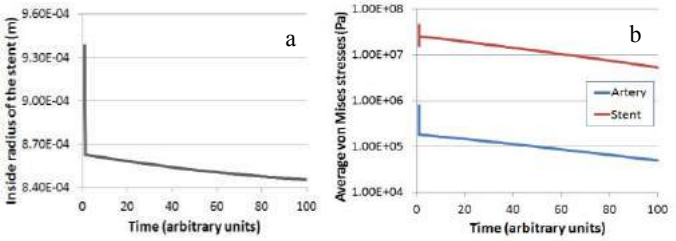

Figure 1 – Time evolution of a: the inside radius of the stent, b: the average von Mises stresses within the stent and the artery during stent degradation. Note the logarithmic scale for the stresses.

BRS degradation is modeled here as a progressive decay in stent mechanical properties driven by both polymer hydrolysis and the mechanical stresses within the polymer. The spatially heterogeneous mechanical stress field within the stent thus induces inhomogeneous degradation within the stent, as can be clearly seen in Fig. 2a which depicts the distribution of the shear modulus μ at the end of degradation (the initial shear modulus is spatially uniform and has the value μ_0). The effect of mechanical loading is most pronounced at strut intersections corresponding to the stent areas subjected to the highest stresses. A plot of the standard deviation of μ (normalized by its average value), a measure of the spatial heterogeneity of stent degradation, reveals that this heterogeneity increases until t=60 and then begins to decrease beyond that point (Fig. 2b). The areas of the stent whose μ decreases the fastest are those subjected to the highest stresses, thus leading to not only a decrease in mechanical properties but also a reduction of the stresses in those areas. Thus, a homogenization of the stresses within the stent ultimately occurs. This may explain the behavior in Fig. 2c.

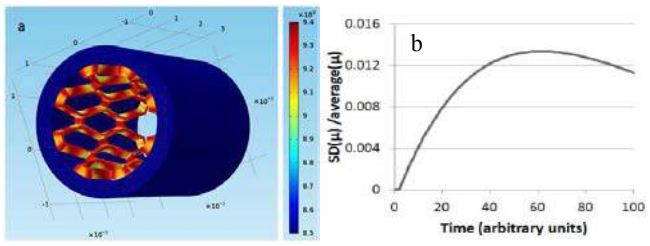

Figure 2 – contour map of the stent shear modulus μ at the end of degradation (a); standard deviation of μ normalized by μ (b)

DISCUSSION

Inserting a stent into an artery disturbs the mechanical environment within the arterial wall and can lead to pathological responses. In the case of a BRS, the stresses in the stent both due to deployment and contact with the arterial wall can accelerate stent degradation and dismantling. Understanding the coupling between stent and artery is thus fundamental to predict the behavior of the inserted device and the remodeling of the vessel. Our model enables us to follow the evolution of stresses both in the stent and the arterial wall with deployment and degradation. Previous studies modeled the deployment of a stent in an artery stenosed by an atherosclerotic plaque [1] or the evolution of mechanical properties during the deployment and degradation of the stent alone [4]. To our knowledge, the dynamic coupling of the stent and the artery during both deployment and degradation has not previously been studied. Residual stresses and artery-induced stresses in the stent lead to an inhomogeneous degradation within the device. This could be used to predict the location of the weakest points of the stent which are expected to be the first to break during stent dismantling. The present results will be combined with a model of stress-induced arterial wall remodeling in order to better understand the mechanobiological ramifications of BRS implantation.

A major limitation of the present work is that stent dismantling is not taken into account. The stent struts may certainly break before the end of the modeled degradation, thus modifying the complex interaction between stent and artery and potentially allowing positive remodeling of the vessel. Another limitation is that the model only considers a healthy artery; further studies should take into account an atherosclerotic plaque. Lastly, the degradation dynamics are very sensitive to the composition of the stent polymer. This model would benefit from more detailed experiments on the degradation dynamics of the polymeric stent to complement the behavior assumed in the present study. Incorporating such measurements into the modeling promises to allow the optimization of BRS design and properties.

SIMVASTATIN DOES NOT ADVERSELY AFFECT THE MECHANICAL AND HISTOLOGICAL PROPERTIES OF THE ACHILLES TENDON IN A DIET INDUCED HYPERCHOLESTEROLEMIA RAT MODEL

Daniel S. Choi (1), Jennica J. Tucker (1), Louis J. Soslowsky (1)

(1) McKay Orthopaedic Research Laboratory
University of Pennsylvania
Philadelphia, PA, USA

INTRODUCTION

Hypercholesterolemia affects more than 27% of adults over the age of 20 in America [1]. In addition to increasing the risk for heart disease, stroke, and peripheral artery disease, previous studies have shown hypercholesterolemia to be a risk factor for tendon ruptures in both the supraspinatus and Achilles tendons [2]. For example, elevated cholesterol levels were identified in 83% of patients with Achilles tendon ruptures [3]. Although statins are widely administered for the treatment of hypercholesterolemia, their effect on the musculoskeletal system, subjected to the systemic influence of high cholesterol, is relatively unknown. Therefore, the purpose of this study was to elucidate the effects of statins on diet-induced hypercholesterolemic rat Achilles tendons [4]. We hypothesized that statin treatment in rats with hypercholesterolemia would improve the mechanical and histological properties of their Achilles tendons.

METHODS

30 adult male age-matched Sprague-Dawley rats (400-450g) were used in this IACUC approved study. Over the course of nine months, 20 rats received a high cholesterol diet to induce hypercholesterolemia [4] and 10 rats received a standard diet. All rats had free access to food and water and underwent weekly weight measurements. After the initial six months, a subset of the high cholesterol diet rats was orally administered a daily dose of simvastatin (20mg/kg) for the final three months while maintaining a high cholesterol diet (HC+S, n=10). The remaining rats did not receive statin, but remained on their high cholesterol diets for the final three months (HC, n=10). Blood samples were taken from all rats at six and nine months to measure their levels of total cholesterol (TC), high-density lipoprotein (HDL), triglycerides (TG), and TC to HDL ratios (TC/HDL) in order to assess hypercholesterolemia. All rats were sacrificed at the end of the nine months, and their right Achilles musculotendinous units were dissected and processed for histological analysis. Prior to mechanical testing, the specimens were thawed and their left Achilles tendon-foot complexes were removed and fine dissected [5,6]. Tendons were uniaxially loaded until failure in fixtures that held the tissue in a configuration resembling physiological conditions (Figure 1). Comparisons were made between all groups for both mechanical and histological assays. Mechanical parameter comparisons were made using one-way ANOVAs with significance set at $p \leq 0.05$ and trends at $p \leq 0.1$. Post hoc t tests with Bonferroni corrections were used to determine directionality. Non-parametric Kruskal-Wallis ANOVAs with significance at $p \leq 0.05$ and trends at $p \leq 0.1$ were used for tendon histological comparisons. Post hoc Mann-Whitney *U* tests with Bonferroni corrections were used to determine directionality.

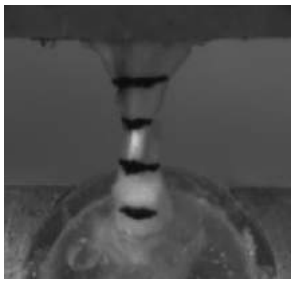

Figure 1: Rat Achilles tendon in fixtures for mechanical testing. The calcaneus is embedded in PMMA (bottom) perpendicular to the loading axis. Stain lines 1 and 2 (from the bottom up) represent the insertion region. Stain lines 2 to 4 define the mid-substance region.

RESULTS

While rats on the high cholesterol diet weighed significantly less than those on the regular diet, no differences in weight were found between the HC and HC+S groups. Serum lipid analysis found significantly elevated levels of TC, HDL, and TC/HDL with significantly decreased levels of TG in the high cholesterol groups compared to the control group at six months. At nine months, the HC+S group exhibited a trend toward decreased TC, significantly decreased HDL, and no significant differences in TG or TC/HDL ratio compared to the HC group.

Mechanical Testing: No significant differences were found in cross-sectional area (Figure 2A), maximum load (Figure 2B), maximum stress (data not shown), percent relaxation (data not shown), or elastic modulus (Figure 2D). A trend towards increased stiffness was found in the HC group when compared to the CTL group. Significantly decreased stiffness was found in the HC+S group when compared to the HC group (Figure 2C).

Histological Assays: At the insertion, there were significantly rounder cells in the HC+S group compared to the HC group with no significant changes in cellularity. At the mid-substance, a trend towards increased cellularity in the HC group compared to the CTL group was found with no significant changes in cell shape (Figure 3).

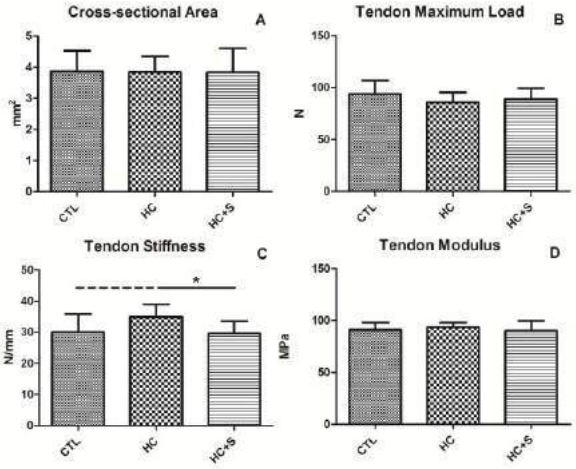

Figure 2: (A) No differences in cross-sectional area. (B) No differences in tendon maximum load. (C) Significant differences in stiffness (p=0.04). (D) No differences in tendon modulus of elasticity. Data presented as mean±SD.

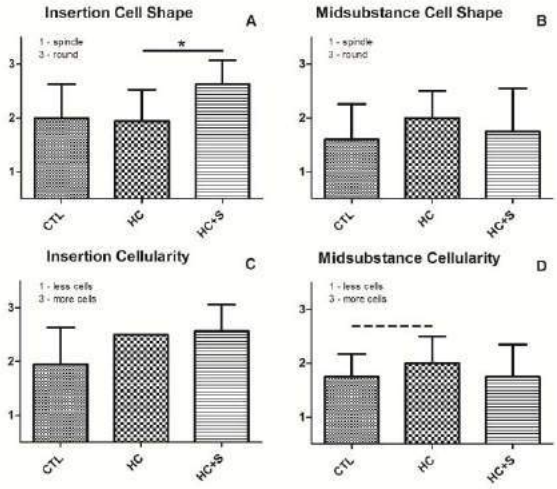

Figure 3: (A) Trend towards cell shape differences at insertion (p=0.06). (B) No differences in cell shape observed at mid-substance. (C) No differences in cellularity at insertion. (D) Trend towards cellularity differences at mid-substance (p=0.09). Data presented as median±IQR.

DISCUSSION

This study investigated the effects of statin treatment in a diet induced hypercholesterolemia model of the rat Achilles tendon. After 3 months of simvastatin treatment following a high cholesterol diet, the stiffness values of tendons in the HC+S group decreased to stiffness values similar to that of the CTL group. All other mechanical parameters were unchanged by statin treatment. From the histological assays, it appears that the statin treatment may cause a rounding of the cells in the insertion region when compared to both the CTL and HC groups. Rounding of cells could potentially be indicative of tendinopathy or chondrogenesis [7]. At the mid-substance region, a trend towards an increase in cell density was found in the HC group compared to the CTL group. The HC+S group did not have such a trend for increased cell density and had cellularity comparable to that of the CTL group which could be a result of the statin treatment. Lower cell density may be indicative of an aging tendon [8]. Previous studies have found decreased mechanical properties and higher predisposition to rupture in non-hypercholesterolemic rats treated with statins [9]. However, in general, our results suggest that statin treatment neither improves nor worsens the mechanical and histological properties of Achilles tendons in hypercholesterolemic rats. Additional studies examining tendon properties at additional time points or examining various dosages of statin treatment may help to more clearly elucidate the effects of statin on tendons present in a hypercholesterolemic environment. A limitation to the current study was the use of a diet-induced model of hypercholesterolemia, which did not take familial causes into account. In addition, the statin treatment did not have the pronounced effect of reducing cholesterol levels to the extent expected. However, the drug was administered at pharmacological doses and any evidence suggesting an adverse effect due to such treatment in either the mechanical or histological properties of the Achilles tendon was not found. While recognizing the study limitations, the results support that statin treatment may be prescribed to hypercholesterolemic individuals without major compromises to Achilles tendon health.

ON MECHANICS AND STRUCTURE OF 3D RANDOMLY CROSS-LINKED FIBROUS NETWORKS

H. Hatami-Marbini (1)

(1) Department of Mechanical & Industrial Engineering, University of Illinois at Chicago, Chicago, Illinois 60607

INTRODUCTION

A large number of biological materials, such as cytoskeleton and extracellular matrix, are composed of a randomly cross-linked fibrous solid skeleton. For instance, the cytoskeleton is a complex network of F-actin, microtubules, intermediate filaments, binding proteins, and different cross-link filaments [1]. Similarly, the extracellular matrix of soft tissues is a three-dimensional network of collagen fibers. Therefore, it is important to determine the mechanical properties of random fibrous structures and understand physical origins of their mechanics. Although random fibrous materials often appear as three-dimensional structures, a majority of previous computational studies in the field have focused on modelling them as a two-dimensional intertwined fibrous networks [2-4]. For instance, Hatami-Marbini and Picu [5] constructed 2D networks by randomly placing fibers of a given length and orientation in a square domain. They defined rigid connections at all points where the fibers cross. The fibers were assumed to have both a bending and a stretching stiffness. Using this model, they studied their mechanical behavior at different length scales and concluded that the mechanics of random fiber networks is controlled by nonaffine deformation on all length scales and their nonaffinity scales as a power law with the scale of observation. It yet remains to determine whether these conclusions hold for three-dimensional networks. The primary objective of the present study is to construct 3D random fiber networks and investigate their non-affine behavior. For this purpose, we extend our 2D strain-based non-affinity measure [5] to 3D and investigate the influence of the characteristic length scales on non-affine behavior of 3D networks.

METHODS

Different realizations of 3D fiber networks are generated by randomly placing fibers of length L_0 with random orientation in a cubic domain of linear dimension L, Figure 1.

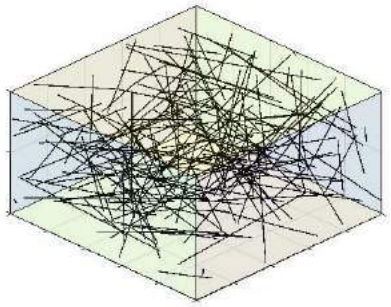

Figure 1: A typical three-dimensional random fiber network generated by depositing straight lines with random orientation in a cubic box.

Rigid connections are assumed between all fibers which are closer than a critical value. The mechanical properties of individual fibers are characterized by axial, bending, shear, and torsional stiffness. The total energy of the system is written as the sum of the strain energies caused by the deformation of all fibers. The energy of a single filament is given by

$$U_f = \frac{1}{2}\int \mu\left(dl/ds\right)^2 ds + \frac{1}{2}\int \kappa_w \left(d^2v/ds^2\right)^2 ds + \frac{1}{2}\int \kappa_v \left(d^2w/ds^2\right)^2 ds + \frac{1}{2}\int \kappa_\phi \left(d\phi/ds\right)^2 ds \quad (1)$$

where v and w are transverse displacements, ϕ is the angle of rotation, κ_w and κ_v are bending moduli, κ_ϕ is the torsional modulus, and μ is the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

stretching modulus. The above energy equation for fibers with circular cross-section gives three unique characteristic length scales: the fiber length, L_0, the mean segment length, l_c, and the square root of the ratio of bending stiffness and axial stiffness, l_b [6].

The deformation of the network subjected to a uniform strain field is found using an energy minimization procedure. Strains are computed on various probing length scales by choosing a quadruplet of network nodes such that they form approximately an equilateral tetrahedron. The displacement field u_i within a tetrahedron is written in terms of its nodal displacements using the finite element interpolation functions. The uniform strain field ε_{ij} associated with each tetrahedron is obtained from the strain-displacement relation. After calculating the three-dimensional strain field, the non-affinity measure is defined in terms of the fluctuations of the deformation gradients relative to their affine estimates, i.e.

$$h_{jk} = \left\langle \left(\varepsilon_{jk}^{\text{nonaffine}} - \varepsilon_{jk}^{\text{affine}} \right)^2 \right\rangle_l \Big/ \left(\varepsilon^{\text{applied}} \right)^2 \qquad (2)$$

In the above equation, $< >_r$ denotes the average of the quantity over all possible length scale r. The above strain-based non-affinity measure is independent of the applied far-field loading and will characterize the average of the displacement gradients over different length scales. This 3D non-affinity measure can be used to investigate the influence of the characteristic length scales on non-affine mechanical behavior of three-dimensional fibrous structures.

RESULTS

In Figure 1, different components of non-affinity measure are plotted for a network with fiber number density of 200 when subjected to uniform uniaxial tensile strain in the x_1-direction. From this plot, it is clear that all components of the non-affinity measure are non-affine and follow the similar scaling.

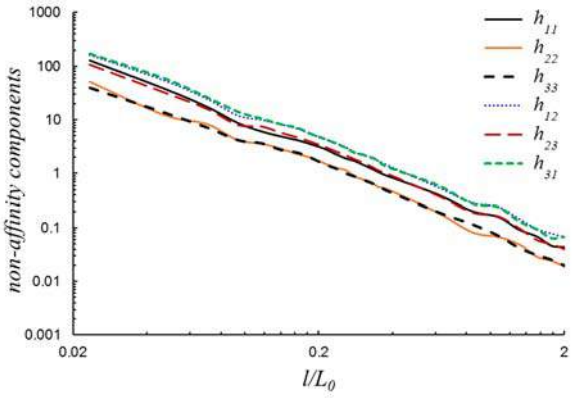

Figure 1: Components of the normalized non-affinity measure as a function of normalized probing length scale for a network with fiber number density of 200. It is seen that all components of the non-affinity measure are non-affine and follow the similar scaling

DISCUSSION

The primary objective of the present work was to develop a new non-affinity measure for characterizing the non-affinity of three-dimensional fiber networks. Previous studies on mechanics of random fiber networks are mainly focused on two-dimensional random fiber networks because 3D simulations are computationally very expensive [2-5]. In this work, we have created 3D networks by depositing random lines with arbitrary orientation in a simulation box. The solution of the system subjected to a uniform far-filed load is then obtained by minimizing the total energy of the system. A new non-affinity measure was constructed such that the mechanical response of the network can be investigated at different length scales. The proposed measure is independent of the applied far-field and has a one-to-one relation with the average (i.e. homogenized) mechanical behavior of the network. Using this measure, it was observed that all components of the non-affinity measure follows a power law scaling with probing length scale, Figure. 2. The exponent of this power-law is almost independent of the far-filed loading. The influence of fiber number density and stiffness was also investigated (results not shown). The differences between the behaviors of 2D and 3D networks were also characterized. It was concluded that although there are certain similarities in the behaviors of 2D and 3D networks, the behavior of 3D networks are more non-affine. Furthermore, the results of numerical models based on 3D fiber networks are closer to those observed in previous experimental studies [6, 7].

INTRODUCTION

Cell-free tissue engineered vascular grafts (TEVGs) that harness in-host growth and remodeling (G&R) capabilities represent an emerging technology that provides an alternate solution to the problems faced by autografts and cell-seeded TEVGs [1]. Despite the remarkable success of this technology in animal models [2], much of its development is based on a trial and error investigation which calls for a more rational design of TEVGs for accelerated development. Our in-house computational G&R tool is one such tool that is being used for numerical hypothesis testing [3] to guide rational design of bi-layered composite grafts: a porous poly-glycerol sebacate (PGS) core and electrospun polycaprolactone (PCL) outer sheath which have shown mature elastin and nerve regeneration in small animals [2].

The main requirement for successful neoartery formation is the effective interplay between PGS degradation and cell proliferation with extracellular matrix (ECM) deposition. Since it has been postulated that one of the main mechanisms of ECM deposition is through the stress driven mechanobological response of synthetic cells, accurate modeling of load transfer from the graft to cells is crucial. Currently there is little experimental data to guide even the qualitative features of the degradation models needed for such analysis.

The G&R theory models the evolving neoartery using a constrained mixture model where each of the constituents is modeled as hyperelastic [4],

$$W(s) = \Sigma W^{\alpha}(s) = \frac{\rho^{\alpha}}{\rho(s)} Q^{\alpha}(s) \widehat{W}^{\alpha} \boldsymbol{C}^{\alpha}_{n(0)}(s) + \int_0^s \frac{m^{\alpha}(\tau)}{\rho(s)} q^{\alpha}(s-\tau) \widehat{W}^{\alpha}(\boldsymbol{C}^{\alpha}_{n(\tau)}(s)) d\tau$$

where, $Q^{\alpha}(s)$ represents the survival fraction of the originally existing material. The superscript α designates the constituents (e.g. components of the evolving ECM and PGS core). In this work, we aim to characterize PGS degradation and use this data to determine an appropriate functional form of the survival function ($Q^{\alpha}(s)$) as well as the degrading strain energy function for the PGS core.

METHODS

Tubular porous PGS vascular grafts with an outer diameter of (1.708 ± 0.039 mm) and thickness of (0.289 ± 0.026 mm) were fabricated using a salt-leaching technique [2]. Since hydrolysis, which can be catalyzed by enzymes, is the main mechanism of PGS degradation, n = 7 samples each were used for hydrolytic and enzymatic degradation. Samples were immersed in 1 ml tubes containing pH 7 adjusted phosphate buffered saline (PBS) kept at 37 °C. Since esterase has been reported to be the primary enzyme responsible for polymer degradation *in-vivo* [5], cholesterol esterase (Sigma-Aldrich) with a concentration of 0.2 units/µg PGS in 1 ml PBS kept at 37 °C was used for enzymatic degradation. The media was replaced every 2 days to maintain enzyme activity. The pH of the media was controlled to be 7.4. In order to understand the degradation characteristics of porous PGS grafts, we examined weight loss and mechanical properties. Dry weight loss was measured by lyophilizing each sample post-degradation. Uniaxial mechanical testing was performed by stretching samples in the longitudinal direction while submerged in PBS. Mechanical properties are expected to be isotropic due to the nature of the manufacturing process. The samples were stretched to failure at a strain rate of 0.005 mm/s. Each sample was also scanned with a resolution of at least 4 µm, before and after degradation using micro computed tomography (Micro-CT; Bruker Corporation – SKYSCAN 1272). This was done to assess the change in porosity during degradation and the average baseline porosity was evaluated to be 75.27%. The samples were evaluated at time points of

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

1, 4, 7, 14, 21 and 28 days since previous *in-vivo* work showed complete degradation of a solid PGS core by one month [6].

RESULTS

The rate of mass loss is of fundamental importance in studying the degradation characteristics of these constructs. Fig. 1 shows the nearly linear rate of mass loss with almost 85% loss at day 21 for enzymatic degradation. This is higher than the 70% mass loss reported at day 35 for solid PGS [6] which is conjectured to be a result of the high porosity of the PGS grafts.

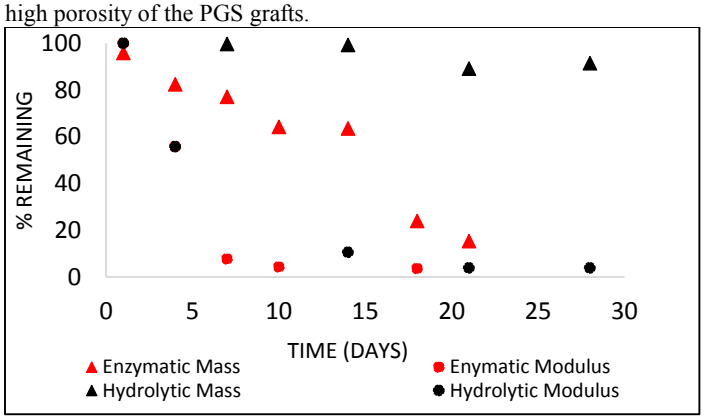

Figure 1: Percent change in mass and modulus of porous PGS in enzymatic and hydrolytic degradation.

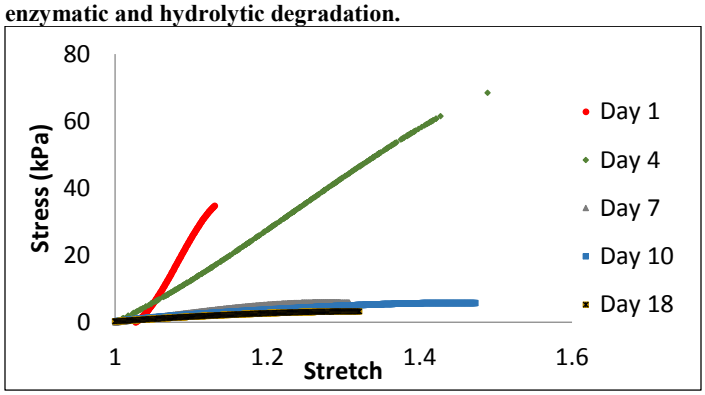

Figure 2: Stress (Piola-Kirchoff) – stretch curve for uniaxial failure test of the PGS scaffold as a function of exposure time to enzymatic degradation.

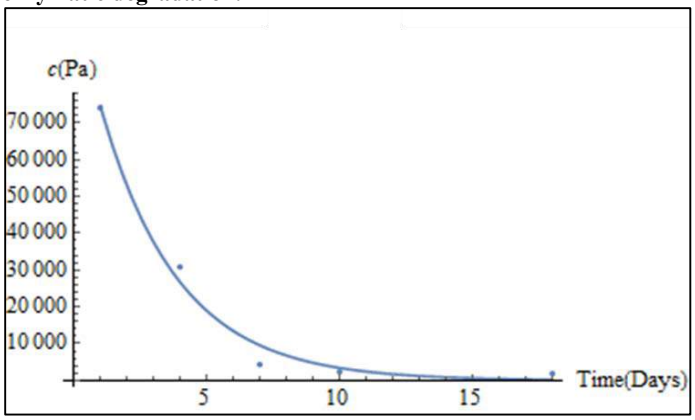

Figure 3: Damage-like function for scaling mechanical properties as a function of exposure time during enzymatic degradation. 'c' is the instantaneous material parameter in the Neo-Hookean model.

Another important functional form required for modeling degradation of the PGS core, is the time dependent mechanical response of the degrading graft. Figures 2 and 3 highlight the rapid loss in stiffness (about 40% at day 4) for both degradation mechanisms at early time points suggesting rapid transfer in load to the developing ECM and outer PCL sheath. A Neo-Hookean model [$W(t) = c(t)\,(I_1 - 3)$] was fit to the enzymatic time-varying mechanical response followed by fitting 'c(t)' as a function of exposure time to enzymatic degradation, Fig. 3. The resulting function $c(t) = C_1 e^{-C_2 t}$, where $C_1 = 212\ kPa, C_2 = 1.04\ 1/sec$ with R^2 of 0.99, represents a damage model for scaling mechanical properties as a function of exposure time.

DISCUSSION

Successful G&R elicited by porous acellular TEVGs as considered in this case rests on balance between porosity induced cell-infiltration and degradation of polymer material. Computational G&R models have proven to be sources of predictive capabilities which can aid in design of these TEVGs. However, sensitivity analysis of these models has shown that their predictive capability is highly dependent on various key parameters like half-life and time dependent mechanical behavior of the scaffold material [3].

This work provides much needed experimental data on the degradation characteristics of TEVGs and will be used to prescribe the survival function for the PGS scaffold. Various models assume a sigmoidal loss in mass [7] while Fig. 1 shows a linear loss in mass for this construct. This trend has also been observed in the *in-vivo* report for a solid block of the same material [6]. This difference in trend from sigmoidal to linear changes the functional form of the survival function and will likely affect G&R predictions. This also demonstrates the need for experimental validation of assumed functional forms used in G&R simulations. While a linear loss of mechanical properties was found during degradation of solid PGS [6], an exponential decrease was observed for our porous grafts. We conjecture this is due to the high porosity of these samples and the mechanisms driving this dependence are currently under investigation.

The current data enables development of an experiment-driven functional form of the survival function and changing mechanical properties during scaffold degradation. This data is crucial for predicting mass kinetics and changing load bearing contributions of the constituents during scaffold degradation. Hence, these findings are essential for appropriately modeling the stress-driven mechanobiological response of recruited ECM-producing cells in degrading acellular TEVGs.

CHARACTERISTIC X-RAY DIFFRACTION METHOD FOR MECHANICAL ANALYSIS OF MINERAL AND COLLAGEN PHASES IN BONE TISSUE

Masahiro Todoh (1), Shigeru Tadano (1)

INTRODUCTION

Bone is often regarded as a composite material consisting of mineral particles and organic matrix (mostly Type I collagen) on a microscopic scale [1-3]. The mechanical properties of bone tissues at a macroscopic scale depend on the structural organization and properties of constituents in the microscopic scale. Considerable attempts have been made to investigate the effect of the microscopic constituent on the mechanical properties of bone. It is the interaction between the mineral and organic material that determines the mechanical properties. However, both mechanical behaviors of mineral and collagen phases are not clear yet.

Because of non-destructive and non-invasive advantages of X-rays and predictive diffraction patterns with crystals or polymers, it has been widely applied to reveal various aspects of materials and in few approaches in the case of biological tissues like bone. In this study, to clear both mechanical behaviors of collagen matrix and apatite crystals in bone, the cortical bone samples were collect from bovine femoral diaphysis. The microscopic mechanical behaviors of both mineral particles of apatite and collagen matrix in bone tissues were observed by wide angle X-ray diffraction (WAXD) and small angle X-ray scattering (SAXS), respectively. In combination with micro-tensile device, both strains of mineral and collagen phases were measured. From those results, the mechanical effect of both components in bone tissues were discussed.

METHODS

Five cortical bone specimens with average sizes of about 10.0 (long) × 2.0 (wide) × 0.2 (thick) mm were cut out from the bovine femoral diaphysis (Age: 23 months old) , where the longer edges of specimens are aligned to the parallel and perpendicular to the bone axis. Rough cuts were done by using a band saw and fine cuts by using a low-speed diamond saw (SBT650, South Bay Technology, Inc. USA). Both ends in 3.5mm length of specimen were bonded to metal plates for fixation to the micro-tensile device by the adhesive.

In this study, the microscopic mechanical behaviors of both mineral particles of apatite and collagen matrix in bone are observed by wide angle X-ray diffraction (WAXD) caused by the lattice structure of apatite crystals and small angle X-ray scattering (SAXS) caused by the periodic structure of collagen molecules, respectively.

The Bragg's law relates the Bragg angle θ to the interplanar spacing d. The microscopic strain ε^H of mineral phase and ε^C of collagen phase can be calculated as the ratio of interplanar spacing d^H and d^C at the deformed state to $d_0{}^H$ and $d_0{}^C$ at the non-deformed state, as Eqs. (1) and (2).

$$\varepsilon^H = \frac{d^H - d_0^H}{d_0^H} = \frac{\sin\theta_0^H - \sin\theta^H}{\sin\theta^H} \quad (1)$$

$$\varepsilon^C = \frac{d^C - d_0^C}{d_0^C} = \frac{\sin\theta_0^C - \sin\theta^C}{\sin\theta^C} \quad (2)$$

where θ_0 and θ are Bragg angles of non-deformed state and deformed state, respectively. Each strain of mineral and collagen phases was calculated by

The X-ray diffraction measurements were performed by X-ray diffractometer (NANO-Viewer, Rigaku Corp., Japan). Characteristic X-ray (Cu-Kα) was generated. The diffraction images were recorded by imaging plates mounted on 81.5 mm and 622.5 mm camera length at WAXD and SAXS experiments as shown in Fig. 1. The specimens were loaded by the micro-tensile device during X-ray diffractions. This device had a load cell (LUX-B-200N-ID-P, Kyowa Electric Instruments Co., Ltd., Japan; Capacity 200 N) and uni-axial stage (TSDM40-15, Sigma Koki Co., Ltd., Japan). The specimens were loaded from 0, 25,

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

50 MPa at bone axial direction and from 0, 10, 20 N at circumferential direction, respectively. Each irradiation time was 30 min.

RESULTS

As the results of WAXD and SAXS, each diffraction image from mineral and collagen phases was recorded as shown in Fig. 2 (a) and (b), respectively. In the WAXD image, (002) and (211) diffractions were strong. In SAXS image, 3rd order diffraction from d =22.6 nm as specific periodic length of collagen molecules. SAXS image also contained a diffuse scattering perpendicular to the bone axial direction.

As the results of WAXD and SAXS with bone axial and circumferential tensile loading, the strains of mineral and collagen phases increased with macroscopic bone tissue strain as show in Fig. 3 (a) and (b), respectively. The strain of mineral and collagen phases were different in the bone axial and circumferential directions. The mineral strain for circumferential direction was 74.3% of axial direction. The collagen matrix strain for circumferential direction was 74.5% of axial direction.

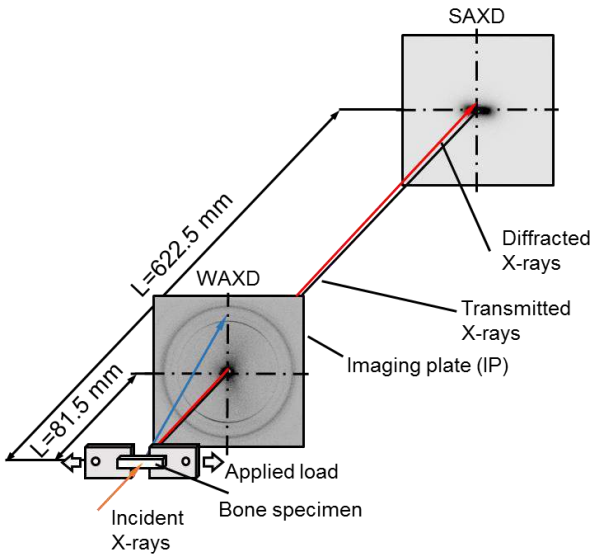

Figure 1: X-ray diffraction system for WAXD and SAXS imaging for bone specimen under tensile loading.

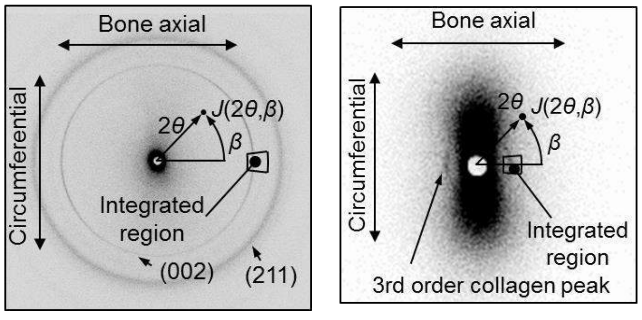

(a) WAXD image (b) SAXS image

Figure 2: X-ray diffraction images by WAXD (a) and SAXS (b) from cortical bone specimen.

DISCUSSION

The microscopic mineral strains were lower than collagen strains. This shows the collagen matrix strain allowed tensile deformation as compared with mineral phase. The strain of mineral and collagen matrix were different in the bone axial and circumferential directions. As the results of tensile tests, the elastic modulus were 11.0 and 8.2 GPa in bone axial and circumferential directions, respectively. This mechanical anisotropy may relate to the differences of microscopic responses of each constituent. In summary, this study could suggest that macroscopic mechanical properties of bone tissue depend on the degree of deformation of mineral and collagen matrix quantitatively.

ACKNOWLEDGEMENTS

The characteristic X-ray diffraction was carried out with X-ray diffractometer (NANO-Viewer, Rigaku Corp., Japan) at the OPEN FACILITY, Hokkaido University Sousei Hall.

MRI BASED CAP THICKNESS AND PEAK CAP STRESS PREDICTION: MAN VERSUS MACHINE

INTRODUCTION

A most common cause of ischemic stroke is carotid plaque rupture. A rupture prone plaque was found to be associated with intraplaque hemorrhage, expansive remodeling, and a large and soft lipid rich necrotic core (NC) covered by a thin fibrous cap [1].

From a biomechanical point of view, the cap will rupture when the stresses in the cap exceed the strength of the cap. Cap stresses can be calculated with Finite Element Analysis (FEA). In carotid arteries, Magnetic Resonance Imaging (MRI) is often used to obtain the geometric input for FEA. MRI has many advantages (e.g. high contrast, large field of view, and non-invasive), but the main drawback is that the MRI resolution is often lower than the thickness of the cap [2]. A recent study showed that median cap thickness of ruptured plaques was only 80 µm (70 – 100 µm), which is roughly six times smaller than the MRI resolution [3]. Nieuwstadt et al. showed that when the cap thickness is lower than the MRI resolution, the manual segmentation performed by a reader overestimates the cap thickness significantly, leading to a gross underestimation of the peak cap stress [2].

Instead of manual segmentation, a model could potentially help to estimate the minimum cap thickness, and thus also peak cap stress. This is especially relevant for thin caps that fall below or are close to the image resolution. The aim of this study is twofold 1) reconstruct the cap based on a model that estimates the minimum cap thickness based on geometric plaque features 2) compare the cap thickness and peak cap stress of readers and the reconstructed geometries with the ground truth to investigate if the model outperforms the reader.

METHODS

A schematic overview of the methods is given in Figure 1. Plaque material was obtained from 34 patients who underwent an endarterectomy. The plaques were sliced at 1 mm interval resulting in 76 carotid cross-sections with 148 NCs. After histological staining, lumen, vessel, and NC contours were manually delineated and these contours are considered to represent the ground truth.

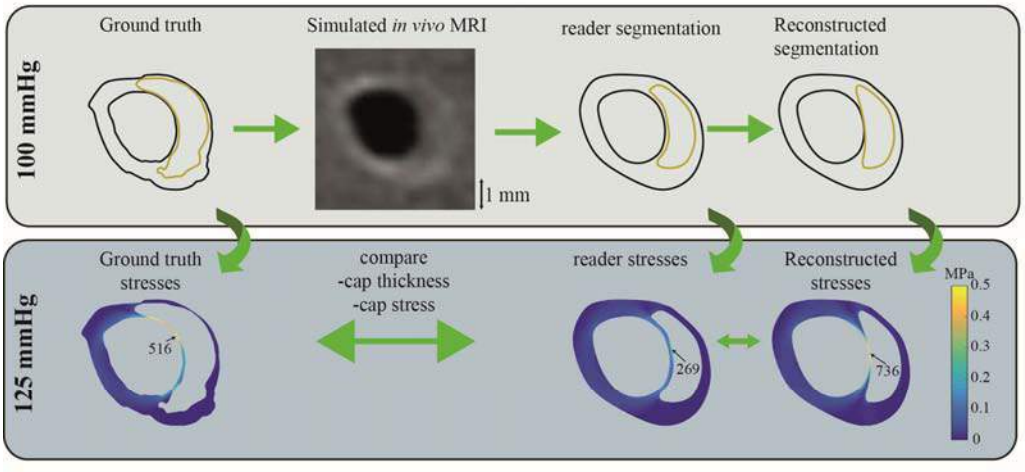

Figure 1: Schematic overview of the methods, each horizontal block represent the state of the geometric at 100 and 125 mmHg.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

In order to estimate the minimum cap thickness a Generalized Estimation Equation model (GEE) was used. The input parameters for this model were NC angle, NC thickness and the distance from lumen to the NC centroid (CentroidDistance), whereas the minimum cap thickness served as the output parameter, see Figure 2. All the listed parameters (except the NC angle) were normalized with respect to vessel wall thickness, in order to correct for plaque size. The normalized cap thickness was estimated at three positions along the NC angle, 25, 50 and 75%. In the model, we assume that the cap is symmetrical around the center of the NC angle, therefore two relationships can be derived for the normalized minimum cap thickness: one for the midcap (CT_{50}) and one for the combined sidecap (CT_{25}/CT_{75}) positions.

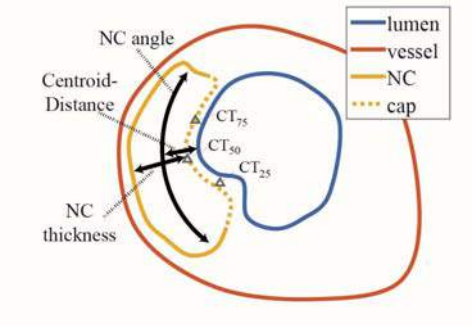

Figure 2: Schematic overview of the input parameters for the GEE model: Necrotic Core (NC) angle, Centroid Distance and NC thickness. The triangles indicate the cap thickness (CT) as estimated by the model. The dotted line represent the cap that is removed, and reconstructed bases on the model.

From a subset (33 cross-sections), containing 44 necrotic cores, the ground truth contours were then used to simulate *in vivo* MRI images with an in-plane resolution of 0.62 mm x 0.62 mm. The protocol is described in more detail by Nieuwstadt et al. [2]. Three experienced MRI readers manually delineated the simulated MRI images. Since, the manual cap contours are not reliable, caps thinner than 0.62 mm from the lumen were removed, see the dotted line in Figure 2. Subsequently, the cap was reconstructed using the CT_{50}, CT_{25} and CT_{75} and a non-uniform rational b-spline.

Abaqus (Dassault Systemes Simulia Corp., Providence, RI, USA) was used for the FEA. A Neo-Hookean, non-compressible, isotropic material model was used, with Young's moduli for the intima and lipid of 1 MPa and 6 kPa, respectively [4]. Peak cap stress was defined as the 99 percentile von Mises stress in front of the necrotic core or in the 15° shoulder region. For analysis, we divided our data into two groups 1) ground truth CT < 0.1 mm (thin caps) and 2) > 0.1 mm (thick caps). The maximum peak cap stress and (error in) peak cap stress are not normally distributed, therefore median and interquartiles were reported.

RESULTS

The GEE model estimated the CT_{50}[-] as: -0.03*NC angle [rad] - 0.35 * NC thickness[-] + 0.82 * CentroidDistance[-] (r^2=0.89 and p<0.05). Similarly, $CT_{25/75}$[-] = -0.03*NC angle[rad] - 0.28*NC thickness[-] + 0.54*CentroidDistance[-] + 0.12 (r^2 = 0.46 and p<0.05).

The minimum cap thickness of the ground truth, reader and reconstructed model geometries were 0.07 mm (0.06 – 0.11 mm), 0.23 mm (0.18 – 0.29 mm), 0.12 mm (0.03 – 0.22 mm), respectively. The cap thickness error (with respect to the ground truth) of the readers is 0.14 mm (0.08 – 0.24 mm). This error was significantly (p<0.01) reduced to 0.07 mm (0.04 – 0.13 mm), when the model was used to reconstruct the cap. For thin caps, the model predicts the minimum cap thickness better than the reader, in contrast to thick caps where the cap thickness estimation does not improve, see Figure 3.

The total peak cap stresses (n=17) of the ground truth, reader and reconstructed model geometries were 516 kPa (336 – 554 kPa), 124 kPa (104 – 269 kPa), 342 kPa (162 – 540 kPa), respectively. The error of the peak cap stress (with respect to the ground truth) for the reader and model was not significantly different (p=0.27), 136 kPa (81.0 – 247 kPa) and 183 kPa (79.3 – 322 kPa) , respectively. For thin and thick caps, no improvement in terms of peak cap stress of the model vs. the reader was observed, see Figure 3.

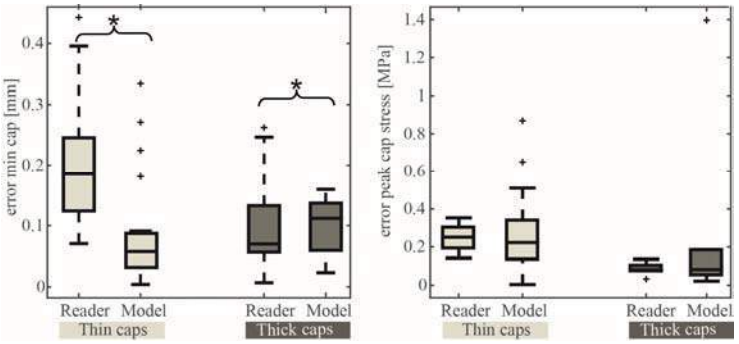

Figure 3: Boxplot of the error of minumum cap thickness (left) and the error of peak cap stresses (right) of reader vs. Model. Light grey depicts the thin caps (<0.1 mm) and dark grey the thick caps (>0.1 mm). The asterisk (*) indicates significant difference (p<0.05).

DISCUSSION

The main finding of this study is that for thin plaques caps the model estimates the minimum cap thickness better than the reader, but does not improve prediction of the peak cap stress.

The cap thickness improvement by the model shows that there is a strong relation between minimum cap thickness and geometric parameters. Although it might be intuitively clear that there might be such a relationship, this relationship was not quantified before and was not reported in the literature. Some clinical studies use cap thickness alone to estimate rupture risk of carotid plaques [3], and this model can potentially be used to improve cap thickness estimation for thin caps.

Interestingly, the minimum cap thickness improvement did not improve the peak cap stress prediction. Previous studies showed that in addition to the cap thickness, lumen curvature and necrotic core shape are important stress predictors [5-6]. In MRI segmented images not all of these features are captured, and important stress predictors might be smoothed and consequently stresses are underestimated. So caution is required when calculating peak cap stresses in the thin caps (<0.1mm) obtained with manually segmented MRI images.

A NEW APPROACH FOR ABDOMINAL AORTIC ANEURYSM LOCAL GROWTH QUANTIFICATION

INTRODUCTION

Abdominal aortic aneurysm (AAA) growth rate is a marker for rupture risk as it potentially reflects undesirable wall remodeling that leads to wall weakening. Currently, expansion rate is measured as change in maximum diameter over time. However, expansion is not uniform and is therefore questionable if measurement of maximum diameter change over time is adequate to capture an increased localized remodeling activity. Therefore, a paradigm shift is needed for a more sensitive quantification of AAA growth, which would not only identify small non-symptomatic aneurysms at high risk and prevent rupture thus saving lives, but also reduce the cost of emergency surgeries.

One of the difficulties in quantifying regional wall growth is that as the aneurysm grows it may elongate, become tortuous, and shift towards one side. Therefore, establishing correspondence of wall regions between follow up scans is not trivial. Even if the AAA is manually co-registered with its follow-up image, using landmarks such as renal arteries [1], the distance between wall surfaces obtained cannot be directly translated into regional growth.

In contrast to vascular disease follow-up studies, ongoing research in other medical fields that deal with regional growth quantification in the presence of shape alteration (e.g. cancer tumors) have exploited non-rigid registration methods. The present study aims at introducing a new, more sensitive method of AAA growth rate estimation based on regional wall surface area change. The proposed methodology is based on iterative closest point (ICP) algorithm and is validated using patient-specific AAAs and their artificially deformed follow-up models. Original and deformed surfaces were discretized into triangular surface meshes and were matched by the algorithm. A new measure of local surface growth is then computed from the distribution of element surface area change. To the best of authors' knowledge, this is the first work that exploits vascular non-rigid registration for AAA disease follow-up.

METHODS

The method is based on open source non-rigid point cloud registration code that implements ICP algorithm for bone surface registration [2]. The code has been adapted to capture smaller deformations that may be present during arterial disease follow-up, has been validated, and evaluated. Input to the code are the triangulated surfaces referred to as Source (surface to be deformed) and Target (surface to be matched by Source). The goal is to obtain a measure of local wall surface deformation based on element area change of the registered Source surface. The code is split into two distinct phases: **Phase 1:** Surfaces are prealigned and a general deformation of the Source surface is performed to best match the Target using Procrustes algorithm. **Phase 2:** Surfaces are finely matched through local non-rigid deformation: for every point p on the Source surface, the K-nearest neighbors are considered, and each neighbor influences the displacement of p based on a Gaussian radial basis centered on p acting as weight function.

To evaluate the method, three dimensional computed tomography (CT) scans of 12 aneurysmatic aortas were used. The aortic luminal and external surfaces were segmented, reconstructed and tetrahedral volumetric mesh of wall and thrombus were obtained. Wall deformation was obtained by applying a uniform pressure in ANSYS. The displacement computed at each node of the external surface was used as reference displacement. By applying a wrap-by-vector with a scale factor from 0.5 to 7 in ParaView, a range of surface deformations were obtained for each AAA model. The Source surface was co-registered with each of the multiple Target surfaces, and results were evaluated

using the following metrics:

- The Overlap coefficient was defined as the percentage of points on Source whose Euclidean distance from the Target is smaller than 1 mm.
- The local registration error (Reg_{err}) is defined as:

$$Reg_{err} = LAC_{real} - LAC_{est}.$$

where LAG: the Local Area Change of each surface element a) due to application of nodal displacements (provided by ANSYS), LAC_{real}, and b) due to registration, LAC_{est}.

- To obtain a global measure of registration error for each case, an Error Index (EI) was defined as the mean plus the standard deviation of Reg_{err}.

Mesh, Initial Distance, and Rotation Sensitivity Analysis

a) The effect of mesh density on overlap coefficient was evaluated using one of the AAA models. b) To assess the effect of initial distance distribution (after prealignment) between Source and Target surfaces on registration accuracy, a Distance Index (DI) was defined as the mean value plus the standard deviation of the distance of each node between Source and Target Surfaces. c) The stability of the method with respect to rigid body motion was assessed. Towards this the Source surface of all cases was first rotated with respect to X-, Z- and both X- and Z-axes for various angles (3º-24º) and then registered to the Target surface.

RESULTS

Mesh sensitivity analysis showed that when mesh density was above 0.75 mm^{-2}, the overlap coefficient was < 0.60, while for mesh densities ranging between 0.15 mm^{-2} and 0.75 mm^{-2} overlap was > 0.94. Furthermore, the EI did not increase with increase of angle rotation, but presented negligible discrete fluctuations.

Initial distance between Source and Target surfaces was, as expected, inversely related to registration accuracy. As distance increased, less surface elements after registration changed their area in accordance with the computed value (from ANSYS). In order to obtain an estimate of error associated with DI, 12 test cases were registered to each of their follow-ups of different Distance Index producing a database of 157 registrations. The cases were grouped per DI range (in 1 mm intervals) with 16 to 23 cases in each group, and the mean and range of EI is presented (Fig. 1).

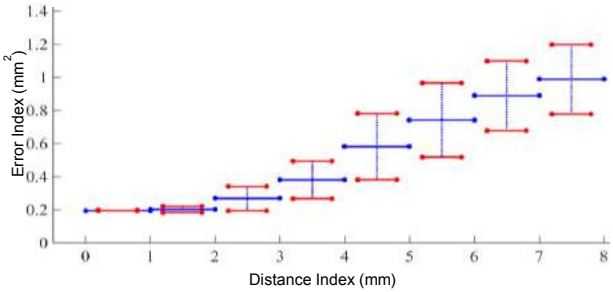

Figure 1: Effect of initial distance between surfaces to the registration error. For every 1 mm of Distance Index, the mean and range (min, max) of error index are presented.

Application on patient-specific follow-ups

The method was applied to surfaces generated from clinical follow-up CT scans of two AAA patients and results obtained are presented (Fig 2). The maximum diameter of the first AAA (Fig. 2A) increased from 35 to 45 mm in 29 months, and the maximum LAC was found at the surrounding area of maximum diameter at the anterolateral region, and equal to 5.6 ± 0.2 mm^2 (DI=1.72 mm, suggesting an EI=0.2 mm^2), or in terms of percentile growth 86.2 ± 3.6 %. The maximum distance between the initial and follow-up image (correspondence) at this location was 8.3 mm. Maximum diameter of the second AAA (Fig. 2B) increased from 50 to 52 mm in 12 months, and the maximum LAC was found at the distal end of the sac, below the region of maximum diameter, and equal to 2.8± 0.2 mm^2, or in terms of percentile growth 34.3 ± 3.6 %. The maximum distance between the initial and follow-up image (correspondance) at this location was 5.5 mm.

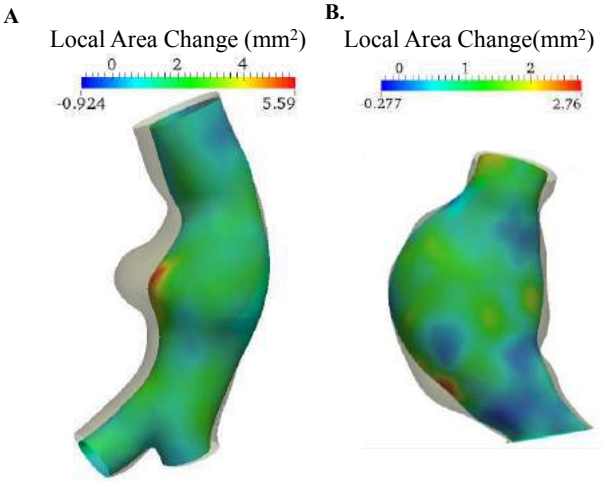

Figure 2: Application of method on two real AAA cases (A, B). Initial surface with distribution of local element area change and follow-up surface (grey, semi-transparent) shown.

DISCUSSION

We propose a methodology based on non-rigid registration in order to obtain a detailed distribution of local vascular growth. Our results suggest that the method can offer a meaningful measure for local area change of AAA wall surface, and provide a useful tool in vascular follow-up studies.

The method was applied for two real patient cases. In the first case, maximum surface growth occurred at the region of maximum diameter. In such cases, the growth rate based on maximum diameter would capture the maximum AAA growth rate. However, in the second case, the maximum surface growth did not spatially coincide with maximum diameter change. In such case the proposed methodology offers accurate growth rate estimates based on local surface deformation analysis.

In contrast to maximum diameter based growth estimation, surface area change based growth estimates cannot be clinically interpreted and evaluated as yet. Based on the two cases analyzed here 5.6 and 2.8 mm^2 surface area change correspond to local surface displacements of 8.3 and 5.5 mm respectively. It is anticipated that multicenter, large cohort clinical studies will assist in providing clinical guidelines based on both local and global surface growth values for improved rupture risk stratification.

INTRODUCTION

Modeling drug transport in tissues has recently gained much attention in the bioengineering community due its vast areas of applications [1]. Such injections often employ a positive pressure infusion directly in the target tissue. It is often referred to as convection enhanced delivery. There are several studies that addressed this problem in the literature. These studies rely on mathematical models of flow in porous media (e.g., Darcy, Brinkman) and are successful in accounting for the existence of capillaries, tissue metabolism, etc. However, these models rely on the assumption that the tissue properties (e.g. permeability) are uniform inside tumors. MicroCT imaging following nanofluid infusion often reveals highly irregular distributions due to the spatial heterogeneity of the tissue [2].

It is of clinical significance to model enhanced convection drug delivery to tissues and accounting for the uncertainty resulting from the structural randomness in the tissue. In the current study, a non-intrusive polynomial chaos (NIPC) approach [3] is used to investigate the effect of random permeability on the positive pressure infusion in a tumor. We note that in the NIPC approach, no modification is needed for the available deterministic simulation tool. This can take full advantage of the contemporary development of high-fidelity computational fluid dynamics (CFD) methods. The information collected from this study can be used to study concentration and temperature field in biological systems with uncertain permeability and porosity.

METHODS

Governing Equations Consider the two dimensional (2D) Darcy's equation in the spherical coordinate system without change in the azimuthal direction,

$$\frac{\partial}{\partial r}\left(\frac{\kappa r^2}{\mu\phi}\frac{\partial p}{\partial r}\right)+\frac{1}{sin\theta}\frac{\partial}{\partial\theta}\left(\frac{\kappa sin\theta}{\mu\phi}\frac{\partial p}{\partial\theta}\right)=0, \quad (1)$$

where p is the gauge pressure, κ is the permeability, μ is the fluid viscosity, and ϕ is the porosity. The boundary conditions are specified as follows:

$$\begin{cases} p=0, & r=R_{tumor} \\ \dfrac{dp}{dr}=\dfrac{-Q\mu\phi}{4\pi R^2\kappa}, & r=R_{needle} \end{cases}. \quad (2)$$

Eq. (1) is discretized with the 2nd order finite difference scheme, and then solved using the Gauss-Seidel iteration.

Non-Intrusive Polynomial Chaos (NIPC) Following the polynomial chaos theory, the pressure p in Eq. (1) is decomposed into separable deterministic and stochastic components as follows:

$$p(\vec{x},\vec{\xi})\approx\sum_{j=0}^{N-1}p_j(\vec{x})\,\psi_j(\vec{\xi}), \quad (3)$$

where $p_j(\vec{x})$ is the jth deterministic component associated with the jth random basis function $\psi_j(\vec{\xi})$. In the generalized polynomial chaos theory, different types of polynomials are used to provide an optimal basis for different continuous probability distribution types. For example, Hermite polynomials are adopted as basis functions for the normal distribution.

In the current study, the point collocation NIPC is adopted. Specifically, N sampling points, i.e., $\vec{\xi}$, are chosen in the random space, and the basis functions $\psi_j(\vec{\xi}), j=1,\cdots,N$, are evaluated on these points. The deterministic numerical solver for Eq. (1) is then used to generate outputs on these sampling points. Finally, the deterministic components $p_j(\vec{x}), j=1,\cdots,N$, can then be computed by solving the following linear system:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\begin{pmatrix} \psi_0(\vec{\xi}_0) & \cdots & \psi_{N-1}(\vec{\xi}_0) \\ \vdots & \ddots & \vdots \\ \psi_0(\vec{\xi}_{N-1}) & \cdots & \psi_{N-1}(\vec{\xi}_{N-1}) \end{pmatrix} \begin{pmatrix} p_0(\vec{x}) \\ \vdots \\ p_{N-1}(\vec{x}) \end{pmatrix} = \begin{pmatrix} p(\vec{x},\vec{\xi}_0) \\ \vdots \\ p(\vec{x},\vec{\xi}_{N-1}) \end{pmatrix}. \quad (4)$$

The mean of the random variable p can then be calculated as

$$E[p(\vec{x},\vec{\xi})] = \int_{\Omega} p(\vec{x},\vec{\xi}) w(\vec{\xi}) d\vec{\xi} = p_0(\vec{x}), \quad (5)$$

where $w(\vec{\xi})$ is the probability density function. The variance of the distribution can be calculated as

$$\begin{aligned} Var[p(\vec{x},\vec{\xi})] &= \int_{\Omega} \left(p(\vec{x},\vec{\xi}) - E[p(\vec{x},\vec{\xi})]\right)^2 w(\vec{\xi}) d\vec{\xi} \\ &= \sum_{j=1}^{N-1} p_j^2(\vec{x}) \int_{\Omega} \psi_j(\vec{\xi}) \psi_j(\vec{\xi}) w(\vec{\xi}) d\vec{\xi}. \end{aligned} \quad (6)$$

The permeability κ is assumed to follow a log-normal distribution, which is expressed as

$$log(\kappa) = \hat{\kappa} = \hat{\kappa}_{ave} + \xi\sigma, \quad (7)$$

where $*_{ave}$ stands for the mean value, and σ is the standard derivation. In the current study, only one stochastic variable ξ (i.e., one random dimension) is investigated.

RESULTS

The physical parameters in the simulation are tabulated in Table 1. Three types of numerical simulations, namely, those with deterministic permeability, random permeability with small variance, and random permeability with large variance are carried out on a 101×51 mesh as shown in Figure 1(a). The pressure contours for the cases with constant permeability of 0.5 md, random permeability with mean value of 0.5 md and $\sigma = 0.2\hat{\kappa}_{ave}$, and random permeability with mean value of 0.5 md and $\sigma = 2\hat{\kappa}_{ave}$ are displayed in Figure 1(b)-(d), respectively. It is clear that if the permeability is constant, the shape of the pressure contour is symmetric about the center. Large randomness in permeability can result in shape asymmetry. The distributions of the random permeability for the cases presented in Figure 1(c) and (d) are displayed in Figure 2(a) and (b), respectively. The statistic information, i.e., the mean and variance of the pressure, for the case with mean permeability of 0.5 md and $\sigma = 2\hat{\kappa}_{ave}$ from the point collocation NIPC analysis is presented in Figure 3.

Parameters	Value
Mean Tumor Permeability, κ	0.5 *md*
Tumor Porosity, ϕ	0.2
Fluid Viscosity, μ	8.9×10^{-4} Pa·s
Infusion Rate, Q	5 μL/min
Needle Diameter	0.5 mm
Tumor Diameter	10 mm

Table 1: Physical parameters in the numerical simulation.

DISCUSSION

From Figure 3 it is observed that if the permeability is a random variable with log-normal distribution, large variation of pressure will occur in the region with large pressure gradient (i.e., the region near the needle). This feature is further confirmed by the random pressure distribution as shown in Figure 1(d). From the simulation results, it is concluded that if all other physical processes are assumed perfect, large variation of the tumor permeability can result in pressure shape asymmetry. This can further induce the asymmetry in the particle concentration field as observed in Ref. [2].

INTRODUCTION

Damage to the retinal ganglion cell (RGC) axons in glaucoma is believed to initiate at the lamina cribrosa (LC) in the back of the eye (Fig 1A). The LC is a meshwork of collagenous beams thought to provide mechanical support to the RGC axons. A clinical observation in some glaucoma patients is regions of the LC (primarily at the LC-sclera interface) with missing collagen beams (Fig. 1B-C) [1]. This phenomenon is called a disinsertion. It is assumed that disinsertions weaken the LC and leave RGC axons in the region more susceptible to mechanical trauma from elevated intraocular pressure.

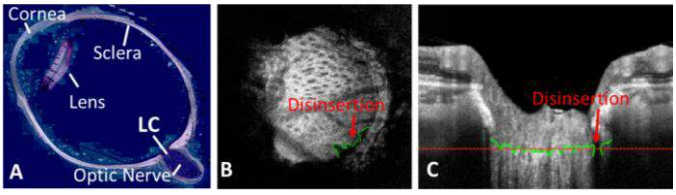

Figure 1: (A) Cross section of the eye showing the location of the LC and Optic Nerve. (B) En face OCT image of a glaucomatous human LC with a large disinsertion (C) Axial view from the same OCT scan. (B-C Adapted from [1]).

In this abstract we investigate the effects a LC disinsertion might have on the IOP induced strains experienced by the neural tissues. Since it is unfeasible to test these effects experimentally, we use a specimen-specific microstructure-based non-linear finite element model (Fig 2).

METHODS

To study the effect that the loss of LC beams has on the mechanics of the neural tissue we tested three different cases: 1) The original, unmodified structure, 2) A model of the same region, with a large disinsertion at the LC-sclera interface and 3) A model of the original region with a central LC beam removed (Fig. 3).

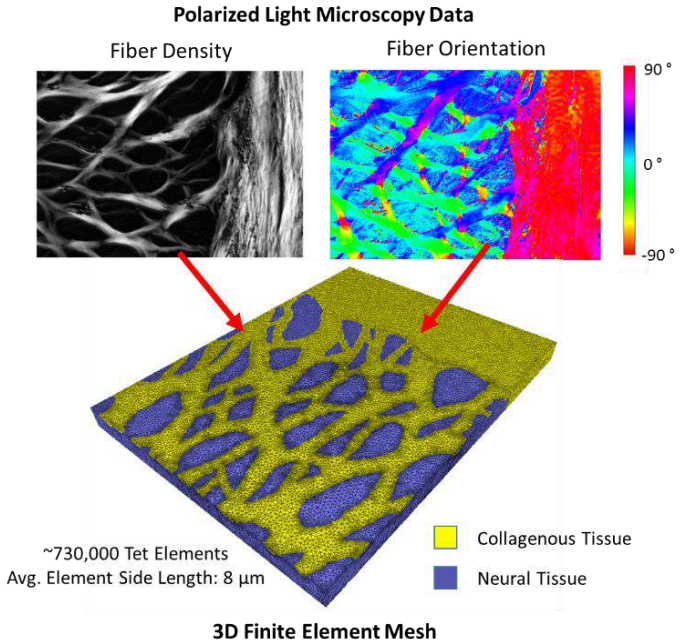

Figure 2: Polarized light microscopy data from a 30 µm thick section of sheep optic nerve head were used to generate the finite element mesh.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

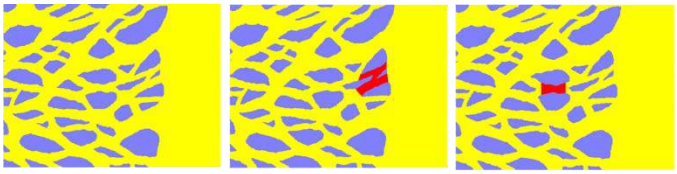

Figure 3: We used three different models to investigate the effects that the loss of laminar collagen beams might have on the neural tissues of the LC. Red regions denote the location of removed beams. Removed regions were considered to have the same material properties as the ground matrix of the neural tissue.

As pictorially described in Fig 2, the model geometry is a 3D reconstruction of a small temporal region of a section of a sheep optic nerve head. Collagen beams and scleral tissues were modeled as nearly incompressible Neo-Hookean solids with a 3D Von Mises distribution of fibers with an exponential-power law strain energy density function. The neural tissue was modeled as a compressible Mooney-Rivlin solid with a perfectly aligned distribution of fibers with an exponential-power law strain energy density function. All parameters of the constitutive formulations were based on literature values [2-3]. Mean collagen fiber orientation was calculated from the polarized light images while the orientation of fibers in the neural tissue was assumed to be along the direction of the axons (out of the plane of the image). A planar, equibiaxial load of 100 kPa (corresponding to an IOP of roughly 28 mmHg [2]) was applied. Finite element analysis was conducted using FEBio v2.3 [4]. To avoid edge effects, only central regions of the models were analyzed.

RESULTS

IOP-induced stresses and strains predicted in the original model varied greatly between the neural tissue pores and the beams, and from pore to pore (Fig 4). Average Green strains were 0.15 in the naso-temporal direction (left-right) and 0.09 in the inferior-superior direction (top-bottom) was 0.09.

A disinsertion reduced maximum strains in the pores adjacent to the removed tissue, however some nearby pores did experience a slight elevation in strain. Interestingly, the disinsertion also seemed to reduce the stresses in beams far from the disinsertion site.

A central defect substantially increased strains in the regions adjacent to the defect, but had little effect on more distant pores. The removal of the central beam reduced the stresses in some smaller beams, and slightly increased stress in the large beams running parallel to the removed beam.

DISCUSSION

Our study suggests that LC disinsertions at the LC-scleral boundary may actually be mechano-protective, reducing peak strains within the adjacent neural tissue. This surprising finding challenges the common assumption that increased collagen content must reduce tissue strain. Instead, removing peripheral LC beams transferred mechanical load to other regions of the LC, potentially protecting the RGC axons in vulnerable regions at the expense of axons in more robust regions. A central defect, however, had a different effect, causing the expected increased mechanical insult in the neural tissues. Further study is needed to determine exactly how the location, organization, and geometry of the beams influence this behavior.

Our model explicitly incorporates both detailed image-based LC beam geometries and complex non-linear material properties which previous models have not wholly accounted for [5]. As a consequence, the IOP-induced strains predicted by our model are very large and inhomogeneous compared with most previous models of the optic nerve head [5]. We have recently observed large IOP-induced strains and wide pore to pore variability in human donor eyes [6]. These findings are in agreement with our model and give us confidence in the results.

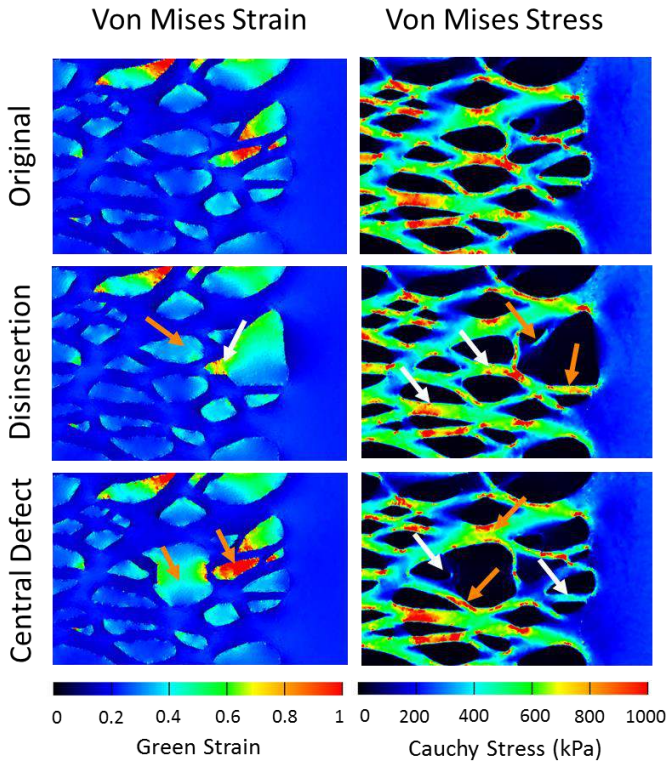

Figure 4: Von Mises strains (left column) and Von Mises stresses (right column) were calculated for each of the three cases. Orange arrows mark locations where stress or strain were increased (compared to original), while white arrows denote a decrease.

Despite this agreement, there are several limitations to this study. While the material properties we use include specimen specific fiber alignment and non-linear stress-strain behavior, they are still derived from non-sheep models [2-3]. Our model also treats the neural tissue and collagen beams as a continuum ignoring the fragile biochemical connections that exist in vivo. Lastly, due to computational expense, our model was limited to a small region of the LC and sclera. We hope to address these issues in our future work.

In summary, LC beam disinsertions may serve as a mechanism for transferring mechanical insult from an IOP-sensitive region to other less susceptible regions, thereby protecting local RGC axons.

IN SILICO AND IN VITRO MODELLING OF FLOW BEHAVIOUR IN LYMPHATIC VESSELS

INTRODUCTION

Breast cancer is the most common cancer form in women, with an estimated 1.2 million new cases worldwide each year [1]. Tumour metastasis to regional lymph nodes is a crucial step in the progression of breast cancer and approximately 90% of cancer related deaths are due to metastasis [2]. It is not yet known why some cancerous cells metastasize from the lymph nodes and others do not, therefore, a fundamental understanding of the response of cells to the forces in the lymph vessels needs to be established. Lymph contains cells that are approximately 6μm and the diameter of breast cancer cells varies from 20-40μm [3]. The dynamics by which breast cancer cells travel through the lymphatic system to distant sites, and eventually establish metastatic tumours, remains poorly understood. There is a considerable wealth of research that examines transport properties of biological cells/particles in microfluidic channels [3-5]. However, the majority of these studies examine very small particles (0.2-1μm) under typical inertial focusing flow rates (30< Re <300) and very limited data is available on the response of large particles (20-50% the channel width) to low Reynolds number Poiseuille flow such as that seen in the lymphatic vessels. Inertial focusing of biological cells/particles in channels is dependent on properties such as particle size, shape and deformability. However, when the channel height approaches the same order of magnitude as the cells, the cells are influenced by the channel walls and the assumption that the cells travel with the local fluid velocity is no longer valid. It has been shown that larger particles tend to lag the fluid velocity but the exact forces that these particles are subjected to are not yet fully understood.

Using both numerical and experimental methods, the effect of breast cancer cells within the lymph vessels and how they respond to the forces generated by the flow field is investigated in this study. Cancer cells can change morphologically in response to local flow conditions. The objective is to determine whether such cells migrate due to morphological changes imposed by the local flow environment. This paper models the fluidic transport behaviour of breast cancer cells through lymphatics by investigating both cell flow (MCF-7's and MDA-MB-231 cells) and particle flow (Microparticles GmbH and Cospheric) in a microchannel at low flow rates (by HTS / LoC standards) which are representative of *in-vivo* conditions in the collecting lymphatics. The longer term goal of this work is to expose metastatic breast cancer cells to an appropriate fluidic context, mimicking their migration through the collecting lymphatics to the sentinel nodal sites downstream of a cancerous tumour.

METHODS

Experimental Methods: Experimental methods, using micro-Particle Image Velocimetry (μPIV) techniques, have been employed to model the flow behaviour of microparticles and breast cancer cells in a polymer 100x100μm channel. Microparticles have been used to simulate the flow of various immune cells contained within the lymph. A range of separate particle sizes and cell sizes are exposed to a low Reynolds number Poiseuille flow and their response to the flow in terms of speed and spatial distribution are analysed and compared. The Reynolds number is 0.08 which is considerably lower than that used in inertial sorting devices, and the particle/cell concentration is representative of that experienced in the collecting lymph *in-vivo*.

The experimental set-up consists of a high speed CCD camera (Imager LX 2M; LaVision, Germany) connected to an inverted microscope (IX73; Olympus, Tokyo) with illumination provided by dual Nd: YAG lasers (New Wave Research, UK). The channel was placed on the stage of the microscope and the flow rate was kept constant at 0.233 μL/min using a syringe pump (Harvard Apparatus, Holliston, MA). Microparticles of diameter; 5μm, 10μm, (Microparticles GmbH, Germany) and 27-32μm (Cospheric, CA) were

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

mixed at a 0.08% wt fraction. These particle sizes and their density were chosen to correspond to the cell sizes and density seen in the lymph vessels *in vivo* [8]. The breast cancer cells were cultured in Dulbecco's Modified Eagle's medium and incubated at 37°c in 5% CO_2 until near confluence before testing.

The μPIV images were processed using the DaVis software (version 8.2.3) from LaVision. The images were evaluated using a cross-correlation method and using a multi-pass interrogation algorithm with a 50% overlap the corresponding velocity fields were obtained. In order to individually track the large particles/cells Particle Tracking Velocimetry (PTV) techniques were employed. Using a combination of μPIV and PTV techniques the disturbed flow field around large particles/cells was investigated.

Computational Methods: Numerical simulations were performed using the commercially available software Star CCM+ Version 10.06.009 (CD-adapco, NY). A three-dimensional model of the microchannel used in the experiments was created and computational fluid dynamic analysis was carried out. The Dynamic Fluid Body Interaction (DFBI) model was employed to model the motion of a cancer cell through a microchannel. The DFBI module enables the implicit unsteady solver to calculate the hydrodynamic forces and moments acting on the cancer cell and solves the governing equations of motion to find the new position of the cancer cell as it travels through the microchannel. The supercomputer facilities of the Irish Centre for High end Computing (ICHEC) were utilized to run these DFBI simulations. An overset meshing strategy was employed and a grid independence study was carried out. The mesh was refined in the area near the particle-fluid interface in order to improve the accuracy of the results whilst simultaneously providing faster computational solving times. Using the DFBI model it is possible to follow a cancer cells progression through a channel due to the applied fluidic forces generated from the lymphatic environment.

RESULTS

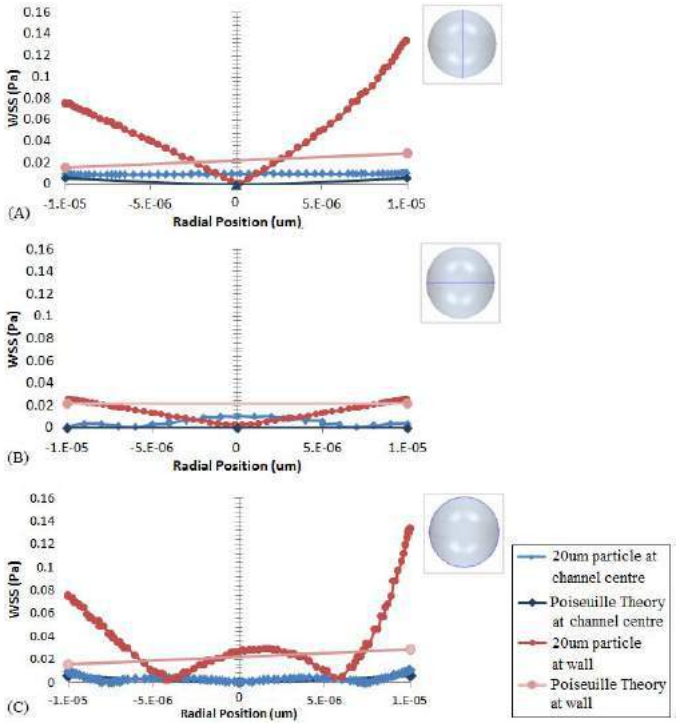

Figure 1: WSS magnitude plotted along the 20μm cell surface in the (A) YZ plane, (B) XY plane, (C) XZ plane.

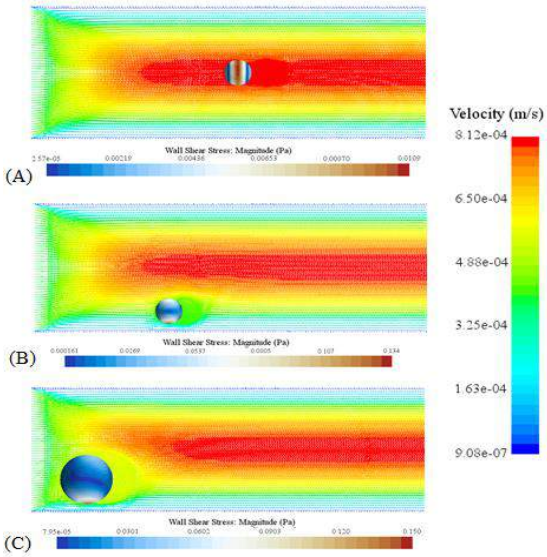

Figure 2: WSS magnitude on cell surface and the disturbed velocity plots, for both 20μm (A) + (B), and 40μm diameter cells (C), at different positions and time points in the flow.

DISCUSSION

The work carried out in this study investigates the migration behaviour of MCF-7 and MDA-MB-231 breast cancer cells to Poiseuille flow within a 100μm square channel. The objective is to determine whether such cells migrate due to morphological changes imposed by the local flow environment, and are compared to solid particles of different sizes as a reference case. The flow behaviour of the cells is largely dispersed and observations indicate that the size of the cell plays an important role in cell motility. Results indicate that cells travelling at the channel centre are subjected to a far lower, more uniform shear stress level than cells travelling close to the channel walls, where high WSS gradients can be seen, as illustrated in Fig. 1.

Figure 2 illustrates the WSS magnitude experienced by cells, of diameter 20μm and 40μm, both at the channel centre and 5μm from the channel wall. The size and position of the cell within the vessel affects the lymphatic fluidic environment to varying degrees. When the vessel height approaches the same order of magnitude as the cells, the cells are influenced by the vessel walls and the assumption that the cells travel with the local fluid velocity is no longer valid. It has been shown that larger cells tend to lag the fluid velocity but the exact forces that these cells are subjected to are not yet fully understood. Further analysis is needed to quantify this effect. Good correlation between measured and predicted velocity profiles was seen with the accuracy of the prediction decreasing with radius. Particle sizes (5-40μm) corresponding to different cell types did affect the results suggesting that cell size, relative to lymph vessel diameter, is an important factor in cell behavior in the flow. This finding could potentially have very important consequences, as it may be possible to elucidate if a particular cancer cell size exists that encourages metastasis within these vessels. Knowledge of this fact could potentially lead to improved screening/treatment methods for patients.

INTRODUCTION

The mechanics of biological fluids is an important topic in biomechanics, most notably for the study of blood flow through the cardiovascular system and related biomedical devices, cerebrospinal fluid flow, airflow through the respiratory system, biotribology by fluid film lubrication, and flow through microfluidic biomedical devices. Biological fluids are generally modeled as nearly incompressible, though compressible flow may be needed to analyze wave propagation as required for example in acoustics (airflow through vocal folds) and the analysis of ultrasound propagation for imaging blood flow.

FEBio is a free finite element software designed to meet the computational needs of the biomechanics and biophysics communities (febio.org)[3]. This study describes the formulation of a novel finite element framework for computational fluid dynamics and its implementation and verification in FEBio. Conventional computational fluid dynamics implementations typically model either isothermal incompressible flow or anisothermal compressible flow. Computational analyses of incompressible flow typically enforce the incompressibility condition using either mixed formulations (where the finite element interpolation of fluid pressure is lower order than that of the fluid velocity) or the penalty method (where the fluid pressure is proportional to the divergence of the fluid velocity via a penalty factor)[4]. These formulations suffer from ill-conditioning of the tangent (stiffness) matrix as the incompressible limit is approached[5] and require methods such as the streamline upwind Petrov-Galerkin stabilization[6] to produce reliable results. Anisothermal compressible flow analyses typically need an equation of state between pressure, density and volume and require the additional solution of the energy balance equation to solve for the spatio-temporally varying temperature.

We propose to overcome these constraints by employing a novel yet straightforward approach to analyze isothermal compressible flow using fluid dilatation (instead of fluid pressure) as an essential variable. Just like fluid velocity, dilatation is a kinematic quantity that can serve as a state variable in the formulation of functions of state (such as viscous stress and elastic pressure). Another benefit of this approach is that the dependence of density on dilatation is obtained by analytically integrating the mass balance equation, as conventionally done in finite elasticity. In effect, we propose to use a finite elasticity approach to describe the elastic compressibility of the fluid, using the dilatation as the only required component of the strain tensor. In this approach, fluid velocity and dilatation are obtained by satisfying the momentum balance equation as well as the fundamental kinematic relation between the time rate of change of the dilatation and the divergence of the velocity.

METHODS

In a spatial frame the momentum balance is $\rho\mathbf{a}=\mathrm{div}\mathbf{T}+\rho\mathbf{b}$, where ρ is the density, $\mathbf{T}$ is the Cauchy stress, $\mathbf{b}$ is the body force per mass and $\mathbf{a}$ is the acceleration, given by the material time derivative of the velocity $\mathbf{v}$ in the spatial frame, $\mathbf{a}=(\partial\mathbf{v}/\partial t)+(\mathrm{grad}\mathbf{v})\cdot\mathbf{v}$. The kinematic relation between the Jacobian of the deformation, $J=\det\mathbf{F}$ (where $\mathbf{F}$ is the deformation gradient) and the velocity is $\partial J/\partial t+\mathrm{grad}J\cdot\mathbf{v}=J\,\mathrm{div}\mathbf{v}$. The virtual work δW used in our finite element formulation is

$$\begin{aligned}\delta W = &\int_\Omega \delta\mathbf{v}\cdot\left(\mathrm{div}\mathbf{T}+\rho\left(\mathbf{b}-\mathbf{a}\right)\right)dv \\ &+\int_\Omega \delta J\left(\frac{\partial J}{\partial t}+\mathrm{grad}J\cdot\mathbf{v}-J\,\mathrm{div}\mathbf{v}\right)dv\end{aligned} \tag{1}$$

where $\delta\mathbf{v}$ is a virtual velocity and δJ is a virtual energy; Ω is the fluid domain and dv is a differential volume in Ω. From the mass balance it

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

follows that $\rho=\rho_r/J$, where ρ_r is the fluid density in the reference configuration. The Cauchy stress is split into a hydrostatic elastic pressure p and a viscous stress $\mathbf{T}^v$, $\mathbf{T}=-p\mathbf{I}+\mathbf{T}^v$, where p only depends on J, e.g., according to ideal gas law or alternatively $p=\kappa(1-J)$ where κ is the fluid bulk modulus. Typically, $\mathbf{T}^v$ describes a Newtonian fluid. This formulation was implemented into FEBio using the standard approach for linearizing δW along increments in $\mathbf{v}$ and J and discretizing the resulting nonlinear system using Newton's method.

RESULTS

We verified this implementation for a wide range of test problems, including closed form solutions for incompressible Newtonian fluids such as planar and circular Poiseuille flow, planar and circular Couette flow, Blasius boundary layer, and Womersley reciprocal flow. Results for lid-driven cavity flow (Fig. 1) compared favorably to the results of Ghia et al.[2] and others [6,7]. Flow past a backward facing step was verified against the CFD analysis of Zienkiewicz et al.[7] (Fig. 2) and validated against the experimental results of Denham and Patrick [1] (Fig. 3). Finally, we illustrate transient flow past a cylinder at Re=100, demonstrating an initial metastable state, which spontaneously breaks into eddies, eventually settling to a cyclical response producing a Karman vortex street (Fig. 4). The average drag coefficient evaluates to C_D=1.26, consistent with experimental observations.

DISCUSSION

This study describes the implementation of a computational fluid dynamics framework in FEBio. Though numerous CFD approaches have been described for incompressible flow in the prior literature[4,7], we believe that our approach, which employs the kinematic constraint between J and $\mathbf{v}$, is novel. In effect, we are able to solve isothermal compressible flows without using the energy balance, yielding the elastic pressure p based on its dependence on J. Nearly-incompressible flow is modeled by employing physically realistic values of the fluid bulk modulus. This formulation uses the same number of nodal degrees of freedom as standard $\mathbf{v}$-p formulations. This implementation extends the modeling capabilities of FEBio to allow investigations relevant to fluid flow in biological systems. It also sets the stage for the future implementation of fluid-solid interactions, which are particularly important in biomechanics.

INTRODUCTION

Cerebrospinal fluid (CSF) has several important functions in the central nervous system (CNS) and abnormal alterations in its production, absorption, and dynamics are thought to be linked with a number of CNS disorders including Alzheimer's disease [1], hydrocephalus [2], and Chiari malformation [3]. *In vivo* measurement techniques including phase contrast magnetic resonance imaging (PC MRI) and intraoperative ultrasound [4] have contributed to the understanding of CSF hydrodynamics. More recently, faster and more detailed assessment of CSF velocities has been achieved using time-resolved three directional PC-MRI sequences (4D Flow) [3]. 4D Flow has enabled the simultaneous measurement of velocities in through-plane and in-plane directions and allows for attaining higher spatio-temporal resolution compared with conventional 2D PC MRI methods within a clinically feasible time-frame. Despite these advantages, 4D Flow measurements of CSF velocities are subject to a number of potential errors and prior to further implementation of this technique, its accuracy must be evaluated. The objective of this work was therefore to assess the accuracy of 4D Flow measurements of CSF dynamics, in terms of velocity magnitude and distribution using an MRI-compatible experimental platform.

METHODS

An anatomically-detailed 3D geometry of the cervical spinal SAS was created based on manual segmentation of T2-weighted MRI images of an adult volunteer and addition of idealized dorsal and ventral spinal cord nerve rootlets [5] (Figure 1 (a)). A phantom model was constructed based on this geometry using the stereolithography technique (Viper si2 SLA system, 3D System Corp., Valencia, CA) and was implemented in an *in vitro* flow system as shown in Figure 1(b). The experimental

platform consisted a computer-controlled pulsatile syringe pump which was connected to the model thorough a custom designed oil-water interface and 7.6 meters of rigid tubing. *In vitro* 4D Flow measurements were performed on a 1.5 T MRI (Achieva, Philips Healthcare, Best, Netherlands) with in-plane and through-plane resolutions of 1.0 and 1.5 mm, respectively. The encoding velocity (V_{ENC}) was set to 15 cm/s and the flow cycle was temporally encoded in 16 phases, corresponding to an acquired temporal resolution of 52 ms. GTFlow software (Gyrotools Ltd., Zurich, Switzerland) was used for the post-processing of 4D Flow data. Computational fluid dynamic (CFD) simulation of CSF flow was carried out based on the same composite geometry and flow boundary conditions using ANSYS FLUENT (ANSYS Inc., Canonsburg, PA) and its results were spatially averaged to match the resolution of 4D Flow measurements (Figure 1(d)). CSF velocities obtained from *in vitro* measurements and CFD were compared in terms of peak values, distribution, and pixel-by-pixel correlation.

RESULTS

Good agreement was observed between CFD and *in vitro* 4D Flow, in terms of spatial distribution and peak magnitude of through-plane velocities with an average difference of 7.5% and 10.6% for peak systolic and diastolic velocities, respectively. Both methods showed anterior dominance of the CSF flow in the axial planes near the cranial end of the geometry (C1) and also regions of elevated flow between nerve rootlets. The discrepancies in velocity magnitude were more pronounced near the nerve rootlets and the edges of the axial planes (red arrows in Figure 2(a)). Pixel-by-pixel comparison of through-plane velocities using linear regression analysis revealed a good correlation between CFD and 4D Flow measurements ($r>0.75$) at most axial planes and timeframes (Figure 2 (b)). Weaker correlation between CFD and 4D Flow were observed at the timeframes corresponding to near zero CSF flow rate and near the cranial end of the geometry, where velocities were smaller due to the larger cross-sectional areas. Much larger discrepancies of in-plane velocities were observed between CFD and 4D Flow compared to those of through-plane velocities. The maximum values of mean correlation coefficients averaged over all axial planes and all timeframes were 0.52±0.19 and 0.50±0.10, respectively for in-plane velocities.

DISCUSSION AND CONCLUSION

The developed experimental platform provided a controlled flow environment, suitable for the assessment of 4D Flow accuracy in measuring CSF velocities. The findings of this study showed a good qualitative and quantitative agreement between *in vitro* 4D Flow measurements and numerical simulation, in terms of through-plane velocities, reflecting the good accuracy of 4D Flow for through-plane velocity quantification. As such, our results support that the previously reported large discrepancies between *in vivo* 4D Flow measurements and CFD [6] were likely due to the modeling simplification of the numerical models and not 4D Flow measurement error. The lower accuracy of 4D Flow in measuring low-magnitude thorough-plane and in-plane velocities is possibly due to the lower signal-to-noise ratio in the low velocity flow regions caused by the high V_{ENC} parameter utilized in the 4D Flow sequence. Improvement of 4D Flow sequences through acquisition of lower V_{ENC} for in-plane velocities or multiple V_{ENC} acquisitions should be performed prior to further consideration of this technique for quantification of low through-plane velocities or secondary flow components.

INTRODUCTION

Abdominal aortic aneurysms (AAA) are characterized by the dilatation of the abdominal aorta by more than half of its original diameter. The pathogenesis of AAAs is mainly based on the evolution of the mechanobiology of the aortic wall caused by variation in its composition due to proteolytic degradation. Being the 13th leading cause of death in the United States and given the asymptomatic nature of the disease, AAAs have a mortality rate of about 90%. Current methods of clinical treatment of AAAs include Endovascular Repair (EVAR) and open abdominal surgery. Few clinical trials have tested the effects of non-specific drugs on AAA growth. The objective of this study was to evaluate the effects of Penta-galloyl glucose (PGG), an elastin and collagen-binding polyphenol, on the growth of murine AAA. The biomechanical evolution of the AAA was studied by evaluating the peak von Mises stress and the biological evolution of AAA was studied by evaluating the MMP-9 activity, which indicates inflammation and degradation of the extracellular matrix.

METHODS

2.1 Animal study

In this study, six Sprague-Dawley rats were used. μMR images and in-vivo molecular images of the rats' abdominal aorta were acquired initially. The rats were divided into control and treated groups. A survival surgery was performed on all subjects, during which aneurysm formation was induced using a calcium chloride ($CaCl_2$) model. A gauze, soaked in 0.5M $CaCl_2$, was applied in the suprarenal location. PGG at body temperature (37 °C) was applied peri-adventitially to the treatment group before the application of 0.5 M $CaCl_2$. During the first follow-up phase, IVIS *in vivo* imaging was done on all the rats after injecting a probe (MMPSense 750 FAST) in the tail vein. MMPSense 750 FAST is an MMP activatable agent that is optically silent upon injection but fluoresces on cleavage by disease-related MMPs. During the second follow-up phase, μMRI was used again to acquire images of the abdominal aorta. *In vivo* imaging was also repeated and fluorescent maps of MMP activity were generated. All the rats were sacrificed and the aortas were harvested for further testing. The thoracic, abdominal aortic and aneurysmal tissues were cut into 25mm^2 square specimens and were then tested using the Cellscale planar biaxial tensile tester.

2.2 Material model parameters

Force-displacement data obtained from the biaxial tests was analyzed to obtain the stress-strain curves for each rat in the thoracic, abdominal and aneurysmal regions of the aorta. The least squares error between experimentally calculated Cauchy stress and its theoretically evaluated value was minimized using a genetic algorithm. The Levenberg-Marquardt algorithm was used to evaluate the Fung material model parameters that define the strain energy density (SED) function as follows:

$$\Psi = \frac{c}{2}(e^{Q} - 1), \tag{1}$$

where $Q = c_2 {E_{\theta\theta}}^2 + c_3 {E_{zz}}^2 + 2 * c_5 E_{\theta\theta} E_{zz} + 2 * c_8 {E_{\theta z}}^2$.

Convexity of the SED function was imposed as a constraint in the optimization procedure according to $c > 0$; $c_2, c_3 > 0$; $c_2 * c_3 > {c_5}^2$. The parameter c_8 was evaluated using the equivalence of the spatial elasticity tensor and stiffness matrix for orthotropic materials, as described in [1]. Thus, $c_8 = \frac{2G_{12}}{c}$. The shear modulus for the rat aorta was obtained from [2] as G_{12}= 137 kPa. These parameters were used to plot the individual Cauchy stress-Green Lagrangian strain plots. The pointwise averaged curve was then obtained for each region of the aorta, from which the corresponding Fung model parameters were

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

evaluated. The average parameter values for each region are presented in Table 1.

Table 1: Fung material model parameters by region (TA: thoracic aorta; AAA: aneurysmal abdominal aorta; AA: abdominal aorta).

Location	c (kPa)	c_2 (kPa)	c_3 (kPa)	c_5 (kPa)
TA (by pointwise average)	299.5	0.5091	0.3502	0.0374

AAA (by c-wise average)	45.37	2.867	1.643	0.7817
AAA (by c-wise average without outliers)	45.37	2.867	1.643	0.7817
AA (by pointwise average)	11.49	2.799	2.454	0.5066
AA (by c-wise average)	38.65	2.118	1.471	0.7897
AA (by c-wise average without outliers)	20.59	2.118	1.471	0.7897

2.3 Biomechanical image analysis

The μMR images of the rats were segmented using in-house segmentation and geometry quantification code (AAAVASC). The contours generated from the segmentation were used to create an STL file of the outer wall by lofting the surface on them using Solidworks. The STL geometry was then smoothened locally and an inner offset surface was created using 3-Matic. The geometry was then imported into ANSYS ICEM, where the finite element mesh was generated and later input into FEBio, an open-source FEA solver, as shown in Fig. 1. The material parameters obtained from biaxial tensile testing were used to evaluate the Young's modulus and shear moduli. The boundaries were fixed and an internal pressure of 120 mmHg was applied to the endoluminal surface. The von Mises stress was quantified using Postview. The same procedure was repeated to evaluate the evolution of wall stress with time and with the growth of AAA.

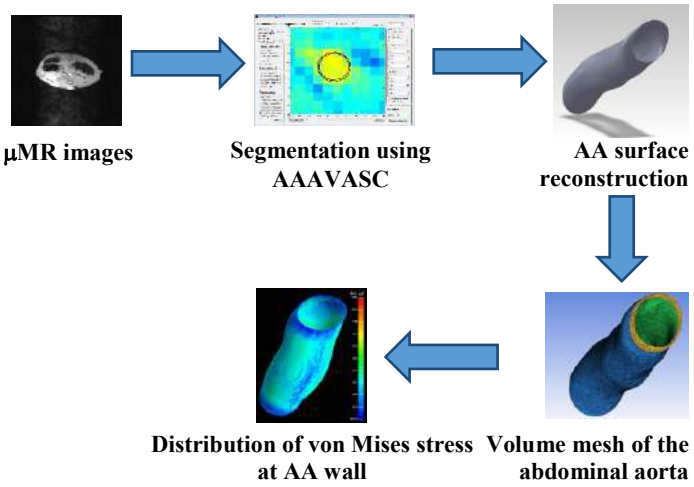

Figure 1: Flowchart for evaluation of stress distribution from μMRI images of the rat aorta.

RESULTS

The distribution of von Mises stress on the wall of exemplary abdominal aortas is presented in Fig. 2. The peak von Mises stresses are 800 kPa for the control (prior to AAA induction surgery), 1.88 MPa for the control (post AAA induction surgery), 904 kPa for the PGG-treated AA (prior to AAA induction surgery), and 1.47 MPa for the PGG-treated AA (post AAA induction surgery). The images from the IVIS microscope after injection of the probe are shown in Fig. 3. The fluorescence intensity map represents the distribution of MMP activity and matrix degradation.

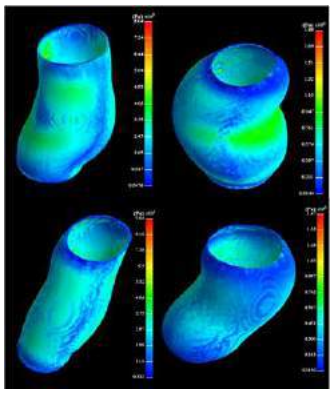

Figure 2: Distribution of von Mises stress (Pa) on the wall of a control (top) and PGG-treated (bottom) abdominal aorta pre- (left) and post- (right) AAA induction surgery.

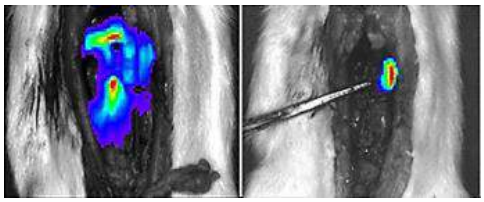

Figure 3: MMPSense Fluorescence intensity map obtained from IVIS images for control (left) and PGG-treated (right) rats.

DISCUSSION

The percentage increases in peak von Mises stress in the control and PGG-treated rats are 134% and 63%, respectively, between pre- and post-AAA induction procedures. Previous studies established that PGG binds specifically to arterial elastin and, in doing so, preserves elastic laminar integrity and architecture. However, this conclusion was based on a low percentage increase in maximum diameter in PGG-treated rats [3]. While the same observation holds true in this study, we also noticed a small percentage increase in peak von Mises stress in PGG-treated rats compared to controls, thus implying potential AAA stabilization. Antibiotics, statins and beta-blockers have been used in clinical trials, but there is limited evidence of their stabilization effects. The limitation of this study, however, is the small sample size of animal subjects. Future studies should focus on the effect of geometry and material parameters on the wall stress.

A 3-D MODEL OF BREAST TUMOR - ENDOTHELIAL CELL INTERACTIONS

Swathi Swaminathan (1), Olivia Ngo (2), Alisa Morss Clyne (1,2)

(1) Mechanical Engineering and Mechanics, Drexel University Philadelphia, PA, USA

(2) School of Biomedical Engineering, Science, and Health Systems, Drexel University Philadelphia, PA, USA

INTRODUCTION

Tumor vasculature is tortuous and hyperpermeable, with increased angiogenesis and inflammation.[1] Blood vessels lined with endothelial cells orchestrate a number of biological processes, most importantly providing the tumor with essential nutrients and oxygen for rapid growth.[2, 3] In the last few decades, the predominant theory has been that tumor progression can be slowed by inhibiting regional angiogenesis and thereby depriving the tumor of essential oxygen and nutrients.[4, 5] However, recent research has shown that increasing blood flow in vivo in the tumor microenvironment through exercise may impede tumor growth and salvage tumor dormancy.[6, 7] Studies have shown that increasing blood flow in tumor vessels reduces abnormalities in microvascular function by normalizing the local angiogenesis and endothelial cell proliferation as well as down-regulating inflammatory processes.[8] It is thus important to understand how blood flow through endothelial cells influence the proliferation of the breast tumors. [9-11]

We hypothesize that increased blood flow to the breast tumor microvasculature normalizes vascular structure and endothelial cell barrier function, which in turn inhibits breast tumor growth. As an initial step in examining this hypothesis, we created a 3D model of endothelial tube – breast spheroid interactions. This was accomplished by allowing the breast cancer cells to form spheroids and the endothelial cells to form tubes on an extra-cellular matrix (ECM). Then, the endothelial tubes were co-cultured with the spheroids.

METHODS

Cell culture

The breast cancer cell line MCF-10A was a generous gift from Dr. Mauricio Reginato (Drexel College of Medicine). MCF10A cells were maintained in DMEM/F12 50/50, 5% horse serum, 20 ng/ml epidermal growth factor (EGF), 500 ng/ml hydrocortisone, 10 ng/ml cholera toxin, 10 μg/ml bovine insulin and 1% penicillin-streptomycin. 3D medium was based on the same recipe without the EGF. Human umbilical vein endothelial cells (HUVEC, Cell Applications) were maintained in EBM-2 (Endothelial Basal Medium) supplemented with 10% fetal bovine serum and EGM-2 Bulletkit. HUVEC medium was changed every two days and cells were used up to passage 12.

3D Breast Cancer Spheroid Formation

60 μL Matrigel (growth factor reduced, Corning) was added to each well of a Falcon 8 chamber polystyrene vessel affixed to a tissue culture treated glass slide and incubated at 37°C for 15-20 minutes to solidify the Matrigel. MCF-10A cells were resuspended in 3D medium with 20% Matrigel and 10 μg/ml EGF at 10,000 cells/ml. 400-450μl of this mixture was added to each chamber well. Medium was replaced every 4 days for the 10-12 days required to obtain hollow spheroids.

Endothelial Tube Formation

Matrigel was prepared as for the MCF-10A cells. 5-10,000 HUVEC were added to each well in EBM-2 (serum and supplements free). Cells were allowed to form tubes overnight (~15 hours).

Co-culturing Spheroids on Endothelial Tubes

Spheroids in 3D medium were carefully pipetted out of their wells and added on to the HUVEC tubes. The co-culture was maintained in 3D medium containing 20% Matrigel and EGF (10 μg/ml) and the interaction between the spheroids and endothelial tubes was observed.

Co-culture Confocal Microscopy

Mono- and co-cultures were fixed with 4% paraformaldehyde, blocked in 10% goat serum + 1:100 F(ab)2 fragment, and then incubated with primary antibodies (1:100) overnight at 4°C. After thorough washing, samples were incubated with secondary antibodies (1:200) for 1 hour in the dark. See Table 1 for primary and secondary antibodies Wells were detached from the slides and sealed with PBS-Glycine and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

coverslips. The labelled samples were then imaged using an Olympus FV1000 confocal microscope.

Table 1: Table of Primary and Secondary Abs

LABELLING COMPONENT	PRIMARY AB	SECONDARY AB
Integrin α6 (MCF-10A)	Rat Hu mab CD 49f	Anti- rat Alexa fluor 488
Nuclei (MCF-10A and HUVEC)	N/A	Hoechst
PECAM (HUVEC)	PECAM1 mouse polyclonal	Anti-mouse Alexa Fluor 647

RESULTS

MCF10A cells cultured on matrigel in the 3D medium gave rise to spheroids after 5-6 days. When the spheroids were allowed to grow for 8-10 days, they underwent a series of morphological changes that resulted in acini-like spheroids with a hollow center, similar to the glandular epithelium *in vivo* (Figure 1a.) After overnight incubation on Matrigel, HUVECs formed capillary–like architectures (Figure 1b). After 24 hours of MCF-10A spheroid and HUVEC tube co-culture, most of the spheroids were observed to be associated with HUVEC tubes as indicated by phase contrast and confocal microscopy (Figure 1c). Co-culture phase contrast images after 48 and 72 hours showed the spheroids seeming to merge with some endothelial tubes, although some tubes remained visible under the spheroid layer (Figure 1d).

DISCUSSION

In this study, we showed that endothelial cells, when grown into tube-like structures, can be co-cultured effectively with breast tumor cells over a short period of time. This method proved successful, whereas other techniques did not. When suspended HUVEC were added to spheroids already in Matrigel, the HUVECs did not adhere well and were often rinsed away in the subsequent labeling process. Previous studies of co-culture showed that endothelial cells became apoptotic or destroyed the spheroids when co-cultured.[2, 3] However, this was not the case in our study.

This model provides a promising method for examining endothelial tube interaction with breast cancer spheroids in 3D co-culture. However, we still must determine how the co-culture is best maintained over time. While this model can provide a better understanding of the organizational and functional endothelial cell–breast cancer interactions *in vitro*, the current model cannot account for flow effects. In the future, we will develop a microfluidic version of the endothelial tubes to assess how blood flow rate impacts endothelial cell – breast cancer interactions. This will pave the way to develop novel treatment methods that disrupt the vessel milieu housing these breast cancer cells

ACKNOWLEDGEMENTS

We thank Dr. Reginato for providing us with the breast cancer cell lines and spheroid culture protocols.

INTRODUCTION

The extracellular matrix (ECM) of articular cartilage provides mechanical resilience over a lifetime of load-bearing use. However, traumatic injury and degenerative processes compromise these mechanical functions, and damaged joint surfaces often require replacement. Tissue engineered constructs can mimic native cartilage, but their clinical use is complicated by cellular heterogeneity [1]. Such cell-to-cell variation is particularly pronounced in mesenchymal stem cell (MSC) populations: within a single MSC population, cells will undergo chondrogenesis to varying extents and over different timescales.

Despite this acknowledged phenotypic heterogeneity in MSCs, many studies investigating the molecular basis of their chondrogenic phenotype rely on bulk assays that average transcription and protein synthesis over an entire tissue-engineered construct. Single cell techniques now allow us to observe these systems with greater biological resolution and to parse cell-to-cell variation. Here, we employ quantitative single-cell methods to answer two principle questions: does transcriptional variation distinguish strongly chondrogenic cells from weakly chondrogenic cells, and how do temporal dynamics in matrix synthesis contribute to chondrogenic heterogeneity? To address these issues, we used single molecule RNA FISH to measure the absolute abundance of traditional differentiation markers, including the matrix protein aggrecan. We paired this analysis with immunofluorescent quantification of pericellular matrix accumulation, and found that, in this case, mRNA abundance is a poor predictor of protein abundance. Additionally, using a novel method to metabolically label nascent proteins with artificial methionine analogs, we traced the process of early matrix deposition, and found that both MSCs and chondrocytes produce matrix heterogeneously, and that the dynamics of matrix secretion differ by cell type.

METHODS

Cell culture: Juvenile bovine MSCs and chondrocytes were isolated as in [2]. Passage 1 cells were encapsulated in 2% agarose micro-gels (μ-gels, ~400 μm in thickness) at $2x10^6$ cells/mL. These μ-gels were cultured in a chemically defined media containing 10 ng/mL TGFβ-3 for up to 21 days. For studies examining nascent matrix synthesis, a methionine-free media formulation was supplemented with either 50 mM of the methionine analog homopropargylglycine (HPG), or 50 mM methionine as a control. RNA FISH: Single molecule RNA FISH was performed as in [3]. μ-gels were simultaneously stained with DAPI and oligonucleotide probes directed against aggrecan and GAPDH. From images, a custom MATLAB script quantified absolute mRNA expression at the single cell level (n=39-113 cells/condition). Matrix accumulation was simultaneously assessed via immunofluorescent staining for aggrecan core protein (Abcam ab3778). Nascent Protein Visualization: Following fixation, Alexa488-azide was reacted with HPG to label proteins that had incorporated the methionine analog during culture [4]. Nuclei and cell membranes were stained with Hoechst and CellMask Orange respectively. For imaging, individual cells were located via nuclear staining, and confocal sections of the cell mid-plane were captured at 100X (n=20-30 cells/group). For each cell, 20 radial intensity profiles emanating from the cell center were mapped, truncated to include only the extracellular domain, and averaged over each cell. Total matrix intensity was calculated by integrating intensity over distance from the cell membrane. Statistics: To compare single cell RNA counts, we constructed a generalized linear mixed model with a log-link function and by-donor random intercepts. Estimated means were compared using t-distributions with Satterthwaite approximations and simulated

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

adjustment for multiple comparisons. Matrix radius and total intensity were compared via t-test.

RESULTS

Mean single cell aggrecan mRNA abundance rose sharply in the first day following exposure to TGFβ and remained high for the duration of culture (day 1 vs 21, not shown). MSCs showed striking cell-to-cell variation in mRNA abundance, with aggrecan mRNA copy number per cell spanning three orders of magnitude (10^0 - 10^2, Fig 1A). Cell-to-cell variation in mRNA abundance was also similar between days 1 and 21 of TGFβ exposure (as measured by coefficient of variation, 0.69 vs 0.72). Thus, gene expression heterogeneity neither emerged nor attenuated with differentiation culture. Other differentiation markers including COMP and Sox9 behaved similarly.

Simultaneous RNA FISH and immunofluorescence for aggrecan RNA and the corresponding aggrecan core protein revealed that, at day 7, ~34% of MSCs had accumulated extracellular aggrecan protein (Fig 1B). While these high chondro-potential cells exhibited greater mean aggrecan transcript abundance than their low chondro-potential counterparts, the shift in mean aggrecan RNA number was small (Fig 1C, 1.35 fold change). Due to the poor separation in mRNA abundance distributions between these two groups, aggrecan mRNA copy number was unable to strongly predict the chondro-potential of individual cells.

One possible explanation of this disconnect between transcript and protein abundance in individual cells is that transcription is a stochastic process comprised of long 'silent' periods punctuated by short transcriptional bursts. In contrast, matrix accumulation reflects the integration of a cell's gene expression history. Towards the goal of linking an individual cell's transcriptional history with its protein output, we utilized amino acid tagging to label nascent extracellular matrix proteins [4]. Methionine analogs metabolically labeled intracellular proteins as well as proteins incorporated into the forming ECM (Fig 2A). After one day in HPG media, both chondrocytes and MSCs demonstrated intracellular labeling, but showed little extracellular labeling. During the next 7 days, ECM progressively extended from the cell border and into the extracellular space (Fig 2B-C). By day 7, both cell types had accumulated a metabolically labeled extracellular matrix comprised of discrete fibers (Fig 2D). The chondrocyte matrix was both more extensive (radius=19.8 vs 3.1 μm, $p<0.01$) and more intensely labeled (total intensity= 165 vs 49 a.u., $p<0.01$) than the MSC matrix. To compare the relative variability of the matrix, we computed CV of total matrix intensity. On day 7, MSCs demonstrated greater matrix variability than chondrocytes (MSC CV =1.84, chondrocyte CV=1.24), likely reflecting MSC's characteristic heterogeneity and slower differentiation kinetics. Intriguingly, by day 9, almost all HPG-labeled chondrocytes exhibited a pericellular ring of low HPG intensity immediately adjacent to the cell membrane. This ring co-localized with pericellular staining of aggrecan core protein, and seemed indicative of cells with a maturing cartilage-like matrix (Fig 2E). Strikingly, such a ring was rare amongst MSCs at the same time point, occurring in only ~5% of MSCs.

DISCUSSION

Here, quantitative single cell analysis of gene expression provided evidence that mRNA abundance of the chondrogenic marker aggrecan is only weakly linked to aggrecan protein expression and the chondrogenic phenotype of an MSC. These cells showed high transcriptional heterogeneity that failed to attenuate with prolonged differentiation. Interestingly, this transcriptional variability was unable to predict the heterogeneity observed in matrix accumulation; that is, cells expressing high elvels of aggrecan mRNA did not necessarily produce the most matrix. Nascent protein labeling via HPG incorporation into methionine-containing proteins (e.g. Col2, aggrecan) confirmed that matrix accumulation varied between cells in both MSC and chondrocyte populations. These results were also consistent with the expectation that ECM accumulates with culture time, and that MSCs and chondrocytes differ in their trajectory and rate of matrix accumulation. Future studies will pair RNA FISH and nascent matrix labeling to more directly link transcriptional abundance with protein deposition into the pericellular space, and may indicate that while instantaneous gene expression does not correlate with total protein accumulation, it can predict short-term matrix production.

INTRODUCTION

Pregnancy disorders such as pre-eclampsia, Intrauterine Growth Restriction (IUGR) and recurrent miscarriage are detrimental to the health of women and their offspring. Regardless of the underlying mechanisms of these diseases, the common histological observations point to abnormalities in the development of the placenta, characterized by inadequate trophoblast invasion and incomplete remodeling of the spiral arteries. The trophoblast is the unique cell type of the placenta and it invades and remodels the maternal spiral arteries to form highly dilated vessels that reduce maternal blood flow resistance and increase uteroplacental perfusion to meet the requirements of the developing fetus. When invasion is inadequate arteries remain, narrow at the opening into the intervillous space and result in disturbed blood flow patterns. This leads to reduced growth of the branches of the placental villous tress and reduced uteroplacental blood flow.

A large variety of factors are thought to influence the migratory behavior of trophoblasts. There is evidence that oxygen mediates trophoblast invasion, although this evidence is conflicting with claims that hypoxia both stimulates [1] and inhibits trophoblast invasion [2]. The disagreement in literature may be due to the different cell types, oxygen concentrations and whether the culture medium was supplemented with growth factors or not. Furthermore, these studies were conducted in static cultures in a single oxygen environment which is one of the limitations of the current *in vitro* models used to study the role of oxygen in placental biology.

In this work, the aim is to create a microfluidic cell invasion assay with a dynamic oxygen gradient to study the migration and invasion of primary human trophoblast cells. We demonstrate the working principle of this device with primary trophoblasts under a chemical gradient of Granulocyte Macrophage Colony-Stimulating Factor (GM-CSF). GM-CSF is a cytokine secreted by uternine Natural Killer (uNK) cells and is known to promote trophoblast migration [3]. We describe how the device is adapted to be representative of the oxygen tension at the maternal fetal interface. From <20 mm Hg at the placental villi (fetal) to approximately 60-80 mm Hg at the decidua (maternal) in the first trimester of pregnancy (Figure 1a). The device used for this study is made up of three channels - a central channel for cell culture and two side channels for cell medium delivery [4] and chemical and oxygen gradient generation (Figure 1b). The device will be used to determine if hypoxia (or low oxygen concentration) inhibits or stimulates trophoblast invasion.

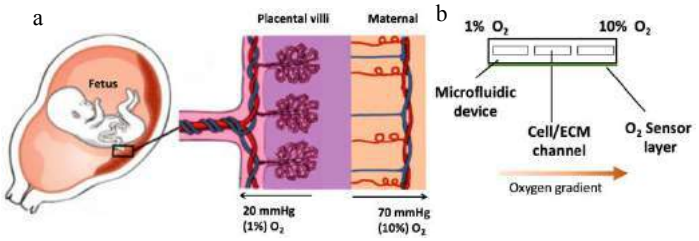

Figure 1: The oxygen gradient in (a) the first trimester of pregnancy and (b) in the microfluidic device.

METHODS

The design of the device is imprinted onto a silicon wafer using soft lithography which acts as a mold to manufacture the device using polydimethylsiloxane (PDMS) [4]. Primary trophoblast cells are encapsulated in matrigel extracellular matrix (ECM) protein and loaded into the central channel of the device 24 hrs before the beginning of the invasion assay. The cells are isolated from first trimester placental and

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

decidual samples taken from routine terminations of pregnancy (6-12 weeks) and tagged with a fluorescently labelled cell tracker. Cell migration is tracked using a LSM700 confocal laser scanning microscope (Zeiss, Oberkochen, Germany) over 12 hrs. Z-stacks of multiple positions are taken and the images are processed using the imaging software Fiji and the built-in plugin TrackMate. Data is generated on the the speed and directionality of cell movement.

For GM-CSF gradient generation, 10 ng/mL was added to cell medium in one channel with no GM-CSF in the other medium channel. To generate an oxygen gradient cell medium is preequlibriated in nitrogen gas in a specially made gas tight vessel coiled with gas permeable tubing. The dissolved concentration of oxygen entering the device is set by the flow rate of liquid through the system which controls the gas diffusion time. The gradient is validated using optical oxygen sensors (Presens, Regensburg, Germany) which records the oxygen concentration at the inlet and outlet of each channel. In addition, a thin film oxygen sensor is fabricated from the oxygen sensitive dye platinum(II) meso-tetrakis(penta uorophenyl)porphyrin (PtTFPP) and bonded to the base of the device. The sensor allows real-time visualization of the gradient by imaging using a fluorescent microscope.

RESULTS

Primary trophoblasts cells were found to migrate towards an increasing concentration of GM-CSF. The direction of cell movement is obtained by analyzing the cell tracks generated by TrackMate. A polar histogram is generated giving the number of cells (inner radial axis) and direction (outer radial axis). The polar histogram for primary trophoblasts cultured with a gradient of GM-CSF and without is shown in Figure 2a and Figure 2b respectively.

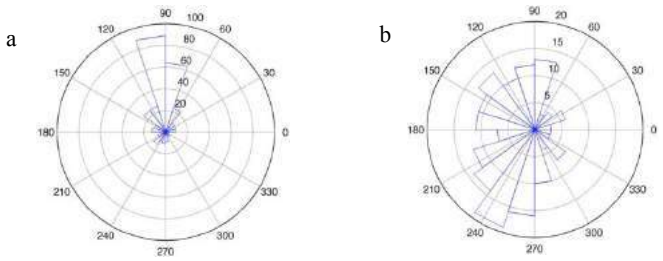

Figure 2: Polar histograms of primary trophoblasts show directed migration under (a) a gradient of GM-CSF compared to random movement with (b) no gradient. Note: difference in inner radial axis scale between (a) and (b).

Generation of an oxygen gradient along the device is confirmed visually using the thin film oxygen sensor (Figure 3a) and by taking an intensity profile along the width of the image (Figure 3b).

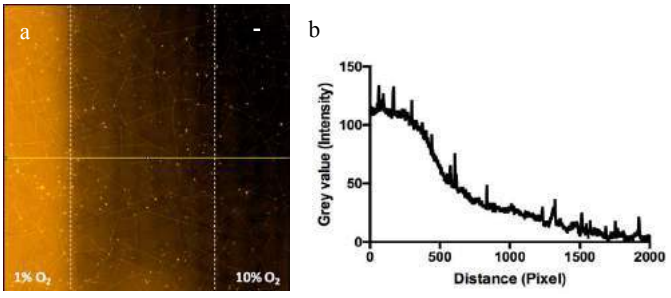

Figure 3: Confirmation of an oxygen gradient generated (a) visually and (b) its subsequent intensity profile. Scale bar: 200 µm.

The oxygen concentration entering and exiting each channel is easily controlled by adjusting the flow rate of liquid (Figure 4). There was no difference between using a syringe pump and operating the flow in a closed loop using a peristaltic pump. As PDMS is gas permeable oxygen readily defuses into the device resulting in higher oxygen concentrations measured at the outlet. An oxygen gradient therefore exists along the device as well as across the device and this gradient was found to be dependent on the flow rate of liquid through the system. This provides a greater range of oxygen gradients which can be studied in a single device.

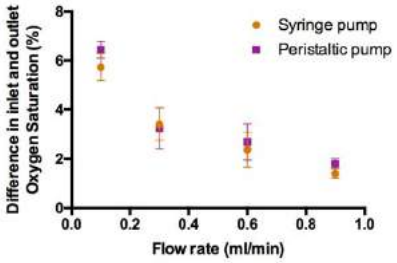

Figure 4: Oxygen concentration at the inlet and outlet of each channel is proportional to the flow rate of liquid.

DISCUSSION

Insufficient trophoblast migration and remodeling of the uterine spiral arteries is associated with poor placental development and outcomes in pregnancy. Methods to study trophoblast migration have mainly used trophoblast cell lines and simple 2D assays. Here, we present a microfluidic device to study primary trophoblast motility in a physiologically relevant microenvironment and in real time. We show that under a chemical gradient of GM-CSF primary trophoblasts migrate towards increasing concentrations of the cytokine when compared to the control. GM-CSF is one of the large variety of factors which are thought to influence trophoblast migratory behavior. Another is oxygen, for which there is inconclusive evidence on its importance on whether hypoxia (physiologically low oxygen) stimulates or inhibits trophoblast migration. Despite a dynamic oxygen gradient between the placental bed and the maternal decidua most *in vitro* studies use single oxygen concentrations, static cultures and assays used are 2D. Here, a microfluidic device is used to recreate the oxygen gradient at the maternal/fetal interface. The gradient demonstrated is dynamic which avoids stratification of oxygen within unstirred medium as in traditional well plate assays. A thin film oxygen sensor allows real time validation of the oxygen gradient using a fluorescent microscope. The oxygen concentration at the cell-medium interface can be determined using the Stern-Volmer relationship. Experiments with primary trophoblast cells under a dynamic gradient of oxygen are ongoing.

INTRODUCTION

Elastic modulus (i.e. Young's modulus) is a parameter used to characterize a b one's ability to deform without experiencing permanent damage. Three-point bending is the traditional method used to measure the elastic modulus in mouse bones. However, three-point bending is a destructive technique and thus cannot be used for *in vivo* longitudinal studies to examine bone quality in mice. Another technique known as reference point indentation (RPI) has emerged recently due to its ability to measure localized bone properties in a non-destructive manner [1].

In this study, we developed a technique to determine the elastic modulus using RPI data collected from the BioDent™ testing platform [2]. We analyzed multiple groups of mouse bones to: (1) assess the sensitivity of the BioDent™ to various factors such as genotype, gender, and age and (2) compare elastic moduli obtained from three-point bending versus RPI testing. This work will contribute toward developing an *in vivo* experimental approach to study bone quality in mouse models of aging as well as developing finite element (FE) models that incorporate the heterogeneous properties of bone.

METHODS

BioDent™ studies were conducted on three different sets of mouse bones. The first study analyzed ulnas that were harvested from 6-month old female TOPGAL mice. These mice were maintained in our colony on a mixed C57Bl/6 x CD1 background and served as a reporter for the β-catenin signaling pathway. Scanning electron microscopy (SEM) was also performed on the ulnas to assess surface defects created by each indentation. The second study was conducted on femurs collected from 4-5 month old β-catenin heterozygous conditional knockout (HETcKO) mice and their littermate controls. The third study examined both gender and age effects in femurs that were collected from C57Bl/6 mice [3] at 6, 12, and 22 months.

RPI tests were conducted on polymethyl methacrylate (PMMA) before and after they were performed on m ouse bones to ensure the quality and stability of the test probe. D uring RPI testing of bones, each sample was secured onto a custom stage and submerged in PBS while a dissection microscope was used to position the reference probe over each indentation site. Multiple sites were selected on the shaft of each bone to investigate regional differences in mechanical properties. For each indentation, a 2 N load was applied for one cycle. Only one cycle was applied because single indentations are sufficient to obtain the elastic modulus [4,5] and because 80-90% of the Total Indentation Distance (TID) can be attained in the first indentation cycle [7].

The elastic modulus was calculated from RPI measurements using two different methods: (1) Oliver-Pharr and (2) Geometric. The Oliver-Pharr (O/P) method was developed by W.C. Oliver and G.M. Pharr to determine the elastic modulus of a material using data from a single cycle. T he accuracy of the elastic modulus depends on the maximum load, maximum displacement, and elastic unloading stiffness (i.e. contact stiffness) [7]. Th e Geometric method is similar to the O/P method but utilizes different values for the area and area function. We also determined the elastic modulus of bones by using a biomechanical analysis procedure that employed three-point bending, microCT, and ImageJ [3]. T he objective was to validate the RPI methodology by comparing the elastic moduli with those obtained from the widely accepted three-point bending method.

RESULTS

Table 1 summarizes the elastic moduli obtained from the TOPGAL ulna based on the location of the indentation site as well as the BioDent™ analysis method employed. RPI testing captured

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

regional differences on the ulna surface as evidenced by higher elastic moduli for the midshaft compared to either the distal or proximal locations. In addition, the O/P method reported higher elastic moduli at the proximal (9%), midshaft (12%), and distal (10%) indentation sites when compared to the Geometric method.

Table 1: Elastic Moduli Obtained through Both BioDent™ Analysis Methods in the TOPGAL Ulna.

Indentation Site	O/P Method (GPa)	Geometric Method (GPa)
Proximal Ulna	4.66	4.24
Ulna Midshaft	5.71	5.08
Distal Ulna	4.97	4.51

Figure 1 shows SEM micrographs from the surface of the TOPGAL mouse ulna at (A) 100x and (B) at 1000x after applying a 2 N load for 1 cycle. The indentation site (indicated by red arrow) was positioned centrally along the longitudinal axis of the ulna. The corresponding microcracks were approximately 25-30 μm wide. Figure 2 shows the elastic moduli for the femurs of (A) HETcKO mice and (B) their littermate controls. C omparisons are also shown according to gender and the BioDent™ analysis method applied. Statistical analysis [8] using one-way analysis of variance (ANOVA) and Tukey HSD test for post-hoc comparisons indicated that there were no s ignificant differences in the elastic moduli obtained from three-point bending versus RPI testing.

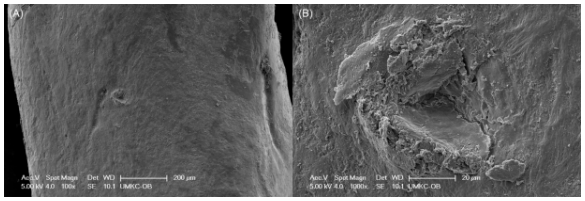

Figure 1: SEM micrographs showing an indentation site and microcracks at (A) 100x and (B) 1000x on the TOPGAL ulna.

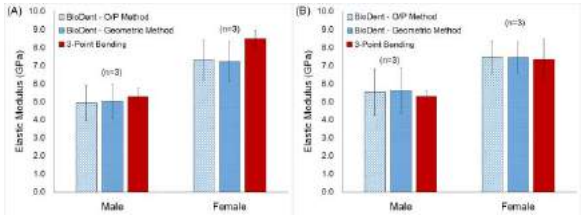

Figure 2: Femur analysis of (A) HETcKO mice and (B) their littermate controls revealed no significant differences in the elastic moduli regardless of the BioDent™ analysis technique used.

Figure 3 shows the elastic moduli for the femurs of (A) male and (B) female C57Bl/6 mice at three different ages. For all age groups, two-way ANOVA revealed that there was no significant difference between the elastic moduli obtained from the O/P and Geometric methods. RPI also exhibited a generally higher variability compared to three-point bending data. In addition, gender based differences in three-point bending data were only found at 6-months (i.e. females with 53% higher elastic modulus than males). However, neither the O/P nor the Geometric method was sensitive to gender based differences in the elastic modulus for all age groups.

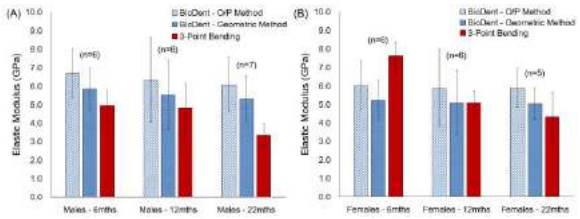

Figure 3: Comparison of elastic moduli obtained from three-point bending and RPI tests of (A) male and (B) female C57Bl/6 femurs.

DISCUSSION

The microcracks observed via SEM on the surface of the TOPGAL mouse ulna (Fig. 1) were also found in previous studies [6,9]. More importantly, RPI testing on the TOPGAL mouse ulna also demonstrated the ability of the BioDent™ to capture localized bone properties (Table 1). Although these findings correspond to *ex vivo* experiments, they are nonetheless encouraging for researchers who may be investigating the applicability of the BioDent™ for mouse bones as small as the ulna.

Elastic moduli measured using the Oliver-Pharr and Geometric methods were not significantly different from those measured by traditional three-point bending (Fig. 2). This finding indicates that the non-destructive RPI technique is equally effective at determining the elastic modulus as the widely established yet destructive three-point bending procedure. Furthermore, these results highlight the potential use of the femur rather than the ulna for *in vivo* assessments of bone quality since the femur possesses a naturally larger surface area and thickness compared to the ulna. However, RPI testing must also be performed on femurs with soft tissue intact to assess the effectiveness of the BioDent™ platform under *in vivo* conditions.

For the C57Bl/6 femurs, both the O/P and Geometric methods produced elastic moduli with higher variability compared to the elastic moduli obtained from three-point bending. The main reason for these differences is most likely due to the inclusion of RPI measurements collected from multiple femur sites to calculate the elastic moduli. As shown in Table 1, RPI testing can already detect regional differences in mouse bones the size of the ulna. Therefore, it is reasonable that larger mouse bones such as the femur would also produce higher variations in the localized bone properties. Conventional three-point bending may be more sensitive to gender and age based differences in the elastic modulus for the C57Bl/6 femur. However, this work shows that a n on-destructive technique for measuring the elastic modulus is achievable for certain mouse bones.

INTRODUCTION

Glaucoma is an ocular disease that is associated with irreversible optic nerve damage and loss of vision. Evidence has shown that glaucomatous optic nerve damage initiates within the optic nerve head (ONH) [1], where the retinal ganglion cell axons exit the back of the eye en route to the brain. The stresses and strains within the ONH resulting from the intraocular pressure (IOP) are thought to play an important role in axonal health and disease. However, the exact mechanism by which mechanical insult can lead to optic nerve damage remains largely unknown.

Many studies have investigated the mechanical response of the posterior sclera during increases in IOP. Recently, there has been an increased effort to directly measure the mechanical response of the ONH to IOP elevation. Deformation within the ONH has been measured using various techniques including confocal microscopy [2], optical coherence tomography (OCT) [3], micro-computed tomography (μCT) [4], and second harmonic generated (SHG) imaging [5, 6]. Such studies have focused mainly on the lamina cribrosa (LC), a mesh-like matrix of collagen fibers through which axons pass through the scleral canal. It is hypothesized that high levels of strain experienced by ONH tissues such as the LC can damage the traversing nerve fibers, impair blood flow, and lead to optic nerve pathology.

Our laboratory has previously used a high-resolution ultrasound speckle tracking method to measure strains within the sclera and cornea [7]. In this study, the technique was used to measure strains within the ONH during increases in IOP. The goal of the study was to map the mechanical response of a transverse ONH cross-section to IOP elevation. We also evaluated the correlation between strain behavior and tissue morphology using histological analyses. Better understanding the IOP-induced strains within the ONH may provide insight into the potential biomechanical mechanisms of glaucomatous optic nerve damage.

METHODS

Thirteen porcine globes and one globe from a human donor (75 years old, Caucasian, male) were tested within 72 hours postmortem. The optic nerve was trimmed to the outer surface of the peripapillary sclera. The anterior portion of the globe was removed using a 7.5 mm trephine. The globe was mounted on a customized pressurization chamber and immersed in 0.9% saline. The chamber was connected to a programmable syringe pump (PHD Ultra, Harvard Apparatus) and a pressure sensor (P75, Harvard Apparatus) to continuously control and monitor IOP.

Each globe was preconditioned using twenty pressure cycles from 5 to 30 mmHg followed by an equilibration period of 30 minutes at 5 mmHg. Inflation testing was then performed by increasing IOP from 5 to 30 mmHg, with 0.5 mmHg pressure steps every 15 seconds. During inflation, a 55 MHz ultrasound probe (Vevo 660, VisualSonics Inc.) was positioned to acquire images along the nasal-temporal meridian of the ONH. At each pressure level, 2D cross-sections of radiofrequency data were obtained. The IOP and data acquisition were controlled using a customized LabView interface (National Instruments).

The acquired RF data was analyzed using a 2D ultrasound speckle tracking algorithm [7]. A grid of points was defined throughout the tissue cross-section, and displacement vectors were calculated for each point during inflation. Least squares strain estimation and coordinate transformation methods were used to calculate through-thickness and in-plane strains.

Histological analyses were performed for the human donor globe and three of the tested porcine globes. All eyes were immersed in a 10% formalin solution for 24 hours prior to histological processing.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The human globe was fixed at an IOP of 15 mmHg, and the three porcine globes were fixed at 5, 15, and 30 mmHg. A tissue section was prepared from each eye along the nasal-temporal meridian, corresponding to the cross-section imaged using ultrasound. The sections were stained using haemotoxylin and eosin staining. The histology images were compared to strain maps to assess the large-scale correspondence between tissue structures and the strain response within the ONH.

RESULTS

Strain maps in the scanned cross-section were obtained at each pressure level for each eye. To quantify the strain magnitudes, the through-thickness and in-plane strains were averaged over the entire ONH cross-section for each eye. At 30 mmHg, the porcine ONH exhibited an overall through-thickness compressive strain of -0.053 ± 0.015 and an in-plane tensile strain of 0.018 ± 0.008 (n=13). The human ONH strains were lower in magnitude compared to the average strains in the porcine eyes, with through-thickness and in-plane strains of -0.012 and 0.006 respectively.

The ONH cross-section was further split into two equal thickness layers to compare the mechanical response of the anterior and posterior regions of the ONH (Figure 1). In the porcine globes, the through-thickness compressive strains at 30 mmHg were approximately 4.4 times larger in the anterior layer compared to the posterior layer (-0.088 ± 0.019 vs. -0.020 ± 0.011, $p<0.001$). The in-plane tensile strains were slightly but significantly higher in the posterior layer (0.015 ± 0.011 vs. 0.021 ± 0.007, $p=0.025$), where substantial strain heterogeneity was also present. Similar trends were found at 15 mmHg. In agreement with the measurements in porcine eyes, larger through-thickness compressive strains were also observed in the anterior human ONH.

A histological section for a porcine eye fixed at 30 mmHg showed a layer of prelaminar neural tissue at the anterior ONH, with a visible LC layer situated between the prelaminar and retrolaminar neural tissue (Figure 2).

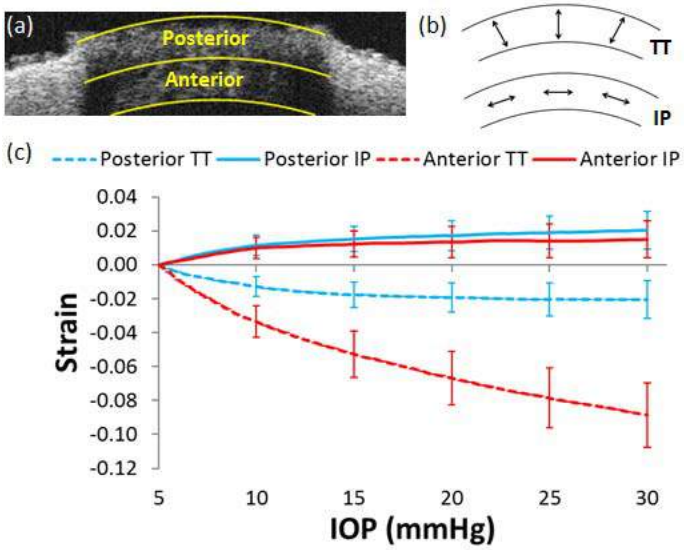

Figure 1: (a) An ultrasound cross-sectional image of a porcine ONH divided into two equal thickness layers, (b) the through-thickness (TT) and in-plane (IP) directions, and (c) the average TT and IP strains in the anterior and posterior layers of porcine ONH (n=13, error bar: standard deviation).

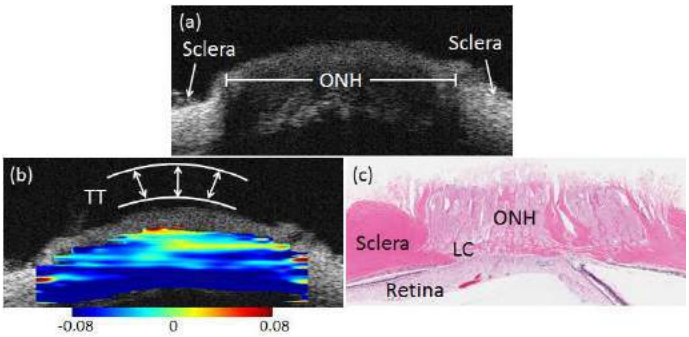

Figure 2: (a) An ultrasound image, (b) a map of through-thickness strain, and (c) a histology image of a representative porcine ONH at 30 mmHg. The region of large through-thickness compression appears to correspond to the prelaminar neural tissue.

DISCUSSION

The strain measurements presented in this study showed the expected through-thickness compression and in-plane tension in the ONH tissue during IOP elevation. A substantially larger through-thickness compressive strain was observed in the anterior ONH, showing a marked difference in the mechanical responses comparing the anterior and posterior ONH.

Histological analyses indicated a potential correspondence between the strain response and anatomical structures. Based on a comparison of the strain map and the histology image from the same eye (Figure 2), it appeared that the largest compression was in the region of the prelaminar neural tissue, whose in-plane stretch was moderate (Figure 1c, red curves). This experimental data provides support to the notion that prelaminar neural compression may play an important role in the onset of glaucoma, resulting in IOP-related axonal transport blockage and neural damage [8]. The mechanical deformation of the LC and retrolaminar neural tissue during inflation appeared to be more heterogeneous and smaller in magnitude than that of the prelaminar neural tissue. Others have also reported considerable strain heterogeneity within the trabecular beams of the LC in response to elevated IOP [5].

The current study was limited to 2D measurements of ONH strain. Future work will extend the strain measurements to 3D to obtain a more complete characterization of ONH deformation, including the measurement of principal and shear strains. The direct measurement of deformation within the ONH tissue volume in its physiological configuration will provide a better delineation of the in vivo mechanical loading and insult experienced by ONH structures and cells during IOP elevations, and help us better understand the mechanical pathways of glaucomatous neural damage.

INTRODUCTION

Osteoporosis is an age-related disease characterized by low bone mass, which leads to a compromised skeletal structure and increased risk of fracture. This disease causes more than 8.9 million fractures worldwide each year with an osteoporotic fracture occurring every 3 seconds [1]. Bone is a dynamic organ that adapts its composition and structural properties in response to its loading environment [2, 3]. Therefore, researchers have sought to better understand both the mechanical and biological mechanisms of increased bone formation to treat osteoporosis [4]. Osteocytes, which constitute the majority of bone cells and are located within the mineralized bone matrix, have been postulated to be the primary mechanosensory cells in bone [5, 6] and would be suitable cellular targets for drug therapies or individualized exercise regimens. However, the precise mechanism in which osteocytes convert mechanical stimuli into biological signals (i.e. mechanotransduction) is not fully understood.

In this study, we developed a 2-D finite element (FE) model to examine the strain response in the osteocyte lacunae and perilacunar regions. We analyzed the variations in lacunar strain based on the perilacunar modulus as well as the osteocyte position and orientation. A 3-D microscale FE model was then developed to analyze lacunar strains in realistic osteocyte geometries rather than idealized ellipsoids. This work is part of a multiscale FE modeling approach that will be used to determine if heterogeneous osteocyte activation corresponds to a minimum strain threshold required to initiate mechanotransduction.

METHODS

FEBio Software Suite [7] was used to create a 2 -D model consisting of the bone matrix, osteocyte lacunae, and perilacunar region. A sinusoidal load was applied to the top surface of the model and a fixed boundary condition was assigned to the bottom surface. As shown in Fig. 1A, six osteocytes were created with two osteocytes oriented horizontally (H1 and H2), two oriented vertically (V1 and V2), and two oriented diagonally (D1 and D2). Strains were analyzed in the three osteocyte subregions as a function of the perilacunar modulus: inner lacunae (Fig. 1B), outer lacunae (Fig. 1C), and perilacunar region (Fig. 1D). Strain ratios were also calculated to compare the maximum strains in the osteocyte subregions to the global strain in the surrounding bone.

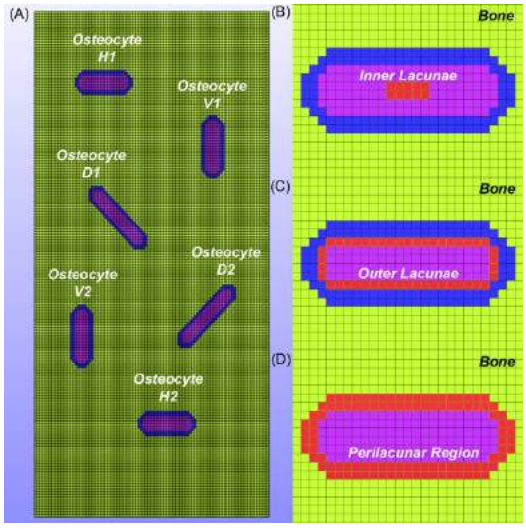

Figure 1: (A) 2-D FE model showing each osteocyte and the (B) inner lacunae, (C) outer lacunae, and (D) perilacunar region.

The 3-D model was developed by importing confocal microscope image stacks of osteocytes into Mimics® Innovation Suite [8] to generate a volume mesh composed of 10-node tetrahedral elements. A sinusoidal load was applied to the top surface of the model and a fixed boundary condition was assigned to the bottom surface. The 3-D model contained seventeen osteocytes of various sizes (Fig. 2A). Strain ratios (i.e. lacunae/bone) were calculated for each osteocyte shown in Fig. 2B.

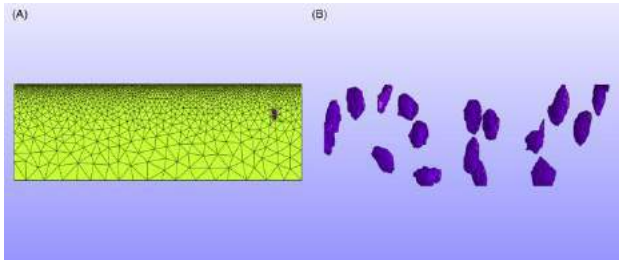

Figure 2: (A) Front view of 3-D FE model with a single osteocyte selected. (B) 3-D FE model showing only the osteocytes analyzed.

RESULTS

Strain ratios of the inner lacunae, outer lacunae, and perilacunar region to the bone matrix are summarized in Tables 1, 2, and 3, respectively. For each osteocyte and their three subregions, the strain ratios decreased as the perilacunar modulus increased. Differences in position also led to lower strain ratios in Ocy H2 compared to Ocy H1 and in Ocy V2 compared to Ocy V1. Conversely, the increased distance from the applied load produced higher strain ratios in Ocy D2 compared to Ocy D1. Finally, osteocyte orientation (e.g. Ocy H1 versus Ocy V1) was found to decrease strains in the inner (~18%) and outer (~24%) lacunae but not the perilacunar tissue.

Table 1: Ratios of Maximum Inner Lacunae Strain to Global Bone Strain (2000 με) for each Osteocyte (Ocy).

Perilacunar Modulus	Ocy H1	Ocy H2	Ocy V1	Ocy V2	Ocy D1	Ocy D2
5 GPa	10.31	9.25	1.92	1.70	9.98	10.86
10 GPa	9.77	8.86	1.80	1.60	9.39	10.16
15 GPa	9.35	8.56	1.69	1.51	8.94	9.64
20 GPa	9.02	8.31	1.59	1.43	8.57	9.21

Table 2: Ratios of Maximum Outer Lacunae Strain to Global Bone Strain (2000 με) for each Osteocyte (Ocy).

Perilacunar Modulus	Ocy H1	Ocy H2	Ocy V1	Ocy V2	Ocy D1	Ocy D2
5 GPa	8.67	7.78	2.11	1.98	6.18	6.66
10 GPa	8.08	7.32	1.96	1.85	5.70	6.11
15 GPa	7.63	6.98	1.85	1.74	5.34	5.71
20 GPa	7.28	6.70	1.75	1.65	5.06	5.40

Table 3: Ratios of Maximum Perilacunar Strain to Global Bone Strain (2000 με) for each Osteocyte (Ocy).

Perilacunar Modulus	Ocy H1	Ocy H2	Ocy V1	Ocy V2	Ocy D1	Ocy D2
5 GPa	1.27	1.11	1.53	1.42	1.10	1.14
10 GPa	1.10	0.99	1.41	1.30	0.96	1.30
15 GPa	0.98	0.87	1.31	1.22	0.86	1.22
20 GPa	0.89	0.79	1.22	1.14	0.78	1.14

Osteocytes in the 3-D model were divided into four subgroups: top surface (n=3), side surface (n=2), bottom surface (n=3), and internal (n=9). Strain ratios for osteocytes found in the top, side, and bottom surfaces fell within ranges of 2.09-6.24, 2.35-3.03, and 1.49-2.63, respectively. Meanwhile, the internal osteocytes yielded strain ratios as low as 1.74 and as high as 2.91.

DISCUSSION

The 2-D model confirmed that the maximum strains in the inner lacunae, outer lacunae, and perilacunar tissue all increased due to their proximity to the applied load. In addition, strains in all three osteocyte subregions were influenced more predominantly by the horizontal and vertical orientations than the diagonal orientation. These findings indicate that the strain response not only depends on the alignment of the osteocyte, but also the osteocyte subregion examined. A better understanding of how mechanical stimuli directly affects the inner lacunae, outer lacunae, and perilacunar tissue may provide evidence that can be used to identify the minimum strain threshold required for osteocyte activation.

The 3-D model presented data similar to the 2-D model in that the lacunae strains varied based on the osteocyte positioning relative to the applied load. When comparing osteocytes near the top surface versus those near the bottom surface, we found that lacunar strains were 28-57% lower in the osteocytes positioned farthest from the applied loading. Furthermore, one of the osteocytes at the top surface exhibited a strain ratio (6.24) that was approximately 3x larger than the others in its subgroup. This finding could be explained by its proximity to the applied load, but the exact coordinates of each osteocyte would be needed for confirmation. Although the 3-D model did not possess any osteocyte subregions that represented the perilacunar tissue, the 2-D model exhibited decreases in lacunae strain as a result of an increased perilacunar tissue modulus. This finding has been observed in previous work [9,10], which examined the strain response in idealized, ellipsoidal osteocyte geometries. However, a key difference between the two aforementioned studies and this work is that our 3-D model comprises a more realistic representation of the typical osteocyte structure and arrangement. Therefore, the strains observed in the lacunar regions should provide a more accurate depiction of the strain distributions found throughout the osteocyte architecture. Future studies will utilize these FE models to correlate strains observed in the osteocyte lacunae with the heterogeneous activation of biological pathways associated with both mechanical loading and bone formation (e.g. Wnt/β-catenin signaling pathway).

INTRODUCTION

Endovascular intervention using Flow Diverter (FD) – a densely woven stent with high metal coverage rate and low porosity – is the prevalent treatment modality in intracranial aneurysms (IAs), especially among the traditionally challenging wide-necked and fusiform aneurysms. FDs are implanted to occlude the aneurysm and facilitate endoluminal reconstruction of the parent artery. Despite good clinical success of FDs, complications like incomplete occlusion and post-treatment rupture leading to subarachnoid hemorrhage have been reported [1]. Implantation of a FD disrupts the flow of blood in the aneurysm, inducing pro-thrombotic conditions. However, for patients with incomplete occlusion these pro-thrombotic environments could not be attained. Therefore to understand the relationship of FD deployment and treatment outcome it is important to gain insight on the flow modifications associated with the pro-thrombotic conditions. Computational fluid dynamic (CFD) analysis of pre- and post-treatment aneurysms can provide flow modifications by FD deployment, and can identify parameters that are associated with the treatment outcome.

In the current study an efficient virtual stenting method was used to mimic the clinical intervention on the patient-specific aneurysm geometries treated with the commercially available flow diverter: the Pipeline embolization device (PED, Covidien/Medtronic). CFD simulations were then performed on these geometries to obtain pre- and post- treatment hemodynamics. Modifications in hemodynamic parameters were calculated and correlated with 12 months clinical outcome.

METHODS

Five patient-specific aneurysms were selected for this study with the approval from the IRB at our institution. All the patients were treated using 1 PED. The following clinical information was collected for each patient (1) 3D digital subtraction angiographic (DSA) image, (2) PED device specification and landing zone and (3) 12 months clinical follow-up information. At the clinical follow-up after 12 months, 3 aneurysms were completely occluded and 2 were partially occluded.

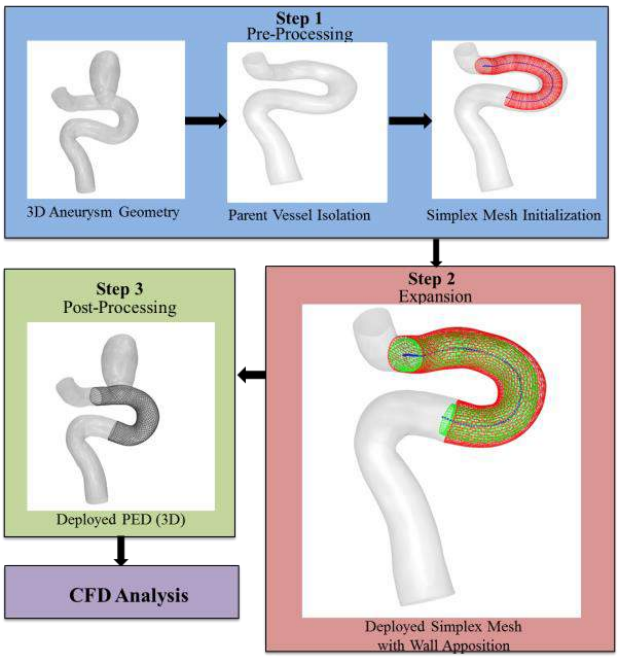

Figure 1: Virtual stenting workflow.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

3D vessel reconstruction of the DSA images was performed using vascular modeling toolkit (vmtk). We then used an efficient virtual stenting workflow [2] to simulate the process of PED implantation in in each aneurysm. The workflow (Figure 1) is divided into three steps: (1) pre-processing, where the parent vessel is isolated and a generalized simplex mesh structure is generated to fit the vessel along its centerline using vessel-specific initialization, (2) expansion, to achieve good apposition of the simplex mesh with the vessel wall and (3) post-processing, where the PED pattern is mapped on the deployed simplex mesh and wires swept into a 3D structure. We improved the existing fast virtual stenting [3] algorithm by integrating the vessel-specific rapid initialization and adaptive expansion force, which led to better efficiency and accuracy of the PED deployment compared to the previous algorithm. The deployed PED was then incorporated into the aneurysm geometry.

CFD simulations were then performed on the pre- and post-treated geometries on STAR-CCM+ v10.02 (CD-adapco, Melville, NY) under steady-state conditions. Blood was modeled as Newtonian fluid, with density 1056 kg/m^3 and dynamic viscosity as 0.0035 Pa-s. The hemodynamic parameters calculated were inflow rate, aneurysmal velocity, vortex coreline length and energy loss (EL) by the PED.

RESULTS

Figure 2 shows the velocity streamlines and vortex corelines for one completely occluded and one partially occluded case. For the completely occluded case, a larger number of vortex corelines are present in the aneurysm before treatment, which are diminished by the implantation of the PED. For the partially occluded case, the vortex corelines are fewer prior to the treatment, but the PED failed to diffuse the vortices, giving a similar distribution of the vortex corelines even after the treatment.

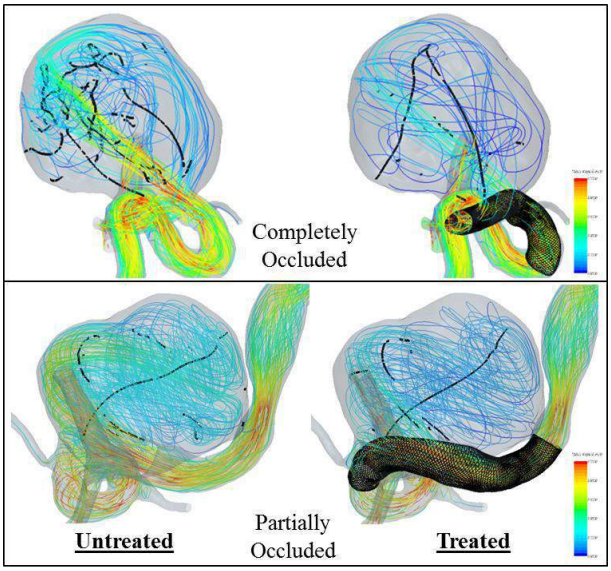

Figure 2: Pre- and post-treatment velocity streamlines and vortex corelines (black) for one aneurysm with complete occlusion and one aneurysm with incomplete occlusion after 12 months clinical follow-up.

Quantification of hemodynamic parameters (Figure 3) showed an average inflow rate reduction of 42.3% in completely occluded cases as compared with 33.7% in partially occluded cases. There was a reduction of 54.5% in aneurysmal average velocity in cases occluded within 12 months, whereas the patent cases had a reduction of 45.6%.

There was a substantial reduction in vortex coreline length and EL for completely occluded cases with a reduction of 45.1% and 29.1% respectively as compared to 21.7% and 9.8% for the partially occluded cases (Figure 3: red dotted box).

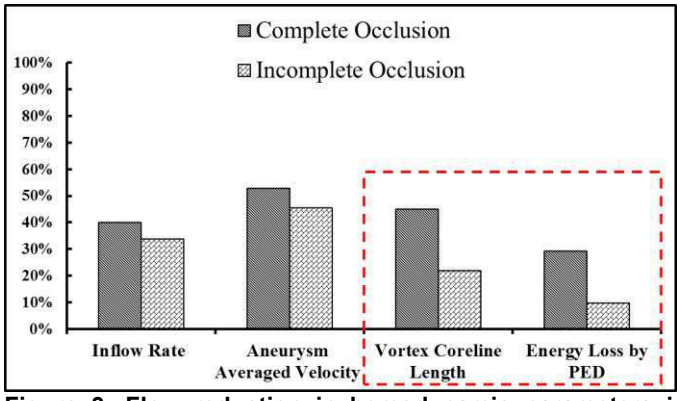

Figure 3: Flow reduction in hemodynamic parameters in aneurysms occluded within 12 months versus aneurysm with incomplete occlusion after 12 months clinical follow-up.

DISCUSSION

The results demonstrate that the bulk flow is reduced in the aneurysm for all the patients treated using the PED. But the reduction in flow parameters like inflow rate and average velocity was comparable in all the patients. However as shown in Figure 3 in red dotted box, there is a noticeably higher reduction of vortex coreline length and EL for aneurysms that occluded within 12 months. This suggests that bulk flow parameters like inflow rate and aneurysmal average velocity may not be linked with the occlusion times. On the other hand, substantial reduction of vortex coreline length and EL in the occluded cases suggest that the localized complex flow in the aneurysm was substantially dispersed into simple flow for completely occluded treated cases, whereas in patent cases the PED was unable to reduce the complex flow inside the aneurysmal sac (e.g. see Figure 2).

Although the patient population is very small to draw any clinically significant conclusion, results do suggest that higher reduction in localized flow into the aneurysm can be associated with the occlusion rate, and eventual outcome of the treatment.

The current study shows preliminary results of an ongoing study which aims at prospectively predicting outcome of different treatment strategies using flow diverters. We plan to increase the sample size of our current study and identify hemodynamic parameters that can predict the outcome of IAs treated using FDs. Based on these parameters a predictive model can be built which can prospectively predict the treatment outcome and aid the clinicians in *a priori* assessment of the outcome of different treatment strategies.

RIBOFLAVIN/UVA COLLAGEN CROSS-LINKING EFFECTS ON TENSILE AND COMPRESSIVE PROPERTIES OF THE CORNEA

H. Hatami-Marbini (1)

(1) Department of Mechanical & Industrial Engineering, University of Illinois at Chicago, Chicago, Illinois 60607

INTRODUCTION

Keratoconus is an eye disorder affecting almost one to five people in every 10,000. In this disease, the progressive non-inflammatory stromal thinning and softening causes the cornea to bulge out due to the intraocular pressure. This changes the normal curvature of the cornea and results in serious vision disorders such as astigmatism and myopia. It has been shown that the riboflavin/UVA collagen cross-linking process can be used to improve the biomechanical properties of keratoconus corneas and stop the progression of the disease [1-2]. In this treatment procedure, cross-links are introduced into the stroma by continuous application of riboflavin solution along with the UVA irradiation. The influence of various parameters of this treatment option, such as the wavelength and intensity of the UVA, is often assessed by the changes that they cause in corneal biomechanical properties. The uniaxial tensile tests are among the most commonly used experimental techniques for this purpose. Using this testing technique, it has been concluded that maximum tensile stress in the riboflavin/UVA treated rabbit, porcine, and human corneas significantly increased [1-3]. We have recently shown that hydration plays an important role in defining the biomechanical properties of the cornea [4-5]. In particular, swollen corneal samples had softer mechanical properties compared with the dehydrated corneas. The present study was designed to extend these previous studies and investigate possible effects of hydration on corneal stiffening due to the riboflavin/UVA collagen crosslinking treatment.

The cornea is a hydrated soft tissue which transmits the incident light while acting as a resilient barrier to the mechanical forces. The cornea is composed of different layers but the stromal layer, is known to be primarily responsible for its mechanical properties. The stroma consists of thin parallel-to-the-surface collagen lamellae embedded in a proteoglycan matrix. In experimental techniques such as inflation and uniaxial tensile experiments, the corneal samples are immersed in ionic solutions to avoid dehydration. Due to the presence of the proteoglycans, this will cause the specimens to imbibe the fluid and swell. The change in fluid content has important effects on the measured properties as shown in recent publications [4-6]. In the present research, we extend these previous studies and characterize the influence of hydration on both compressive and tensile properties of the collagen cross-linked corneas.

METHODS

Fresh bovine and porcine sample were obtained from a local slaughterhouse and transferred to the laboratory on ice. Bovine samples were used for uniaxial tensile tests and porcine samples were used for unconfined compression experiments. From each eye globe, a corneal scleral ring was dissected with a scissor. Corneal scleral rings were divided into control and collagen cross-linked groups [7]. The collagen cross-linked groups were cross-linked using a custom-made cross-linking device. Prior to UVA/riboflavin collagen crosslinking, all samples were placed in 0.1% riboflavin with 20% dextran T500 solution until they reached an equilibrium swelling state. A Pachymeter (DGH Pachette 3, DGH Technology, Inc., Pennsylvania, USA) was used to measure the thickness of samples and ensure that they reached equilibrium. The specimens were placed on a semi-sphere surface in order to mimic their natural in-vivo curvature and were subjected to the UVA irradiation with an irradiance of 3 mW/cm^2 for 30 minutes. During this period, drops of riboflavin solution were added on their surface every five minutes. After the UVA/riboflavin crosslinking treatment, a double blade cutting device and trephine were used to punch either a rectangular strip or a disk from corneal sclera rings. The strips were prepared from nasal-temporal orientation and were used in uniaxial

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

tensile tests while the corneal disks were used to character size the unconfined compression behavior [7-8].

The uniaxial tensile tests were done using a dynamic mechanical analyzer (RSA-G2, TA instrument, Delaware, USA). First, the cross-linked specimens were soaked in the Ophthalmic Balanced Salt Solution or being dehydrated in air until their thickness reached the thickness of one of the three thickness groups, i.e. 500, 700, 900, 1100, and 1500 µm. The strips were then secured between the clamps of the DMA machine and the immersion chamber was filled with mineral oil in order to prevent any swelling/deswelling during the experiments. All samples were subjected to a preconditioning step for creating a similar stress-strain history in them. The preconditioning procedure included five rapid loading/unloading cycles followed by three short stress-relaxation steps. The experiments were done by applying 5% axial strain with a displacement rate of 2 mm/min. During the experiments, the applied force was measured and the stress was calculated from dividing the recorded force by the initial cross-sectional area of the strips. Similar experiments were done on untreated samples. For unconfined compression experiments [8], a compressive tare stress was used to determine the initial thickness of the corneal disks and successive stress-relaxation tests were conducted by bringing the head down. Compressive strain steps of 5% with a given displacement rate. The experimental data was modelled using a transversely isotropic material model in order to determine the material properties at different levels of hydration.

RESULTS

Figures 1 and 2 show the tensile stress-strain behavior of untreated and riboflavin/UVA collagen crosslinked corneal strips at different thicknesses, respectively. In both treated and untreated groups, it is seen that tensile properties became stiffer with decreasing thickness (hydration). Furthermore, it is seen that within a specific thickness group, the collagen cross-linking procedure significantly increased the tensile strength of the cornea. It is noted that the hydration of the samples can be estimated using the hydration-thickness relation, H_w=3.7ln(t/0.295) [6]. This relation gives average hydration of 2.0, 3.2, 4.1, 4.9, and 6 mg water/ mg dry tissue for samples with average thickness of 0.5, 0.7, 0.9, 1.1, and 1.5 mm respectively..

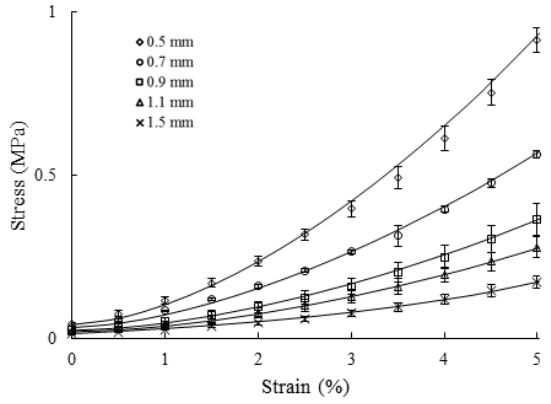

Figure 1: Stress-strain of untreated bovine cornea at different levels of thickness (hydration).

DISCUSSION

The primary objective of the present work was to determine the influence of hydration on tensile and compressive properties of the riboflavin/UVA collagen cross-linked cornea. Figures 1 and 2 show that the riboflavin/UVA collagen crosslinking procedure has strengthened the tensile properties of the bovine cornea, which is similar to the effect of this procedure on porcine, human, and rabbit corneas. Furthermore, this plot shows that the stiffening effect of the collagen cross-linking treatment, as measured by uniaxial tensile testing method, is hydration dependent. In Figure 3, we plotted the tangent modulus of the collagen cross-linked corneal strips at different levels hydration and compare them with the tangent modulus of the untreated bovine corneas.

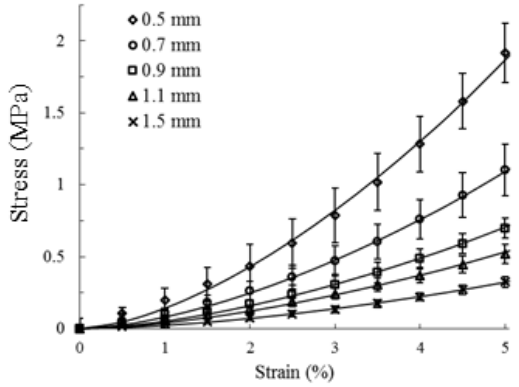

Figure 2: Stress-strain of the collagen cross-linked bovine corneal strips at different levels of thickness (hydration).

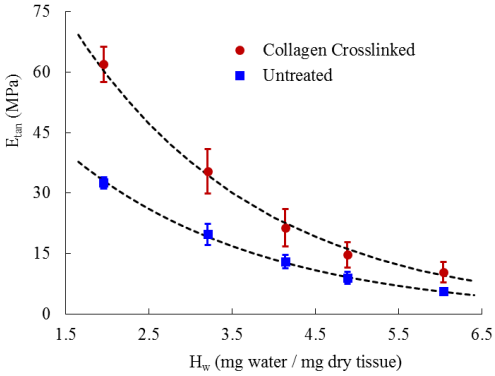

Figure 3: Tangent modulus of the collagen cross-linked and untreated corneal strips at different levels hydration.

Figure 3 clearly shows that an accurate estimate of the stiffening effects of collagen crosslinking is only possible if the tensile behavior of treated and untreated specimens is measured at the same level of hydration. The presentation will expand on these studies and discuss the behavior of the specimens in unconfined compression (results not shown here).

INTRODUCTION

Microscale tensile testing demonstrates that tendon loads are transferred between discontinuous fibrils via shear of the interfibrillar matrix [1]. Moreover, tendon exhibits macroscopic strain-softening at strains beyond the elastic limit [1, 2], which can be explained by plastic deformation of the interfibrillar matrix [3]. However, the mechanisms of recovery at the microscale (e.g., fibril strain and interfibrillar sliding) and their relationship to macroscale mechanics (e.g., nonlinearity and modulus) are unknown. Specifically, it is unclear whether the observed plastic deformation of the interfibrillar matrix contributes non-recoverable tendon damage. Here, we (1) measured the unloaded recovery of tendon following tensile loading, (2) quantified microscale deformations and classified them as elastic, viscoelastic, or non-recoverable (i.e., plastic/permanent), and (3) established relationships between macro- and micro-scale recovery. Thus, the objective of this study was to elucidate mechanisms of tendon damage at multiple length scales.

METHODS

Sample Preparation: Tail tendon fascicles from 6-7 month Sprague-Dawley male rats were dissected, stained with 10 μg/ml 5-DTAF (Life Technologies), and tested on a custom-made uniaxial testing device mounted on an inverted confocal microscope (LSM 5 LIVE) as previously described [1]. Macroscale tissue strain was measured using applied ink markers and a CCD camera. Microscale deformation, including fibril strain and fibril sliding, was measured using four photobleached lines separated by 125 μm.

Multi-scale Mechanical Testing: Samples were preloaded to 0.5g to define the reference length, preconditioned (5 cycles of 4% grip strains), and loaded to either 2, 4, 6, or 8% grip strain, defined as the "baseline" (Fig 1). Strain was held constant for a 15 min relaxation period and then unloaded to the reference length (Fig 1). Each fascicle was assigned to a rest or no rest group. The no rest group was immediately loaded to failure, whereas the rest group was held at its reference length for 60 min before loading to failure. Microscale images were acquired only for the rest group including: reference image before loading, at the beginning and at the end of the relaxation period, and every 10 minutes during the 60 min rest. Finally, each fascicle was ramped to failure, defined as the "diagnostic" (Fig 1). The strain rate was 1%/s for all loading. In all, we performed multiscale mechanical testing on 8 groups (2, 4, 6, and 8% strain, each with rest or no rest, with n=7 fascicles per group).

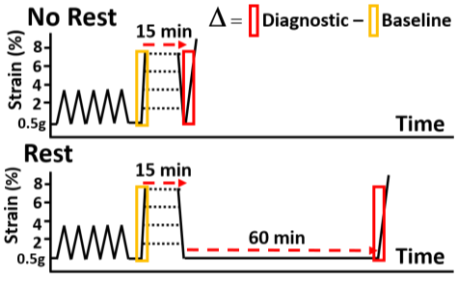

Fig. 1: Mechanical testing protocol

Data Analysis: Macroscale stress-strain response was fit with a nonlinear model [4] that optimized for the transition strain (the end of toe-region) and linear region modulus. These properties were calculated for the baseline and diagnostic ramps, and change in each property was determined, Δ = Diagnostic – Baseline (Fig 1). A linear regression was performed between macroscale parameters and tissue strain. An extra-sum-of-squares F-test was performed to test significant differences between rest and no rest groups. The 2% strain group was excluded for macroscale analysis because transition strain and linear modulus are not evident at this low strain level.

Microscale mechanical properties (fibril strain and interfibrillar sliding) were determined from confocal microscope images [1]. Fibril

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

strain was defined as the change in distance between pairs of photobleached lines, and interfibrillar sliding was the averaged tortuosity of these lines. Microscale deformations were then decomposed into the recoverable (elastic and viscoelastic) and non-recoverable portions, where recovery is defined as the time dependent return of microscale properties during the rest period. A linear regression was performed between the microscale parameters and tissue strain and also between the macro- and microscale parameters. Significance was set at the 95% confidence level for all analyses.

RESULTS

The macroscale Δ transition strain increased with tissue strain (Fig 2A, rest group $R=0.62$, $p<0.005$; no rest group $R=0.22$, $p=0.36$), suggesting damage related to tendon elongation. In addition, the Δ linear region modulus decreased with tissue strain (Fig. 2B, rest group $R= -0.73$, $p<0.005$; no rest group $R= -0.50$, $p<0.05$), which suggests strain dependent damage. Notably, there was no difference between the rest and no rest groups for transition strain slope (rest group: 0.23; no rest group: 0.18, $p>0.8$) or modulus slope (rest group: -6827MPa; no rest group: -6537MPa, $p>0.9$), suggesting non-recoverable macroscale changes and permanent damage to the tissue.

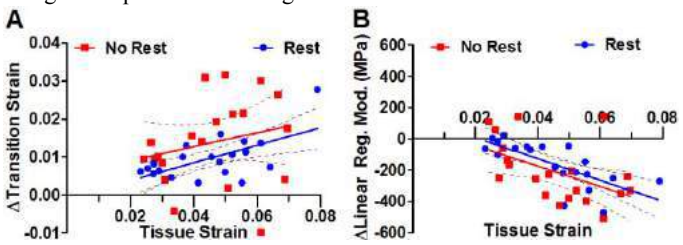

Fig. 2: Correlations between Δ transition strain (A) and Δ linear region modulus (B) with strain. No difference between no rest and rest group indicate non-recoverable permanent damage.

Microscale mechanical testing was used to investigate the structural source of the observed macroscale damage. Fibril strain elastically recovered in all strain groups with total recovery greater than 99.5% (Fig 3A). These findings suggest no fibril damage. Conversely, the interfibrillar sliding did not fully recover, with up to 50% non-recoverable sliding (Fig 3B), suggesting permanent damage. Fibril sliding recovery was also time-dependent, composed of both elastic (instantaneous) and viscoelastic recovery (Fig 3B).

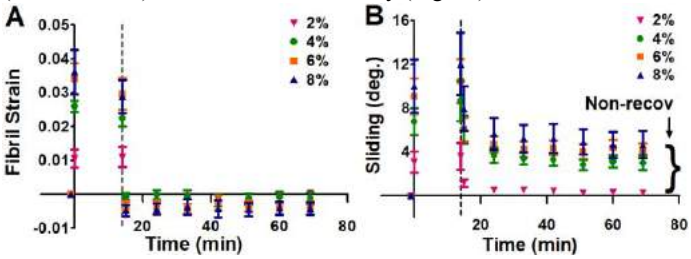

Fig. 3: Time course shows fibril strain fully recovered (A), but interfibrillar sliding recovery was incomplete (B). The dotted line represents when samples were unloaded. Error bars in SEM.

Surprisingly, while elastic sliding recovery was strain dependent (Fig 4A, $R= -0.53$, $p<0.005$), viscoelastic sliding recovery was not correlated with strain, and averaged 27.5± 8.9% across all strains (Fig 4B). This implies that the increase in non-recoverable sliding with tissue strain (Fig 4C, $R=0.64$, $p<0.0005$) was due to elastic sliding recovery. When relating the macro to micro parameters, non-recoverable sliding correlated with Δ transition strain (Fig 4D, $R= 0.57$, $p<0.005$), which suggests that the change in tissue transition strain may be caused by microscopic non-recoverable interfibrillar sliding.

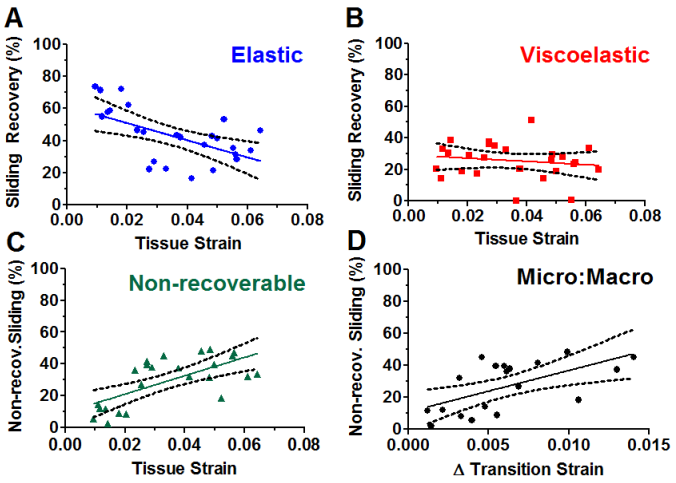

Fig. 4: Interfibrillar sliding is composed of elastic sliding recovery (A), viscoelastic sliding recovery (B), and non-recoverable sliding (C). The non-recoverable sliding contributed to the increase in translation strain (D).

DISCUSSION

This study elucidates mechanisms of tendon damage by measuring multiscale unloaded recovery following tensile loading. At the macroscale level, stretching past the elastic limit produces permanent damage (Fig 2), as expected. At the microscale level, the complete elastic recovery of the fibril strain suggests no damage to the primary load bearing collagen fibrils (Fig 3A). However, non-recoverable sliding increases with tissue strain due to a decrease in elastic sliding recovery (Fig 4A). This suggests that permanent elongation in tendon is primarily due to damage in the interfibrillar matrix, which is consistent with the assumption of plastic interfibrillar sliding within our shear lag model [1, 3]. In addition, non-recoverable sliding correlates with Δ transition strain (Fig 4D), suggesting that the observed permanent increase in transition strain can be explained by interfibrillar matrix damage at the microscopic level.

Although molecular structures responsible for matrix recovery are unknown, we hypothesize small diameter collagen fibrils may be a major contributor in elastic sliding recovery. Previously, our lab confirmed a network of small diameter fibrils connecting larger fibrils and these smaller fibrils may transfer loads between larger diameter fibrils [5]. At low strain, these undamaged elastic small fibrils may drive elastic sliding recovery but at high strain may lose helicity and destabilize [6]. Furthermore, we hypothesize that the non-collagenous matrix may be a major contributor in viscoelastic sliding recovery.

This study makes important advances on previously reported permanent elongation in overloaded tendon [7] and observations of microscale elastic recovery in tendon [8] by quantifying the time-dependent recovery and non-recoverable damage at multiple length scales. These findings are important in gaining insight into musculoskeletal injuries and designing rehabilitation strategies.

INTRODUCTION

Cell migration is known to play an important role in a number of physiological events in living body such as morphogenesis, wound healing, and tumor metastasis. In the majority of such events, cells move as a group, called collective cell migration. Compared to a single cell migration, the mechanism of collective cell migrations has not been understood well and attempts have been made in simple experimental setups exemplified by "wound healing" assay [1, 2]. However, this technique is vulnerable to artefacts associated to the creation of the wound. To overcome such limitations, Doran et al. [3] have proposed a new experimental device using MEMS techniques. A significant advantage of the device was the ability to maintain an intact surface prior to the commencement of the analysis of collective cell migration.

MEMS techniques have also been employed to measure cellular behaviours at micro- and nano-scales. One of such applications is an array of micropillars, where cellular traction forces can be determined from the deflection of the micropillars [4]. The purpose of the present study is to clarify the mechanism of collective cell migration at single cell level. To do this, we adopted the micropillar technology and integrated the micropillar arrays into a novel multichannel device [3]. With such novel experimental setup, traction force distribution within a cell collectivity was evaluated, which may reflect positional differences in mechanical roles of individual cells in collective cell migration.

METHODS

Mouse NIH 3T3 fibroblasts were cultured in DMEM (Gibco, USA) supplemented with 10% of FBS (Gibco) (DMEM + 10%FBS) at 37°C/5% CO_2 and used for experiments described below. A PDMS-made cell migration device was designed based on a device previously reported [3] and fabricated by standard photolithography and soft-lithography [4]. The current device consists of a reservoir (15.5 mm x 16.8 mm) with a flat surface for establishing a confluent cell monolayer, attached with microchannels for cell migration (Fig. 1). Each set of six microchannels branching off the reservoir converges at a single syringe port. Of six channels, four channels have arrays of micropillars (2 - 3 μm in diameter, 6.5 μm in height) at the bottom surface for the measurement of cell traction forces during migration, whereas the remaining two channels have a flat surface and serve as reference channels.

As shown in Fig. 1, a suspension of NIH 3T3 cells at a concentration of 5 x 10^5 cells/mL in DMEM + 10%FBS was loaded to the reservoir from the open top, following the sealing of the top of microchannels with the thin PDMS film. Due to the surface tension at the interface between the reservoir and the microchannels, the medium did not enter the channels. The cells were incubated at 37°C/5% CO_2 until a confluent monolayer was formed within the reservoir.

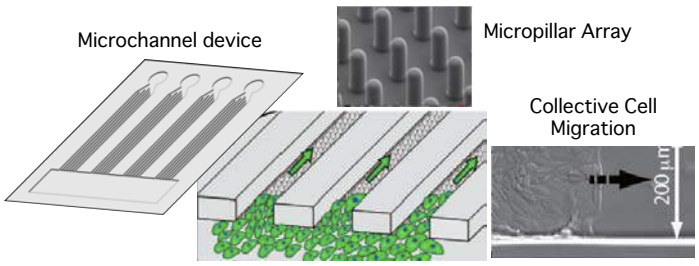

Fig. 1 Microchannel device with micropillar arrays.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

At the day of experiments, the device containing a confluent cell monolayer was set on a microscope stage. Cell migration was initiated when the microchannels were backfilled with the medium from the syringe port. A set of microscopic images of the top of micropillars including cells and the bottom of the same micropillars was obtained every 10 minutes with a x10 objective lens attached to an inverted microscope (IX81, Olympus, Japan). To determine traction forces for individual cells in a monolayer that demonstrated a collective migration, each individual cells was identified from microscopic images. Cellular traction forces were determined by measuring the deflection of the top of the micropillars [4]. Bright-field images were acquired using a CCD camera (ORCA-R2, Hamamatsu Photonics K.K., Japan) and the deflection was obtained through an image analysis using Image J (NIH). For small deflections, the micropillars behave like simple springs such that the bending force is directly proportional to the deflection of the micropillars. The spring constant of the micropillars was indirectly determined by cross-calibration.

RESULTS AND DISCUSSION

After the onset of cell migration experiment, the cells migrated into microchannels with both flat surface and micropillar substrates throughout a 26 h experimental period. Traction force microscopy was performed for the migrating cells (Fig. 2). In the analysis, cells on the moving front (leading cells) and those behind the leading cells (submarginal cells), particularly cells on the second and third rows, were chosen, as it was reported previously that cells within a certain distance from the moving front mainly committed to the forwarding movement of a cell collectivity [1]. It was observed that all the cells analysed generated traction forces but with different degrees. The leading cells generated traction forces over 10 nN at their leading edges, directing the backward of the moving direction. Cells on the second row generated smaller magnitude of traction forces. Most of traction force vectors directed the backward as in the case of the leading cells. Further small magnitude of traction forces was observed in cells on the third row, and the directions of these forces were varied compared to those from the cell on the first and second rows.

The present study demonstrated mechanical behaviour of cells within a moving collectivity at single cell level using a newly fabricated device combining elastic micropillar and microchannel structure. The results obtained demonstrate that cells consisting of collective cell migration generate traction forces with different magnitudes and directions depending on their relative positions, possibly reflecting positional differences in mechanical roles within a moving cell group. In particular, a gradual increase in the magnitude of traction forces towards the moving front may suggest reductions in the degree of cell-cell mechanical connections. Because cells near the moving front need to move forward and tug the rest of the cells within the collectivity, these cells may need to loosen cell-cell interactions and actively migrate like single cells. It remains to study how cells recognize their relative positions to modulate cell-cell and cell-matrix interactions and how mechanical/biochemical signals are transmitted between cells to achieve such coordinated cellular behaviours.

CONCLUSIONS

Measurement of traction forces, generated by cells to their local environment, has been proposed as a quantitative way to study mechanical behavior of collective cell migration. We measured the traction forces exerted by mouse NIH 3T3 fibroblasts during migration using a multichannel migration device with micropillars. It is assumed that cells on the front line generated large traction forces and migrated actively as single cells, pulling adjacent cells forward, whereas the movement of cells after the third row was restricted by mechanical linkages between their neighboring cells that generated smaller traction forces.

ACKNOWLEDGEMENTS

The present study was partially supported by JSPS Bilateral Joint Research Project (Japan-Australia, in collaboration with Prof. Justin Cooper-White). The device was fabricated at Creative Research Institution 'Sousei', Catalysis Research Center and Nanotechnology Research Center of Research Institute for Electronic Science at Hokkaido University.

INTRODUCTION

In the US, nearly 40,000 patients undergo mitral valve (MV) repair or replacement each year due to mitral regurgitation [1]. Due to the complications associated with mechanical and bioprosthetic valve replacement, the procedure of choice has become MV repair. However, recent studies have indicated that the long-term durability of surgical repair is significantly less than previously thought [2-4]. Patients undergoing MV repair for myxomatous disease had a 10% to 16% recurrence rate of MR that required reoperation within 10 years of surgery and patients with functional MR had a 30% recurrence rate at 6 months post-surgery and up to 60% after 3 to 5 years [2-4]. Repair failure was linked to the excessive tissue stress imposed by the sutures and the annuloplasty ring—non-physiological stresses on the tissue lead to suture dehiscence in both leaflets and annulus. Understanding the underlying mechanobiology of the compensatory response of mitral valve interstitial cells (VICs) to stress overload is necessary for developing better modeling tools and improving surgical repair. This study uses an *in vitro* system to answer specific questions on MV mechanobiology and provides insight into the micromechanics of surgically repaired MV by identifying cellular deformation as a potential mechanical basis for surgical repair failure.

METHODS

Bioreactor design & validation: The tissue strip bioreactor used is a modified version of the one previously described [5]. Cyclic stretch is applied with a stepper motor linear actuator. An in-house LabVIEW virtual instrument (VI) is used to control both the linear actuator and the load cell and collect load data and actuator displacement.

Tissue preparation and Bioreactor Treatment: For each bioreactor treatment group, n = 8 MVs were used (Fig. 1). Fresh porcine hearts were collected from young hogs from a local USDA approved abattoir. Rectangular strips (11.5 mm x 7.6 mm) were dissected from the clear zone of the anterior leaflet, sutured, mounted into the cyclic stretch bioreactor, then cyclically stretched for 48 hours (at either 0%, 10%, or 30% stretch) at 1.17 Hz within an incubator maintained at 37°C and 5% CO_2. At the end of each treatment, samples were either fixed or snap-frozen for further analysis as described below.

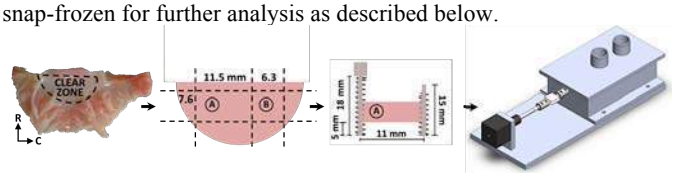

Figure 1: MVAL samples for bioreactor treatment. Rectangular samples are sutured on the sides using springs and mounted into the load-sensing tissue strip bioreactor.

Cell and tissue deformation: A group of n = 9 valves was used for microenvironment and cell deformation analysis. Briefly, MVAL samples were mounted on the bioreactor, subjected to a single extension of 10, 20, or 30% strain, and fixed along the circumferential direction with 2.5% EM grade glutaraldehyde for 4 hours. The fixed tissue was prepared using standard protocol, sectioned (70 nm), and imaged using transmission electron microscopy. VIC cytoplasmic and nuclear aspect ratios were calculated by measuring the major and minor axes of the cytoplasm and nucleus, respectively. *Tissue Deformation:* A second group of fixed tissue was used for collagen fiber alignment. Briefly, the fixed samples were dehydrated, cleared in a graded glycerol/water solution and stored in 100% glycerol. A non-polarized laser was passed through the tissue. The normalized orientation index (NOI) was used to quantify tissue deformation.

ECM Biosynthesis and Cell activation: Samples were fixed with formalin, embedded in paraffin, sectioned (5μm), and stained with

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Movat pentachrome to analyze layer-specific morphological changes. Staining for α -SMA was performed to quantify VIC activation. Collagen, elastin, and glycosaminoglycan content were quantified using the Sircol, Fastin, and Blyscan assays, respectively.

Finite Element Numerical Prediction of VIC deformation: Using our macro-micro finite element (FE) model of the MVAL [6], a representative volume element of the fibrosa layer that takes into account microstructural composition was constructed. Displacements imposed by the bioreactor on the tissue were used as the boundary displacements of the RVE. MVIC deformation in the fibrosa layer was simulated and quantified by the ratio of the cytoplasmic over the transmural dimensions, defined as the nuclear aspect ratio (NAR).

RESULTS

Tissue micromechanics increase nonlinearly with strain: The collagen fiber alignment data shows that overall tissue alignment remains the same at 10% and 20%, indicating that the collagen fibers do not undergo any major changes at physiological strains. This said, at the 30% strain, there is a substantial increase in fiber alignment, highlighting the non-linear MVAL micromechanics (Fig. 2). Interestingly, VIC deformation shows a similar trend, whereby cytoplasmic deformation decouples from nuclear deformation at hyper-physiological strain levels and increases sharply.

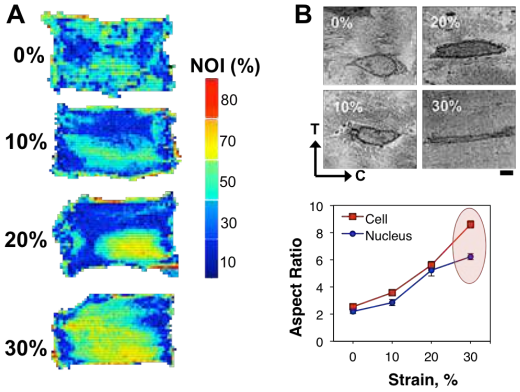

Figure 2: (A) Collagen fiber alignment maps. (B) Representative MVIC from samples at different strain levels. Scale bar: 5 µm.

Cellular activation initiates in the outer layers of the MV: In non-diseased valves, VICs have a quiescent, fibroblast-like phenotype. When activated, the VIC phenotype changes as they begin to exhibit myofibroblast properties, mainly an upregulation in α-smooth muscle actin (α-SMA). Immunohistochemistry of α-SMA shows that the cells in the outer layers, thus, the atrialis/spongiosa and ventricularis, begin to express α-SMA before the cells in the fibrosa layers at 20% strain level. At 30% strain, cells across all layers of the MV express α-SMA.

Biosynthetic activity increases at hyper-physiological levels: When activated to their myofibroblast phenotype, VICs exhibit increased biosynthetic activity. Results from the Sircol colorimetric assay show a significant increase in collagen biosynthesis at hyper-physiological levels. This is in line with not only the increased α-SMA expression, but also the changes observed in tissue micromechanics and cellular deformation (Fig. 3). Results from the Blyscan assay reveal sulfated-glycosaminoglycan (s-GAG) leaching into the media, which is characteristic of valve tissue that undergoes physiological cyclic stretch *in vitro*. This said, the level of leaching decreases at hyper-physiological levels, suggesting an upregulation of s-GAG synthesis at these levels. The repeated measures design allows us to analyze the data sample-by-sample and identify outliers.

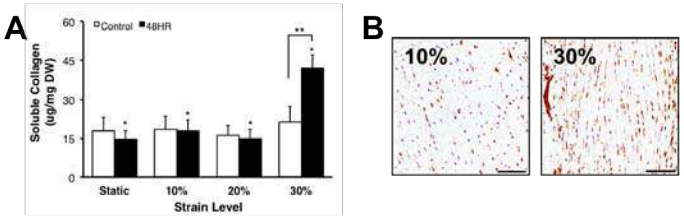

Figure 3: (A) Acid-Pepsin soluble collagen before and after cyclic stretch treatment at different strain levels. B) α-SMA expression in samples subjected to 10% and 30% strain. Scale bar: 250 µm

MVIC NAR can be used as a tool to link the current uniaxial bioreactor to physiological deformation modes: Simulations of MVIC NAR in the fibrosa layer using the macro-micro MV FE model were in agreement with the experimental measurements. Under physiological biaxial deformation modes (ranging from 0 to 150 N/m), MVICs in the fibrosa have an NAR that ranges from 2.5 to 3.5, respectively. When linked to the uniaxial deformation mode, such a NAR occurs when the tissue is strained by ~12.5% in the circumferential direction. When deformed above the physiological range (NAR>3.5), MVICs appear to be activated and exhibit substantial biosynthetic activity as indicated by the colorimetric assay results.

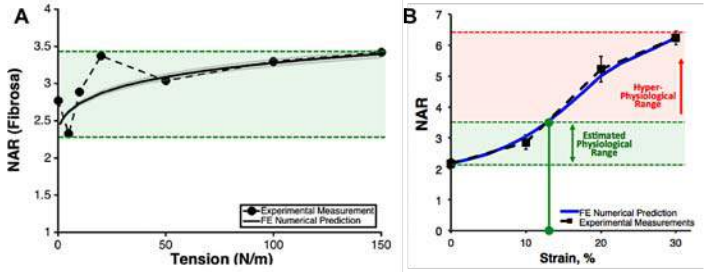

Figure 4: (A) NAR under equibiaxial deformation modes. (B) Simulated vs. Experimental NAR under uniaxial stretch. The MVIC NAR from the biaxial system can be used to link the uniaxial system to physiological and hyper-physiological deformation modes.

DISCUSSION

Results from this study reveal an important link between MV micromechanics and MVIC biosynthetic response, primarily an increase in VIC activation and biosynthetic activity at NAR>3.5. This study provides important insights into the micromechanics of surgically repaired MVs by identifying cellular deformation as a potential mechanical basis for surgical repair failure**.** Though novel and a first attempt to link MVIC deformation to biosynthetic response, this tissue strip bioreactor does not replicate the micromechanics of the physiological environment, which impose strains on both radial and circumferential directions. Future work will focus on improving the *in vitro* system by designing a more physiologically realistic bioreactor that imposes biaxial deformation modes on the valve tissue.

INTRODUCTION

The mitral valve (MV) is an integral part of the left ventricle (LV), connected via the papillary muscles (PMs) and annulus. Changes to the geometry or contractile motion of the LV thus affect the external boundary conditions of the MV, which in turn place the MV leaflets in a state of altered strain. In response to this, the MV undergoes a complex process of growth and remodeling (G&R) in an attempt to adapt to its new ventricular environment.

Pregnancy represents a non-pathological, LV volume overload paradigm for increased MV loading. It has been shown to produce rapid, dramatic changes in the mechanical behavior and structure of MV leaflet tissue [1,2]. Interestingly, the mechanical behavior of the MV anterior leaflet undergoes a biphasic change during pregnancy; with the apparent stiffness of the leaflet increasing significantly in early pregnancy but returning to normal by the end of pregnancy [1]. In contrast, a more recent investigation into structural changes of MV collagen during pregnancy uncovered no biphasic changes, but instead found only monotonic changes in mass fraction, fiber direction, and fiber alignment [2].

The objective of the present study was to reconcile these two sets of seemingly contradictory results by using a structural constitutive modeling approach that could unify the biphasic mechanical and monotonic structural trends of these previous studies. This goal sets the stage for developing a comprehensive G&R model of MV tissues.

METHODS

Data Collection and Processing. Experimental methods for tissue harvest and mechanical testing have been described previously [1]. Briefly, fresh MV anterior leaflets from 5 never-pregnant heifers (NP) and 10 pregnant cows (P) at a variety of post-conception time points were excised, and their dimensions were measured. A rectangular specimen from the belly region of each anterior leaflet was mechanically preconditioned and loaded under a membrane tension-controlled equibiaxial protocol to a peak tension of 60 N/m in both directions. The Green-Lagrange strain ($\mathbf{E}$) and second Piola-Kirchhoff stress tensors ($\mathbf{S}$) were calculated at each loading state, referenced to the current excised state. To establish direct correspondence between NP and P material behaviors, the constitutive relation for all specimens was expressed with respect to a single pre-pregnant reference configuration, estimated from dimensional changes for P specimens.

Constitutive Model. We utilized a meso-scale structural constitutive model (MSSCM) for MV leaflet tissues [3]. Under this formulation, the total stress in the leaflet was assumed to be the weighted linear sum of the stresses borne by the underlying collagen and elastin fiber networks. The collagen phase is modeled at the level of an undulated fiber ensemble, which exhibits the properties of a unidirectional population of collagen fibers having a bounded distribution of slack strains with lower bound E_{lb} and upper bound E_{ub}. We modeled the distribution of slack strains D with mean μ_D and standard deviation σ_D using a beta distribution to describe the recruitment of fibers in an ensemble.

We defined a beta-distributed orientation distribution function (ODF) $\Gamma(\theta)$ mapped onto $\left[-\pi/2, \pi/2\right]$ with mean μ_Γ and standard deviation σ_Γ, which describes the directional density of fibers at any angle θ from the circumferential axis. The total stress in the collagen network is the sum of stresses along all ensemble directions, weighted by the ODF.

In accordance with previous findings, the elastin phase was modeled as the superposition of two orthogonal populations. Skipping several derivation steps, the sum of the stresses borne by collagen and elastin, weighted by mass fractions ϕ_c and ϕ_e respectively, yields the total tissue-level $\mathbf{S}$ as

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\mathbf{S}(\mathbf{E}) = \phi_c \eta_c \int_{-\pi/2}^{\pi/2} \Gamma(\mu_\Gamma, \sigma_\Gamma, \theta) \left[\int_0^{E_{ens}} \frac{D(\mu_D, \sigma_D, E_{lb}, E_{ub}, x)}{2x+1} \left(1 - \sqrt{\frac{2x+1}{2E_{ens}+1}}\right) dx \right] (\hat{N} \otimes \hat{N}) d\theta + \phi_e \left[\eta_e^C (I_4 - 1)(\hat{N}_C \otimes \hat{N}_C) + \eta_e^R (I_6 - 1)(\hat{N}_R \otimes \hat{N}_R) \right] \quad (1)$$

where $\{\eta_c, \eta_e^C, \eta_e^R\}$ are the effective stiffness moduli of collagen, circumferential elastin, and radial elastin, respectively; $E_{ens} = \hat{N}^T \mathbf{E} \hat{N}$ is the strain for an ensemble pointing in $\hat{N}$; $\{\hat{N}_C, \hat{N}_R\}$ are the circumferential and radial direction vectors, respectively; $I_4 = \hat{N}_C{}^T (\mathbf{F}^T \mathbf{F}) \hat{N}_C$; and $I_6 = \hat{N}_R{}^T (\mathbf{F}^T \mathbf{F}) \hat{N}_R$. The contributions of the collagen and elastin terms can be easily decomposed.

Parameter Estimation. Collagen and elastin moduli were fixed and volume fractions were taken from previous findings [2]. The remaining structural parameters of the recruitment function D and ODF Γ were estimated using a Differential Evolution search algorithm implemented in Wolfram Mathematica [3].

RESULTS

Leaflet Dimensions. Reanalysis of previous dimensional results from [2] showed that circumferential and radial leaflet lengths increase monotonically with fetal age, reaching growth stretches of 1.4 and 1.2 respectively by term (Figure 1; $R^2 = 0.510$ and 0.226, $p < 0.01$).

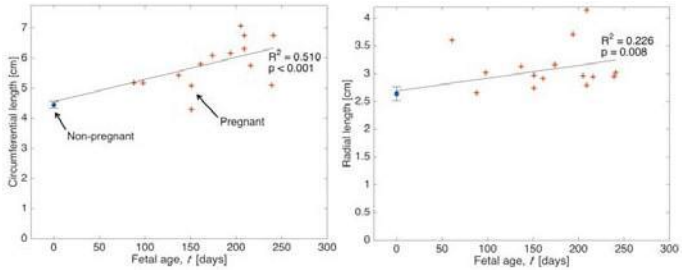

Figure 1: Circumferential (left) and radial (right) leaflet lengths versus fetal age, showing a monotonic increase in both.

Model Fitting. The MSSCM generated excellent fits to the mechanical data, achieving $R^2 = 0.940$ on average (Figure 2).

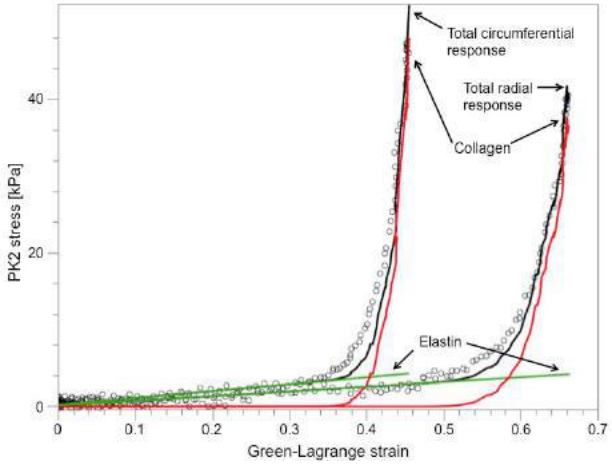

Figure 2: Sample fit, showing collagen and elastin contributions.

Collagen Fiber Orientation. The preferred fiber angle μ_Γ increased significantly in pregnancy (7° in P specimens compared to 3° in NP, $p = 0.035$). In addition, the splay of collagen fibers σ_Γ decreased modestly in early pregnancy but then increased continuously beyond its NP value ($p = 0.036$).

Collagen Fiber Recruitment. The mean stretch value at which collagen fibers were recruited (calculated from μ_D) was found to correlate strongly with fetal age (Figure 3; $R^2 = 0.572$, $p = 0.006$). Specifically, the results show a sharp drop from NP in early pregnancy, followed by a gradual return to NP range during middle and late pregnancy. In contrast to the results, passive stretching to match the dimensional changes would have caused recruitment stretch to decrease monotonically, since fibers would become progressively less crimped. Our results are thus evidence of the significant role that G&R play in actively changing the fiber structure of the MV.

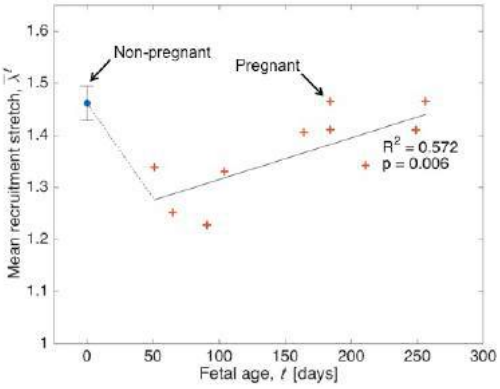

Figure 3: Mean recruitment stretch for both NP and P specimens, showing a trend that mirrors that of the leaflet's extensibility.

DISCUSSION

In this study, we have used a structural constitutive model to directly deduce changes in collagen fiber architecture during pregnancy. Our results provide the first detailed structural information of MV remodeling *in vivo*. While the changes in ODF parameters are primarily monotonic, continual G&R bring about a biphasic trend in mean recruitment stretch mirroring that of the mechanical response of the leaflet, which exhibits decreased extensibility in early pregnancy and a full recovery of the pre-pregnant response by term [1].

While early pregnancy parameter results are consistent with what would be expected under passive stretching (i.e. no G&R), the results deviate significantly from that trend after about 80 days. We hypothesize that G&R in the MV is mediated by deformations of the embedded interstitial cells [4], which would suggest that there is a threshold of abnormal cellular deformation beyond which G&R is triggered in an effort to restore homeostasis and physiological function. Future studies must aim to draw a more intimate connection between these mechanical and biological realms of valvular G&R under overload-induced conditions of increased leaflet strain.

INTRODUCTION

In glaucoma, the progressive loss of the retinal ganglion cells (RGCs) in the optic nerve head leads to permanent vision loss and eventual blindness. The intraocular pressure (IOP) is associated with the prevalence and severity of glaucoma damage, and the level of IOP is used to screen for the disease. Animal studies have shown that a chronic increase in IOP causes glaucoma damage, and lowering pressure slows the progression of damage in the majority of patients. However, there is a wide distribution of IOP among glaucoma patients and among those without glaucoma. While glaucoma patients on average have higher IOP, nearly half of those with glaucoma damage have IOP in the normal range. Moreover, a significant number of those with higher IOP do not have glaucoma damage [1-4]. These observations suggest that the susceptibility of the ONH to glaucoma damage might depend on its mechanical response of the ONH and surrounding sclera. Computational modeling studies of the posterior sclera have suggested that the elastic modulus of the LC and sclera strongly correlates with the strains experienced in the LC [5].

Both clinical and laboratory studies have measured differences in the mechanical behavior and structure of the posterior sclera, LC and ONH of glaucoma and normal eyes. Structural changes in glaucoma include the remodeling of the anisotropic collagen fiber and elastin structure at the lamina cribrosa [4] and axial elongation and thinning of the sclera [6-8]. Hommer et al [9] measured an increase in ocular rigidity with the progress of open-angle glaucoma. Downs et al [10] found a larger relaxation modulus for scleral strips from monkey eyes with experimentally induced early glaucoma. Girard et al measured a stiffening of the sclera [11]. Coudrillier et al [12] reported a thickening of the peripapillary sclera, slower circumferential creep rates, and a stiffer behavior in the meridional direction of the peripapillary sclera in human eyes with glaucoma. Few studies have measured the mechanical behavior of the lamina cribrosa. In this study, we present a method to measure the three-dimensional deformation field in the lamina cribrosa under controlled inflation. The method uses laser-scanning second harmonic generation microscopy to image the collagen structures of the deforming volume of the lamina cribrosa and digital volume correlation for deformation mapping.

METHODS

Six human eyes from 5 donors (ages 26-71) obtained within 48 hours post-mortem had the choroid and retina removed, the optic nerve removed at the sclera (the myelin line), and the posterior sclera mounted on a custom inflation chamber. The pressure was raised to 5, 10, and 45 mmHg. A Zeiss LSM 710 NLO microscope, tuned to 790nm with a band pass 390-410nm filter, was used to acquire two duplicate stacks of the LC structure using second harmonic generation (SHG) imaging at each pressure. The SHG stacks were treated with Huygens Essential deconvolution algorithm using a theoretical point spread function (SVI) and local adaptive histogram equalization (FIJI) to enhance contrast. The Fast Iterative Digital Volume Correlation (DVC) algorithm [14] was used to post-process the SHG stacks to calculate the 3D displacement fields and correlation error. The correlation coefficient was used to remove poorly correlating subsets and Gaussian filtering was used to remove local error spots. Strains were calculated by fitting a high order polynomial function to the displacement field and taking the gradient locally. The LC was divided into 4 quadrants surrounding the central retinal artery and vein (inferior-nasal (IN), inferior-temporal (IT), superior-nasal (SN), superior-temporal (ST). The principal strains were averaged and analyzed for regional differences.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Displacements and strains in the LC exhibited substantial variation in the plane but not through the thickness (Figure 1). The average shear strains (in plane: -0.15±0.14%, out of plane: -0.22±0.23%, 0.19±0.34%) were significantly smaller than the normal strains. For nearly all eyes, the strain at 45mmHg along the inferior-superior axis (3.02±1.09%) was larger than along the nasal-temporal axis (2.03±0.75%). The maximum principal strain was largest in the IT quadrant and smallest in the IN quadrant. In paired t-tests, the maximum principal strain in IT was significantly larger than in IN (p=0.026) and nearly significantly larger than in SN (p=0.067) and IT (p=0.076).

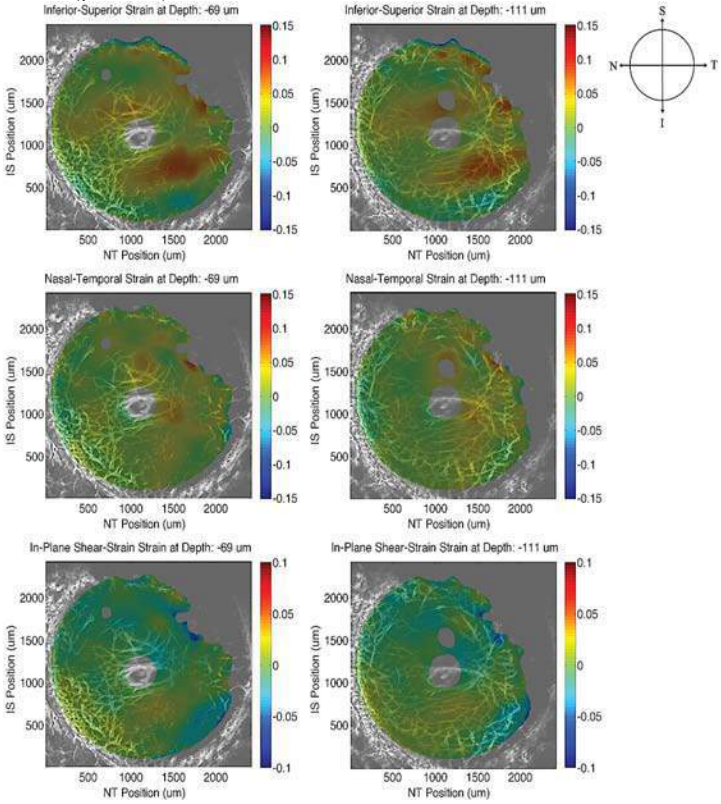

Figure 1, Contour plots of the in-plane normal and shear strains for the LC of a 57-year old Caucasian male

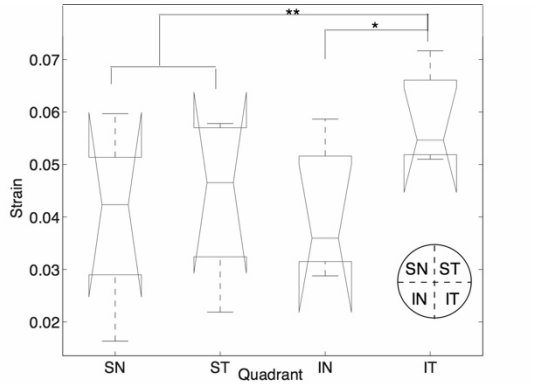

Figure 2, Maximum principal strain in the human LC at 45 mmHg. The IT quadrant was statistically larger than the IN (*p<0.05), SN and ST (p<0.1) quadrants.**

DISCUSSION

This study demonstrates that the configuration of collagen in the human LC, imaged by SHG in an inflation experiment, can be correlated using DVC. This allows for the calculation of 3D displacement and strain fields at high resolution for in-vivo LC tissues as a function of applied pressure. Preliminary data suggests strong anisotropy in the strain response of the LC, which may help to explain the progression of axonal damage in glaucoma. The current body of research indicates that glaucoma pathologically remodels the tissues of the ONH in a way that causes constriction of the nerve cross-section and "cupping" at the ONH, a phenomenon where the rim of the tissue making up the ONH narrows and deepens. RGCs with larger diameter are damaged first indicating straining of the nerves may be a major cause of damage. The injury pattern typically expresses in an hourglass shape with preferentially greater injury at the superior and inferior poles. [1] Our results indicated greater strains in the inferior-superior direction which would lead to warping of the ONH cross section and greater strains on the RGCs at the inferior and superior poles, which agrees with known glaucoma damage patterns. The main limitation of the study is insufficient resolution to calculate accurate out of plane strains.

WHEN THEATRE COMES TO CAPSTONE DESIGN: OH HOW CREATIVE THEY CAN BE…

INTRODUCTION

The creative process is fun, complex, and sometimes frustrating, but it is critical to the future of our nation and progress in science, technology, engineering, mathematics, as well as a multitude of other fields. Part artist and part scientist, successful innovators and entrepreneurs are fueled by a passion to find a solution. A pursuit of innovation can be instilled at an early age and, properly fostered, can help develop students into 21st century creative scientists, engineers, and innovators [1]. It may seem quite unconventional to some, but successful engineers and artists share many qualities particularly in areas of creativity. How this creativity is manifested in the engineer and artist sometimes varies widely. Engineers often create with more tangible materials such as metal and plastic while artists may create with more abstract materials (e.g. paint, voice, instrument, body, etc). This divergence in creative expression is due in part to the educational experience of each discipline. By the time most engineers and artists reach undergraduate education they are on very different paths in how they acquire, interpret, and present knowledge. As a teacher and mentor of many engineering students, I see the value of having innovative, creative, self-motivated, and sometimes fearless individuals who can develop unique solutions. We often hear this referred to as "thinking outside the box". It turns out, that most artists are innovative, creative, self-motivated, and mostly fearless in their craft. Thus, we set out to see if implementing methods of active learning typical to the theatre department could impact the creativity of senior capstone design students in the Bioengineering department.

METHODS

Senior Bioengineering (BE) capstone design students (n=45) were allowed to self-select into groups (n=5 per group) based upon capstone design projects pre-identified by the faculty mentors facilitating the class. A sub-set of these students (3 groups; n=15 total students) were randomly assigned to be in the experimental (E) group. All other students were assigned to be in the control (C) group.

Prior to the beginning of coursework, all students completed a validated survey measuring engineering design self-efficacy [2]. Albert Bandura's theory of self-efficacy proposes that people's beliefs in their capability to achieve a task affect their actual ability to achieve that task--if they have the requisite skills. Noted psychologist Bandura points to numerous studies showing that people who rate their self-efficacy high for a particular task will be more motivated, and will perform better, than people with more ability who rate their self-efficacy lower [3]. Self-efficacy theory is very relevant to creativity, since experts point out that a system designed to educate students for the industrial age squashes the creativity out of them. Students are conditioned to believe they inherently lack creativity, and any approach to creativity education must address this issue and help students to rediscover their innate creative potential [4].

The control and experimental groups both received standard instruction, but in addition the experimental group received one hour per week of creativity training developed by a theatre professor. Having taken a faculty development leave in 2010/2011 to design a course in creativity for non-arts majors which she has since taught annually, the professor and a graduate assistant led the engineering students in a condensed version of her creativity course. This active learning process integrated techniques drawn from actor training, improvisation, and theatre of the oppressed [**5]** with creative problem-solving methods drawn from multiple research-based sources [6]. For instance, a short lecture comparing convergent and divergent thinking was immediately followed by a theatre exercise in which the class, divided into two

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

groups, put divergent thinking into action by quickly inventing forty ways to cross a room. Theatre games helped the students develop a safe, supportive environment in which students could begin to venture outside their comfort zones. Unless one is willing to risk trying something new—and making mistakes--one can't be creative. Theatre exercises also enabled students to open their minds, question assumptions, and see things differently, since creativity is more about seeing things differently than seeing different things. Other exercises involved active listening, framing and reframing their creative problems, using analogies to brainstorm solutions, and evaluating and refining solutions.

Following the semester, the students again completed the self-efficacy survey. The surveys were examined to identify differences in the initial and final self-efficacy as well as to compare change in the experimental and control groups over the course of the semester. An analysis of variance was used to compare the experimental and control groups with $p<0.05$ considered significant.

RESULTS

Students in the experimental group reported more than a two-fold (4.8 (C) vs 10.9 (E)) increase of confidence in their ability to perform engineering design following a single semester of creativity education (Figure 1 column a). Substantial increases in student confidence were seen in other surveyed areas as well with the exception of prototype development (Figure 1 column f) and design evaluation (Figure 1 column g). Additionally, students in the experimental group were more motivated (4.2 (E) vs 0.2 (C)) (Figure 2) and less anxious (-7 (E) vs -6.2 (C)) (Figure 3) when engaging in engineering design following the semester of creativity instruction.

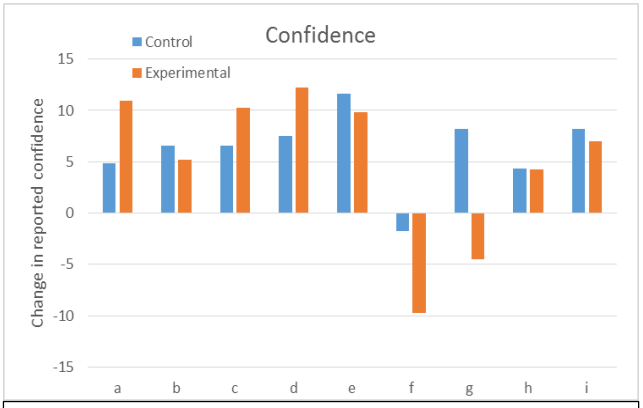

Figure 1. Student self-reported change in confidence in the engineering design process following a semester using a "curriculum of creativity".

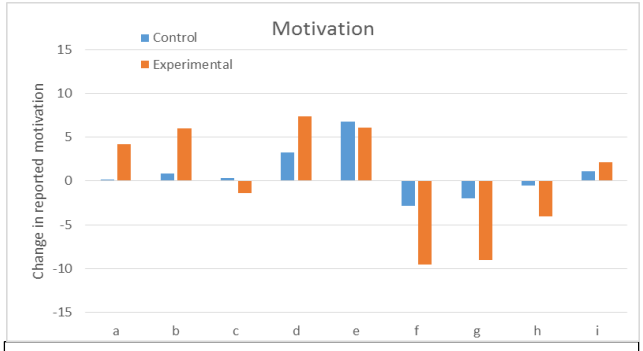

Figure 2. Student self-reported change in motivation in the engineering design process following a semester using a "curriculum of creativity".

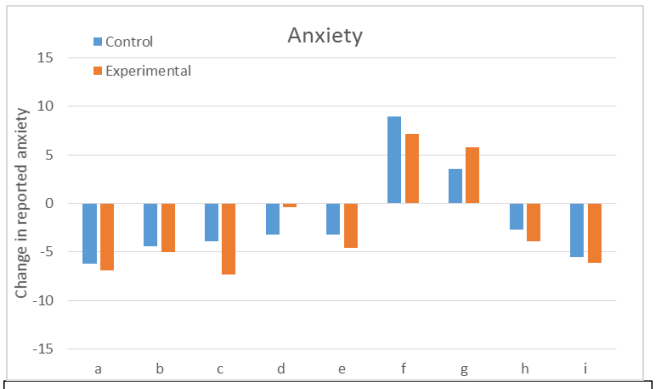

Figure 3. Student self-reported change in anxiety in the engineering design process following a semester using a "curriculum of creativity".

The only surveyed area in which students in the experimental group were significantly less confident and motivated as well as more anxious than students in the control group was in the area of constructing a prototype and evaluating their design (Figures 1-3 columns f and g). Prototyping and design evaluation were not a focus of the class in general and such tasks were not covered in the creativity curriculum. However, plans are underway to include activities to strengthen these areas in future classes.

DISCUSSION

The results of this pilot study indicate there is significant potential to improve engineering students' creative self-efficacy through the implementation of a "curriculum of creativity" which is developed using theatre methods. Further research is needed to evaluate the long term effects of such instruction. We also intend to investigate if this type of instruction can be deployed throughout other courses along the spectrum of the engineering undergraduate education. This pilot work provides promising initial data which can help refine methods and shows the potential for increasing student creativity using an unconventional approach.

INTRODUCTION

Both injury and disease reduce synovial fluid's ability to lubricate articular cartilage, and recently, inferior lubrication has been linked to chondrocyte apoptosis [1]. However, the specific biological mechanisms and mechanical thresholds that lead to this cell death remain unknown. Both cell death and mitochondrial (MT) dysfunction within articular chondrocytes can accompany impact injuries, and both are correlated with tissue strain [2-3]. Additionally, tissue strain during articulation is a function of both lubricant composition (i.e., friction coefficient) and depth from the tissue surface [4-5]. Thus, the goals of this study were: 1) to measure the depth-dependent shear strains of cartilage for friction coefficients that span the range between injury and disease, and 2) to connect these results to cellular changes within articular cartilage including cell death and MT dysfunction. Collectively, these data will help to describe what role inferior lubrication may play in the progression of cartilage damage.

METHODS

Cartilage was obtained from the femoral condyles of 1-3 day old bovids. Friction coefficients were measured against glass under 15% normal strains while lubricated by either PBS or equine synovial fluid (ESF). Samples were articulated for 30 cycles at 1 mm/s (Fig 1A) then allowed to reequlibrate in DMEM for 90 minutes. This set-up was mounted in parallel on an inverted confocal microscope, and local shear strains of 5-DTAF stained cartilage were measured by tracking the displacements of photobleached lines (Fig 1B). Slid samples and controls without 5-DTAF were stained with either calcein AM and ethidium homodimer (for live and dead cells, respectively) or MitoTracker Green (MTrG) and tetramethylrhodamine methyl ester (TMRM) (for all MT and functional MT, respectively). Percent cell death and MT dysfunction were calculated through image analysis conducted using ImageJ.

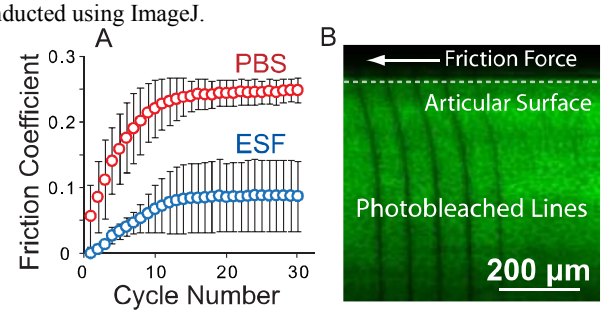

Figure 1: (A) Friction coefficients for PBS- and synovial fluid-lubricated cartilage (n=4). (B) Frictional shear strains are tracked on a confocal microscope.

RESULTS

The friction coefficient of cartilage lubricated by ESF was 70% lower than PBS (0.08 to 0.26, Fig 1A), and depth-dependent shear strain profiles scaled similarly (Fig 2). In the ESF lubricated cartilage, shear strains near the surface were ~4% and leveled off to ~1% in deeper tissue, but for the PBS group, shear strains were over 9% near the surface and under 5% in deeper tissue. In non-slid control tissue, minimal cell death was found (Fig 3CD). For ESF-lubricated cartilage, cell death was localized to the region less than 50 μm from the surface, within the two most superficial cell layers (Fig 3BD). However, for PBS-lubricated cartilage, cell death extended over 100 μm from the articular surface (Fig 3AD). In contrast to cell death data, sliding in both PBS and ESF caused MT dysfunction in the superficial zone (top most 100 μm).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

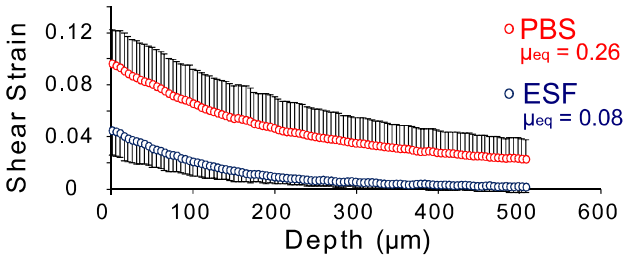

Figure 2: Frictional shear strains are dependent on lubricant composition, friction coefficient (μ_{eq}), and tissue depth (n=6-7).

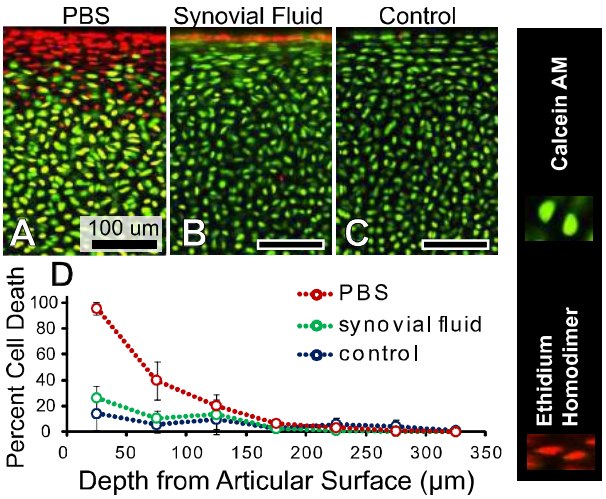

Figure 3: (A-C) Live dead staining of cartilage with different friction conditions. (D) Cell death was most pronounced in the superficial 100μm of PBS-lubricated cartilage (n=4).

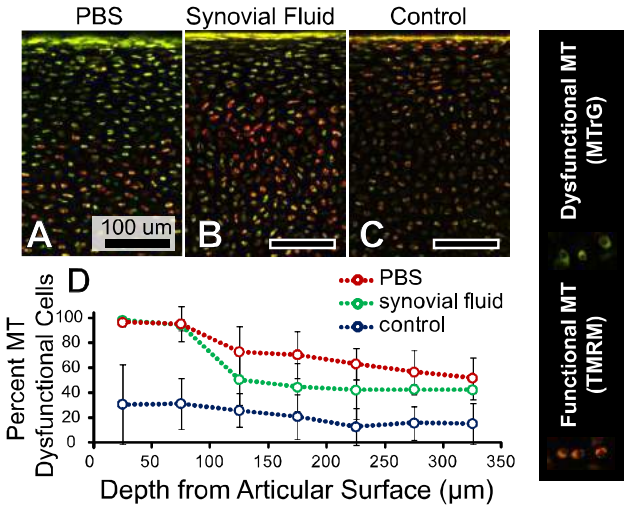

Figure 4: (A-C) MT staining of cartilage with different friction conditions. (D) MT dysfunction was most pronounced in the superficial 100μm of PBS- and ESF-lubricated cartilage (n=4).

For the control tissue, colocalization of MTrG (staining all MT) and TMRM (staining only polarized MT) occurred within functional chondrocytes near the surface (within 100 μm) (Fig 4CD). However for both ESF and PBS, colocalization of both MTrG and TMRM was rare within the superficial tissue (Fig 4).

DISCUSSION

This study connected cartilage friction coefficient with depth-dependent shear strains in cartilage to understand mechanical cues that lead to both cell death and MT dysfunction (Fig 5). We revealed significant cell death within the superficial 100 μm of cartilage lubricated by PBS where shear strains ranged from 7% to 9% (Fig 5A). This region is known to have increased apoptosis in joints with high boundary friction [1]. Conversely, minimal cell death was detected in the ESF-lubricated tissue, likely due to the lower shear strains (~4%, Fig 5B). Interestingly, both ESF- and PBS-lubricated cartilage displayed mitochondrial dysfunction within the superficial 100 μm of tissue. While this result can be attributed to cell death in the PBS group, it is likely that live cells in the ESF group may be destined for MT-mediated apoptosis. Notably, although the deeper chondrocytes in the PBS group were exposed to high shear strains (~4%) there was little evidence of MT dysfunction (Fig 5C). However, superficial cells in the ESF group experience similar shear strains but displayed pronounced MT dysfunction (Fig 5D). This phenomenon may indicate that the chondrocytes in the different regions of articular cartilage respond differently to mechanical signals regarding both necrosis and apoptosis, and that dysfunctional cells may be an important target for restabilization and ultimate prevention of PTOA.

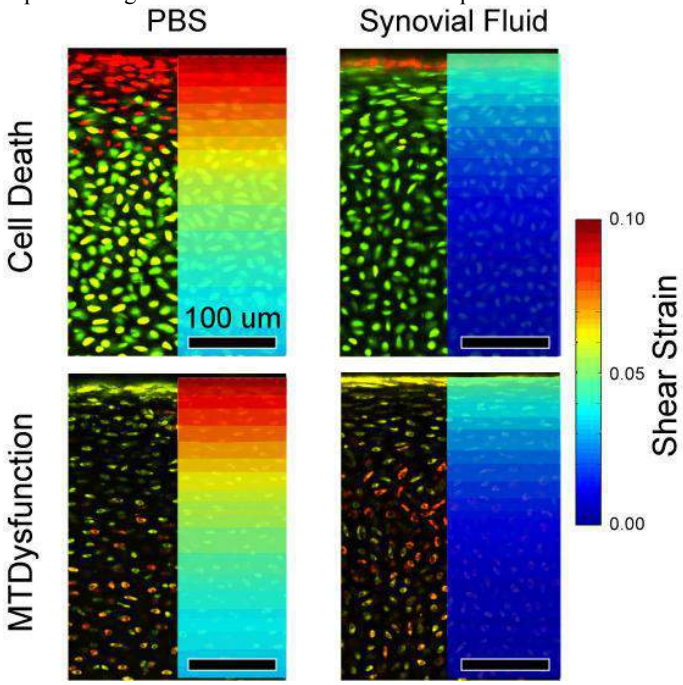

Figure 5: Strain field overlays reveal the relationships between shear strain and both cell death and MT dysfunction. For PBS-lubricated tissue, cell death and MT dysfunction were localized to high strain regions. For ESF-lubricated tissue, minimal cell death, but significant MT dysfunction were localized to superficial tissue.

THE INFLUENCE OF GEL STIFFNESS ON GROWTH FACTOR GENE EXPRESSION OF SCHWANN CELLS

Carlisle R. DeJulius (1), Rebecca Kuntz Willits (1)

(1) Department of Biomedical Engineering
The University of Akron
Akron, Ohio, U.S.A.

INTRODUCTION

There are an estimated 360,000 instances of injury to peripheral nerves per year in the United States. These injuries can be very debilitating to patients, causing paralysis in the worst cases. If regeneration is possible, the unaided rate of neuronal repair is 1mm/day[1]. Schwann cells are glial cells in the peripheral nervous system that provide support to neurons. Under normal conditions, Schwann cells insulate axons to protect them while secreting neural growth factors such as glial cell line-derived neurotrophic factor (GDNF) and neurotrophin-3 (NT-3)[2]. When nerves are damaged, Schwann cells serve to break down debris and encourage regeneration of the neurons. Studies of nerve regeneration seek a method to speed the growth rate of injured neurons. One option is to use a three-dimensional scaffold to act as a bridge between the severed ends. This study makes use of poly(ethylene glycol) (PEG) hydrogels as an eligible material. PEG is suitable because both the mechanical and chemical properties of PEG gels can be easily modified[3].

Because Schwann cells are vital to neuronal health, this project aims to investigate the gene expression of these cells with particular focus on key growth factors. Previous work has shown increased proliferation of Schwann cells within 3D scaffolds with modulus of ~500 Pa[2]. Therefore, we hypothesized that the expression of growth factors in Schwann cells are up-regulated gels of similar stiffness to maximum proliferation.

METHODS

Isolating RNA from Cells Cultured in PEG Hydrogels: Primary rat Schwann cells were isolated for other studies to ~100% purity (via S-100). PEG gels were prepared using 3kDa PEG diacrylate (PEGDA) at a concentration of 5% by mixing PEGDA, 0.5% Irgacure (photoinitiator), and phosphate-buffered saline (PBS). Cells were encapsulated in the gels at a concentration of 400,000 cells/mL. Trizol was added to the gels, and after centrifugation, the Trizol-cell solution was removed to a new tube and chloroform was added to enhance phase separation. The RNA was precipitated using 100% isopropanol. The pellet was washed 3 times with 75% ethanol and resuspended in molecular biology-grade water. A DNA digestion was performed using PerfeCTa DNase I Kit (Quanta Biosciences). RNA quality was evaluated using gel electrophoresis and spectroscopy.

Testing Stiffness of PEG Hydrogels: Oscillatory shear rheometry (8mm parallel plate) was used to measure the shear modulus (G*) of the hydrogels (n=4 for each test). The strain was kept constant at 5% and moduli were taken at 10rad/s. The goal G* were selected to match a previous study[2] at 130Pa, 240Pa, 560Pa, and 720Pa. ANOVA was used to test significance of results ($p<0.05$).

Evaluating Gene Expression of Schwann Cells: RNA of sufficient quality was reverse transcribed to cDNA using qScript cDNA Synthesis Kit (Quanta Biosciences). Amplitaq Gold 360 Mastermix was used to perform PCR, and gene expression was evaluated with gel electrophoresis. The genes of interest are listed in **Table 1** and include growth factors and growth factor receptors. The intensity of the gel electrophoresis bands was analyzed using ImageJ software. All gene expression was normalized to the housekeeping gene β-actin. ANOVA was used to test significance of results ($p<,0.05$).

RESULTS

Isolating RNA from Cells Cultured in PEG Hydrogels: Several changes were made when optimizing the Trizol RNA isolation procedure for cells cultured in 3D gels. First, the gels were incubated in Trizol for 15 minutes instead of the manufacturer suggested 5 min to allow for complete lysing. The Trizol-cell solution then had to be separated from the gel, as stated previously. At this point, the isolation procedure continued as it would for cells cultured on 2D substrates. During RNA quality testing, it was determined that soluble PEG

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

interfered with absorbance, so gel electrophoresis was solely used to check quality. Further work determined that PEG contamination did not interfere with subsequent reverse transcription or PCR.

Testing Stiffness of PEG Hydrogels: G* for 12 PEG concentrations were obtained (**Figure 1, n=4**). Using this curve, the PEG concentrations needed for the desired stiffnesses fell between 3.5 to 4.5%. However, the lower concentrations of PEG (**Figure 2**) followed a different trend when separated from the higher concentrations. More data will be collected within this range of PEG concentrations to determine the correct concentrations of PEG.

Evaluating Gene Expression of Schwann Cells: The quality of the housekeeping gene primer and the other primers used has been confirmed; the products show single bands on an agarose gel at the correct molecular weight. Preliminary work has investigated the gene expression of Schwann cells cultured in 2D on PEG gels. Results indicated that mRNA for *TrkB* and *p75* is significantly up-regulated in 3% gels (n=4) when compared to 5% gels (n=4), with no significant difference between 3% and 7% gels (n=1). mRNA for *TrkC* was significantly up-regulated in 3% gels when compared to 5% and 7% gels. In contrast, the mRNA for *GDNF, NT3* and *TrkA* was significantly up-regulated in 5% gels when compared to 3% and 7%. However, it is clear that n must be increased for 7% gels to truly determine significance.

DISCUSSION

Schwann cells are vital to the healing and maintenance of nerves. Manipulation of the cells' gene expression could lead to important clues to optimal conditions for nerve regeneration. This study focused on plain PEG hydrogels because their mechanical properties can be easily varied by changing PEG concentration. It was shown that the stiffness of the PEG gels increases with increasing PEG concentration (**Figure 1**), agreeing with expectations and other work.

Marquardt and Willits obtained a shear modulus of 69.23±4.27Pa for 3% gels, 479.49±9.79Pa for 4% gels, and 992.24±36.07Pa for 5% gels[3]. Their result for 4% gels agreed with the results presented here. However, the result for 5% gels obtained was over twice as high as their result. Minor differences existed between the protocols; e.g., Marquardt and Willits prepared their solutions using DI H_2O instead of PBS[3]. However, potentially more significant was that they tested the gels using 25-mm parallel plate oscillatory shear rheometry as opposed to 8-mm parallel plate. The size difference may be of particular note because the smaller surface area of 8-mm tests could lead to more drying, and thus increased modulus. This outcome will be explored in future work.

Our preliminary results indicated that *GDNF* expression was up-regulated in 5% gels when compared to 3% and 7% gels. Therefore, we are interested to determine if there is a parallel increase in glial growth factor expression in 3D. Zhou et al found Schwann cell proliferation was maximum in 3D gels with a 5x lower modulus than previous 2D studies[4]. Extrapolating this result to the work here, a 5% gel is approximately 5x higher than the 3D modulus that Zhou reported to be optimal for proliferation (563.8 ± 66 Pa)[2]. Therefore, gels of this modulus will be of interest as we continue to gather gene expression data, particularly as both *GDNF* and *NT3* expression was increased in 2D. The up-regulation of these two key growth factors could help to explain why Zhou saw increased proliferation at this modulus.

To date, we have obtained an efficient and effective method of extracting RNA from Schwann cells cultured in 3D. This method could be extended in the future to other cell types or materials. A curve for the shear modulus of PEG gels has been constructed and will be used to determine concentrations to match the target moduli. The gene expression of Schwann cells at these different moduli will be evaluated for information about how a 3D environment influences these cells' behavior, with particular focus on supporting nerve regeneration.

INTRODUCTION

Many painful and physically debilitating conditions involve subfailure damage to connective tissues. As collagen is the major structural component of connective tissues, tissue injury and disease due to over-use, repeated subfailure injury, and trauma presumably involve damage to the hierarchical structure of collagen at one or more physical scales. While previous studies have documented clinically relevant mechanical damage to connective tissues following subfailure loading [1, 2], the exact nature of damage to collagen across its hierarchy of structure is poorly understood. A handful of indirect studies have indicated molecular level collagen damage occurs during overloading [3, 4], but there is no conclusive experimental evidence to indicate the extent, location, or mechanism of molecular level failure of collagen during subfailure loading.

A tissue-level imaging technique capable of directly detecting collagen damage at the molecular level would be highly useful for understanding the relationship between tissue injury and molecular damage. Collagen hybridizing peptide (CHP), a small synthetic peptide consisting of Gly-Pro-Hyp amino acid repeats, mimics the triple-helical molecular structure of natural collagens [5] and binds to unfolded collagen strands [6]. Considering the ability of CHP to hybridize with the unfolded collagen triple helix, we hypothesized that carboxyfluorescein (CF) labeled CHP (CF-CHP) could be used to detect and quantify molecular level damage to collagen caused by mechanical loading. Steered molecular dynamics (MD) simulations allowed us to investigate the molecular response of the collagen triple helix under loading with atomic resolution, enabling identification of the dominating molecular mechanism of permanent mechanical damage to fibrous collagens in load bearing tissues.

METHODS

Tail tendon fascicles were dissected from Sprague-Dawley rat tails. Individual fascicles were separated and tested by a single or cyclic fatigue tensile stretch protocol on a custom material test system. Single stretch samples were preloaded to 0.03 N then strained at 0.5 % per second to 1.0, 2.5, 5.0, 7.5, 9.0, 10.5, 12, 13.5, or 15% clamp strain (n=3 samples per group). Unloaded samples were used as a negative control (n=5). For cyclic stretching, preconditioned samples were preloaded to 0.03 N then loaded at 1 Hz from 1-5% clamp strain for 10, 100, or 1000 cycles or at 0.1 Hz from 1-5% clamp strain for 10 or 100 cycles (n=3 samples per group). Control groups for cyclic testing consisted of unloaded and preconditioned-only samples (n=3 each group). All tests were performed with samples immersed in 1× PBS.

Following testing, samples were unloaded from the test system and stained using CF-CHP of sequence CF-G_3-$(GPO)_9$ [7]. Individual samples were incubated overnight at 4 °C in 500 µl of 7.5 µM monomeric CF-CHP in 1× PBS. Following staining, samples were washed three times with 1 ml of 1× PBS for 30 minutes at room temperature to remove unbound CHP. Samples were stored in 1× PBS at -20 °C until imaging.

Entire stained fascicles were imaged for CF fluorescence using an automated widefield fluorescence microscope. Fascicles were mounted in 1× PBS and imaged at 4× magnification using the FITC channel and 488 nm excitation. Fluorescence intensity was measured by a thresholding segmentation method. For single stretch samples, the stained region was isolated by thresholding using Otsu's method [8]. Cyclically stretched samples were thresholded by subtracting the average pixel intensity of the unloaded control samples and using the positive valued pixels for intensity measurement. The mean pixel intensity of the identified regions was calculated and used as the measurement of CF-CHP staining intensity.

Steered MD simulations were performed using a representative homotrimeric Type-I α-1 collagen molecule comprised of ten [Gly-X-Y] triplets from a location near the 930-Lys intermolecular crosslink in *Mus musculus* [9]. Periodic boundary conditions were applied to all directions. Each simulation was performed in the isothermal-isobaric ensemble (pressure = 1 atm and temperature = 310 K) with 2 fs simulation time step using a rigid bonds model for all of the covalent bonds between hydrogen atoms and other heavy atoms. Energy minimization and equilibrium simulation was performed before mechanical test. The steered MD method was used to deform the molecule to a specified strain with a constant loading speed of 0.002 Å/ps. Simulations were performed with either tension dominant loading that stretches the whole triple-helical collagen molecule or shear dominant loading that corresponds to pulling a single strand out of the triple helix. Following removal of the tensile load, the structure was allowed to stress relax for 40 ns. Solvent accessible surface area (SASA), a measure of molecular unfolding, was computed during the last 20 ns of the relaxation simulation.

RESULTS

There was a significant effect of applied strain on measured fluorescence intensity ($p < 0.001$) of single tensile stretch samples with incrementally applied strain (Fig. 1a). Statistical analysis separated the samples into three groups: the samples tested to strains between 0 and 7.5%, a second group containing 9 and 10.5% strain samples, and a final group containing 12-15% strain samples. Comparison of mechanical testing and fluorescence intensity data (Fig. 1a) revealed that onset of significant CHP binding, which took place between 7.5-9% strain, corresponded to the onset of microstructural tissue damage, indicated by a decrease in material tangent modulus (red line in Fig. 1a).

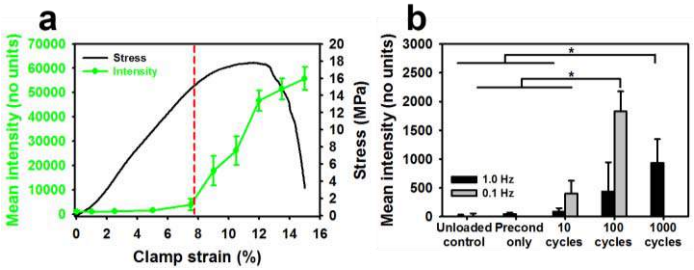

Figure 1. (a) Mean pixel intensity (n=5 0% strain, n=3 1-15% strain, mean ± std) and average strain vs. strain plot for the 15% strain group (n=3). (b) Mean fluorescence intensity vs. fatigue loading condition for samples loaded between 1-5% strain at 0.1 and 1.0 Hz (n=3, mean ± std, * p<0.05).

For cyclically stretched samples, there was a significant effect of the number of cycles on fluorescence intensity ($p<0.001$, 0.1 Hz loading; $p=0.014$, 1.0 Hz loading), with both frequency groups displaying statistically significant fluorescence increase with increased loading cycles (Fig. 1b).

Computational MD simulations revealed that shear dominant loading leads to failure at 12.7% strain, while tension dominant loading showed no signs of failure up to 20% strain. Failure in the shear dominant loading also led to irreversible unfolding of the triple helical collagen model starting at 13.6% strain, observable both by a visible structural change (Fig. 2a) and increased SASA (Fig. 2b).

DISCUSSION

Using CHP, we demonstrated for the first time that irreversible unfolding of collagen molecules is a critical feature of the mechanical failure process in tendon fascicles. In addition, computational simulations indicated that shear-dominant stress transfer, which results in pulling one strand out of the collagen triple helix, is the most likely mechanism of collagen unfolding during tensile overload. Recently, Veres et al. reported that mechanical overloading causes permanent denaturation of collagen molecules in tendon even under subfailure tissue loading, as measured by the enthalpy of thermal unfolding and trypsin digestion [10]. The computational simulations revealing collagen triple helix unfolding due to shear dominant loading, which occurs by stress transfer through molecular sliding and intermolecular crosslinks, are consistent with the collagen deformation mechanisms of molecular stretching and intermolecular sliding proposed by Sasaki and Odajima [11]. In addition, this sliding and shear dominant damage mechanism is in agreement with the gradual accumulation of molecular damage revealed by CHP binding, as breaking of covalent bonds in the peptide backbone or intermolecular crosslink is a highly energetic process that is expected to result in catastrophic tissue failure.

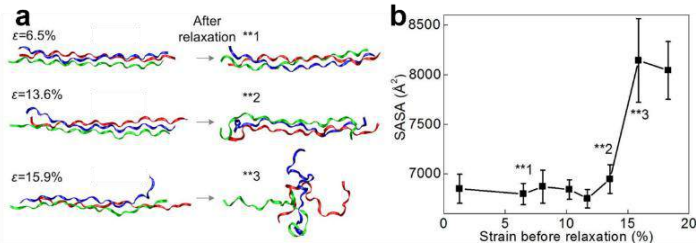

Figure 2. (a) Simulation snapshots taken before and after relaxation simulation for shear-dominant loading to 6.5, 13.6, and 15.9% strain. (b) SASA vs. applied strain (mean ± std) computed during the last 20 ns of relaxation. Increased SASA corresponds to the unfolding observed in the simulation snapshots.

Our results provide an explanation for the progression of mechanical damage in collagen-rich tissues, as well as implications for initiation of the inflammatory response and subsequent healing. Collagen molecular damage prior to fiber-scale tissue disruption and CHP binding to fatigue loaded samples suggest that subfailure damage initiates as collagen triple helix unfolding long before progressing to disruption or damage of structures at larger physical scales. This unfolding of collagen molecules can expose cryptic cell binding domains that are known to elicit healing responses including cell recruitment, damaged collagen removal, and new collagen production [12]. Thus, CHP binding provides an unprecedented tool for detecting collagen mechanical damage in connective tissues, and offers an exciting potential for translational application to the diagnosis, staging, and treatment of connective tissue disorders and injury.

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a life-threatening disease characterized by increased pressure in the right heart and arteries supplying blood to the lungs[1]. In PAH, the pulmonary arteries remodel and constrict, decreasing luminal cross section and increasing vascular resistance. Eventually, the increased pressure results in right ventricular failure, which compromises cardiac output and portends a poor prognosis.

Various studies have demonstrated links between altered cellular glucose metabolism and PAH[2,3]. PAH patients showed increased pulmonary uptake of 18 F-labeled deoxyglucose on PET/CT when compared to healthy controls, indicating increased glucose uptake in the lung[4]. Increased glucose metabolism can elevate hexosamine biosynthetic pathway (HBP) flux, which increases the post-translational protein modification O-GlcNAcylation.

In O-GlcNAcylation, a single sugar is added to serine and threonine residues of nuclear and cytoplasmic proteins[5]. Protein O-GlcNAcylation is important in cellular processes such as transcription, stress response, apoptosis, glucose sensing, and cell signaling in a variety of diseases including diabetes, Alzheimer's, and cancer[1,6]. In PAH, pulmonary aortic smooth muscle cells showed increased HBP flux and enhanced O-GlcNAc transferase (OGT), the enzyme which catalyzes protein O-GlcNAcylation. In endothelial cells, high glucose and elevated HBP flux increased endothelial nitric oxide synthase (eNOS) O-GlcNAcylation and thereby decreased eNOS phosphorylation and nitric oxide (NO) bioavailability at baseline and in response to insulin and blood flow[7-10]. However, the effect of increased glucose metabolism on pulmonary arterial endothelial cell NO production in response to changes in blood flow has not yet been investigated. The goal of this study is to determine how altered glucose metabolism in human PAEC impacts NO production in response to flow.

METHODS

Human umbilical vein endothelial cell (HUVEC) and human pulmonary artery endothelial cells (HPAEC) response to chronic flow was assessed using a parallel plate flow chamber. Cells were seeded at 17,000 cells/cm^2 on collagen coated 25 x 75 mm glass slides for 48 hours and then subjected to 24 hours of 20 dynes/cm^2 shear stress. Glass coverslips were coated with 10 mg/ml of collagen Type 1at 37^{o}C for 3 hours prior to cell seeding.

Endothelial cell morphological response to chronic flow was determined by actin fiber alignment. Cells were fixed in 4% paraformaldehyde and permeabilized with 0.1% Triton X-100. Actin fiber alignment was assessed by labeling actin filaments and nuclei with 165 nM rhodamine phalloidin and 0.2 mg/mL bisbenzimide, respectively. Samples were imaged with a 20x objective in an Olympus 1X81 inverted confocal microscope. Actin fiber alignment was analyzed using a custom edge detection Matlab program developed[11].

For glucose studies, HUVECs and HPAECs were seeded at 17,000 cells/cm^2 on 60 x 15 mm culture dishes for 48 hours and then incubated in high glucose (30 mM), D-mannitol (osmotic control) or glucosamine (2-5 mM) for 0 to 4 hours under static conditions.

Endothelial cell protein O-GlcNAcylation in response to glucose or glucosamine was determined by Western Blot. Samples were prepared by scraping cells off the surface in ice-cold lysis buffer (20 mM Tris, 150 mM NaCl, 1% Triton X-100, 2 mM EDTA, 2 mM PMSF, 0.1% SDS, 2 mM Na_3VO4, 50 mM mM NaF, 10% glycerol, complete protease inhibitor, pH 7.4). Samples were then centrifuged for 10 min at 10,000g, 4^{o}C to remove insoluble material. Cell lysates were normalized for protein content, separated by SDS-PAGE on a 4–12% Bis-Tris gel, and transferred to a nitrocellulose membrane.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

After blocking in 5% Bovine Serum Albumin (Sigma), membranes were incubated with primary GlcNAc antibody (Cell Signaling) overnight at 4ºC followed by a secondary horseradish peroxidase-conjugated antibody for 2 hours at room temperature. GAPDH was used as the loading control. Protein bands were detected using an enhanced chemiluminescence kit (Western Lightning, PerkinElmer), and visualized with a Fluorchem digital imager (Alpha Innotech). Band intensity was quantified using AlphaEase FC software.

Statistical analysis was performed with GraphPad Prism. Each experiment was performed in duplicate or triplicate and repeated three times. Comparisons between two groups were analyzed by Student's t-test, and comparisons among multiple groups were analyzed by two-way analysis of variance with a Tukey post-hoc test. Statistical significance is indicated by *p<0.05, **p<0.01, or ***p<0.001.

RESULTS

HPAECs exposed to 24 hours of shear stress (chronic) in a parallel plate flow chamber showed a 17% increase in actin fiber alignment as compared to static controls (Figure 1), demonstrating that HPAECs respond morphologically to shear stress.

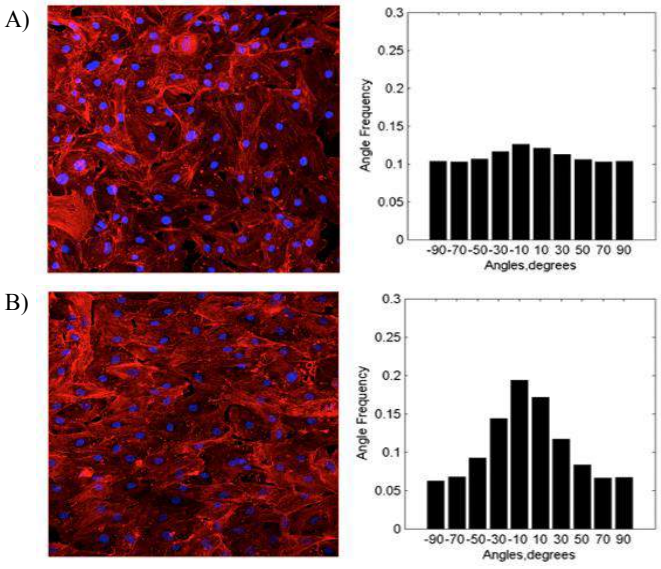

Figure 2: Actin Fiber Alignment of HPAECs

A) Static Healthy HPAECs B) Healthy HPAECs after 24 hour flow C) Percent Alignment of Healthy HPAECs: Static vs. Flow

O-GlcNAclyation increased when HUVECs were exposed to more than 3 hours of 30 mM glucose and 5 mM glucosamine (Figure 2).

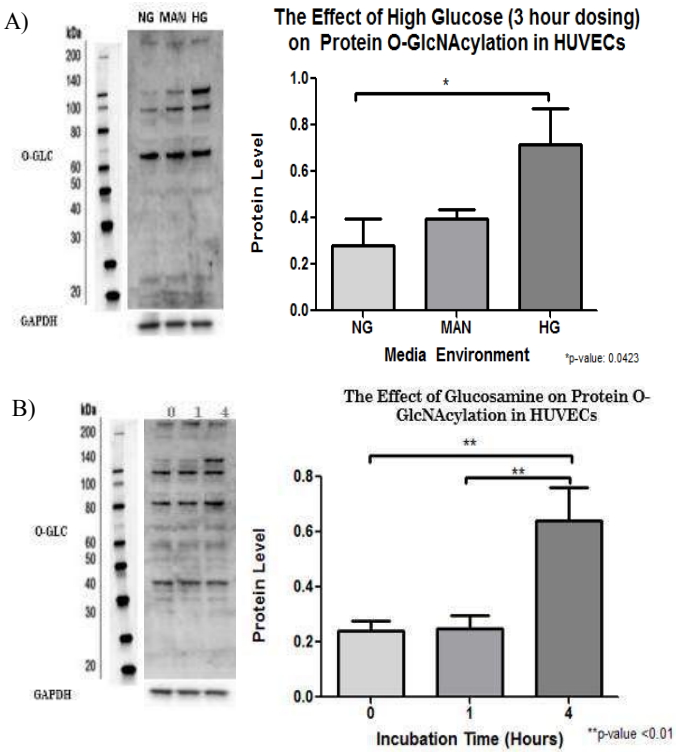

Figure 1: HUVECs in hyperglycemic environments

A) 30 mM high glucose B) 5 mM Glucosamine

DISCUSSION

These data suggest that HPAECs respond similarly to chronic shear stress as other macrovascular endothelial cell types. In addition, increased HBP flux increases protein O-GlcNAclyation in human endothelial cells. HPAECs have an altered glucose metabolism, yet little is known about how this affects other cell properties. We and other have shown that altered glucose environments can affect macrovascular endothelial cell mechanotransduction[12,13]. My findings may elucidate the links between altered glucose and altered HPAEC function in PAH, giving insight into pulmonary hypertension.

In the future, we will determine HPAEC protein O-GlcNAcylation in high glucose/glucosamine, examine the effects of acute flow on HPAEC protein O-GlcNAcylation and p-eNOS, and determine any changes in HPAEC protein O-GlcNAclyation with chronic flow.

INTRODUCTION

Tibia fractures in the proximal head require screws to be applied to the fracture site for proper fusion to occur without misalignment, at which point whether or not to remove the hardware is at the surgeon's discretion. Patients with osteoporosis are at a higher risk of fracturing bone. Literature is inconclusive if removal would benefit the patient, as complications from both screw removal and non-removal have been reported.[1-3] Screw removal may compromise bone integrity, whereas remaining screws risk migrating and proliferating microfractures.[1-4] Through computational analysis, this study investigates the effects of screw removal at the proximal tibia site in both healthy bone and osteoporotic bone, and its effect on the biomechanics of articular cartilage and surrounding tissue to better assist the surgeon's decision to remove hardware post-fusion.

METHODS

A generic bone model comprising of cortical and cancellous bone was used for this study, and its 3D geometry was reconstructed using 3-matic and Mimics software (Materialise, Belgium). The material properties for bone were taken from previous studies.[1] The simulated properties of the bone material were then altered to represent biological data of osteoporotic bone found in studies.[8,9] A layer of 3mm of articular cartilage was added to the two tibia condyles and modeled as a biphasic material.[10] A total of four scenarios were simulated: intact tibia (I), tibia with titanium screws (S), tibia with holes (H), and tibia with holes filled with calcium sulfate polymer (P) (figure 1). As per instructions of a surgeon, screws were inserted into the subchondral bone. A mechanical load simulating the gait of a 70 kg 30 year old man was applied to the bone model, and a computational analysis was conducted with FEBio Suite (University of Utah) to yield stresses in the cartilage and subchondral bone.[11]

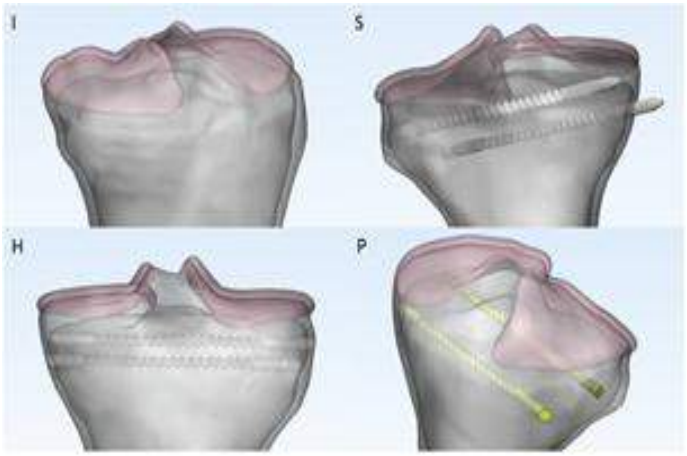

Figure 1: Models of the generic bone with cortical and cancellous bone and cartilage. (I) Intact tibia (S) Tibia with titanium screws (H) Tibia with the screw removed with unfilled holes (P) Tibia with a calcium sulfate polymer filling the holes.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

Effective stress and effective fluid pressure in the cartilage were identical among the models (data not shown). In contrast, the effective stress in the subchondral bone changed according to the simulated scenario (figure 2), with healthy bone not differing significantly from osteoporotic bone except with the polymer filling. The tibia with unfilled holes produced the largest peak stress of 1.64 MPa in healthy bone, and 1.61 MPa in osteoporotic bone at the cortical/cancellous interface at the holes sites. This suggests that holes compromise the integrity of the bone. The calcium sulfate had the largest difference of peak stresses between healthy and osteoporotic bone; it induced peak stresses of 1.21 MPa in healthy bone and 1.09 MPa in osteoporotic bone at the cortical/cancellous interface at the polymer site. This is outside the range of the intact tibia, which has peak stresses of 1.14 MPa for healthy bone and 1.11 MPa for osteoporotic bone. Screws induced the second highest peak stresses, with 1.29 MPa for healthy bone and 1.34 MPa for osteoporotic bone.

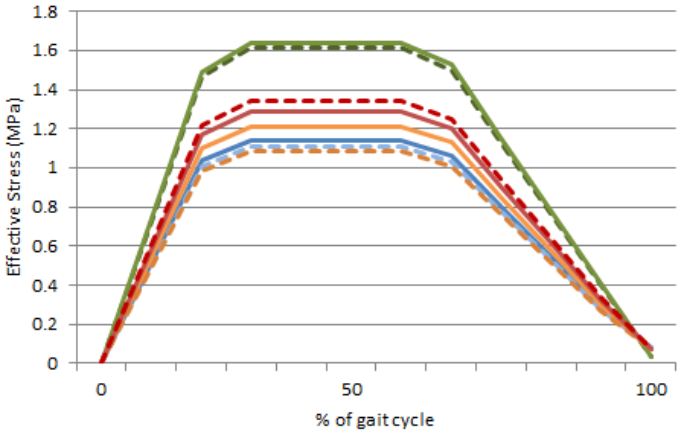

Figure 2: Peak values of effective stress computed at screw holes during gait. (Blue) Intact tibia. (Red) Titanium screws. (Green) Unfilled holes. (Orange) Holes filled with a calcium sulfate polymer. Solid lines represent healthy bone; dotted represents osteoporotic bone.

DISCUSSION

The results of this study suggest that the geometric and mechanical alterations that screws cause in the bone in both healthy and osteoporotic bone may not directly affect cartilage. Different outcomes are observed in the subchondral bone. It is observed that screw holes produce higher levels of mechanical stress at the cortical/cancellous interface when compared to those scenarios including the presence of screws or polymer filling in both cases. This is because both cancellous and cortical bones tend to collapse at the screw holes thus increasing the Lagrange strains (data not shown). In contrast, when holes are filled with polymer whose mechanical properties are similar to that of cancellous bone, stresses in the subchondral bone most closely match those found in the intact tibia scenario. However, the difference between healthy and osteoporotic bone is most significant with polymer fillings. The similar values between osteoporotic and healthy bone are expected; the simulated trials were with a single step, where the mechanical instabilities in osteoporotic bone are unlikely to affect stress levels.

This study suggests that the presence or absence of the hardware in the tibia may not directly cause post-fracture cartilage complications such as osteoarthritis. Also, hardware removal post-fracture fusion should be accompanied by filling the holes with polymer whose mechanical properties resemble those of the natural cancellous bone in both healthy bone and osteoporotic bone in order to preserve subchondral bone integrity.

INTRODUCTION

This research details an improved modeling approximation technique for biohybrid devices using a widely available tool. Previous studies have shown that cellular contraction can be roughly approximated in finite element analysis (FEA) simulations using the built in thermal contraction capabilities [1]. While many models simulate cellular contraction using individual forces or cell-substrate interface traction forces, approximations using a calibrated thermal contraction model greatly reduce computational runtime. In order to approximate cellular contraction using thermal contraction, a relevant thermal expansion coefficient (TEC) is needed.

While a wide range of biohybrid actuators have been developed [2-5], many such devices are based on the actuation of a thin layer of cells on one side of a biocompatible substrate [6]. This results in a device that functions as a cantilever. Previously, we have used a modified Stoney's approximation to calculate the stress in the cell layer, and subsequently calculated the TEC based on a linear thermal stress-strain relationship [7]. However, this technique resulted in a wide range of TEC values, and required experimental calibration of a correction factor. In the current study, we instead treat the deformed cantilever as a bi-layer beam with two thermal contraction coefficients (as in a thermostat). Using this technique, the current study identified an improved range of TEC values for approximating cellular contraction using native thermal contraction capabilities in FEA software packages.

METHODS

In this study, the deflections of 13 muscular thin films (MTFs) [8] as the result of cellular contraction were used to calibrate or validate TEC variables α and ΔT for use in FEA simulations. The coefficient of thermal contraction along the cell contraction direction is denoted as α and the driving temperature was denoted as ΔT. Six samples were used for calibration while 7 samples were saved and used as a test set for comparing the simulation to experimental values.

Model Calibration

For this study two calibration methods have been compared. First, the TEC was calibrated based on a calculated stress in the cell layer, which can be calculated based on the deflection or radius of curvature (ROC) of the device during contraction. Based on this approximation, a model was developed to reproduce the experimental contraction force. The first method for approximating the cell stress is to apply Stoney's equation [9]:

$$\sigma_c = \frac{1}{6Rt_c}\left(\frac{E_s {t_s}^3}{\left((1-\nu)(t_s+t_c)\right)} + \frac{E_c {t_c}^3}{\left((1-\nu)(t_s+t_c)\right)}\right) \quad (1)$$

where R is the experimentally measured radius of curvature of the beam, ν is the poisson's ratio, t_c and t_s are the thicknesses of the cell and substrate layers, respectively, E_c and E_s are the moduli of the cells and substrate, respectively. The TEC was then determined using the linear thermal stress-strain relationship:

$$\alpha\Delta T = \frac{\sigma_c}{E_c} \quad (2)$$

The second method for model calibration is to calculate the TEC directly based on the ROC by treating the cantilever as a bi-layer beam with each material having different material and thermal properties [10]. By assuming that the TEC of the substrate is 0, this model was reduced to:

$$\alpha\Delta T = -\frac{1}{R}\frac{(E_s t_s^2 - E_c h_c^2 + 4E_s E_c t_s t_c (t_s+t_c)^2)}{6E_c t_c (E_s h_s h_c + E_s h_s^2)} \quad (3)$$

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

The TEC was determined for the minimum and maximum contraction states for 6 randomly selected MTF samples using both techniques, resulting in four TEC ranges.

Simulation

Muscular thin films were simulated in ANSYS Mechanical APDL using two dimensional plane strain elements. MTFs were comprised of a bi-layer cantilever with a fixed boundary condition on one end. Contraction in the cell layer was approximated using an orthotropic coefficient of thermal contraction. While the calibration technique results in a value for $\alpha\Delta T$, ANSYS requires α and ΔT to be entered separately. Therefore, $\Delta T = 1$ for the purposes of this study. In the direction of the desired contraction, the calculated α was implemented, while the TEC in all other directions was set to zero.

The 7 test sample geometries (Figure 1) were simulated using the average, average minus one standard deviation, and average plus one standard deviation for each of the four calibrated TEC cases, and the resulting deflections were compared to the experimental values.

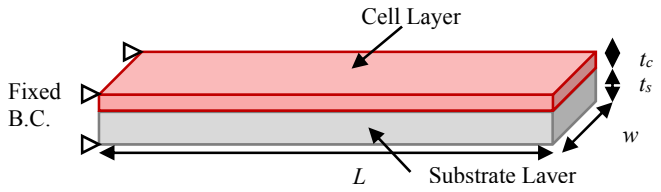

Figure 1 Schematic of cantilever MTF

RESULTS and DISCUSSION

TEC calibration using the basic Stoney's approximation resulted in a TEC range of -0.216 ± 0.024 for the minimum contracted state and -0.387 ± 0.11 for the maximum contracted state, while calibration using the thermostat model resulted in a minimum range of -0.145 ± 0.016 and a maximum range of -0.26 ± 0.075 (Figure 2).

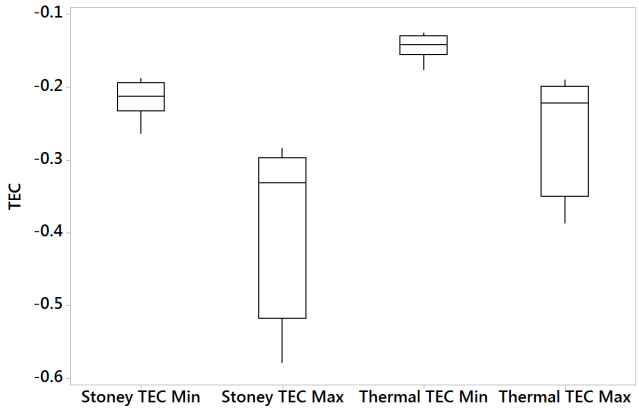

Figure 2. Box and whisker plot of the TEC ranges for the minimum and maximum contracted states calibrated using Stoney's approximation and the Thermal model on the six calibration samples.

Each MTF configuration was simulated across the projected range of TEC values. In both the minimum (Figure 3) and maximum (Figure 4) contracted states, the thermal model performed better than the calibration using Stoney's approximation when compared to the experimental deflection. In the case of the minimum contracted state there was no significant difference between the experimental deflection and the simulation using the Thermal calibration technique (T-test: p = 0.246). However, the Stoney's calibration technique in both cases, and the Thermal technique for the maximum contraction did vary significantly from the experimental deflection (T-test: $p<0.05$).

The use of the thermostat based model results in an improved simulated deflection over that provided by the uncorrected Stoney's calibration technique.

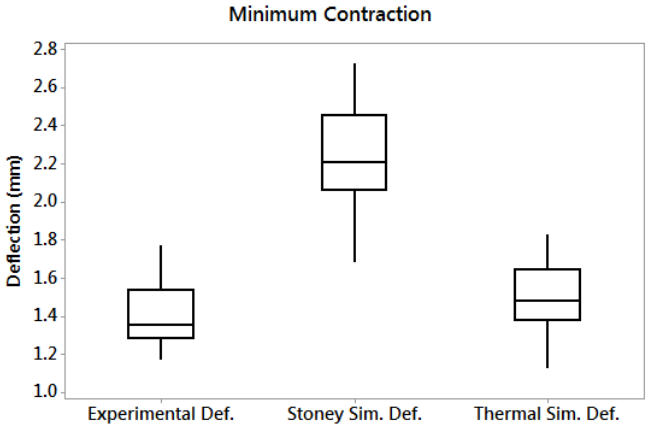

Figure 3. Box and whisker plot comparing the experimental and simulated MTF deflection in the minimum contracted state using the seven test samples.

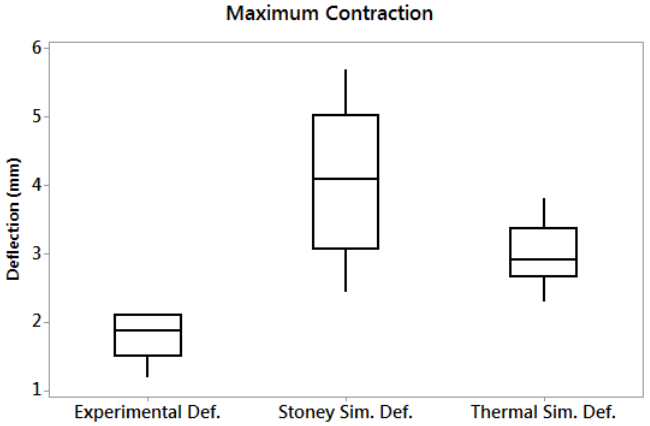

Figure 4. Box and whisker plot comparing the experimental and simulated MTF deflection during maximum contraction using the seven test samples.

DRILL-SPECIFIC HEAD IMPACT EXPOSURE IN YOUTH FOOTBALL PRACTICE

Eamon T. Campolettano, Steve Rowson, and Stefan Duma

Biomedical Engineering and Mechanics
Virginia Tech
Blacksburg, VA 24060

INTRODUCTION

Youth football players represent 70% of all players in the United States, and yet the level of research into head impact exposure within this population is limited when compared to that of high school, collegiate, and professional football [1]. The prevailing thought for concussion mitigation today is to limit head impact exposures, primarily through proper teaching and rule modification [2].

Recently, researchers have begun to instrument youth football players with helmet-mounted accelerometer arrays to quantify head impact exposure and concussion tolerance [1, 3]. Daniel et al instrumented seven players on one team and reported that most high magnitude impacts occurred in practice, rather than games [1]. The findings from that study were part of the process that led to rule changes in the Pop Warner organization [3]. The following year, Cobb et al followed three youth football teams and found that teams adhering to the policy changes experienced a 40% reduction in overall impacts relative to those that did not [4].

While these studies provided valuable insight to head impact exposure in youth football players, they looked at practices and games as a whole, with little analysis quantifying the causation of high magnitude impacts. The objective of this study was to analyze youth football practices and determine which drills produced high magnitude impacts. The results of such analysis conducted on a larger scale could be useful for future research or further policy implementation to mitigate head impact exposure in youth football.

METHODS

This study investigated head impact exposure among youth football players. Two youth football teams composed of 9-11 year old players were included in this study approved by the Virginia Tech Institutional Review Board. Guardians provided written consent and the youth players verbally assented to participation. A total of 34 players (average age of 9.99 ± 0.74) chose to participate and received helmets instrumented with accelerometer arrays associated with the HIT System.

The HIT System consists of a six accelerometer array that is mounted inside of a Riddell Revolution or Speed helmet. The accelerometers are spring-mounted so that contact with the head is maintained for the duration of the impact. This ensures measurements of head acceleration, rather than helmet acceleration [5]. Players wore the instrumented helmets at each practice and game throughout the season. When an individual data channel exceeded a 14.4 g threshold, data acquisition automatically triggered, capturing 40 ms of data, including 8 ms of pre-impact data. Impact data were then wirelessly transmitted from the helmets to the sideline computer, where the data were processed to compute linear and rotational resultant accelerations according to previous research [6, 7].

Games and practices were filmed to facilitate video verification of head impacts. For every impact greater than or equal to 40 g in practice, video was used to identify the specific drill/activity associated with impact. Each of these impacts was assigned one of nine classifications corresponding to the drill that resulted in the impact (Table 1). Furthermore, practice film and activity logs kept for each day of practice were used to determine the total time spent practicing each drill type and to assess the relative severity of drills to each other.

Impact rates were computed on a per hour basis. Byar's method, which retains high levels of accuracy for both small and large counts, was used to compute 95% confidence intervals for these rates [8]. Empirical cumulative distribution functions (CDF) were also determined for each drill for linear resultant acceleration.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Table 1. Each impact over 40 g was classified as being associated with one of the following drills. Most drills resulted in tackling. Most time was devoted to drills with game situation fidelity.

Practice Drill	Description
Blocking Drill	Drills focused on teaching blocking
Tackling Drill – Blocker Present	Tackling drill with at least one blocker present as well as a ball carrier and tackler.
Tackling Drill – No Blocker Present	Tackling drill where only a ball carrier and tackler participate
King of the Circle	Player in middle of circle rushes at player on perimeter of circle.
Scrimmage	Full 11 vs. 11 offense vs defense
Offense vs. Defense	Small scale (5 v 5 up to 8 v 8) offense vs. defense
Offense or Defense	11 offensive or defensive players with 3-4 proxy players on the other side
Passing or Running Drills	Pass catching or rushing drills
Other	All other activities

RESULTS

For the season, 408 impacts that exceeded the 40g threshold were video verified, with 314 (77%) occurring in practice and the remaining 94 (23%) in games. The number of impacts, as well as time spent, for a particular drill varied greatly over the course of the season, necessitating the use of a normalized impact rate for comparisons to be made. Impacts per hour for each drill were computed with 95% confidence intervals for thresholds of increasing linear acceleration severity (Fig. 1). Drills involving tackling resulted in a higher rate of impact than those that did not. Increasing severity thresholds resulted in lower rate of impact across all drills. No players in the study sustained a concussion.

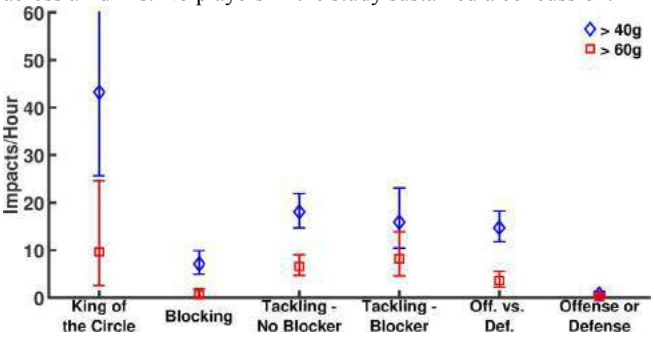

Figure 1. The heavy contact and rapid nature of King of the Circle led to the highest impact rate of all practice drills. Drills resulting in a tackle were found to lead to higher impact rates as well.

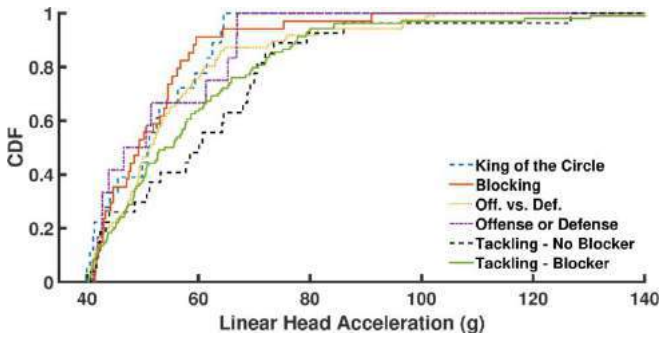

Figure 2. Tackling drills were found to have the largest proportion of impacts over 70 g.

CDFs were determined for linear acceleration magnitudes for the selected drill types (Fig. 2). Though consistent up to 60 g, the non-tackling drills were less frequently associated with accelerations of greater magnitude. Tackling drills were associated with greater severity head impacts than non-tackling drills.

DISCUSSION

Previous work into youth football head impact exposure has investigated magnitude and frequency of impacts, as well as the effect of style of play on those values [4, 6]. The proportion of high magnitude head impacts in youth practices (77%) was found to be consistent with the 79% found by Daniel et al [1]. Looking at practices in more detail, impact rate differed markedly between drills with and without tackling for all severity levels. Those without tackling resulted in fewer than 10 impacts above 40 g per practice-hour while drills involving tackling exceeded this. King of the Circle produced high magnitude impacts more frequently than any other activity because of the speed at which it is performed (Fig. 1). Each player rushes three times at a different defender and the drill continues until all have the opportunity. Notably, this drill was carried out for the shortest amount of time of all those assessed. Further, no impact from King of the Circle exceeded 70 g (Fig. 2). Tackling drills, with or without blockers, were associated with the highest proportion of impacts over 70 g. With a high impact rate and magnitude, these drills, as carried out by the teams in this study, expose players to heightened head impacts. Of note is that the two teams in the study spent the most time conducting either Offensive or Defensive drills. These drills resulted in a very low rate of impact and closely mimicked game play. Off. vs. Def. also exhibited fidelity to game situations, and the high impact rate observed there stems from the smaller number of players involved. This enabled players to achieve greater momentums and produce higher magnitude impacts.

Certain limitations pertaining to this study should be noted. The HIT System is associated with random error up to 15.7% for individual acceleration measurements, but the average error is only 1% [9]. Variations in head impact exposure data between the two teams in this study were present.

Head impact kinematic data for two youth football teams of players 9-11 years old were collected in order to assess the effect of specific practice drills on impact exposure. Much of practice time was spent in non-contact scenarios, but contact drills presented high rates of exposure to the athletes. Coaches and league organizers can use these data to structure practices in ways that work to mitigate high magnitude impacts. Further research into practice drill impact exposure at all levels of football is necessary to further player safety and characterize exposure on a larger scale.

INTRODUCTION

Meniscal allograft transplantation, MAT, is a salvage procedure intended to replace extensively degenerated menisci [1]. Although MAT is successful in alleviating symptoms and improving knee function in the short- to medium-term, long-term outcomes are highly variable. It is generally believed that the magnitude of change in joint contact mechanics has a relationship with the onset and progression of cartilage degeneration [2]. While changes in contact mechanics after meniscal injury have been quantified in cadaveric studies [3, 4] the biological response of articular cartilage to those changes have not been explored.

The primary objective of this study was to determine the effect of MAT on *in vivo* patient-specific knee joint contact mechanics. The secondary objective was to explore the relationship between pre- to post-MAT changes contact mechanics and early biological changes to knee joint articular cartilage. To satisfy these objectives we developed a platform of tests consisting of: an *intraoperative* protocol for the direct measurement of knee joint contact stress, and a *pre- and post-operative* quantitative magnetic resonance imaging (qMRI) for the evaluation of changes in cartilage thickness, composition and collagen structural organization of cartilage matrix.

METHODS

Five subjects (2M/3F, age: 21 ± 4 years, weight: 71.8 ± 14.3 kg) scheduled to undergo meniscal transplantation were enrolled in this study following IRB approval. All patients had undergone prior total meniscectomy, and showed no signs of advanced chondral degeneration on preoperative MRIs. Two subjects (*subjects 4, 5*) underwent isolated meniscal transplantation, while the remaining three subjects underwent MAT in addition to ACL reconstruction (*subject-1*), revision ACL reconstruction (*subject-2*), and osteochondral allograft transplantation (OATS) in the weight-bearing zone of the femoral condyle (*subject-2, 3*).

Imaging: All subjects underwent imaging of the knee prior to surgery and at their follow-up visits (3 to 6 months) on a clinical 3.0 T scanner (GE Healthcare, Waukesha, WI). Cartilage thickness was assessed using a coronal 3D high-resolution spoiled gradient echo (SPGR) sequence, with voxel dimensions = $1.5\times0.27\times0.27$ mm^3. Proteoglycan content was assessed using T1ρ mapping, with the acquisition parameters: 4 time of spin lock (0, 20, 40, 60 ms), and voxel dimensions = $3\times0.58\times0.58$ mm^3. Collagen fiber organization and water content was assessed by T2 mapping, with echo time = 7.2, 14.4, 21.6, 28.8, 36.0, 43.2, 50.4, 57.6 ms, and voxel dimensions = $3\times0.58\times0.58$ mm^3. SPGR images were manually segmented to create a 3D model of articular cartilage and bone. T2 and T1ρ relaxation times within the tibial cartilage were calculated by fitting a mono-exponential decay equation. The T1ρ and T2 values on 2D slices were then overlaid on the 3D anatomical surface model of the tibial plateau to create the 3D mapping (Fig. 1) [5].

Intra-operative contact stress measurement: During surgery, contact stress on the tibial plateau surface was quantified using a thin-electronic sensor (Tekscan Inc., Boston, MA). The sensor was calibrated and trimmed to accommodate to the shape of the tibial plateau, then sterilized using ethylene oxide. The sensor was passed through a small arthrotomy from anterior to posterior by pulling the posterior tab via a passing suture placed through a posterolateral incision (Fig. 2A), and its position was adjusted arthroscopically to cover the entire tibial plateau. A custom designed surgical boot was used to manually apply an axial force to the foot until 50% body weight was reached (Fig. 2B). The boot was equipped with a load cell (Model: 31/1432-04, Honeywell Inc.) to monitor the applied force in real-time. Contact stress and contact area were evaluated before

(meniscectomy condition) and after allograft placement (transplanted condition).

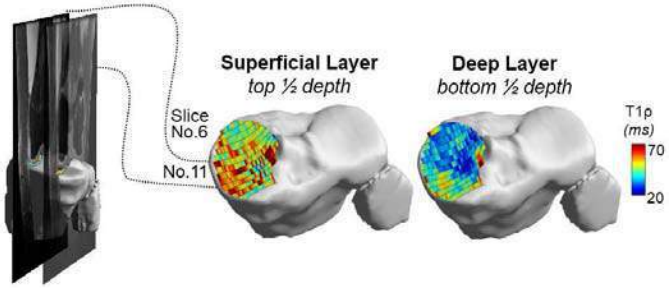

Figure 1. Reconstruction of 3D T1ρ mapping of the tibial cartilage

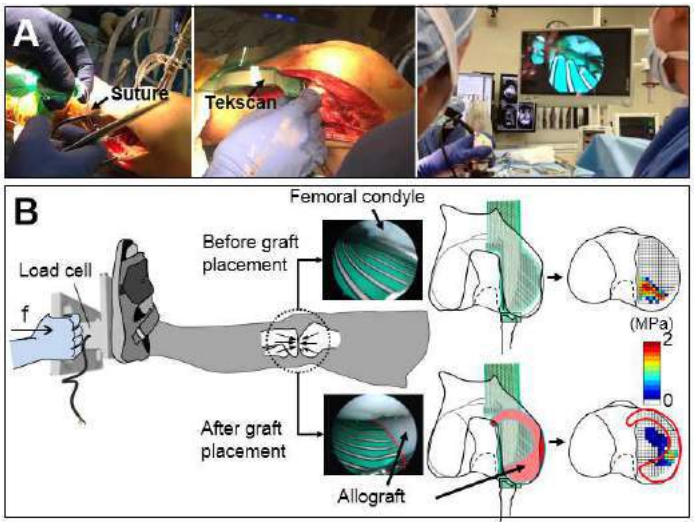

Figure 2. (A) Photo and schematic (B) of intraoperative measurements

RESULTS

For the meniscectomized condition, tibial plateau peak contact stresses of 1.96 ± 0.39 MPa (range: 1.67 MPa to 2.64 MPa) and contact areas of 160 ± 44 mm^2 (range: 120 mm^2 to 225 mm^2) were quantified. Following meniscal transplantation, increases in contact area of 29% and decreases in peak contact stress of 17%, on average occurred compared to the meniscectomy condition.

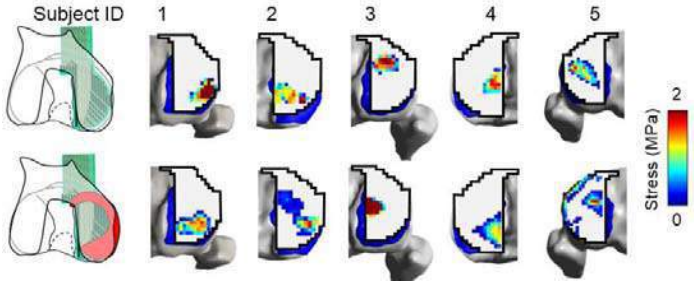

Figure 3. Contact stress at meniscectomy condition (top row), and after graft placement (bottom row)

Follow-up scans were obtained for subjects #1, 2 & 3 at 6 months, for subject #4 at 5 months and for subject #5 at 5 months. Our analysis was focused on the tibial cartilage of the affected compartment. There were minimal changes (< 1%) in average cartilage thickness at follow-up scans within both cartilage-cartilage (CC) and cartilage-meniscus (CM) contact zones (Fig. 4C). At follow-up scans, the average T1ρ were shorter than their preoperative levels within the CM values zone (superficial layer: -11% ± 17%, deep layer: -6% ± 14%, Fig. 4A). In contrast, changes were less remarkable within the CC zone (superficial layer: -3% ± 17%, deep layer: 0% ± 14%). We observed prolonged T2 values within the CC zone of the deep layer (8% ± 23%, Fig. 4B) while there were smaller increases (< 3%) within the CM zone and in the superficial layer.

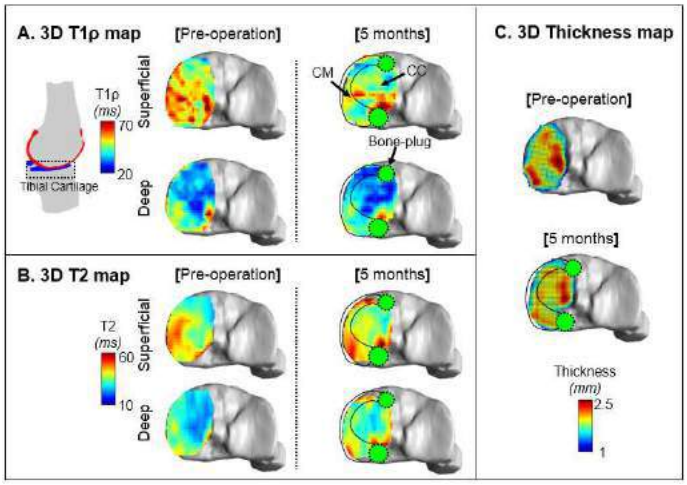

Figure 4. Preoperative and postoperative (A) T1ρ, (B) T2 and (C) thickness map of tibial cartilage of a representative subject (*subject 4*)

DISCUSSION

We have applied a newly developed platform technology to quantify the effect of MAT on intra-operative knee joint contact stresses and the subsequent biological response of articular cartilage in a pilot cohort of 5 patients. The majority of patients (4/5) exhibited decreased peak contact stress and increased contact area, suggesting that meniscal transplantation plays an important role in redistributing joint loads, at least in the immediate post-operative environment. Follow-up MRI taken at 3 to 6 months demonstrated decreased T1ρ values in tibial articular cartilage, specifically in the region beneath the meniscal allograft, suggesting increases in proteoglycan content and decrease in water content within the zone. A concomitant prolongation of T2 values was found primarily within the central region of the tibial plateau, suggesting moderate increased disorganization of the collagen network within this region. Minimal differences in cartilage thickness were found over the short time frame of this preliminary study. In summary, our pilot study indicates that the contact mechanics of MAT are highly patient-specific. But irrespective of patient-to-patient variability, MAT results in a chondro-protective effect, even at short follow-up [6]. Longer follow-up imaging data in a larger cohort will be required to determine if immediate post-operative patient-specific changes in joint contact mechanics after MAT are predictive of outcome.

FUNCTIONAL EVALUATION OF EXOSKELETON CONTROL STRATEGIES FOR TREATING CROUCH GAIT IN CEREBRAL PALSY

Zachary F. Lerner, Diane L. Damiano, Thomas C. Bulea

Rehabilitation Medicine Department
Clinical Center
National Institutes of Health
Bethesda, Maryland, USA

INTRODUCTION

Cerebral palsy (CP) is the most common chronic motor disability in children, with a reported prevalence of 2-2.5 per 1,000 births [1]. More than 50% of individuals with CP exhibit crouch gait [2], a pathological walking pattern characterized by excessive bilateral knee flexion and elevated knee extensor joint moments [3]. Orthopaedic surgery may result in short-term improvements in crouch that often did not persist with time and growth and may exacerbate weakness, excessive anterior pelvic tilt or knee hyperextension. More effective treatment strategies that can preserve or augment strength for those with CP, and thereby help to maintain gait function, are needed.

Powered exoskeletons as well as some orthoses have the potential to assist gait in children with neurological deficits and restore or improve their joint biomechanics while worn [4]. However, we not aware of any orthotic or robotic assistance devices that specifically seek to "treat" crouch gait, i.e. lead to improved gait function when the device is removed. The potential contributors to crouch gait, including spasticity, contracture, poor motor control, and muscle weakness, pose challenges for the design and control of such devices in individual patients. More research is needed to determine appropriate exoskeleton control strategies that successfully treat this heterogeneous gait disorder.

Individuals with crouch gait have excessive knee flexion at initial foot contact and throughout stance. Therefore, in treating crouch gait, it may be useful for a powered knee exoskeleton to provide assistance either during the swing phase, acting to extend the knee prior to initial contact, during the stance phase, acting to support the body, or both.

The goal of this study was to evaluate the ability of our custom exoskeleton to provide knee extension assistance during the stance and swing phases of gait, and how the different modes of assistance affect knee joint angles in a child with crouch gait from CP.

METHODS

Exoskeleton Design & Control Strategies

We developed a novel exoskeleton to provide knee extension assistance that integrated custom-molded orthotic braces, motors, transmissions, and sensors (Fig. 1). Our motor controller implemented a finite state machine that divided the gait cycle into stance, early swing, and late swing phases. We evaluated three modes of assistance (Figure 2); a **swing assist** condition that specified a constant extensor torque during the late swing state (3.5 Nm), a **stance assist** condition that specified constant extensor torque during the stance state (3.5 Nm), and a **stance & swing assist** condition that specified extensor torque during stance and late swing states.

Figure 1. The subject walking assisted by our exoskeleton.

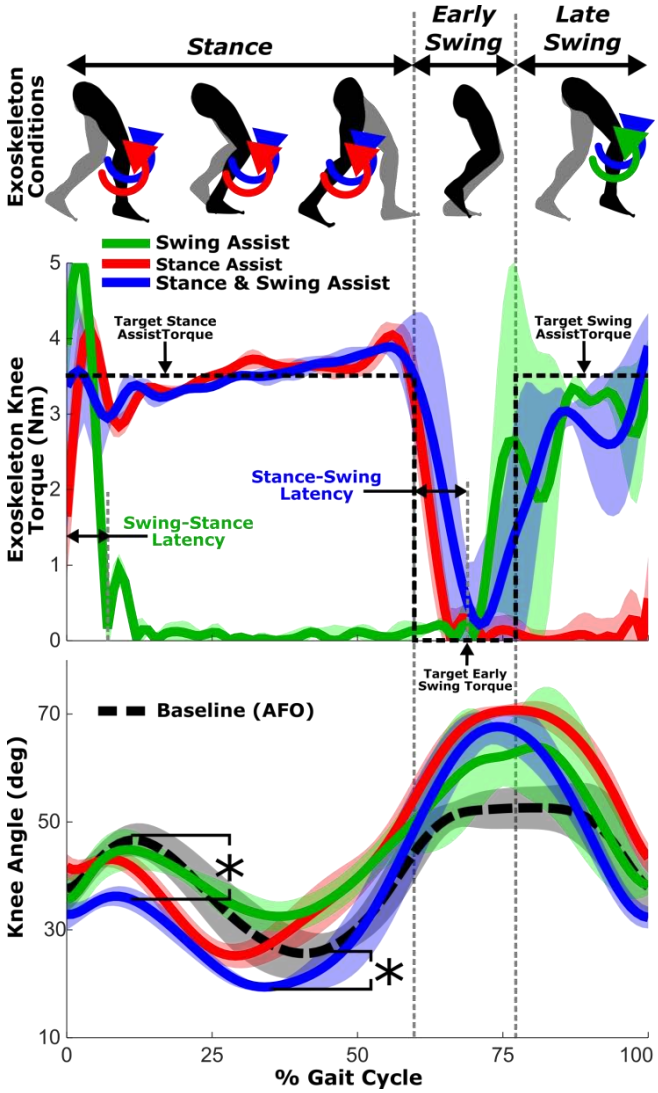

Figure 2. Exoskeleton conditions (top), measured torques (middle) and knee angles (bottom) for the right leg. Shaded regions represent ±1SD from the mean. * Indicates (p<0.05).

Participant Information

We recruited a 6 year old boy with CP and crouch gait, and obtained written informed consent and assent from the parent and the child, respectively. The Institutional Review Board at the National Institutes of Health approved this study.

Gait Analysis

The participant acclimated to the exoskeleton over 4 visits. On the 5th visit, he first walked over ground using his own AFOs (baseline condition), and then with the powered exoskeleton under the three exoskeleton conditions. We used a full-body marker set and 10 motion capture cameras (Vicon, Oxford, UK) to collect kinematic data. Joint angles were computed in Visual 3D (C-Motion, Germantown, MD). Torque from each of the exoskeleton's motors were measured by a sensor mounted on the drive shaft at the knee and was synchronized with the motion capture system.

Functional Exoskeleton Evaluation

The performance of our motor control algorithm was evaluated by comparing the desired (specified) assistive torque to the actual assistive torque measured from the torque sensor. We also evaluated how walking with the different exoskeleton conditions affected knee joint kinematics compared to the participant's baseline gait pattern, statistically analyzed via one-factor ANOVA procedures.

RESULTS

Measured assistive knee torques and computed knee joint angles across the conditions for the right (more affected) leg are shown in Fig. 2. The average root mean square error (RMSE) between the specified (target torques depicted in Fig. 2) and measured assistive torques was 0.91 Nm across all of the exoskeleton conditions. The average latency from when the controller changed state to when the specified torque setting was reached (as depicted in Fig. 2) was 52 ms. The shortest latency occurred during the transition to stance phase in the stance assist condition; the longest latency was from stance to early swing.

Maximum knee flexion during stance was reduced by 10.2° (right limb, $p<0.001$) and 5.3° (left limb, $p=0.003$) in the stance & swing assist condition compared to baseline; peak knee extension during stance increased by 5.4° (right limb, $p=0.002$) and 8.5° (left limb, $p<0.001$) in this condition as well. Knee range of motion increased for all of the exoskeleton conditions compared to baseline.

DISCUSSION

Motorized exoskeletons have the potential to provide customizable and adaptable control strategies to assist individuals with crouch gait. In this study, we evaluated the ability of our exoskeleton to provide assistance during different phases of the gait cycle because the many potential contributors of crouch gait suggest that the same level and timing of assistance is unlikely to be ideal for every patient. Our results suggest that the performance of the exoskeleton motor control conditions were adequate for providing assistance during each of the specified gait phases. Motor latencies were of similar duration to those of biological processes (e.g. muscle contractions), and therefore likely appropriate for human-machine interactions.

Our primary finding is that the powered assistance successfully reduced the amount of crouch in our participant. Overall, the stance & swing assist condition yielded the largest improvement in knee extension, followed by the stance assist condition. Peak knee flexion during swing was greater during all exoskeleton conditions compared to the baseline condition, representing a more normal kinematic pattern. A consequence of this was that while the exoskeleton was able to assist knee extension during terminal swing in the swing and stance & swing conditions, the limb needed to travel through a greater range of motion. Therefore, the potential benefit of the swing assistance may have been mitigated.

The results of this study are encouraging; we are currently evaluating how our exoskeleton and assistive conditions affect muscle activity, neuromuscular control, and gait mechanics in a larger cohort of children with crouch gait caused by CP. Areas of continued and future research include the development of adaptive control algorithms that may be used in long-term rehabilitation to reduce crouch while maintaining or improving strength.

INTRODUCTION

Rotator cuff tears are a significant clinical problem with an incidence greater than 30% in the general population [1]. Age-related degeneration has been proposed as a significant intrinsic factor likely related to the development of rotator cuff tears [2]. Furthermore, in the case of re-tears of surgically repaired degenerative rotator cuff tears, failure typically occurs at the tendon-suture interface [3], thus indicating poor tissue quality in these regions likely due to tendon degeneration. Previous studies assessing tendon degeneration of intact and torn rotator cuff tendon through histological analysis [4-6] found a strong relationship between age and degeneration; i.e. tendon degeneration increased with age. Additionally, regions with greater tendon degeneration were localized to areas adjacent to chronic rotator cuff tears. However, these studies typically take samples only from a single region of the tendon, and do not account for localized degeneration that may exist elsewhere in the tendon.

Recent findings using computational models of supraspinatus tendon tears indicate that different regions of a tendon may experience different magnitudes of mechanical strain relative to the location of a tear [7]. Similarly, differences in localized degeneration may relate to the ability of tendon tissue to resist tear propagation or suture pull-out during or after repair. Therefore, the objective of this study was to investigate histological differences in localized rotator cuff tendon degeneration in tendons with and without chronic rotator cuff tears. It was hypothesized that 1) degeneration would be worst at the insertion of the supraspinatus tendon to the humerus, the most common location for tears, and 2) degeneration around the tear will be worst in the stress-shielded region medial to the rotator cuff tear.

METHODS

Four intact fresh-frozen cadaveric shoulders (55 ± 12 years, 3 female, 1 male) and four shoulders with small rotator cuff tears isolated to the supraspinatus tendon (70 ± 9 years, 3 female, 1 male) were procured with permission from the University ethical oversight board. Supraspinatus and infraspinatus tendons were split into anterior and posterior halves of approximately equal width using a No. 11 scalpel blade. Tendon biopsies (dimensions of ~2 x 4 mm) were then taken near the myotendinous junction, tendon mid-substance, and the insertion for each tendon half. For tendons with an existing chronic tear, three samples were taken from around the tear: one sample from the medial edge of the tear, one from the anterior edge of the tear, and one from the posterior edge of the tear. All samples were fixed in 10% buffered formalin solution for at least three days, embedded in paraffin, and sectioned at a thickness of 5 µm. All slides were stained with H&E to visualize tendon morphology, and then imaged using a light microscope with a 20x objective lens across the full tendon thickness.

All histological images were graded by three independent observers for tendon degeneration using a semi-quantitative scale. Four main parameters were chosen to evaluate tendon degeneration: collagen fiber organization, tenocyte nuclei shape, tenocyte cell number, and lipoid degeneration [5, 8]. The chosen grading scale was modified from Sano et al. to create a 4-point scale of degeneration (0 = no change, 1 = slight localized change <25% of tendon area, 2 = multifocal change 25-50% of tendon area, 3 = diffuse or global change >50% of tendon area) [4]. Each histological image was graded by each observer using this 4-point scale for the four degeneration parameters, and the scores of the parameters were summed to generate an "overall" degeneration score. The scores of the three observers were then averaged to determine an overall degeneration score for the degeneration parameters for each sample.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Degeneration was compared for the three locations along the proximal-distal tendon length and the three locations around the chronic tear using ANOVA with post-hoc Games-Howell test with significance set at $p < 0.05$. Degeneration between tendons with and without chronic tears was compared using independent samples Mann-Whitney U tests.

RESULTS

In the shoulders with a tear, the anterior-posterior tear width was 14.8 ± 11.8 mm, and the medial-lateral tear width was 11.0 ± 7.0 mm. All tears exhibited a classic "crescent" shape. All tendons showed various stages of tissue degeneration, with some intact tendons showing nearly no degenerative changes (Figure 1A) and others showing significant fatty infiltration (Figure 1B) and loss of fiber organization (Figure 1C). Qualitatively, the worst degeneration was located around the chronic supraspinatus tear (Figure 1C). Grading among the three examiners showed good inter-rater reliability (ICC = 0.89).

No statistically significant differences were found in total degeneration, fiber organization, nuclei shape, or cellularity by location. However, the myotendinous junction showed a greater amount of lipoid degeneration compared to the tendon mid-substance or insertion ($p < 0.001$) (Table 1, Figure 1B). Similarly, lipoid degeneration was the only parameter to show a statistically significant difference between tendons with and without rotator cuff tears (Table 1). The medial edge of the rotator cuff tears showed small increases in most degeneration parameters compared to the anterior and posterior edges, especially for cell shape and total degeneration (Table 2). However, these differences were not statistically significant.

DISCUSSION

The results of this study indicate that age-related degeneration is a wide-spread phenomenon for intact tendons and those with small rotator cuff tears, and is not localized to the tendon insertion, refuting the hypothesis under study. However, lipoid degeneration in the tendon was found to be much greater near the myotendinous junction, indicating that muscle fatty infiltration may also result in tendon degeneration. Therefore, the clinical relevance of these results is that the risk of suture pull-out may be greater when this region is mobilized for rotator cuff repair. Although tears typically occur at the tendon insertion, degeneration does not appear to be worse there. Other factors such as biological processes or local strain distributions may more likely influence the location of tear initiation and propagation.

Interestingly, between the intact and torn tendons, lipoid degeneration was the only parameter that showed a statistically significant difference. This supports the notion that age-related tendon degeneration likely occurs prior to the development of a rotator cuff tear. Conversely, when the material properties of the tissue are reduced due to degeneration, tissue strains become sufficient to initiate a tear that can grow over time and result in further degeneration. Additionally, no statistically significant differences were found between the medial and anterior/posterior edges of the tear, indicating that although the medial edge of the tear becomes unloaded, it does not become more degenerated than the rest of the tissue surrounding the tear.

A limitation of this study was that only H&E staining was performed to assess degeneration based on changes in tendon morphology. While H&E staining was sufficient to find significant differences in key degenerative parameters, future work will include more rigorous biochemical procedures, including stains specific to collagen, fat, GAGs to better quantify degeneration.

This study provides insights on age-related degeneration in intact and torn rotator cuff tendons. Such tendon degeneration is not always macroscopically visible to surgeons, leading to overestimation of the quality of rotator cuff tissue during repair. The long-term goal of this work is to better quantify the etiology of rotator cuff tear progression and provide a guide for orthopaedic surgeons by defining a "danger zone" of poor tissue around a rotator cuff tear.

INTRODUCTION

Valve interstitial cells (VICs) reside in heart valve tissues and play critical roles in tissue maintenance, but also contribute to heart valve diseases [1]. VICs are myofibroblast-like cells with tissue remodeling activity due to collagen production and contraction activities mediated by α-smooth muscle actin (α-SMA) stress fibers. The VICs are activated by mechanical stimuli during tissue repair, development, and remodeling, and removed as they complete their role. The VICs are sensitive to their surrounding microenvironments, and excessive and persisting environmental changes cause the improper regulations of VICs, contributing the progression of valve disease. Thus, it is important to characterize how the external mechanical stimuli translate into and activate the VICs, and how the different activation levels affect the VIC's internal mechanics and their mechanical response to the surrounding tissues.

Contractile properties of the VICs are connected to their valve tissue remodeling and repair capabilities, as well as initiation of pathological process. However, their contractile mechanism are not well understood. Thus, in order to understand the complex biomechanical behaviors of the VICs in cellular and subcellular levels, we need to develop a computational model of the VICs that is capable of capturing their responses to mechanical stimuli from surrounding tissues under wide range of activation states. Such a model can integrate the various and often disparate experimental findings by deciphering the underlying mechanisms and provide us with insight that would otherwise be difficult or impossible to obtain from experimental data and observations alone.

The objective of this study is to develop an improved computational model of a VIC by incorporating a more realistic stress fiber model. Then, by integrating the experimental data of the AVICs into the model, we studied how the stress fibers in the AVICs adapt to different activation states, and how the different components of the stress fibers, F-actin and α-SMA, affect the stress fiber biomechanics.

METHODS

We carried out the microindentation experiment on AVICs cultured on a flat thin-layered collagen substrate over a glass. We used a spherical indenter with 5 μm diameter. We controlled the activation states of the AVICs with different chemical reagents to alter the biomechanical properties of the stress fibers. Then, using the experimental data from different experimental groups, we studied how the different components of the stress fibers (α-SMA and F-actin) influenced the stress fiber biomechanics, such as their stiffness and contractile strength. We have five experimental groups: Cytochalasin D pretreated group (CytoD), Control groups with 5 mM and 90 mM KCl treatments (C5 and C90 groups, respectively), and transforming growth factor-beta1 (TGF-β1) pretreated groups with 5 mM and 90 mM KCl treatments (T5 and T90 groups, respectively). For each group, we extracted the indentation depth vs force curves, which were later fit to the computational model.

Immediately following the microindentation, α-SMA, F-actin, and nucleus were stained with and fluorescent images were taken to quantify the expression levels of α-SMA and F-actin for each group. Z-stacks were also taken using confocal microscopy to determine the appropriate AVIC and nucleus geometries and stress fiber orientations for each activation state. The expression levels of α-SMA and F-actin, AVIC and nucleus dimensions, and stress fiber orientations were averaged for each group and used for the input for the computational model.

The computational model of an AVIC was developed by extending the "basic" model of a VIC from our previous study [2]. The improved model can capture more realistic stress fiber mechanical responses. The main improvements are: 1) more realistic stress fiber geometry taken

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

from experiments, 2) more realistic stress fiber contraction model. The computational domain consists of three subdomains: Ω_{cyto}, Ω_{nuc}, and Ω_{ind}, which describe the cytoplasm, nucleus, and rigid spherical indenter, respectively (Figure 1). The cytoplasm was considered as a solid mixture of basal cytoplasm and oriented stress fibers. The basal cytoplasm was modeled as a nearly-incompressible neo-Hookean material. The stress fibers were modeled as the ensemble of oriented 1D fibers with passive elastic and active contractile responses with their orientation described by a continuum orientation density function. The active contraction of the stress fibers were modeled by length-tension relationship (f_l) multiplied by the maximum contraction strength (f_0):

$$f(\bar{\phi}_{\alpha-SMA}, \bar{\phi}_{F-actin}, \lambda) = f_0(\bar{\phi}_{\alpha-SMA}, \bar{\phi}_{F-actin}) f_l(\lambda)$$
$$f_0(\bar{\phi}_{F-actin}, \bar{\phi}_{\alpha-SMA}) = f_{F-actin}\bar{\phi}_{F-actin} + f_{\alpha-SMA}\bar{\phi}_{\alpha-SMA} \quad (1)$$

where f_l only depends on 1D stretch (λ) and f_0 is a linear combination of expression levels of F-actin and α-SMA ($\bar{\phi}_{F-actin}$ and $\bar{\phi}_{\alpha-SMA}$, respectively). Two constants: $f_{F-actin}$ and $f_{\alpha-SMA}$, were determined using experimental data. The AVIC and nucleus dimensions, F-actin and α-SMA expression levels, and stress fiber orientation density were determined from the experiments and fed into the computational model. Then, using the indentation depth vs force curves from the simulations and experiments, the model parameters were determined.

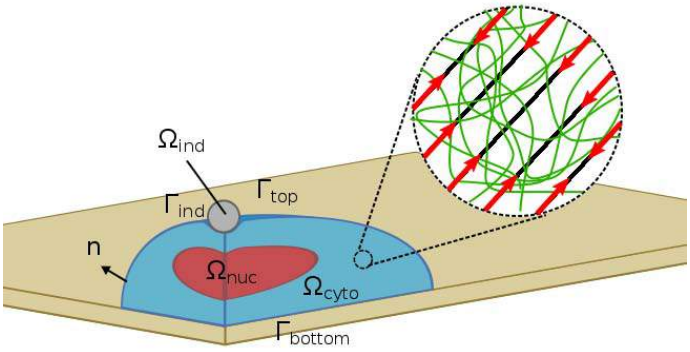

Figure 1: AVIC model framework.

RESULTS

The primary result in this study is that we separated the contributions of the F-actin and α-SMA to the overall contractile strength of the stress fibers (Figure 2). In Figure 2, green and blue columns represent the contributions of the F-actin and α-SMA to the contractile strength of the stress fibers within AVICs for each group determined by (1). The treatment with 90 mM KCl and pre-treatment with TGF-β1 activated the AVICs, enhancing the contractile strength of the stress fibers. In addition, the overall contractile strength of the stress fiber was dominated by the α-SMA contribution, which is consistent with the previous experimental observations that incorporation of the α-SMA into stress fiber significantly enhances the contractile activity of the VICs [3].

To better understand the interaction between the AVICs and substrates, we calculated the total force that the AVIC exerts on the substrate for each group. The calculated total forces are: 0 nN, 71.8 nN, 86.6 nN, 142.6 nN, and 158.5 nN for CytoD, C5, C90, T5, and T90 groups, respectively. The total force calculated from the TFM experiments are: 35.2±9.6 nN (n=15), 544.9±114.5 nN (n=13), and 932±393.5 nN (n=8), respectively for Blebbstatin treated, control, and TGF-β treated groups (unpublished data from Dr Billiar's lab). Note that Blebbstatin disrupts the stress fiber structure, just as CytoD does. Although the total forces calculated in this study were smaller than the TFM data, the trends stayed the same: the relative increase of the total force from the C5 to T5 group in this study was 2.0 while the relative increase of the total force measured by TFM from the control to TGF-β treated group was 1.7. Thus, our model can be used to capture the trend in the total force that AVICs exert on the surrounding substrates. The larger total forces in the TFM experiment may be resulted from the stronger contractile force near the ends of the AVIC, as observed for fibroblasts [4].

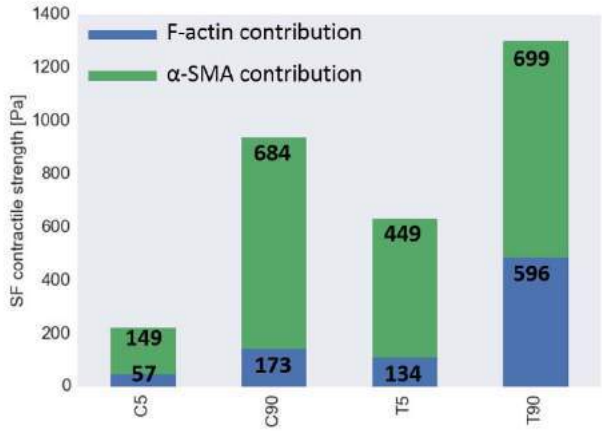

Figure 2: Contributions of the F-actin and α-SMA to the maximum SF contraction strength (f_0) for each group.

DISCUSSION

We have developed the improved computational model of the AVICs that consists of the different mechanical constituents of the stress fibers. We have incorporated the detailed data of the AVIC under microindentation experiment into our model to derive the insight in the stress fiber biomechanics, which was previously unable to obtain due to the complexity of the mechanisms and difficulty of directly analyzing the subcellular mechanics. We have found that the both F-actin and α-SMA contribute to the stress fiber force generation. However, as previously reported, the incorporation of α-SMA into the stress fibers have dominant effect on the increase in the stress fiber contractile strength. This increase in the stress fiber contractile strength also influenced the traction force that the AVICs exert on the substrates. Thus, in order to understand how the AVICs interact with the surrounding environment, it is critical to model the stress fiber mechanics with the α-SMA component. We hope that our study can provide an improved view of the stress fiber force generation mechanics within the AVICs.

INTRODUCTION

In this study we investigate the earliest signs of damage in articular cartilage (AC) following mechanical trauma and thus inform the development of treatments for osteoarthritis (OA).

OA is a painful and debilitating joint disease that develops when AC degrades, exposing the underlying bone. Today, OA is one of the leading causes of disability in the United States. Moreover, at least 12% of OA develops after a distinct, mechanically traumatic event, such as a sports injury [1]. Current research recommends that OA interventions target the disease early, in what may be thought of as pre-OA. At this early stage, the AC has been damaged but true clinical OA has yet to develop [2-3]. Thus, in the search for a treatment, it is critical to understand the early pathogenesis of OA. However, little is known about the earliest stages of AC degeneration, especially in the minutes to hours after trauma [4]. Recent studies show that chondrocyte respiratory dysfunction and death are early indicators of AC damage [4-6]. In particular, mitochondrial depolarization may be a key precursor to cell death and the eventual onset of OA.

Therefore, in this study, we investigate how chondrocyte dysfunction and death develop in the minutes to hours after impact trauma.

METHODS

To study the kinetics of chondrocyte dysfunction after mechanical trauma, we used a custom rapid impact device combined with a novel direct-imaging method to monitor individual cells over time in whole tissue. Cylindrical explants (n=3, 6 mm diameter, 3 mm deep) were extracted from the medial condyle of 1-3 day old bovines. Samples were cut perpendicular to the articular surface, creating two opposing hemiclyinders (Fig. 1A). Hemicylinders were then stained with Hoechst 33342 (1 µg/mL for 50 min) to highlight dead cell nuclei, MitoTracker Green (MTG, 200 nM for 50 min) to highlight all mitochondria, and Tetramethylrhodamine (TMRM, 10 nM for 30 min) to highlight polarized (healthy) mitochondria only. The two samples were mounted to the impactor's backplate and then loaded into the PBS bath of the impactor, as described previously [7]. One of the two hemicylinders was impacted at approximately 1 MPa over 5-10 ms using a 0.8 mm diameter rod. The second sample served as an unimpacted control. Samples were imaged using confocal fluorescence

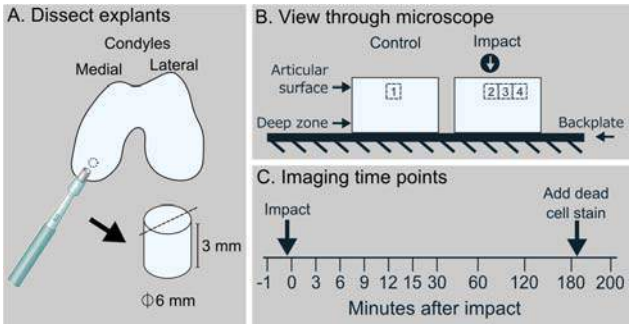

Figure 1. Experimental design. Samples were (A) dissected from medial condyle and stained with Hoechst, MTG, and TMRM, and then (B) mounted in the impactor on a confocal microscope. Control samples were imaged at one position and impact samples at 3 positions. (C) Positions were imaged before and for 3 h after impact. Samples were then stained with EthD and imaged again.

microscopy with 20× magnification (424 µm field of view) at different positions relative to the impact, as depicted in Fig. 1B. All imaging positions were centered 424 µm below the articular surface, to avoid artifacts from imaging at the surface. Positions 2-4 were adjacent fields of view, with position 2 centered under the impact. Samples were imaged at these positions before and for multiple time-points after impact, as described in Fig. 1C. Then, at 3 h after impact, samples were additionally stained with ethidium homodimer (EthD, 2 µM for 20 min) to highlight dead cells, and imaged again to determine the fate of each cell.

Images were processed in MATLAB to extract cellular changes after impact. Images were first registered to align them over time and then thresholded to segment individual cells. The average TMRM signal of each cell was tracked over time and cells that lost more than 75% of their initial TMRM signal were marked as depolarized. The difference between TMRM images before impact and at 15 min after impact was also calculated.

RESULTS

After impact, mitochondria depolarized rapidly (Fig. 2, 3). Confocal images revealed dramatic mitochondrial depolarization

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

within the first 15 minutes after impact, especially directly under the impact (position 2, Fig. 2). This rapid depolarization was confirmed by survival curves based on each cell's decrease in TMRM signal over time (Fig. 3).

Confocal images further revealed that rapid mitochondrial depolarization and cell death were linked. Cells that showed mitochondrial depolarization within 15 minutes after impact stained for cell death at 200 min, while cells that depolarized later did not (Fig. 2).

Moreover, mitochondrial depolarization and cell death varied based on distance from the impact (Fig. 2, 3). Directly under the impact (position 2), there was widespread mitochondrial depolarization and cell death. Further away from the impact (positions 3-4), there was some depolarization and death, but less than at position 2. In comparison, images at position 1 revealed little to no depolarization or death in the control sample.

DISCUSSION

Using a novel direct-imaging method to track individual chondrocytes in whole AC, we revealed that, near the impact location, mitochondria begin to depolarize immediately after trauma. Furthermore, only cells whose mitochondria depolarize by 15 min after impact have died by approximately 3 hours after impact. These effects are strongest closest to the impact and weaker further away.

These cells that depolarize and die quickly after impact may initiate the biological instability and feed-forward loop that drives cartilage degradation and OA development. As such, this subset of damaged cells may be a key target for mitoprotective therapies or other treatments that interrupt cellular deterioration. These results further emphasize that potential OA treatments should be focused very early after trauma, perhaps within the first hour.

The location-dependence of cellular dysfunction also provides insight into OA initiation after trauma. Recent studies have shown a similar position-dependence in the cell death that develops immediately after impact injury [7]. In particular, the mitochondrial dysfunction observed in this study appears to correlate with the impact-induced strain profile described in Bartell, et al [7]. This implies that strain during rapid impact leads to mitochondrial dysfunction, cell death, and the ultimate development of OA.

Overall, this method expands the current ability of the field, enabling us to study the earliest changes in AC after mechanical trauma. In particular, these results provide a detailed understand of how AC degrades and how potential therapies may prevent OA from developing.

ACKNOWLEDGEMENTS

This work was funded by in part by the NIH (R21-AR062677), the NSF (CMMI-1536463), and the Harry M. Zweig Fund for Equine Research. L.R.B. was also supported by the NSF GRFP (DGE-1144153). Imaging data was acquired through the Cornell University Biotechnology Resource Center, with NYSTEM (CO29155) and NIH (S10OD018516) funding for the shared Zeiss confocal microscope.

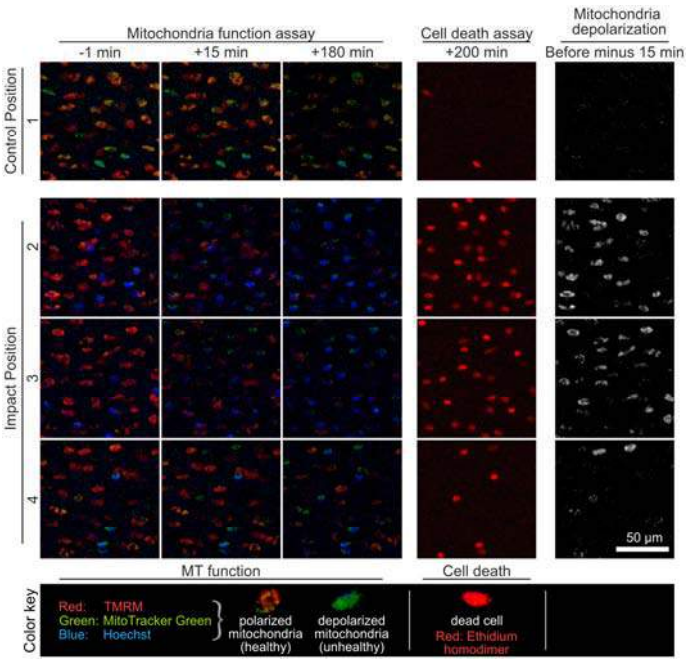

Figure 2. <u>Impact causes rapid, location-dependent mitochondrial dysfunction</u>. Example confocal images show mitochondria function (columns 1-3) and cell death (column 4) at the different sample positions in the control (row 1) and impact (rows 2-4) samples. The difference between TMRM signal before impact and at 15 mins after impact is also shown (column 5). The mitochondria assay is shown before impact, 15 min after impact, and 180 min after impact. For mitochondria function images, red (TMRM signal) indicates polarized mitochondria, while a loss of red over time (exposing the underlying green stain) indicates depolarization. For cell death images (column 4), red indicates dead cells. Images in the same row are from identical locations.

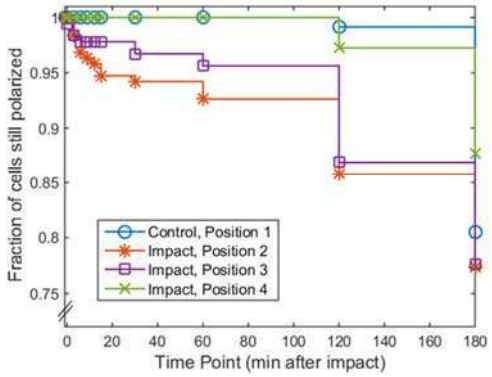

Figure 3. <u>Survival curve quantifies rapid, location-dependent mitochondrial dysfunction after impact</u>. This plot shows the fraction of polarized mitochondria over time in control (position 1) and impact (position 2-4) samples. Cells that lost more than 75% of their initial TMRM signal were marked as depolarized. Overall, cells depolarize rapidly, with more depolarization closer to the impact location.

INTRODUCTION

The initiation and propagation of rotator cuff tears are poorly understood, despite an incidence of over 30% [1]. Numerous studies have shown the importance of tendon surface strains on the initiation and propagation of rotator cuff tears [2, 3]. Additionally, computational models have been developed to further investigate the mechanical environment of the rotator cuff [4,5]. However, these models use simplified geometry or isotropic elastic material properties, which are not representative of the true properties of tendon tissue and can have a drastic effect on the predicted strains. Therefore, the objective of this study was to develop and experimentally validate a three-dimensional finite element model of supraspinatus tendon using subject-specific geometry and anisotropic material properties to predict strains in intact supraspinatus tendon at multiple joint angles. The model was considered valid if the difference between experimental and predicted strains was less than the experimental repeatability of 3%.

METHODS

An intact, cadaveric shoulder (male, 70 y.o.) was dissected to isolate the rotator cuff tendons. A 6 x 4 array of markers was affixed to the bursal and articular surfaces of the tendon (Figure 1). The humerus was potted in epoxy putty and loaded into a custom jig that allowed for positioning of the tendons. Geometry of the shoulder and markers were obtained using a soft-tissue CT scanning protocol at 70 degrees of glenohumeral abduction (GE Lightspeed 16, Milwaukee, WI).

Next, the humerus was secured to a materials testing machine (Instron, Model 5965) and the supraspinatus tendon was clamped to the crosshead for loading at 70 degrees of abduction (Figure 1). The infraspinatus was loaded with 22 N to simulate load sharing with the supraspinatus. A 4-camera video tracking system was used to track marker positions during testing (Spica Technology, Kihei, Maui HI). After 5 N preload and preconditioning (5-50 N, 10 cycles), the preload was reapplied and the reference strain configuration was recorded. Next, cyclic loading was performed (5-200 N, 50 cycles, 20 mm/min) and marker locations were recorded at the peak of the final load cycle. This process was repeated at 90 degrees. Maximum principal Green-Lagrange strain was calculated at the centroid of each element created from sets of four surface markers (total of 30 elements). Calculations were performed by inputting the reference and strained configurations of the surface markers into ABAQUS (ABAQUS/CAE 6.4) [6].

Next, the tendon was split into thirds of equal anterior-posterior width to determine material properties. After measurement of cross-sectional area with 2% accuracy (NextEngine 3D Scanner HD), each third was loaded to failure and stress-strain curves were generated. A transversely isotropic fiber reinforced Neo-Hookean model was chosen to represent the behavior of the tendon [7], and a set of material constants were calculated using a least squares approach (MATLAB). The humerus and cartilage were represented as fixed rigid bodies.

Humerus and tendon geometry were segmented from CT data (Mimics 15, Materialize) and converted to a solid model. The mesh for finite element modeling (Hypermesh, Altair Engineering) consisted of 14350 nodes and 63439 tetrahedral elements. This mesh was chosen after testing convergence with a change in strain of less than 1%. Displacement-driven finite element analyses were performed for each joint angle using custom non-linear code [8] and displacements recorded at 200N. A 22N load was applied to the infraspinatus to mimic experimental conditions. Inhomogeneous material properties were assigned to the supraspinatus by varying material parameters in the anterior-posterior direction based on experimental data.

Maximum principal Green-Lagrange strains for each element were computed. The nodes nearest to the center of each marker were recorded to make comparisons within the same regions of interest as

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

experimental conditions. The strains of all tetrahedral elements bounded within each experimental strain element were recorded and averaged to determine an average strain for each region. This value was compared to the strains for each experimental surface element [6]. For validation, the average difference in strain between model and experiment must be less than the experimental repeatability of 3% strain.

RESULTS

Experimentally, the largest maximum principal strains were found on the articular side of the tendon, with the largest strain observed being 13.4% at 90 degrees of abduction (Figure 2A). On the bursal side, the largest strain was 11.7%, also at 90 degrees of abduction (Figure 2B). On average, maximum principal strain was 2% strain higher at 90 degrees of abduction than at 70 degrees. Strains increased in magnitude further away from the tendon insertion, and decreased in magnitude on the articular side from anterior to posterior. On the bursal side, strains decreased from posterior to anterior in reverse of the articular side.

Qualitatively, the model predicted a similar pattern of strain as the articular side of the supraspinatus, with strains decreasing closer to the insertion (Figure 2A). On the bursal side, the model predicted a pattern more similar to the experimental strains on the articular side (Figure 2B) Predictions of average strains at 90 degrees were within 3.6% strain of experimental values for the bursal side and 3.1% strain for the articular side. At 70 degrees, predictions for the bursal side were within 2.2% strain and for the articular side were within 3.6% strain. On the bursal side, strain predictions were most different from experimental closer to the insertion (Table 1). On the articular side, predictions were most different in the middle row of markers. Strains in the anterior-posterior direction were most different closer to the infraspinatus.

DISCUSSION

This study developed and validated a subject-specific 3D finite element model for prediction of tendon strains at two glenohumeral joint angles. Bursal and articular surface strains predicted by the model were close to within 3% strain of the experimentally determined values, but the model had difficulty predicting experimental strains near the insertion and infraspinatus tendon, indicating potential boundary effects that are currently not accounted for by the model. Additionally, experimental measures and model predictions were similar to previous studies that have shown similar patterns and magnitudes of strain [9,10]. Previous models of intact rotator cuff tendon using simplified geometry and isotropic elastic material properties found highest stresses to be located on the articular side of the tendon and that the magnitude of stress increased with joint angle, similar to the predictions of the model in the present study for strain [4,5].

Unlike previous models of the rotator cuff, this model uses experimental validation with subject-specific geometry and anisotropic, inhomogeneous material properties that better represent the behavior of the tendon. Overall, this model establishes a framework to predict the effect of loading on tendon strain, providing a useful tool to better evaluate the mechanical environment of the supraspinatus tendon as it relates to rotator cuff injury. Based on the validation data, this model will be improved by varying material parameters at the tendon insertion and where fibers from the infraspinatus merge with the supraspinatus to better account for local differences in material properties. Ultimately, by introducing "tears" of different geometry, location, and chronicity into the intact tendon geometry, this model can be used to predict tendon strains for investigating risk factors for rotator cuff tear initiation and propagation.

The model has been only validated for the region medial to the tendon insertion. However, the goal of this model is to predict tear propagation within the region most common to rotator cuff tears, and therefore it can serve as a basis for further studies. Future directions for the model include contact boundary conditions between tendon and cartilage to validate the model at lower abduction angles. This information will provide surgeons with updated guidelines for proper management of rotator cuff tears to minimize the time and costs associated with rotator cuff tear treatment.

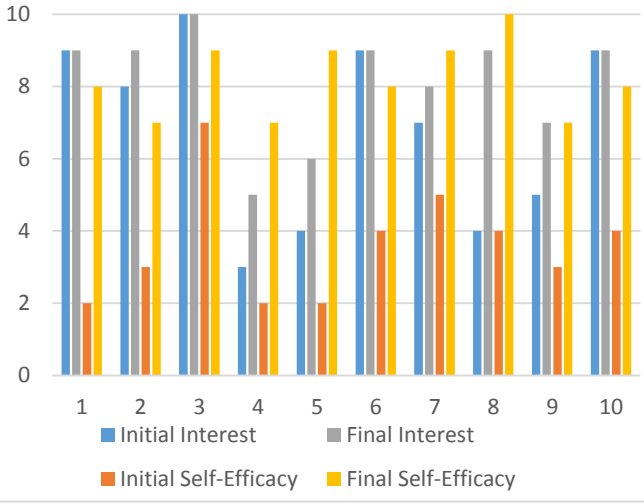
INTRODUCTION

The importance of engaging and inspiring young scientists and innovators cannot be understated. The future of technological advancement is critical to advancing an ever more complex society, and without new ideas and new innovators, we will swiftly be left behind. Therefore, there are numerous efforts underway to increase participation in science, technology, engineering and math (STEM). However, for individuals who are not trained in developing curriculum or teaching at the elementary school level, it is daunting and often discouraging to embark on such an endeavor no matter how important it may be. One avenue which allows University level scientists and engineers to disseminate their research to elementary school children is the STEM club. STEM clubs can be simple and informal with limited required resources to well-funded outreach programs with strong ties to one's University. In this pilot work, I wish to share some of the experiences in implementing a rather informal STEM club at my hometown elementary school. A fun and active program was introduced and implemented as a curriculum of instruction for students in the area of creativity and innovation of new solutions using a translational analysis approach which involved the use of technology including 3D printing. The instruction was based in part on the "Biodesign" textbook [1], findings on creativity in the classroom [2], along with other resources. Over the course of two weeks, students were be facilitated through a process of 1) observing physical phenomena which was of interest, 2) identification of needs, 3) brainstorming solutions, 4) concept generation in an *in silico* (virtual) environment, and 5) design optimization. Students were provided access to the necessary *in silico* technology (i.e. Solidworks) as well as 3D printing technology (ZCorp 3D printer) which were made available from my research lab.

METHODS

Self-identified interested elementary students (n=10 3rd-5th grade) were selected from math and science classes of a local elementary school. Students were polled (scale 1-10 with 10 being high interest and or efficacy) to determine their initial self-efficacy and interest in science and math (Figure 1). Students were then instructed to seek out any problem that interested them and which may have a technological solution (a few examples were provided as guidance). Students were to watch the news, read newspapers or magazines, and/or poll their friends and families. After one night of research, two potential problems were

Figure 1. Self-reported interest and self-efficacy in math and science



Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

identified for further analysis from the long list of possibilities compiled. The first was the development of a new water filter (perhaps for use in underdeveloped countries or in water bottles), and the second was a heatsink to keep computers and/or game consoles cooler. General and specific needs for each were discussed such as size requirements, costs, surface area, and materials. A brainstorming session was facilitated to develop as many creative solutions to the problems as possible. Minimal input from the PI was included in an attempt to avoid stifling creativity and thinking. Next, students were asked to translate their ideas into *in silico* computer models using computer aided design (CAD) methods. Students were given an introduction to Solidworks (Dassault Systèmes, Waltham, Massachusetts, USA), and then asked to create a model which was no more than 1" in dia and 5" in length which had a maximum surface area for filtration and/or heat transfer. Initial designs ranged from the simplistic to the very complicated (Figure 2). Each student presented their designs and explained their rationale to the group. Alternative strategies were discussed in the context of design improvement/optimization. Finally, students were facilitated through a process of design refinement until they reached their self-identified "optimal" solution (Figure 3). Students were again polled (scale 1-10 with 10 being high interest and or efficacy) to determine their self-efficacy and interest in science and math following the exercises and instruction (Figure 1).

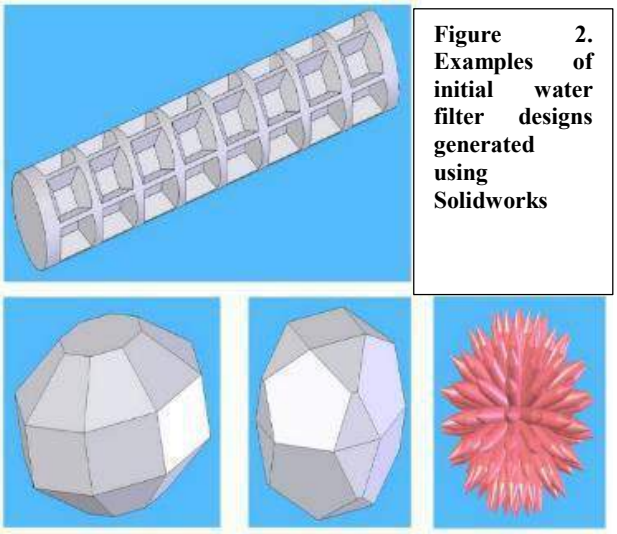


Figure 2. Examples of initial water filter designs generated using Solidworks

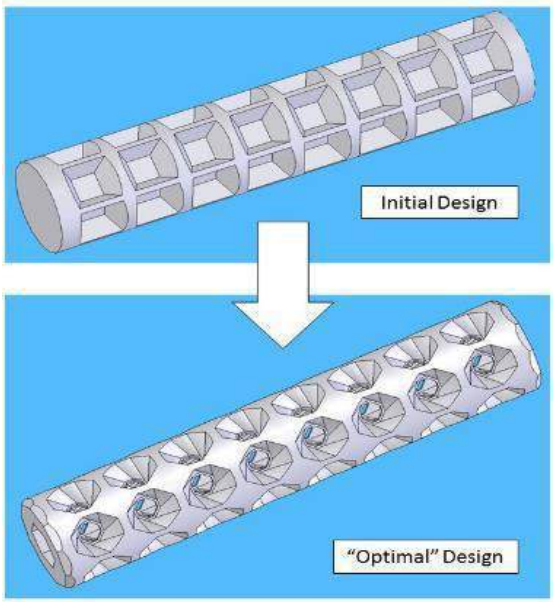

Figure 3. Examples of initial water filter designs and "optimal" final design

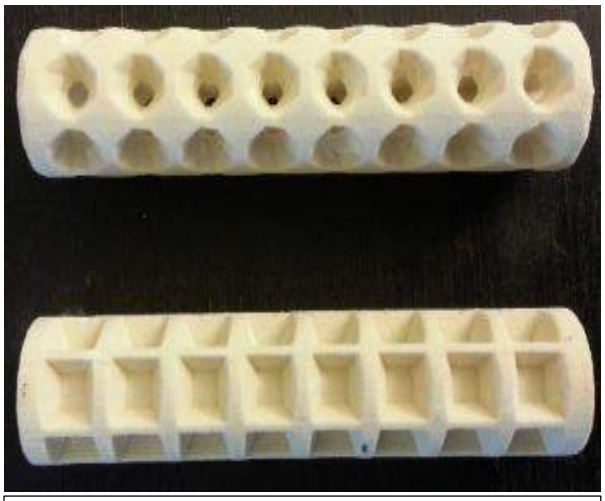

Figure 4. Examples of 3D printed water filter designs

RESULTS

In general, student interest in math and science remained the same although there was a trend toward an increase in interest following the exercises. Student's perceived self-efficacy was substantially increased following the active learning activities indicating the potential for improvement using similar methods.

*S*tudents were provided the opportunity to 3D print their designs, including initial and "optimal" final designs (Figure 4), using a ZCorp Z400 3D printer currently in use for research purposes at the PIs lab.

DISCUSSION

The opportunity for hands-on active learning including generating *in silico* and 3D printed solutions had a tremendous impact on the students involved. Additionally, the process was very fulling to the instructor and the faculty contacts. The implementation of STEM clubs need not be so complex as to stifle implementation. Even an informal implementation such as was seen in this exercise has measurable and lasting impact on student's passion for STEM.

INTRODUCTION

Blood vessel formation is essential for tissue development and regeneration and contributes to tumor growth and metastasis [1]. Physical cues such as the mechanical properties of the extracellular matrix are known to modulate vessel formation [2], but the mechanisms by which vessels respond to these mechanical signals are poorly understood [1].

Yes-associated protein (YAP) and transcriptional activator with PDZ-binding domain (TAZ) were recently identified as potential key mediators of cellular mechanotransduction [3]. These paralogous transcriptional co-activators translocate to the nucleus and activate the TEA-domain (TEAD) family of transcription factors to promote transcription of pro-proliferative and anti-apoptotic genes [4]. YAP and TAZ are regulated by two opposing pathways: cytoskeletal tension [3], which promotes YAP/TAZ activation through nuclear translocation, and cell-cell contact-mediated inhibition through the Hippo pathway Ser/Thr kinases, large tumor suppressor 1 and 2 (Lats1/2), which restrict YAP and TAZ to the cytosol [4]. YAP and TAZ regulate organ size and cell differentiation [3-4], and YAP, but not TAZ, has been reported to promote angiogenesis and embryonic vasculogenesis [5-6]. However the roles of YAP and TAZ in neovascular mechanotransduction are unknown.

We hypothesize that YAP and TAZ are essential mediators of endothelial progenitor cell mechanotransduction of extracellular matrix rigidity. We used endothelial colony forming cells (ECFCs), circulating endothelial progenitor cells capable of undergoing post-natal vasculogenesis, the *de novo* formation of vessels, *in vivo* [7]. ECFCs enhance vessel formation in response to matrix stiffness [8], however a mechanism has yet to be identified.

METHODS

ECFCs isolated from umbilical cord blood were cultured in endothelial growth medium (EGM-2) with 10% FBS. YAP and TAZ were depleted using either YAP, TAZ, YAP and TAZ, or non-targeting siRNA, and efficiency of depletion was assessed by Western blot (data not shown). YAP and TAZ mechanosensitivity in ECFCs was assessed on soft and stiff 2D substrates using tunable polydimethylsiloxane (PDMS). ECFC migration and vasculogenesis were evaluated in wound migration, 2D Matrigel tube formation, and 3D collagen matrix vasculogenesis assays. YAP and TAZ activation during ECFC migration was assessed by immunofluorescence in the wound migration assay. YAP and TAZ subcellular distribution was quantified in regions of interest (ROI) of 957 μm by 100 μm. YAP and TAZ intensity in each ROI was normalized to cell number and basal expression, and data were fit to an exponential decay function by least squares regression. Mechanical control of YAP and TAZ localization during 3D vasculogenesis was evaluated in collagen fibril matrices of defined architecture, enabling control of matrix rigidity independent of matrix density, as described previously [8]. Matrices formulated from oligomeric collagen fibrils contain native cross-links that form stiffer matrices (G'=1049 Pa) than monomeric collagen (G'=305 Pa), while maintaining the same ligand density [6]. ECFCs embedded in oligomeric matrices and transplanted into immunocompromised mice were recovered and stained for YAP, TAZ, human cysteine rich angiocrine-61 (Cyr61), connective tissue growth factor (CTGF), and human CD31.

RESULTS

ECFC YAP and TAZ exhibited matrix mechanosensitivity on stiff PDMS, with nuclear localization of stiff (130 kPa) and cytosolic localization on soft (5 kPa) PDMS (Fig. 1). ECFC migration was significantly impaired by YAP and/or TAZ depletion though TAZ

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

knockdown had a more pronounced effect that was statistically identical to YAP/TAZ co-depletion (Fig. 2AB). Both YAP and TAZ were activated in migrating ECFCs in a position-dependent manner; both nuclear localization and total YAP/TAZ expression follow an exponential decay from the migrating front (Fig. 2C, D, and E). Migration-dependent nuclear localization correlated with increased cell density and decreased cell area, readouts for contact inhibition and cytoskeletal activation, respectively (data not shown).

YAP and/or TAZ depletion significantly reduced 2D tubular network formation on matrigel in a dose-dependent manner, with loss of both YAP and TAZ abrogating tube formation at all time points (Fig. 3A). ECFCs embedded in oligomeric collagen readily formed large tubes whereas monomeric matrices form smaller tubes with less extensive networks (data not shown). Depletion of YAP and TAZ decreased cell spreading and abrogated vessel formation in oligomer matrices (Fig. 3B). Embedding cells in stiff oligomer collagen matrices resulted in nuclear localization of YAP (Fig. 3C) and TAZ (data not shown), and nuclear exclusion in soft matrices (Fig. 3C).

Collagen matrices laden with human ECFCs implanted *in vivo* were stained for hCD31, YAP, TAZ, Cyr61, and CTGF (Fig.4). ECFCs formed a functional human neovascular plexus that integrated with the host vasculature, and exhibited strong expression and nuclear localization of YAP and TAZ. Downstream targets of YAP and TAZ, Cyr61 and CTGF, were expressed throughout matrices but primarily at vessel walls.

Figure 4: Collagen matrices implanted in vivo stained for human CD31, YAP, TAZ, CTGF, and human Cyr61.

DISCUSSION

Taken together, these data suggest that YAP and TAZ are essential for mechanical regulation of ECFC vasculogenesis. YAP and TAZ were expressed and regulated by matrix rigidity in ECFCs, in both 2D and 3D. Depletion of YAP and/or TAZ impaired ECFC migration, tubular network formation and vasculogenesis in 2D and 3D. Loss of YAP resulted in a mild phenotype, suggesting a potential compensatory function for TAZ, which may indicate a more dominant role than YAP in vasculogenesis; ether because TAZ is more highly expressed or a more potent transcriptional activator in ECFCs.

YAP and TAZ expression and nuclear localization correlated inversely with cell density and proportionally with cell area, indicating that Hippo and cytoskeletal activation may act in concert to regulate YAP and TAZ activation during migration of initially confluent ECFCs, with regulation of both total expression and subcellular distribution. This may be attributable to increased transcription and/or reduced degradation of both YAP and TAZ in migrating ECFCs.

These results indicate that YAP and TAZ are essential for ECFC vasculogenesis and mechanotransduction, and based on *in vivo* YAP and TAZ target gene expression we hypothesize that YAP and TAZ mediate ECFC vasculogenesis through Cyr61 and CTGF expression.

INTRODUCTION

Heart disease has become the number one leading cause of death in the US with around 6 million deaths each year. To better understand the global heart contraction and relaxation, it is essential to obtain the knowledge in heart muscle organization, as well as how the complex multilayered helical architecture is mediated by 3D cardiac extracellular matrix (ECM) that spans from epicardium, to myocardium, to endocardium. However, the majority of the previous research on cardiac ECM has mainly focused on collagen in heart, while little has been done to study elastin, another important component in the heart ECM [1-2]. In this study, we aim to delineate and quantify the 3D elastin network in the epicardium of the porcine left ventricle.

METHODS

Fresh porcine hearts (~6 months old) were obtained from a local abattoir. To acquire the 3D image of the elastin network, epicardium samples (12 mm × 12 mm × 1 mm) were dissected from the base, middle and apex regions of the left ventricle in both the anterior and posterior locations (Figure 1).

Laser scanning confocal microscopy (LSCM) was applied to visualize and image the 3D elastin network under red channel (elastin autofluorescence, CY3, Ex = 543 nm) with z-stack imaging technique. The 3D z-stack images covered a thickness range from 40 to 70 μm at ~1 μm interval. All images were acquired with a 12-bit gray scale and a dimension of 1024 × 1024 pixels. ImageJ (NIH, Bethesda, MD) was used to create a 3D projection of the first 15 μm thick layer, the last 15 μm layer, and the full thickness of image stack. Elastin fiber orientation and distribution in different layers were then quantified using OrientationJ plugin. For histological assessment, tissue samples were fixed in 10% formalin for 72 hours and stained with Movat's pentachrome, in which elastin is stained black, heart muscle stained red. In-house custom written software was also used to reveal other 3D features of the epicardial elastin network.

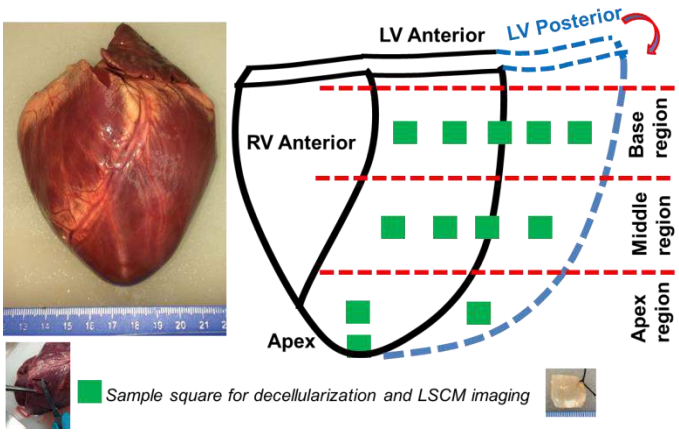

Figure 1: Schematic illustration of the left ventricle showing locations of sample dissection.

RESULTS

We first validated that the fiber image signals in LSCM images are elastin specific since under the same condition the decellularized myocardial layer, which dominantly consists of collagen network, produces no detectable signals (Figure 2B). On the other hand, elastin fiber signals were detected not only in the decellularized epicardial layer (Figure 2A) and the decellularized endocardial layer (Figure 2C), but also around vascular wall (Figure 2D) which is primarily composed of elastin fibers.

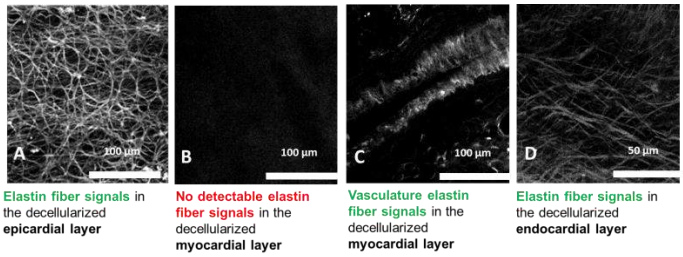

Figure 2: LSCM image signals are elastin specific.

We were able to create a first-order mapping of the elastin network in the epicardium of the left ventricle. Elastin fibers were found to be abundant in the epicardium and exhibit certain patterns, which were highly correlated to their anatomical location in the left ventricle. The elastin fiber orientation and fiber alignment were found to often take one pattern/orientation at the surface layer, but change to another pattern/orientation when reaching to the deep layer. As an example, Figure 1 showed an epicardial elastin fiber pattern observed in the left ventricle apex region, in which we noticed a 3D meshwork in the surface of the epicardium (first 15 µm depth) and a highly oriented wave elastin fiber arrangement in the last 15 µm thick of the epicardium (Figure 3).

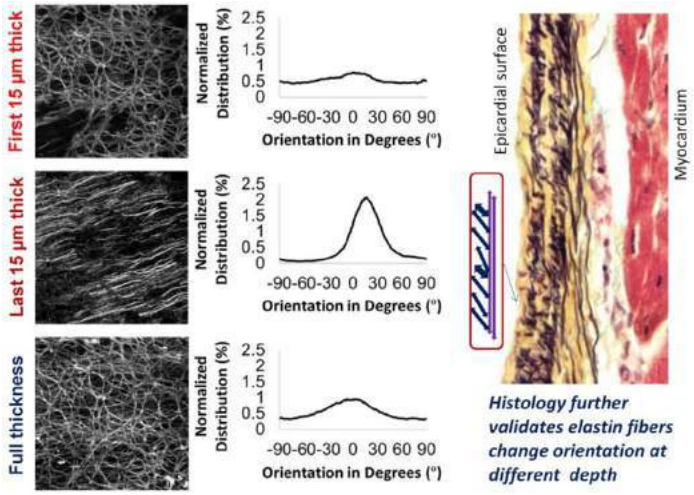

Figure 3: Epicardial elastin network shows depth-dependence in the apex section. The depth-dependence is also verified by histological observation.

DISCUSSION

Our study revealed a first-order mapping of the epicardial elastin network in the left ventricle. We found that the elastin network in the left ventricle showed certain patterns that were correlated to their anatomic locations. Besides the location variation, epicardial elastin network also showed a 3D structural alteration from the surface layer to the deep layer. Overall, the observed elastin fiber pattern, fiber orientation, and fiber alignment might serve certain mechanical function that helps coordinating the heart contraction and relaxation. Future work will be focusing on understanding the structural-functional relationship of this 3D elastin design in the left ventricle.

INTRODUCTION

Airway smooth muscle plays a key role in lung homeostasis and disease pathologies. Lung diseases such as COPD and asthma exhibit increased airway smooth muscle (ASM) mass as compared to healthy individuals with varying levels of ASM density and key differences between inflammatory responses [1]. Current studies associated with COPD and asthma lack good animal models leading to a poor understanding of the cellular and molecular mechanisms driving airway remodeling. Recent data focuses on testing with whole airways or isolated ASM cells. These approaches are limited due to the lack of biological insight with whole airway samples and the lack of structural and environmental cues in isolated cells. It is important to find a physiologically and anatomically correct airway model to achieve an accurate, controllable, and highly observable in vitro platform to study intracellular pathways in normal tissue remodeling and diseased states.

To successfully create an in vitro airway model requires mimicking the biological and architectural cues on the micro and nano levels. A strong biologically active material is achieved by combining a naturally derived substance with a synthetic polymer possessing superior mechanical strength. Natural materials offer more benefits than exclusively synthetic scaffolds because of cellular-extracellular matrix (ECM) interactions including tissue-specific signaling with proteins (i.e. collagen, elastin, fibronectin, and laminin) [2]. Specifically using ECM derived directly from lung parenchyma ensures the scaffold will have the appropriate ratio of structural proteins for the proper signaling and maintenance of lung cell phenotypic expression [3].

The architecture of the natural ECM can further be mimicked by fabricating the scaffold with a nanofiber structure similar to that of natural ECM with the use electrospinning. Electrospinning is a highly controllable and versatile technique using high electric potentials to develop nanofibers mimicking the natural fibers throughout the human body [4]. When layered randomly into a three dimensional mat, the resulting scaffold has a highly porous architecture allowing nutrient movement, cell infiltration, and a mechanical strength closer to natural tissue. The goal of this study was to create an airway smooth muscle construct utilizing a scaffold electrospun with PLLA and decellularized pig lung ECM (DPLECM).

METHODS

Scaffold Fabrication: Pig lungs (donated from Smithfield Hams) were decellularized by established protocol [5] using detergents and ionic solution, lypholized at -80^{0}C, then freezer milled using SPEX 6700 to a fine powder. 140mg and 70 mg of powdered PLECM were combined with 3 mL Hexafluoro-2-propanol (HFP) and mixed for 24 hours on a vortexer. 400 mg PLLA in 1 mL of HFP was mixed for the same period of time. The PLECM solution was poured into a syringe and pushed through a 150x150 mesh count stainless steel type 304 wire cloth into the PLLA solution and vortexed again for an hour to create the final PLLA/PLECM/HFP solution. Solutions with 35 mg, 17.5 mg, and 0 mg PLECM with 100mg PLLA per mL HFP were electrospun onto a rectangular or cylindrical mandral using the parameters in Table 1 which were arrived at by the establishment of a stable Taylor cone.

Table 1.

[PLECM]	Flow Rate	Voltage	Distance
35 mg/mL	4 mL/hr	27 kV	27 cm
17.5 mg/mL	4 mL/hr	27 kV	27 cm
0 mg/mL	4 mL/hr	15 kV	27 cm

Scaffold Characterization: Scaffold hydrophobicity testing by water contact angle was done using the sessile drop method with 5 µL dH2O. Elastic properties of PLLA scaffolds with varying amounts of PLECM (17.5 mg/mL, 35 mg/mL, and 0 mg/mL) under wet and dry conditions were determined using MTS Bionix 200 with TestWorks 4.0 Software, using established tensile testing protocols. Scaffolds with various concentration of ECM were fixed for Scanning Electron Microscopy (SEM, JEOL LV-5610)imaging to show fiber size and architecture. To verify the precence of ECM protiens post electrospinning, Mason's Trichrome staining of all scaffolds were done to compare ECM protien staining density.

Biocompatability: 35mg/mL and PLLA only scaffolds were seterilized and seeded with human airway smooth muscle cells (HASMCs, Lonza) for 1 week and imaged by SEM. All samples were dried using a Tousimis Critical point dryer, carbon coated, and imaged using SEM. PLECM/PLLA scaffolds of different concentrations were placed in a 24-well TC plates and sterilized. A

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Live/Dead cell viability assay (Thermo Fisher Scien tific) was performed to quantify the number living and dead cells after 48 hours. HASMCs were also seeded on coatings of 35 mg/mL PLECM without any PLLA, 35 mg/mL PLECM with 100 mg/mL of PLLA, 100 mg/mL PLLA without PLECM, and TCP for one week to assess gene expression using qPCR.

Statistical Analysis: All experiments with a m inimum of N=3. One way ANOVAs with Tukey post hoc were performed with GraphPad software. P<0.05 was considered significant.

RESULTS

Electrospinning PLLA and PLLA/PLECM composite scaffolds created a nanof ibrous scaffold with the diameter and morphology visualized with a JEOL LV-56-10 SEM. Figure 1 shows an average fiber thickness of 409.64nm and an aver age scaffold thickness of 0.2 5mm at (A) 250 0x and (B) 1000x magnification. To assess the h ydrophobicity of the PLLA and PLECM scaffolds, the water contact angle w as determined to have dropp ed significantly by 17.78° with addition of 35 mg/mL PLECM compared to P LLA only (data not shown).

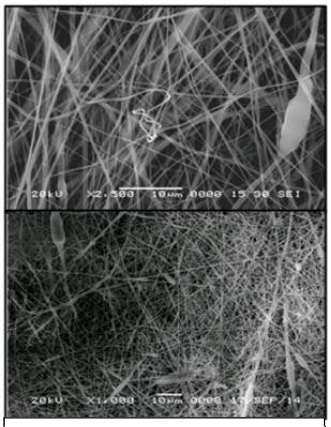

Figure 1. SEM of electrospun Fibers of 100 mg/mL PLLA + 35 m g/mL

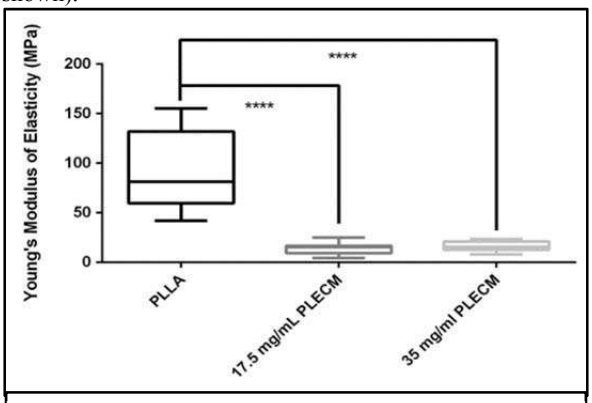

Figure 2. Tensile Testing of PLLA scaffolds with various amounts of PLLA under wet conditions.

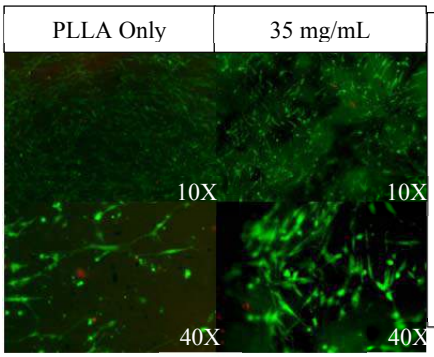

Figure 3. Liv e/Dead cell viability assay of HASMCs on PLLA only and 35 mg/mL PLLA/PLECM scaffolds for 48 hours after attachment. Green is live and red is dead.

The presence of PLECM in the scaffold significantly decreased the elastic modulus of th e electrospun scaffold closer to that of native tissue (0.17-2 MPa, [6]) as compar ed to a fully synthetic PLLA scaffold (Fig. 2).

HASMCs were then seeded onto the surface of the scaffolds with various PLECM concentrations for 1 week and imaged with SEM. HASMC behavior s howed a qualit ative increase in confluen cy over the scaffolds that contained PLECM over those that were composed of only PLLA (data not shown). A 48 hour Live/Dead cell viability assay results shown in figure 3 revealed support of HASMCs on both scaffolds with increased cell death (red) on PLLA only scaffolds.

DISCUSSION

The importance of ECM in promoting complex biolog ical signaling both in vitro and in vivo has be en confirmed in pr evious research [7]. These earlier studies showing ben efits of incorporating various other d ecelularized ECM tissue into regener ative scaffolds supported our hypothesis that incorporation of PLECM into a synthetic electropsun scaffold will be an ideal m aterial for in vitro airwa y smooth muscle. Electrospinn ing a fibrous scaffold with and without PLECM allowed us to contro l alignment, filament size, and thickness of the filament matrix to develop a nanofibourous mat that mimics the natural structure of the lung. The nanofiber diameter and stru cture we have achieved are within rang e of the optim al fiber diam eter to represent natural ECM arch itecture, allowing for proper m echanical and structural stimulation for natural cell differentiation.

By creating an in vitro environ ment that closely resembles the in vivo environment we can more e fficiently and controllably study airway smooth muscle phenotype. The advantages that n atural ECM offer have been exploited in this study to develop a customizable nanostructure, mechanical profile, and degrad ation properties with practical biological signaling. O ur scaffold has been optimized for an accurate human analog for s mooth muscle function in the airwa ys. In vivo, SMCs exhibit a specific str ucture and organization modulated by mechanical forces transferred to ce ll cytoskeletal filaments thr ough ECM proteins. SMCs will rem odel the ECM around it, attaching in a highly organized 3D structure to for unified baseline contractile forces with the ability to perform more extreme contractions. Smooth muscle ECM remodeling and ke y contractile and relaxing proteins detection make this model physiologically relevant.

In conclusion, the addition of PLECM to a P LLA electrospun scaffold will offer characteristics similar to that of native lung tissue. The data suggests that the extracellular matrix allows for increased cell attachment and proliferation through biological signaling and mechanical stimulation. These similarities allow this structure to become a model for normal smo oth muscle behavior, eliminating the need for inadequate animal models for studying airway remodeling.

DAMAGE MODELING OF A HUMAN TIBIA AND FIBULA FRACTURE CAUSED BY A MIXED MARTIAL ARTS KICK

A. Lamont (1), V. Nguyen (1, 2), R. Bertucci (1), Y. Hammi (1), M.F. Horstemeyer (1), J. Liao (1,2), H. Rhee (1), L. Williams (1,2), R. Prabhu (1,2)

INTRODUCTION

Mixed Martial Arts (MMA) is a sport in which two athletes engage in combat with their hands and feet, each seeking to defeat the other by knock out, submission, or by the unanimous decision of judges. On December 28, 2013 during the Ultimate Fight Championship (UFC) 168 event at the MGM Garden Arena in Las Vegas, Nevada, MMA and UFC athlete Anderson Silva suffered a compound fracture of his left tibia and fibula bones in a location above the ankle[1]. While common for MMA artist to sustain lower extremity injuries[2,3], such extent of a leg injury does not occur often on the professional level. Studies show that damage to the lower extremities are fairly common, occurring in roughly 30.4% of the studied cases[4]. More specifically, damage to the lower leg was determined to occur in 4.3% of the studied cases[4].

The objective of this study was to analyze the bone fracture damage caused by the kick through a finite element analysis (FEA) to further understand the biomechanics of the compound fracture. The study also provides additional verification of the simulation through comparison with Von Mises stress data from previous results and literature.

METHODS

GIMP[5] and Windows Live Movie Maker (Microsoft Inc., WA, USA) were implemented to perform image analysis of the injury. A video was obtained that offered a front and side view of the kick[6] and images were collected in a frame by frame manner at both viewing angles. The displacement, velocity, and acceleration of the legs were calculated from images to obtain an initial estimation of the force.

Next, Adams/View^{TM} rigid body dynamics software by MSC was used to design a low-fidelity macro-scale rigid body model of the kick. After measuring the length of the legs and hips of Silva and the initial locations of his ankle, knee, and hip joints, a model was able to be developed representing Silva's lower body. Additionally, the defending leg of Chris Weidman was measured and added to the rigid body model. Each joint of each athlete model was given a rotational motion function that represented the rotational displacement and velocities calculated in the image analysis. After changing the material description of the model to bone,=, Adams/Post Processor was used to produce graphical data to determine the maximum force of the kick. This kicking force was then compared to kicking forces found in other studies to determine its relative strength.

Abaqus/CAE^{TM} FEA software by Dassault Systemes was implemented to perform a FEA on the injury. A lower extremity orphan mesh was imported for both Silva and Weidman. After placing the meshes and defining the material characteristics for skin, muscle, and bone as elastic materials [7,8,9,10,11] rotational velocity BCs were produced according to the data collected in the image analyses and rigid body dynamics model.

Then damage criteria was added to the material model in the FEA. Assuming the failure model of the bone has two components, plastic and ductile damage. Plastic behavior depends on the progression of yield stress with plastic strain, while modeling ductile damage requires certain constants. From literature, the constants used were a fracture strain of 0.035 and a stress triaxiality, a ratio of hydrostatic to deviatoric stress that constraints plastic deformation, of 0.333[12]. Using the criteria above, the simulation calculated the ductile damage caused by the kick.

Animations of the FEA results were created and analyzed to determine the magnitude and location of the damage in both the tibia and fibula from contact to the end of the simulation at 0.09 seconds. We developed failure causation conclusions by comparing the time of failure in the simulations to published data on the biomechanical properties of human bone.

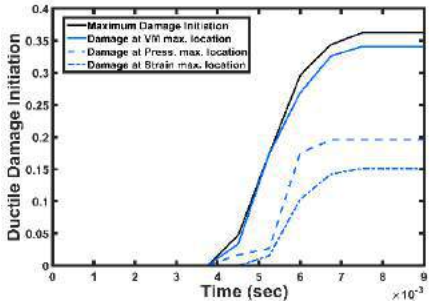
RESULTS

The FEA simulations revealed information regarding the location and development of damage in Anderson Silva's tibia and fibula. Figure 1 shows the ductile damage initiation for the tibia and fibula in addition to damage at maximum Von Mises stress, pressure, and strain.

a)



b)

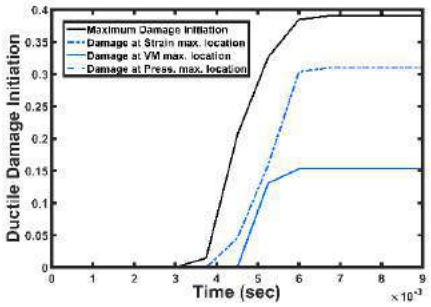


FIGURE 1: THE DUCTILE DAMAGE INITIATION, DAMAGE AT OVER TIME AT THE MAXIMUM LOCATION FOR (A) TIBIA AND (B) FIBULA. THE GRAPHS SHOW THE EVOLUTION OF PEAK DAMAGE VS. TIME AT STRAIN COMPARED TO DAMAGE AT PEAK PRESSURE AND VON MISES LOCATIONS.

The damage of the tibia can be indicated to occur in Figure 2(a), and the damage of the fibula in Figure 3(a). Figure 3(b) and Figure 3(b) show the maximum damage caused by the kick. The locations of peak damage in Figures 2 and 3 correlate well.

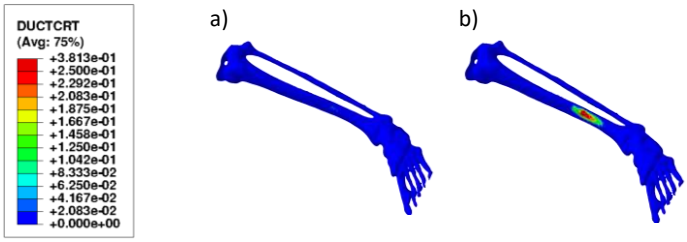

FIGURE 2: THE DUCTILE DAMAGE CRITERIA FROM THE FEA IS DEPICTED AS A FRACTION OF DAMAGE CRITERIA INITIATION. IN (A) and (B) A VIEW OF THE TIBIA AT 0.045 AND 0.09 SECONDS.

DISCUSSION

The objective of the study was to calculate damage and to validate the simulation model. In comparison to the damage occurred at the point-of-contact and location of either maximum pressure or Von Mises. As shown by the damage initiation graph and the FEA animation, the damage began to occur in the tibia and fibula approximately 0.04 seconds, and Figure 1 shows damage in the tibia is mostly caused by Von Mises stress while damage in the fibula is caused by strain.

The FEA simulations offer data to support the following conclusion: After the initial contact of the legs, Silva's bone began to bend as his foot continued to rotate. The bending of the tibia concentrated stress at the apex of the bend which ultimately caused the bone to yield and fracture. The continuation of motion in the foot caused the fibula to bend just above its connection to the foot. Like the tibia, this bending caused the fibula to fail.

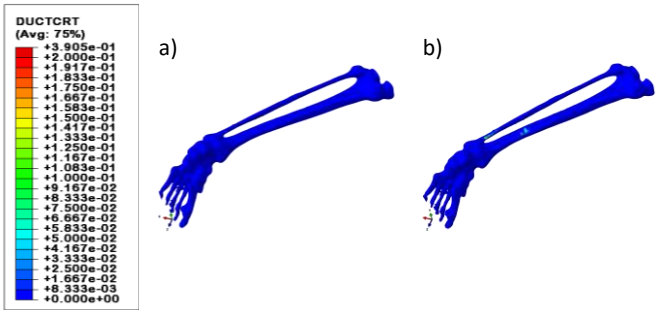

FIGURE 3: THE DUCTILE DAMAGE CRITERIA FROM THE FEA IS DEPICTED IN FRACTION OF DAMAGE CRITERIA INITIATION. IN (A) AND (B) A VIEW OF THE FIBULA AT 0.045 SECONDS AND 0.09 SECONDS.

Using this model, future studies could include effect of certain safety equipment such as a shin guard in lack of damage and/or of modified velocities or rotation of the kicking leg simulating difference between improper and proper technique. These studies would benefit new MMA students, or even skilled MMA fighters, perfecting the technique to avoid severe injuries seen here.

"CONTEMPORARY ISSUES IN …. BIOENGINEERING": A NEW REQUIRED COURSE ADDRESSING SEVERAL CURRICULAR CONCERNS

Steven W. Day (1, 2), Robert J. Stevens (1)

(1) Department of Mechanical Engineering
Rochester Institute of Technology
Rochester, NY, USA

(2) Department of Biomedical Engineering
Rochester Institute of Technology
Rochester, NY, USA

INTRODUCTION

We present the design and implementation of an online course called "Contemporary Issues in …" (herein called CI) that addresses significant teaching/learning/assessment issues within the Department of Mechanical Engineering in the College of Engineering at Rochester Institute of Technology. Specifically, we have: *1) The desire to relate student co-op experiences to coursework.* 2) *A Need to satisfy Institute and ABET writing Requirements* and 3) *A need for delivery and assessment of content related to contemporary issues, ethics, economics, life long learning, and societal impact*. It has historically been particularly difficulty to demonstrate delivery and assessment of related ABET program outcomes (f, h, i, and j) as they are generally not the central topic in core engineering courses that are required of all students.

This course helps address the "hard-to-reach" program outcomes, draw on students co-op experiences, and have had some writing requirements that help to satisfy ABET and Institute policy. We believe our model of a standardized, but customizable course is innovative and helps address the issues described above.

METHODS

We applied a design methodology to create this course. We first identified the overall goals that we hoped to accomplish. We then identified specific course outcomes. Lastly, we designed a method of delivering content in a way that ensured some uniformity across offerings, but allows the instructor to customize the section to a particular interests. Lastly, assignments were designed to assess the achievement of these outcomes

Some of the overall goals of the course stem from the following:
Feedback from our Industrial Advisory Committee: The most common requests from employers are related to "soft" skills, including the ability to effectively communicate technical material to management, justify the value proposition of engineering investments and alternatives, awareness of the context of an engineering solution (both from a society and company market perspective).
ABET: We had some experience with elective courses taught within the department that provided a meaningful way for us to address ABET f, g, h, i, and j (professional and ethical responsibility, effective communication, impact of engineering solutions in a broad context, lifelong learning, and contemporary issues) for a small subset of students. We wanted to integrate these aspects into this required course.
Professionalism: All students are required to complete one full year of paid work experience before graduating. We want this course to serve as a way to better link student co-op experiences to their coursework on campus.
RIT required Writing Intensive Course: Institute Policy requires that each department offer at least once course for which the evaluation of the quality of writing is a substantial (>20%) of the grade for that course.
KGCOE Ethics Curriculum: The College of Engineering Ethics Committee has proposed 5 learning objectives to be incorporated into a 3rd year course. Integration of these into the Contemporary Issues family of courses would ensure that all students satisfy these requirements.
FE Exam and licensure: The FE exam includes some topics, such as economics and professional licensure that are not covered in any of our other required courses. We wish to address those in this class.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

RESULTS

This process described here resulted in a course that contains common content, but that can be "flavored" to appeal to specific interests of students and faculty by including three types of content: 1) Common Lecture 2) Material common to sections, but customized for flavor, and 3) Flavor specific (Fig 1). The common content (e.g. ethics, economics, writing,) and assessment activities are the same for all sections, but the flavoring of the course helps students engage and to recognize the potential application of the common material to their specific interests. To date, we have offered seven sections of the course over the past three semesters. Four flavors of the course (Energy and the Environment, Bioengineering, Automotive, and Aerospace) have been offered. Table 1 includes the key elements of the course.

Table 1: Course Elements. Except for the feasibility report, each of these is repeated on a weekly basis. The content included is a typical weekly example, but actual content certainly varies from week to week.

	Example of Content	Method
Common Lecture	Ethical Decision making tools, including line-drawing and flow charting.	Monday lecture. All sections/flavors in attendance
Flavored Lecture	Medical and health-care related Ethics	Wednesday lecture, sections meet separately
Discussion	Ethical and economic considerations of Medicare approval of a new medical device	Online in small discussion groups throughout week with one in-class discussion.
Quiz	Multiple choice questions on readings and lectures for both common and flavored content.	Online
Problem Sets	Students implement methods from general and flavor content in a typical problem set format.	Weekly and submitted online.
Feasibility Assessment	Evaluate the technical feasibility as well as economic and societal impact of an emerging technology.	Staged assignments throughout semester culminate in a technical brief.

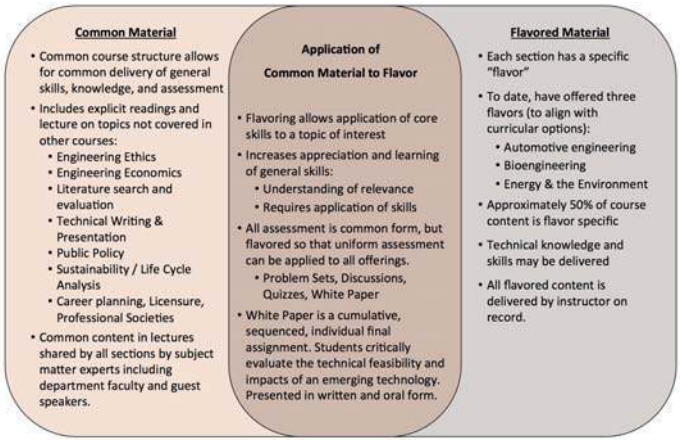

Figure 1: Schematic of the types of course content, including content common to all sections, content unique to each section (flavored) and that the common material is applied to the flavor.

Results of student self-reported learning indicates that the course is generally effective in all stated learning outcomes (Fig 1).

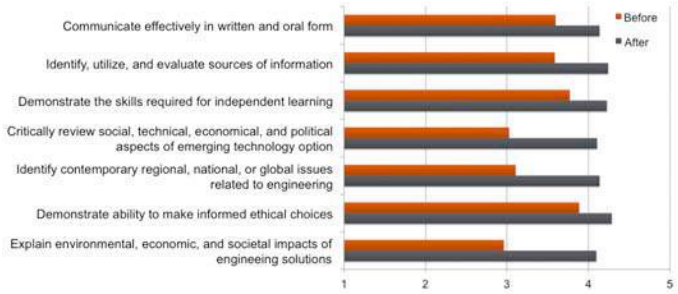

Figure 1: Follow directions for Figures in the instructions document. Figure captions are centered below the graphic.

DISCUSSION

This course as a required course very clearly ensures exposure of the undergraduates to each of these critical topics. Student self-reported learning indicates that it is effective in most or all of the stated course outcomes, but we do not have more rigorous evaluation of student learning.

There has been some variation in the way that the course was delivered over the past two years, including two sections offered online, and inter-instructor variability. This seems to greatly affect student perceptions of the course, although we don't currently have enough information to be certain what the most effective mode of delivering this course is.

ACKNOWLEDGEMENTS

The authors wish to acknowledge collaborating instructors for providing us with student learning outcomes data.

INTRODUCTION

Neonatal Brachial Plexus Palsy (NBPP) continues to occur in 1.1-2.2 out of 10,000 births [1]. The brachial plexus (BP) is a network of nerves that originate in the neck and run through the shoulder to the arm [2]. Stretching of the BP or avulsion of the roots can occur during birth when the infant's shoulder impacts with the bony pelvis of the mother due to maternal (endogenous) forces as well as clinician-applied (exogenous) forces [2,3]. Since *in vivo* measurements of the endogenous and exogenous forces, fetal shoulder deformation, and the response of the BP are difficult to assess during delivery, computational and physical models are used. However, a complete lack of biomechanical properties and data on the neonate BP limits the correct assessment of the risk of injury using these models. The goal of this study is to determine the biomechanical properties of the BP using a neonatal porcine model (piglets).

METHODS & MATERIALS

Samples: 133 fresh neonatal (3-5 days old) piglet BP cord segments (Chord, Division and Nerve) were harvested from 9 piglets and immediately preserved in 1% BSA (bovine serum albumin) until testing. The BP segments were divided into two groups based on tensile displacement rate. Group A (n=54) specimens were subjected to a stretch rate of 0.01 mm/s and those in Group B (n=79) were subjected to a stretch rate of 10 mm/s.

Testing Apparatus: An ADMET material testing machine (eXpert 7600, ADMET Inc., Norwood, MA) was used to stretch the BP Segments (Fig. 1). Stretch rates were controlled by built-in GuageSafe software (ADMET Inc., Norwood, MA). Each BP segment was anchored by specially designed and fabricated clamps (Fig. 2). The padded side facing the segment helped minimize the stress concentration at the clamping site [4,5,6]. A digital microscope was used to obtain images of harvested BP segments before stretch (5X; Digital Microscope, Elmwood Park, NJ). A 2mm scale (Leitz,Ernst-Leitz-Wetzlar GmbH, Germany) at the same magnification measured the segment diameter.

The segments were clamped with no initial tension prior to stretch. Each BP segment was stretched at the assigned rate (0.01 mm/s or 10 mm/s) until complete failure. During this test, the load and displacement data was acquired. Failure site was recorded and the clamps were checked for the presence of BP tissue. No tissue in the clamps implied that the tissue had completely slipped, and the results of those experiments were disregarded.

Data Analysis: Maximum stress and corresponding strain were calculated from the obtained load-displacement data during tensile testing. Load data and the cross sectional area was used to calculate nominal stress.

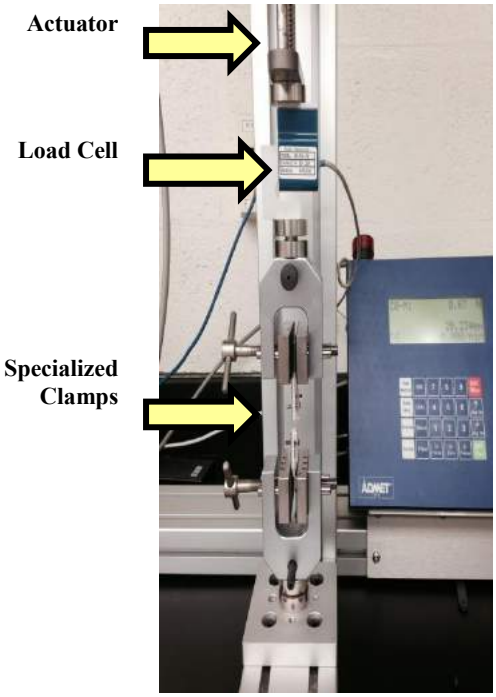

Figure 1: Biomechanical Testing Machine

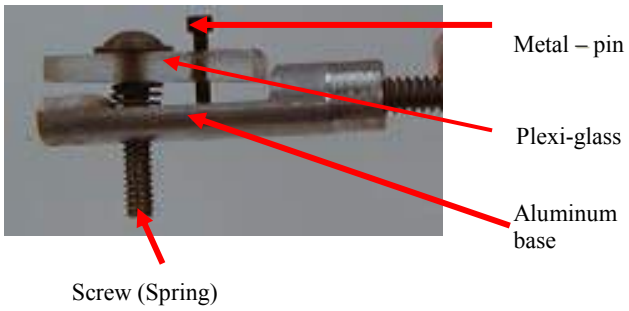

Figure 2: Clamp Fabrication

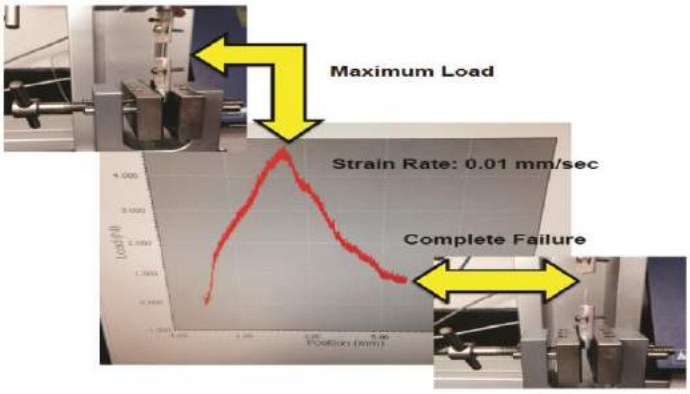

Figure 3: Preliminary Testing of BP Cord Segment at 0.01 mm/sec

RESULTS

Nerve rupture typically occurred immediately after reaching the proportional limit as shown in Fig. 3. Table 1 contains experimental data for brachial plexus segments tested at both quasistatic and dynamic rates.

Table 1: Mechanical Data of BP Segments

	Root/Cord		Division/Trunk		Nerve	
Rate	0.01 mm/s	10 mm/s	0.01 mm/s	10 mm/s	0.01 mm/s	10 mm/s
Stress (MPa)	1.1 ± 0.1	2.5 ± 0.1	4.9 ± 0.1	7.8± 0.2	15.6+ 0.9	24 + 1
Strain (%)	25 ± 3	23 ± 1	32± 1	31 ± 1	35 ± 3	36 ± 1.5
n	18	28	25	24	11	27

DISCUSSION

- Failure Stress and Strain were highest in the Nerve segment, followed by Division/Trunk and lowest in the Root/Cord segment
- Strain rate effect was observed with a lower failure stress at the quasistatic rate than at the dynamic rate for all BP segments. This is because the nerve tissue acts in a viscoelastic manner and becomes stiffer at a faster strain rate.

Overall, the experiment data provides detailed biomechanical properties of the BP tissue. The data obtained from studying the BP at these two rates helps better understand the associated injury mechanisms since this information can be used to develop a biofidelic computational model that accurately illustrates the predisposing risk factors for BP injury.

INTRODUCTION

The lymphatic system is fundamental to fluid hemostasis, cell trafficking and immune responses. The dysfunction of lymphatic system is associated with a wide range of pathologies like lymphedema. The lymphatic vessels transport lymph from the interstitium back to the great veins in the venous system through a series of contractile units, known as lymphangions, and one-way valves to prevent back flow. The lymphatic system must impart energy on the fluid to transport flow up the adverse pressure gradients that occur in vivo from gravitational forces and unfavorable pressure difference between the interstitium and central venous pressure. The required energy to sustain lymph flow is mainly provided by rapid/phasic contraction of unique lymphatic smooth muscle cells that has functional features and myosin isoforms found in both vascular smooth muscle cells and cardiac muscles. It has been shown that both active (e.g., myogenic and tonic contractions) as well as passive (e.g., distension of vessel) mechanical properties of the wall regulate lymph transport. Hence, a series of pumps and valves are utilized to propel flow and overcome opposing pressure gradient across the network. Recently, models of the lymphatic system have been developed to shed insight on the influence of various morphological features, mechanical properties, and biological parameters on lymphatic pump performance [1, 2]. Here, we adapt our previously published constitutive model of a lympangion to support a series of lymphangions to establish a framework for studying the maximum pressure generation of a lymphangion chain in series [2]. Using a previously developed NIR imaging technique developed in our lab for measuring lymphatic pumping pressure non-invasively in vivo [3], we compare our computational model (developed with geometric and mechanical data taken from the rat thoracic duct) with in vivo measurements from rat tail lymphatic.

METHODS

Mathematical Model. To model mechanical behavior of the lymphatic vessels, a constitutive framework is used to obtain both active (contractile) and passive mechanical parameters (e.g., distension) in response to mechanical stimuli (e.g., transmural pressure). The framework is based on a microstructurally motivated four fiber model for lymphatic vessels. In this framework, the Cauchy stress consists of active stress (due to action of smooth muscle cells) and passive stress (due to mechanical passive behavior or vessel morphology) as

$$\mathrm{T}^{\mathrm{pas}} = -\mathrm{pI} + \frac{2}{\det(\mathrm{F})}\mathrm{F}\frac{\partial \mathrm{W}}{\partial \mathrm{C}}\mathrm{F}^{\mathrm{T}} \quad (1)$$

where $\mathrm{T}^{\mathrm{pas}}$ is passive stress, F is the elastic deformation gradient, W is the strain energy density function originally proposed by Holzapfel, C is the right Cauchy-Green, I is the identity tensor, and p is the Lagrange multiplier. The active contractile behavior was also adopted from Rachev and Hayashi [4] as

$$T^{act} = 0.5 * T_{act}^{sys} * \lambda_\theta \left[1 - \cos\left(\frac{2\pi}{t_c}(t)\right)\right]\left[1 - \left(\frac{\lambda_M - \lambda_\theta^e}{\lambda_M - \lambda_0}\right)^2\right] \quad (2)$$

where $\mathrm{T}^{\mathrm{act}}$ is active, $\mathrm{T}_{\mathrm{act}}^{\mathrm{sys}}$ is a parameter dependent on the activation of the smooth muscle, λ_θ is the circumferential stretch of the vessel, λ_M is the stretch at which the contraction is maximum, $\mathrm{T}_{\mathrm{act}}^{\mathrm{sys}}$ regulate the magnitude of maximum spontaneous contraction, λ_0 is the stretch at which force generation ceases, t_c is contraction period, and t is time. The passive and active model's parameters were chosen from Caulk et

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

al [2], in which experimental data from rat thoracic duct was fit to the model. The contraction time is assumed to be 2 seconds. To model the valve function in a chain, we used a valve-resistance model by Bertram et al [1], which accounts for the valve resistance as function of pressure drop across the valve as

$$Q_V = \frac{\Delta p_V}{R_V} \tag{3}$$

$$R_V = 600 - 12 * 10^7 \left[\frac{1}{1 + exp(-0.02(\Delta p_V))} - 1\right] \tag{4}$$

where Q_V is flow rate, Δp_V is pressure drop, and R_V is resistance across the valve. Using an optimization algorithm in Matlab, the constitutive and fluid models are solved simultaneously to satisfy mass conservation in the chain of vessels. In the process, the inlet pressure is assumed to be 2 cm_H2O and the outlet pressure is increased up to the pressure at which flow rate decrease below 10% of the flow rate at an outlet pressure equal to 2 cm_H2O. The simulations are repeated with various lymphangion numbers in the chain. The geometrical parameters of a single lymphangion and active parameters associated with the lymphatic smooth muscle cells are summarized in Table 1.

In vivo-Experiments. Utilizing an occlusion cuff on the rat tail with near-infrared (NIR) imaging we were able to measure the maximum occlusion pressure at various locations along the rat tail at which flow can be detected. The procedures involve the intradermal injection of an appropriately sized NIR probe near the distal tip of the tail, which is subsequently transported from the injection site by the lymphatic. Occlusion is achieved through feedback control of a pressure cuff, placed at various locations proximal to the injection site, with a customized VI written in LabView. The pressure reading from the experiment, which we refer to as the effective pumping pressure, is equivalent to the maximum back pressure in the model in which the last valve can be opened and flow achieved.

RESULTS

Figure 1 depicts the relationship between maximum outlet pressures which can be overcome by a chain of lymphatic vessels as a function length. The maximum back pressure was calculated for chains with different number of working lymphangions in series. As shown, the maximum outlet pressure increases with the number of lymphangions in the chain.

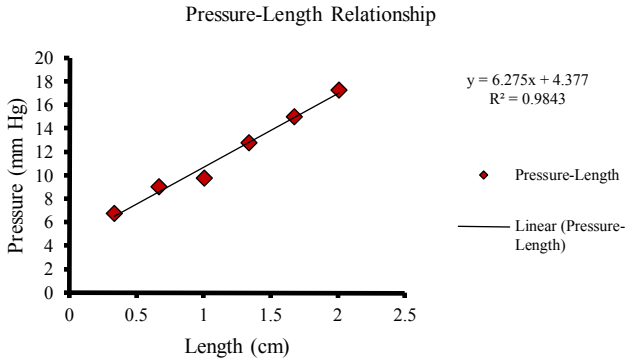

Figure 1 The pressure-length relationship along lymphatic chains of rat thoracic duct using the computational framework.

Table 1 Constant parameters associated with lymphangion's geometry and constitutive model for active mechanical behavior [2].

parameter	*unit*	*value*
Diameter of lymphangion	μm	252
Thickness of lymphangion	μm	33.7
Length of lymphangion	cm	0.335
T_{act}^{sys}	Dyne/cm^2	118620
λ_M	-	1.7636
λ_0	-	0.6119

Figure 2 shows the pressure-length relationship along rat model. The length refers to the distance from the tip of tail. This figure demonstrates that along a lymphatic chain the maximum occlusion pressure in which flow can be achieved increases.

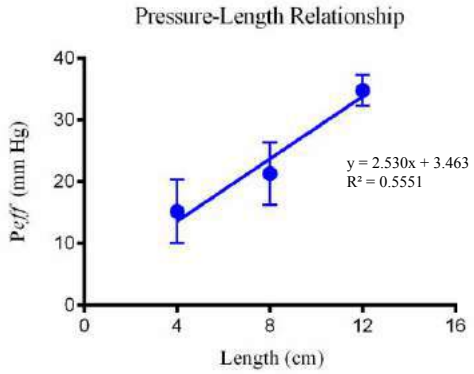

Figure 2 The pressure-length relationship along rat tail lymphatics using NIR imaging technique.

DISCUSSION

Both the computational and the experimental results provide evidence that adverse pressure gradients can be overcome by increasing the overall pumping capacity of the chain through the addition of lymphangions. Interestingly the rat thoracic duct is on average about 3-times larger than the collecting lymphatics in the rat tail, which could explain the greater slope in the computational data when compared to the experimental. Whether there is a scaling law that determines the pumping capacity of a lymphangion chain is an important area of future work. However the overall similarity of the results is encouraging given that mechanical and geometric properties of rat tail lymphatics are largely unknown and difficult to assess experimentally. Further elucidation of the mechanical properties of lymphatic vessels from various anatomies and disease states will be important for understanding how these factors lead to pump failure in lymphedema.

INTRODUCTION

The maintenance of normal permeability through the renal glomerular capillaries is a vital and tightly regulated process ensuring the proper filtration of blood. The capillary wall ultrafilter, however, is also subjected to large hydrostatic pressures, meaning that it must be stiff enough to oppose distension but still be porous enough to allow filtration. The glomerular capillaries are well adapted to their function. They are composed of a basement membrane (GBM) with specialized cells on the inner and outer surfaces. The GBM is mostly composed of type IV collagen, laminin, and proteoglycans, of which collagen IV is the primary component responsible for the mechanical stability of the capillaries. The GBM is also responsible for at least 50% of the capillary wall's resistance to plasma filtration [1, 2].

The opposing challenges of mechanical stability and high permeability must remain in balance, even as the capillaries are growing, remodeling, or responding to abnormal conditions [3]. Without tight regulation of transcapillary flow, the capillaries could enter a dangerous positive feedback loop. For example, an increase in pressure in the glomerular capillaries could increase the stresses and strain on the epithelial cells. In response, the cells would deposit more material into the GBM, but that would have the side effect of reducing permeability and again increasing the hydrostatic pressure. Clinically, patients with chronic hypertension present with leaky capillaries, thicker basement membrane, abnormal glomerular filtration rate, and damage to the epithelial cells [4]. Our goal is to investigate how a GBM remodeling scheme would function when subjected to the constraint that capillary pressure increases to maintain constant filtration rate in response to changes in GBM permeability.

METHODS

The GBM was simulated in a multiscale model (Fig. 1) that allows us to link the nanoscale structure of the collagen IV network with the response of the capillaries on the microscale [5]. Collagen IV networks were modeled as three-dimensional networks of rods with connectivity of 4. The glomerular capillary was modeled as a ring section of a thin cylindrical tube. Normally, the hydrostatic pressure acting on the capillary wall is approximately 40 mmHg. We examined two scenarios that involved an increase from nominal pressure by 7 mmHg and 10 mmHg, which inflates the capillary ring from its resting state. The transcapillary flow, Q, through the deformed collagen IV networks is the target filtration rate which must be maintained constant during the remodeling process. The permeability of the fibrous network was calculated by modeling the media as a spatially periodic array of cylinders with defined drag parallel and perpendicular to the cylinders [6].

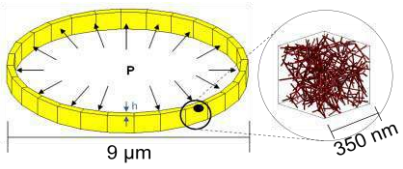

Figure 1: Multiscale model of glomerular basement membrane.

Remodeling, that is deposition and removal of collagen IV, was simulated by changing the radius of the already existing collagen fibrils based on specific rules. From the work of Bhole et al., 2009 [7], it is known that collagen fibers under tension are protected from degradation. Therefore, the rate of collagen removal was defined as in Eq. 1:

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

$$\left(\frac{dr}{dt}\right)_{removal} = -k_1 exp\left(-k_2\left(\lambda_{fibril} - 1\right)\right) \quad (1)$$

where k_1 and k_2 are constants taken from [8] and λ_{fibril} is the stretch ratio of the collagen IV fibril.

Two cases were considered for the addition of collagen IV material: (1) material added at a constant rate; (2) the rate of addition was dependent on the circumferential strain of the capillary (Eq. 2).

$$\left(\frac{dr}{dt}\right)_{addition} = k_3 exp\left(k_2\left(\lambda_{capillary} - 1\right)\right) \quad (2)$$

where k3 is also a constant from [8] and $\lambda_{capillary}$ is the circumferential stretch ratio of the capillary. The net change in collagen fibril radius at each remodeling step is then the sum of the addition and removal rates.

The GBM was remodeled over 500 time steps and the transcapillary flow was held constant during remodeling, representing the physiological needs of the capillary. For comparison, a case was also considered where remodeling was performed at constant hydrostatic pressure.

RESULTS

Over the 500 remodeling steps, the transcapillary flow was held constant (not shown). As seen in Figure 2, when the filtration rate is maintained and the deposition of collagen IV material is dependent on the strain of the system, the hydrostatic pressure increases for ~100 steps and then levels off, for an increase of between 20% and 40% (the increase was larger with the higher initial pressure). In the case of constant rate of collagen addition, the pressure did not fully equilibrate in the provided remodeling time. In all cases, there was net positive deposition of material, though the amount was twice as large in the strain-dependent addition case for both inflation pressures. The diameter of the capillary decreased significantly, almost returning to the initial resting diameter of 9 um. In the strain-dependent cases, the decrease was slightly larger than in the constant deposition case. Finally, circumferential stress in the capillary increased by a different amount for all cases. The largest increase was for the GBM remodeled at constant addition rate and initially inflated by 10 mmHg. The smallest increase in stress was observed for the opposite remodeling case.

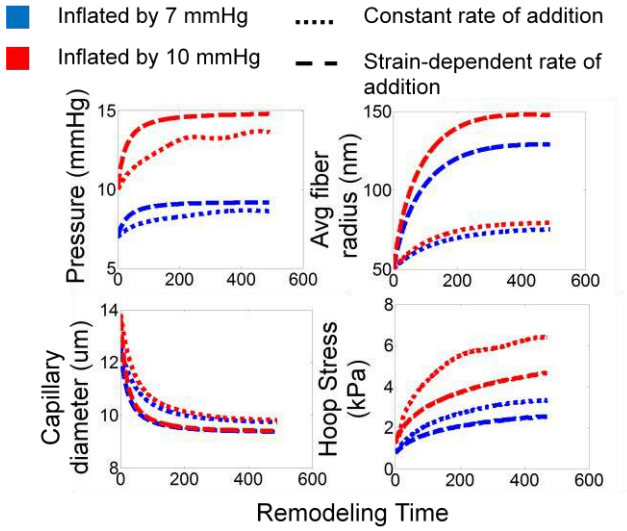

Figure 2: Response of the glomerular capillary system to remodeling at constant transcapillary flow.

In comparison to the constant transcapillary flow remodeling case, as seen in Figure 3, remodeling performed at constant pressure (initial inflation of 10 mmHg, constant rate of addition) results in a decrease in the transcapillary flow, a small decrease in the amount of newly deposited collagen IV, the same diameter decrease, and a decrease in the circumferential stress by half.

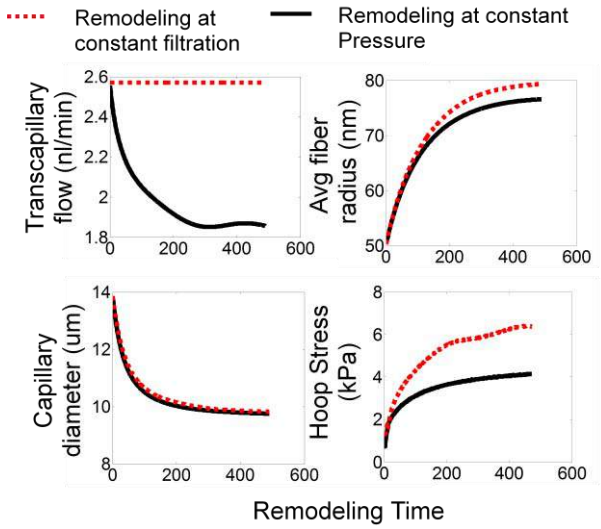

Figure 3: Comparison of remodeling at constant transcapillary flow and constant pressure. Both are done at 10 mmHg initial inflation and constant rate of collagen IV addition.

DISCUSSION

Generally, remodeling done at constant flow rate protected the system, which was not possible with remodeling at constant pressure. Inflating the capillary resulted in increased deposition of collagen IV. To maintain constant filtration rate, the hydrostatic pressure had to increase, but at the same time, the diameter of the capillaries reduced back to normal, lowering the strain of the epithelial cells. The stress on the GBM did increase, but the increased amount of collagen would stiffen the GBM, allowing it to withstand the higher stresses. In contrast, remodeling performed at constant pressure also resulted in increased deposition of collagen IV and reduction in the capillary diameter, but the large reduction in filtration would significantly hinder the kidneys ability to filter blood plasma.

We saw that when the glomerular cells had the ability to sense and respond accordingly to changes in their environment, the response was quicker and stresses were lower. In the simpler case of the system having a constant addition rate of collagen IV material, the response was not always stable and it resulted in larger stresses

INTRODUCTION

Single lower leg injuries such as a sprained ankle or a fractured foot area common occurrence. According to the Cleveland Clinic there are over 23,000 reported ankle sprains in the United States each day [1]. The patients may be recommended to use a wheelchair, rollator, crutches single knee scooters or other types of assistive devices based on their age, nature of the injury and the general health of the user.

There are many products on the market to provide mobility to people with single leg injuries or conditions. According to medical device distributors [Binson's, Livonia MI] however; there is a shift from conventional mobility devices like crutches and canes, to more mobile and innovative devices like single knee scooters [**Figure 1**].

Although there are more single knee scooters being used today than ever before, many patients do not choose this device because it is expensive, heavy and difficult to place in the vehicle when not in use. This project focuses on improving the portability of the single knee scooter.

"There is a need to create a single leg mobility device that is lightweight, compact and inexpensive, giving all users the ability to handle and store the device when not in use."

Figure 1 –A common knee scooter has four wheels and weighs approximately 30 lbs.

PRODUCT DESIGN

The "*Fold-and-Go*" scooter design was developed in order to create an innovative new solution that reduces weight, cost, and bulk of current scooter designs while adding an increase in portability. While some current designs on the market are labeled as "folding," the space saving is minimal and the devices often only include features such as collapsible handlebars. As shown in Figure 1, the *"Fold and Go"* knee scooter features a fully collapsible frame as well as retractable handlebars which allows the device to easily fold into a compact shape.

In addition to the folding frame, the device is constructed from lightweight aluminum tubing while featuring a significant reduction in size and weight achieved by the simple and compact design. This allows the device to be easily folded and carried or stored in the back of a vehicle, for example.

In order for the device to be easily foldable and user friendly, a four bar linkage system is used to allow the main lower wheel platform to fold up while simultaneously folding the knee rest and vertical support post up. The design features a foldable knee pad located above a vertical tube that supports the weight of the user as well as aid in the folding mechanism of the device. At the base of the main vertical handlebar post, a simple two position locking mechanism allows the user to transfer the device from the open to folded position. Once the locking mechanism switch is pressed, the user simply folds the knee brace upwards which utilizes the four bar linkage system to pull up the base of the scooter and lock it in position. From there, the handlebars can be collapsed for additional reduction in package space. The device features a knee pad height adjustment option allowing the user to adjust the height in one inch increments. This adjustment will be achieved by a series of mounting holes spaced 1" apart in the vertical support sections of the device. See Figure 2 below for a profile view rendering of the knee scooter in fully open, half folded, and fully folded position.

Figure 2 - Side profile progressive image showing how the device is going to fold flat when not in use.

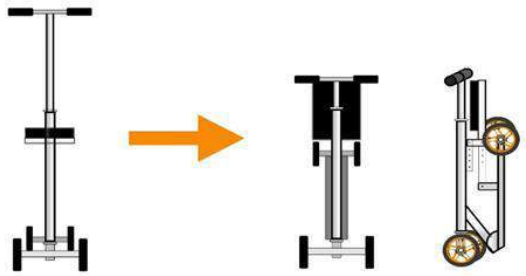

Figure 3 – Front profile progressive image showing how the device is going to fold flat when not in use.

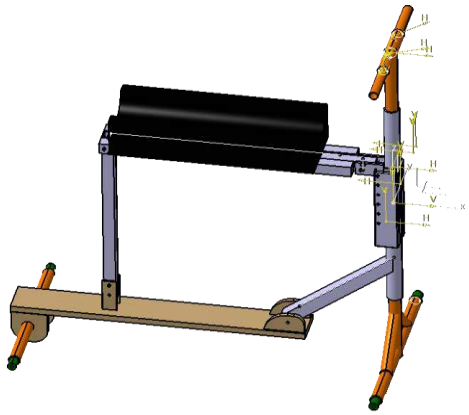

Figure 4 – Preliminary prototype CAD model of the device.

MARKET ANALYSIS & BUDGET

Currently, Over 6.8 million people use personal mobility devices and of those, 40% are estimated to be unable to perform their desired daily activities. We are looking to target any patient 12 years and older who has a single lower leg injury or condition. This device is specially designed to aid in the recovery from injuries, conditions and surgical procedure of the lower limb. Unlike Crutches this device allows the affected limb to be supported which is a key part of the healing process. Furthermore, this device helps to keep the patient from straining the knee of the uninjured leg.

According to the Cleveland clinic, 23,000 people in the United States sprain or strain their ankle every day[1]. According to twin city press, ten million sets of crutches are sold in the US each year. According to Grandview Research, the market for premium rollators and scooters is going to grow nearly 15% from 2014 to the year 2020[3].This projected growth is greater than the growth expected in walking aids over the same time frame. This growth is estimated to increase from 4.5 billion in 2012 to roughly 8 billion in 2018 [**Figure 5**].

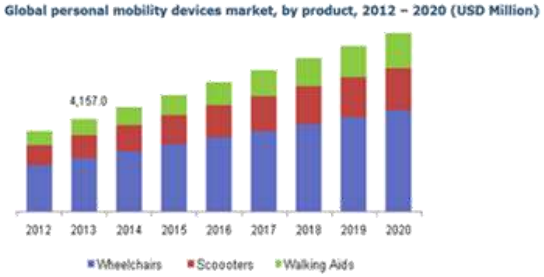

Figure 5- Estimated market broken down by current mobility devices

Below is an itemized budget with justification for each item. **[Table 1].**

Table 1- Itemized budget for development of this product.

Senior Design Budget Break Down			
Item	**Break Down**	**Cost**	**Justification**
Materials	Aluminum Tube	$200.00	Enough aluminum tube to account for multiple iterations of the final design
	Aluminum stock	$75.00	Enough aluminum stock for multiple iterations of the final bracketry design
	Welding rods	$25.00	Package of aluminum welding rods
	Casters w/ bearings	$50.00	4 polyurethane casters with bearings
	Hand Grips	$25.00	Ergonomic hand grips
	Paint	$25.00	Finish
	Razor Scooters	$100.00	Used razor scooters for evaluation and scrap parts
Machining	Machine Shop Labor	$150.00	If necessary to source out the machining of brackets due to time constraints with our equipment. If sourcing is required, request for donations from the machine shop (in the form of materials, labor or both) would be made.
	Machine Shop Parts	$200.00	
Testing	Additional Sensors / Markers	$100.00	Any additionally markers or sensing devices to collect data accurately
	Testing set up	$50.00	Material for making any testing fixture or stand that will be needed
Other	Fasteners	$25.00	High grade fasteners for assembly
	Bushings	$25.00	Bushings and or bearings to decrease handle bar turning efforts
	Weld Fixture	$100.00	May be necessary to ensure the components do not warp during the welding process
	Gas Mileage	$100.00	Gas mileage for picking up parts, materials etc.
Total		**$1,250.00**	

ACKNOWLEDGEMENTS

We would like to thank our advisors, Eric Meyer and Mansoor Nasir with their help with this project. Additionally, we would like to thank Binson's (Livonia, Michigan) for feedback on current devices and Alro Steel (Livonia, Michigan) for material and service donations.

ADDRESSING IATROGENIC INJURY DUE TO TRAUMATIC URETHRAL CATHETERISATION

Eoghan M. Cunnane (1), Niall F. Davis (2), Connor V. Cunnane (1), Rory O'C. Mooney (1), John A. Thornhill (2), Michael T. Walsh (1),

(1) Centre for Applied Biomedical Engineering (CABER), Health Research Institute (HRI), Materials and Surface Science Institute (MSSI), Mechanical, Aeronautical and Biomedical Engineering (MABE) Department, University of Limerick, Limerick, Ireland.

(2) Department of Urology, Tallaght Hospital, Dublin, Ireland.

INTRODUCTION

Urethral catheterization is frequently performed in health care settings. Almost 25% of hospitalized patients are catheterized during inpatient stay[1]. The estimated incidence of iatrogenic catheter related urethral injury is 0.3% to 3% but this may underrepresent the true incidence[2,3]. Urethral injury typically occurs in men when the anchoring balloon of a Foley catheter is inadvertently inflated in the urethra[4]. Urethral rupture can lead to the long-term complication of urethral stricture disease and may require urethral reconstruction in severe cases[5]. This study seeks to address this issue by quantifying the cost of this problem on a sample of Irish hospitals, characterising the key urethral tissue mechanical properties pertaining to this mechanism of injury and characterising the user and manufacturer variability of urethral catheter inflation properties. This information is then utilised to develop a novel medical device aimed at eliminating this clinical issue.

METHODS

The incidence and cost of iatrogenic urethral injuries was prospectively monitored in Tallaght Hospital and surrounding district hospitals over a 5 month period. The cost of managing catheter related injuries was recorded to determine the economic impact of this issue on the healthcare system. This cost was estimated by adding the cost of resources utilised to treat the injured patient.

The key mechanical properties of urethral tissue pertaining to catheter related injury are the distension that the urethra can undergo prior to rupture and also the corresponding pressure in the catheter at rupture. To characterise these properties and identify the values pertaining to urethral injury, the anchoring balloons of urethral catheters were intentionally inflated in the bulbar region of porcine urethras maintained *ex vivo* (n=21). Catheter pressure was monitored during inflation using a pressure transducer. Retrograde urethrography was performed to identify urethral injury and also to measure internal urethral diameter.

The user and manufacturer variability of commercially available urethral catheters was investigated by characterising the inflation properties of catheters from several manufactures. Inflation of anchoring balloons was performed at atmospheric pressure by different users (n=8). A pressure transducer was used to measure inflation pressures and video extensometry was used to measure balloon inflation profiles. Manufacturer variability was investigated by applying constant forces to the plunger of syringes attached to the anchoring balloon. These forces are designed to mimic 'heavy-handed', 'intermediate' and 'light-handed'. Three brands of commercially available urethral catheters were investigated (n=3 per brand). The potential to mitigate the identified user and manufacturer variability using a flow resistance approach was then investigated. Flow resistance to the anchoring balloon during inflation was increased by reducing the cross sectional area of the syringe outflow and the impact of this resistance on user and manufacturer variability was examined.

RESULTS

Prospective monitoring of iatrogenic urethral injuries in Tallaght Hospital and surrounding district hospitals over a 5 month period revealed 11 iatrogenic urethral injuries that required invasive urological intervention. 6 of these injuries were recorded in Tallaght Hospital and the remaining 5 injuries were recorded in the district hospitals. 10 of these injuries related to balloon dilation in the urethra. The remaining injury was a bladder rupture. As 6,500 urethral catheterisations are performed annually in Tallaght Hospital, this extrapolates to an incident rate of 0.3% which corresponds with

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

previously reported rates[2]. The cost of injury acute management, excluding litigation, during this 5 month period was €80,000. This extrapolates to an annual cost of €192,000 to treat iatrogenic urethral catheter injury in a single Irish hospital. A device that could completely prevent this injury, and that cost the hospital €4 per device, would cost the Tallaght Hospital €26,000. This would result in a saving for this particular hospital of €166,000 or over 85% of the cost currently spent on treating this preventable incident.

Urethral injury was observed in 5 of the porcine samples tested following retrograde urethrography. Further analysis of catheter pressure and internal diametric strain revealed that samples remained free from rupture bellow an internal diametric strain vale of 50% and a catheter balloon pressure of 150kPa, Figure 1. The threshold above which urethral injury occurs is 150kPa catheter pressure or 50% diametric strain. Such values can be utilised to design a safety device that eliminates the potential for iatrogenic urethral catheter balloon dilation injuries.

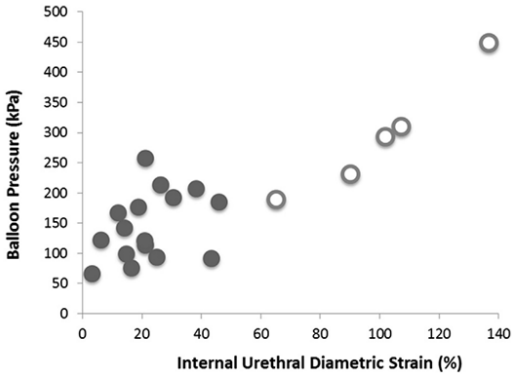

Figure 1: Maximum catheter balloon/urethral pressure and internal diametric strain recorded for each of 21 urethral samples tested. Open circles indicate ruptured urethral samples. Filled circles indicate unruptured samples. Figure clearly demonstrates safety cutoff of 50% internal urethral diametric strain and/or maximum balloon pressure cutoff of 150 kPa before urethral rupture.

During user variability investigation, variations in maximal inflation pressures ranged from 75 to 355 kPa and variations in average flow rates ranged from 19.94-69.08 ml/min. During manufacturer variability investigation, the maximum 'light-handed' inflation pressures ranged from 175kPa to 197kPa for each catheter brand while maximum 'heavy-handed' inflation pressure range increased from 563kPa to 634kPa. Increasing the flow resistance by reducing the cross sectional area of the syringe outflow reduced maximum inflation pressure to below the rupture threshold of 150kPa.

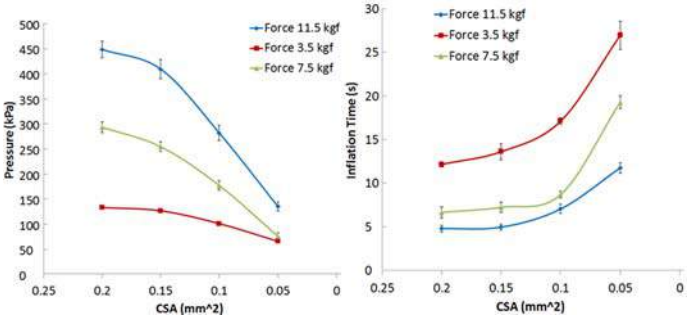

Figure 2: Pressure and inflation time versus flow resistance for the three weights that correspond to high (11.5kg), intermediate (7.5kg) and low (3.5kg) forces applied by different users.

DISCUSSION

A safer urethral catheter system to eliminate the potential for iatrogenic urethral catheter balloon dilation injuries was designed based on the parameters characterized in this study. The novel syringe system is composed of a safety valve that activates at 150 kPa to prevent trauma and an orifice that restricts flow to eliminate user and manufacturer variability. This device has been studied in male cadavers and operated reliably, Figure 3. The device is scheduled to undergo clinical trial in March of this year.

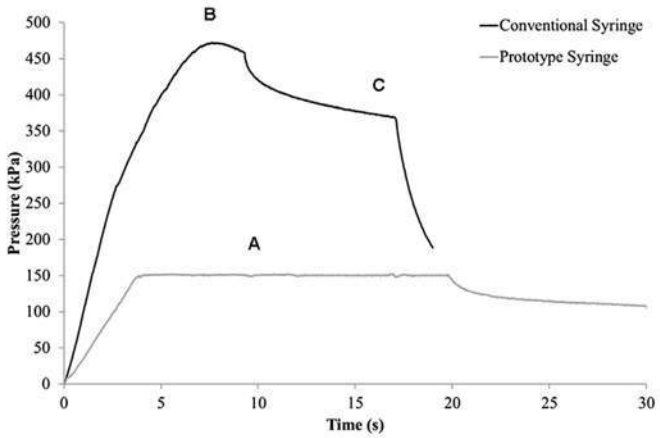

Figure 3: Pressure profiles of catheter inflated in cadaveric urethra using flow resistance technique with syringe pump at infusion rate of 30 ml per minute. Testing was performed with standard (black curve) and prototype (gray curve) syringes. Prototype curve clearly shows safety of novel prototype safety syringe as maximum inflation pressure was limited to safe plateau pressure of 150 kPa up to 20 seconds (s), when inflation process was completed (A). In contrast, flow resistance approach with standard syringe achieved inflation pressure of 450 kPa (B). Inflation pressure decreased at approximately 8 seconds, indicating that urethral threshold pressure was breached. Pressure continued to decrease until inflation was discontinued at approximately 16 seconds (C).

MOLECULAR CONTROL OF DIFFERENTIAL GROWTH DURING LOOPING OF THE EMBRYONIC SMALL INTESTINE

Nandan L Nerurkar, Cliff J Tabin

Department of Genetics
Harvard Medical School
Boston, MA, USA

INTRODUCTION

The dramatic changes in tissue shape that underlie embryogenesis necessitate precise, stereotyped regulation of physical forces. To ensure that these forces arise at the right location and time with the right orientation and magnitude, they must be prescribed by genetic and molecular cues. We know very little about how this is accomplished during development. Here we investigate the molecular signals responsible for coiling of the small intestine, a process driven by mechanical buckling due to differential growth of adjoined tissues [1]. This process allows the human gut to achieve four times the adult height, and is essential to intestinal function. Errors in looping are associated with a wide range of congenital gastrointestinal defects.

The vertebrate gut begins as a straight, simple tube that is anchored dorsally to the body wall by a thin membranous tissue, the dorsal mesentery. In the chick embryo, looping of the small intestine begins at embryonic day (E) 5, and is completed by E16 (Fig. 1A). Previous work from our group demonstrated that looping occurs due to rapid elongation of the gut tube against the dorsal constraint of the mesentery, which elongates much slower [1]. This results in compressive forces that buckle the tube into its looped configuration; when the tube and mesentery are separated, the loops disappear (Fig. 1B). This mechanism has been supported by both physical and computational models of strain mismatch between a thin membrane and a long tube (Fig. 1C-E). Despite a clear physical understanding of gut looping, it is unknown how tissue growth and stiffness are ascribed at the molecular level to regulate this process. In any context, at present we lack an integrated understanding of how the intracellular signaling events that drive development relate to the physical properties that define tissue shape during morphogenesis. Here we identify BMP signaling as the key signal regulating differential growth and therefore looping morphogenesis of the small intestine.

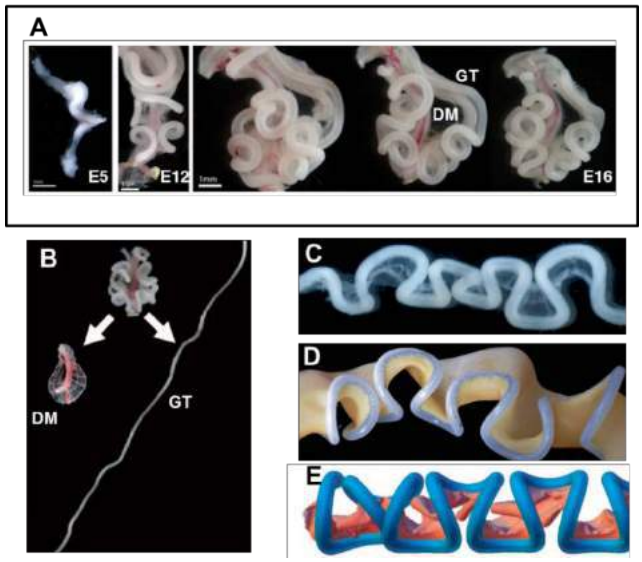

Fig. 1: A) gut tube transforms from straight at E5 to looped by E16; looping is highly stereotyped (GT=gut tube, DM = dorsal mesentery). B) Separation of GT amd DM causes loss of loops. C) Intestinal loops at E16. D) tubing stitched to prestretched rubber membrane following release of prestretch. E) Computational model of differential growth. Fig. 1 adapted from [1].

hybridization using established protocols. To misexpress genes in the developing chick gut *in ovo*, eggs were windowed at E5, and a replication competent avian retrovirus, RCAS, was injected at the base of the yolk stalk. Using established methods, *GFP*, *noggin*, and *bmp2* were cloned into the RCAS vector [3]. Infected guts were collected from E12 to E16 to assess BMP activity (phospho-smad 1/5/8 immunofluorescence), cell proliferation (Edu incorporation), and morphometry and residual strain.

RESULTS

To identify candidate genes, we first screened for the expression of key developmental genes in the small intestine, looking for expression patterns that favor either the gut tube (elongates rapidly) or the attached dorsal mesentery (elongates slowly). The BMP pathway showed a strong dorsal bias in expression, with *bmp2* strongly expressed in the dorsal mesentery and its attachment to the gut tube (i.e. the inner curvature of loops), but absent from the ventral gut tube (outer curvature, Fig. 2A). Expression of BMP receptors *bmpr1b* and *bmpr2* was also dorsally biased (not shown).

We next developed a viral misexpression strategy to disrupt BMP activity in the gut. Specificity and robustness of infection were confirmed by RCAS-GFP infection (Fig. 2B). To broadly disrupt BMP activity, we overexpressed the BMP antagonist *noggin*; this effectively diminished endogenous BMP signaling (Fig. 2C, D). Strikingly, BMP inhibition resulted in a dramatic decrease in intestinal loops (Fig. 3A, B). This was accompanied by an increase in dorsal mesentery perimeter (Fig. 3C-E), despite no change in gut tube length (Fig. 3F). As a result the residual strain between tube and mesentery was reduced by 2-fold (Fig. 3G). We next misexpressed *bmp2* to observe whether activation of the BMP pathway will result in more loops. RCAS-Bmp2 infection resulted in a robust increase BMP signaling (Fig. 2E), and had a striking effect on looping morphology. The number and tightness of coils increased with *bmp2* misexpression (Fig.4). In particular, regions of 'hyperlooping', or nesting of loops within loops, were observed with *bmp2* over expression. Such hyperloops were never observed in wildtype or RCAS-GFP infected guts.

These findings suggest that differential growth in the looping small intestine is modulated by BMP signaling. Specifically, we propose that bmp2 in the dorsal mesentery suppresses cell proliferation and therefore elongation. This is why inhibition and activation of the pathway result respectively in a decrease and increase in differential growth. To test this, we looked next at the effect of BMP signaling on cell proliferation in the mesentery. As expected, inhibition caused a significant increase in proliferating cells while *bmp2* overexpression decreased the number of proliferating cells in the dorsal mesentery.

DISCUSSION

The physics of intestinal looping have been recently elucidated [1]. Here we exploit this detailed understanding of buckling morphogenesis in the gut to ask the question of how molecular signals modulate physical forces during development. We identified BMP signaling, and bmp2 in particular, as key regulators of differential growth in the small intestine. While we have demonstrated that cell proliferation, and consequently elongation rate, are inversely related to BMP activity, it is unclear to what extent looping phenotypes are the result of other changes, such as the mechanical properties of gut tube and mesentery, or changes in tissue geometry. To test this, we are currently performing tensile testing experiments to measure the effects of BMP activity, and will incorporate these findings into a previously developed computational model of gut buckling. This will allow us to precisely determine the physical determinants of looping morphogenesis that are determined by BMP signaling. Finally, we are examining the natural variation in intestinal loop morphology among closely related avian species to determine whether evolutionary modulation of morphogenetic forces in the gut can be explained by differential regulation of the BMP signaling pathway.

INTRODUCTION

Approximately 800,000 people in the United States have a stroke each year of which 30% to 66% of all stroke survivors have impaired hand functions [1-3]. Hand impairments are mostly recognized by spasticity, inability to open/close hands, inaccurate finger and hand movements, and poorly modulated fingertip forces [4]. Continuous Passive Motion (CPM), and Patient Assisted Movement (PAM) are two common therapeutic interventions, which capitalize on the brain's inherent neuroplasticity to increase adaptation to stroke [5-7]. For these therapeutics to be effective, the duration, intensity, and consistency of therapy as well as patient compliance are all vital factors. However, a shortage of resources and compliance will hinder the return of hand functionality. While it has been shown that robotic motion can provide many of these attributes, no dedicated system has been made which can effectively apply post-stroke hand therapy. To address this need, a soft robotic rehabilitation system (Fig. 1) capable of monitoring and assisting hand motion for post-stroke patients has recently been developed [8, 9]. To apply this system to the clinical population, it is vital to understand the kinematic interaction between such a robotic glove and the human hand to ensure patient safety and performance. This abstract compares simulation and experimental data on a human finger with a corresponding robotic digit to evaluate the viability of the current design for rehabilitation purposes.

METHODS/RESULTS

Glove and Soft Robotic Digits:

This system consists of five sensorized robotic digits and a wearable fixture along with a programmable control unit that monitors and modulates the trajectory of the fingers (Fig. 1(a)). CPM can be applied through this system by setting the motion parameters of the control unit.

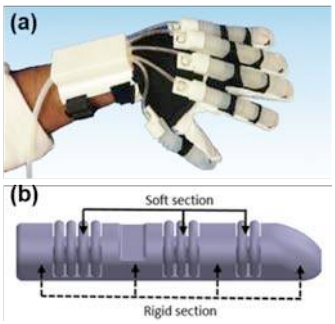

Figure 1: (a) Prototype of the robotic glove, (b) CAD model of a single robotic digit.

Finger motion is accomplished by pneumatically actuated soft robotic digits based on a hybrid soft-and-rigid actuator technology which uses inflatable and deflatable bellows to produce a bending movement along the joints (Fig. 1 (b)) [8]. As shown in Fig. 1(b), the robotic digit consists of three bellow-shaped soft sections and four rigid sections (in an alternative order) in correspondence to three joints, three phalanges with the metacarpal. Computer simulations of the soft robotic digit have been examined for finger range of motion (ROM) at each joint: metacarpal phalangeal (MCP), proximal interphalangeal (PIP), and distal interphalangeal (DIP) (Fig. 2). The numerical simulation studies of the soft robotic digit have shown that the resulting relative angles between rigid sections at MCP, PIP, and DIP (Fig. 2(a)) can reach full anatomical ROM (MCP: 0-90º; PIP: 0-100º, DIP: 0-70º [10,11]) at a single actuation pressure of 24.3kPa, as shown in Fig. 2(b).

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

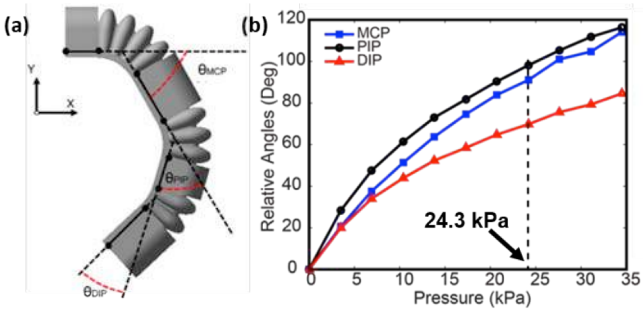

Figure 2: (a) Relative angles between MCP, PIP, and DIP sections, (b) ROM for each joint with respect to actuation pressure.

Kinematic study:

A kinematic study was carried out to compare one subject's index finger with a robotic digit using a motion capture system (Motion Analysis Corp, Santa Rosa, CA). The motion capture system is capable of detecting the position of markers placed along the digit to within 0.25mm and angular positions to within 5˚. This study determined the functional anatomical ROM requirements at each joint for both the robotic digit and index finger. To identify the motion parameters, reflective markers were placed on the joints and phalanges (Fig. 3(a) and (b)). Both the subject and robotic digit moved the finger for flexion/extension while the x, y, and z coordinates of the markers were recorded. Figure 4(a) shows the robotic digit's angular data for the DIP, PIP and MCP joints while Fig 4(b) shows this data for a human finger.

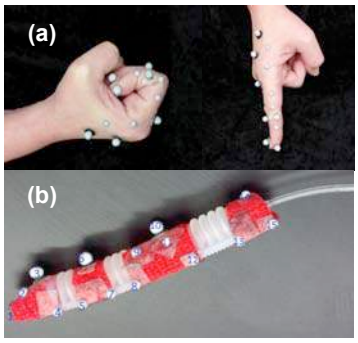

Fig 3: Marker placement on (a) a subject's finger index and (b) a single soft robotic digit.

The achieved ROM for MCP, PIP, and DIP joints of the robotic digit are 85˚, 96˚, and 53˚, respectively, which are in good agreement with the full anatomical ROM. It should be noted that the human finger (MCP: 45˚, PIP: 75˚, and DIP: 45˚) did not quite reach its full ROM during testing due differences in functional range of motion versus isolated joint range of motion. However, these robot achieved ROM are consistent with the functional ROM of the human fingers.

DISCUSSION

A hand therapy glove has been designed to provide flexion and extension of the fingers as an adjunct to hand therapy. A prototype has been fabricated based on initial design parameters and is able to provide joint ROM based on the literature. Functional grasp parameters have been experimentally measured in a human finger and will be used for future design improvements.

Future work: Experimental data will be collected with the robot on the hand to provide optimal control parameters for passive motion of the digits. Other important kinematic parameters include the center of rotation (COR) and dorsal skin lengthening of the human finger. The COR of the robot finger will need to coincide with the corresponding finger joint to ensure proper motion in the hand [12]. The dorsal skin of the human finger stretches during finger flexion, for example 12 mm of lengthening has been reported when the PIP is at 90˚ of flexion [13]. This lengthening effects the joint location of the corresponding robotic digit, causing misalignment. To accommodate for this, the robotic digits will be designed to match this lengthening. Once improved design parameters are obtained, these data will be used to modify the robotic glove for clinical evaluation.

INTRODUCTION

Osteoporosis is a medical condition affecting the bones, causing them to become brittle and fragile. The condition affects a large number of people worldwide, including over 200 million women; about one-tenth of women over 60 years-of-age and about two-thirds of women over 90 years-of-age are diagnosed with osteoporosis [1]. Osteoporosis can lead to various medical problems, including fractures and kyphosis. More than 8.9 million fractures occur annually from osteoporosis [2]. Those who develop vertebral fractures from osteoporosis have a higher risk of fracture within the next 1-2 years [3]. In order to help prevent fractures, the National Osteoporosis Foundation recommends a 10 lb. lifting limit [4].

Several vertebral fractures can cause a curve in the spine, known as kyphosis, resulting in forward curving of the spine and hunching of the back. Kyphosis can cause serious pain and complications due to muscles, tendons, and ligaments being strained from the curve of the spine [5]. Kyphosis affects approximately 4-8% of the general population and is most commonly caused by osteoporosis [6, 7].

Criteria taken into consideration for surgical treatment of kyphosis include the severity of the curve, the balance of the patient, and neurological symptoms of the patient [8]. According to the Scoliosis Research Society, surgical treatment is recommended if the curve of the spine becomes greater than 80° and the patient is experiencing pain [9]. Spinal fusion is the most common solution for severe cases of kyphosis. Although the patient may experience a feeling of the same or greater mobility after surgery, such motions are accomplished by overcompensation in spinal discs and/or the hip joint adjacent to the fusion site [10]. Often, medical professionals provide the advice of avoiding the B.L.T.'s (bending, lifting, and twisting) immediately post-surgery [11]. As the healing process continues, lifting and twisting are generally accepted movements; however, due to the mechanics of the spine, bending remains a post-operative restriction. If osteoporosis was the original cause of the kyphosis, the lifting limit of 10 lb. also remains as a restriction for the patient.

With the restrictions of being unable to bend the spine and a 10 lb. lifting limit, patients may find it a challenge to maintain their independence. Through interviews and clinical observations with spinal fusion patients with and without osteoporosis, the most common and difficult tasks to perform were recorded. Further insight regarding the most significant needs of spinal fusion recipients in their postoperative lifestyle was gained through interviews with technical experts including orthopedic surgeons, neurosurgeons, research engineers, physical therapists, and occupational therapists. The following user needs statement was developed from these observations and interviews with patients and clinicians:

> Spinal fusion recipients require a means to increase ability to perform activities of daily living that require bending, while minimizing bending torque and compressive stresses on the spine. Patients with osteoporosis must take further caution to prevent bone fractures elsewhere in the body.

Our ultimate goal is to prevent the need for subsequent surgeries due to compression fractures by minimizing the most significant post-operative injury risk factor. We hope to eliminate the tendency for spinal fusion recipients to perform the risky, habitual behavior of spinal flexion in order to accomplish a variety of daily tasks. Our team aims to design an assistive device that reduces the bending torque and anterior axial compression on the vertebrae near the fusion region while allowing patients to perform lifting activities and tasks that would traditionally require truncal bending.

PRODUCT DESIGN

The goal of the design was to create a simple reaching aid that was more functional and user friendly than devices currently available on the market. After an analysis of current reaching aids, three main areas were of issue. These were support on the arm, required grip strength, and device length (reach). This design eliminates these three problems.

The CAD model of the assistive reaching device is shown in Figure 1. The device consists of four parts, as labeled in Figure 1: 1. Wrist brace, 2. Handle, 3. Body, 4. Grippers. The wrist brace is broken down into a C-shaped cuff and a support piece. Together, these attach to the body of the device using a clamp with a wingnut. The wrist brace can be adjusted in length to fit all sizes of users. The handle consists of a frame, two locks, and a pulling mechanism. The frame is used to support the hand and allow for control of the device. The pulling mechanism is used to operate the grippers and secure objects. The locks are used to lock the pulling mechanism in place so the user does not have to transmit a continuous pull. Inside of the pulling mechanism is a retraction mechanism that allows the device to be operable at any length. The body of the device is a twist to lock pole. The body can be adjusted in length for use or for storage. Lastly, the

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

grippers are similar to standard reaching aids. This portion of the design is a 2 arm gripping system. It will have a component on the end of each arm to create more friction between the device and the object for a more secure connection.

The operation of this device is as follows: The user must insert their hand and lower arm into the wrist brace and secure it to the arm. The user then places their palm against the most superior portion of the handle with their fingers reaching down, touching the pulling mechanism. From here the user may reach towards an object they want to retrieve. Once the object is between the grippers, the user will pull the pulling mechanism towards the superior portion of the handle frame. Once the user has a secure grip on the object, they will use their thumb to turn the lock on the top portion of the handle. This locks the handle in place so that no more grip force is needed to operate the device. From here, the user may bring the grips towards them and grab the object while unlocking the pulling mechanism.

By creating a design that is as simple as possible, not only is it effective, but it is very reliable. This design combines aspects of support, ease of use, and dynamics to create an optimized device. The wrist brace transfers a significant portion of the load along the forearm rather than concentrating forces at the wrist in order to reduce the risk of distal radial fracture in users with osteoporosis [17]. The locking mechanism allows for an easier-to-use device with better control than the current market's devices. The extendable and retractable body also allows for a dynamic, portable, and multifunctioning device. This combination of designs will boost the device above all current market options.

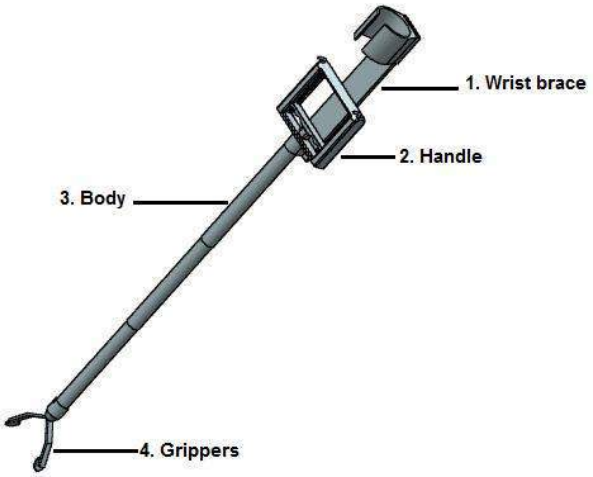

Figure 1. CAD model of the design with parts labeled

BUDGET & MARKET ANALYSIS

As this is a simple design and is operated mechanically, the design budget is fairly small. Materials to create each component of the device are inexpensive. The functional prototype will only be needed to ensure the overall concept of the device will work. We estimate a prototyping cost of $400 for materials, manufacturing, and assembly. Fatigue and strength testing will be done on the materials of the final device to ensure that the device will not fail under expected loads or during normal use patterns. Fatigue and strength testing of components will add another $500 to the budget, for a total of $900.

Because similar devices are currently sold in the market at very low costs (typically under $20 [18]), our device will have to compete with these low costs. The early prototyping costs were in the range of buying a reaching aid from an online source. When manufacturing is scaled up, the costs will similarly be very low. We will aim for a competitive sales price, hopefully achieving as low as $20. While this is more expensive than some similar devices on the market, features of this device and the longer expected lifetime make up for the higher cost. Because this device has components such as the wrist brace and locking mechanism, it has the ability to pick up a wider range of objects than current devices. Also, since the device is adjustable in length, it will be able to be used in various environments and is easier to transport compared to current devices. This device is a new and improved reaching aid; it addresses all of the needs identified by users, creating the best version to date.

This device will be beneficial to anyone with problems performing tasks that require a bending of the spine. This includes, but is not limited to, spinal fusion patients, patients that are wheelchair bound, users of mobility assist devices, and the elderly. There are over 400,000 spinal fusions performed in the US annually [16]. According to the CDC in 2010, roughly 3.6 million people in the United States, about 1.5% of the total population, used wheelchairs or similar device, and 11.6 million people, about 4.8% of the total population, usde assistive mobility devices such as canes, crutches or walkers [15]. In these cases, potential users need a means of performing activities of daily living that require bending while still using their mobility assist device. Thus, the potential market size for this device is large; it is also not likely that the demand for this type of device will significantly drop from its current point.

INTRODUCTION

Military helicopter pilots, soldiers, heavy duty vehicle drivers and others working in vibratory environments sustain cyclic loading as a part of their activities [1]–[3]. Many studies have been conducted to understand the mechanical response of the lumbar spine under cyclic loading, with a primary focus on experiments from human cadaver spines [4]–[6]. While finite element modeling (FEM) to understand the internal responses of disc components have primarily concentrated on acute loading of lumbar and cervical spines [7], some repeated loading simulations are also published on the lumbar spine [8]. However, cyclic loading studies on the human cervical spine combining experimental data and FEM are limited. The objective of this study is to develop and validate a three-dimensional FEM of the human C4-C5 intervertebral disc using in-house experiments and determine the stress strain distributions within its components in an attempt to explain the potential mechanisms of disc injury.

METHODS

The finite element model of the C4-C5 disc with the associated superior and inferior end plates was developed from CT images. The nucleus pulpous and annulus ground substance were modeled using solid hexahedral elements. The annular fibers were modeled with five pairs of concentric quadratic shell layers embedded in the ground substance [7]. The superior and inferior cartilaginous and bony endplates were modeled using shell elements. The element size was 0.5 mm, and the model was composed of 8,740 solid hexahedral elements and 18,636 quadratic shell elements. The geometry represented the average area and disc height of the C4-C5 disc segments tested at 2 Hz for 10,000 cycles. The material properties for the ground substance were obtained from in-house experiments, performed on disc segments before cyclic loading, described later.

The material properties for the endplates, nucleus and annular fiber components were obtained from literature [7]–[9]. The annular ground substance was modeled as a hyper-viscoelastic material. The nucleus was modeled with an elastic modulus of 1 MPa and a Possion's ratio of 0.45. The annular fibers were modeled as hyper-elastic (Aruda-Boyce) material, and tension-only material properties were varied from the inner most layer to the outer most layer. The bony endplates were modeled with an elastic modulus of 5,600 MPa and a Poisson's ratio of 0.3, and uniform thickness of 1 mm. The cartilaginous endplates were modeled with an elastic modulus of 24 MPa and a Poisson's ratio of 0.4, and uniform thickness of 0.8 mm. The cyclic loading was applied in two steps: (1) a uniform load of 150 N at 2 Hz was applied to the superior end plate, and (2) a direct cyclic step simulating 10,000 compression cycles based on the previous step history.

The model was validated by conducting experiments with two female (mean age 47±23years) C4-C5 disc segments. Pre-test antero-posterior and lateral radiographs and computed tomography (CT) scans of the spinal columns were obtained. All tests were done in a physiologic chamber by maintaining the specimen in a heated water bath during the entire loading period. Tension-compression and viscoelastic tests were conducted, and this was followed by subjecting the specimens to 150 N of compressive force at a frequency of 2 Hz for 10,000 cycles. Tension-compression and viscoelastic tests were repeated after the cyclic loading. The specimens were x-rayed after the loading period.

The initial output of the FEM was used to extract displacement-time responses and compare with the experimental corridors, expressed as mean and plus and minus one standard deviation. Stress analysis outputs consisted of determining profiles of maximum and minimum principal stresses and strains, vector directions, and Von Mises stresses

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

in the constituents of the disc and endplates. Patterns of these internal distributions were used to infer the potential mechanisms of load transfer within the disc components under cyclic loading.

RESULTS

The displacement-cycle responses from the model were within the experimental mean plus minus one standard deviation corridors (Figure 1). The displacement was greater during the initiation of the loading process and reduced exponentially in the first 2,000 cycles, followed by a plateau showing the effect of viscoelasticity in this first 2,000 cycle period. The Von Mises stress distribution in the disc at the end of the step 2, that is, 10,000 cycles is shown (Figure 2). The residual stress was maximum in the annulus and concentrated along the periphery. The residual Von Mises stress in the nucleus was approximately one-tenth of the annulus and was concentrated along the outer circumference. As expected, the annular fibers had the least residual stress, concentrated in the innermost layer.

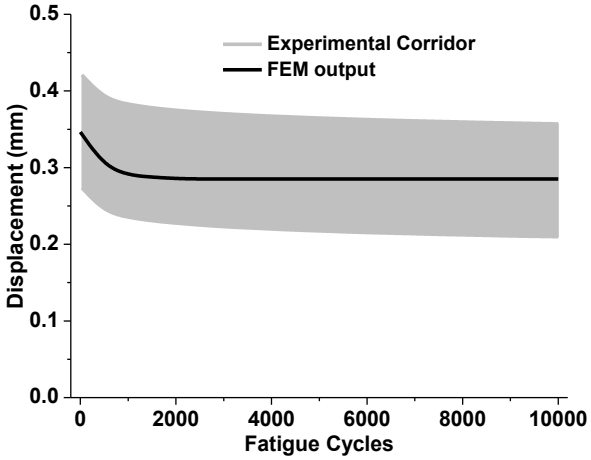

Figure 1: Comparison of the cyclic response from FEM with experimental corridor (Shaded region)

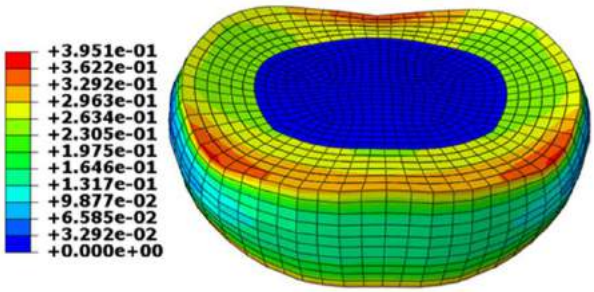

Figure 2: Von Mises stress distribution

The principal stresses were considerably lower than the Von Mises stresses, indicating the development of the shear stress during the cyclic loading process. This was also evident from the direction vectors of the principal stresses. The principal strains were found to be maximum in the annulus ground substance and fibers. The tensile stresses and strains occurred in the radial direction, whereas the compressive stresses and strains occurred in the axial direction.

DISCUSSION

This is the first study to conduct cyclic loading experiments simulating physiological situations and use its inputs and outputs to develop and validate a three-dimensional FEM of the C4-C5 disc. Following validation, the internal responses of the components of the discs were extracted from stress analysis. Although the external cyclic loading was axial, the response of the cervical disc was multi-modal: compressive and shear stresses were developed due to anisotropy. The concentration of the minimum principal stresses at the annulus nucleus boundary along the anterior and posterior direction can lead to circumferential tears, and the maximum principal stresses concentrated at the annulus and cartilaginous endplate boundary can lead to radial tears in the disc, thus explaining a mechanism of internal disc failure due to cyclic loading and correlating with clinical observations of radial and circumferential tears [10]. The development of the shear stresses in association with the peak principal stresses may lead to delamination of the disc under cyclic loading in human cervical spines. It is known that the posterior annulus is supplied by the sinuvertebral nerves, and the anterior and lateral regions are supplied by autonomic nerves [11]. The compression of the annulus and the presence of the nerves in these regions may elicit discogenic pain in patients sustaining cyclic loading from occupational and military activities. The present study offers an explanation for these clinical phenomena.

INTRODUCTION

In the US alone, heart failure (HF) affects 2.4% of the population (> 5 million) and ~ 1 million new HF cases are reported annually, incurring annual direct expenditures of $31 billion in 2012 [1]. Due to the dearth of donor hearts and the increasing number of end-stage HF patients, left ventricular assist devices (LVAD) are increasingly being utilized as long-term destination-therapy (DT) devices [2]. However, neurologic events (especially embolic) continue to be one of the primary causes of mortality and morbidity in LVAD patients [3]. Blood flow through the inflow cannula and outflow graft is largely inertia-driven; consequently, hemodynamics in the left ventricle (LV) vary substantially between different surgical configurations.

While LVADs vary in their design (axial/ centrifugal flow), innovation in surgical LVAD inflow cannulation has remained stagnant, and implantation strategies vary widely among surgeons. The LVAD is connected to the heart and the circulatory system via an inflow cannula and outflow graft, with the inflow cannula typically placed in an apical orientation in the left ventricle. Thrombotic events from LVADs can be attributed to mechanisms such as non-physiological blood flow, hemolysis and subsequent platelet activation. A potential putative etiology of LVAD thrombosis is misalignment of the inflow cannula which has been described clinically but until now not quantified.

This project aims at elucidating the influence of LVAD inflow cannula angle configuration and the impact of LV size, on LVAD thrombogenicity, agnostic of LVAD design.

METHODS

This study used unsteady computational fluid dynamics (CFD), virtual surgery, in-vitro patient-specific flow visualization and PIV and Lagrangian analysis on 3D patient-specific models of the left ventricle to evaluate thrombogenic potential of LVAD inflow cannula orientation and LV size.

Virtual Surgery: Using a CT-derived, 3D patient-specific model of the LV, virtual surgery was performed via SOLIDWORKS and Vascular Modeling Toolkit software by implanting the LVAD inflow cannula at various orientations (-14^0, -7^0, 0^0, 7^0 and 14^0) with respect to surgical 0^0 (line connecting the mitral valve to the apex of the LV) (See Figure 1). LV size was varied by creating larger / smaller LV models and implanting a standard-sized LVAD inflow cannula at the apical location of the LV, with zero angle orientation.

CFD and boundary conditions: Tetrahedral meshes were created for all patient models using ANSYS ICEM CFD. Unsteady CFD was performed in ANSYS FLUENT (Ansys Inc., Canonsburg, PA) modeling blood as an incompressible Newtonian fluid with density ρ = 1060 kg/m^3 and dynamic viscosity μ = 0.0035 Pa-s, as well as a shear-thinning non-Newtonian fluid [4]. Platelet (particle) motion and behavior was analyzed using FLUENT's multi-phase simulation option (discrete phase for platelets). Inertialess platelets (particles) were released periodically from the mitral valve. Patient-specific pulsatile mitral valve flow (obtained from Echo Doppler measurements) was prescribed as inflow conditions, and was modulated based on cardiac output (Figure 1(b)). A pressure-implicit with splitting of operators (PISO) scheme was used for spatial calculations and a second-order implicit scheme was used for temporal calculations. Grid convergence was performed, and the resulting meshes contained between 2 and 3 million grid points, depending on the LVAD and LV configuration.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Minimum thrombogenic performance (MTP) evaluation: In addition to Eulerian parameters such as pressure and wall shear stress (WSS), Lagrangian tracking was performed on all platelets traversing through the computational domain. The particle stress history (SH) was obtained as SH = $\int_{t_0}^{t} \tau(X(t'), t')dt'$, where τ is the local instantaneous shear stress magnitude at time t' and $X(t')$ is the platelet's location at that time instance. Additionally, the residence time (RT) of the platelet was also recorded. MTP for each configuration was evaluated based on the SH and RT to determine levels of platelet activation.

RESULTS

Trajectories for neutrally-buoyant particles (surrogates for blood-suspended cells) were computed for 10 cardiac cycles. Comparison of the results for both particle RT and SH demonstrated that residence times and integrated shear-histories of particles that have exited the ventricle within 3 cardiac cycles was statistically the same, regardless of the inflow cannula position, within the middle of the range studied thus far [-7^0,$+7^0$]. After three cardiac cycles, a large number of stagnated platelets were found recirculating in the ventricle. A large increase of stagnated particles was found for the largest inflow cannula angles (-14^0 and $+14^0$), with the surgical 0^0 configuration presenting the lowest apparent thrombogenicity. Investigation of the effect of LV size revealed increased stagnation, higher cumulative shear history along the trajectories and increased global WSS for smaller ventricles.

DISCUSSION

Despite the LVAD throughput being many times the volume of the fully distended LV, a very large percentage (~ 40%) of blood-suspended particles entering the ventricle lingered even after 3-5 cardiac cycles. Stagnation zones (Figure 1 (c), (d) and (e)) indicate the possibility of some of these particles being trapped for much longer times (investigation is underway for further quantification), with increased potential of platelet activation, prior to entering the LVAD. Results thus far indicate that deviation away from the surgical 0^0 configuration is unfavorable and may have serious implications for thrombosis.

INTRODUCTION

Many cell types align in response to cyclic stretch, and this alignment response is thought to play an important role in function, such as shear stress sensing in endothelial cells and anisotropic scar tissue formation in skin, tendon, and heart. Interestingly, although most 2D *in vitro* stretch experiments cause cells to align perpendicular to applied cyclic stretch, *in vivo* fibroblasts and collagen in healing scar typically align parallel to stretch. Recently, Obbink-Huizer et al. proposed a hypothesis to explain this discrepancy [1]. They postulated that in tissue or in 3D culture systems, compaction transverse to the loading direction outweighs the cyclic stretching – in other words, cells still avoid strain, but they avoid the (larger) compaction strain more strongly than the (smaller) applied stretch.

To date, only limited experimental data are available to assess this hypothesis. Foolen et al. designed a collagen gel loading system that allowed them to perform either uniaxial cyclic stretching (in x_1 with x_2 left free to compact) or *strip* uniaxial cyclic stretching (in x_1 with x_2 constrained) [2]. In the gels that underwent uniaxial cyclic stretching, cells aligned parallel to the constraint, per previous studies. In the gels that underwent strip uniaxial cyclic stretching, most cells showed no alignment response. Foolen also found that alignment responses changed as gels were cultured longer prior to stretching, but the role of compaction in this phenomenon was unclear. In order to better separate the alignment responses of rat cardiac fibroblasts to compaction vs. stretch in 3D culture, we developed a system that allows us to independently prescribe compaction in the loading and transverse directions, prior to and during the application of cyclic uniaxial stretch.

METHODS

Adult rat cardiac fibroblasts were isolated from Sprague-Dawley rats and used to populate collagen gels using published methods [3]. Gels were poured into negative PDMS (Dow Corning, Sylgard 184 Silicone Elastomer Kit) cruciform molds with small sponges at the arms and allowed to polymerize for 4h in the incubator in a 100mm X 15 mm Petri dish. Petri dishes were pre-coated with a 1-2mm layer of PDMS to prevent collagen from adhering to the surface of the dish. Then, the gel was either isotropically restrained for 24h (prerestrain) by pushing two small pins through each sponge into the PDMS layer, or the gel was allowed to float free and isotropically compact (precompact) for 24h.

An overview of all loading conditions can be found in Table 1. Nineteen prerestrained gels were fabricated. Three gels were fixed after the initial 24h period to serve as controls. The remaining gels were transferred to CellScale MechanoCulture B1 devices (for pictures and videos of the devices, see [4]). In the devices, four gels were uniaxially constrained in the x_1 direction, four were subjected to uniaxial cyclic stretch in the x_1 direction, four were equibiaxially constrained, and four were subjected to strip uniaxial cyclic stretch (stretch applied in the x_1 direction and x_2 direction held fixed). Thirteen precompacted gels were fabricated. Three gels served as control gels, five gels were uniaxially constrained in the x_1 direction, and five were subjected to uniaxial cyclic stretch in the x_1 direction. Cyclic stretch was performed at 10% amplitude and 0.5Hz.

After the stretch protocols, the gels were fixed in 10% formalin for 24h and the F-actin was stained using Alexa Fluor 488 Phalloidin (Thermo Fisher Scientific, A12379). A confocal microscope captured z-stacks through the entire thickness at three different xy-locations in the center of each gel. The resultant images were converted to binary (fluorescent pixels = white, dark pixels = black), and white pixel clusters above a certain size threshold were identified as cells. Using MATLAB, each cell's centroid and boundary were identified, and vectors originating from the centroid and ending around the cell

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

boundary were created. The radius and angle of each vector was used to compute the direction (mean angle, MA) and the degree of cell alignment (mean vector length, MVL).

Table 1: Summary of gel culture and mechanical loading conditions. Prerestrain: 24h control (green), uniaxial constraint/cyclic (blue), equibiaxial constraint/strip uniaxial cyclic (light blue). Precompact: 24h control (orange), uniaxial constraint/cyclic (red). Numbers in parenthesis indicate the number of gels.

Culture Conditions before load t=0h → 24h	Mechanical Loading Conditions t=24h → 48h
Prerestrained gels (19)	None, fixed after initial 24h (3)
	Uniaxial constraint (4)
	Uniaxial 10% cyclic (4)
	Equibiaxial constraint (4)
	Strip uniaxial 10% cyclic (4)
Precompacted gels (13)	None, fixed after initial 24h (3)
	Uniaxial constraint (5)
	Uniaxial 10% cyclic (5)

Cells with MVL ≤ 0.3 were classified as circular (unaligned), cells with MVL > 0.3 and $-45^o < MA < 45^o$ were classified as parallel, and cells with MVL > 0.3 and $45^o < MA < 90^o$ or $-90^o < MA < -45^o$ were classified as perpendicular. Note that stretch was always applied in the x_1 direction, which corresponds to 0^o. The MVL threshold was determined by visual assessment of the MVLs assigned to differently shaped cells. Differences in the fraction of circular cells and parallel cells were each assessed with one-way ANOVA followed by Tukey multiple comparisons post hoc tests (Prism, GraphPad Software, San Diego, CA).

RESULTS

Prerestrained control gels showed similar numbers of circular, parallel, and perpendicular cells after 24h of culture (Fig. 1). Uniaxial cyclic stretching for an additional 24h induced a significant increase in the fraction of circular cells compared to control ($p<0.001$, Fig. 1); these uniaxially stretched gels also contained more circular cells and fewer cells aligned parallel to the loading axis than gels constrained uniaxially but not stretched ($p<0.01$, Fig. 1).

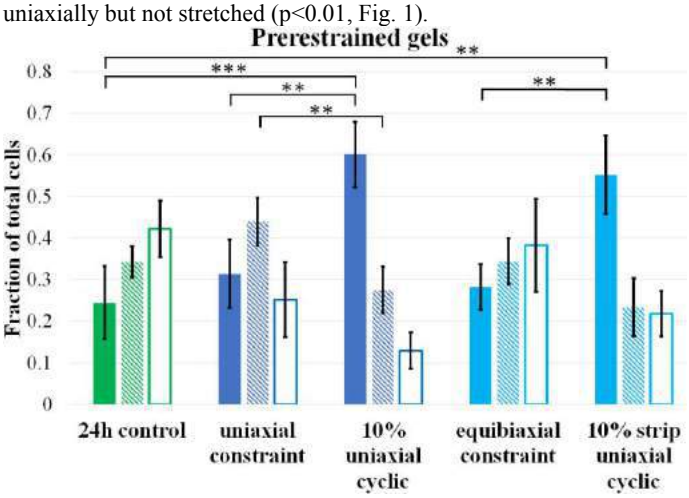

Figure 1: Fraction of circular (solid), parallel (striped), and perpendicular (open) cells in prerestrained gels following mechanical loading. Bars are color coded to match Table 1.

Gels undergoing either uniaxial constraint or uniaxial cyclic stretch were free to compact transversely; we next performed equibiaxial constraint and strip uniaxial stretch tests to eliminate this transverse compaction and isolate the effects of stretch. In these tests, the fraction of circular cells still increased during cyclic stretch compared to equibiaxial constraint ($p<0.01$) and control ($p<0.01$), with no significant changes in number of parallel cells (Fig. 1).

Finally, we examined the effect of precompaction. About half the cells in precompacted, uniaxially constrained gels aligned parallel to the direction of constraint (Fig 2). In contrast to prerestrained gels, precompacted gels subjected to uniaxial cyclic stretch showed no significant change in cell distributions compared to gels under uniaxial constraint. Thus, allowing the gels to compact before mechanical loading appeared to reduce cell responsiveness to stretch.

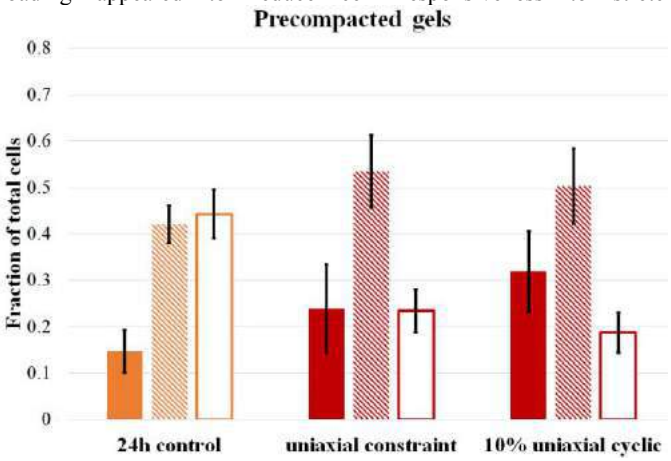

Figure 2: Fraction of circular (solid), parallel (striped), and perpendicular (open) cells in precompacted gels following mechanical loading. Bars are color coded to match Table 1.

DISCUSSION

We performed tests aimed at separating the effects of compaction and applied stretch. Gels that were restrained for 24h (prerestrained) showed significant changes in cell alignment in response to 10% cyclic stretch, compared to gels that were constrained but not stretched. Unexpectedly, these responses did not depend strongly on whether the direction transverse to the stretching axis was free to compact (uniaxial cyclic case) or prevented from compacting (strip uniaxial cyclic case). Regardless of transverse boundary conditions, cyclic stretch in the x_1 direction induced a significant increase in the number of circular cells. The reason for the large number of circular cells observed in these experiments is unclear. One possibility is that this represents a transition state for cells that are changing alignment in response to mechanical stretch; experiments to evaluate the evolution of this response at later time points are underway. Because we saw similar responses at 2.5% and 5% cyclic stretch (data not shown), it seems unlikely that the increase in number of circular cells reflects stretch-induced cell damage.

In contrast to prerestrained gels, gels that were allowed to compact for 24h (precompacted) prior to stretch showed no difference in cell alignment when stretched cyclically or simply constrained. Thus, we conclude that compaction of fibroblast-populated collagen gels alters the fibroblast alignment response to cyclic stretch. We hypothesize that compaction may decouple macroscopic and microscopic (cell-level) strains by altering collagen gel structure.

INTRODUCTION

Heart failure (HF) affects 2% of the US population, and over 1 million new cases are reported annually, incurring an annual treatment cost of over $30 billion [1]. Dearth of donor hearts and increasing HF cases have led to left ventricular assist devices (LVAD) transitioning from their original intended purpose of bridge-to-transplant (BTT) to long-term destination therapy (DT) devices [2]. VAD patients remain at elevated risk for cerebrovascular events, with high incidence of ischemic stroke, one of the most devastating complications of this therapy [3]. In the light of increasing use of LVADs as DT devices, focus is shifting to reduce thrombogenicity of LVADs and to re-evaluate implantation strategies.

The LVAD is surgically connected to the heart and circulatory system via an inflow cannula and outflow graft, with the outflow graft typically anastomosed to the aortic arch, proximal to the brachiocephalic artery and distal to the aortic sinus.. Primarily previous studies have focused on flow across the LVAD with little emphases on other factors such as; implantation, blood pressure and native cardiac output management. Additionally, in most studies, focus was only on global flow parameters in an Eulerian frame of study such as wall shear stress.

This project aims at elucidating the influence of LVAD outflow graft anastomosis configuration, and the coupling of intermittent aortic valve opening, on LVAD thrombogenicity, agnostic of LVAD design.

METHODS

This study used unsteady computational fluid dynamics (CFD), virtual surgery and Lagrangian analysis on 3D patient-specific models of the aortic arch and great vessels to determine efficient LVAD implantation and blood pressure management strategies.

Virtual Surgery: Using a CT-derived, 3D patient-specific model of the aortic arch and great vessels, virtual surgery was performed by anastomosing LVAD outflow grafts at different configurations (45^0, 60^0 and 90^0) to the aortic root (Figure 1 (a)). Virtual surgery was performed using software such as SOLIDWORKS and Vascular Modeling Toolkit.

CFD and boundary conditions: Tetrahedral meshes were created for all patient models using ANSYS ICEM CFD. Unsteady CFD was performed in ANSYS FLUENT (Ansys Inc., Canonsburg, PA) modeling blood as an incompressible Newtonian fluid with density ρ = 1060 kg/m^3 and dynamic viscosity μ = 0.0035 Pa-s. Platelet (particle) motion and behavior was analyzed using FLUENT's multi-phase simulation option (discrete phase for platelets). Inertialess platelets (particles) were released periodically from the LVAD outflow graft and intermittently from the aortic valve (see below, Figure 1 b and c). A continuous flow boundary condition was used for the inlet (LVAD outflow graft), and physiologically relevant peripheral vascular resistances were used in a lumped parameter model at the outlets. A pressure-implicit with splitting of operators (PISO) scheme was used for spatial calculations and a second-order implicit scheme was used for temporal calculations. Grid convergence was performed, and the resulting meshes contained between 2 and 3 million grid points, depending on the LVAD configuration.

Native cardiac output management: To investigate the influence of intermittent aortic valve opening, unsteady flows at different frequencies and ejection fractions were integrated into a left ventricle inflow model. The ejection frequency was programmed for one partial ejection every 2 – 6 cardiac cycles. Platelets (particles) were ejected from the aortic valve inlet during every ventricular ejection.

Copyright 2016 The Organizing Committee for the 2016 Summer Biomechanics, Bioengineering and Biotransport Conference

Minimum thrombogenic performance (MTP) evaluation: In addition to Eulerian parameters such as pressure and wall shear stress (WSS), lagrangian tracking was performed on platelet surrogates traversing through the computational domain. The particle stress history (SH) was obtained as SH = $\int_{t_0}^{t} \tau(X(t'), t')dt'$, where τ is the local instantaneous shear stress magnitude at time t' and $X(t')$ is the platelet's location at that time instance. Additionally, the residence time (RT) of the platelet was also recorded. MTP for a particular configuration was evaluated based on the SH and RT to determine levels of platelet activation and accumulation.

RESULTS

LVAD outflow graft configurations: Global WSS was reduced for acute angles at one location (aorta near the root of the brachiocephalic branch), but no configuration globally minimized the WSS on the arterial walls. However, Lagrangian tracking of suspended platelets (discrete particles) revealed significant hemodynamic changes for the various configurations. The particles' SH and RT indicated that the percentage of particles with long RT and elevated SH decreased strongly for acute angles (Figure 1, (d) and (e)).

Intermittent aortic valve opening: Maximum global WSS resulting from the impingement of the jet from the LVAD outflow graft was reduced due to aortic valve opening, as the aortic flow coupled with the impinging jet, reducing the stagnation point flow on the contralateral wall. Here, too, suspended platelet tracking analysis revealed reduced SH and RT for acute configurations with the aortic valve opening once every 5 cardiac cycles. More importantly, the intermittent aortic flow aided in the early transport of stagnated particles just distal to the aortic valve, thereby reducing the time for platelet activation.

DISCUSSION

Optimal outflow graft configuration analysis can be performed based on suspended cell tracking computations. This study suggests that acute graft angle configurations minimize thrombogenicity by lowering the integrated shear stress 'felt' by the platelets and their residence times. Aortic valve opening, even at low cardiac output and low frequency (half the natural ejection volume occurring once every 5 cardiac cycles) reduced Wall Shear Stress compared to no Aortic Valve opening. Thus, a VAD management strategy permitting intermittent aortic valve opening coupled with acute angle (~45^0 - 60^0) LVAD outflow graft implantation could potentially reduce stroke risk.

INTRODUCTION

There are approximately 600 million liquid biospecimens including serum and plasma collected from patients, currently stored in biorepositories across the U.S. and the world, with the number increasing at a rate of 20 million samples per year **(1)**. These biospecimens are generally stored for future biomarker research and verification, where the availability of high quality biospecimens is integral. However, even when best practices are followed, and the biospecimens are frozen immediately after collection and processing, cryogenic storage, and freeze-thaw alone, can impose harsh chemical and mechanical stresses that can damage proteinaceous biomarkers and significantly compromise sample quality. Additionally, cryogenic storage is costly, with an estimated cost of $100 million annually **(2)**.

This research focuses on developing a room temperature stabilization technology for storing achievable serum and plasma samples. A sugar based electrospun matrix is designed to adsorb and isothermally vitrify liquid biospecimens. When vitrified, all biochemical reactions in the biospecimen can be stopped without exposure to extreme stresses induced by cryogenic storage and freeze-thaw **(3)**. The removal of water during isothermal vitrification will significantly reduce sample volume and storage requirement, while room temperature stabilization will not only reduce storage cost but also make the samples less vulnerable to failures such as power shortage, equipment breakdown and human error that can occur in cryogenic storage facilities. Additionally, this technology will eliminate the need for thawing, re-aliquoting and re-freezing of large samples (which are known to introduce sample modifications), since dried samples can be readily divided by breaking them into smaller pieces.

METHODS

To produce the sugar-based electrospun matrix, a solution containing 1.2 M trehalose (TRE) and 0.025 M dextran (DEX) was rigorously mixed for 24 hours. The solution was then electrospun at a flowrate of 0.003 mL/min through a 15 kV gradient across a 15 cm gap. Electrospun woven matrices were then stored into disks, placed in 24-well plates and stored in a vacuum chamber before use. Five low concentration excipients, known to impede various protein denaturation mechanisms were added at their identified optimum concentration. The selected excipients and their concentrations are: 1.5% glycerol, 1% PEG, 0.1% Tween 20, 0.3% gluconic acid and 0.2% glucamine.

Lactate dehydrogenase (LDH), a known freeze-thaw sensitive cancer biomarker was used for matrix optimization. A model serum solution containing 50 mg/mL bovine serum albumin (BSA) was spiked with 8 μg/mL LDH and 150 μL was added to 250 mg electrospun matrix. The samples were then dried in a vacuum chamber prior to re-suspension and subsequent enzymatic activity analysis. Enzymatic activity of treated samples was compared with values obtained for the untreated (fresh) control (taken as 100%).

The optimized matrix was further validated using four additional biomarkers: C-reactive protein (CRP), prostate specific antigen (PSA), matrix metalloproteinase-7 (MMP-7), and C3a, representing various storage sensitivities. The upper limit concentrations of the test biomarkers were spiked into the model serum prior to isothermal vitrification. Enzyme-linked immunosorbent assay (ELISA) was conducted to measure protein recovery. All experiments were conducted in at least 3 replicates. A two-tailed student's t-test was used to measure statistical significance of recovery between desiccated samples and the fresh control.
