To investigate sensitivity of stress prediction to the material parameters, analyses with two material sets: $E = 1.0E5$ MPa, $\nu = 0.3$ and $E = 1.0E8$ MPa, $\nu = 0.4999$ are conducted. The stress distributions are compared with those from the pure displacement method. The contours of von Mises stress from the two formulations are shown in Figure 3 and 4. It can be observed that, for the mixed formulation, the stress contours from the two material sets are very close to each other (Figure 3 (a) and Figure 3 (b)). In contrast, the solutions from the displacement method differ significantly (Figure 4 (a) and Figure 4 (b)). The results show that, in this case, the mixed formulation is insensitive to the material parameters while the displacement formulation is not.

DISCUSSION

This study shows that the mixed formulation can significantly improve the performance of 8-node solid element when the material approaches the incompressibility limit. Considering that almost all

biological soft tissues are incompressible or nearly incompressible, the mixed formulation appears to be indispensable for accurate stress prediction in tissue structures. In particular to the AAA, it is known that typical AAAs are statically determined structures wherein the wall stress depends minimally on the wall material and that the inverse method helps to capture this property [1]. However, for the displacement formulation, this property could be compromised numerically due to the treatment of the incompressibility constraint. We have shown that the mixed method can pointedly address the numerical issue and provide stress solutions that are insensitive to material parameters even at the incompressibility limit. For *in vivo* stress analysis, since the material parameters are impossible to know on a patient-specific basis, it is prudent to employ methods that can produce material-insensitive stress solution if/when the physics dictates so. The inverse mixed formulation appears to fit this goal. Convergent studies with different mesh levels are also conducted. The results show that, when the mesh level is refining to a certain level, the displacement and stress results converge nicely to stable values. Due to the page limits, these results are omitted here.

INTRODUCTION

The exact cause of abdominal aortic aneurysm (AAA) is still unknown and damage to the structural proteins of the extracellular matrix (ECM) has been postulated as one of the chief etiologies for aneurysm development. As the arterial ECM primarily comprises elastin and collagen fibers, these proteins have been the focal point of studies related to pathological origins of AAA and their resultant changes in tissue biomechanics. The formation of intraluminal thrombus (ILT), complicates the overall understanding and interplay of the ECM protein's structure-function relationship. Glycosaminoglycans (GAGs) are one such class of proteins that is directly linked with the elasticity of arterial ECM [1]; however, its role in AAA mechanics is still not entirely understood. In this study, we aim to find an association between patient-specific AAA wall mechanics and geometric indices with region-based aneurysmal tissue protein quantifications (GAGs).

METHODS

Patient Data – Five human AAA underwent surgical repair at Allegheny General Hospital - AGH (Pittsburgh, PA) and their computer tomography angiography (CTA) images were obtained upon approval by the AGH Internal Review Board. These images were further utilized for biomechanical quantification and geometric characterization. The surgical procedure involved removal of the ILT and its associated wall tissue from the left anterolateral portion of the AAA. These specimens were subsequently classified into abluminal, medial and luminal ILT regions, and wall tissue sections, and utilized for histological characterization.

Biomechanical Analysis and Quantification of Geometric Indices – The CTA images were segmented using an in-house image segmentation and geometry quantification tool (AAVASC) [2, 3] (Fig. 1). The Matlab® (Mathworks, Natick, MA) based package

allowed us to segment the AAA into their respective domains: lumen, ILT, and outer wall.

Figure 1. Steps involved in post-processing CTA images to generate masks (AAVASC) and for calculation of geometric indices [3].

The two-dimensional images were reconstructed utilizing surface meshing to recreate the 3D AAA model. This model was then utilized for geometric calculations and the geometry used to generate tetrahedral volume meshes using ANSYS ICEM (Ansys Inc., Canonsburg, PA). Finite element analysis (FEA) was performed using the ADINA (Adina R&D Inc., Watertown, MA) solver with an intraluminal pressure of 120

mmHg. Results of the FEA simulations were post-processed to quantify the first principal stress distribution on the AAA wall using ANSYS Enight, from which the peak wall stress (PWS) was computed. 1D, 2D, 3D size and shape, and wall thickness geometric indices were calculated as a part of the morphometric analyses.

Histology – The AAA specimens underwent routine histological processing while the slides (5-7 μ m thick sections) were stained with Alcian Blue for GAGs, imaged on an Olympus CX41 microscope at 4x magnification and the images stitched using Microsoft Image Composite Editor. The stitched images were then quantified using the Fiji (GitHub, San Francisco, CA) extension of ImageJ (National Institutes of Health, Bethesda, MD), which was used to semi-automatically perform GAG distribution in each image (in luminal, abluminal, medial, and wall tissue sections). All image based-quantifications were performed in triplicate.

Statistical Analysis – Patient-specific data obtained from FEA, geometric indices, and histology were expressed as mean \pm std. deviation. To test the differences in GAG distribution across the locations, one-way ANOVA was applied with Tukey's pairwise comparison. Next, to evaluate the inter-relationship between the tissue GAG expressions and PWS or geometric indices, Pearson's correlation was performed. Data was considered significant at $\alpha = 0.05$.

RESULTS

GAG distribution in the ECM across the four regions were found to be significantly different from the ILT luminal to the wall tissue regions ($p < 0.001$). More specifically, GAG content of luminal, medial, and abluminal regions was found to be lower than the wall tissue region ($11.8 \pm 1.6\%$ vs. $12.7 \pm 1.7\%$ vs. $14.7 \pm 2.9\%$ vs. $18.7 \pm 2.2\%$; $p = 0.0006$) (Fig. 2).

Figure 2: GAG distribution across the ILT and wall tissue regions.
*denotes significant differences at $\alpha < 0.001$.

PWS exhibited a strong negative association with the medial GAG distribution ($r = -0.9836$, $p = 0.0025$) (Fig. 3, Table 1). Conversely, AAA asymmetry (β ; given by $1 - \text{ratio of the distance between the lumen centroid and the centroid of the cross section where maximum AAA diameter is located, to the max AAA diameter}$) exhibited a strong positive association with the GAG distribution in the aforementioned ILT location ($r = 0.9425$, $p = 0.0164$). Further, the correlation of abluminal GAG distribution was strongly associated with the following wall thickness indices: (i) positively with $t_{w,skew+}$; and negatively with $t_{w,skew-}$ (skewness indicates whether the distribution of wall thickness is normal, positively skewed, or negatively skewed); (ii) negatively with $t_{w,modeVar}$ (mode of the variance of wall thickness), $t_{w,minVar}$ (minimum variance of the wall thickness), $t_{w,median}$ (median of the wall thickness), and $t_{w,mode}$ (mode of the wall thickness), respectively (see Table 1). Wall tissue GAG distribution exhibited a strong association with the 3D size index γ , which is the ratio of AAA ILT volume to vessel volume ($r = 0.8825$, $p = 0.0475$).

DISCUSSION

Contrary to previous literature, GAGs were observed in the AAA wall and ILT. Pooling of GAGs between the elastic lamellae has been postulated as the prime cause of thoracic dissecting aneurysms [4], which is uncommon in AAA. However, the phenomenon of increased PWS with lowered GAG expression (Fig. 3) is a clear evidence that their role is more mechanical (contractile and elastic) in nature. Removal of GAGs from the arterial ECM has been shown to increase stiffening of the tissue and induce loss of viscoelasticity [1]. In addition, higher amounts of GAGs in the ECM of the wall compared to the ILT regions suggests the notion that oxygen is limited in the ILT. The interaction between ILT and the aortic wall is complex, and the increase in GAG expression in the AAA wall, but not in ILT, suggests a possible elasticity gradient from the adventitial to the luminal surface of the aneurysmal aorta (Fig. 2).

Figure 3: Strong negative association of PWS with medial GAG distribution.

Table 1: Correlation of region-wise GAG distribution with PWS and geometric indices.

INTRODUCTION

Fatal cardiovascular events such myocardial infarction and stroke are majorly caused by atherosclerotic plaque rupture (1). Plaque rupture is a biomechanical event that occurs when local plaque stresses exceed strength. Plaque stresses can be assessed with computational techniques, such as finite element (FE) modelling. Accurate representation of the plaque material behavior is a must for correct plaque stress assessment (2).

Atherosclerotic plaque tissue is highly heterogeneous, composed of various structural components. For accurate regional stress assessment, it is of great importance to measure the component-wise material properties of atherosclerotic plaques. However, mechanical properties data of atherosclerotic plaques is scarce and mainly limited to gross properties of plaques (3). Recent studies did component-wise material characterization of plaques using inverse FE approach (4,5). However, this technique is computationally expensive as it requires FE updating iteratively. Hence, faster techniques are required, especially for in-vivo characterization and clinical use in the future.

A fast approach for material characterization is the virtual fields method (VFM), which is based on the principle of virtual work (6). Since the date VFM was established, it was employed by various engineering applications and also recently in the cardiovascular biomedical field for healthy arteries (7). The current study applies the VFM to material characterization of heterogeneous atherosclerotic plaque tissue, for the first time. Here we present the derived virtual fields for the particular application of intraluminal pressurization of atherosclerotic arteries and the validation of the approach using synthetically generated experimental data.

METHODS

VFM principle and derivation of the virtual fields

VFM employs the virtual work principle, which can be for a given solid of volume V in the absence of body forces and for a (pseudo-)static loading written as follows:

$$-\int_V \sigma : \varepsilon^* + \int_S \mathbf{t} \cdot \mathbf{u}^* = 0 \quad (1)$$

where σ is the Cauchy stress tensor, ε^* is the virtual strain (small strain definition) tensor derived from the virtual displacement vector \mathbf{u}^* , and \mathbf{t} is the distribution vector of the traction loads exerted on the surface S . VFM utilizes full-field deformation measurements of the investigated structure. Together with a predefined constitutive law, the deformation fields are used to obtain the Cauchy stress tensor σ . In case of an incompressible hyperelastic material description with a strain energy density function ψ , the stress tensor σ is obtained from:

$$\sigma = -pI + 2 \cdot \frac{\partial \psi}{\partial F} \cdot F^T \quad (2)$$

where p is the hydrostatic pressure term enforcing incompressibility constraint, I is the identity tensor, and F is the deformation gradient tensor obtained from full-field deformation measurements. The material parameters to be determined with VFM are integrated in the strain energy density function ψ .

VFM principle (Eqn 1) requires describing kinematically admissible virtual displacement fields \mathbf{u}^* . Choosing the fields smartly is a key issue as the final analytical equation(s) obtained from Eqn 1 must enable the evaluation of the unknown material constants in the strain energy density function ψ .

In an ideal case of homogeneous full-field deformation, same number of virtual fields, and hence analytical equations derived from Eqn 1, as the number of unknowns would be sufficient to solve the

system of the equations. However, in case of heterogeneous full-field deformation measurements, noise in the measurements and nonlinearity of the material properties the identification strategy requires use of a minimization technique and virtual displacement fields more than the number of equations. For this study, trust region reflective technique integrated in a custom-developed MATLAB code was utilized as the minimization algorithm and the system of the analytical equations obtained from Eqn 1 by prescribing multiple virtual fields is used in the minimization to identify the unknown material parameters. The first phase of the study included finding appropriate virtual fields for the specific application of intraluminal pressurization of atherosclerotic plaques.

Validation study

As this is the first study applying VFM to the intraluminal pressurization of atherosclerotic plaques, the derived virtual displacement fields and the VFM approach required validation. Therefore, synthetic full-field displacement measurements of atherosclerotic plaques for physiological intraluminal pressure of 100 mmHg were computed with FE modelling. The ten FE models were based on ten realistic plaque morphology obtained from histology segmentation of human carotid plaques (Figure 1). Incompressible Neo-Hookean material models, described by a single material constant C , were assumed for the plaque components. The C -values for the four components were: fibrous tissue=120 kPa, calcified tissue=423 kPa, lipid rich tissue=5 kPa, and the arterial wall=250 kPa (8,9). In the end, the VFM-estimated values were compared against these “ground-truth” values.

Sensitivity analysis

The sensitivity of the employed VFM approach to the number of the prescribed virtual fields and on the initial guesses for the C -values of the four plaque components was investigated. Ten initial guesses were generated randomly within the range of 1-1000 kPa for the four components.

Figure 1: FE models for validation analysis were obtained from segmented carotid plaque histology images

RESULTS

Because of the incompressibility condition a strong requirement in the search of the virtual fields was that the trace of the virtual strain fields was equal to zero, but resulting in non-zero integral evaluations in Eqn 1 at the same time. We identified a smart choice of an in-plane displacement field fulfilling these requirements to be $u^* = [x/(x^2+y^2), y/(x^2+y^2), 0]$. Multiplying this field by $\cos^n(\Theta)$ and $\sin^n(\Theta)$, where $\Theta = y/x$ and n defines the order, and rotating the field m -times with increments of π/m , new virtual displacement fields were acquired. In the end, the number of equations obtained equaled to m -times- n .

As expected, the maximum relative error of the VFM-estimated C -values compared to the ground truth decreased by increasing the number m and/or n . The error values for the fibrous tissue component are illustrated in Figure 2. Approximately 120 virtual fields were sufficient to achieve an error of $< 5\%$.

Figure 2: Dependency of the relative error for fibrous tissue component between VFM-derived C -values and “ground truth” on number of rotations, m and order of trigonometric functions, n .

An illustrative case of $m=12$ and $n=12$ showed an excellent estimation of the C -values by VFM. The median error for all VFM evaluations of 10 plaque cases and 10 initial guesses (in total 100 evaluations) combined resulted in VFM-derived C -values for fibrous tissue as 122 kPa, for wall as 258 kPa, for lipid as 7 kPa and for calcified as 457 kPa (Table 1). The highest absolute error was for the calcified tissue (34 kPa) with a relative error of 8%. The VFM evaluation for this illustrative case took < 10 min using the developed MATLAB code in a decent PC (Intel i7, single core, RAM=16GB).

Table 1: VFM-results of an illustrative case

Component	C-value (kPa)	
	Ground truth	VFM estimate
Fibrous tissue	120	122
Lipid	5	7
Calcified tissue	423	457
Arterial wall	250	256

DISCUSSION

In this study, VFM was used for the first time for atherosclerotic plaque mechanical characterization. The validation analysis showed high accuracy of the VFM approach for the particular application, demonstrating the great potential of VFM for heterogeneous plaque characterization from full-field deformation data. In-vivo full-field plaque deformation can be acquired from MRI and ultrasound. Moreover, the computational time required for the VFM approach was in the order of minutes, much shorter than e.g. inverse FE approach, which might take hours or days. Hence, the developed VFM technique has great potential to be used for in-vivo plaque characterization.

INTRODUCTION

Quantifying the individual role of microstructural features in affecting organ-level heart function and tissue-level ventricular mechanics requires a validated and efficient finite element (FE) implementation of a microstructural-based constitutive model. To the best of our knowledge, such a microstructural-based FE modeling framework is currently lacking. To address this gap, we developed and experimentally validated a microstructural FE model of the left ventricle (LV) with a realistic 3D geometry and muscle fiber architecture to describe the passive mechanics of myocardial tissue during inflation. The model was implemented using an open-source FE library FEniCS.

METHODS

Microstructural Constitutive Model Formulation. A microstructure-based constitutive model was developed to describe the passive mechanical behavior of the myocardium. The total strain energy function (SEF) of the myocardium W_{total} is assumed to be represented by the volume-weighted sum of that of its constituents, i.e.,

$$W_{total} = \phi_g W_g + \phi_m W_m + \phi_c W_c - p(J - 1) . \quad (1)$$

where (ϕ_g, W_g) , (ϕ_m, W_m) and (ϕ_c, W_c) are the (volume fraction, SEF) of the ground matrix, muscle fibers and collagen fibers, respectively, with $\phi_g + \phi_m + \phi_c = 1$. In Eq. (1), J is the determinant of deformation gradient tensor and p is the Lagrange multiplier to enforce incompressibility. The SEFs W_g and W_m are prescribed to be an isotropic Neo-Hookean and an exponential function of the muscle fiber stretch, respectively. Taking into account the collagen fibers waviness and spatial arrangement (**Fig. 1**) in a stochastic manner [1], the SEF of the collagen matrix is given by

$$W_c = \frac{C_4}{2} \int_0^{2\pi} \int_0^\pi \left[\int_0^{\epsilon_c(\theta, \phi)} D(x) \frac{(\epsilon_c(\theta, \phi) - x)^2}{1 + 2x} dx \right] R(\theta, \phi) d\phi d\theta \quad (2)$$

where $D(x)$ is a prescribed waviness distribution function, $R(\theta, \phi)$ is the spatial distribution function, C_4 is the elastic modulus of the collagen fiber and ϵ_c is the uniaxial strain of the individual collagen fiber.

Fig. 1. Schematic of microstructural model showing muscle fiber orientation with a linear transmural variation from 70° (endocardium) to -40° (epicardium) and the local arrangement the collagen fibers with respect to the local muscle fiber.

Parameter Estimation. We used the biaxial mechanical test data obtained from 6 specimens of the canine mid-wall myocardium from a previous experiment [2] to estimate the constitutive model's parameters. A nonlinear programming solver "fmincon" in MATLAB was used to find optimal parameters that minimize the sum of squared residuals between the model predictions and measurements of the stress-stretch relations. These fitted model parameters were then prescribed in the FE framework to simulate passive filling of the LV.

FE Simulation of LV Passive Filling. Based on experimental measurements, a truncated ellipsoidal LV geometry with unloaded volume of ~20 ml and a linear transmural variation of muscle fiber helix angle (Fig. 1) is prescribed in the FE framework. We computed pressure-volume relationship as well as strains to compare with an independent set of measurements made in the intact LV. The load taken up locally by individual tissue constituent in the LV was also computed.

RESULTS

Biaxial Fitting. The microstructural constitutive model shows very good fit to the biaxial measurements (Fig. 2). The fitted structural parameter values are also within the range of microscale measurements made on individual tissue constituents (e.g., collagen fiber stiffness and tortuosity as well as cardiac muscle elastic modulus) [3].

Fig. 2. Comparison of the fitted and experimental Cauchy stress-stretch data for a representative specimen.

FE model predictions. The pressure-volume curves predicted by the FE LV model using the 6 sets of parameter values framework all fell within the measurements range [4]. Tortuosity-pressure relationship of the collagen fibers computed from the fitted parameter values are also largely in agreement with the measurements [5] (Fig. 3).

Fig. 3. Comparison of the inflation pressure-volume and tortuosity-pressure curves derived from 6 sets of fitted model parameter values and their mean values with measurements.

Effects of collagen ultrastructure. The global LV stiffness is very sensitive to the collagen fiber waviness and spatial orientation as measured by the collagen fiber azimuthal angle ϕ . Decreasing the mean collagen fiber waviness and increasing ϕ lead to a reduction in the LV volume at a fixed pressure (Fig. 4).

Myocardial Stress. The simulation results show that the contribution of cardiac muscle fiber is substantial at all transmural locations, accounting between 40 – 70% of the total stress. The contribution of collagen fibers to the total stress increases from 22% at the epicardium to 96% at the endocardium. Interestingly, the results also show that at 60% transmural depth, the contribution of collagen fibers starts to exceed that of the muscle fibers (Fig. 5).

Fig. 4. Sensitivity of LV function to collagen network ultrastructure.

Fig. 5. Transmural variation of the contribution of individual constituent to the total muscle fiber stress at 8 mmHg.

DISCUSSION

We have developed and validated a microstructure-based constitutive model of the passive myocardium in a three-dimensional FE modeling framework with measurements made across multiple scales; i.e., at the constituent, tissue and organ levels. Calibrated against the tissue-level biaxial test data derived from the mid-wall of the canine myocardium, the fitted parameter values are consistent with microscale measurements made on individual cardiac tissue constituents and the FE model predictions using these values are in agreement with independent measurements from experiments on the intact canine LV.

We found that the LV function is sensitive to the collagen fiber network ultrastructure and the load taken up by tissue constituents varies with LV location. The latter finding has implications on pharmaceutical therapies that target specific tissue individual constituent; e.g., attenuating myocardial fibrosis and reducing myocyte titin stiffness in heart failure with preserved ejection fraction. Specifically, this finding suggests that reducing LV passive stiffness by altering collagen fiber network is most effective if applied to the sub-endocardial region. Conversely, altering myocyte stiffness to reduce LV stiffness is most effective when applied to the sub-epicardial region.

A THERMODYNAMICALLY MOTIVATED CROSS-BRIDGE CYCLING FRAMEWORK TO PREDICT MYOFIBRIL REMODELING UNDER CONDITIONS ASSOCIATED WITH LV HYPERTROPHY

Eoin McEvoy (1), Patrick McGarry (1)

(1) Discipline of Biomedical Engineering,
National University of Ireland Galway,
Galway, Ireland

INTRODUCTION

Heart failure is a global pandemic affecting over 25 million people worldwide. This inability of the heart to sufficiently perfuse the body may follow from cardiac eccentric hypertrophy, a medical condition whereby the ventricle becomes thinner and longer, often onset by an increased diastolic blood volume. Cardiomyocytes undergo longitudinal cell growth and addition of sarcomeres in-series [1]. The contractility of this thin ventricle wall is dramatically reduced, and, consequently, the volume of blood ejected during systole is reduced. While there have been significant advances made in the field of cardiac modelling in recent years [2,3] the cell-level mechanisms that drive hypertrophy have yet to be uncovered. In this study, we investigate the effects of pathological loading conditions on contractility and remodeling of cardiac myofibrils.

MODEL DEVELOPMENT

Contractility and remodeling: Transient force generation in cells is governed by cycling of myosin heads within the sarcomere, with an attachment transition rate

$$k_a = k_d \exp([1/kT]\{\delta\mu_a - \phi + F\Delta\}) \quad (1)$$

obtained from equilibrium [4]. Here, the myosin strain energy ϕ is generated by hydrolysis of ATP and depends on the sarcomere strain rate $\dot{\epsilon}_n$ (Fig. 1(a)). The local concentration of parallel myofibrils \hat{n} is governed by equilibrium between bound and unbound contractile proteins, with the thermodynamically

consistent rate equation for fibre formation/dissociation [5] given as:

$$\dot{\hat{n}} = \frac{\hat{N}_u}{\hat{n}} \omega_n \exp\left(-\frac{\hat{n}(\mu_{ab} - \mu_u)}{k_B T}\right) - \hat{n} \omega_n \exp\left(-\frac{\hat{n}(\mu_{ab} - \mu_b)}{k_B T}\right), \quad (2)$$

where μ_b and μ_u are the free energies of the bound contractile proteins in a myofibril and unbound proteins, respectively, μ_{ab} is an activation barrier. \hat{N}_u is the protein availability, whereby the total number of available contractile proteins, bound and unbound, is a conserved quantity. ω_n is the collision frequency of unbound molecules, k is the Boltzmann constant, and T is the absolute temperature. \hat{n} is the number of actin-myosin sarcomeres along the length of a myofibril, with the kinetic remodeling law as follows:

$$\dot{\hat{n}} = -\frac{1}{\hat{n}} \left(\frac{\hat{N}_u}{\hat{n}}\right)^2 \left[\psi(\tilde{\epsilon}_n) - \frac{\partial \psi}{\partial \tilde{\epsilon}_n} (1 + \tilde{\epsilon}_n)\right] \frac{\alpha_n}{\mu_{b0}}, \quad (3)$$

where ψ is the internal sarcomere energy which increases with increasing strain $\tilde{\epsilon}_n$, and α_n is a rate constant. As shown in Fig. 1(b) the model dictates that the remodeling process is initiated to achieve an optimal overlap of the actin/myosin filaments (e.g. more sarcomeres are added in-series when the filaments become highly stretched).

Tissue modeling: The active molecular/cell framework is combined with a passive hyperelastic myocardium model [6], with the anisotropic stress component given by:

$$\boldsymbol{\sigma}_{aniso} = \sum_{m=f,s} 2a_m(I_{4m} - 1) \exp[b_m(I_{4m} - 1)^2] \mathbf{a}_m \otimes \mathbf{a}_m + a_{fs}I_{8fs} \exp(b_{fs}I_{8fs}^2) (\mathbf{a}_m \otimes \mathbf{a}_m + \mathbf{a}_m \otimes \mathbf{a}_m), \quad (4)$$

where I_{4f} , I_{4s} , and I_{8fs} are anisotropic invariants and \mathbf{a}_m ($m = f, s$) is a unit vector indicating the myofibre or sheet orientations in the deformed configuration. The operator \otimes is the dyadic product of vectors resulting in a second-order structure tensor. a_m and b_m ($m = f, s, fs$) are anisotropic material parameters for each contribution. An idealized left ventricular geometry is developed (with fibre directions varying spatially across the heart wall) and active beating is simulated. Physiological boundary conditions are applied to the tissue for (i) blood volume in a healthy state (V_h), and (ii) increased diastolic blood volume (V_p). Cell remodeling following the application of pathological loading conditions is investigated.

Figure 1: (a) Schematic of actin-myosin cross-bridge cycling under shortening, isometric, and lengthening boundary conditions; (b) Remodeling of myofibrils subjected to overstretching (reduced actin/myosin overlap). Sarcomeres are added in-series and the parallel concentration of myofibrils is reduced.

RESULTS

The predicted ventricle pressure for healthy conditions is shown in Fig. 2(a), and the Cauchy stress in the fibre (f) direction in Fig. 2(b). The cell tension that develops is not instantaneous, but transient due to the dynamic attachment of myosin heads (as motivated by calcium signaling and the tissue strain state). The influence of altered diastolic blood volume ΔV_d on the number of in-series sarcomeres \hat{n} is shown in Fig. 2(c). Higher applied ΔV_d translates to an increased ventricle wall strain (thereby increasing the internal sarcomere strain ε_n). The consequent reduction in actin/myosin overlap lowers the availability of myosin heads and therefore the active contractility (increasing the sarcomere free energy). Simulations predict that the steady state values of \hat{n} will thus increase with increased ΔV_d . However, due to the constraint on the number of contractile proteins, the parallel concentration of myofibrils $\hat{\eta}$ is lowered (Fig 2(d)) and the overall contractility of the tissue is reduced.

DISCUSSION

In this study a thermodynamically motivated model for cell contractility is implemented to simulate the behaviour of the myocardium during the cardiac cycle, predicting correct patterns of ventricle pressure. We demonstrate that eccentric hypertrophy is initiated by a higher wall stretch associated with an increased

venous return, to restore an optimal overlap of the actin/myosin filaments. Such a fundamental understanding of the mechanisms that drive remodeling could facilitate the development of advanced diagnostic models to predict if and when heart failure will occur.

Figure 2: (a) Predicted ventricle pressure over cardiac cycle; (b) Cauchy stress σ_f^{tot} in fibre (f) direction at peak systole; Predicted (c) number of in-series sarcomeres \hat{n} and (d) parallel concentration of sarcomeres $\hat{\eta}$ following application of increased diastolic blood volume $\Delta V_d = V_p/V_h - 1$.

CONTRACTILITY MODELLING TOWARDS PREDICTING ECCENTRIC HYPERTROPHY IN A PATIENT-SPECIFIC HEART MODEL

INTRODUCTION

Eccentric hypertrophy is a medical condition whereby the ventricle wall becomes thinner and longer, typically onset by an increased diastolic blood volume. At the cell-level, this is characterized by longitudinal cell growth and addition of sarcomeres in-series [1]. As the disease progresses, the contractility of the thin-walled structure is reduced and, therefore, the pumping ability of the heart is impaired. While there have been several advances in patient-specific finite element simulations of the heart [2], previous models implemented phenomenological representations of tissue contractility [3]. In contrast, the current study implements a thermodynamically motivated model for actin-myosin cross-bridge cycling in cardiac myocytes [4]. Predictions of contractility for this thermodynamic cross-bridge cycling model are compared to results for widely used phenomenological models. In particular, the influence of pathological increases to diastolic blood volume on tissue contractility and remodeling is investigated.

METHODS

A linearized form of myocyte strain during a cardiac cycle is implemented in a 1D framework, to simulate the effect of pathological boundary conditions on active force generation of myofibrils. Contractility is simulated via the phenomenological model of Walker *et al.* [3], and the thermodynamically motivated model of McEvoy *et al.* [4]. The Walker model for myofibril stress is given as:

$$\sigma_{af}(t, E_{ff}) = \frac{T_{max}}{2} H(E_{ff}) \left[1 - \cos(\omega(t, E_{ff})) \right], \quad (1)$$

where t is the cycle time, E_{ff} is the myocyte strain in the fibre direction, and T_{max} is the maximum isometric tension generated by a sarcomere. The function $H(E_{ff})$ describes the influence of stretch mediated calcium signaling, such that

$$H(E_{ff}) = \frac{Ca_0^2}{C a_0^2 + EC a_{50}^2(E_{ff})}, \quad (2)$$

where Ca_0 is the peak intercellular calcium concentration, and $EC a_{50}$ is the length-dependent calcium sensitivity. ω is a time-dependent relation, given by:

$$\omega(t, E_{ff}) = \begin{cases} \pi \frac{t}{t_o} & 0 \leq t \leq t_o \\ \pi \frac{t-t_o+t_r(l)}{t_r} & t_o \leq t \leq t_o + t_r(l) \\ 0 & t \geq t_o + t_r(l) \end{cases}, \quad (3)$$

$$t_r(l) = ml + b, \quad (4)$$

$$l(E_{ff}) = l_r \sqrt{2E_{ff} + 1}, \quad (5)$$

where t_o is the time to reach peak tension, m and b are constants, and l_r is the stress-free sarcomere length. Material parameters are consistent with those reported by Baillargeon *et al.* [2].

In the thermodynamically motivated model for actin-myosin cross-bridge cycling developed by McEvoy *et al.* [4], the attachment of myosin is dependent on molecular-level boundary conditions. The active myofibril stress caused by cell contractility is given by:

$$\sigma_f(t, E_{ff}) = \sigma_{iso} \frac{T_s(t, E_{ff})}{T_{s0}}. \quad (6)$$

Here, σ_{iso} is the maximum isometric stress of a myofibril, T_{s0} is isometric sarcomere tension, and T_s is the current sarcomere tension.

$$T_s(t, E_{ff}) = \hat{m}_a(t, E_{ff}) \kappa_m \Delta_m, \quad (7)$$

where \hat{m}_a is the normalised number of attached myosin heads, κ_m is the myosin tail stiffness, and Δ_m is a distribution of tail extensions. The evolution of \hat{m}_a is described by a kinetic equation, with

$$\frac{d\hat{m}_a}{dt} = -k_d \hat{m}_a + k_a \hat{m}_d, \quad (8)$$

where \hat{m}_d is the normalised number of detached myosin heads, and k_a and k_d are rate coefficients derived from steady state equilibrium.

Furthermore, the McEvoy framework computes the steady state concentration of sarcomeres in-parallel and in-series, which depend on the strain state and myofibril/sarcomere stress σ_f . The (normalized) number of sarcomeres in-series is given by:

$$\hat{n} = \begin{cases} -\frac{1}{\hat{n}} \left(\frac{\hat{N}_u}{\hat{\eta}} \right)^2 \left[\psi(\tilde{\epsilon}_n) - \frac{\delta\psi}{\delta\tilde{\epsilon}_n} (1 - \tilde{\epsilon}_n) \right] \frac{\alpha_n}{\mu_{b0}} & \text{if } \frac{\delta\psi}{\delta\tilde{\epsilon}_n} \leq 0 \\ -\frac{\hat{n}}{4} \left[\psi(\tilde{\epsilon}_n) - \frac{\delta\psi}{\delta\tilde{\epsilon}_n} (1 + \tilde{\epsilon}_n) \right] \frac{\alpha_n}{\mu_{b0}} & \text{else} \end{cases}, \quad (9)$$

where \hat{N}_u is the normalized number of unbound proteins, ψ is internal sarcomere energy, α_n is a rate constant, and μ_{b0} is the sarcomere energy in its ground state. The internal strain within a sarcomere is given by

$$\tilde{\epsilon}_n = \frac{1+E_{ff}}{\hat{n}} - 1. \quad (10)$$

The (normalized) concentration of sarcomeres in-parallel is determined from:

$$\dot{\hat{n}} = \frac{\hat{N}_u}{\hat{n}} \omega_n \exp \left[-\hat{n} \frac{\mu_{ab} - \mu_u}{k_B T} \right] - \hat{\eta} \omega_n \exp \left[-\hat{n} \frac{\mu_{ab} - \mu_b}{k_B T} \right], \quad (11)$$

where ω_n is the collision frequency of unbound molecules, μ_{ab} is the an activation barrier, μ_u is the standard enthalpy of unbound cytoskeletal proteins, μ_b is the standard enthalpy of n^R bound cytoskeletal proteins, k_B refers to Boltzmann's constant, and T is absolute body temperature. Material parameters implemented are consistent with those reported by McEvoy *et al.* [4].

RESULTS

The computed active contractile stress is shown in Fig. 1, for both the Walker *et al.* [3] model and the thermodynamically motivated model of McEvoy *et al.* [4]. These models present a level of conformance in the active stress generated at physiological strains (Fig. 1(a,b)). With an increase in strain (associated with increased diastolic venous return), the Walker *et al.* [3] model predicts a reduced relaxation rate due to the dependence on E_{ff} (Fig. 1(c,d)). However, the McEvoy *et al.* [4] model predicts a reduction in peak stress due to myofibrillar remodeling onset by a reduced actin-myosin overlap, consistent with progression of eccentric hypertrophy [1].

Figure 1. Myofibril stress modelled from both the Walker *et al.* phenomenological model [3], and the McEvoy *et al.* cross-bridge model [4]. Stress is calculated from a myocyte strain cycle of (a) $E_{ff}^{max} = 10\%$, simulating normal physiological myocyte contraction. (b) $E_{ff}^{max} = 25\%$, simulating mild pathological

myocyte contraction. (c) $E_{ff}^{max} = 40\%$, simulating pathological myocyte contraction. (d) $E_{ff}^{max} = 80\%$, simulating severe pathological myocyte contraction.

Fig. 2(a) shows the evolution of the area concentration of sarcomeres in parallel, $\hat{\eta}$. Fig. 2(b) shows the evolution of the axial concentration of sarcomeres in series, \hat{n} . At steady state $\hat{\eta}$ is predicted to decrease with increasing myocyte strain. In contrast, \hat{n} increases with increasing myocyte strain. This indicates a high myocyte strain (due to a high diastolic ventricular blood volume) leads to in-series addition of sarcomeres. This necessitates a reduction of the area concentration of sarcomeres in parallel, leading to thinning and elongation of the ventricle wall.

Figure 2. Thermodynamic cross-bridge cycle model predictions of the evolution of (a) area concentration of sarcomeres in parallel $\hat{\eta}$, and (b) axial concentration of sarcomeres in series \hat{n} .

DISCUSSION

In eccentric hypertrophy a reduction in wall thickness is accompanied by a reduction in actively generated myocardium contractility [1]. In this study we demonstrate that our thermodynamically motivated cross-bridge cycle model correctly predicts a decrease in sarcomere concentration and contractility following volumetric overload. Our prediction that diastolic blood volume overload results in increased axial concentrations of sarcomeres in-series and decreased area concentration of sarcomeres in parallel provides a sub-cellular explanation for the development of eccentric hypertrophy. In contrast to our cross-bridge cycle model, the phenomenological contractility model of Walker *et al.* [3] incorrectly predicts that peak myofibril contractility is independent of the myocardium strain.

Our thermodynamically motivated cross-bridge cycle model has the potential to provide patient specific diagnosis of hypertrophy and impaired cardiac function.

INTRODUCTION

Cardiovascular disease is the single leading cause of death worldwide with an estimated 17.3 million deaths in 2016, representing 31.5% of all global deaths [1]. With a 5-year mortality rate of 50%, heart failure remains (and will remain in the foreseeable future) one of the most common, costly, disabling and deadly medical conditions. In a traditional biomechanical sense, cardiac growth and remodeling can be considered a protective and reparative homeostatic mechanism. Combined with chronic alterations in the heart's hemodynamic loading conditions however, these mechanisms can lead to pathological anatomical and physiological changes that depress cardiac performance and eventually lead to heart failure. Hypertrophy is often progressive, but the time course and extent of progression is highly patient-specific. The most pertinent clinical question tends to be prognostic where anticipation of the rate of progression is essential for treatment planning [2]. The mechanobiological factors regulating the hypertrophic response of the heart have been the subject of extensive research throughout the past decades [3], and still remain up for debate. Consequently, cardiac growth models have the potential to provide mechanical insights in disease onset and progression, which can aid clinical decision-making or the design of emerging therapies. Considerable debate remains as to which stimuli are necessary to include in mechanistic growth laws. Most evidence, both at tissue and cellular levels, points to mechanical factors as mediating stimuli. In eccentric hypertrophy, end-diastolic wall stress was initially considered as a stimulus, but later studies opposed this hypothesis and implied that end-diastolic strain at the tissue level may be a more realistic stimulus [3]. In this study we investigate this hypothesis and assess the ability of the corresponding growth law to capture experimentally observed trends in a unique animal study where eccentric hypertrophy was characterized across multiple scales at once.

METHODS

The progress of eccentric hypertrophy was studied over a period of 8 weeks in six Yorkshire domestic pigs. At the start of the study, moderate to severe mitral valve regurgitation was created in the left ventricle by disrupting one or more chordae. To characterize changes on the organ level, bi-weekly echocardiograms were taken to compute the left ventricular end-diastolic and end-systolic volumes (EDVs and ESVs), stroke volumes, ejection fractions, and wall thicknesses. For the cell level characterization, endomyocardial biopsy samples were collected at the day of mitral valve chordae disruption and at bi-weekly follow-ups. These biopsy samples were histologically prepared and examined to characterize myocyte width (MW) and length (ML). The changes and uncertainty in measured organ and cell level variables across different subjects were analyzed using Bayesian inference, where it was postulated that the measurements are drawn from log-normal distributions that evolve linearly over time. To take into account the variability between subjects and, at the same time, take advantage of the entire acquired dataset, we postulate a hierarchical model, i.e., that the measurements between subjects are related. We assumed that the different parameters that describe the log-normal means of a measurement at a certain time and their log-normal standard deviations are respectively drawn from a normal distribution and a Half-Cauchy or Lewandowski-Kurochiwa-Joe distribution. Using a Hamiltonian Monte Carlo method, we performed a statistical inference which results in statistically predictive posterior distributions of the measured quantities of interest [4].

To correlate changes in end-diastolic volume to changes in myocyte morphology, we adopted a transversely isotropic kinematic-based growth model where the overall deformation is given by $\mathbf{F} = \mathbf{F}^e \cdot \mathbf{F}^g$ [5]. Here, the growth deformation \mathbf{F}^g maps the original reference state to an intermediary unstressed grown state. The elastic

deformation, F^e maps the intermediary state into the intact, loaded state. Only F^e contributes to the stress state of the tissue. The growth tensor was defined as $F^g = I + (\vartheta^{\parallel} - 1) \mathbf{n} \otimes \mathbf{n}$ where the eccentric growth multiplier ϑ^{\parallel} is updated if the elastic stretch in the fiber direction, λ^e , exceeds a critical physiological threshold value λ^{crit} , which was assumed to be equal to the local fiber stretch at the end of diastolic filling:

$$\vartheta^{\parallel} = \tau^{-1}(\lambda^e - \lambda^{crit}) \quad (1)$$

Left-ventricular finite element models were created for each animal based on the echocardiography images at the minimum cavity volume of the cardiac cycle, which was assumed to be a stress-free state. The tissue's elastic response of the myocardial tissue was characterized by the classical Holzapfel-Ogden model [6] and calibrated for each subject specifically in accordance to our previous studies [7, 8]. The complex myocardial fiber architecture was incorporated using a rule-based method where the myofibers's helical angle varies transmurally from $+60^\circ$ (endo) to -60° (epi). Next, the uncertainty in end-diastolic volumes for each pig, quantified using Bayesian inference as described earlier, was introduced into the growth models. We achieved this by considering 500 samples of each pig's end-diastolic volume evolution distribution. For each sample, the corresponding evolution in end-diastolic volume was used to simulate the tissue's growth response. Instead of performing a forward growth simulation (see Figure 1) for each of these 500 samples for each pig, we trained a subject-specific Gaussian process regression using 20 training and 10 validation simulations to predict the median longitudinal growth multiplier based on the imposed changes in end-diastolic volume due to mitral regurgitation. For each pig, the 500 medians of the simulated longitudinal growth multipliers were then compared to 500 samples of the posterior myocyte length measurement distributions and the overlap was quantified.

Figure 1: Simulated stretch-driven fiber growth evolution in the volume-overloaded pig #6 heart. Time evolution of the simulated regional longitudinal growth multiplier for pig #6 over a time span of 8 weeks.

RESULTS

Based on 28 echocardiography measurements and the Bayesian inference analysis, the average end diastolic volume (EDV) and end systolic volume (ESV) increased from 67.9 ± 20.6 ml and 30.2 ± 9.5 ml at baseline to 100.2 ± 17.9 ml and 51.3 ± 9.0 ml at week eight, which lead to a decreased ejection fraction. On a weekly basis, this meant an EDV increase of $+5.95\%$ /week, with a rapid increase between weeks 6 and 8 (see Figure 2 for the EDV evolution of pig #6). Based on 460 histological myocyte width and length measurements and the Bayesian inference analysis, the ML increased on average from $85.45 \pm 22.30\mu\text{m}$ to $107.75 \pm 26.57\mu\text{m}$ while the average MW remained relatively constant at $13.55\mu\text{m}$. On a weekly basis, this translates into an average ML increase of $+3.26\%$ /week with a steeper increase between weeks 6 and 8 (see Figure 2 for the ML evolution of pig #6).

Propagating the quantified uncertainty on volume overload through the six different subjects resulted in a quantified uncertainty of the computationally predicted endocardial myocyte lengths (500 simulations for each pig). Comparing these simulation results with the

500 predicted samples from the Bayesian inference uncertainty of the measured myocyte lengths for each pig, the average agreement between simulation and experiment was 52.7%, ranging from an excellent agreement of 85.7% for pig #5 to a poor agreement of 6.0% for pig #2 (see the agreement of 67.7% for pig #6 in Figure 1). Knowing that pig #2 was the largest pig of the study, and considering this pig as an outlier, the average agreement for the remaining pigs was 62.0%.

Figure 2: Changes in end diastolic volume and myocyte length in response to left ventricular volume overload for pig #6 (left & mid). Gray dots represent individual measurements of EDVs and MLs respectively, solid gray lines represent the medians computed using Bayesian inference and dashed black lines the corresponding 95% confidence intervals. Color contours from black to white highlight the probability density from high to low. **Simulation and experiment of chronic myocyte lengthening across endocardial wall in response to left ventricular volume overload for pig #6 (right).** Blue and red probability density functions represent computationally simulated MLs in the endocardial wall and experimentally measured MLs respectively, both with uncertainty.

DISCUSSION

Predictive cardiac growth models are a potentially important clinical tool to assess disease progression and optimize treatment in heart failure patients. To quantify the predictive power of these models, this study proposed a systematic experimental and computational approach to correlate how hemodynamic changes lead to changes in myocyte morphology. Using machine learning tools, the individual organ scale and cell scale behavior of each animal was interpreted in view of the collective behavior of all animals, which allowed us to quantify the uncertainty on our experimental and computational results. For each pig, we created and calibrated a finite element model of the left ventricle, to simulate the hypertrophic tissue reaction to volume overload based on a stretch-driven eccentric growth law. Subsequently, the uncertainty on end-diastolic volume overload was propagated through each of these subject-specific cardiac models, which resulted in a quantified uncertainty on predicted myocyte morphology changes. Considering pig #1, #3, #4, #5 and #6, the considered growth law alone predicts the changing myocyte morphology with an accuracy of 62.0%.

INTRODUCTION

Right ventricle failure (RVF) is a fatal disease and contributes significantly to the morbidity and mortality in a variety of cardiovascular diseases¹. The mechanical behavior of the RV (e.g., stiffness) is closely related to its physiological function². However, the understanding of the mechanical property changes in failing RVs is still limited. Most previous studies have assumed the RV to be orthotropic but ignored the viscoelastic behavior. It is known that the ventricle is an anisotropic and viscoelastic tissue³. Therefore, the changes in RV anisotropic and viscoelastic properties during pressure overload remains a key knowledge gap.

The goal of the study is to investigate the changes of the RV anisotropic and viscoelastic properties under chronic pressure overload. Using a newly revised model of pulmonary artery constriction (PAC) in adult sheep, we established RV failure and performed *ex vivo* biaxial mechanical tests to determine RV mechanical properties. We hypothesize that the remodeling in failing RVs leads to changes in anisotropic and viscoelastic properties compared to the healthy controls. Our findings of the RV

biomechanical changes will assist with the understanding of the biomechanical mechanisms of RV failure secondary to chronic pressure overload.

METHODS

All procedures were approved by IACUC at Colorado State University. RV failure was established by chronic pressure-overload using a newly revised PAC method in ovine. Briefly, patient specific, graded PAC was performed on week 0 and 4 in 8-month-old male sheep and the animals were euthanized 11 weeks after the initial PAC (N=3). Age-matched male healthy sheep were used as controls (N=3). Hemodynamic measurements were obtained prior to euthanasia. Then, RV tissues were harvested and the equibiaxial mechanical tests (at stretch rate of 15 mm/min) were performed. We failed to obtain the mechanical data in one PAC RV. The RV outflow tract direction was marked as the longitudinal direction. Cauchy stress (σ) and Green's strain (ϵ) were calculated from the experimental data as done previously⁴. Elastic moduli (E) were obtained as the slopes of the loading curve in the last cycle in three different strain ranges (low: 0-0.04, middle: 0.04-0.08, high: 0.08-0.12).

The hysteresis loop was obtained from the experimental data. Copyright 2019, SB³C Foundation, Inc.

loading and unloading curves. Then, the stored energy (W_s) and viscosity (a) were quantified by the area beneath the loading curve and the width of the loop at the mid-stress, respectively (Fig. 1). Finally, histology analysis was performed for RV collagen content using Picrosirius red staining. Student's t-test was performed and $p \leq 0.05$ was considered significant.

Figure 1. Measurement of the viscosity using the width of the hysteresis loop at middle stress (σ_{mid}).

RESULTS

The 11-week patient-specific, graded PAC led to the development of RV failure, which was evidenced by significant increases in RV systolic pressure (RVSP) and Fulton Index and reduction in stroke volume (Table 1). Accumulation of collagen occurred in the RVs (Table 1, $p=0.07$ control vs. PAC).

Table 1. Hemodynamic and biological changes of the ovine RVs under chronic pressure overload. * $p < 0.05$.

	Control	PAC
RVSP (mmHg)	22.7 \pm 1.1	43.6 \pm 8.2 *
Stroke Volume (mL)	108.2 \pm 19.2	72.4 \pm 9.6 *
Fulton Index (%)	28.4 \pm 1.3	43.0 \pm 3.5 *
Total Collagen Content (%)	3.6 \pm 1.0	6.1 \pm 1.4

In terms of the mechanical changes, we found that in general, the RV elastic moduli (E) tended to increase in the longitudinal direction (Fig. 2A) in all strain ranges (Table 2). But there were no changes in E in the circumferential

Figure 2. Changes of low strain elastic modulus (A) and viscosity (B) of the RV in different directions.

Table 2. Measurements of E in the longitudinal direction (L) and W_s in both directions (L, C) in the RVs.

	Control	PAC
E_{low} , L (kPa)	12.7 \pm 2.8	108.9 \pm 84.4
E_{mid} , L (kPa)	23.4 \pm 7.1	257.6 \pm 249.9
E_{high} , L (kPa)	210.3 \pm 132.0	1065.3 \pm 1170.4
W_s , L	2.1 \pm 0.8	3.6 \pm 0.3 †
W_s , C	2.9 \pm 1.8	2.3 \pm 0.6

direction (data not shown). Similar trends were seen in the stored energy (W_s) (Table 2; † $p=0.08$), which is an indicator of the elasticity of the tissue. These data suggest a change in the anisotropic property under pressure overload. The RV tended to be stiffer in the circumferential direction (Fig. 2A; $p=0.09$) in the baseline (which is consistent with our unpublished data); however, after PAC, it tended to be stiffer in the longitudinal direction. Lastly, we quantified the viscosity by the width of the loop at the mid-stress. We observed increased viscosity in the PAC RV in the circumferential direction (Fig. 2B; $p=0.05$).

DISCUSSION

This study is the first to investigate the anisotropic and viscoelastic mechanical properties of adult ovine RVs and their changes under pressure overload. In this pilot study (with small Ns), we obtained novel findings in the biomechanical changes of the failing RVs: 1) A strong trend of change in RV anisotropic behavior was observed after the pressure overload. The RV was stiffer in the circumferential direction initially and became stiffer in the longitudinal directions after PAC. This may be related to the accumulation of collagen as well as the change in the collagen fiber angle (data not shown). 2) An increased viscosity of the RV was observed in the circumferential direction. This indicates more energy loss over a cardiac cycle in the diseased RV. Future study will recruit more animals and include functional analyses of the RV. Our study will bring more insights into the mechanism of the development of RV failure.

INTRODUCTION

An estimated 700,000 acute ischemic strokes (AIS) occur each year in the United States, as a result of embolic occlusion of a cerebral artery. In spite of the improved recanalization rates of cerebral arteries, by means of novel stent retriever devices, 15% of patients' arteries still cannot be recanalized. In addition, 17% of patients with successful arterial recanalization die within 90 days [1]. Currently there is little understanding as to why some thromboemboli are successfully removed, and others are not. In order to improve our understanding of thromboemboli adhesion and removal in AIS, we must first be able to characterize the mechanical properties and accurately model the behavior of thromboemboli. Therefore, we are developing embolus analogs from bovine whole blood to mimic the properties of human thromboemboli in AIS patients. Since most biological tissues are stored in paraformaldehyde (PFA), this study seeks to characterize the mechanical properties of bovine embolus analogs fixed in 4% PFA solution to those unfixed, in order to develop relationships to the behavior of thromboemboli *in vivo*.

METHODS

Bovine embolus analogs were created using a 1:1 ratio, of platelet rich plasma (PRP) and red blood cells (RBC). Calcium chloride (CaCl₂) was then added, in a 1:50 CaCl₂ to PRP ratio, in order to reverse the effects of CPDA in blood collection bags and restore the blood's coagulation properties. The mixture of PRP, RBC and CaCl₂ was injected into 3D printed cylindrical blood clot molds (Fig 1A) via a syringe, and left over night to form cylindrical bovine embolus analogs, with approximate diameters of 7 mm. Exact embolus analog dimensions were measured and recorded, using calipers for later stress and strain calculations. Of the 10 fully developed bovine embolus analogs, half were tested right

away while the other half were stored for another 24 hours in a 4% PFA solution, for fixation similar to clinically obtained samples. To determine the mechanical properties of the bovine embolus analogs, both cyclic compression and stress-relaxation tests were performed. The incremental loads were applied and measured using a Lloyd Tensile Testing (AMETEK Inc., Largo, FL) device and 3D printed compression pieces designed to connect to the device (Fig 1B).

Figure 1: A) 3D printed cylindrical blood clot molds, with bovine blood clots, and B) uniaxial tensile device attachment pieces, holding a bovine embolus analog.

For compression testing, the analogs were loaded to a strain of 10% at a rate of 1 Hz to replicate the expected loading conditions of cyclic aspiration. Ten fixed and ten unfixed embolus analogs were loaded for each mechanical test (cyclic loading and stress-relaxation) and stress-strain hysteresis and stress-relaxation curves were extracted. Using in-house MATLAB code, the average curves were determined for each of the loading conditions and embolus analog types. Lastly, we fit the stress-relaxation data to a 3-term Prony series (Eq. 1):

$$g(t) = g_{\infty} + g_1 \cdot e^{-\frac{t}{z_1}} + g_2 \cdot e^{-\frac{t}{z_2}} \quad (1)$$

Where g_{∞} , g_1 , and g_2 are the characteristic amplitudes, z_1 and z_2 are the characteristic relaxation times, and t is the time.

RESULTS

The average cyclic loading data set for both the fixed and unfixed bovine blood clots (Fig 2).

Figure 2: A) Fixed and B) unfixed bovine embolus analog loading data.

Lastly, the average stress-relaxation data sets for both the fixed (Fig 3) and unfixed (Fig 4) bovine blood clots were fit to 3-term Prony series.

Figure 3: A) Fixed bovine embolus analog stress-relaxation data and B) average data fit to a 3-term Prony series.

For the fixed embolus analogs, referring to (Eq.1) the characteristic amplitudes were determined to be 0.3795, 0.2715, and 0.3343 and the relaxation times were 0.8206 and 9.1753.

Figure 4: A) Unfixed bovine embolus analog stress-relaxation data and B) average data fit to a 3-term Prony series.

For the unfixed embolus analogs, referring to (Eq.1) the characteristic amplitudes were determined to be 0.2376, 0.5847, and 0.1796 and the relaxation times were 10.0076 and 3.0877.

DISCUSSION

This experiment outlines a developed procedure to create bovine embolus analog and a method to characterize the mechanical properties of these analogs, both unfixed and fixed in 4% PFA. Specifically, the stress-strain curves representing the cyclic loading, show the difference in the measured stress between the fixed bovine embolus analogs and those unfixed is about an order of magnitude, with the fixed being stiffer. However, the average cyclic loading data sets have very similar curve shapes. In addition, by fitting the stress-relaxation curves to the 3-term Prony series, respectively, the experimenter can compare between the two sets, as well as compare to future human thromboemboli retrieved from AIS patients. The stress-relaxation curves are very similar, looking at the curves they both decrease to about 0.4, or 60% relaxation, in approximately 20 seconds. In future work, histology will be performed on both sets of embolus analogs.

ASSESSMENT OF ASCENDING AORTIC WALL STRESSES FOR NONDISSECTED PATIENTS WITH BICUSPID AORTIC VALVE AND DISSECTED PATIENTS WITH TRICUSPID AORTIC VALVE

S. Ravi (1), D. A. Vorp (1), S. Maiti, PhD., (1)

Pittsburgh, PA, United States of America

INTRODUCTION

Acute ascending aortic dissection, also known as Type A dissection, or TAAD, is a life-threatening condition in which a tear in the intimal layer of tissue of the aortic wall allows blood to collect within the tear site and delaminate the vessel wall, often propagating the dissection in antegrade or retrograde fashion. As fluid continues to fill within the vessel wall, the wall becomes pressurized and flow is compromised by constriction of the aortic vessel while aneurysmal volume increases. Once it becomes too large, TAAD patients are at risk for blockages in the vessel and/or a rupture of the vessel itself [1]. Typically, the aortic valve is a tricuspid valve (TAV), but bicuspid aortic valves (BAV) are the most common congenital heart condition that occurs in approximately two percent of the population. According to clinicians, it is of common opinion that BAV patients are of greater risk for dissection than TAV patients [2].

Currently, surgical repair of ascending aorta is based upon having an aneurysmal diameter greater than 5.5 cm, and even lower for BAV patients [4]. However, data from the international registry of acute aortic dissection (IRAD) has shown that approximately 62% of patients with TAAD have aortic diameters distinctly less than 5.5 cm, demonstrating the necessity for an improved metric in characterizing aneurysms [1]. From a biomechanical perspective, dissection is caused by the mechanical failure of the aortic wall, when the wall stress exceeds the wall strength. Thus, quantification of aortic wall stress has the potential to provide additional dissection risk indicator. In this study, two cohorts of patients – one of BAV patients with stable aneurysms, one of dissected TAAD patients with TAV phenotype – were examined to quantify the longitudinal and circumferential stresses of each group while providing insight into how the biomechanics of BAV patients may differ from those of TAAD patients.

METHODS

Patient scans were collected by the University of Pittsburgh Medical Center in Shadyside from the Cardiovascular Department. Scans were collected with patient consent and IRB approval. CT scans of patient chest cavities were taken, and GE proprietary segmentation software within the Volume Viewer was used to isolate the aorta, generating a 3-dimensional image. The images were exported as DICOMs within a new set of aorta-specific axial slices. Any artifacts in the resulting surface model were removed in Mesh Mixer version 4.0 (Autodesk). Additionally, the surface models were smoothed to ensure that they contained one surface and contained enough details to capture the shape of the aorta. The smoothed engineering model was then meshed with 3-noded triangular elements in Trelis (Sandia National Labs). The resulting finite element meshes for the aortic models contained 30,000-50,000 elements to be used for computational model formation. Once processed through Trelis, a custom nonlinear finite element software was used to pressurize the model to 200 mm Hg (approximately 26.67 kPa). The material of the aorta wall was taken to be isotropic and hyperelastic relevant to BAV patients [2]. The material model considered is described in [2]. The finalized models were viewed through Paraview (Kitware, STATE) to display the map of longitudinal and circumferential stresses across the aortic surface model. Nodal stresses across the map were exported in an Excel document, in which mean and standard deviation (SD) were calculated to find the maximum at the 95th percentile of stresses to exclude noise. The results were plotted in a box and whisker plot created in IBM SPSS Statistical Software.

RESULTS

A total of nine BAV and eight TAAD patients were included in this study. Stress analyses for TAAD patients were taken from a

Figure 1A: Representative stress map of BAV patient showing longitudinal stress when aortic model pressurized to 200 mm Hg previous publication from our group [1]. The average peak longitudinal stress maximum was 209.2 ± 11.7 kilopascals for BAV patients versus 172.3 ± 36.6 kPa for those of TAAD patients (Figure 2A). On the other hand, the average peak circumferential stress maximum was 382.6 ± 21.2 kPa for BAV patients versus 492.3 ± 138.7 kPa for those of TAAD patients. The difference between the two groups (BAV and TAAD) circumferential stresses is significant ($p=0.001$, student's t-test) as are the longitudinal stresses ($p=0.001$).

Figure 1B: Representative stress map of BAV patient showing circumferential stress when aortic model pressurized to 200 mm Hg

dissected. Because both aortic models were pressurized to the same magnitude, the lower longitudinal stress of BAV patients demonstrates lower risk of failure for BAV patients' aortic walls. From a biomechanics perspective, these results are contrary to some published literature. Although, clinically, BAV patients are thought to be more vulnerable to dissection than other patients with aneurysms, the results of this study show that biomechanically BAV may not be as high of a risk as previously thought [1,3].

There were a few limitations that can be improved upon in future works. The necessity of smoothening the model to run finite element analysis could have compromised the accuracy of the aortic surface from the CT scans. As meshes move through the different smoothening software utilized, it may have been slightly altered in geometry and thickness before being pressurized. Furthermore, during the analysis, by using an isotropic constitutive model it is assumed that stiffness is similar in both the longitudinal and circumferential stresses. Future methods can investigate other methods of analysis that may separately analyze both stiffnesses. Furthermore, during the calculation of the 95th percentile max, it was assumed that the stresses were distributed normally.

These findings support the use of biomechanics-based paradigms to predict aortic dissection event. Investigating multiple patient groups, we can continue to create a patient-specific metric based on biomechanics rather than aortic dimensions that will improve our ability to classify aneurysms and predict dissection patterns. By delving into this new approach, physicians can have a better method in determining whether intervention is required to treat aneurysms more accurately.

ACKNOWLEDGEMENTS

I would like to thank Dr. Spandan Maiti for allowing me to conduct research under him. I would also like to thank Drs. Leonid Emerel and Thomas Gleason from the University of Pittsburgh Medical Center for providing patient aortic geometries for this research endeavor. Finally, I would like to thank Ronald Fortunato for teaching me the background biomechanics and software used to successfully complete this project.

APPLICATION OF DIGITAL IMAGE CORRELATION TO THE LOCAL STRAIN ANALYSIS OF MOUSE AORTAS: NOVEL METHOD TO CREATE SPECKLE PATTERN

Liya Du (1), Brooks A. Lane (1), John F. Eberth (1,2), Susan M. Lessner (1,2)

INTRODUCTION

Digital image correlation (DIC) is a non-destructive and non-contact optical technique to measure deformation and strain of materials. The method is based on optically tracking the displacements of a speckle pattern created on the material surface. In the case of soft tissues such as mouse aorta, there are several advantages to using DIC since it can provide local, rather than global, deformations and it is suitable for large strain measurements, typical of soft tissues taken to failure ^[1] ^[2].

For the optimal use of DIC, several requirements should be met for speckle patterning: 1) randomness, 2) high contrast, 3) appropriate size of speckle in the field of view (3-5 pixels), and 4) firm attachment of speckle to specimen during deformation. In previous DIC studies of soft tissues, the methods employed to create a speckle pattern include the use of an airbrush to spray dye or paint on the specimen, or coating the sample with toner powder. However, biological samples must be partially dehydrated before applying paint which may affect the mechanical properties of the specimen, and toner powder is too hydrophobic to adhere well on specimens when submerged in aqueous solution during mechanical testing. In addition, it is difficult to evenly distribute paint or toner powder on the surface of a hydrated biological specimen ^[2]. Therefore, a novel method utilizing colloidal gold particles to create a speckle pattern on mouse aorta is proposed in this work. Based on their unique surface chemistry, chemical inertness and stability in aqueous environments, colloidal gold particles are a promising new candidate for speckle patterning for DIC strain

measurements of mouse aorta and similar small biological specimens ^[3].

METHODS

Colloidal gold particles were synthesized by reducing chloroauric acid (HAuCl₄) in ascorbic acid solution. In this method, 250 µl of 0.1 M chloroauric acid was added into 10ml of 0.3M ascorbic acid solution with vigorous stirring for 15 min. The solution was then incubated at room temperature for at least 96 h. Gold nanoparticles start to aggregate, and eventually the size of aggregated gold particles can be tuned in the range of 1-10 µm. The suspension was centrifuged (5000 rpm/2min) to remove acidic supernatant, and the remaining precipitated gold particles were resuspended in phosphate-buffered saline (PBS) solution. The mouse aorta samples were soaked in the colloidal gold particle suspension. Due to coordinate covalent and hydrophobic interactions, spontaneous adsorption of gold particles onto the mouse aorta surface occurs to form a random speckle pattern. The patterned sample was mounted on a Bose mechanical test bed to conduct uniaxial tensile tests with CCD camera tracking the displacement of the speckle pattern on the mouse aorta samples. Strain fields were analyzed using VIC-2D software. Image acquisition and DIC settings include 2 MP Point Grey camera, 25 mm macro lens, 35 x 35 subset for VIC-2D.

Ten consecutive images of a stationary speckled mouse aorta in the Bose set-up were captured and analyzed in VIC-2D for system error analysis.

RESULTS

Figure 1 shows a random speckle pattern created on the mouse aorta specimen. The size of a typical random speckle covers 3-5 pixels in each direction. In Figure 2, the intensity histograms of patterned specimens had greyscale values in the range 60-255, indicating a sufficient level of contrast between the mouse aorta and the speckle pattern for reliable image matching by DIC. Figure 3 demonstrates that after the sample has been submerged in PBS for 1 hour, the random speckle pattern is still stable in an aqueous environment.

In Figure 4, strain measurement of speckle patterned mouse aorta was compared over the whole specimen (a) and in the central region (b) in the y-direction during a uniaxial mechanical tensile test. In Figure 4a, ϵ_{yy} is not uniform on the sample due to bending and friction at the mounting arms during deformation. Thus, the local strain of mouse aorta in uniaxial tension can be obtained from the central region as illustrated in Figure 4b.

For system error analysis, the corresponding pseudo-strain measurements (mean, median and standard deviation) for ϵ_{xx} , ϵ_{yy} and ϵ_{xy} are summarized in Table 1.

Fig. 1. Patterned mouse aorta mounted on Bose set-up

Fig. 2. Intensity histogram analysis of region of interest illustrated in Figure 1

Fig. 3. Patterned mouse aorta submerged in PBS for 1 hour

Fig. 4. Strain analysis of mouse aorta in y-direction (a) over the whole specimen; (b) in the central region;

Table 1. System error analysis: pseudo-strain data in different directions

	ϵ_{xx}	ϵ_{yy}	ϵ_{xy}
Mean	0.00228	-0.00065	-0.00435
Median	-0.00357	0.0043	-0.00643
Standard deviation	0.01134	0.01254	0.00666

DISCUSSION

The novel method utilizing colloidal gold particles to create a speckle pattern on mouse aorta shows promising results compared to previous patterning methods. The colloidal gold particles can form random, stable, high contrast, suitable sized speckles on mouse aorta suitable for DIC analysis to track the specific pattern before and after deformation to measure local strain of mouse aorta. Thus, it can be considered as an efficient patterning method for future application of DIC strain measurements in soft biological tissues.

INTRODUCTION

Myocardial fiber orientation plays an important role in cardiac systolic and diastolic function, distribution of cardiac wall stress and electrical propagation [1]. Structurally, the myocardium is a layered composite made of myofibers, collagen and an amorphous ground matrix with 69%, 29% and 2% volume fractions respectively [2]. Myocardial fibers are stacked with counterclockwise rotations throughout the heart wall. Transmural variation of fiber orientation in myocardial tissues leads to unique structural and biomechanical properties. Remodeling of myofibers and alterations in transmural fiber orientations can lead to drastically different tissue properties in diseased conditions such as pulmonary hypertension (PH), in which the right ventricle (RV) experiences increased tissue stiffness and anisotropy due to fiber remodeling [3]. Knowledge of the kinematics of myocardial fibers helps understanding the contribution of fiber-level myocardial structure to tissue function and tissue-level mechanical properties. However, myocardial wall thickness often complicates the study of fiber kinematics transmurally.

Albeit very high resolution and sensitivity, the depth limit of optical techniques such as confocal (100 μm limit) or multi-photon microscopy (1600 μm limit) prevents practical applications of these technologies for analyzing intact myocardial architecture. In order to study the 3D static architecture of myocardial fibers, several studies have employed diffusion tensor magnetic resonance imaging (DTMRI) techniques [4]. Even though DTMRI provides detailed information on the static architecture of myofibers, this process is time consuming and effects of exposure to ionizing radiation, cost-effectiveness and restrictions on MRI-safe materials limit its applicability for benchtop and clinical applications for a larger population. On the other hand, ultrasound imaging is a cost-effective technique that has been widely used for real-time cardiac diagnosis. However, detecting myofibers

require ultrasound imaging at a much higher frequency than conventional applications, which leads to increased speckle noise and lower signal to noise ratio [5]. In the current study, we aim to employ an enhanced mathematical framework to analyze high-frequency ultrasound images for effective quantitative assessment of 3D myofiber orientations in the RV wall under loading conditions.

METHODS

Square specimens were harvested from the R2 zone [4] of fresh-frozen porcine right ventricular myocardiums. Specimens were then embedded in a 6% gelatin gel (Sigma-Aldrich, St. Louis, MO) and scanned under static conditions for algorithm development and verification purposes. RV specimens were scanned at 40 MHz using a high-frequency ultrasound scanner (Vevo 2100, FUJIFILM-VisualSonics, Toronto, Ontario, Canada). 3D scans of the RV wall were generated by a stack of 2D images at 32 μm increments throughout the tissue thickness (acquired using an electrical servo stage). Since the high frequency of ultrasound scans results in a significant speckle noise level in the acquired images, similar to previous studies [5], a nonlinear anisotropic diffusion filter (NLADF) was used to reduce the noise levels using the anisotropic diffusion equation [6]:

$$I_t = \text{div}(c(x, y, t)\nabla I) = c(x, y, t)\Delta I + \nabla c \cdot \nabla I \quad (1)$$

here, I is the image intensity in 2D space, and c is the anisotropic diffusion tensor. The NLADF filtering framework is based on the diffusion equation and helps reducing the noise levels while keeping the main features of the image and their respective orientations [6] (Fig. 1). Filtering was performed using a previously developed multi-scale decomposition framework for myocardial tissues [5]. The resulting image was then denoised and masked using Otsu's threshold. Despite considerably reduced noise levels, the high speckle noise in the original image leads to myofibers represented in interrupted pieces. In order to

establish connectivity between different fiber segments, a coherence enhancing diffusion filter (CEDF) was used [7]. The CEDF filtering framework functions similar to the NLADF algorithm, except that c is replaced by a tensor with similar eigenvectors, but with eigenvalues chosen in a way that diffusion happens along the highest coherence direction and helps completing disconnected segments while keeping the orientation of image features (Fig. 1). At this stage, instead of performing a multi-scale decomposition on the CEDF resulting image (as employed in previous studies [5]), the filtered image via NLADF is fed to the CEDF algorithm and then directly masked and thresholded for fiber detections. The resulting image is denoised and myofibers are detected via skeleton extraction. The result was then converted to a binary format from which myofibers were detected and quantified using the Hough transform. Fiber distributions were plotted in a histogram and a probability density function (PDF) was fitted to the distribution at each section throughout the RV thickness. Finally, histological staining (H&E) was performed on the tissue specimen for comparison purposes. Fiber orientation of histological scans were detected using Image J (imagej.nih.gov).

Following algorithm verification, RV specimens were loaded using a custom-built uniaxial loading device that allows real-time ultrasound imaging of the tissue. Transmural fiber orientation of the tissue was analyzed before and after 10% strain loading.

Figure 1: The framework used to detect myofiber orientations

RESULTS

The developed method shows acceptable estimations of the transmural variation of myofiber orientation in the RV wall (Fig. 2). A combination of NLADF, CEDF, image denoising techniques and quantitative line detection algorithms are able to estimate the orientation of myofibers with less than 5% error (representative results: 86 vs 89.6 deg at 2% thickness and 159.2 vs. 159.3 deg at 25% thickness; 0% thickness defined at epicardium).

Analyzing the orientation of myofibers under loading (Fig. 3) reveals fiber remodeling in the loading direction as well as increase in the alignment (orientation index) of myofibers as a result of the applied strain (representative result: fiber remodeling from 5.6 deg to 3.7 deg under 10% stain at 65% thickness).

DISCUSSION

In this study, a framework was developed for quantitative assessment of transmural myocardial fiber kinematics under loading conditions. Fiber orientations detected via processed high-frequency ultrasound images demonstrated acceptable accuracy compared to histological staining. Displacement controlled loading resulted in reorientation of myofibers along the loading direction with increased orientation index. This is in agreement with previous computational studies on the effects of loading on soft tissue fiber remodeling [8].

Figure 2: Representative orientation estimations using ultrasound imaging and the developed framework vs. histological staining

Figure 3: Representative myofiber reorientation detection using a custom uniaxial testing device and the developed framework

In the current setup, investigating biaxial fiber kinematics is limited due to restrictions on ultrasound attenuation that requires ultrasound scans being performed from at least one free side of the tissue. Custom loading grippers equipped with ultrasound probes will be developed for future studies to enable real-time high-frequency ultrasound scans during biaxial testing.

Nevertheless, the developed framework demonstrates promising capabilities in analyzing 3D myocardial fiber orientations under loading. This can help better understanding the underlying connection between myofiber architecture and tissue-level RV mechanical behavior and has potential applications for RV failure diagnostics in pulmonary hypertension as well as applications to the left ventricle and general cardiac function assessment.

INTRODUCTION

Cardiovascular disease is the leading cause of death globally and remains the number one cause of death in the United States [1]. A myocardial infarction (MI) is caused by an arterial blockage preventing blood from flowing to a part of the heart, thus restricting tissue oxygenation and resulting in myocardial cell death. Approximately every 40 seconds an American will have a MI, resulting in 114,023 citizens killed in 2015 [1]. In 2013, MI was one of the 10 most expensive medical conditions treated in hospitals [1]. Therefore, there is a huge need to improve treatment efficacy to reduce the number of Americans killed by this awful disease and alleviate the socioeconomic burdens.

When the flow of blood is blocked to an area of the myocardium, the cardiomyocytes downstream of the occlusion become necrotic as the cells are no longer provided with oxygen [2]. Therefore, the contractility of the heart is compromised, resulting either in sudden death, or leading to ventricular remodeling and eventually heart failure [1-3]. Echocardiography is the standard cardiac imaging technique for humans and small animals as it is noninvasive, inexpensive, widely available, and has a short imaging and post-processing time [4-7]. The standard measurements obtained from M-mode echocardiography to assess left ventricle (LV) function are chamber dimensions, wall thickness, ejection fraction (EF), and fractional shortening (FS), which, as indices of global cardiac function, lack the sensitivity to detect subtle changes in regional LV performance at the early stages of disease progression [4,8-9].

Speckle tracking techniques with strain analysis overcomes this issue by tracking the movement of the myocardium, based on the speckles generated from the reflection and scattering of the ultrasonic beam which varies according to the tissue density [4-7,9]. Commercially developed algorithms have been used to calculate the circumferential, radial, and longitudinal strain and strain rate globally

or regionally across 6 anatomical segments of the LV, after injury of the left anterior descending (LAD) artery in murine models [4-5,9].

Since 1986, the standard of care for acute MI is reperfusion therapy to reduce injury, preserve LV function, and decrease mortality; however, it must occur within hours of the ischemic event and, although it can reduce the extent of injury, it does not completely restore normal cardiac function [3,10]. EphrinA1-Fc (EA1) intramyocardially administered at time of injury has been shown to significantly decrease ischemic damage of the myocardium post-MI [2,10]. The EA1 treatment is delivered to the anterior wall to the right of the occlusion, leading to decreased injury and preservation of global function. The impact on damage and function in the specific region affected by this treatment relative to regions that don't receive the treatment are unknown. Therefore, being able to analyze strain in more regions would reveal earlier detection of LV dysfunction, and determine specifically where EA1 is affecting the contractile function of the LV.

The purpose of this study is to develop a methodology to analyze the strain and strain rate in mice post-MI and treatment at 12 equal segments along the myocardium and compare these results to the VevoStrain software (VisualSonics, Toronto, Canada) strain values. This methodology will be used to determine the LV function and effectiveness of the treatment. In the future this will optimize the treatment process by determining the location being treated and extent of treatment to the infarct and remote regions of the heart.

METHODS

This study was approved by the East Carolina University Institutional Animal Care and Use Committee (IACUC AUP#Q228d) and conforms to the guidelines by the National Institute of Health for the Care and Use of Laboratory Animals. Data was collected in Greenville, NC.

Experimental Protocol. Mice (10-14 weeks) were anesthetized with an intraperitoneal injection of 20 µl/g body weight of tribromoethanol (20 mg/ml) and mechanically ventilated. The LAD coronary artery was temporarily ligated using an 8-0 suture. Sham controls were performed with the suture pulled through the heart without ligation. Within 1 minute of coronary ligation, an intramyocardial injection of either 6 µg IgG-Fc or 6 µg EA1 (both in 6µl) was given.

Image Acquisition and Commercial Processing. Echocardiography was performed blindly to surgical procedure and injection with the Vevo 3100 (VisualSonics, Toronto, Canada) diagnostic ultrasound with a 30MHz linear-array transducer used. All acquisitions were performed on conscious, restrained mice in supine position at 24 hours post-MI. Standard parasternal long-axis and short-axis 2D gray-scale echocardiographic images were obtained. M- and B-mode images were acquired at a frame rate of >300 frames/second. Mice were then anesthetized with lethal intraperitoneal injection of 0.1 mL pentobarbital (390mg/ml). To detect LV remodeling, 3-4 consecutive cardiac cycles were manually selected with the VevoStrain software. The endocardium was manually traced by selecting points along the endocardial border at a frame between systole and diastole. The epicardium was then automatically traced. The software then calculated the strain and strain rate for the 6 standard segments along the LV with the embedded code.

Novel Image Processing Protocol. Echocardiographic images obtained in Digital Imaging and Communications in Medicine (DICOM) format were analyzed offline using MATLAB (MathWorks Inc., Natick, Massachusetts). The speckles were averaged across 3-4 consecutive cardiac cycles which were manually selected. To quantify strain, a region of interest was selected where the motion of the speckles in this area were tracked. The region of interest is the area between the epicardial and endocardial of the LV. The contours of the epicardium and endocardium were semi-automatically traced. Perpendicular lines were then generated connecting these contours. To determine strain and strain rate of the LV, a block-matching method will be used to track blocks containing the same speckle pattern in the defined search area frame-by-frame for the previously selected cardiac cycles. Displacement of the generated lines will be calculated from the starting location to end location. This will be used to calculate strain with Equation 1.

$$\varepsilon = \frac{(L-L_0)}{L_0} \quad (1)$$

The LV will be divided into 12 equal segments. The peak strain values across the region of interest will be averages for the 12 segments. Radial and circumferential strain are determined from short-axis images, and radial and longitudinal strain are determined from long-axis images. To measure strain rate, the shift in the displacement will be divided by the time between frames, using Equation 2.

$$\varepsilon \text{ rate} = \left[\frac{(L-L_0)}{L_0} \right] \times \text{sec}^{-1} \quad (2)$$

To validate the results, the novel strain analysis will be compared to the VevoStrain software data. The results from the novel method will be averaged into the six segments to get comparative values. In addition, these strain measurements will be averaged across the six segments to get global values.

Statistical Analysis. A one-way ANOVA was used to determine statistical significance between experimental groups for longitudinal strain rate and global strain values.

RESULTS

To-date strain in 6 segments has been calculated using commercial code. The longitudinal strain rate for the EA1 treated mice exhibits

similar results to the sham mice compared to IgG-Fc treated mice (Figure 1). EA1 mice produces intermediary global strain.

Figure 1: Longitudinal strain rate (1/s) and global strain (%) results from VevoStrain software.

Thus far, the contours of the defined region of interest have been traced (Figure 2) using the novel processing code, with perpendicular lines connecting these contours. The speckle tracking is currently being developed.

Figure 2: Epicardial and endocardial contour tracing with novel processing code

DISCUSSION

Cardiac dysfunction lessened in mice treated with EA1 after 30 minute infarct and 24 hour reperfusion. LV dyssynchrony, represented by strain rate, decreased in EA1 mice compared IgG-Fc mice, signifying EA1 hearts experienced uniform contractions, similar to that of sham hearts. The global strain results indicate that LV remodeling is minimized with EA1, leading to improved contractile performance. Current challenges being faced with the development of the novel code are poor image quality resulting in lost speckles, and the small size of a mouse heart, making it difficult to analyze the LV in smaller regions.

STRUCTURAL CHANGES IN THE PROGRESSION OF PULMONARY ARTERIAL HYPERTENSION

Erica R. Pursell (1), Daniela Valdez-Jasso (1)

(1) Bioengineering
 University of California San Diego
 San Diego, CA, USA

INTRODUCTION

Pulmonary arterial hypertension is a disease characterized by elevated blood pressure in the pulmonary system. Traditionally, increases in pressure are thought to be due to increased resistance from the peripheral lung vasculature. However, proximal vascular remodeling has been shown to be a predictor of risk for cardiovascular events such as pulmonary arterial hypertension [1].

While changes in the mechanical response of tissues can be indicative of vascular remodeling, quantification structural changes can better describe the vascular response to elevated loads. A study by Pursell *et al* indicated that in a monocrotaline rat animal model of PAH, the axial elastic modulus of the left pulmonary artery (LPA) initially decreases followed by an increase at the late stage of the disease [2]. While the study also indicated fibers become aligned in the axial direction, the circumferential stiffness increased in both LPA and RPA segments with significant changes in the RPA. Inconsistencies in mechanical and structural changes may be due to the manual tracing of the fibers. Therefore, this study aims to determine a more robust method of characterizing structural and organizational modifications of collagen fibers.

METHODS

Proximal LPA segments were harvested from male Sprague-Dawley rats (Charles River Laboratories). At 8 weeks of age, rats in hypertensive groups were treated with a subcutaneous monocrotaline (MCT) injection to induce PAH and left for 1 week (MCTW1, n = 3), 2 weeks (MCTW2, n = 6), 3 weeks (MCTW3, n = 5), and 4 weeks (MCTW4, n = 6) to reach varying stages of disease. Rats in the normotensive group were randomly injected with a saline solution (n = 2) or not given any treatment (n = 2). Hemodynamic measurements indicated no difference in the normotensive animals. The segments were

then stretched to their *in-vivo* ($\lambda_z = 1.4$) length and imaged under a multiphoton microscope (MPM) via second harmonic generation to capture the collagen fibers.

A custom MATLAB code was used to identify collagen fibers in the MPM images and determine their individual fiber orientations (Figure 1) and tortuosities (Equation 1). First, noise was removed from images with a Weiner filter using neighborhoods of 10x10 pixels. Edges were then isolated with a canny edge detection method and the fibers were skeletonized using the MATLAB function, *bwmorph*. Fiber endpoints were identified, and pixels were traced from each endpoint until another endpoint was reached to determine the length of the fiber. The Pythagorean theorem was then used to determine the straight path between endpoints and this segment was used in determining the fiber orientation. Duplicate fibers and fibers with length less than 50 pixels or tortuosity over 2 were discarded as visual inspection indicated these were fragments of fiber tracings. The fiber tracing code was verified with fabricated fiber images and manual tracings of fibers with FIJI.

$$\tau = \frac{L}{C} \quad (1)$$

Here, L is the length of the curved fiber and C is the distance between the two ends of the fiber. As fibers become straighter, L and C become closer in value and tortuosity approaches a value of 1.

Figure 1: Depiction of fiber orientations. Fibers aligned in the axial direction have an angle of 0° and circumferential fibers, an angle of ± 90°.

The probability density functions of tortuosity and fiber orientation were determined and fitted with a Burr (Equation 2) and normal distribution (Equation 3), respectively.

$$f_{\tau} = \frac{\frac{kc(\frac{\tau}{\alpha})^{c-1}}{\alpha}}{\left(1 + \left(\frac{\tau}{\alpha}\right)^c\right)^{k+1}} \quad (2)$$

$$f_{\theta} = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(\theta-\mu)^2}{2\sigma^2}\right) \quad (3)$$

In the Burr distribution (f_{τ}), k and c are shape parameters while α is a scale parameter. For the normal distribution (f_{θ}), μ is the mean and σ is the standard deviation. The average distribution for each group was then plotted for comparison.

RESULTS

Our code was able to identify the edges of collagen fibers (Figure 2) and determine the tortuosity and fiber angle of collagen fibers imaged via multiphoton microscopy.

Figure 2: Representative MPM fiber tracing with collagen fibers (green) and the detected edges (red) taken from a hypertensive animal (left), and normotensive animal (right).

Probability densities of tortuosity were created for each sample and fitted with a probability density function (Figure 3, right). The averages of the probability density function parameters were then used to compare the tortuosity distribution of each group (Figure 3, left).

Figure 3: Probability density function fitted to the distribution of tortuosity measurements from a normotensive vessel (left). Average tortuosity distributions for normotensive animals in blue, MCT week 1 in orange, MCT week 2 in yellow, MCT week 3 in purple, and MCT week 4 in green (right). Note: tortuosity shifts to the left for MCT week 4.

The distributions of the tortuosity values were similar for normotensive through MCTW3, though the peak for MCTW1 was slightly lower than that of the normotensive group. The distribution for MCTW4 shifted to

the left, indicating that the fibers are becoming straighter. Furthermore, the fiber orientation became more aligned in the late stage of disease

Figure 4: Probability density function fitted to the distribution of angle measurements from a normotensive vessel (left). Average angle distributions for normotensive animals in blue, MCT week 1 in orange, MCT week 2 in yellow, MCT week 3 in purple, and MCT week 4 in green (right). Note: fibers are more axially aligned in MCT week 4, indicated by the tighter distribution.

DISCUSSION

In this study, structural changes in proximal left pulmonary arterial segments were quantified via a fully automated custom MATLAB code. Edges of fibers were traced and used to determine fiber orientation. Here, the average distribution of tortuosity and fiber orientation was similar between normotensive and MCTW1-3, except for a slightly wider distribution in the MCTW1 group. Interestingly, Pursell *et al* found that vessels the axial Young's modulus decreased from the normotensive to early disease stage (MCTW1), though the modulus increased in the advanced stage of the disease (MCTW4) [2]. This is consistent with our finding that fibers have both a tighter distribution in the axial direction and decreased tortuosity the late stage of PAH (MCTW4). While this work was able to determine structural changes in pulmonary arteries via analysis of multiphoton images, these methods are very time consuming and costly. Therefore, future studies aim to determine mechanical models that can incorporate structural parameters such as the GOH model which incorporates the probability density function of fiber orientations to determine the mechanical contribution of groups of fibers [3].

DYNAMIC MECHANICS OF CYCLICALLY STRETCHED VASCULAR SMOOTH MUSCLE CELLS

Taylor M. Rothermel (1), Patrick W. Alford (1)

(1) Department of Biomedical Engineering
 University of Minnesota – Twin Cities
 Minneapolis, Minnesota, USA

INTRODUCTION

Vascular smooth muscle cells (VSMCs) are the most prevalent cell type in arteries, and loss of function of VSMCs is implicated in cardiovascular disease, which is a leading cause of death globally. VSMCs exist in a dynamic mechanical environment characterized by cyclical stretching in which they are able to rapidly adapt to maintain vessel integrity [1]. Cellular microbiaxial stretching (CμBS) has previously been used to measure the mechanical properties of cells in response to applied strain [2]. Here, we investigate the mechanical behavior of human VSMCs when exposed to cyclical stretching.

METHODS

CμBS constructs were constructed as described by Win et al [2]. Briefly, polyacrylamide (PA) gels with elastic modulus of 13.5 kPa were adhered on top of elastomeric PDMS membranes fixed between custom brackets. The gel was microcontact printed with aspect ratio 4 rectangular islands of fibronectin with dimensions 32 μm x 128 μm.

Human umbilical artery VSMCs were cultured according to standard methods and were seeded onto the micropatterned gel constructs at a density of approximately 5000 cells/construct (Fig. 1(a)). The cells were serum starved for 24 hours before experiments. All experiments were conducted in serum free media at 37 C° and 5% CO₂.

Constructs were loaded into the biaxial stretcher (Fig. 1(b)) and cyclically stretched parallel to their long axes. An initial set of images of the cell and fluorescent bead layer were taken. A cyclic square-wave-form stretch with peaks of 0% and 15% strain, each held for 3 minutes, was then performed (Fig. 1(c) and Fig. 1(d)). Cells were imaged at 1 Hz for 24 minutes. Cells were then lysed and cell free images of the bead layer were taken at each strain.

A similar stretching protocol was implemented to find the stresses at the end of the relaxation cycle. Bright field and fluorescent images

Figure 1: (a) Schematic of cell on fibronectin patterned on polyacrylamide gel [2], (b) the CμBS device [2], (c) representative bright field images of VSMCs at 0% and 15% strain, (d) stretching protocol, and (e) schematic detailing the relationship between the cell traction stresses, cross sectional area, and first Piola-Kirchhoff stress. Scale bar: 20 μm.

were taken of the cell and bead layer shortly before the end of the 3 minute time period at each strain. This was repeated for 10 cycles.

CμBS microscopy was used to measure material properties of the cells before and after cyclical stretching. Equibiaxial strains were incrementally stepped from 0% applied strain to 15% applied strain and then back down to 0% applied strain in intervals of 5% applied strain. At each interval bright field and fluorescent bead images were acquired.

Particle image velocimetry was used to compare relative substrate displacement between cell and cell free image pairs. Traction stress

vector fields were determined from the deformation fields using an unconstrained Fourier transform traction cytometry algorithm [3]. The vector field of size n was composed of substrate traction stress vectors, $\mathbf{T}^n = T_x^n \mathbf{e}_x + T_y^n \mathbf{e}_y$, where \mathbf{e}_i is the unit vector in the i direction. Substrate traction forces were defined by $\mathbf{T}^n \mathbf{a}^n$ where \mathbf{T}^n is the vector acting on the area, \mathbf{a}^n , of the discrete surface n . Substrate traction forces are balanced by cell forces at their interface. Cell forces were defined as $\mathbf{f}^n = f_x^n \mathbf{e}_x + f_y^n \mathbf{e}_y = -T_x^n \mathbf{a}^n \mathbf{e}_x - T_y^n \mathbf{a}^n \mathbf{e}_y$. Forces oriented away from the cell midline were denoted as positive and tensile. The total tensile force $f_x = \sum_n f_x^n r_x^n / |r_x^n|$ and $f_y = \sum_n f_y^n r_y^n / |r_y^n|$, where $\mathbf{r}^n = r_x^n \mathbf{e}_x + r_y^n \mathbf{e}_y$ is the vector that described the location of surface n with respect to the cell center. The first Piola-Kirchhoff (PK1) stresses, represented by $P_x = f_x / (2A_x)$ and $P_y = f_y / (2A_y)$, can be calculated at the midplane of the cell using the total tensile force and the undeformed cross sectional area of the cell (Fig. 1(e)).

Immunofluorescent staining was done according to a standard protocol for nuclei (DAPI), actin (phalloidin), and paxillin.

RESULTS

When VSMCs were exposed to square-wave stretching, we observed that the stress decreased over time when held at a constant 15% strain. When returned to 0% strain, the stress dipped below the initial stress before increasing with time though not recovering fully to the initial stress (Fig. 2(a)). To examine if this behavior continued over multiple cycles, cells were cyclically stretched and the stresses normalized to the initial stress at 0% strain. The same behavior was demonstrated during each cycle (Fig. 2(b)). The stress that the cell relaxed to at each step appeared to change with each cycle, so we examined the stress every three minutes for 10 cycles. With each cycle, the stresses generated by the cell appeared to decrease and at a faster rate for the 15% strains than the 0% strain (Fig. 2(c)).

Figure 2: (a) Trace of the stresses over time (solid line) during one stretching cycle with initial stress (dashed line) for a representative cell and corresponding traction fields for the points marked by lettered red circles, (b) temporal stresses (solid line) for cyclically stretched VSMCs normalized to initial stress (dashed line) ($n = 3$) (mean \pm standard deviation), (c) stress at the end of each cycle (as indicated by red dots in (b)) for ten stretching cycles at 0% and 15% strain ($n = 27$) (mean \pm standard deviation).

To determine the effect of cyclical stretching on the mechanical properties of the cell, the stress during equibiaxial stretching was compared between cells that were and were not cyclically stretched. The cyclically stretched cells appeared to demonstrate less hysteresis in the direction of the long axis compared to the unstretched cells (Fig. 3(a)). To investigate any change in the cellular structure as a result of the cyclical stretching, fluorescent images of cells stained for nuclei and actin were acquired (Fig. 3(b)). The actin alignment was analyzed and showed that actin in the unstretched cells were slightly more aligned than the in stretched cells (Fig. 3(c)).

Figure 3: (a) Cell stress-strain curves under biaxial stretching for cells before and after cyclical stretching ($n = 9, 13$) (mean \pm standard deviation), (b) representative fluorescent images of VSMCs stained for nuclei (blue) and actin (green), (c) actin orientations of VSMCs before and after cyclical stretching for 10 cycles ($n = 7, 8$) with inset showing detail of the peak of the orientation distribution. Scale bar: 20 μm .

DISCUSSION

Previous studies have shown that VSMCs remodel and adapt to their mechanical environment [1]. Here, we describe how VSMCs react to cyclical stretching in a dynamic mechanical environment. The cells demonstrate remodeling during cyclical stretching that alters stresses generated by the cell and the actin structure of the cell. This knowledge can be used to form more robust mechanical models of cell behavior.

INTRODUCTION

The zebrafish (*Danio rerio*) is a growingly popular animal model in fundamental cardiovascular research. Low maintenance costs, ease of genetic manipulation and fast generation times are a few advantages of this vertebrate model organism. So far, the overwhelming majority of the conducted studies have focused on embryonic and larval zebrafish, taking advantage of their transparency for imaging purposes and their tractability for higher throughput applications. Nevertheless, adult zebrafish can also be very useful to evaluate progressive diseases, such as post-injury ventricular remodeling, and to validate hypotheses generated in embryonic or larval models [1]. Despite some obvious major anatomical differences, the essential cardiovascular physiology of humans and zebrafish is highly similar. Many human cardiovascular drugs have been shown to have similar or even identical effects on zebrafish physiology and zebrafish genetic models have already recapitulated numerous human cardiovascular disorders [2]. What is less well understood, however, are biomechanical aspects of the zebrafish circulation. Given the increased awareness of the role of mechano-biology in cardiovascular (patho)physiology, a better understanding of the biomechanical factors of the zebrafish circulation may be equally important as our understanding of its biological functions. While computational models play an important role in human cardiovascular biomechanic research, finite element models covering the cardiovascular biomechanics of either developing or adult zebrafish are, to the best of our knowledge, non-existent.

The cardiac anatomy of zebrafish consists of the sinus venosus, one atrium, one ventricle, the bulbus arteriosus and ventral aorta. Paired vessels starting from the ventral aorta provide blood flow to the gills and rejoin at the dorsal aorta [3]. The blood pumped by the ventricle passes the bulbus arteriosus, which functions as a non-contractile elastic reservoir, before it enters the ventral aorta. The functioning of the

bulbus as an elastic reservoir has several advantages as it smoothens the effect of systolic pressure, which is necessary because of the delicate vasculature of the gills, and also helps to maintain the pressure during diastole. Furthermore, the elastic recoil of the bulbus results in an extended, i.e., more continuous, flow into the gills and ensures adequate gas exchange this way. The aims of this study are to (i) develop a 3D finite element model of the bulbus arteriosus and (ii) to assess the constitutive material law that allows us to mimic the pressure-diameter relation of the bulbus.

METHODS

Basics of the bulbus arteriosus

The bulbus is pear-shaped, tapering towards the ventral aorta, and has three distinct layers (Figure 1, left): the adventitia, outer media and inner media. A small layer of endothelial cells forms the intima [3,4]. As in arteries, mainly elastin, collagen and smooth muscle cells determine the mechanical behavior of the bulbar wall. Fibers in the inner and outer media are orientated longitudinally and circumferentially respectively. Whereas arteries have J-shaped pressure-diameter (P-D) loops, the bulbi of teleost fish (including the zebrafish) have r-shaped P-D loops. The r-shape arises from a steep initial rise in pressure followed by a compliant plateau phase [4]. The steep initial pressure rise is due to the very small lumen dimensions at low pressures, and the longitudinal elements almost completely occlude the bulbus at zero pressure. The stiffness of a bulbus is much lower than that of an artery, and this, together with the high extensibility, explains the efficient recoil and compliant plateau phase. All this allows the bulbus to maintain ventral aortic pressures and flows over a large volume range [5].

Finite Element model of the bulbus arteriosus – constitutive models

Version 5.4 of COMSOL Multiphysics® was used to study the mechanical behavior of the bulbus. A 2D axi-symmetric model was

sufficient to capture the mechanical behavior and allowed for a reduction in computational effort. We implemented and compared different (hyperelastic) material models to check whether or not the unique and unusual r-shape of the bulbar P-D loop could be obtained. Note that for all hyperelastic materials, the stress-strain relation can be derived from a strain energy density function as explained in [6].

Neo-Hookean and Mooney-Rivlin model The classical example of a hyperelastic material model is the Neo-Hookean model. The Mooney-Rivlin model is another hyperelastic material model which has proved to give good results for modeling certain types of biological tissue. Both material models are isotropic, and furthermore will assume that the bulbus is incompressible. The strain energy density functions for the Neo-Hookean and Mooney-Rivlin model are then, respectively:

$$W = \frac{c}{2} (I_1 - 3) \quad (1)$$

and

$$W = \frac{c_1}{2} (I_1 - 3) + \frac{c_2}{2} (I_2 - 3) \quad (2)$$

where c, c_1, c_2 are stress-like material parameters and I_1, I_2 are invariants of the right Cauchy-Green tensor. Both the Neo-Hookean and Mooney-Rivlin model are built-in in COMSOL Multiphysics 5.4®.

Holzapfel-Gasser-Ogden (HGO) model Whereas the two models just described are purely phenomenological, (parts of) the histology of the bulbus can be included with the HGO model. The strain energy density function is now split into two parts:

$$W = W_{isotropic} + W_{anisotropic} \quad (3)$$

where for the isotropic part for example equation (1) or (2) can be used. In this case, we will use the classical Neo-Hookean model. The anisotropic part accounts for the fibers and their orientation within the bulbar wall, treating the bulbus as a fiber-reinforced material. The anisotropic part of the strain energy density function can be written as the sum of the following expressions [6]:

$$W_4 = \frac{k_1}{2k_2} (\exp(k_2(I_4 - 1)^2) - 1) \quad (4)$$

$$W_6 = \frac{k_1}{2k_2} (\exp(k_2(I_6 - 1)^2) - 1) \quad (5)$$

where k_1 is again a stress-like material parameter, k_2 is a dimensionless material parameter and I_4, I_6 are the fourth and sixth invariants of the same tensor as before. These invariants depend on the fiber directions and introduce another parameter, β , which describes the angle between the spiraling fibers. Figure 1 (right) provides a visualization of the anisotropic part of the strain energy density throughout the bulbar wall. Note the circumferential and longitudinal direction in the outer and inner media respectively. The right image presents the bulbus at zero pressure, which explains the very small lumen (diameter of 0.05 mm).

Figure 1: Left-a cross section of the bulbus clearly visualizing the three layers, separated by bars. Copyright left image: Hu et al. [3]. Right-a visualization of the anisotropy of the strain energy density function throughout the bulbar wall of our COMSOL model.

We implemented the HGO model in COMSOL Multiphysics® as a user-defined hyperelastic material model, and looked at the bulbus as a three-layered structure which leaves 12 material parameters to be

defined (summarized in Table 1 - IM: inner media, OM: outer media, A: adventitia).

Table 1: material constants for the constitutive models

Neo-Hookean		Holzapfel-Gasser-Ogden							
c	265 Pa	c_{IM}	250 Pa	$k_{1,IM}$	50 Pa	$k_{2,IM}$	0.8	β_{IM}	90 deg

RESULTS

The P-D loop was generated for the different material models by simulating the inflation of the bulbus. The comparison experimental data was based on [3],[4] and [5]. Note that due to the r-shape of the P-D loop, a large difference in diameter is observed over the physiological pressure range (which is approximately 0.8-2.2 mmHg [3]). The curves in blue, green and purple indicate the best fit for the Neo-Hookean, Mooney-Rivlin and HGO model respectively. Taking into account the observed fiber directions, the β -parameter in the HGO model was set to 90° (i.e., longitudinal), 0° (i.e., circumferential) and 60° in the inner media, outer media and adventitia respectively. As depicted in Figure 2 for the inner media (IM), changing the β -parameter from the observed (longitudinal) value resulted in a bad fit of the P-D loop.

Figure 2: Simulation of the pressure-diameter (P-D) loop with the different material models. For each case, the best fit is depicted.

DISCUSSION

The COMSOL Multiphysics® simulations show that the typical r-shape of bulbar P-D loops can be obtained with the proposed material models. Both the P-D loop of our Mooney-Rivlin and HGO model agree well with the comparison data. We consider the fact that the HGO model can include (parts of) the histology of the bulbus as a crucial advantage compared with the purely phenomenological Mooney-Rivlin model, although, based on these first results, the (possible) superiority of the 3-layered HGO model is far from clear. More simulations are necessary, but we hypothesize that the 3-layered HGO model will provide more plausible stress distributions within the bulbar wall. Furthermore, at pressures above the physiological range, it is reported that the stiffness of the bulbus increases again [4], something which is impossible to obtain with the Mooney-Rivlin model. Experimental data is necessary and will lead to a more correct tuning of the different parameters. All findings in this study contribute to the search for a physical and physiological model of the mechanics of the bulbus, a key component in the cardiovascular system of the zebrafish. We can conclude that this study provides a strong basis for a mechanical model of the bulbus and once this model is completely validated, the step towards a Fluid-Structure Interaction (FSI) model of the bulbus can be taken.

INTRODUCTION

The aortic valve (AV) tissue exhibits highly nonlinear, anisotropic and heterogeneous material behavior due to its complex microstructure. A thorough understanding of AV functional characteristics can shed light on its function in health and disease. In this work, we highlight a previously unexplained aspect of AV function: the role of leaflet residual strains. Leaflet residual strains are defined as the remaining strains in the intact AV after all external forces have been removed. Presence of residual strains indicates that a stress-free state does not exist in-vivo. Therefore, to be able to make accurate stress estimations of AV and determine their effects on AV dynamic behavior, it is important to quantify these residual strains by determination of AV stress-free configuration.

Yet, in spite of its importance, to date, the effect of residual strains on in-vivo dynamics of AV has never been quantified or simulated systematically. In a recent study the existence of substantial residual strains in human AV using 3D echocardiographic (3DE) imaging and excised leaflet geometry was demonstrated [1]. However, since determination of the effects of all states (stress-free, in-situ, etc.) by direct measurement in humans is not possible, we took a computational modeling approach. However, the leaflet residual strains measured in [1] (Figure 4.a) have not been incorporated in current simulations of the AV. Thus, in the present work we developed a computational framework to determine the residual strains in the AV leaflets and to investigate its influence on AV dynamics based using the human in-vivo results obtained in [1].

METHODS

We first define the kinematic state β_0 as the excised unloaded state where AV leaflets were removed from the heart. We define β_1 as the in-vivo configuration of the AV when the transvalvular pressure is zero,

just before leaflets contact. In order to introduce residual strains in our finite element model, we developed a two-step protocol (Figure 1). First, we created the ex-vivo configuration β_0 . Starting with the known unloaded configuration β_1 , with an estimated non-uniform deformation gradient F we shrink the geometry of the valve.

Figure 1: Implementation of residual strains in AV model.

The appropriate scaling factors are obtained from the ratio between excised and in-vivo key dimensions (i.e. free edge and attachment edge length ratio) clinical data provided in [1]. We use the results of Fig.5 in the aforementioned paper to estimate the behavior of the leaflet in-vivo

and ex-vivo and design our objective function for the optimization purpose. For this process, we used the function *fminsearch* in the Optimization Toolbox of MATLAB. Second, we recreated the in-vivo unloaded configuration β_1 . Starting with the virtually created ex-vivo configuration β_0 , we applied a Dirichlet displacement boundary condition along the edges of the leaflets to solve for the leaflet deformation which returns AV to its in-vivo geometry. For this purpose, we used a thin shell isogeometric structure dynamic finite element solver developed in [2] and implemented the constitutive material model described in [3] as a subroutine into our solver where the material parameters are determined by fitting the predicted stress-strain curves to the corresponding experimental data set of native human AV. We then calculated the resulting strains. Following this step, we applied physiological loading taken from [2] to simulate the in-vivo loaded configuration where the duration of the cardiac cycle is 0.76 s.

RESULTS

The predicted AV dynamics with and without residual strains were first compared in the fully opened and fully closed states (Figure 2). The model that considered residual strains, captures triangle opening behavior. Conversely, for the model without residual strains the material behaves less stiff, results in twists at the fully closed stage and also it fails to capture accurate opening behavior.

Figure 2: Comparison of AV dynamics for 2 cases with clinical imaging data: with and without including residual strain.

We also examine the effect of changing residual strains level on valve dynamics by adjusting radial shrinkage scaling factor Λ_r . The strain distribution for different levels of Λ_r is obtained (Figure 3). Decreasing Λ_r corresponds to increasing the level of residual strains which causes the material to behave stiffer, therefore, strain gradient reduces within the leaflet (i.e. more uniform strain distribution).

Figure 3: Total strain distribution at the fully-closed state for different levels of residual strains (from left to right more residual strain is induced to the model), deformation of the valve colored by maximum in-plane principal Green-Lagrange strain (MIPE).

We compared our results with some previous studies. In particular with regional principal stretch variation presented in [1] when the valve is fully closed. In general, the results are in good agreement with previous studies. For example, the radial stretches have been reported to be higher than the circumferential ones. Moreover, circumferential stretches are close to one over the leaflet (Figure 4.a). However, a direct comparison of stretch values is not possible. We also simulated the

coupling of the aortic root, AV, and the surrounding blood flow through several cardiac cycles using our immersogeometric fluid-structure interaction (FSI) methodology (Figure 4.b).

Figure 4: (a) Comparing principal stretch contours at fully-closed configuration to [1], (b) Residual strains incorporated in FSI framework for simulation of blood flow velocity and maximum in-plane principal Green-Lagrange strain (MIPE) in a cardiac cycle.

DISCUSSION

In general, we observed that including residual strains had a substantial influence on overall leaflet dynamics. Specifically, it had the largest effect on the shape of the AV leaflet in the fully-opened (maximum forward flow) configuration. During the leaflet deformation from just-coapted (zero transvalvular pressure) to fully-loaded (maximum transvalvular pressure), the circumferential strains was close to unity over the leaflet. This difference in functional geometry might also influence flow in the sinus and aortic root interactions. Interestingly, we also noticed that even though the AV did not support any measurable pressure gradient in the just-coapted state, the leaflets were significantly strained with respect to the excised state. Higher strains near the commissures and lower strains in the coaptation zone is observed as the region near commissures experiences the highest stress concentrations and the coaptation area is where leaflets come in contact. Moreover, we observed that including the residual strains decreases the strain gradient within the leaflet, and increases the apparent tissue stiffness; therefore, decreases the range of valve deformation.

Functionally, we and others have shown that residual strains in heart valves and other soft tissue (i.e. arteries) depends primarily on elastin fibers. Therefore, consideration of residual strains in AV takes charge of the elastic part of the leaflet mechanical response and causes the collagen fibers to become stiffer at higher stresses. A deeper study on this issue constitutes an important aspect for future research.

EFFECTS OF -80°C FREEZING ON THE BIOMECHANICAL RESPONSE OF TRICUSPID VALVE LEAFLETS

Samuel D. Salinas, Margaret M. Clark, Rouzbeh Amini

Department of Biomedical Engineering
The University of Akron
Akron, OH, USA

INTRODUCTION

The short-term storage of frozen soft tissues is advantageous from the standpoint of tissue availability and the amount of time needed to conduct experiments. A plethora of tissue types have been tested previously, indicating that there is negligible effect on the mechanical response of tissues due to freezing [1-3]. On the other hand, a number of studies, focusing on tissues such as arteries, aortas, tendons, ligaments, and cartilage offer insights that may contradict with the abovementioned studies [1,4]. Such opposing results suggest that freezing-induced changes in mechanical properties may be tissue-dependent.

Our research team is interested in biomechanical studies of the tricuspid valve (TV), an atrioventricular valve on the pulmonary side of the heart. The TV apparatus is composed of three leaflets: anterior, posterior, and septal leaflets. We have previously conducted biaxial mechanical testing on freshly excised TV leaflets. However, to the best of our knowledge, the effect of freezing on the mechanical response of TV leaflets has not yet been determined [5]. As such, the aim of this study was to examine the feasibility of using frozen porcine TV when fresh TV is unavailable. We hypothesized that the biaxial mechanical response of porcine TV leaflets does not change following storage in phosphate buffered saline (PBS) at -80°C and subsequent thawing.

METHODS

Fresh porcine hearts were collected from a local slaughterhouse and transferred to our research laboratory in chilled PBS. The three TV leaflets ($n = 9$ for anterior and posterior, $n = 8$ for septal) were then isolated and kept in PBS at room temperature. Careful attention was given to align the direction of biaxial stretching with the radial and circumferential directions of the leaflet as defined previously [5]. Once mounted on our custom-built biaxial testing machine, five loading protocols with radial-to-circumferential stress values (in kPa) of

127:127 (equibiaxial), 95.25:127, 127: 95.25, 63.5:127, and 127:63.5 were applied. Nine preconditioning cycles were applied to each sample. The maximum stress of 127 kPa in this study was approximated based on a right ventricular pressure of 30 mmHg. The sample was then removed and placed in a six-well plate filled with PBS and promptly stored in a -80°C freezer. The same specimens were re-tested between one to three days later with the same procedure described above.

Positional data of the fiducial markers were analyzed with an in-house MATLAB (Nantick, MA) script, as described previously [5]. Briefly, the Green-Lagrangian strain tensor \mathbf{E} was defined as

$$\mathbf{E} = \frac{1}{2}(\mathbf{C} - \mathbf{I}) \quad (1)$$

where \mathbf{I} was the identity matrix, and \mathbf{C} , the right Cauchy-Green deformation tensor, was defined as $\mathbf{F}^T\mathbf{F}$. The deformation gradient tensor \mathbf{F} was obtained from the positional data of four fiducial markers at each deformation state. The normal components of the first Piola-Kirchoff stress (i.e., P_{11} and P_{22}) were defined as

$$P_{(ii)} = \frac{f_i}{A_o} \quad (2)$$

where f_i was the force applied in the i^{th} direction and A_o is the corresponding undeformed cross-sectional area. The resulting stress-strain responses were then averaged for each protocol. Since deformation values were calculated in tensorial quantities and mechanical tests were conducted in a number of different loading conditions, the invariants of the right Cauchy-Green deformation tensor were used as scalar metrics for comparison between fresh and frozen samples. In particular, I_C , the first invariant of \mathbf{C} was defined by

$$I_C = tr(\mathbf{C}) \quad (3)$$

and II_C , the second invariant of \mathbf{C} was defined by

$$II_C = \frac{1}{2}[(tr \mathbf{C})^2 - tr \mathbf{C}^2] \quad (4)$$

Statistical analysis was performed using the Kruskal-Wallis test for I_C and II_C at identical stress levels between fresh and post-frozen for all

five protocols and leaflets, with significance level set as $p\text{-value} < 0.05$. Utilizing the law of Laplace and a physiological right ventricular pressure of 25 mmHg, we estimated an equibiaxial stress level of 85 kPa for comparison of fresh and post-frozen samples. We similarly adjusted the stress levels across the other four protocols to 72:96, 96:72, 54:108, and 108:54 (circular points in Fig. 1A) for comparison.

RESULTS

Across all protocols, visual examination of the average responses collected before and after freezing showed a *slight* increase in compliance for all three leaflets post-freezing, as shown in Fig. 1 for the equibiaxial protocol (127:127). However, analyzing the first and second invariants of the right Cauchy-Green strain tensor, we found no statistically significant difference between pre- and post-freezing samples. Figure 2 demonstrates the average first and second invariants pre- and post-freezing across all 5 protocols for the anterior leaflet. Data for the other two leaflets were similar (not presented), i.e., no significant difference was observed.

DISCUSSION

The aim of this study was to determine whether the mechanical response of TV leaflets could be maintained after storing specimens at -80°C . When comparing the deformation of the frozen leaflets at predefined stress levels with those of the fresh leaflets, we found no significant differences. For this study, we have conducted statistical comparisons of the deformation values only for a few selected values of the stress tensor. Similar comparison at other stress levels can provide further evidence of the similarity of the tissue responses before and after freezing. We expect no significant differences at *other* stress levels since visual examination of the stress-strain response (Fig. 1) demonstrate overlapping values and similar trend at any stress level.

Figure 1: (A) Circumferential versus radial stress values of five testing protocols; the circular markers show the stress levels used for comparison of the strain invariants between pre- and post-freezing samples. Average response curves for (B) the anterior, (C) posterior, and (D) septal leaflets for the equibiaxial test. Shaded regions are standard errors.

Figure 2: (A) the first and (B) second invariants of the right Cauchy-Green deformation tensor for the anterior leaflet. Error bars are standard error ($n = 9$).

The similarity in mechanical responses pre- and post-freezing suggest that the extracellular matrix (ECM) architecture, particularly that of collagen, did not deviate much from its initial pre-freezing alignment. Although not significant, the increase in compliance (both in radial and circumferential directions) may be attributed to a disruption in ECM fiber alignment due to the movement of water as ice crystals were formed. Further imaging analysis of the microstructure (e.g. similar to analysis of ocular tissues conducted by Gogola et al. [6]) could provide insights as to how microstructural parameters such as ECM fiber orientation and/or crimp could be affected by freezing.

In summary, consistent with our initial hypothesis, we observed no significant difference in mechanical response of TV leaflets induced by short term storage at -80°C . Such an outcome is advantageous as the fresh tissues may not be always readily available on the day of experiments. In addition, while one should be cautious in extending the outcomes of animal studies to their human counterparts, the lack of difference between fresh and previously frozen samples is of particular importance for human tissues. In particular, access to fresh donor tissues are scarce and requires strong ethical arguments for usage in mechanical testing experiments.

INTRODUCTION

The mitral valve (MV) and the tricuspid valve (TV), also named the atrioventricular heart valves (AHVs), are responsible for regulating unidirectional blood flow from the atria into the ventricle via proper cyclic closing and opening of the valve leaflets. Proper leaflet function relies on the valve leaflet tissue's microstructural components (e.g., collagen fibers, elastin, and glycosaminoglycans (GAGs)) [1]. Maintaining valvular function utilizing surgical reparative techniques is associated with a survival benefit. Previously, the clear zone portions of both the MV and TV leaflets have been characterized, and the mechanical testing results revealed an anisotropic, nonlinear mechanical response [2-3]. These studies provided insight into the mechanical characteristics of the respective tissue layers: the collagenous fibrosa being the major load-bearing layer, and the elastin-rich layers being responsible for the tissue's low-stress elasticity.

In addition, studies [5-6] have quantified the biomechanical role of the GAGs in aortic valve leaflets. Despite these earlier investigations in aortic valve tissue biomechanics, quantifications of the GAGs' contributions to leaflet mechanical behavior have not been made for the AHVs. Thus, there is a need for comprehensive investigations of the GAGs' biomechanical role in the AHV leaflet function, which will lead to greater refinement of AHV leaflet microstructure knowledge and have implications with regard to surgical valve preservation versus replacement. The goal of this study is to fill this gap in knowledge through biaxial mechanical characterization of AHV leaflet tissues before and after enzymatic treatment to remove the GAG constituent.

METHODS

Tissue Preparation: Healthy porcine hearts (80-140 kg, 1-1.5 years of age) were obtained from a local abattoir (Country Home Meat Co., OK) on the same day as animal slaughter. The central portions of

the excised leaflets were sectioned into 10 x 10mm specimens (**Fig. 1a**), and three measurements were averaged to obtain the tissue thickness.

GAG-Degradation Procedure: To examine the GAG contributions to AHV leaflet tissue mechanics, force-controlled biaxial mechanical tests were performed prior to and after an enzyme-based GAG degradation procedure previously developed for the aortic valve leaflets [6]. In brief, an enzyme solution consisting of 30 Units/mL of enzyme Hyaluronidase type VI-S and 0.6 Units/mL of enzyme Chondroitinase ABC from *Proteus vulgaris* in 100 mM Ammonium Acetate Buffer Solution (AABS) was prepared with an adjusted pH of 7.0. The MVAL/TV leaflet specimen was placed in a 1.5 mL vial tube filled with the prepared GAG-degradation solution and continuously shaken for 100 minutes at 37 °C, with which enzyme-treatment time was determined by histology-based GAG content quantification (**Fig. 1b**).

Figure 1. (a) Dissection of the MV and TV anterior leaflets into 10 x 10mm specimens, and the experimental setup for biaxial mechanical testing. **(b)** Alcian blue-stained histological images, demonstrating the progression of the GAG constituent removal associated with various enzyme treatment durations. Scale bar = 200 μ m.

Biaxial Mechanical Testing: For biaxial mechanical testing the prepared MVAL or TVAL specimen was mounted using a set of 4 BioRake tines to a commercial biaxial testing system (BioTester–CellScale, Canada) equipped with a 1.5N capacity load cell. The tissue’s circumferential direction, with which the majority of collagen fibers are oriented, was aligned with the testing x-direction while the radial direction was aligned with the testing y-direction (**Fig. 1a**).

For quantification of the GAG contribution to the overall leaflet’s mechanical behavior, a sequential biaxial mechanical testing procedure was performed, including: (i) *control testing* — untreated (control, C) MVAL or TVAL specimen (effective testing size 7 x 7mm); (ii) *GAG degradation* — enzymatic removal of glycosaminoglycans; (iii) *post GAG-removal testing* — enzyme-treated specimen (denoted by -T; effective testing size 5.5 x 5.5mm). Biaxial mechanical testing performed before and after GAG removal consists of a previously developed force-controlled biaxial mechanical testing protocol [3], with a preconditioning step, followed by 10 cyclic loading cycles at various membrane tension ratios ($T_x:T_y = 1:1, 0.5:1$, and $1:0.5$).

Biaxial Data Analyses: The DIC functionality of the BioTester system was used to obtain time-dependent positions of the four fiducial markers. The time-dependent marker positions were then used to compute the deformation gradient \mathbf{F} , and subsequently the principle stretches in the circumferential and radial directions (λ_{circ} and λ_{rad}). The membrane tensions (T_x and T_y) associated with each deformation gradient were computed using the load cell’s force reading and each specimen’s effective testing region edge length.

Statistical Analysis: Results are represented as the mean \pm SEM (standard error of the mean). To determine the statistically significant differences between the control and enzyme-treated groups of both the MVAL and TVAL a two-tail Student’s *t*-test was performed. A *p*-value < 0.05 was considered to be statistically significant, and a *p*-value < 0.1 was deemed nearly statistically significant.

RESULTS

Comparing the control and enzyme-treated groups with regard to the equi-biaxial loading ratio ($T_x:T_y = 1:1$), it was observed that the GAG-degraded specimens experienced greater stretches than the control specimens in both the circumferential and radial directions. In the circumferential direction, this difference was 5.4% for the MVAL and 4.7% for the TVAL, while for the radial direction the difference was 5.3% for the MVAL and 7.6% for the TVAL (**Fig. 2**). These differences were determined to be statistically significant (MVAL, $p < 0.007$; TVAL, $p < 0.034$). Similar trends in stretch and statistical significance were observed for the non-equibiaxial loading protocols.

The tissue stretch values for the equi-biaxial protocol ($T_x:T_y = 1:1$) were further used to compare the anisotropic index ($AI = \lambda_{rad} / \lambda_{circ}$) for the MVAL and TVAL. The MVAL tissues demonstrated minimal change between the control and treated AI values (1.055 ± 0.022 vs. 1.052 ± 0.022 ; $p = 0.910$), whereas the TVAL tissues revealed a slight, statistically insignificant, increase in AI (1.031 ± 0.017 vs. 1.059 ± 0.028 ; $p = 0.148$).

In addition, the preconditioning stretches (λ_{circ}^{PPC} and λ_{rad}^{PPC}), defined as the tissue deformations between the tissue mounting configuration and the post-preconditioning configuration primarily due to the preconditioning effect, were shown to be greater post-treatment for both the circumferential and radial directions. Specifically, the circumferential direction preconditioning stretch was 2.1% greater for the MVAL ($p = 0.128$) and 2.7% greater for the TVAL ($p = 0.111$). The radial direction preconditioning stretch was 3.9% greater for the MVAL ($p = 0.039$, statistically significant) and 4.8% greater for the TVAL ($p = 0.072$, nearly statistically significant).

Figure 2. Mean \pm SEM of the tissue stretch responses of the control (C) and enzyme-treated (T) groups for the (a) MVAL tissue specimens ($n=7$), and (b) TVAL tissue specimens ($n=6$): $T_x:T_y = 1:1$.

DISCUSSION

From biaxial mechanical testing, it was found that the removal of the GAGs from the AHV leaflet resulted in a statistically significant difference in leaflet peak tissue stretch, with greater extensibility observed in each direction after GAG removal. Previous studies of GAG contribution to heart valve leaflet function have been performed primarily on the aortic valve leaflets [5-6]. In these studies, it was found that GAG removal from the AV leaflets resulted in a greater buckling behavior, a greater flexural rigidity, and differences in tensile viscoelastic properties. In contrast, in our study, it was found that a removal of GAGs from the MVAL and TVAL resulted in statically significant changes in extensibility. One possible explanation may be that the greater contribution of GAGs could be attributed to the difference in the AV and AHV leaflet structures, as the AV does not contain the atrialis layer present in the AHV leaflets.

This study has successfully provided insight into the previously uninvestigated mechanical contribution of the glycosaminoglycans to AHV leaflet function. The findings of this study suggest that GAGs are responsible for regulating the extensibility of the tissue, acting as a mediator between the atrialis and fibrosa layers. Study limitation may warrant future examinations: the effective testing area for the tissues being different before and after enzyme treatment and no investigations been made on the effect of the testing size on the observed mechanical properties. Nevertheless, findings from this study will be useful in enhancing the understanding of the leaflet microstructure that would be essential to the refinement of AHV computational models. In addition, these results could help guide development of therapeutics for valvular heart diseases, including medical therapy, valve repair techniques and replacement prostheses.

INTRODUCTION

The most popular replacement heart valves continue to be bioprosthetic heart valves (BHV) fabricated from xenograft biomaterials. While these devices have many benefits such as immunogenicity and better flow dynamics, failure due to structural deterioration mediated by fatigue and/or tissue mineralization continues to be the central issue plaguing the current designs [1]. Even moderate improvements to its current 10–15 years lifespan can have significant impacts for many patients. However, despite decades of clinical BHV usage and growing popularity, evaluating the durability of BHV design remain very empirical, and the mechanisms underlying their failure remains poorly understood. For example, in vitro accelerated wear testing (AWT) is the only device-level method for evaluating durability. Yet only visible structure damages are used for analysis. Thus, there is a profound need for the development of novel simulation technologies for better understanding and predicting of the changes in the mechanical properties of BHVs at the tissue level.

The dominant fatigue mechanism during the initial stages of cyclic loading is permanent set. Permanent set occurs in BHVs due to the use of glutaraldehyde to suppress the immunogenic response to the xenograft tissue, where the crosslinks formed are reversible at room and body temperature. However, this also has profound effects on the mechanical properties of the tissue, including allowing the microstructure and stress-free configuration of the tissue to gradually change without inducing structural damage. We have shown through the structural constitutive model we developed that permanent set alone can explain all structural and mechanical changes in the BHV biomaterial in the first 50-70 million cycles of testing, and that this process eventually seizes, and the final stress-free geometry depends on the collagen fiber architecture of the tissue [2]. In this work, we developed a numerical framework for simulating the time evolving properties of

BHVs at the device level based on the structural constitutive model [2] and attempt to predict the geometric and structural change that occurs with long-term cyclic loading. We will use this framework to evaluate some initial BHV designs and how they affect the unloaded geometry, collagen fiber architecture, and how the BHVs deform.

METHODS

Permanent set model. Consider the simplest case for permanent set, the 1-D model held at a fixed stretch. The original material is in the reference state Ω_0 and is deformed to the configuration Ω_t . The spontaneous breaking and reforming of the glutaraldehyde allow some of the tissue to break from Ω_0 and reform in Ω_t . The resulting changes in the reference configuration of the connect the collagen fibers architecture and change the mechanical properties of the tissue (Fig. 1) [2]. The stress of the tissue can be described using a structural model incorporating the changing collagen fiber architecture [3], where the strain energy is given by

$$\Psi = \Psi_{matrix} + \Psi_{collagen} + \Psi_{interactions}. \quad (1)$$

In the general case, the mass fraction of tissue in the original reference configuration can be described as a function of time, $b(t)$, and the mass fraction of materials formed in the new configuration, $a(t, \Omega(s))$, needs to be extended to be a function of both time and the loaded configuration at time s , $\Omega(s)$, in other words the strain history. The stress of the crosslinked tissue is thus given by

$$\mathbf{S}(t) = b(t)\mathbf{S}_{\Omega_0} + \int_0^t a(t, \Omega(s))\mathbf{S}_{\Omega(s)}ds. \quad (2)$$

Effective model framework. One major challenge hindering time evolving simulations incorporating structural information is the large

Figure 1: A representation of permanent set in a 1D case held at constant strain. The mass fraction of tissue gradually changes to the loaded state (Ω_t), changing the reference configuration (Top) while convecting the collagen fiber architecture (Bottom)

computational cost. We estimate the computational cost of the structural model [2] is five magnitudes higher due to the quadruple integral involved. It is for this reason that we developed an effective constitutive model approach to improve the efficiency of such simulations [4]. The form of this effective constitutive model is

$$\Psi_{eff} = c_0(e^Q - 1). \quad (3)$$

$$Q = b_1 E_{11}^2 + b_2 E_{22}^2 + b_3 E_{12}^2 + b_4 E_{11} E_{22} + b_5 E_{11}^4 + b_6 E_{22}^4 + b_7 E_{11}^3 E_{22} + b_8 E_{11} E_{22}^3 + b_9 E_{11}^2 E_{22}^2 + b_{10} E_{11}^4 E_{22}^2 + b_{11} E_{11}^2 E_{22}^4 + b_{12} E_{11}^2 E_{22}^2 E_{12}^2 + b_{13} E_{11} E_{22}^2 E_{12}^2.$$

This form both can fully capture the response of the structural model and has similar computational costs to other phenomenological approaches. Equation 3 is used for the quasi-static simulations, whereas the structural model (Eqn. 1) is used to determine the model parameters c_0 and b_i (Fig. 3).

Numerical Simulation Framework. The numerical simulation can be divided into 3 main stages. (1) Setting up microstructure, material properties and geometry in the initial uncycled state, 2) perform quasi-static simulation to find the current loaded state, 3) updating the material properties of the structural constitutive model at the local material level, and 4) updating the new post cycling reference geometry at the device-level and changes in the local microstructure. Step 2-4 are repeated for each time subsequent time step until the last time step (Fig. 2).

Figure 2: Implementation for the permanent set (PS) simulation divided in to four main stages.

RESULTS

BHVs undergoes significant changes in geometry in response to permanent set, especially in the first 25 million cycles. This process gradually stops after around 40-50 million cycles. The regions that undergo most permanent set are the belly region, the center of the free edge, and the regions near the commissures, where the leaflets initially make contact (Fig. 3). The belly region and the center of the free edge have the least support from the surrounding two leaflets which causes them to deform more. The regions near the commissures are the points where the leaflets initially meet during the closing motion. These regions are also the most common regions of failure in BHVs. We were also able to predict the change in the collagen fiber architecture and found that the belly region and the free edge undergoes the greatest degree of realignment, causing the fibers to spread.

Figure 3: Simulations of BHVs with initial geometries is based on A) the Edward pericardial valve, and B) altered to have greater belly region curvature. The color shows the maximum principal component of the local change in reference configuration.

DISCUSSION

We have developed a complete time-dependent framework for the numerical simulation of BHVs in response to permanent set under long-term cyclic loading. This simulation utilizes the predictive mechanism based constitutive model for the permanent set effect in exogenously crosslinked soft tissues that we previously developed. We have shown that we can use this simulation to predict how the evolving geometry, microstructural and material property changes. This framework opens the possibility of optimizing the initial BHV design to the final geometry after permanent set has seized, where it will operate for its remaining 9- to 14-year lifespan. These results can then be extended to predict regions with increased likelihood of structural damage, where the collagen fibers are over-stretched or held in a constant extended state. Thus, accounting for the permanent set effect is especially important in the design of BHVs to better improve their performance and durability.

INTRODUCTION

Heart valve disease is striking the western world with an ever-increasing prevalence rate [1]. Among the most common valvular lesions, ischemic mitral regurgitation (IMR), appears within one month of infarction in the growing population of patients who have suffered cardiac arrest [2]. While two major surgical solutions for IMR (repair and replacement) have improved significantly over the past three decades, the success with a high mortality rate [3]. Consequently, there is an eminent need for improving treatment options to help patients who suffer from MV disorders, especially IMR.

It is widely believed that to achieve better patient outcomes, MV treatments need to be tailored to each patient's conditions. Image-based computational modeling of the MV provides a promising approach to this issue by allowing for quantitative assessment of different treatment options through simulating the valvular response to repair on a patient-specific basis. However, the clinical application of MV *in silico* simulations has always been hindered by the fact that imaging MV in the clinic cannot resolve the complete geometry of the valve with sufficient spatiotemporal resolution for computational modeling. In the present study, we addressed this issue through developing functionally equivalent models of the chordal structure to build high-fidelity image-based models of the complete MV and in turn simulate MV repair surgery. Our methodology uses only the information that is available prior to surgery and successfully showcases how image-based computational models of the MV can be used to provide additional insight into patient-specific response to annuloplasty repair of the valve.

METHODS

Three patients were randomly selected from the Cardiothoracic Surgical Trial Network (CTSN) for this study. We processed real-time 3D echocardiographic (rt-3DE) images for these patients from before

and after undergoing the annuloplasty surgery to extract patient-specific leaflet geometries (Figure 1). For each patient, the pre-operative open valve model was converted into a 3D triangulated mesh using Poisson disk resampling and ball pivoting algorithms. The acquired mesh was then morphed to the closed leaflet geometry through a hyperelastic shape-warping technique that enforced the closed leaflet shape through a level-set penalization.

Figure 1, (a) rt-3DE images of the MV were interactively processed to develop patient-specific geometric representations of the MV leaflets for both end-diastolic and end-systolic states (b).

Briefly, in this method the ventricular side of the leaflet geometry is first pressurized till the reference open shape transforms to the vicinity of target closed shape. Then, a locally corrective pressure field enforces the final adjustments such that the morphed leaflet mesh from the open state matches the closed leaflet image data. The details of our shape-matching technique including the image processing pipeline, leaflet constitutive relation, and finite element analysis framework can be found in Rego et al. [4].

Figure 2, the pipeline to develop functionally equivalent chordal models is shown from surgeon's view.

As mentioned above, the chordal part of MV apparatus cannot be fully resolved via *in vivo* imaging modalities. We have addressed this issue in detail in our previous studies on the MV chordae tendineae (MVCT) by analyzing the micron-resolution characteristics of the chordal anatomy [5] and more recently developing functionally equivalent chordal models [6]. In the present study, we followed the same approach to build patient-specific synthetic chords that can reproduce the effect of native MVCT on the closing behavior of the MV apparatus (Figure 2). To build functionally equivalent chords, at first the open leaflet mesh was uniformly sampled in 3D to acquire a point cloud of the chordal insertions on the leaflet. This point cloud was then mapped to the closed state using the computed registration field, *vide supra*. Next, the average papillary muscle (PM) locations also extracted from rt-3DE imaging data were connected to the morphed insertion locations to build single strand chords. The constructed chordal model was then merged with the leaflet geometry, morphed back to the open state, and calibrated to the pre-operative state to build a complete model of the MV apparatus.

To predict the effects of annuloplasty repair surgery on each patient, the post-operative valvular configuration was simulated by applying the displacement boundary conditions on the annulus and PM heads (Figure 3). We used the commercial Finite Element software package Abaqus explicit to perform the closing simulations using a non-linear quasi-static solver with direct time integration and automatic time-stepping. The constitutive relation to model the mechanical behavior of the leaflets and chords and details of our finite element models can be found in Rego et al. [4] and Khalighi et al [6].

Figure 3, the gray and golden curves respectively correspond to pre- and post-operative annular shapes.

Figure 4, the simulation results show a high level of fidelity in predicting post-operative closed valvular geometry

RESULTS

The simulation results showed that our modeling approach can be used to reliably predict the closing behavior of the MV following annuloplasty surgery using pre-operative imaging data (Figure 4). In addition, we computed the leaflet deformation fields in the local surface directions which demonstrated the effects of undersized annuloplasty ring on the entire leaflet (Figure 5). Interestingly, the comparison of pre- and post-operative deformation patterns revealed that the circumferential strain and stress decreased significantly in the entire leaflet while radial components of the strain and stress remained mostly the same before and after the annuloplasty repair surgery.

Figure 5, the directional strain fields computed for a representative patient in pre- and post-operative states are shown.

DISCUSSION

Simulating the MV response to surgery from clinical imaging data allows for refinements to treatment planning and optimization of repair surgery procedures. In this study, we presented a pipeline that allows for patient-specific modeling of the MV to predict the valvular response to annuloplasty repair with high predictive power. Our framework only relies on the clinically obtainable imaging data prior to the MV repair operation and thus can be extended into a virtual surgery tool that provides surgeons with additional insight into the patient-specific valvular response to different treatment options.

INTRODUCTION

The potential clinical benefit of patient-specific biomechanical models of cardiovascular disease remains an unrealized goal, often due to difficulties in non-invasively acquiring necessary kinematic data. This is particularly true in assessing bicuspid aortic valve (BAV) disease, the most common cardiac congenital defect in humans which leads to premature and severe aortic stenosis/insufficiency (AS/AI) [1]. However, assessment of BAV risk for AS/AI to determine treatment on a patient-specific level is hampered by large anatomic variations that remain largely unquantified. There is thus a need for simulation techniques that can directly integrate individualized BAV geometry and deformation data from *in vivo* imaging modalities. Towards this goal, we have extended an approach developed for human mitral valve (MV) [2] to determine tri-leaflet aortic valve (TAV) and BAV leaflet deformations based on clinically obtained *in vivo* imaging data.

METHODS

Data acquisition. Data was acquired from multiple individuals at several points in the cardiac cycle and segmented using previously developed methods [3]. Imaging data was collected on a patient-specific basis for individuals with TAV and for those with BAV. During segmentation, the Raphe labels were applied to BAV data sets on leaflets where a Raphe existed (Figure 1).

Spline surface fitting. The segmented imaging data was fit with a Non-uniform Rational B-Spline (NURBS) surface as follows. First, a closed NURBS curve was fit to the leaflet boundaries and converted into an open NURBS surface. The

Figure 1. Representative segmented image of a BAV.

surface was matched to the segmented image data by least squares error minimization between the surface and segmented data points. In areas of data sparsity, Sobolev regularization was used to stabilize the least squares fit [4].

Strain estimation. To acquire diastolic deformation fields across the entire aortic valve (AV) leaflet surface non-invasively, we utilized a previously validated image-based strain estimation method developed by our group [2], which yields local strain information directly from clinical-quality *in vivo* images. An essential feature of our approach is that it does not rely on physical markers to extract surface deformations; we thus did not assume any material point correspondence between open-state and closed-state images when estimating diastolic strains. Instead, we exploited the fact that the gross

subject-specific closed-state geometry of the leaflets can be precisely acquired from diastolic scans, and developed the following method to enforce this closed shape during a finite element (FE) simulation of AV closure: While pressurizing the open-state valve mesh, we penalized any mismatch between the simulated and true (i.e. imaged) closed shapes of the leaflets using a local corrective pressure field (LCPF), which was at any instance and location linearly proportional to the shortest distance between the FE mesh and the true AV medial surface. In this way, the LCPF locally “pushed” regions of the AV so that the imaged closed-state geometry was matched (Figure 2). In addition to the LCPF, data points along the basal attachment of the AV were mapped from the open to the closed state by matching points using the NURBS surface parameterization.

Figure 2. Image-derived and simulated diastolic AV geometries. The LCPF yielded a geometry that was within 0.5 mm of the true geometry at all points.

To further validate our method, we applied the strain estimation method to a computationally generated NURBS geometry of a bioprosthetic TAV implant, with locally prescribed collagen fiber orientation distributions and material properties (Figure 3). This validation approach had the distinct advantage of allowing for the comparison of our estimated stretch fields to ground-truth local stretch maps for the modeled TAV, which were obtained via isogeometric analysis.

Figure 3. Definition of local material directions in the TAV.

RESULTS

The technique was able to capture the complex, heterogeneous leaflet deformation field of the AV. Moreover, our non-invasive method was able to yield strain estimates within 5% of their ground truth value over the entire leaflet surface (Figure 4). Resulting strain fields also corresponded well with results of structural simulations based on population-averaged fiber structural data and *in vivo* measurements from previous studies [5]. Based on the observed spatial resolution of the observed resultant strain field, this approach is sufficiently

sensitive to capture the effects of variations in Raphe geometry as well as patient-specific heterogeneity in the in-plane deformations of both TAV as well as BAV leaflets.

Figure 4. In-plane stretch in the normal TAV, showing the capability of the method to capture substantial regional heterogeneity as well as directional differences in strain.

DISCUSSION

We demonstrated the ability of our approach to non-invasively capture the deformation of an individual’s TAV or BAV from *in vivo* imaging data with high sensitivity and regional detail. Deformation is a key parameter in the clinical assessment of valvular function, and serves as a direct means to determine regional variations in structure and function. This study is an essential step toward patient-specific assessment of BAV based on correlating leaflet deformation and AS/AI progression, as it provides a means for assessing patient-specific strain patterns.

INTRODUCTION

The three leaflets of the tricuspid heart valve (TV) function in a demanding and dynamic mechanical environment. Specifically, leaflets undergo tension, shear, and flexure with every heartbeat. To maintain their function under those conditions, the leaflets have evolved into structurally and biologically complex tissues. The stress environment, tissue structure, leaflet mechanics, and valve function are all interrelated. In fact, the leaflets of the left atrioventricular valve, the mitral valve (MV), have been shown to be able to grow and remodel in response to changing stress environments, in order to adapt to disease for example. Despite a mature understanding of the biomechanics of MV leaflets, little is known about TV leaflets. For instance, it is not clear how TV leaflet constituents influence their host's mechanical behavior. Toward elucidating the structure-function relationship of the TV leaflets, Amini Khoiy et al. characterized the biaxial anisotropic nonlinear behavior of porcine TV leaflets [1]. Additionally, Pham et al. quantified the mechanical properties and structural properties of human TV leaflets with biaxial testing and histology, respectively [2]. Most recently, Jett et al. used biaxial testing and histology to elucidate the material properties and gross biological structure of porcine TV leaflets [3]. However, there remains a need to understand how mechanosensing constituents (i.e. resident cells) influence the biological structure of TV leaflets and may thus, regulate their mechanical behavior. As such, the objective of this work is to elucidate the structure of mechanosensitive constituents (i.e. cells) and their micro-mechanical matrix (i.e. extracellular proteins, collagen), and its effect on tissue mechanics in ovine TV leaflets. This knowledge may have important implications for our understanding of TV behavior in altered stress environments, such as disease states, and developing TV-specific surgical techniques and devices.

METHODS

Toward this objective, we excised three tricuspid valves from six month-old healthy Dorset sheep. We excised 7x7 mm tissue samples from all three leaflets' (i.e. anterior, posterior, septal) belly region. Using a digital thickness gauge, we measured their average thicknesses. We applied four marker dots to each sample and photographed the stress-free reference configuration. We then mounted, preconditioned, and tested each sample in five biaxial configurations using a biaxial tension device. Simultaneously, we imaged the four marker dots to acquire in-plane strains. After biaxial testing, we prepared the same samples for two-photon microscopy. To this end, we applied a cell-permeant nuclear counterstain. To ensure full thickness image acquisition, we then applied a glycerol optical clearing solution under sonication. We imaged three locations in 10 μ m z-step increments, through the entire thickness. At each imaging site, we epicollected the second harmonic generation of collagen and the fluorescence of the nuclear stain.

We isolated and analyzed the downstrokes of all biaxial loading configurations. We informed deformation gradients via strain image tracking, and calculated membrane tensions from raw force and displacement data. To account for mounting strain, we applied the additional deformation gradient from the stress-free state to the end of the downstroke. To analyze the preferential collagen fiber distributions, we used the ImageJ plugin, Directionality, and fit von Mises functions to the fiber distribution data at all locations and depths. For each sample, we normalized and averaged all location's von Mises distributions into a single distribution at each depth. We then averaged and interpolated the von Mises distributions by leaflet, through the thickness. Lastly, we utilized an in-house MATLAB code to analyze cell nuclei morphology at all locations and depths. We analyzed these parameters via similar averaged and interpolated histogram approaches described above.

RESULTS

Results for equibiaxial loading are presented in Figure 1. We found that all leaflets exhibit similar behavior in the circumferential direction. When contrasting circumferential with the radial direction, the posterior leaflet exhibits strong anisotropy, while anterior and septal leaflets behave similar to one another with less degrees of anisotropy.

Figure 1: (A) Circumferential and (B) radial equibiaxial behavior of anterior, posterior and septal leaflets. Insets: (A) Definitions of circumferential and radial directions for tricuspid valves. (B) Biaxial sample as mounted for testing.

The collagen distribution and cell nuclei morphology analyses are presented in Figure 2. We found that the mean collagen fiber direction for anterior ($\mu = 74.2 \pm 4.5^\circ$), posterior ($\mu = 72.7 \pm 1.8^\circ$) and septal ($\mu = 72.5 \pm 1.2^\circ$) leaflets is similar at all depths, while fiber orientation dispersion ($\kappa = 1.45 \pm 0.20$, $\kappa = 1.62 \pm 0.12$, and $\kappa = 1.23 \pm 0.31$, respectively) vary by leaflet and depth. Additionally, we found that cell nuclei orientation vary by depth and leaflet, preferentially aligning in the circumferential direction. Specifically, nuclei orientation of the posterior leaflet is less dispersed than anterior and septal leaflets. Eccentricity is similar among all leaflets by depth.

DISCUSSION

In this study we explored the tissue mechanics and constituent structure in healthy ovine TV leaflets using biaxial tension testing and two-photon microscopy. Specifically, we investigated and compared the structure and distribution of cell nuclei and their collagen matrix through the depths of all three TV leaflets, and analyzed these with respect to the tissue biaxial behavior.

All samples showed a classic nonlinear J-shaped curve. We found that the posterior leaflet exhibits the most anisotropic behavior of the leaflets, agreeing with the findings of both Amini Khoiy et al., and Jett et al. However, in our study, the anterior and posterior leaflets showed limited degrees of anisotropy, in disagreement with Amini Khoiy et al., Pham et al., and Jett et al. Possible reasons for the disagreement may arise from our use of a truly stress-free reference configuration, as opposed to the other studies that measure strain from the mounted state. Moreover, Amini Khoiy et al. and Jett et al. studied porcine TV leaflets, and Pham et al. studied human TV leaflets.

Figure 2: (A) Coordinate system and orientation map. (B) Composite image of collagen fibers (green) and cell nuclei (blue) (scale bar = 100 μm). (C) Collagen orientation distributions and (D) cell nuclei morphological distributions.

The mean collagen orientation is consistent between leaflets and through the leaflet thickness, with slight deviations toward the radial axis at the atrialis ($\sim 0-10^\circ$). The most interesting finding is how collagen fiber dispersion varies both by leaflet and depth. For all three leaflets, collagen orientation is mostly uniform through depth, but is widely dispersed in fibrosa/ventricularis layers ($> 60\%$). Additionally, the posterior leaflet has the largest region of low dispersion, which may explain its large anisotropic behavior compared to the other leaflets. We also found that the cell orientations for all three leaflets agree with the orientation profiles of collagen, suggesting that the cells and collagen are aligned, potentially for mechanical reasons. The posterior leaflet cells had the lowest orientation dispersion among leaflets, similar to the posterior leaflet's collagen profile. Cell nuclei eccentricity was similar among leaflets by depth, but may be indicative of certain cell phenotypes (i.e. endothelial v. mesenchymal/interstitial). An additional analysis of cell membrane morphology would complement our study.

These data are necessary for understanding TV behavior in normal stress environments. They also provide the platform for comparison among altered stress environments, such as disease states.

ACKNOWLEDGEMENTS

We would like to acknowledge Matthew Bersi, PhD, for his assistance in analyzing cell nuclei morphology.

INTRODUCTION

It has long been recognized that collagen fiber architecture (CFA) plays the key role in the mechanical behavior of collagenous soft tissues. However, a barrier to deeper understanding of the biomechanical behavior of collagenous soft tissues is the lack of methods for rapidly collecting CFA data in a non-destructive, non-contacting, full field manner. Typical transmitted light techniques e.g. small angle light scattering are too slow to be able to capture near real-time data on CFA dynamics and require modification to clear tissue. Polarized Spatial Frequency Domain Imaging (pSFDI) is a recently developed reflectance imaging modality that can rapidly obtain high-resolution fiber architecture data over wide fields of native tissues with controlled transmural measurement extent without the need for specimen optical clearing or sectioning [1]. Moreover, the CFA information can potentially be used as a form of texture for Digital Image Correlation (DIC) to create full-field, pixel resolution displacement fields without the need to apply some form of visual texture. Furthermore, while both the CFA and DIC deformation data can be represented and stored in various ways, Non-uniform Rational B-Splines (NURBS) surfaces represent a convenient and compact way of representing both types of data as smooth, continuous fields with a single, unified set of basis functions.

In the present study, we have combined pSFDI and NURBS based DIC into an experimental/computational system that can rapidly collect soft tissue specimen structure, strain, and stress information from a single experimental setup without specimen alteration. This combined approach allows us to investigate collagen fiber kinematics, particularly the affine kinematic model, which is widely used in computational models of fibrous tissues, with high spatial resolution.

METHODS

pSFDI system Our pSFDI imaging system has been previously described [1,2]. Briefly, a digital micro-mirror device (DMD) projected

spatial frequency patterns through a linear polarizer (LP) onto the soft tissue specimen. The image of this spatial frequency pattern was captured through the same LP by a CMOS camera (Figure 1). This system was able to collect the pSFDI image data for a single spatial frequency over the full 2 cm x 2 cm field of view in approximately 5 seconds.

Data acquisition. The pSFDI imaging system was integrated with our planar biaxial testing device [3]. Native bovine pericardium (BP) specimens were presorted by their fiber preferred direction (PD) and then mounted onto the biaxial testing system with the fiber PD aligned with the test system's X1 axis. The specimens were then tested to an equibiaxial stress level of 225 kPa in a stepped loading protocol. pSFDI imaging data was collected at each step in the loading protocol. After the pSFDI images were collected over the stepped load protocol, the protocol was repeated with standard DIC speckle texture in order to compare deformation fields computed using the pSFDI texture versus the standard texture. Standard DIC speckle texture in the form of acrylic paint was applied to

Figure 1. Schematic of pSFDI system detailing major components.

Figure 2. Specimen mounted on test device. NURBS mesh overlaid

the CFA orientation distribution function (ODF).

DIC. The processed pSFDI image data was converted to grayscale images. A custom Python program was used to perform a NURBS based DIC analysis [4] on the grayscale images to produce full field maps of the sample in-plane deformation (**F2D**). An advantage to the NURBS based approach is that it enforces global continuity on the computed deformation field, thus eliminating non-physical deformations that can sometimes occur with traditional window based DIC analysis methods. First, a NURBS mesh is superimposed over the reference image (Figure 2). A trial deformation field is then created by displacing the control points of the mesh. Then the zero normalized sum of squares difference (ZNSSD) is computed between the pixels in the reference image mesh and corresponding pixels in the deformed image mesh. The L-BFGS-B algorithm is used to minimize the scalar ZNSSD value over mesh control point displacements. The minimizing control point displacement values are interpolated with the NURBS basis functions to create the full field deformation map.

Figure 3. Changes to specimen fiber preferred direction (PD) and degree of anisotropy (DOA)

Affine kinematics. The affine kinematic model states that the total number of collagen fibers in a volume element of a tissue remains

the specimen using an airbrush (Figure 2). The stepped loading protocol was repeated with grayscale images of the speckle texture captured at each load step. The raw pSFDI images were processed with a custom Matlab program (MathWorks, Natick, MA) to produce maps of the CFA of the pericardium specimen which included information on fiber preferred direction (PD) and the degree of anisotropy (DOA), which correlates with the normalized orientation index (NOI) of

constant under deformation. The relationship between the fiber PD vectors in the reference \mathbf{N} and deformed \mathbf{n} configurations is given by

$$\mathbf{n} = \mathbf{F}_{2D}\mathbf{N} \quad (1)$$

The orientation distribution function between the reference and deformed configurations, $\Gamma(\theta)$ and $\Gamma(\beta)$, respectively are related via

$$\Gamma(\beta) = \frac{\lambda_N^2}{\det(\mathbf{F}_{2D})} \Gamma(\theta) \quad (2)$$

where λ_N^2 is the square of the stretch in the fiber direction. Measured fiber PD data from the specimen reference configuration was used in conjugation with the computed **F2D** in this affine relationship to predict the value of the fiber PD in the deformed configuration. This predicted value was compared with the actual measured fiber PD.

Figure 4. Deformation fields shown as stretch in the two biaxial test axis direction.

RESULTS

CFA. The pSFDI system captured the complex changes to the fiber PD and DOA with high spatial resolution (Figure 3). As expected, the CFA showed increased alignment under load as evidenced by the increase in DOA value. The DOA measurement also showed evidence of the CFA rearranging around the suture hook attachments used to mount the specimen to the biaxial testing device.

Deformation. The CFA data collected by pSFDI was shown to be a viable form of texture for DIC and the resulting deformation fields (Figure 4) showed regional variability in agreement with deformation fields computed from the standard DIC texture. Mean percent error for stretch in X1 was $2.5e-3 \pm 1.1e-5$ and $1.8e-3 \pm 8e-6$ for X2.

DISCUSSION

Our pSFDI system was able to capture the changes to bovine pericardium CFA over the full specimen in near real-time without the need to do any specimen preparation. This CFA data in turn was a viable texture for NURBS based DIC to compute the full field deformation map for the specimen. This combined experimental/computational approach represents an integrated way to simultaneously collect data on specimen CFA, strain, and stress in a single setup in near-real time. While the initial results are promising, we will continue to validate the approach for other types of soft tissues and biomaterials. We will also validate our deformation measurements computed using the pSFDI data as the DIC texture to measurements made using the traditional powder speckle texture approach. Finally, we have used the computed strain fields in combination with the CFA information to validate the affine kinematic model (1,2) and showed good agreement between the measured data and the affine model.

THE ROLE OF SCLEROSTIN IN CALCIFIC AORTIC VALVE DISEASE

J. Ethan Joll (1) and W. David Merryman (1)

(1) Biomedical Engineering
Vanderbilt University
Nashville, TN, U.S.A.

INTRODUCTION

Calcific aortic valve disease (CAVD) is the most common disease of the cardiac valves and is an increasing concern in ageing populations. 1.5 million patients suffer from the disease and half of all untreated severe cases of CAVD result in death within two years [1]. Progression of the disease is characterized by the aortic valve becoming fibrotic and calcified, reducing valvular compliance and limiting blood flow into systemic circulation. This process - termed aortic stenosis – causes pressure overload, which leads to heart failure and death if left unchecked. Recent work investigating sex differences in CAVD show that women experience a larger degree of fibrosis while men preferentially experience calcification, indicating a potential difference in disease progression [2].

Currently, the only effective treatment for CAVD is valve replacement. There are no available pharmaceutical treatments. This is due to the unclear molecular mechanisms that govern the initiation and propagation of the disease. CAVD is known to be an actively regulated bioprocess involving a number of resident and invading circulating cells and various aberrant molecular pathways [3]. Sclerostin has recently been identified as a key regulator of bone homeostasis, playing a key role in the bone resorption axis. Sclerostin acts as a Wnt antagonist, which reduces the production of new bone matrix [4]. In addition, it facilitates the production of RANKL in osteocytes which causes osteoclastogenesis, increasing the resorption of bone [5].

Recent work has shown that sclerostin is produced in the aorta as well as the calcified aortic valve [6-7]. A recent phase III clinical trial for Romosozumab, a sclerostin blocking antibody, showed strong effects in bone, but was flagged for an increase in cardiovascular events. To date, there is only one direct study of the effect of sclerostin in cardiovascular disease, with Krishna et al. showing a protective effect in the development of angiotensin-II induced aortic aneurysm and

atherosclerosis [8]. Based on the increasing amount of interest in sclerostin in cardiovascular disease and its potential as a drug target, this study aims to determine the role of sclerostin on the development of calcific aortic valve disease in cells and mice in order to more fully understand the implications of targeting this protein for treatment of disease.

METHODS

To generate mouse aortic valve interstitial cell lines (mAVIC), mice carrying the Immorto gene aged 4-6 weeks were sacrificed and the aortic valve leaflets were isolated. Tissue was digested using collagenase and cells were allowed to adhere to gelatin-coated tissue culture dishes. Aortic valve interstitial cells were confirmed by positive staining for α -smooth muscle actin and morphological characteristics. Nine cell lines were generated.

The direct effect of sclerostin on mAVIC's was assessed using a recombinant mouse protein at 1 ng/mL (R&D Systems). Cells were treated with control media or media supplemented with sclerostin for 6 hours. RNA was harvested and isolated using the Trizol method (Thermo Fisher Scientific). Expression of pro-CAVD RNA markers was assessed using quantitative polymerase chain reaction (qPCR).

A genetic mutant model was utilized to assess the role of sclerostin in the development of CAVD in a mouse model. Wild-type and mice carrying a heterozygous or homozygous deletion of the SOST gene were generated. At 10 weeks they were transitioned to a high-fat/high-cholesterol chow (Test Diet). The mice were aged for twelve months with echocardiography of the aortic valve performed at 2.5, 4, 6, 9, and 12 months. Long-axis velocity waveforms were measured using a custom Matlab script to assess changes in peak aortic velocity and mean gradient to characterize the development of CAVD.

N=9 cell lines were used in this study. N=20 mice were used in each genotype divided evenly between male and female sex. D'Agostino- Pearson normality test was performed to assess data distribution. Student's t-test was used to test for significance between two groups. One-way analysis of variance was used to test for differences between multiple groups. Two-way analysis of variance was used to test the effects of sex, mutation, and their interaction in the animal study. For non-normally distributed data, the non-parametric variants of these tests were utilized.

RESULTS

Administration of recombinant sclerostin protein caused an increase in expression of *Col1a1* in female cell lines but a corresponding decrease in male cell lines indicating a different mechanism of action. α -SMA expression increases in both male and female cell lines at a similar level (fig. 1).

Figure 1: Sclerostin protein causes differential expression of collagen-1, increasing in females and decreasing in male cell lines.

Sclerostin causes the expression of RANKL in osteocytes which regulates osteoclastogenesis. However, this is a pro-disease factor in the development of CAVD [1]. Interestingly, an increase in expression of RANKL non-significantly ($p=0.1271$) correlated with α -SMA (fig 2, left) and significantly ($p=0.0191$) correlated with collagen (fig 2, right). Additionally, RANKL expression increased in males and decreased in females, indicating a potential sex-dependent regulation of this factor.

Figure 2: Pro-disease factor, RANKL, correlates positively with α -SMA expression (left) but negatively with *Col1a1* (right). Triangles correlate with cell lines derived from male mice.

Echocardiographic parameters of CAVD were measured at 4 months of age in sclerostin mutant mice (fig. 3). Male and females differed significantly. With deletion of sclerostin, male mice had increased peak systolic velocity (fig. 3, top left) and mean gradient (fig. 3, top right) trending toward significance ($p=0.2$ and $p=0.07$ respectively) indicating a potential protective effect of the sclerostin on valve health. The opposite was true in females with a trending improvement of velocity (fig. 3, bottom left) and gradient (fig. 3 bottom right) with removal of sclerostin gene, indicating it is potentially a negative regulator of disease in this sex ($p=0.08$ and $p=0.07$ respectively).

Figure 3: Deletion of the SOST gene diminishes valve function in males (top) and improves function in female (bottom).

DISCUSSION

CAVD is a disease that currently affects a significant number of people and will continue to be a public health concern in ageing populations. The lack of an available pharmaceutical treatment due to a poor understanding of the disease process is a major barrier in treating this disease.

This study begins to elucidate the role of sclerostin in CAVD. Sclerostin protein causes a potential shift to a disease phenotype in mAVIC's *in vitro*. There appear to be sex-differences at the cellular level. In human CAVD, females have shown to develop fibrosis while men tend toward calcification. This is supported by the data presented here with sclerostin causing collagen expression increases in female mAVIC's and the opposite for male. RANKL could be a potential regulator as male cells increased expression and females decreased. This tracked positively with α -SMA expression but negatively with collagen, indicating possible involvement of multiple pathways that interact with sclerostin in CAVD. In mice, female aortic valve performance improves with deletion of sclerostin while the opposite is true for males, providing more evidence for potential sex differences.

There are several limitations to this study that lend to future work. RANKL as a mediator of the sclerostin cellular effect is only correlation and needs to be directly investigated. Mouse data is currently not statistically significant. However, four months being relatively early for a full phenotype makes a stronger phenotype at later time points likely.

The role of sclerostin in cardiovascular disease remains unclear. However, this research reveals that this protein may be involved in the sex-dependent initiation or progression of calcific aortic valve disease.

A SPATIAL MEAN CURVATURE MAP OF THE AORTIC VALVE - RELEVANCE TO CALCIFICATION

Amanda Barreto, Asad M. Mirza, Sharan Ramaswamy

Department of Biomedical Engineering
Florida International University
Miami, Florida, United States

INTRODUCTION

Critical calcific aortic valve disease (CAVD) is a health condition which will require prosthetic valve replacement. The disease is expected to increase from 2.5 million cases in 2000 to 4.5 million in 2030 worldwide [4].

Calcification in the aortic valve is a highly regulated process which may be linked to early elastin degradation. For example, the expression of the MMP-12 gene activates inflammation in the valves leading to the fragmentation of elastin in the valve extracellular matrix (ECM), which in turn, may contribute to an increase in calcium deposits, hence leading to critical CAVD [3].

Functionally, the aortic valve is made up of three leaflets that facilitate unidirectional blood flow during systole. Subsequently, in the diastolic period, the leaflets close, thereby preventing blood regurgitation [1]. The deformation of the leaflets leads to a complex mechanical stress distribution through the course of the cardiac cycle, which is difficult to readily monitor.

Here, we hypothesized that tracking of aortic valve leaflet shape could be readily achieved via its time-dependent curvature during the cardiac cycle. The leaflet curvature changes could subsequently be used as a biomarker to assess abnormal valve extracellular matrix (ECM) remodeling activity, a potential precursor to CAVD. As a first step, the objective of the present study was to identify the mean anatomical spatial curvature distribution in an aortic valve without calcified deposits.

METHODS

A 3-dimensional model of a calcific aortic valve was acquired commercially (Materialise Inc, Plymouth, MI). The valve possessed calcific nodules, which were computationally removed to model a healthy valve (Fig 1A. and 1B.). The 3D model of the valve depicted a

temporal position corresponding to the early diastolic period, when it was still slightly open.

Meshlab (ISTI-CNR, Pisa, Italy) was used to subdivide the mesh wherein every edge was split in its midpoint (Fig 1C and 1D). Duplicate vertices were removed and then a Laplacian function was used to smoothen any unevenness in the mesh. The normal values for vertices of the mesh were then calculated using the average of the nearest 10 neighbor vertices. The mesh was then saved in the polygon file format (PLY) for further processing.

An in-house script (MATLAB, Mathworks, Natick, MA) was used to import this mesh and calculate the mean leaflet curvature. The x,y,z data was parametrized to u, v and their respective normal were input into equation (1) below and solved for the principle curvatures (k_{min}, k_{max}) given by Meusnier's theorem [5].

$$k(\varphi) = \frac{e\varphi^2 + 2f\varphi + g}{E\varphi^2 + 2F\varphi + G} \quad (1)$$

where, φ is $\frac{du}{dv} = \tan(\theta)$, (e, f, g) and refers to the inner product of either u, v and their respective normal vector. Similarly, (E, F, G) refers to the inner product of points u, v with themselves. The mean curvature was then calculated as

$$k_{mean} = \frac{k_{min} + k_{max}}{2} \quad (2)$$

Mean curvature quantification was computed along the three cusps of the aortic valve geometry. Specifically, three points were extracted from each leaflet's: free edge, belly region, and close to the aortic wall. This process was performed on both the inflow (ventricularis) and outflow (fibrosa) sides of the valve.

RESULTS

The mean curvature for the ventricularis (A) and fibrosa (B) sides of the aortic valve was computed (Fig. 2). The nearest 50 vertex points at the

center of the region of interest were averaged together to report the curvature values (Table 1) for the various regions of the leaflet (free edge, belly, and aortic wall).

Figure 1: (A) Aortic valve with calcific nodules. (B) Aortic valve after computational removal of calcific nodules. (C) Default mesh. (D) Subdivided by midpoint scheme mesh.

Figure 2: Mean curvature maps across all three leaflets (A) Ventricularis and (B) Fibrosa sides of the aortic valve.

DISCUSSION

The increasing rate of patients experiencing critical CAVD each year demands earlier diagnosis of the disease, to enable more effective patient management. Elastin protein is a key component of the valve’s ECM and plays an important role in its function. The degradation of elastin has been associated with CAVD [3,8]. Since elastin content and

structure contributes towards the leaflet temporal shape during the cardiac cycle, a measure of the valve’s elastin status may be possible via the leaflet curvature, a potential bio-marker for early CAVD detection.

Table 1: Mean Curvature Across Aortic Valve Leaflets of the Ventricularis and Fibrosa Path

Ventricularis				Fibrosa			
	Free Edge	Belly Region	Wall		Free Edge	Belly Region	Wall
Non	.98	.41	.59	Non	1	.55	.37
Right	.99	.25	.53	Right	1	.65	.33
Left	1	.32	.51	Left	1	.49	.35

Our results showed that the mean curvature was relatively high along the free edges of the leaflet on the fibrosa-side (Fig. 2). Our preliminary observations (unpublished) associate much higher mean curvatures with loss of elastin in aortic valve tissues. In addition, the non-coronary cusps exhibited higher mean curvatures compared to the left and right coronary cusps (Fig. 2). The non-coronary cusp has previously been shown to be more susceptible to calcification [7]. Collectively, the current findings suggest that the non-coronary cusp may be a specific leaflet that may be monitored for longitudinal mean curvature tracking, as a measure of elastin content. Particularly, the free edge may be a specific anatomical location that could be targeted, as the current results indicate that its elastin content is relatively low, potentially making it vulnerable to calcification.

While our results give some evidence to the importance of using curvature as a predictive marker for CAVD there were various limitations to our study. We only examined a single early diastolic time-point for the aortic valve geometry. Therefore, an immediate next step in this work will be the evaluation of dynamic curvature changes in the aortic valve leaflets over the cardiac cycle, utilizing an *a priori* identified curvature metric that co-relates strongly with elastin content in the aortic valve.

INTRODUCTION

Tumor invasion, as a critical step in cancer progression and metastasis, requires tumors cell spreading on extracellular matrix (ECM) *in vivo*. Mounting evidence has demonstrated that the physical properties of the ECMs play a key role in cell migration and spreading [1, 2]. It is commonly believed that focal adhesions (FAs), which anchor the cell to the ECM as well as serve as hubs for the exchange of biological and mechanical stimuli [3, 4], are responsible for such mechano-sensitivity of cells.

Cells probe the stiffness of their surroundings by gauging the resistance of FAs to actin retrograde flow generated by intracellular myosin contractions [4, 5]. FAs, acting like molecular clutches, alter the movement of actin intracellular structures by providing a tunable connection to the ECM [5]. Based on this picture, the well-known motor clutch model [5, 6] was developed, which successfully predicted the dependence of cell adhesion traction (and consequently cell spreading) on ECM rigidity.

Beyond substrate rigidity, most natural ECM materials such as collagen, fibrin and tissues are viscoelastic in nature and exhibit a strong frequency-dependent mechanical response. Interestingly, it was reported recently that cell spreading can be enhanced by stress relaxation of a cell culture substrate (e.g., alginate, polyacrylamide), which was dependent on the elastic modulus of the ECM [2, 7]. This was explained by local remodeling (leading to increased ligand density) of the matrix during deformation [2], which corresponds to a plastic rather than viscous response. On the other hand, our own experiments suggest that viscosity has a negligible effect on how cells spread. However, it is unclear how a purely viscoelastic substrate can have different effects on cell spreading. By modifying the motor clutch model, we developed a theoretical model capable of revealing the physical mechanisms governing the cellular response to viscoelasticity.

METHODS

Model description: myosin motors pull the actin filament bundle towards the cell center, generating retrograde flow of actin. The molecular bonds/clutches, connecting the F-actin with the substrate, were assumed to be able to randomly break or re-engage with a dissociation or association rate of $r_{off,i}$ or r_{on} respectively. The master equation describing the evolution of the state of each clutch can be written as:

$$dP_{b,i}/dt = (1 - P_{b,i})r_{on} - P_{b,i}r_{off,i} \quad (1)$$

Engagement of the clutches leads to slowing down of the retrograde flow allowing the polymerization at the leading edge to push the cell membrane forward resulting in the spreading of the cell. Based on the Bell's model, the dissociation rate is expected to increase exponentially with $F_{c,i}$, that is

$$r_{off,i} = r_{off}^0 \cdot \exp(F_{c,i}/F_b), \quad (2)$$

where F_b is a characteristic force and r_{off}^0 represents the breaking rate of clutches in the absence of any force. Recent experiments demonstrated that FAs grow on stiff substrates through the recruitment of integrin to the adhesion complex via talin unfolding [8, 9]. Following the model developed by Elosegui-Artola *et al* that describes such FA reinforcement [9], the association rate r_{on} is replaced by

$$r_{on} = r_{on}^0 (1 + \alpha (F_a - F_{cr})), \quad (3)$$

once the average clutch force F_a has surpassed a force threshold F_{cr} . For viscoelastic ECMs, we modeled as a standard linear viscoelastic solid material, and the force-displacement relation is given by

$$(k_a + k_l)\eta dx_s/dt + k_a k_l x_s = k_a F_s + \eta dF_s/dt. \quad (4)$$

Here k_a and k_l are the additional and long-term stiffness of substrate respectively, while η represents the viscosity for dashpot (Fig. 1a). We use both Kinetic Monte Carlo based on Gillespie algorithm and

analytical solution by solving ordinary differential equation (ODE) to simulate the process of cell spreading. All simulations and analysis were carried out in MATLAB.

Fabrication method: Viscoelastic polyacrylamide gels are fabricated by integrating viscous linear polyacrylamide (5%) in the structure of an elastic cross-linked polyacrylamide network (8%). Viscoelastic hyaluronic acid gels are fabricated by combining covalent and supramolecular crosslinking hyaluronic acid. More details can be seen in the work of Gong *et al.* [10].

RESULTS

By treating the substrate as a standard linear viscoelastic solid (Fig. 1a), we found that an intermediate level of viscosity can promote cell spreading when the ECM rigidity is relatively low. As for high rigidity, the large tension borne by the clutches triggers an increase in their binding rates as well as an increase in the integrin density (clutch reinforcement), which saturates the cell response to substrate stiffness and eliminates any role of viscosity. These data are presented in heat maps of spreading response in the parameter space spanned by the substrate and cellular timescales (Fig. 1b).

The competition between extracellular timescales (ECM relaxation timescales) and intracellular timescales (focal adhesion lifetime and clutch binding timescale) leads to the viscoelastic regulation (Fig. 1a). For low ECM rigidity, maximum cell spreading is achieved at an optimal level of viscosity, where the substrate relaxation time τ_s falls between the timescale for clutch binding τ_b and the characteristic binding lifetime τ_l (Fig. 1c regime II). This is because viscosity stiffens soft substrates on a timescale faster than the clutch off-rate, which enhances cell-ECM adhesion and subsequent cell spreading. Conversely, for stiff substrates (Fig. 1b reinforcement regime), talin unfolding triggers integrin recruitment and viscosity does not influence cell spreading since the number of bound clutches is saturated.

Figure 1 (a) Schematic of the motor clutch model of a cell attached to a viscoelastic ECM modeled as a standard linear solid. (b) Heat map of spreading speed, V_s , plotted as a function of the long-term stiffness, k_l , and viscosity, η , for $k_a = 1$ pN/nm. (c) Schematic of three regimes for effect based on relaxation timescales: I) when $\tau_s \ll \tau_b$, the viscoelastic ECM has the same effect on cell spreading as an elastic ECM with long-term stiffness k_l . II) when $\tau_s \approx \tau_b$, maximum spreading is observed on viscoelastic ECMs. III) when $\tau_s \gg \tau_b$, the viscoelastic ECM gives the same spreading speed as an elastic ECM with the initial stiffness $k_a + k_l$.

To further verify the predictions of our model, we performed cell spreading experiments on viscoelastic ECMs synthesized by different methods. Our model successfully explains the viscoelastic regulation of cell spreading for three completely distinct types of hydrogels (HA, polyacrylamide, alginate) with different ways of imparting viscoelasticity (supra-molecular interactions, semi-interpenetrating network, ionic crosslinking), different stiffness (range from $10^{-1} - 10^1$ pN/nm), and different cell types (human MSCs, 3T3 fibroblasts, U2OS osteosarcoma line). By capturing the mechanism by which substrate viscoelasticity affects cell spreading across a wide range of material parameters, our model provides a useful tool for designing biomaterials that optimize cellular adhesion and mechano-sensing.

DISCUSSION

Most viscoelastic ECMs possess multiple relaxation timescales. To determine which relaxation timescale is most significant, we also developed a practical way to calculate the effective relaxation timescale of viscoelastic ECM regarding their influence on cell spreading. First, relaxation time spectra were obtained from stress relaxation data of viscoelastic substrates. Then, we picked the most significant timescale (i.e., the highest peak for $\tau_s \geq \tau_b$) from relaxation spectrum as the effective timescale. Explicit simulations with multiple timescales confirmed that our choice of the effective timescale faithfully describes the dynamic cell spreading on viscoelastic substrates [10]. In cases where there are multiple prominent relaxation times beyond the binding timescale, simulations show that the resulting cell spreading is approximately a weighted average of the effect for each timescale.

Previous studies suggested that the effects of substrate viscoelasticity on cell spreading are due to local substrate densification and plastic flow [2]. However, these experimental results can be reproduced by our model, demonstrating that viscoelasticity alone is capable of explaining their findings. Overall, we have developed an analytical model that incorporates the viscoelastic relaxation time spectrum and successfully explains the effects of substrate viscoelasticity on cell spreading. It can also help predict cell spreading over the full parameter space for viscoelastic substrates, which will enable the rational design of biomaterials.

INTRODUCTION

Fibrosis is a central component of several untreatable interstitial lung diseases including idiopathic pulmonary fibrosis (IPF), which possesses an average expected patient survival of 3–5 years post-diagnosis [1]. Our current understanding of the progression of fibrosis involves a stepwise cascade whereby tissue damage leads to macrophage accumulation and cytokine release, which in turn triggers the proliferation and differentiation of resident fibroblasts into an expansive myofibroblast (MF) population. Considered the major cellular drivers of fibrotic diseases [2], MFs cause eventual organ failure through excessive extracellular matrix (ECM) secretion, remodeling and crosslinking. The differentiation of fibroblasts into MFs is known to be influenced by both biochemical and physical cues from the tissue microenvironment [3–5]. In particular, it has been suggested that a sufficiently stiff matrix is a prerequisite to MF differentiation; below a threshold matrix stiffness, fibroblasts fail to activate into MFs even in the presence of potent fibrotic soluble cues such as transforming growth factor β 1 (TGF- β 1) [6]. These studies implicate matrix mechanics as a required signal for MF induction, however, previous *in vitro* studies primarily employed 2D elastic culture surfaces to model healthy vs. fibrotic tissues [7]. In contrast, fibroblast-macrophage interactions and MF differentiation occur within the lung interstitium, the fibrous 3D tissue spaces surrounding lung parenchyma. To provide a synthetic model of the interstitium for studying the dynamics of fibrosis, we have developed fiber-reinforced hydrogel composites (FHC) with controllable fibrous microstructure. These materials which support fibroblast and macrophage culture can be degraded and remodeled by cells over time. Using this system, we

examined the effect of 3D fibrous microstructure on myofibroblast differentiation *in vitro*.

Figure 1: Fiber-reinforced hydrogel composite fabrication technique. DexVS fibers are electrospun, UV crosslinked under a photomask used to define fiber length, collected, and encapsulated in user-defined 3D hydrogels at varying fiber

METHODS

Fiber fabrication: Dextran vinyl sulfone (DexVS) was dissolved at 60% w/v in 1:1 water:dimethylformamide with 0.015% Irgacure 2959 photoinitiator and electrospun into a thick fibrous mat. A photomask was used to photopolymerize fiber segments of defined lengths. These fibers were then hydrated, purified by centrifugation, and coupled with cell adhesive ligand RGD at a concentration of 2mM. **Hydrogel encapsulation:** Fibers were resuspended in 5% w/v gelatin methacrylate (GelMA) hydrogel solutions containing cells and 0.02% LAP photoinitiator. **Cell culture:** Human dermal fibroblasts (HDF) and normal human lung fibroblasts (NHLF) were cultured in DMEM with 10% FBS and murine bone marrow derived macrophages (BMDMs) were cultured in RPMI with 10% FBS and 10 ng/ml M-CSF. Cells were encapsulated in GelMA fiber reinforced hydrogels and cultured for 7-14 days with or without 5ng/ml TGF- β 1. Media was

changed every 2 days. **Visualization:** 3D cultures were fixed with 4% paraformaldehyde and immunostained for YAP (Abcam ab52771) and α SMA (Sigma A5228) with counterstaining for cell nuclei (DAPI) and F-actin (phalloidin). 3D image stacks were collected on a Zeiss LSM800 confocal microscope.

RESULTS

To model ECM microstructural changes during the transition from healthy to fibrotic lung interstitium, we generated 3D matrices with a tunable input density of DexVS fiber segments encapsulated in a bulk GelMA hydrogel (**Figure 1**). We cultured human dermal fibroblasts in non-fibrous controls, low (FD 0.5% vol.) and high (FD 1% vol.) fiber density matrices for 7 days in the presence of TGF- β 1, and then stained for F-actin and yes-associated protein 1 (YAP), a transcriptional co-activator previously associated with MF differentiation. Cells in fibrous composites exhibited higher spread area compared to non-fibrous controls, and YAP nuclear localization was nearly two-fold higher at high fiber density (FD 1% vol.) compared to controls (**Figure 2a,b**). Potentially due to YAP-induced proliferation, we also noted increased cell density and multicellular clusters with high fiber density (**Figure 2b**), similar to the fibroblastic foci observed histologically in fibrotic tissues. When culturing normal human lung fibroblasts (NHLFs) for 14 days in the presence of TGF- β 1, we observed significantly greater staining for the MF marker α SMA in fiber-reinforced (FD 1% vol.) compared to control conditions (**Figure 2c,d**).

Figure 2: A) Representative images of HDFs in control or fiber-reinforced hydrogels (day 7) stained for YAP (magenta) and F-Actin (cyan). Cell nuclei outlined in yellow; scale bar: 10 μ m. B) Corresponding quantification of YAP and cell density. C) Images of NHLF α SMA (magenta) expression (day 14) in control and fiber-reinforced hydrogels in the presence of TGF- β 1. DexVS fibers depicted in white; scale bar: 50 μ m. D) NHLF α SMA quantification. * indicates significant difference with p-value < 0.05.

To examine if hydrogel composites could support fibroblast-macrophage interactions that lead to MF differentiation, we performed 3D co-culture experiments with NHLFs and mouse macrophages. After 7 days of co-culture, we noted nearly a 200% increase in α SMA staining in co-cultures as compared to fibroblast monocultures lacking TGF- β 1 supplementation (**Figure 3a,b**). Interestingly, NHLF differentiation into MFs due to macrophage co-culture was more pronounced and occurred faster than in monoculture conditions supplemented with 5ng/ml TGF- β 1 (**Figure 3b**) – the established concentration used *in vitro* to model a soluble profibrotic stimulus.

DISCUSSION

This work introduces fiber-reinforced hydrogels to model the interstitial tissue spaces where fibrotic changes unfold. These composites can be fabricated with a bulk hydrogel of choice,

Figure 3: A) Fibroblast (monoculture, top) and fibroblast-macrophage (co-culture, bottom) encapsulated within FHCs at day 7, showing maximum projections of nuclei (yellow), macrophages (white), F-actin (cyan), and α SMA (magenta); scale bar: 50 μ m. B) Quantification of α SMA staining intensity. * indicates significant difference with p-value < 0.05.

while presenting cells with a highly tunable fibrous topography. Initial findings with dermal and lung fibroblasts are in line with numerous *in vivo* studies correlating fibroblast proliferation and MF differentiation with an increasingly dense fibrous microstructure in the interstitium. In composites with lower fiber density, significant differences in spread area, YAP activity, and cell density relative to non-fibrous controls were not observed (**Figure 2b**). As healthy interstitial tissue is naturally fibrous, low fiber density may reflect a homeostatic ECM architecture. Although only fiber density was explored in this work, future studies employing this model could allow for a more extensive investigation into how 3D fibrous microstructure influences fibroblast and macrophage phenotypes.

While fibroblast monoculture studies have improved our understanding of MF differentiation, previous clinical trials targeting solely MFs were largely unsuccessful in halting disease progression and reducing patient mortality [9,10]. Recent efforts have shifted toward the role of supporting cell types such as macrophages; the first FDA approved drugs for IPF, Pirfenidone and Nintedanib, target innate immunity in addition to fibroblasts [11,12]. The intricacies of how fibrotic ECM affects innate immunity, and how immune cells directly influence resident fibroblast population is not fully understood. This approach enabling long term co-culture of macrophages and fibroblasts in a structurally relevant matrix will support future studies examining dynamic interactions between these cells mediated by the ECM. In summary, this work establishes a biomimetic model of fibrotic interstitial tissue, where physical and soluble fibrotic cues from the microenvironment can be modeled via fibrous ECM and macrophage incorporation, respectively. This model will provide further insight into fibroblast- and macrophage-ECM interactions, and would be a suitable platform for drug screening applications and high-resolution time-lapse microscopy.

ARCHITECTURE AND FUNCTION OF CHICK EMBRYONIC HEART CELLS ARE MEDIATED BY GEOMETRIC ECM PATTERNING CUES

Bernard L. Cook III (1), Patrick W. Alford (1)

(1) Department of Biomedical Engineering
University of Minnesota
Minneapolis, MN, USA

INTRODUCTION

Heart formation begins with migration of bilateral pre-cardiac cell populations towards the embryo's midline (Fig. 1A-1B), a process driven by germ layer sheet folding and cell movements along protein gradients. At the midline, these populations merge to form the primitive linear heart tube (Fig. 1C). Subsequent morphogenesis, or shape change, of the heart tube involves symmetry breaking and bending (Fig. 1D) to eventually produce a functional heart. Disruption of these processes can result in congenital heart defects (CHDs), the leading cause of death in infants younger than one year [1]. Morphogenesis is a fundamentally mechanical process. Extracellular matrix (ECM) protein gradients and cell contractility gradients direct proper migration of and fusion of bilateral pre-cardiac cell populations to fuse at the embryo's midline to form the primitive linear heart tube, respectively [2,3], while actin polymerization is necessary to drive bending of the linear heart tube to adopt a C-shape [4]. Notably, F-actin arrangement of heart tissue varies between the inner and outer curvature of the heart (Fig. 1E-1G) and disrupting this native arrangement can reverse left-right asymmetry decision for heart looping suggesting that local cytoskeletal changes might drive global shape changes [5,6]. Here, we culture embryonic heart cells explanted from chicken embryos onto ECM micropatterns to determine how ECM architecture influences both F-actin arrangement and active force generation.

METHODS

Construct preparation. Custom constructs used for micropatterning cells were prepared. Dow SYLGARDTM 527 polydimethylsiloxane (PDMS) was spin-coated onto glass coverslips.

Micropatterning constructs. PDMS stamps were prepared using standard photolithography techniques. Stamps with aspect ratio 1

Figure 1: A) Pre-cardiac cells (“heart fields” (HF), dotted red) migrate (green) towards embryo midline (yellow). B) HF fold out of plane, continue towards midline. C) HF fuse to form the primitive linear heart tube (HT, red). D) HT bends and rotates to form a C-shape. E) Whole-heart explant stained for F-actin, depicting both inner and outer curvature (IC and OC, respectively). White arrows on left and right highlight F-actin structure at F) OC of heart and G) IC of heart, respectively. Scale: A=600 μ m, B-D=300 μ m, E=30 μ m, F-G=10 μ m.

(AR1) and aspect ratio 4 (AR4) “islands” with areas of $4000\ \mu\text{m}^2$ (AR1: $63\ \mu\text{m} \times 63\ \mu\text{m}$, AR4: $127\ \mu\text{m} \times 32\ \mu\text{m}$) were incubated feature-side-up with $50\ \mu\text{g/mL}$ fibronectin in deionized water for 1 hr at room temperature. Excess fibronectin solution was removed from the stamps, and then stamped onto UV-treated custom constructs. Constructs were blocked with 1% pluronics for 5 min.

Preparation of chicken embryos & heart explants.

Fertilized White Leghorn chicken eggs were incubated on their side in a humidified, 38.5°C environment for 46-56 hrs to yield embryos at Hamburger & Hamilton stages 9-14. Filter paper hole-punched with a “figure-8” pattern was gently set on top of the vitelline membrane surrounding the embryo and allowed to adhere. Then, cuts through the vitelline membrane were made around the filter paper to remove the embryo and vitelline membrane attached to the filter paper. The embryo was rinsed in PBS and placed in a 35 mm tissue culture dish with 1 mL of ice-cold PBS for further dissection. Hearts were explanted under a Lumar dissection scope. To remove hearts, microdissection scissors were used to make incisions through the omphalomesenteric veins and the primitive conus (Fig. 1B, labeled “OV” and “C,” respectively; cut lines shown in blue). All explanted hearts were placed in 4°C Dulbecco’s Modified Eagle’s Medium (DMEM) in a microcentrifuge tube before further processing.

Heart cell extraction & seeding constructs. Heart explants were further digested prior to seeding cells onto stamped constructs. Explants in DMEM were centrifuged, media removed, and resuspended in 0.25% trypsin-EDTA warmed to 37°C for further digestion. Heart cells were then seeded onto stamped constructs in DMEM supplemented with 10% chick serum and 1% penicillin-streptomycin. Cell-seeded constructs were incubated at 37°C in a humidified, 5% CO_2 environment until they were ready to be assessed.

Immunohistochemistry & cell structure quantification.

Cell structure on both AR1- and AR4-stamped constructs was assessed at both 4 and 24 hrs post-seeding. Cells were fixed with 4% PFA and stained with phalloidin and DAPI to assess F-actin structure and nuclei, respectively. Cell islands were imaged on an inverted fluorescent microscope. F-actin alignment for individual micropatterned islands was determined by applying a custom MATLAB code to F-actin fluorescent images.

Traction force calculation. Cell traction forces were determined using standard traction force microscopy (TFM) techniques [7]. Briefly, fluorescent nanoparticles were embedded in custom PDMS constructs. Constructs were stamped with ECM micropatterns and seeded with cells as described. Using an inverted fluorescent microscope, fluorescent bead layers beneath cell islands were imaged with cells and without cells to capture with-cell and cell-free bead images. Particle image velocimetry (PIV) and Fourier transform traction cytometry (FTTC) plugins in ImageJ were applied to with-cell and cell-free bead images for individual islands to determine cell traction forces.

RESULTS

Heart explant cells remained viable in culture for 24 hrs as observed by beating of patterned islands (data not shown). Cells cultured for 4 hrs possessed interconnected F-actin “rings” surrounding individual nuclei (Fig. 2A, first column) on both AR1 and AR4 fibronectin islands, characteristic of epithelial cells and evident in stained whole-hearts (Fig. 1C). However, cells cultured for 4 hrs often did not span the entire area of ECM islands. Cells cultured for 24 hrs had less-apparent F-actin rings surrounding individual nuclei. Moreover, cell islands appeared to more thoroughly adopt the fibronectin island shape and possessed F-actin filaments spanning over nuclei, suggesting out-of-plane growth and remodeling.

Figure 2: A) Embryonic heart cells cultured on aspect ratio 1 (AR1, top row) and aspect ratio 4 (AR4, bottom row) ECM islands stained for F-actin (green) and nuclei (blue) after 4 and 24 hours in culture (left and right columns, respectively). B) F-actin alignment of cell islands. Scale in A) = $20\ \mu\text{m}$.

Alignment data suggests that AR4 cell islands undergo F-actin remodeling between 4 and 24 hrs in culture, while AR1 cell islands undergo little to no remodeling (Fig. 2B). Cells patterned on AR1 islands have nearly isotropic alignment and undergo little remodeling in the plane of the cells. F-actin in cells patterned on AR4 islands is primarily aligned with the long-axis of the island after 4 hrs in culture and undergoes substantial remodeling to align more strongly with the long axis of the ECM island after 24 hrs in culture.

DISCUSSION

Here, we found that embryonic chick heart cells cultured on fibronectin ECM islands adopt F-actin alignment and remodel F-actin dependent on ECM island shape. Cytoskeletal structure responds to ECM shape, and informs active cell-generated forces. Studies show that extracellular architecture influences cytoskeletal structure and active force generation in individual cells and embryos [8,9]. Taken in context of such studies, our results suggest that ECM geometrical constraints influence F-actin alignment and may influence cell-generated forces and morphogenetic behavior of the heart. Understanding how ECM shape cues guide F-actin structure and cell-generated forces may help explain heart morphogenesis phenomena like existence of endodermal contraction gradients responsible for fusion of cardiac fields and actin-driven C-bending of the linear heart tube. Future work seeks to determine how differences in ECM shape influence cell-generated forces.

INTRODUCTION

Chiari malformation type 1 (CMI) is a neurological syndrome that is diagnosed when the tonsillar position (TP) is below the foramen magnum [1]. Individuals with CMI are known to experience a wide range of symptoms, notably occipital headaches, neck pain, sleep apnea, dysphagia, dropping attacks, dizziness, photophobia and balance problems [2]. While a TP below the foramen magnum is considered to be radiological evidence for CMI, recent studies have shown that TP alone may not be sufficient to identify individuals with symptomatic CMI. Smith et al. reported 1–2% of individuals with TP greater than 5 mm but no CMI symptoms [3]. Strahle et al. found 10 times more asymptomatic individuals with a TP greater than 5 mm than symptomatic CMI individuals [4]. Due to inconsistencies between TP and identification of symptomatic CMI, several studies have examined various brain morphometrics in an effort to find additional markers that are unique to CMI subjects [5,6].

In this study, we assessed the dysmorphism and volumetric differences in the 3D morphology and spatial position of the clivus and sphenoid sinus in CMI and control subjects. We hypothesized that 3D clival parameters are significantly smaller in CMI subjects as compared to control subjects. In addition, we explored the aeration of the sphenoid sinus and the area of the sella turcica for CMI subjects and controls.

METHODS

Computed tomography (CT) images of 30 adult females diagnosed with CMI (age = 34.4 ± 7.9 yrs. [mean \pm standard deviation], BMI = 33.5 ± 9.4) and 30 control subjects matched by age and BMI (age = 35.3 ± 9.2 yrs., BMI = 34.5 ± 7.1) were evaluated. All patient information including demographic data, health-related data, and CT scans were voluntarily submitted by the CMI subjects through the *Chiari1000* project [5]. All the CT scans were de-identified and void of patient data. An OsiriX DICOM PACS server (Pixmeo SARL, Geneva, Switzerland) was used to store and process the CT scans at The University of Akron. Control CT scans were received from the Cleveland Clinic (Cleveland, Ohio) after Institutional Review Board (IRB) approval (#18-250).

Due to variations in head orientation during the CT image acquisition, image registration was performed on each image set such that skull position and orientation were in the same 3D plane with respect to a reference image set (Fig. 1). By aligning the images in the

same 3D plane before comparison, any differences in the position of the clivus or sphenoid sinus that were due to head orientation during the CT image acquisition were eliminated. The clivus and sphenoid sinus were manually segmented on the registered 3D CT image sets using the open source software ITK-SNAP (see Figure 2).

Figure 2. A typical image: (a) before and, (b) after registration.

Figure 1. Screenshot from ITK-SNAP during segmentation of the clivus and sphenoid sinus: a) axial view of the clivus bone, b) sagittal view of the clivus, c) coronal view of the clivus, d) axial view of the sphenoid sinus, e) sagittal view of the sphenoid sinus, and f) coronal view of the sphenoid sinus.

A total of 18 parameters were measured for the clivus, sphenoid sinus, and sella turcica. Nine parameters were measured for the clivus (i.e., volume; surface area; difference in spatial position of the centroid (x-, y-, and z-axis) for CMI subjects compared to the centroid of the controls; width; thickness; height; and length). Clivus length was measured using *ITK-SNAP*. The other eight measurements of the

clivus—which included volume; surface area; spatial position in the x-, y-, and z-axis; width; thickness; and height—were conducted using the *regionprops3* function in MATLAB (MathWorks, Natick, MA) and an in-house software developed in MATLAB.

Measurements for the eight parameters of the sphenoid sinus were conducted in a manner similar to those for the clivus. The final parameter examined was the area of the sella turcica. The sella turcica—identified as the area that extends from the base of the pituitary fossa up to the line connecting the tuberculum sella and the dorsum sellae—was traced in the midsagittal plane as shown in Figure 3.

RESULTS

Of the 18 parameters analyzed, 11 parameters were found to be significantly different in CMI subjects as compared to controls: six for the clivus, four for the sphenoid sinus, and one for the sella turcica (as shown in Table 1). A consistent trend was noticed for the clivus, where the size of the clivus in CMI subjects was smaller overall. This trend can be clearly seen in Figure 3, which shows a side-by-side visual comparison of the clivus of a typical CMI subject and that of a control with a similar age and BMI. The opposite trend was seen for the sphenoid sinus, where the sphenoid sinus was larger in CMI subjects. Most notably, our measurements revealed the clivus volume to be 31% smaller in CMI subjects as compared to controls. In contrast, the sphenoid sinus was found to have a 38% larger volume in CMI subjects as compared to controls. In addition, the sella turcica area was found to be 27% smaller in CMI subjects compared to controls.

Table 1. Morphometrics for CMI subjects and controls (differences are reported as mean values for CMI subjects subtracted from those of controls).

Parameters	Chiari	Controls	p
	Mean (SD)	Mean (SD)	
Clivus volume (cm ³)	9.7 (2.3)	14 (2.9)	< 0.01
Clivus surface area (cm ²)	5.2 (0.8)	7.2 (1.1)	< 0.01
Clivus length	42.1 (4.3)	46.6 (3.7)	< 0.01
Clivus width (mm)	44.3 (3.2)	47.2 (2.9)	< 0.01
Clivus thickness (mm)	37.4 (4.9)	46.8 (9.4)	< 0.01
Clivus height (mm)	36.3 (4.9)	39.1 (3.2)	0.01
Sphenoid sinus volume (cm ³)	9.3 (3.0)	6.7 (1.9)	< 0.01
Sphenoid sinus surface area (cm ²)	4.0 (1.0)	3.2 (0.7)	< 0.01
Sphenoid sinus thickness (mm)	33.7 (5.7)	28.9 (4.9)	< 0.01
Sphenoid sinus height (mm)	23.4 (3.4)	20.3 (2.1)	< 0.01
Area of sella turcica (mm ²)	69.7 (22)	95.1 (24)	< 0.01

Figure 3. Side-by-side comparison of CT sagittal view of the sphenoid sinus in a CMI subject (left) and an age- and BMI-matched control (right): Lateral view of (a) sphenoid sinus and (b) clivus for the CMI subject. Lateral view of (c) sphenoid sinus and (d) clivus for the control. The red dashed line shows the trace line used to determine area of the sella turcica: TS, tuberculum sella; DS, dorsum sella; the area labeled as # in the image at the left represents invagination of the clivus in the CMI subject.

DISCUSSION

This study identified osseous morphometric differences in several cranial structures (the clivus, sphenoid sinus, and sella turcica) between CMI subjects and controls. The first significant finding from our analysis was a smaller clivus volume in CMI subjects. This finding of a reduced clivus volume in CMI has not been reported in the literature to date. The importance of such a finding is unclear, although it does follow the trend of previous reports of underdeveloped osseous structures in CMI subjects such as shorter clivus length and a smaller posterior cranial fossa [1]. Although previous studies have not quantified clivus volume in CMI subjects, there is evidence that the abnormally small PCF in CMI implicates cranial constriction as the most likely cause for the extension of the cerebral tonsils below the foramen magnum [7]. Clivus length was also found to be significantly smaller in CMI subjects (4.5 mm shorter) compared to controls in the present study; this result is supported by previous reports in the literature [1,5]. While a shorter clivus length in CMI subjects is well established, some studies reported no statistical differences [8]. Based on the 3D morphometric analysis, we found the clivus to have a significantly reduced width in CMI subjects as compared to controls. Milhorat et al. also reported a smaller clival width in CMI subjects [7].

During the analysis of the clivus, a consistent trend was visualized in CT images of CMI subjects: invagination of the anterior clivus was observed, which increased the pneumatization of sphenoid sinus anterior to the clivus. To quantify the increased pneumatization, the sphenoid sinus 3D morphology was evaluated in the present study. Interestingly, the volume and surface area of the sphenoid sinus were found to be 38 and 24% larger, respectively, in CMI subjects as compared to controls. The sphenoid sinus volume of 6.7 cm³ for the controls in our study is similar to the value of 7 cm³ reported by Yonetsu et al. [9]. Overall, the results herein are novel, as no studies in the literature have reported the clivus volume, sphenoid sinus volume, and sella turcica area differences for CMI subjects as compared to controls. These findings can serve as additional diagnostic criteria for CMI.

In conclusion, 3D morphology of the clivus and sphenoid sinus is significantly smaller in CMI subjects when compared to controls. In addition, the centroid position of the clivus and sphenoid sinus were shown to be similar in CMI subjects and controls. These results confirm our hypothesis that 3D clival parameters are significantly smaller in CMI subjects as compared to controls. Future work should focus on investigating how the 3D morphology of osseous structures can further our understanding of the pathophysiology of CMI.

INTRODUCTION

Tissues in the musculoskeletal system are continuously subjected to mechanical forces that regulate homeostasis during normal tissue function [1-3] and in degeneration and regeneration after injury [4-5]. We recently posited that this same mechanical environment could be used to control drug release and enable the therapeutic delivery of molecules when needed, leading to improved outcomes and faster healing. To that end, we developed mechanically-activated microcapsules (MAMCs) for on-demand drug delivery using a custom micro-fabrication system [6]. Here, we extended the application of this new technology by developing a suite of MAMCs with different mechano-activation and degradation profiles, and probed the stability of their mechano-activation after culture in physiologic environments, including residence *in vivo* (subcutaneous implantation) and in the context of maturing tissue engineered constructs.

METHODS

Spherical MAMCs were fabricated using a glass capillary microfluidic device [5]. An inner solution of bovine serum albumin (BSA) (with Alexafluor488-BSA for visualization) was used as a model drug while the middle phase contained 85:15 poly (lactic co-glycolic) acid (PLGA) (with Nile Red for visualization). MAMCs were collected in various molar solutions of NaCl. This was done to increase collecting solution osmolarity and cause capsule shrinkage during hardening (osmotic annealing) (**Fig. 1A**). After hardening, MAMC diameter and shell thickness were measured using confocal microscopy (**Fig. 1B-C**). To evaluate microcapsule mechano-activation, MAMCs were subjected to compression between parallel plates at 0.5% strain/sec. to loads of 0.25-5N, with rupture assessed via confocal microscopy (**Fig. 1D**).

To probe MAMC mechano-activation in a 3D 'repair'/tissue maturation model, small (D: 30.7 μ m, t: 2.8 μ m) and large (D: 54.5 μ m, t:

1.6 μ m) MAMCs (at 1.2x10⁵ MAMCs/mL per type) were embedded into a 2% agarose hydrogel along with bovine MSCs (60x10⁶ cells/mL). Cylindrical constructs (ϕ =4mm, t=2.25mm) were cultured for 5 weeks in chondrogenic media (+TGF- β 3) (**Fig. 2A**). At 1 and 5 weeks, constructs were subjected to Live/Dead staining, sectioned and stained for glycosaminoglycan (GAGs, Alcian Blue) and collagen (Picrosirius Red) content, and tested for mechanical properties [6]. Additional samples were dynamically compressed between parallel plates (from 2-20% strain at 5Hz) for 1 or 5 hrs. and subsequently imaged to determine mechanically-induced release of MAMC contents (**Fig. 2B-F**).

In another study, MAMC stability was analyzed in basal media (with 10% FBS) and bovine synovial fluid *in vitro* for up to 28 days at 37°C (**Fig. 3A-B**). To investigate MAMC stability in a physiological environment, small or large MAMCs were embedded in 500kPa PEGDA hydrogels at 0.2% v/v and implanted subcutaneously in athymic rats for up to 28 days (**Fig. 3C**). At day 7 and 28, rats were sacrificed and hydrogels were extracted and imaged, after which they underwent dynamic compression as previously described (**Fig. 3, C-D**) to probe their retention of mechano-activation.

Normally distributed data was analyzed by one-way or two-way ANOVA followed by Tukey's post-hoc; non-normally distributed data was analyzed via Kruskal-Wallis test with Dunn's Multiple Comparison or Bonferroni post-hoc.

RESULTS

MAMCs of different thickness and diameter were prepared through controlled osmotic annealing. Those with thicker shells and smaller diameters (i.e. higher t/D ratio) had an increased resistance to rupture (**Fig. 1C-D**). MSC-laden constructs matured over time, as illustrated by an increase in GAG and collagen staining around encapsulated MAMCs (**Fig. 2C**). The construct equilibrium modulus

increased from $17.8 \pm 4.7\text{kPa}$ at week 1 to $149.2 \pm 20.5\text{kPa}$ at week 5. This increased matrix stiffness resulted in greater activation of MAMCs within constructs when subjected to 5 hrs. of dynamic loading on day 28, with larger MAMCs remaining more sensitive to load (Fig. 2E) compared to smaller MAMCs (Fig. 2F). Large MAMCs were less stable over time *in vitro* in synovial fluid, while small MAMCs remained patent (and retained their inner contents) over a 28-day period in all solutions (Fig. 3A-B). A similar trend was observed with MAMCs implanted subcutaneously, yet by 28 days, a greater percentage of MAMCs of both sizes had lost patency compared to *in vitro* incubation (Fig. 3C). However, large MAMCs continued to rupture more than small ones after 5 hrs. of dynamic compression (Fig. 3, E).

Figure 1: MAMCs were fabricated and collected in solutions +/- NaCl for osmotic annealing (A). This generated MAMCs with differences in diameter (d) and shell thickness (t), which were observed via confocal microscopy (B) (scale bar = 100μm) and quantified (C). Direct compression of MAMCs showed an increased resistance to rupture under load with increasing t/D ratios (D). (* p<0.05 vs. 0 hrs, # vs. 30.7/2.8μm)

DISCUSSION

In this study, we expanded the range of microcapsule dimensions that could be produced, creating a suite of MAMCs with a wide range of mechano-sensitivity and stability profiles. Furthermore, we demonstrated the utility of MAMCs in a healing, matrix growth and maturation setting by showing higher activation of MAMCs upon sufficient matrix deposition (compared to little activation before matrix production). MAMCs in cell-laden constructs did not alter cell viability or hinder matrix production, and these co-encapsulated MAMCs retained their contents throughout culture. We also evaluated, for the first time, MAMC stability in an *in vivo* setting. Varying MAMC size and shell thickness resulted in different MAMC stability profiles with *in vivo* incubation, with higher t/D MAMCs demonstrating higher stability both *in vitro* and *in vivo*. Taken together, these data demonstrate the potential of this MAMC technology for on-demand mechanically-mediated drug delivery. Utilizing MAMCs with different rupture profiles could enable the sequential delivery of different therapeutic molecules necessary at different stages of healing and regeneration, providing improved tissue repair and more rapid return to function.

INTRODUCTION

Understanding growth and changes in tissue morphology over time is useful for designing treatments and therapies after injury of mechanically loaded tissues. Finite element (FE) modeling offers one way to simulate 3D musculoskeletal tissue growth and study how it is affected by biological and biomechanical conditions. Tissue growth has been simulated using node-based (e.g. thermal expansion [1,2]) and element-based approaches (e.g. osmotic swelling [3]) as mechanisms to serve as surrogates to model biological processes such as cell division. Despite the usefulness of both approaches, it is unclear how to directly relate the coefficients governing node- and element-based growth. To develop comparable models and aid in interpretation across models, it would be useful to determine the mathematical relationship between the two approaches. According to thermal expansion theory, the volumetric thermal expansion coefficient (α_V) is equal to 3x the linear thermal expansion coefficient (α_L) for a given isotropic material [4]. We propose that this principle will hold, such that the coefficient implemented in the element-based (volumetric) model must be 3x the coefficient used in the node-based (linear) model to cause similar growth. Additionally, existing element-based approaches implement growth within a constitutive model [3] while the existing node-based approach does not [1]. Correspondingly, we hypothesize that tissue material properties will affect comparisons across models, with stiffer materials restricting growth in the element- but not the node-based model. Therefore, the objective of this study was to determine under what conditions existing element- and node-based growth approaches produce comparable results and to assess the impact of modulus on these comparisons.

METHODS

Element-based FE models of tissue growth based on existing literature were developed in FEBio (v.2.6.4) [5] via osmotic swelling

[3] using Equation (1), in which an increased ratio of internal (C_r) to external solute concentration (C_E) with constant solid volume fraction (ϕ) causes an expansion (ΔV) of elemental volume (V).

$$\Delta V = V * (C_r / C_E - \phi - 1) \quad (1)$$

Node-based FE models were developed in Abaqus (v.6.13) via the mechanism of thermal expansion [1,2] using Equation (2), in which increased temperature (ΔT) with linear thermal expansion coefficient (α_L) causes expansion (ΔL) of the distance (L) between nodes.

$$\Delta L = L * \alpha_L * \Delta T \quad (2)$$

To relate the models, Equation (1) was equated to the volumetric thermal expansion as shown in Equation (3), with volumetric thermal expansion coefficient (α_V).

$$\Delta V = V * \alpha_V * \Delta T \quad (3)$$

The system was solved for C_r with $\phi = 0$, and the relationship shown in Equation (4) was derived and implemented in the element-based model.

$$C_r = C_E (\alpha_V * \Delta T + 1) \quad (4)$$

In both models, a rudiment composed of a cylinder with a hemispherical end was used as the initial geometry (Fig. 1). Growth stimulus was applied as a linear function of normalized distance along the rudiment (Fig. 1), and implemented through Equations (1) and (4) as a temperature differential (ΔT).

To compare node-based to element-based growth, the element-based model was run with expansion coefficients, α_V , equal to 1x, 2x, 3x, 4x, and 5x the α_L (0.08) of the node-based model, with modulus of 1 kPa. To evaluate the effect of material properties, elastic modulus was varied from 1kPa to 1GPa, using the conversion ratio from the prior simulations resulting in the minimum difference between the element- and node-based models.

All simulations were iterated through 10 growth cycles. Maximum height and width of the rudiment were recorded after each cycle, and percent differences were calculated between the models.

Figure 1: (A) Growth stimulus ($\Delta T(y)$) was implemented as a linear function of normalized distance along the rudiment. (B) A simple rudiment geometry was simulated through element-based and node-based growth for 10 cycles of growth.

RESULTS

Rudiment heights in element- and node- based models were most similar in simulations when the element-based growth coefficient was 3x the node-based growth coefficient (Fig. 2). Element-based predictions were 14%, 4%, and 8% different in height compared to node-based simulations for 2x, 3x, and 4x coefficients, respectively (Fig. 2B). Rudiment widths were also most similar between the two models for simulations when the element-based growth coefficient was 3x the node-based growth coefficient. However, widths were nearly as similar between the models when the element-based growth coefficient was 4x the node-based coefficient. Element-based predictions were 20%, 7%, and 8% different in width compared to node-based simulations for 2x, 3x, and 4x coefficients, respectively (Fig. 2C).

Figure 2: (A) Rudiment geometry after 10 cycles of growth. Rudiment height (B) and width (C) after 10 cycles of growth with element-based growth coefficient equal to 1x, 2x, 3x, 4x, and 5x the node-based growth coefficient.

Over the tested modulus range of 1 kPa to 1 GPa using a 3x coefficient, element-based growth decreased in a sigmoidal manner as modulus was increased, with growth decreasing most from 0.1 MPa to 10 MPa (Fig. 3). Node-based growth was unaffected by modulus. Predictions between models were most similar at low modulus

($E=1\text{kPa}$), with 4% and 7% differences in height and width, respectively, after 10 cycles (Fig. 3B-C).

Figure 3: Modulus influenced growth in element but not node-based models. (A) Rudiment geometries after 10 cycles of growth. Rudiment height (B) and width (C) after 10 cycles of growth for varying modulus values.

DISCUSSION

In this study, we simulated musculoskeletal tissue growth using existing element- and node-based approaches, compare growth between the two approaches, and studied the effect of material properties on growth. We found that to create comparable element- and node-based models of growth, osmotic swelling should use an expansion coefficient that is approximately 3 times the expansion coefficient for linear (node-based) thermal expansion. This is consistent with volumetric versus linear thermal expansion theory [4]. The element-based model experiences slightly less growth than the node-based model at this coefficient value, likely because elements are additionally constrained by growth of adjacent elements while nodes move independently.

Further, we found that high tissue modulus restricted growth in the element-based, but not node-based, model, since the element-based approach implements growth within a constitutive model relating stress and strain, while the node-based approach does not. This allows growth in the element-based approach to be influenced by local and neighboring tissue stiffness. Thus, care must be taken to use low modulus values during growth simulations if comparisons are to be made to node-based approaches. Future work will extend these computational approaches to study growth of biological tissues and investigate how growth of musculoskeletal tissues is affected by mechanical stimulation.

INTRODUCTION

Each year, more than 40,000 people in the United States undergo surgery for mitral valve (MV) repair, frequently as a treatment for mitral regurgitation brought on by myocardial infarction (MI) [1]. Currently, the preferred method for repairing the MV is through the insertion of an annuloplasty ring, which constricts the mitral annulus sufficiently for the leaflets to coapt and thus for valve function to be restored. Long-term efficacy of this repair procedure remains a major challenge, however. A full 30% of patients experience recurrence of ischemic regurgitation within 6 months of surgery, and more than 60% have regurgitation within five years [2]. Repair failure is primarily attributed to changes in the geometry of the MV annulus, whose shape is severely altered post-MI and during ring implant, as well as to permanent displacement of the papillary muscles, which coincides with post-MI left ventricular distention [3]. These dramatic changes cause stress overload throughout the valve apparatus, leading to irreversible leaflet tissue damage, and ultimately the return of ischemic regurgitation [4].

In addition to altered loading, growth and remodeling in the MV following MI and after surgery undoubtedly also play a major role in determining the success or failure of repair. Recent work has uncovered evidence of significant cell activation and matrix turnover in the MV leaflets following MI [5]. Due to the established causal link between tissue strain and cell-driven remodeling mechanisms [6], a detailed account of tissue-level deformation patterns in the post-MI MV can provide substantial insight into the current biosynthetic state of the valve. In the present study, we examined how the *in vivo* diastolic and systolic geometry and deformation patterns of the MV change after MI, in an effort to gain a deeper understanding of the driving factors behind post-MI valvular remodeling. This foundation is an essential prerequisite for future efforts to design, optimize, and simulate novel MV repair devices and surgical strategies on a patient-specific basis.

METHODS

Following established protocols [7], real-time three-dimensional echocardiography (rt-3DE) images were acquired from eight non-diseased adult Dorset sheep. Each subject was imaged pre-MI, immediately post-MI ($t = 0$ wk), four weeks post-MI ($t = 4$ wk), and eight weeks post-MI ($t = 8$ wk). At each time point, representative end-diastolic and end-systolic images of each subject were traced in parallel cross-sections spanning the MV from commissure to commissure, with the annulus, individual leaflets, and coaptation zone labeled separately. Starting from the segmented end-diastolic rt-3DE image of each MV, we constructed subject-specific meshed geometries of the entire leaflet surface, including both the annular and leaflet free-edge boundaries. The end product of this processing step was a complete subject-specific leaflet geometry for each specimen (Figure 1). Circumferential and radial material directions were then defined as in Rego et al. [8].

Figure 1: Pipeline for MV geometric modeling, starting from non-invasive rt-3DE images of the valve.

To determine systolic deformation fields across the entire MV leaflet surfaces non-invasively, we utilized a previously validated image-based strain estimation method developed by our group [8], which yields local strain information directly from clinical-quality *in vivo* images (Figure 2). Essential features of our approach are that it does not require knowledge of the MV chordal structure nor exact mechanical properties, which cannot be extracted from rt-3DE. Moreover, our method does not rely on physical markers to extract surface deformations; we thus did not require any material point correspondence between open-state and closed-state images when estimating systolic strains. Instead, we exploited the fact that the gross subject-specific closed-state geometry of the leaflets can be precisely acquired from systolic scans, and developed the following method to enforce this closed shape during a finite element (FE) simulation of MV closure: While pressurizing the open-state valve mesh, we penalized any mismatch between the simulated and true (i.e. imaged) closed shapes of the leaflets using a local corrective pressure field (LCPF), which was at any instance and location linearly proportional to the shortest distance between the FE mesh and the true MV medial surface (Figure 2). In this way, the LCPF locally “pushes” regions of the MV so that the imaged closed-state geometry was matched.

Figure 2: (a,b) Snapshots of a simulated valve throughout a FE simulation with shape enforcement, in 3D and 2D.

(c) Coordination of boundary conditions and loads that are applied to ensure proper closure and shape enforcement.

To estimate strains between two subject-specific diastolic scans (from different time points), the same strain estimation method was applied, only without atrioventricular pressurization. To allow for both biomechanical and clinical interpretations, all systolic strain fields were then expressed with respect to both pre-MI and current diastolic states.

RESULTS

Analysis of rt-3DE images showed that the MV annulus is substantially dilated post-MI, consistent with previous findings [9]. Moreover, both leaflets were severely tethered post-MI, causing them to exhibit greater tenting in closure (Figure 3). Paired t-tests revealed that at $t = 4$ wk and $t = 8$ wk, both annular orifice area and leaflet surface area were significantly greater than their pre-MI values, with average increases of 20% and 16% respectively ($p < 0.05$ for all).

Figure 3: Post-MI changes in annulus and leaflet shape over time.

These MI-induced effects propagated throughout both leaflets to yield substantial changes in strain patterns. Following MI, *diastolic* stretches in both circumferential and radial directions changed substantially, though with significant regional heterogeneity, and mostly stabilized by $t = 4$ wk (Figure 4). In *systole*, when referenced to the pre-MI diastolic configuration, directional stretches remained largely unchanged over much of the leaflet (Figure 5, top). Referenced to the current time's diastolic configuration, however, systolic stretches became time-dependent (Figure 5, bottom), suggesting that the MV's post-MI remodeling is driven mostly by alterations in diastole.

Figure 4: Diastolic directional stretch fields over time.

Figure 5: Systolic radial stretch, with respect to both pre-MI and current diastolic configurations.

DISCUSSION

Our results shed significant light on the post-MI state of the MV. Interestingly, while the valve underwent drastic changes in both geometry and mechanical behavior following MI, most of these appear to stabilize over about four weeks. Mechanistically, the results suggest that the MV mostly responds passively to MI over this initial period, undergoing a permanent deformation induced by altered boundary conditions. Further investigation is required, however, to establish whether remodeling occurs over longer time scales post-MI. In our ongoing work, we are building upon the present study to investigate how fiber architecture, tissue composition, and biosynthetic activity in the MV change following MI, which will allow us to draw connections between tissue-level deformations and cellular behavior *in vivo*.

A MACHINE LEARNING MATERIAL MODEL FOR SOFT TISSUE REMODELING

Wenbo Zhang (1), Tan Bui-Thanh (2), Michael S. Sacks (1)

<p>(1) Willerson Center for Cardiovascular Modeling and Simulation Institute for Computational Engineering and Sciences Department of Biomedical Engineering The University of Texas at Austin Austin, TX, USA</p>	<p>(2) Department of Aerospace Engineering and Engineering Mechanics Institute for Computational Engineering and Sciences The University of Texas at Austin Austin, TX, USA</p>
--	---

INTRODUCTION

When complex mechanical behaviors are involved, the high-fidelity mesoscale/multiscale methods for soft tissue constitutive models are attractive and predictive but are also computationally very demanding. Traditional phenomenological models have simple forms based on physical insight, but they often lack the ability to be predictive. For example, for remodeling of the bioprosthetic heart valve (BHV), predictive structural constitutive models have been developed for time independent and time evolving properties of exogenously crosslinked collagenous soft tissues under cyclic loading [1,2]. To simulate novel BHV designs or further identify underlying mechanism, efficient computational methods are crucial.

Neural networks approaches are an attractive alternative attention because of their high representation capability, flexible designs, and high speed when properly trained. To this end, we investigated possible approaches to build a neural network (NN) model that can replicate the responses of detailed structural models for soft tissue with manageable computational costs. The fact that the NN model was trained on analytical model instead of experimental data helped to implicitly impose proper regularization so that the fitting problem was well-defined. In this paper, we considered a particular analytical model, i.e. a recently developed full structural model for cross-linked soft tissue [2].

METHODS

The structural model for cross-linked tissues [1,2] has three contributions from the matrix, the collagen fibers, and the fiber-fiber interaction,

$$\Psi_{cro} = \Psi_{mat} + \Psi_{col} + \Psi_{int}. \quad (1)$$

The matrix term is a modified Yeoh model. The collagen term is an ensemble average over the fiber orientation distribution function (ODF) Γ_n , and the recruitment distribution function (RDF), Γ_s ,

$$\Psi_{col} = \phi_{col} \eta_c \int_{\theta} \Gamma_n(\theta) \int_1^{\lambda_n} \Gamma_s(\lambda_s) \left(\frac{\lambda_n}{\lambda_s} - 1 \right)^2 d\lambda_s d\theta. \quad (2)$$

where, ϕ_{col} is the mass fraction of matrix, η_c is the modulus of the collagen fibers, $\lambda_n = \sqrt{n \cdot \mathbf{C} \cdot n}$ is the stretch in $n = n(\theta)$ direction, λ_s is the slack stretch, λ_n / λ_s is the true stretch after collagen fibers are straightened. The interaction term, Ψ_{int} , is more computational costly since it involves a quadruple integral. To accurately compute the quadruple integral with tensor product quadrature rule, it requires $21^4 = 194481$ quadrature nodes. This gives rise to the need of an efficient surrogate model that can replicate the behavior of the structural model while respect the fundamental physical principles.

To be physically meaningful, Ψ needs to be non-negative everywhere. The tangential stiffness matrix $\mathbf{C} \in \mathbb{R}^{3 \times 3}$, is symmetric and positive definite everywhere $\mathbf{C}(\mathbf{E}) \in \mathbb{S}_{++}^3$, $\forall \mathbf{E}$. Also, the material frame indifference is automatically satisfied as long as we are using \mathbf{E} , which is defined on the reference configuration.

Then, this becomes a function approximation problem. Since the stress-to-strain map is continuous and we can restrict its support to a compact set in \mathbb{R}^3 , it is feasible to use the single/multi-layer perceptron for function approximation by the universal approximation theorem.

$$\begin{aligned} &\text{find} \quad \tilde{\mathbf{S}}(\mathbf{E}), \\ &\text{min} \quad \frac{1}{|I_{tr}|} \sum_{i \in I_{tr}} (\tilde{\mathbf{S}}(\mathbf{E}^{(i)}) - \mathbf{S}^{(i)})^2. \end{aligned} \quad (3)$$

The design of the NN model is shown in Figure 1. We use one hidden layer with 21 neurons with the sigmoid function as activation function and post-multiply the third component of the output by the shear strain to control the oscillation effect.

Figure 1: The neural network for strain-to-stress mapping.

The data set for training and validation, $D = \{(\mathbf{E}^{(i)}, \mathbf{S}^{(i)})\}_{i=1}^n$, are generated by the structural model. We can restrict our attention to a bounded range of strains, defined as component-wise inequality $\mathbf{E}_{lb} \leq \mathbf{E} \leq \mathbf{E}_{ub}$, instead of the whole space \mathbb{R}^3 , because large strains/stresses are of little interest for real-world applications. Denote the index set as I_{tr} for the training part, and I_{val} for the validation part. The validation data are 2.5 times denser than the training one.

Figure 2: Validation results for the NN model.

RESULTS

We used Adam [3] for training, even though Adam does not guarantee convergence for some convex optimization problems [4]. We found the algorithm converges for our cases. Since the function is

continuous, we use the maximum norm of the discrepancy between $\tilde{\mathbf{S}}(\mathbf{E}^{(i)})$ and $\mathbf{S}^{(i)}$ for all i ,

$$\max_{i \in I_{val}} \|\tilde{\mathbf{S}}(\mathbf{E}^{(i)}) - \mathbf{S}^{(i)}\|_{\infty}, \quad (4)$$

to calibrate the validation error.

In Figure 2, we show the fitting results in comparison with validation data for $E_{11} - E_{22}$ plane, $E_{22} - E_{12}$ plane and $E_{11} - E_{12}$ plane. As it shows, all the cases give good fitting results. The validation error for this neural network is 27.6851 kPa. In Figure 2 (g), the error is comparable to the rounding error. If we use the third output of the hidden layer as the shear stress without post-multiplying the shear strain, the validation error for the trained neural network is 92.8646 kPa and the shear stress S_{12} oscillates when the shear strain E_{12} is zero as shown in Figure 3.

Figure 3: Shear stress oscillation for $E_{12}=0$.

DISCUSSION

In this work, we have for the first time examined building a NN model as a surrogate constitutive model for a high-fidelity but computationally costly soft tissue model. We show results for the NN model to fit the data, i.e., the strain-to-stress mapping, and it shows reasonable convergence results. The present NN with only 21 neurons can serve as an efficient surrogate model for detailed structural model. We also introduce a scheme to control the numerical oscillation in the fitting results. Therefore, the present work serves as a proof-of-concept for the use of neural networks in replicating the same response as the predictive structural model with improved efficiency. Thanks to the flexibility of the NN model, it paves the way for applying machine learning methods for simulation of soft tissues and identifying its mechanical properties to much broader applications. We are currently extending it to time dependent models that include fatigue and growth for simulating the long-term behavior of soft tissues.

INTRODUCTION

Aortic aneurysm-related deaths have increased by 52% globally in the last two decades [1] and, more precisely, abdominal aortic aneurysm (AAA) is one of the leading causes of death in men [2]. In AAA patients, the risk of aortic vessel rupture increases with increasing aneurysm size and growth rate; but to date the exact etiology is not clearly understood. Increases in elastase and collagenase activity, leading to the loss of mechanical tissue strength, has been postulated as one of the primary causative factors of AAA-related ruptures [3]. Naturally, anti-inflammatory or matrix metalloproteinase inhibiting chemicals are the primary choice for stabilizing the aortic extracellular matrix (ECM). Pentagalloyl glucose (PGG) is one such polyphenolic compound known to bind with elastin and collagen, and stabilizes the ECM [4, 5]. In this study, we evaluated the ability of PGG to restore simulated AAA enzymatic damage (elastase + collagenase) to porcine abdominal aortic tissues.

METHODS

Biomechanical testing – Three porcine abdominal aorta tracts were obtained from a local abattoir, with six specimens each per group (n = 18). The specimens, of approximate size 7 x 7 mm, were divided into groups as native (N), elastase digested (E) (1 hour in enzyme solution of 1.5 mg/mL elastase and 0.5 mg/mL collagenase), and PGG treated (P) (12-hour incubation in 0.6 mg/mL PGG [2-4] after enzymatic treatment). Testing was performed in a 37°C saline bath with a CellScale© Biotester (Waterloo Instruments Inc., Ontario, Canada) with metallic clamps securing the specimens with the orientation shown in Fig. 1. Specimens were preloaded up to 2 g, preconditioned ten times in the physiological range, and stretched under tensile strain up to ~30%. Force and extension data were recorded, from which engineering stress and strain were calculated to generate stress-strain curves.

Figure 1: Experimental setup for biaxial tensile testing of porcine abdominal aorta specimens. The specimen shown belongs to the native tissue group (N). n = 18 specimens were tested using CellScale BioTester® submerged in saline solution at 37°C.

Mechanical parameters such as stretch ratio (λ_θ), given by Eq. (1), and ultimate Cauchy stress (σ_{ult}), given by Eq. (2), were calculated.

$$\lambda_\theta = \frac{l}{l_0} \quad (1)$$

$$\sigma_{ult} = \frac{F_{ult} * \lambda}{A_t} \quad (2)$$

Green-Lagrange strain was calculated from the stretch ratios and parameters such as tensile modulus and anisotropy index were subsequently computed. The tensile modulus (slope of the curve) for the circumferential and longitudinal directions, and the anisotropy index, were calculated for each group at different strain levels (33%, 66%, and

95%). The strain energy density was also evaluated for each group by calculating the area under the stress-strain curve (AUC) for both tissue orientations.

Constitutive Modeling – To characterize the material behavior of these porcine aortic tissues, a Holzapfel-Gasser-Ogden (HGO) multilayer material model (Eq. 3) was fitted to the experimental stress-strain data,

$$\Psi = \frac{c}{2}(I_1 - 3) + \sum_{\text{layer=media, adventitia}} \sum_{i=4,6} \frac{k_1}{2k_2} [\exp(k_2(I_i^{\text{layer}} - 1)^2)] \quad (3)$$

where c , k_1 , k_2 are model parameters, I_i^{layer} are the i^{th} invariants of the Cauchy stress tensor per artery layer, and α_M and α_A are the angles of the collagen fiber bundles in the arterial tissues. A Levenberg-Marquardt algorithm was utilized to generate the best subset of material constants that can minimize the differences of the sum of squares between the experimental data and the model.

Statistical analysis – Differences between the biomechanical data obtained from the three groups (N, E, and P) were analyzed by ANOVA using SPSS (IBM Corp., Armonk, NY). Pairwise comparisons were performed using Tukey's tests with results considered significant when $p < 0.05$.

RESULTS

Using the HGO model, the phenomenological behavior of the specimens was captured for the N, E, and P groups (an exemplary curve is shown in Fig. 2), with their respective material constants described in Table 1. The tensile modulus of the P group was greater than the N and E groups at 33% strain in both circumferential (0.0681 ± 0.0392 MPa $> 0.0273 \pm 0.0129$ MPa $> 0.0214 \pm 0.0116$ MPa) and longitudinal directions (0.0628 ± 0.0435 MPa $> 0.0222 \pm 0.0205$ MPa $> 0.0181 \pm 0.0097$ MPa) (Figs. 3A-B; $p < 0.05$). Similarly, AUC was found to be greater for the P group than the N and E groups for the circumferential (0.0093 ± 0.0049 MPa $> 0.0033 \pm 0.0013$ MPa $> 0.0033 \pm 0.0015$ MPa) and longitudinal directions (0.0086 ± 0.0055 MPa $> 0.0023 \pm 0.0014$ MPa $> 0.0026 \pm 0.0014$ MPa) (Figs. 3C-D; $p < 0.05$). The tensile modulus at 66% and 95% strains for both directions, and the anisotropy index, were not significant ($p > 0.05$).

Figure 2: HGO model fitting with exemplary stress-strain curves from the native group (N).

Table 1: HGO material model constants for the three experimental groups.

Groups	c (MPa)	k_1 (Pa)	k_2 (-)	α_M (degrees)	α_A (degrees)
Native	0.033	0.493	0.889	23.834	18.288
Enzyme	0.024	0.620	0.982	19.455	20.882
PGG	0.054	0.528	0.681	50.859	31.813

Figure 3: Biomechanical parameters for the native (N), elastase-digested (E), and PGG-treated (P) porcine abdominal aorta specimens. Circumferential modulus at 33% strain – CM₃₃ (A), longitudinal modulus at 33% strain – LM₃₃ (B), and area under the curve for circumferential (C) and longitudinal (D) directions were significant across the groups ($p < 0.05$; denoted by *).

DISCUSSION

The aforementioned three types of specimens in this study were chosen to represent healthy, aneurysm pathology, and PGG-treated-aneurysm tissue conditions, respectively. By using a mixture of enzymes (collagenase and elastase), we successfully compromised the porcine abdominal aorta extracellular matrix (ECM), evident from the reduced biomechanical strength. The addition of PGG after enzymatic degradation led to a recovery of the arterial biomechanical properties (Figs. 2 & 3). This restoration of mechanical integrity stems from the intricate bonds forged by PGG, which specifically crosslinks arterial elastin and collagen [4, 5]. Currently, there are limited non-surgical treatment options for AAA patients, and hence, it is important to understand the changes that are introduced by administration of PGG locally (as in this study), and perhaps in future systemic administration for treating AAA. Forthcoming investigations will focus on the microstructural changes in the tissue due to PGG treatment and potential translation of this work toward *in vivo* applications.

INTRODUCTION

Acute joint trauma resulting from accidents or sports injuries may trigger a cascade of degenerative events within cartilage leading to post-traumatic osteoarthritis (PTOA), a significant cause of morbidity in aging populations¹. Many studies link PTOA to increases in collagen and proteoglycan degradation², decreases in protein synthesis, changes from collagen type II to type I synthesis³, and apoptosis and necrosis of chondrocytes⁴, among other mechanotransductive responses. Such changes result from deleterious responses from either chondrocytes (mature cells in articular cartilage) or chondroprogenitor cells (multipotent cells capable of chondrogenic differentiation)⁵.

We used genetic markers to observe activity of both chondrocytes and progenitor cells. In particular, we observed chondrocyte proliferation using the protein Ki67⁶, which marks active phases expressed during the cell cycle⁷. We also observed changes in the pivotal transcription factor Sox9, which serves as a master regulator of cartilage formation and differentiation, and is a widely accepted marker of chondrocytes and chondrogenic progenitor cells⁸. We also studied activation of phosphorylated Epidermal Growth Factor Receptor (pEGFR), which is a tyrosine kinase receptor with multiple roles in development, homeostasis, and disease⁹.

It is well established in the current literature that mechanical impact or compression injury of articular cartilage results in changes in gene expression that lead to matrix degradation and catabolic cellular responses; however, many of these studies generate visible macroscale damage to the articular surface of cartilage^{10,11}. Especially in early disease stages, when damage may not be visible and when microcracks in the network of collagen¹² likely form, how mechanical factors affect cell function remains unknown. In this study, we aimed to determine the mechanotransductive response of chondrocytes to low-energy impacts to cartilage.

METHODS

In total we tested 98 full-thickness cylindrical specimens (Ø 3 mm) with both cartilage and subchondral bone intact from two bovine medial femoral condyles, received on ice within 48 hours from slaughter (Animal Technologies, Inc., Tyler, TX). We assigned specimens to one of three impact groups (none, 1.5 mJ/mm³, 3.2 mJ/mm³) and measured the time-course (0, 24, 48, 72 hours post-impact) localization of Sox9, Ki67, and pEGFR via immunohistochemistry.

Mechanical Impact Test: We impacted the articular surface of specimens from the 1.5 mJ/mm³ and 3.2 mJ/mm³ impact groups in unconfined compression using a drop tower with a flat metal platen (Ø 12.4 mm)¹². We impacted samples at 0.5 m/s¹². We calculated the actual impact energy density (E_{imp}) applied to each specimen using

$$E_{\text{imp}} = \frac{mv_{\text{imp}}^2}{2\pi r^2 t}, \quad (1)$$

where m is the total mass applied, v_{imp} is the velocity of the load carriage at the moment of impact, r is the specimen radius, and t is the specimen thickness. We measured the acceleration and force at a sampling rate of 100,000 Hz. Post-impact we rinsed samples in PBS. For the control group, the specimens rested in PBS for the duration of the test.

Cell Culture and Fixation: We placed the specimens in the 0-hour time-course groups in 4% paraformaldehyde (Sigma, St. Louis, MO). We placed the remaining specimens in 1 mL of sterile media comprised of DMEM/F12 (Gibco, Gaithersburg, MD), 0.05 mg/mL ascorbic-acid-2-phosphate (Sigma), 0.1% bovine serum albumin (Sigma), 10% fetal bovine serum (Atlanta Biologicals, Flowery Branch, GA), 100 units/mL penicillin (Gibco), and 100 µg/mL streptomycin (Gibco) for culture at 37°C and 5% CO₂ for 24, 48, or 72 hours post-impact and changed this daily. Once we removed these specimens from culture, we fixed them

in 4% paraformaldehyde (Sigma) for four days, and decalcified using 14% EDTA with NH_4OH (Sigma) for four days at 4 °C with rocking.

Histology and Immunohistochemistry: We stained matrix proteoglycans with 1% aqueous Safranin O (Sigma) counterstained with Weigert's Iron Hematoxylin (Poly Scientific, Bay Shore, NY) and 0.02% aqueous Fast Green (Fisher Scientific, Hampton, NH). For immunohistochemistry, we de-paraffinized, rehydrated, and incubated a subset of slides with citrate antigen retrieval buffer followed by 3% hydrogen peroxide, blocking solution, and overnight incubation with primary antibodies in blocking buffer¹³. We diluted the following primary antibodies to 1:1000: rabbit anti-Ki67 (Abcam, Cambridge, MA); rabbit anti-Sox9 (Abcam); and rabbit anti-pEGFR (Abcam). We incubated slides with a biotinylated anti-rabbit secondary antibody which we detected using a Vectastain Elite ABC kit (Vector Laboratories) and chromogenic detection with DAB (Vector)¹³.

Imaging and Image Analysis: We imaged slides using a Nikon Eclipse E800 light microscope and obtained full cross-sections using a 4x objective, and three to five images of central regions of the immunohistochemically stained slides with 0-600 pixels of overlap using a 20x objective. We excluded sample edges. We used images from specimens stained with Safranin O to qualitatively assess the integrity of the articular surface. We recreated full-thickness cross-sections from the 20x images using Fiji's Grid/Collection Stitching Plugin¹⁴ for ImageJ (NIH, Bethesda, MD), and determined boundaries for the superficial (SZ), middle (MZ), and deep zones (DZ) using morphology of the lacunae and the cellular arrangement. For each antibody, we quantified positive and negative cellular staining within each zone, and calculated the percent positive cells.

Statistical analyses: We tested for normal distributions of the percent positive cells for each antibody using the Shapiro-Wilk Test for normality. We used separate two-way ANOVAs to evaluate the effects of impact and time on the percent positive cellular localization of each antibody within each zone and included impact level and time as fixed effects, and both the thickness of each specimen and the cow identifier as covariates. We used post-hoc tests to evaluate significant differences among treatment combinations for interactions, and used separate linear regressions to investigate interactions between impact energy density, first Piola-Kirchhoff stress, and engineering strain with the percent positive cells.

RESULTS

In Fig.1, we show distributions of the percent positive cells for each antibody separated by through-thickness zone and time in culture. We found no significant differences in the interaction of impact group and time as predictors for zonal response of percent positive cells for Ki67 and pEGFR. However, we found that positive cellular localization of anti-Sox9 in each zone varied with respect to time. For anti-Sox9, we found statistically significant differences ($p < 0.05$) in SZ at 48 hours, and MZ and DZ at 0, 24, and 72 hours. We did not find statistically significant differences in the total number of cells for any antibody and zone at any time. We also found significant inverse relationships between Sox9 localization in the MZ and DZ for all three predictors.

DISCUSSION

This study is the first to demonstrate changes in Sox9, a master regulator of chondrogenesis, in response to low-energy impact loading. We used low-energy impacts that are below the threshold that induces cell death, which can be as low as 5 mJ/mm^3 ¹⁵. We selected 1.5 and 3.2 mJ/mm^3 as non-injurious, low-energy impacts that have 25% and 40% probability of microcracking the network of collagen¹². Alternatively, we found mechanical stimuli that positively influence mechanotransductive responses. Here mechanotransduction refers to the

processes through which cells sense and respond to mechanical stimuli by converting them to biochemical signals that elicit specific cellular responses. We identified mechanical impacts that upregulated Sox9, and determined that impact energy density is a better predictor of positive cellular Sox9 than first-Piola-Kirchhoff stress or engineering strain. Additionally, our low-energy impacts did not alter cell proliferation or pEGFR signaling.

Although there are no definitive cellular markers for chondroprogenitors, they express Sox9 among other markers and migrate towards damaged articular cartilage matrix. We distinguished between chondroprogenitors and mature chondrocytes by migration inferred by comparing proliferation with the total number of cells in each through-thickness zone. Since the number of cells present in any zone did not change with increased Sox9, the changes we observed may come from mature, non-migratory chondrocytes. Thus, low-energy impacts may have no effect on chondroprogenitor cells, but may affect mature chondrocytes.

INTRODUCTION

The coordinated events that give rise to zonal tendon/ligament insertions into bone (i.e., enthesis) during development are well established. These mechanisms are less known in the adult because traditional reattachment surgeries of avulsed tendon to bone result in disorganized scar and do not re-establish a zonal enthesis. Ligament injuries, such as the anterior cruciate ligament (ACL), are often reconstructed by passing a tendon graft through a bone tunnel, which does yield zonal attachments. Therefore, ligament reconstructions can serve as a test platform to better understand the mechanisms that drive adult zonal tendon-to-bone repair. Tunnel integration following ACL reconstruction is driven by cells outside the graft [1], presumably from the bone marrow stroma. However, markers that define this progenitor population and the signaling pathways that regulate the repair response are not established. Quiescent resident mesenchymal progenitor cells expressing α -smooth muscle actin (α SMA) have been shown to contribute to new bone formation and fracture repair [2]. Moreover, α SMA expression is increased in the amplifying progenitor population following injury. The objective of this study was to label α SMA amplifying progenitor cells to determine their relative contribution to tendon-to-bone attachments and surrounding bone during tunnel integration following ACL reconstruction.

METHODS

Institutional IACUC approved all relevant procedures in this study. Experimental Design. Inducible Cre mice driven by α SMA (SMACre^{ERT2}) were crossed with Ai9-tdTomato Cre reporter mice resulting in double positive mice (SMACre;tdTom). These mice were then crossed with transgenic Col1a1(3.6kb)-CFP mice. The triple positive mice were used to trace the contribution of α SMA-expressing cells in the bone marrow to Col1a1-expressing cells within attachments formed during the tunnel integration process. ACL reconstruction

surgery was performed in 3-4 month old mice (20 total). Anterior drawer tests were performed on a subset of mice just after surgery (N=5-6/group) while remaining mice were assessed histologically at 1, 2, and 4 weeks post-surgery (N=3-5/group). Tamoxifen was injected on either post-surgery days 0, 3, and 6 (Early Injection Group) to target the original amplifying progenitor pool or days 7, 10, and 13 (Late Injection Group) to target α SMA-expressing cells after the initial expansion. All mice were injected with demeclocycline (DEM) one day before sacrifice to demarcate regions of active mineral deposition in the tunnel and surrounding bone. ACL Reconstruction. All surgical procedures were performed under a microscope. The right knee joint of each mouse was subjected to surgical transection of the ACL followed by reconstruction (ACLR). Three 3-4 cm long tail tendons were harvested, sutured at both ends with 7-0 nylon, and maintained in PBS during surgery. The ACL was transected with a 27G needle. After confirmation of significant anterior drawer and intact PCL, 27G needles were used to drill tunnels originating at the ACL femoral and tibial footprints through the femur and tibia. The tendon graft was passed through the tunnels and fixated to the external cortices of the femur and tibia with metal washers. At 1, 2, and 4 weeks post-surgery, mice were euthanized via CO₂ asphyxiation and both hindlimbs were harvested. Stability of the knee joint was confirmed macroscopically, and the reconstructed limb was processed for histology. Biomechanical Testing. Following sacrifice on the day of surgery, left hindlimbs were isolated and removed of all extraneous soft tissue. All capsule ligaments, including the cruciates and collaterals, along with the menisci were left intact. The distal half of each tibia was potted in PMMA. The potted tibial end was fixed in a custom fixture on the material testing machine that allowed for adjustment of tibial plateau angle. The distal end of the femur was lowered into another custom fixture that could control knee flexion by rotating the femur around the joint center of rotation. The knee joint was tested for anterior and posterior stability by cyclic loading between

$\pm 0.4N$ for 10 cycles and the 10th cycle was used to quantify stability. Samples are defined as: Intact – intact left knee, ACLT – ACL transected left knee (transected on testing machine after testing intact), ACLR – ACL reconstruct right knee, ACLRT – ACLR graft transected right knee (transected on testing machine after testing ACLR). **Multiplexed Mineralized Cryohistology.** Reconstructed hindlimbs were fixed in formalin and embedded in OCT. Tape-stabilized, frozen mineralized sagittal sections of the knee were collected and each section was subjected to four rounds of imaging including 1) fluorescent GFP reporters and mineralization label, 2) tartrate-resistant acid phosphatase (TRAP) fluorescent staining, 3) alkaline phosphatase (AP) fluorescent staining, and 4) toluidine blue (TB) staining. Layered composite images of these rounds were made in image editing software. **Histological Analysis.** Labeling efficiency (% tdTom⁺ cells) of mineralized fibrocartilage of attachments and osteocytes in newly formed bone was quantified using Fiji. **Statistical Analysis.** One-way ANOVA with state of ACL ($\alpha = 0.05$, Bonferroni post-hoc) was used to compare biomechanical parameters. Mann-Whitney U test ($p < 0.05$) was used to compare differences in tdTom⁺ labeling efficiencies.

RESULTS

Biomechanical Analysis. Anterior drawer test showed that reconstruction restored 47% of anterior stability compared to ACL transected limbs (Fig 1D). **ACL Reconstruction.** By 2 weeks post-surgery, SMACre;tdTom⁺ cells infiltrated the graft (Fig. 2B), anchored collagen fibers to underlying bone (Fig. 2C), and expressed AP (Fig. 2D) near the tidemark (Fig. 2 dotted line) as they mineralized the fibrocartilage to create a zonal attachment. **Fate Mapping of SMACre;tdTom⁺ Bone Marrow Progenitor Cells.** SMACre;tdTom⁺ cells contributed to 30-50% of all cells within the mineralized fibrocartilage of the attachments with no statistical difference between groups ($p > 0.05$, Fig. 3A). Mineralized fibrocartilage was not present at 1 week post-surgery. SMACre;tdTom⁺ cells expressed high levels of Col1a1(3.6-kb)-CFP within the remodeling tendon graft. CFP intensity decreased with time with lowest intensities at 4 weeks. One week post-surgery, SMACre;tdTom⁺ cells formed woven bone adjacent to the tunnel interface. After 1 week, most of the stromal expansion was over and the SMACre;tdTom⁺ cells began forming new bone or attachments. Two weeks post-surgery, bone surrounding the tunnels was more organized (B in Fig. 2A) which continued to 4 weeks post-surgery. Labeling the original amplifying progenitor pool during the first week of repair resulted in significantly higher labeling efficiency of osteocytes in newly formed bone at D28 ($p < 0.05$, Fig. 3B). Interestingly, there was a significant drop in labeling efficiency with time in the late injection group (D14 vs D28) but not the early injection group (D7 vs D28) (Fig. 3B).

DISCUSSION

Recreating the spatiotemporal events needed to create a functional zonal tendon-to-bone attachment are critical to producing a functional repair. The murine ACL reconstruction model in this study can serve as a test platform to specifically target cells, genes, and pathways that regulate zonal tendon-to-bone repair. Overall, the SMACre;tdTom mouse model is efficient at targeting cells that contribute to tunnel integration and the targeting can be tuned temporally. While α SMA-expressing bone marrow progenitor cells have been shown to produce new bone during repair [2], this study demonstrates that they also have the potential to produce fibrocartilage within bone tunnel attachments. A limitation of this study was that not all cells within newly formed bone at 1 week post-surgery can be confirmed to be osteocytes. Future studies will use the SMACre^{ERT2} mice to target specific genes and pathways involved in entheses development to determine their functional role in adult tendon-to-bone repair.

INTRODUCTION

Biomechanical failure of the extracellular matrix in cerebral aneurysm wall tissue can lead to loss of biomechanical integrity culminating in catastrophic rupture of the wall. The fatality rate associated with rupture of intracranial aneurysms is 45% and long term disability rate is 64% [1]. Thus, there is a pressing need to understand failure behavior of the arterial wall. Studies of the pre-failure biomechanics of the artery wall are common in the literature, and more recently, our group and others have analyzed tissue failure as a progression from the pre-failure response to complete failure in an attempt to understand the role of tissue structure in failure. However, the sub-tissue level biomechanical mechanisms governing overall wall tissue failure are still not fully understood. In this abstract, we present a cohesive volumetric finite element (CVFE) modeling approach that incorporates tissue failure properties as model parameters, and assesses their role in governing overall tissue failure behavior. Our model is capable of simulating spontaneous initiation, propagation, and coalescence of multiple tears within the tissue leading to complete specimen level mechanical failure. Using this model, we simulated experimental uniaxial stress-stretch experiments on human and sheep arterial tissues while simultaneously recapitulating image-derived data on overall tissue failure behavior. We also quantified the spatially heterogeneous sub-tissue level damage evolution using this model. We found tissue damage initiates before the peak of the stress-stretch curve is achieved, and the peak is correlated with the intrinsic tissue strength. We also found that tissue fracture toughness controls the post-peak biomechanical behavior.

METHODS

We utilized the CVFE approach to model the evolution of tissue damage and ultimate tissue failure. In this method, the mechanical response of the bulk (volumetric) domain is governed by a hyperelastic constitutive response while a separate failure constitutive law, defined by the potential tear interface, governs the tissue failure response. A generalized structure tensor (GST) based model including fiber dispersion [2] was employed to simulate the anisotropic behavior of the fibrous soft tissue. Following earlier works on material failure behavior [3,4], we postulated that tissue failure is a gradual and irreversible process localized within a process zone. Potential failure

sites were placed at the edges of the finite elements, and were prescribed with a cohesive failure law relating traction and separation across the evolving tear [5].

The cohesive failure law in opening mode and shearing mode relates tractions t_n and t_t in normal and tangential directions, respectively with corresponding normalized displacement jumps $\bar{\Delta}_n$ and $\bar{\Delta}_t$ as:

$$t_n = \frac{S}{1 - S} \frac{\sigma_{max}}{S_{init}} \bar{\Delta}_n, \quad t_t = \frac{S}{1 - S} \frac{\tau_{max}}{S_{init}} \bar{\Delta}_t \quad (1)$$

where the displacement jumps are normalized by critical displacement jumps Δ_{nc} and Δ_{tc} in corresponding directions. Further, $S := \min[S_{init}, \max(0, 1 - \bar{\Delta})]$, an internal damage parameter that depends on the normalized displacement jump $\bar{\Delta} := (\bar{\Delta}_n^2 + \bar{\Delta}_t^2)^{1/2}$, in the process zone, thus coupling these two modes of failure. σ_{max} and τ_{max} , the intrinsic tissue tensile and shear strength, respectively, were set equal and were estimated from the peak of the experimental stress-strain curve for arterial tissue [6]. Fracture toughness for two modes, denoted as G_I and G_{II} , were set equal, where fracture toughness is defined as the energy per unit area required to create a new tear. This property was used as a free parameter of the model, and was calibrated to recapitulate experimentally observed modes of failure reported in [6]. Critical displacements Δ_{nc} and Δ_{tc} were calculated from $G_I = \frac{1}{2} \sigma_{max} \Delta_{nc}$ and $G_{II} = \frac{1}{2} \tau_{max} \Delta_{tc}$.

Multiphoton microscopy of the organization of collagen fibers within human and sheep arteries were reported in a previous publication from our group [6]. Based on this data, we modeled the collagen fibers using two fiber families with mean directions of $\pm 5^\circ$ about the circumferential direction, and with a small planar fiber dispersion ($\kappa = 0.05$). Other GST model parameters representing fiber and matrix stiffness were calibrated by performing nonlinear regression of the model predicted stress-strain curves against the experimental ones reported in [6] using Matlab (R2018a, Mathworks, Natick, MA).

We simulated both rectangular and dogbone specimens of equal length (7.1mm), grip to grip length (3.5 mm), width at clamp (2 mm), and thickness (250 μ m). The steel clamp used to fix the tissue, being of much higher stiffness than the tissue and the insert material layer

was idealized as rigid and not explicitly modeled. Rather its effect was modeled as a uniform gripping pressure on the contact surface of the insert material between the grip and tissue specimen. The insert layer between the clamp and specimen was modeled as a cuboid with a thickness of 0.787 mm and a contact surface of 1.8 mm by 2 mm.

To mimic the experimental loading conditions, we first applied a uniform clamping pressure of 12.5 kPa then stretched the tissue uniaxially until failure. Reaction forces at each load step were used to calculate the average Cauchy stress, approximated as the reaction force divided by the current cross-sectional area was computed mid-specimen. The R Factor was defined as the area under the post-peak Cauchy stress versus stretch curve divided by the area under the total curve.

All statistical analyses were conducted using SPSS (IBM Corp., Armonk, NY). For the comparison of two groups with normally distributed data, a two-sample independent t-test was conducted. If the data were not normal, a Mann-Whitney test was conducted. Comparison between two or more groups was performed using a one-way independent ANOVA followed by a Bernoulli post hoc test. Results of the correlation analysis were reported in terms of non-parametric Spearman's correlation coefficient (r). The alpha level of significance for all statistical tests was set at $\alpha < 0.05$.

RESULTS

Figure 1 presents the stress-stretch curves along with the axial stress contours on the specimen surface for three different uniaxial simulations with cases of increasing stiffness and a constant fracture toughness combination of 2 kJ/m² in the medial layer and 4 kJ/m² in the adventitial layer. To investigate the micromechanics of the failure process, we monitored the evolution of the internal damage parameter of the cohesive failure law, S . In particular, we superimposed the evolution of the internal parameter S on the stress-stretch curves in the top panels of Figure 1. Consistent with our experimental study of uniaxial failure in human cerebral and sheep carotid arteries [6], the peak stress (Point B) in Figure 1 was not associated with complete tissue failure or a large change in cross section for these cases. Rather, various degrees of material softening due to distributed tissue damage could be observed at the peak stress. This finding held for the entire cohort of specimens tested in our study that covered a wide range of material properties, two specimen geometries, and boundary conditions. In agreement with experiments [6], the post-peak response of the simulations varied from abrupt to gradual failure. In abrupt failure cases, the media and adventitia both failed together, Figure 1(a,c), whereas in the gradual failure case the medial and adventitial layers fail sequentially Figure 1(b). Black arrowheads in Figure 1 designate the locations of complete failure ($S=0$) in the tissue.

For all specimen shapes and insert materials considered here, the magnitude of peak stress was statistically similar to the intrinsic tissue strength, though the peak stress was consistently higher. For example, the average peak stress for the low and high strength cases were 16.01% ($p=0.95$) and 13.56% ($p=0.98$) greater than their respective input intrinsic strengths. We also did not find statistically significant differences in peak stress due to varying fracture toughness (G11-G48) for low ($p=0.08$) or high ($p=0.05$) strength tissue except between the lowest and highest toughness cases G11 and G48 ($p=0.02$). However, the post-peak (peak stress to complete failure) stress-stretch curve transitioned from abrupt to gradual with increasing fracture toughness. This was quantified by a positive correlation between R Factor and fracture toughness for all parametric studies with varying parameters of strength, protocol, and stiffness.

Figure 1: Stress distributions during uniaxial loading to failure. (a) and (c) represent high cohesive strength cases while (b) represents the low cohesive strength case. A dogbone specimen is shown in (a), while (b) and (c) are rectangular samples.

DISCUSSION

Prior to this work, there was very limited data on the relationship between tissue failure progression and the tissue failure properties. Our analysis demonstrates that tissue failure is a continuous process starting from localized softening followed by initiation, propagation and coalescence of multiple tears leading to complete separation of the specimen. It is of importance that uniaxial peak stress corresponds to localized tissue softening and partial damage in the highly stressed regions, rather than complete tissue failure. For example, peak stress was always associated with the reduction of the internal damage parameter, S , from its initial value, indicating onset of material softening. This is consistent with the experimental observations in [6].

We found that for low strength tissues, the higher tissue fracture toughness consistently resulted in a gradual post-peak response. However, for tissues with high strength, the fracture process tends to be abrupt for all combinations of media and adventitia fracture toughnesses studied. High strength tissues can absorb substantial amounts of strain energy prior to the onset of failure. As a result, there is a buildup of mechanical energy released during fast tear propagation. In contrast, lower pre-failure strain energy enables the tissue to absorb additional post-peak energy before the complete failure. Our work reveals how intrinsic material failure properties, namely strength and fracture toughness, control the specimen scale tissue mechanical failure behavior including the post-peak failure response. In summary, our parametric study shows the post peak response in failure testing deserves greater attention than it currently receives, as it provides information about the failure process that could have substantial consequences for living tissues.

INTRODUCTION

Cellular interactions with the surrounding extracellular matrix (ECM) guide fundamental behaviors such as spreading, migration, and proliferation, and thus play an important role in tissue homeostasis and disease pathogenesis [1,2]. In particular, cells can interrogate diverse physical aspects of their microenvironment and respond accordingly over various timescales. As biophysical properties of native tissue ECMs and natural biomaterials (such as collagen and fibrin gels) are challenging to experimentally modulate, synthetic materials such as polyacrylamide or poly(ethylene glycol) have been crucial in investigating the role of matrix properties in cell behavior. While these synthetic materials offer controllable and modular design, they fail to mimic the complex mechanical and topographical properties of fibrous tissues. We have previously demonstrated the cell's ability to physically remodel matrix fibers influences initial cellular mechanosensing events such as cell spreading and adhesion formation [3], but how these initial responses impact the longer-term cell response has not been explored.

Fibrosis is one context where a deeper understanding of mechanosensing in fibrous microenvironments would be invaluable. A central component of many diseases, fibrosis has been implicated in 45% of all deaths in the developed world [4]. The principal cells that drive this disease are myofibroblasts (MFs). Differentiated from hyper-proliferative fibroblasts, MFs contribute excessive ECM synthesis and contractile forces that cause tissue stiffening and eventual organ failure. However, due to a lack of biomaterial platforms that accurately capture the fibrous structure and mechanical behavior of the stromal tissue spaces where fibrotic processes take hold, we lack an understanding of how properties of fibrous ECM influence cell proliferation and MF differentiation. In this work, we developed a novel fibrous material composed of electrospun of dextran vinyl sulfone (DexVS) with tunable

mechanical properties that supports long-term culture of fibroblasts to examine MF activation as a function of matrix stiffness.

METHODS

DexVS Synthesis: Dextran was reacted with divinyl sulfone following a previously described procedure [5]. Briefly, dextran (5 g) was dissolved in 250 mL of sodium hydroxide (100 mM) solution under vigorous stirring before addition of divinyl sulfone (12.5 mL). The reaction proceeded for 3.5 minutes before termination by addition of hydrochloric acid. Product was dialyzed against milli-Q water for 3 days and then lyophilized. DexVS was characterized by H-NMR and a vinyl sulfone/dextran repeat unit ratio of 0.4 was determined.

Electrospinning: DexVS was dissolved at 0.7 g mL⁻¹ in a 1:1 mixture of milli-Q water and dimethylformamide with 0.6% (w/v) LAP photoinitiator. This solution was electrospun and crosslinked via UV light and LAP photoinitiator. Fibers were collected on poly(dimethylsiloxane) (PDMS) arrays of circular wells produced by soft lithography. DexVS matrices were then functionalized with cyclo [Arg-Gly-Asp-D-Phe-Lys(Cys)] (cRGD) to facilitate cell attachment.

Cell Culture: Normal human lung fibroblasts (NHLF) were cultured in DMEM containing 1% penicillin/streptomycin, L-glutamine, and 10% fetal bovine serum. To induce MF differentiation, NHLFs were cultured for 7 days and supplemented with transforming growth factor beta (TGF- β 1, 10 ng/mL).

Mechanical Testing: Young's moduli of suspended DexVS fiber matrices were measured by microindentation with an SU8 cylindrical indenter affixed to a tungsten filament following a previously described method [3]. **Staining and Microscopy:** Cells were fixed in 4% paraformaldehyde for 10 min at room temperature. To stain the actin cytoskeleton and nuclei, cells were permeabilized, blocked in 1% bovine serum albumin, and stained simultaneously with phalloidin and DAPI. For α -SMA immunostaining, samples were permeabilized,

blocked for 1 h in 1% fetal bovine serum, and incubated with α -SMA antibody (1:2000, Abcam #7817) for 1 h at room temperature. Fixed samples were imaged on a Zeiss LSM 800 laser scanning confocal microscope. **Statistics:** Statistical significance was determined by ANOVA or Student's t-test where appropriate, with significance indicated by $p < 0.05$.

RESULTS

Fibrous matrices were fabricated by electrospinning DexVS onto collection substrates such that fibers were suspended over an array of microfabricated wells (Fig. 1a). Exposure to UV light in the presence of photoinitiator (LAP) crosslinks DexVS, enabling control over the Young's moduli of individual fibers and bulk matrices. Crosslinking proved sensitive to the concentration of LAP photoinitiator during UV exposure, duration of UV exposure, and LAP concentration within the electrospinning solution. Through these means, the Young's moduli of matrices were tunable between 0.6 and 4.02 kPa (Fig 1b,c). To confirm that DexVS matrices require functionalization for cell adhesion and do not passively absorb serum-borne ECM proteins, the adhesive peptide cRGD was coupled to substrates at variable concentrations. Cell spreading proved highly sensitive to the amount of cRGD, with no spreading noted in the absence of cRGD. As cell spreading was maximal at 100 μ M, this concentration was utilized for all subsequent studies (Fig. 1e). Cell viability on DexVS matrices was confirmed via live/dead assay, demonstrating negligible cell death on both soft (0.6 kPa) and stiff (3.8 kPa) matrices (Fig 1d).

Figure 1. a) Schematic of multi-well substrate supporting suspended matrices of DexVS fibers coupled with cRGD. Young's modulus of DexVS matrices as a function of (b) LAP concentration, duration of UV exposure, and (c) LAP concentration within the electrospinning solution. d) Soft and stiff DexVS networks are biocompatible and have no effect on cell viability. e) Cell spreading as a function of cRGD concentration. Scale bar: 100 μ m. All data presented as mean \pm std.

We next utilized DexVS fibrous matrices to examine the influence of ECM stiffness on MF activation. Previous studies on polyacrylamide hydrogels have shown that stiff matrices are required for MF activation [6]. We cultured NHLFs for 7 days in the presence of TGF- β 1, a potent

soluble mediator of MF activation. Cells seeded on soft matrices revealed high levels of matrix reorganization and fiber recruitment as compared to those on stiff matrices (Fig 2a, DexVS). Interestingly, higher levels of proliferation (as quantified by EdU assay) and MF activation (as quantified by positive α -SMA immunostaining) were noted on soft DexVS matrices (Fig 2a-c) as compared to non-deformable stiff matrices.

DISCUSSION

In this work, we established a new synthetic fibrous material to study longer-term cell responses. DexVS was synthesized and processed into suspended fiber matrices with tunable stiffness that support long-term (7+ days) cell culture. We utilized this system to study the influence of fibrous matrix stiffness on MF activation, an important step in the fibrotic cascade. Contrary to previous results with hydrogels, decreased matrix stiffness led to increased proliferation and α -SMA expression, two hallmarks of fibrotic tissues. We hypothesize that this is due to fiber recruitment in softer matrices, as this has previously been shown to increase local ligand concentration and promote focal adhesion maturation and resulting signaling [3]. Future work will more rigorously investigate the relationship between MF activation and physical remodeling of the matrix. Furthermore, DexVS matrices may be a valuable setting to study cell-ECM interactions during other long-term processes such as stem cell differentiation, tissue homeostasis, and disease pathogenesis.

INTRODUCTION

Pentagalloyl Glucose (PGG) is a naturally occurring polyphenolic compound that has a variety of biological effects, including several cardiovascular health benefits [1, 2].

Figure 1: PGG-mediated activation and suppression of molecular pathways with relevance to vascular health. The inset illustrates in vitro PGG-based tissue treatment for extracellular matrix (ECM) stability. Adapted from Patnaik et al. [2]

PGG works as an antioxidant in the body and reduces reactive oxygen species (ROS) buildup in arterial tissues, which is potentially damaging to DNA, proteins, etc.. Prior to evaluating the antioxidant potential of PGG, it is important to establish its toxicity level. In this study, we aim to investigate the *in vitro* toxicity effects of PGG on murine macrophages (MP).

METHODS

MP cells were routinely cultured in a 96-well cell culture plates with a density of 1×10^3 cells using DMEM culture media supplemented with 10% FBS and 1% antibiotics at 37°C, 5% CO₂ environment. After 24 hours, these cells were subjected to dose-dependent PGG treatments (0.1% w/v; Sigma-Aldrich, MO, USA) of 0, 250, 500, 750, and 1000 µL. 4% paraformaldehyde fixation of the cells was performed as a positive control. Cell viability was assessed using a MTT assay for each treatment group – control, PGG-treated (250, 500, 750, and 1000 µL), and fixative-treated (n = 6 each). Absorbance of each well was quantified at 570 nm using a plate reader (BioTek® Instruments Inc., Winooski, VT) and results were reported as mean ± standard deviation. Microscopic images (10x) of the MP cells were obtained for each group (Leica Microsystems) and their 3D surface analysis was performed using ImageJ (National Institutes of Health, Bethesda, MD). Statistical analysis (ANOVA with Dunnett's for comparison with control) was performed using GraphPad® 5.0 to analyze differences in the MTT assays across the groups. All experiments were repeated six times. Data was considered significant at $\alpha = 0.05$.

RESULTS

After a 24-hour incubation period, we found that the highest dosage of PGG (1000 µL) was not cytotoxic to MPs and did not show any extracellular matrix (ECM) crosslinking compared to fixed cells. Cells treated with PGG showed morphological characteristics similar to the control cells, as shown in Figs. 2a-e. There was no cross-linking observed in the control and PGG-treated groups (Figs. 2a-e). Further, the surface plot features of MPs treated with 1000 µL of PGG resembles the control condition closely, compared to the fixed group (see Figs. 3a-c).

Figure 2: Microscopic characteristics of MP cells. (a) Control sample of MP cell with no PGG, (b) MP cells with 250 µL of PGG, (c) MP cells with 500 µL of PGG, (d) MP cells with 750 µL of PGG, (e) MP cells with 1000 µL of PGG and lastly, (f) MP cells that were fixed with 4% paraformaldehyde. Each scale bar represents 100 microns.

Figure 3: 3D surface plot of MP cells in (a) control, (b) 1000 µL of PGG, and (c) fixative conditions (4% paraformaldehyde). Blue denotes a more compact topography, which is indicative of a more cross-linked ECM.

From the MTT assay, dose-dependent increases in PGG concentration did not exhibit any change in cell viability. There was significant difference in cell viability between the control and fixed groups, as illustrated in Fig. 4. However, there were no pairwise differences observed between the control and PGG groups.

Figure 4: PGG toxicity analysis using MTT assay. * denotes significant difference across the groups and the bars indicate the pairwise differences in the data.

DISCUSSION

There are concerns about PGG being a strong cross-linking agent, which may lead to stiffening of arteries [3]. For the application of PGG to arterial aneurysmal tissues, PGG-mediated crosslinking can be beneficial to restore the extracellular matrix integrity [1] and enhance its biomechanical properties (which are otherwise compromised due to inflammatory secretions from macrophages and other sources [2]). It is critical that in addition to the extracellular matrix (ECM) stabilization, PGG should not affect the native cells. In our investigation, we found that after a 24-hour incubation with MP cells,

- the highest dosage of PGG (1000 µL) was not cytotoxic, and
- PGG did not show any ECM cross-linking compared to the fixed cells.

The present work supplements the several beneficial elasto-regenerative potential of this natural polyphenolic compound. The ultimate goal for the use of PGG in pathological conditions is to reduce inflammation by lowering the ROS levels.

Further investigation is needed to evaluate changes in secretory protein profile that can directly influence the oxidative stress developed in the cellular environment. Next, we aim to evaluate the ROS activity of these cells by using CellRox® deep red reagent and flow cytometry analysis. The results from such study will help us translate the application of PGG into animal models, and can potentially assist in formulating a pharmacological intervention for vascular diseases such as aortic aneurysms, atherosclerosis, etc.

INTRODUCTION

Precise robotic motion is ever-present within our cells in dynamic proteins like ATP synthase and kinesin. Functioning much like macroscopic machines, these proteins have multiple components and defined motion paths. Engineers across many disciplines use inorganic- and bio-materials to create nano- and micro-robots with similar functionality. Structural DNA nanotechnology, pioneered by Nadrian Seeman [1] and Paul Rothemund [2], enables researchers to design and fabricate DNA-based structures with nanometer-scale spatial control by employing well understood DNA base pairing and nucleic acid synthesis methods. This attractive technology has produced structures with controllable size, shape, and flexibility and has recently been expanded to kinematic mechanisms [3] and modular structures [4]. As the aspiration of biocompatible programmable machines moves closer to reality, a requirement for control over these devices arises.

Recent advances have demonstrated controlled motion of DNA devices, primarily using DNA handles and strand invasion to bind or displace reconfigurable components [3, 5, 6] with timescales of minutes or longer. Here, we present two strategies for actuating DNA-based mechanical devices in near real time. First, we demonstrate an approach using a simple modification to existing devices that adds a network of weak binding sites on complementary components for environmentally controlled

rapid actuation [7]. A network of weak DNA handles is activated by increasing cation concentration, which raises the avidity of the network to join the two components. Likewise, reconfiguration is quickly reversible in decreased salt conditions. Second, we present an innovative method for real-time actuation using a magnetic stimulus [8]. Micron-scale rigid arms couple magnetic beads to nanoscale devices for direct manipulation through an externally applied magnetic field. This level of spatiotemporal control over DNA devices can serve as a foundation for real-time manipulation of molecular systems.

METHODS

DNA devices were constructed following procedures from Castro et al. [9]. Briefly, ~8000 nt viral DNA was mixed with ~200 synthetic oligonucleotides designed to self-assemble into predetermined geometries in a buffered solution with 18 mM MgCl₂. The solution was subjected to rapid heating to 65 °C then slowly cooled in a thermal annealing ramp over ~2 days to 25 °C. Structures were purified using polyethylene glycol precipitation with buffer exchange. Structure characterization primarily involved imaging on a FEI Tecnai G2 Spirit transmission electron microscopy (TEM) and a Bruker AXS Dimension Icon atomic force microscope (AFM). Bulk actuation response for cation-activated hinges was measured using Förster resonance energy transfer (FRET) calculations from ensemble

fluorescent intensity in a Horiba FluoroMax-4 spectrofluorometer. Kinetic studies for both systems involved single-molecule fluorescent imaging performed on a Nikon TiE inverted total internal reflection fluorescence (TIRF) microscope with a Dual-View light-splitting cube for FRET calculations. External magnetic fields were applied using four orthogonal electromagnets, which provided in-plane magnetic fields and a central solenoid which provided out-of-plane magnetic fields. All experiments were performed at room temperature.

RESULTS

In order to demonstrate two rapid actuation methods, we modified DNA origami hinges as example mechanisms. Figure 1 shows two 18-helix rectangular bundles with flexible single-stranded DNA connections forming a hinge axis. Extending specific DNA strands to include short binding sequences (blue and green overhangs), allows us to program these hinges to change conformation under the presence of certain ionic conditions. By defining specific sequences on each arm, we can program the actuation pathway. For instance, the sequence of blue overhangs in Figure 1 is weakly complementary to that of the green overhangs on the opposite arm. Increasing cation concentration strengthens DNA base-pairing interactions, closing the hinge. Lowering the cation concentration through buffer exchange promptly reverses this reconfiguration. We studied four design variables that modulate the actuation response of our devices: the number of overhang connections, the strength of these connections, the torsional stiffness of the hinge, and the cation used, exhibiting the ability to precisely tune actuation response. A key advantage of actuating DNA devices using ion-mediated control of localized overhangs is the potential for fast response. To investigate the opening and closing kinetics of our ion-activated hinges, we used a single-molecule FRET assay to show transitions occurring on millisecond time scales as buffers are exchanged every few seconds (Figure 1, right).

Figure 1: Ion-activated actuation uses weakly complementary sequences on opposing surfaces to trigger reconfiguration under the presence of increased cation conditions. Single-molecule FRET studies show that these transitions occur on millisecond ($\lesssim 200$ ms) time scales. Scale bars = 50 nm.

To demonstrate our magnetic actuation method, we built a DNA origami rotor and hinge, which both use nanoscale components to assemble micron-scale filaments. The DNA

origami filaments have a cross section of 56 helices for enhanced rigidity. Figure 2 shows a hinge with a magnetic bead attached to the end of one arm with the other arm immobilized (not shown). Using a rotating magnetic field, the mechanisms are rotated with precision of $\sim \pm 10^\circ$, varying slightly with the different systems being controlled. The strength and frequency of rotation of the magnetic field can be adjusted to tune actuation response. This system couples micron-scale control systems with nano-scale engineering for real time actuation of rotational devices.

Figure 2: Control of DNA origami assemblies via externally applied magnetic fields using a low-cost platform that enables actuation into many distinct configurations with sub-second response times. Scale bars = 1 μ m.

DISCUSSION

Given recent advances in structural DNA nanotechnology, the rapid manipulation capabilities established here could bring nanodevices for nanomanufacturing and biosensing closer to reality. Both approaches are amenable to a variety of complex devices, which we envision can serve as a foundation for nano- or micro-scale robotic systems based on DNA origami assemblies. Importantly, our actuation strategies can be carried out using low-cost platforms with simple DNA modifications or off-the-shelf electromagnets and could be applied to new and existing devices to enable low-cost real-time manipulation of a wide range of dynamic DNA assemblies.

INTRODUCTION

Cell mechanical behavior measured at the single-cell-level is a high-level indicator of complex and integrated molecular changes that occur during physiological and pathophysiological processes. Due to the label-free nature of intrinsic cell mechanical properties, mechanical phenotyping, or grouping of cells based on mechanical behavior, has promising applications for fundamental cell biology research and in clinical settings for disease diagnostics and therapeutics.

The high-throughput capabilities of microfluidics have made possible exciting mechanical phenotyping studies of large populations of cells [1-4]. However, while extremely high-throughput mechanical phenotyping devices have significant clinical applications, the platforms sacrifice simplicity of modeling that would allow for measurement of intrinsic cell mechanical properties that is independent of the microfluidic device. For these existing devices, the deforming force is dependent on cell size and for some, pressure fluctuations due to transient occlusion of parallel channels. We have taken another strategy to deform cells with steady viscous forces that only depend on channel geometry and fluid parameters, avoid contact with device walls, and obtain a symmetric cell deformation so that we can achieve close agreement with modeling conditions, and therefore obtain more accurate mechanical property measurements.

The objective of this work is to introduce an extensional flow microfluidic platform that measures the mechanical properties of suspended cells and rigorously accounts for the full set of field equations and boundary conditions. To demonstrate a measurement capability of this device, we utilized a creep measurement technique to extract mechanical properties of cell-sized alginate hydrogel microparticles. We also present preliminary differential mechanical measurements of pancreatic cancer cell sub-lines with established drug resistant phenotype, an emerging component of our on-going project to

understand the mechanisms that make rare subpopulations of tumors drug resistant and more invasive.

METHODS

A microfluidic extensional flow device, commonly called a cross-slot, consists of two channels that intersect at 90 degrees, generates a linear planar extensional flow field. The initially spherical cells or microparticles focused to the center streamline elongate into prolate ellipsoids in the extensional flow region that has a uniform extensional strain rate (Figure 1). Devices were made of polydimethylsiloxane (PDMS) and fabricated using standard soft lithography techniques. Channel dimensions are 100 μm deep and 500 μm wide.

Alginate microparticles were fabricated using an emulsion technique from 0.5% (w/v) sodium alginate and suspended in aqueous 0.5% (w/v) methylcellulose ($\mu = 15 \text{ mPa}\cdot\text{s}$). Sphere sizes were 10-50 μm . Cultured cells were trypsinized and suspended in 0.5% (w/v) methylcellulose with an approximate density of 1M cells/mL.

To perform mechanical property measurements, the microparticle or cell suspension were infused with a syringe pump into both cross-slot inlet channels (flow rate 1050 $\mu\text{L/hr}$, extensional strain rate 35 s^{-1} , channel average flow velocity 5.8 mm/s). Sphere deformation in the extensional flow region was imaged using an inverted microscope (Zeiss Axiovert 200M) with a 10x objective under brightfield (alginate microparticles) or phase contrast (cells) microscopy. For alginate particles, movies were captured with a Phantom VEO-E 340L high-speed camera at 8000 frames/s, and cell movies were capture with a Photometrics Prime95B sCMOS camera at ~ 80 frames/s.

The time evolution of strain for a single microparticle or cell as it passes through the extensional flow region was quantified from a sequence of 4 - 15 images (cells) or 60-100 images (alginate particles). Mechanical property parameters were obtained through linear

regression on the observed strain ε vs. time t data on a linear (alginate) or log-log (cells) plot applying the appropriate model (models in Results). Microparticle strain was defined as $\varepsilon = (a - b)/(a + b)$, where a and b are the long and short axes, respectively, of an ellipse fitted to the outer edge of the microsphere/cell. The custom image processing and modeling fitting was performed in MATLAB.

RESULTS

Our mechanical model is a single analytic equation that relates the time-dependent sphere deformation to suspending fluid flow because we chose experimental parameters such that both the flow field and the deformable viscoelastic sphere can be described by linear theories (Stokes flow and linear viscoelasticity, respectively). Using the viscoelastic correspondence principle [5], the Laplace-transformed viscoelastic solution is obtained directly from the corresponding elastic solution [6]. The final result for a Kelvin-Voigt viscoelastic solid (spring and damper in parallel, creep compliance $J(t) = J_0(1 - e^{-t/\tau})$) is obtained upon inversion:

$$\varepsilon(t) = \frac{5}{2} \mu \Omega J_0 (1 - e^{-t/\tau}) \quad (1)$$

where the suspending fluid parameters are viscosity μ and extensional strain rate Ω and the sphere Kelvin-Voigt parameters creep compliance J_0 and retardation time τ .

Figure 1: Alginate microparticle deforming in cross-slot device and results of Kelvin-Voigt fit to strain data (n = 8).

Cells have been shown to obey the power-law [7] under many conditions, and this constitutive law (relaxation modulus $G(t) = G_0(t/t_0)^{-\alpha}$) yields the model:

$$\varepsilon(t) = \frac{5}{2} \frac{\mu \Omega}{G_0} \left(\frac{t}{t_0} \right)^{\alpha} \frac{\sin(\pi \alpha)}{\pi \alpha} \quad (2)$$

where G_0 is the reference stiffness at an arbitrary time t_0 and $0 < \alpha < 1$ is the fluidity parameter (0 for Newtonian fluids, 1 for elastic solids).

DISCUSSION

We have demonstrated a new microfluidic measurement technique that performs high-throughput creep measurements to obtain the time-dependent shear modulus of any viscoelastic sphere. By observing cells/spheres over 10-20 ms, we capture the creep curve plateau, not just the initial rapid increase in strain. The advantages of our measurement

technique compared to previous designs include no need to calibrate the deforming force due to lack contact with walls, a simpler deformation shape that is easier to accurately capture in recorded images, and the measurement of time-dependent (viscoelastic) as opposed to time-independent (elastic, after initial transients have died out) properties. Our platform has the potential to be a repeatable, precise, and accurate technique. The data here are preliminary, and we are in the process of validating the alginate microparticle data with bulk rheometer and AFM measurements. The quality of data will also improve once our analysis code is robust enough to process thousands of cells.

Our alginate particles are softer than previous reported alginate measurements, but that is expected considering alginate is known to degrade in water and we used older microparticles that sat in water for two months. The equivalent frequency range of our platform is limited to about one decade, compared to ~ 8 decades for a rheometer. This is a drawback the specific materials use to make our microfluidic device.

The PANC1 and PANC1OR pancreatic cancer cell sublines are genetically matched yet possess contrasting invasive potential, chemoresistance, cellular architectures, and also viscoelastic mechanical properties according to these preliminary data. Our forthcoming work could be particularly informative since the drug sensitive/resistant cells here come from a common lineage thus allowing for the first time a direct correlation of mechanical phenotype and drug responsiveness.

Figure 2: Power-law mechanical properties for PANC1 cells (n = 17) and PANC1OR cells (n = 34). The chemoresistant, more invasive PANC1OR cells are softer (smaller G_0) and more fluid (larger α). Cell staining from our collaborator's earlier work [8] demonstrates the different subline mechanical phenotypes.

ACKNOWLEDGEMENTS

The PANC1/PANC1OR cells were provided by our collaborator Jon Celli (Physics, UMB). The project was funded by the University of Massachusetts Boston Healey Research Grant Program.

INTRODUCTION

Our prior work has demonstrated acceptable outcomes for porous polymer scaffolds implanted as inferior vena cava interposition grafts in SCID/bg mouse models with no evidence of catastrophic failure because of extensive neotissue deposition prior to complete polymer degradation [1]. Yet, the long-term behavior of these grafts remains different from that of native vessels, suggesting a need for improvements in implant design. Computational models of vascular graft growth and remodeling (G&R) can both describe and predict neovessel formation [2,3], and recent studies have incorporated key scaffold parameters such as microstructure and degradation behavior within the G&R framework. Furthermore, formal optimization methods have been used computationally to identify parameter values in vascular G&R, suggesting that a coupling of these computational models can yield parameter values that lead to a particular G&R outcome [4], which depends of course on the objective function minimized by the optimization procedure. Herein, we examine a G&R framework coupled to an optimization procedure with the aim of optimizing graft design parameters.

METHODS

A constrained mixture model of vascular growth and remodeling was adapted to include mass production due to the immune response associated with implantation of a polymeric scaffold and from mechanobiological principles suggesting that cells seek to promote mechanical homeostasis [5]. Immuno-

driven matrix production was parameterized in terms of the scaffold microstructure such that mass production was sensitive to changes in the pore size and fiber diameter of the construct. Mechano-mediated matrix production occurred as the stiff polymeric constituents degraded and the inflammatory response resolved, leading to increased loading of mechano-sensitive constituents. Changes in graft constituent mass densities were computed throughout the G&R time course with different times treated as a series of quasi-static equilibrium states. Such a model allowed output of relevant metrics of evolving graft behavior that were then compared to native properties to identify the scaffold microstructure and degradation profile that minimized differences in native and graft behavior throughout the G&R time course.

An objective function that promotes optimal graft behavior not only prevents catastrophic failure, but also promotes native-like neovessel behavior. Minimizing the deviation in graft radius from the native venous radius represents a correlate for dilatation and stenosis, which can occur as a result of a blunted or an exuberant inflammatory response, respectively. Graft compliance, that is, the change in graft diameter for a given change in pressure, can be used as a metric of structural stiffness that considers both geometric and material effects in determining graft mechanical behavior, which modulates the loading of adjacent vessels. Material stiffness has been shown to be an important indicator of vessel microstructural health, with changes in stiffness linked to disease processes [6]. Therefore, the chosen objective function sought to minimize

the root mean squared deviation in graft radius, compliance, and material stiffness from that of the native vessel. Numerical optimization was performed with the Surrogate Management Framework (SMF) [4,7], which is a non-intrusive, derivative-free method that enables an easy coupling with the G&R framework.

RESULTS

The coupled G&R/SMF model produced a graft design with improved matching of radius, compliance, and material stiffness relative that of the native vein throughout much of the G&R time course, which is to be contrasted with the current state-of-art empirically determined graft (Fig. 1A-C). While matching was particularly close for radius, with less than a 1% deviation from native at the end of G&R over 100 weeks, compliance and material stiffness continued to deviate by more than 10% and 40%, respectively, at the end of G&R (Fig. 1D). Additional simulations showed that closer matching of either compliance or material stiffness required a tradeoff in matching for the other metric due to an inverse correlation.

Optimal graft microstructure was found to differ from that used in the experimental grafts, with larger fibers necessary to promote robust matrix production in the immuno-compromised SCID/bg mice. Additionally, rapid degradation of the scaffold material was found to be favorable as it allowed the evolving neovessel to more quickly match the native radius, while the more robust immune response prevented dilatation (Fig. 1A).

DISCUSSION

Numerous studies have attempted to experimentally identify improved scaffold properties for tissue engineering scaffolds via an iterative (trial and error) design process. Such studies provide valuable data on the cellular response to specific changes in scaffold design, such as the effect of fiber diameter on cellular infiltration [8]. However, experimentally determining an optimal graft design is costly, both in terms of resources and time. We suggest here that computational models can be used to identify improved candidate scaffold designs, which could accelerate the design process for tissue engineered constructs. Furthermore, the G&R framework allows us to look beyond catastrophic failure and attempt to match functionally significant vessel properties, such as compliance and material stiffness.

Of course, in vivo experiments examining graft outcomes with the candidate scaffold will be necessary to validate the model prediction. Such validation experiments will also provide additional data, which can then be used to inform and refine the modeling framework. Such feedback between experiment and simulation highlight the complementary nature of these tools to enable rational tissue engineering design.

INTRODUCTION

Omens and Fung showed that, if a radial cut is applied to an equatorial slice of a rat heart, the rat's left ventricle (LV) exhibits an open angle-like morphology, revealing residual stress in the LV wall [1]. However, the heart's epicardial layer, with elastin as the dominant component, has not been well investigated, specifically on how it contributes to ventricular biomechanics. During our dissection of tissue samples from the heart surface with the epicardial layer and heart muscle, we noticed this bi-layered surface strip always curls towards the epicardial side. This surface curling reveals the existence of residual stress in the epicardial layer. In this study, we developed a curling angle measurement technique to prove and characterize the residual stress in the LV epicardial layer.

METHODS

Fresh porcine hearts (~ 6-month old, Yorkshire) were obtained from a local abattoir. Both circumferential (CD) and longitudinal (LD) LV surface strips (~15 mm×5 mm×1.5 mm) were dissected from seven locations (**Figure 1A**). The epicardial strip dimensions were determined to achieve optimal curling behavior (**Figure 1B**). The intact native hearts were fixed in 10% buffered formalin, and the fixed LV surface strips were then dissected to accurately capture the natural surface curvature of the heart as a reference. Each dissected tissue strip was immersed in 1X PBS to achieve free-floating and stress-free status, and the side-view digital pictures were taken after the full occurrence of curling (~1 minute). ImageJ was then used to analyze the curly-enclosed angle ($\theta_{\text{curly-enclosed}}$) from the native strip and the natural

angle (θ_{natural}) from the formalin-fixed strip. The total curling angular change (θ_{Δ}) was defined and calculated as: $\theta_{\Delta} = 360^{\circ} - \theta_{\text{natural}} - \theta_{\text{curly-enclosed}}$ (**Figure 1C**).

RESULTS

We successfully used the heart surface strip curling as a means to reveal and characterize the residual stress of the epicardial layer (effect of epicardial elastin in essence). Heart surface strips showed various degrees of curling in different anatomical locations. Circumferentially (**Figure 2A**), θ_{Δ} revealed that (i) the larger curling happened in the lateral locations (B2, M2) when compared to the anterior l (B1, M1) and posterior locations (B3, M3); (ii) the apex location had the largest circumferential curling. Longitudinally (**Figure 2B**), (i) the curling was larger in the anterior locations (B1, M1) when compared to the lateral (B2, M3) and posterior locations (B3, M3); (ii) again, the curling in the apex location was dramatically large.

Figure 1: (A) Sample preparation plan for circumferentially and longitudinally dissected LV surface strips. (B) Illustration showing the curling phenomenon of the heart surface strips. (C) Calculation of total curling angular change.

Figure 2: Measurements of total curling angular change in the circumferentially-dissected (A) and longitudinally dissected (B) heart surface strips at seven anatomical locations.

CONCLUSION

The observed heart surface curling clearly reveals the existence of residual stress in the epicardial layer. In other words, the epicardial layer is under tension when it covers the unpressurized intact heart. However, after a strip is dissected out from the heart, the boundary condition that restricts the elastin network from contraction does not exist anymore. As a result, the contraction of the epicardial layer bends the tissue strip and then a curling morphology occurs.

INTRODUCTION

The need for three-dimensional (3D) culture models in research and medical applications has become increasingly important due to their ability to mimic in vivo tissues along with its extracellular matrix (ECM). 3D bioprinted models will help us understand the effects of microgravity on cellular organization of the cytoskeleton, intracellular signalling mechanisms and gene expression and on cellular apoptosis [1]. Over the past two decades, research has shown that exposure to microgravity in space leads to post flight orthostatic intolerance in astronauts and cardiovascular dysfunction is a key mechanism responsible for this occurrence [2]. Microgravity-induced adaptive alterations in vascular structure and function contributes to vascular dysfunction, the main component responsible for cardiovascular problems. Endothelial cells (ECs) which cover the entire inner surface of blood vessels, play a crucial role in maintaining the functional integrity of the vascular wall and little is known on the effects of microgravity on ECs. There is limited research data available about vascular dysfunction during and post spaceflight. Researchers have been trying to interpret the role of oxidative stress in cardiovascular related disorders. Reactive oxygen and nitrogen species are thought to contribute to pathogenesis of many cardiovascular disorders (CVD) including atherosclerosis, hypertension and congestive heart failure [3]. Because reactive oxygen species (ROS) are capable of rapidly inactivating nitric oxide (NO) and since endothelial function is characterized by nitric oxide bioavailability, it is an important indicator of vascular health. NO is an important protective molecule in the vasculature and endothelial NO synthase (eNOS) is responsible for most of the vascular NO produced. A variety of enzymatic and non-enzymatic processes can generate ROS and NO in mammalian cells. ROS are highly dependent on their concentration in the tissue, when present in moderate and high levels it triggers oxidative damage. There

is still limited understanding about the pathways involved with vascular dysfunction in microgravity and is the focus of this research.

METHODS

3D Bioprinted Cellular Construct

Hydrogel is prepared using sodium alginate (Fischer Scientific) and gelatin (Sigma-Aldrich) that is dissolved respectively in DI water and 10X PBS solution under constant stirring to make a 5% (w/v %) solution. Human Umbilical Vein Endothelial Cells (HUVECs) (PromoCell) are maintained in fresh endothelial cell growth medium and are then used to bioprint cellular constructs at a range of 2.216×10^6 cells/ml - 8.38×10^6 cells/ml using the syringe-based extrusion (SBE) system. The cellular construct is then crosslinked with 0.5M calcium chloride (Fischer Scientific). The channels present in the construct as shown in Figure 1A allow transport and diffusion of oxygenated perfused media to the cellular environment to maintain cell viability. The cellular construct is then placed in the microgravity simulator system a 3-D clinostat Gravite available at NASA KSC as shown in Figure 1B. After exposure to microgravity, the tissue constructs are embedded in Tissue-tek and sectioned (5-mm-thick slices).

DHE Assay

Dihydroethidium (DHE) is a cell-permeable compound, it enters the cells and interacts with $O_2^{\bullet-}$ to form oxyethidium, which in turn interacts with nucleic acids to emit a bright red color detectable qualitatively. Each sample is washed with PBS before staining at a conc. of 5 μ M reconstituted in Krebs solution. After 30-min incubation, imaging is performed using a Nikon C1 Confocal fluorescence microscope. Nikon EZ-C1 Freeviewer (V 3.90) software is used for image acquisition. Five different fields were counted for each sample. ImageJ software is then used for measuring exposure of red

fluorescence to evaluate ROS production in the construct as shown in Figure 2.

Nitric Oxide Assay

Nitric oxide released by the cells is measured using a fluorescence probe 4-Amino-5-Methylamino-2',7'-Difluorofluorescein Diacetate (DAF-FM) at 5 μ M conc. diluted in 1X PBS which produces a green fluorescence (488nm) after exposure to simulated microgravity as shown in Figure 3. After 30-min incubation, imaging is performed using a Nikon C1 Confocal fluorescence microscope. Nikon EZ-C1 Freeviewer (V 3.90) software is used for image acquisition. Five different fields are counted for each sample. ImageJ software is then used for measuring and evaluating NO production in the construct.

RESULTS

Two factors, space radiation and microgravity are prominently involved in ROS and NO generation in biological systems. ROS production is facilitated in specific organs and tissues including neuronal and cardiovascular systems. Results from simulated microgravity demonstrates increased ROS production and reduced NO bioavailability as shown in Figures 4 and 5 respectively. The tissue constructs that are not exposed to microgravity (ctrl) yields higher NO production and decreased ROS when compared to the constructs exposed to microgravity. This shows an increase in oxidative stress, which is due to the decrease in NO production and increase in ROS production, resulting in endothelial dysfunction, and thus can lead to CVD during spaceflight. Statistical analysis of NO and ROS revealed a significant decrease in the microgravity samples ($p < 0.05$).

Figure 3: Fluorescence confocal microscopy images of NO released by the cells.

Figure 4: Fluorescence intensity measurement of ROS obtained from the cellular constructs.

Figure 5: Fluorescence intensity measurement of NO obtained from the cellular constructs.

DISCUSSION

The architectural design of the cellular construct bioprinted is optimized to improve the diffusion limitation in the 3D constructs and test for mechanical stabilization. Despite all the advances, there isn't a model to investigate vascular dysfunction under the influence of microgravity. It is anticipated that 3D cell culture models will provide significant advantages including more physiologically relevant representations of cell morphology, proliferation gradients, response to drugs, gene expression, and overall cell behavior. Many studies have reported that cells can sense mechanical stresses, including variation of gravitational forces due to the changes in the forces that are transmitted across transmembrane adhesion receptors which link the cytoskeleton to the ECM and to other cells [4]. The results presented in this study demonstrates that exposure to microgravity affects the endothelial cells by increasing production of ROS as shown above by uncoupled eNOS which in turn causes further production of superoxide anion rather than NO which contributes markedly to this pathophysiology. Further experimentation based in simulated microgravity can advance our knowledge of the relationship between altered cellular mechanisms and on the vasculature of the tissue. Understanding oxidative stress in the space environment may help us understand the pathophysiological process and contribute to solving the problems caused due to exposure to microgravity and radiation.

INTRODUCTION

The nuclear lamina protein, Lamin A/C (LMNA), mutations can cause pathologies in multiple organs [1]. For example, the progeria disease is associated with a mutation to the LMNA gene, and it leads to a devastating early aging and death. In contrast, other LMNA gene mutations do not cause early aging, but instead have a subtler effect with patients presenting only with heart disease symptoms [2-4]. However, the mechanisms by which the LMNA mutation emerges exclusively in the heart muscle are unknown. One important avenue that needs to be explored is the unique mechanical environment of the heart, which could trigger pathological changes. We aimed to study the mechanisms that lead to these differences in vitro with patient specific cell-lines.

METHODS

Here we will present a study of 10 cell-lines negative for mutations or with four different types of LMNA mutations: 1) Hutchinson-Gilford progeria syndrome LMNA gene mutation, 2) LMNA splice-site mutation (c.357-2A>G, p.N120Lfs*5), 3) LMNA nonsense mutation (c.736 C>T, p.Q246X), and 4) LMNA missense mutation c.1003C>T (p.R335W) in exon 6 [5]. Fibroblasts from each of these cells lines were cultured and subject to a variety of mechanical stimulation akin to those experienced by cells in the myocardium. The cells were then fixed and stained to visualize the nuclei, actin fibrils, and the underlined remodeled fibronectin. To analyze this data, we applied existing algorithms to quantify the reorganization of actin in response to mechanical stimulation by calculating both the actin orientational order parameter. Additionally, we analyzed the nuclei population in each sample for the number, defective percentage, nuclear area, and eccentricity. Furthermore, some of the fibroblast cell-lines were used to create patient specific

iPS-derived cardiomyocytes. PATIENT's and CONTROL's fibroblasts (from skin biopsy) were reprogrammed to iPSCs (Fig. 1A) and differentiated to cardiomyocytes (Fig 1B-C). The PATIENT and CONTROL iPSC-derived cardiomyocytes were cultured and immunostained for Nuclei, actin fibrils, and Sarcomere (Fig 1B: blue, green, and red, respectively). The tissues were imaged with a confocal microscope, and the stained architectures were quantified. The presence of sarcomeres was used to confirm proper differentiation. Moreover, for the functional assay, iPSC- derived cardiomyocytes were evaluated by the "Heart-on-a-Chip" device based on the muscular thin film (MTF) technology. The cardiomyocytes can either contract spontaneously or they can be paced using a myopacer at 0.5-2 Hz by field stimulation electrodes. The dynamics of the tissue constructs were recorded and analyzed using ImageJ and Matlab software. Data for PATIENTs and CONTROLs chips were collected and analyzed for frequency and stress as a function of time for all conditions tested.

Figure 1: Time-line of differentiation. (A) iPSC colony; (B) Sarcomeres (red) in iPSC-derived cardiomyocytes; (C) time line.

RESULTS

It was found that mechanical stimulation alone applied to fibroblasts results in almost no significant differences (Fig. 2) between PATIENT and negative CONTROL lines for either tissue organization (Fig. 2) or nuclear morphology (Fig. 3).

Figure 2: Organization of Actin Fibrils and extracellular matrix for PATIENTs, Negative CONTROLs, and a progeria cell line (positive control). Purple – no stretch, yellow – stretch at 1 Hz.

Figure 3: (A) Nuclei identified as defective (red) or normal (green). (B) The percent of nuclei as defective in each sample for all cell lines.

There are some minor family specific variations (Fig. 4). However, it is unlikely that such minor changes could lead to major pathological responses.

Figure 4: An example of subtle differences between the families of PATIENTs: (i) Nuclear area for static (purple) and stretch (yellow) conditions; lines with x's indicate no significance. (ii) A significant matrix referencing the red labels on (i). (iii) Examples of small and large nuclei.

In contrast, our data shows significant differences between iPSC-derived cardiomyocytes of PATIENTs and CONTROLS in frequency and active stress (Fig. 5). When the CONTROL tissues are paced, the measured frequency matches the induced frequency (Fig. 5A – black line trend on blue points). In contrast, when PATIENT tissues are paced, the actual frequency does not match the pacing frequency, which can be due to LMNA mutation and could be a cause of heart disease initiation. It is also interesting to note that the variation in measured frequency for paced tissues is much greater for PATIENTS

than CONTROLS. The active stress was measured as the difference between the systolic and diastolic stresses (Fig. 5B). For negative CONTROLS tissues, the active stress increased when the tissues were paced. In PATIENTS, the active stress does not increase, which is another indication that the cells from the PATIENTS lines do not respond to pacing. Moreover, negative CONTROLS tissues have significantly higher active stress than the PATIENTS (Fig. 5B).

Figure 5: (A) Frequency response of PATIENT (red) and CONTROL (blue) tissues; right side of plot shows the results of no pacing – i.e. the spontaneous contraction. (B) Generated stress by the cardiac tissues.

DISCUSSION

Our cardiomyocyte results demonstrate that it is possible to construct an iPSC-derived cardiomyocyte in vitro model that differentiates between CONTROL and PATIENT populations. This is significant because the PATIENTS do not develop heart disease until they are at youngest in their 30s and sometimes in their 60s. With this work, we demonstrated that it is possible to see the consequences of this mutation within a reasonable lab experiment time frame.

Our stretcher results, in contrast, do not show that simple mechanical perturbation (which exists in contracting cardiomyocytes) is sufficient to cause significant differences in fibroblast morphology. There are two possible explanations for this – mechanical and biological. In terms of mechanics, it is possible that the stretch regime chosen for our experiments does not sufficiently recapitulate the cardiac tissue environment to trigger the mutation pathology. Alternatively, it is possible that the biological differences between fibroblasts and cardiomyocytes are dictating the location of the pathology. This will need to be further investigated.

INTRODUCTION

Aortic aneurysm (AA) is a chronic inflammatory disease of the aortic wall whereby degeneration of healthy tissue triggers progressive dilation of the vessel. Approximately 5 million people >50 years present with abdominal AA in the US [1,2] and over 200,000 new abdominal AAs are diagnosed annually [3]. AA rupture occurs when the aortic wall tissue can no longer bear the load induced by physiological forces due to advanced degeneration. This event is responsible for 15,000 high-mortality events annually in the US alone [4]. Wall degeneration can be attributed to changes in structural macromolecules, specifically, elastin degradation coupled with disorganization of the collagen network [5].

Currently, surgical intervention is the only option available to AA patients and the decision to intervene is primarily governed by aortic diameter measurements. Adult patients are recommended for surgery once their AA exceeds a "critical diameter" of 5.5cm. However, no non-surgical treatment option is available to patients who fall below the threshold despite the pronounced risk of rupture in this cohort. A targeted treatment to arrest degeneration and/or induce regeneration of functional elastic and collagen fibers could offer a viable non-surgical therapeutic option for patients with sub-critical AA dilations.

Work by our group has shown that periadventitial delivery of adipose-derived stromal stem cells (ASC) to a growing elastase-induced mouse aneurysm slows dilation and preserves elastic lamellae [6]. More recent unpublished work by our group has linked this elastin inducing effect to the products secreted by ASC. Specifically, we have shown that ASC conditioned media (CM) can stimulate elastic fiber assembly by healthy adult SMCs using a multi-level elastogenesis analysis. However, it is currently unknown if this elastogenic effect is caused by free factors within the CM or factors packaged within extracellular vesicles (EVs). EVs are cell-derived phospholipid membrane based nano-particles that present with functional surface/membrane proteins and contain protein and RNA species that can replicate the therapeutic effects of their parent cell [7]. Determining the specific fraction of the ASC CM that induces elastogenesis is critical to developing a well-defined and translatable treatment option. This study therefore tested if

ASC derived EVs induce deposition of elastin and collagen fibers by aortic smooth muscle cells (SMCs) within three-dimensional *in vitro* fibrin gel constructs and if these fibers are mechanically functional. We compared the effect of ASC derived EVs to ASC CM and ASC CM that has been depleted of EVs (dEV CM) in order to de-couple the effects of free and encapsulated factors.

METHODS

Healthy adult human SMCs were purchased from ATCC and loaded within 3D fibrin gel constructs. Fibrin gel constructs were fabricated as previously described [8] using 200µL of fibrin and a SMC seeding density of 5×10^5 cells/mL. A fibrinolysis inhibitor (12mM aminocaproic acid) was used to halt construct breakdown. Gels were plated on either stiff (tissue culture plastic) or soft (Flexcell plates) substrates. Culture media was changed every 48-72 hours for 30 days.

ASC CM was generated by culturing primary ASCs in two T175 tower flasks (5 layers in each) for 48 hours. ASCs were cultured in 1:1 DMEM:F12 supplemented with Pen-Strep, Fungizone and 10% FBS that had been depleted of EVs via 18 hours of ultracentrifugation at 120,000g. EVs were isolated from ASC CM using differential ultracentrifugation. Specifically, the CM was centrifuged at 250g to remove cells, 2500g to remove debris, filtered through 0.2 µm to remove apoptotic bodies and then pelleted via ultracentrifugation at 100,000g for 70 minutes. EVs were characterized using transmission electron microscopy (TEM) to determine morphology, dynamic light scattering (DLS) to examine size and bicinchoninic acid assay (BCA) to quantify EV protein content before and after lysis using 2% SDS.

Treatments applied to the gels included: (1) No Treatment (NT): SMC growth-supplemented media; (2) Non-Conditioned Media (NCM): a 1:1 combination of SMC growth-supplemented media and fresh ASC culture media, (3) ASC CM: a 1:1 combination of SMC growth-supplemented media and ASC conditioned media; (4 and 5) 1x and 3x EV: a 1:1 combination of SMC growth-supplemented media and fresh ASC culture media supplemented with two different concentrations of EVs, and (6) dEV CM: a 1:1 combination of SMC

growth-supplemented media and ASC CM that has been depleted of EVs via differential ultracentrifugation.

Ninhydrin (insoluble elastin) and hydroxyproline (collagen) protein assays were used to quantify macromolecule deposition as a percentage of total protein within the stiff and soft substrate gels [9]. Uniaxial tensile testing of soft gels was performed using an Instron #5543A device. Mechanical properties are reported as the modulus of the response curves in the low and high stretch regions.

RESULTS

Characterisation of EVs demonstrates that (1) the particles are spherical and cup-like in appearance which is typical of EVs, (2) there are two distinct populations of particles that represent exosomes (~70nm) and microvesicles (~300nm) and (3) total protein content is increased upon lysis of the EVs indicating that protein is encapsulated within the EV's phospholipid membrane (Figure 1).

Figure 1: Morphology, size and total protein content of EVs isolated from ASC CM.

Both EV groups and the ASC CM group show similar levels of elastin deposition after 30 days in stiff substrate gels that are greatly increased compared to dEV CM, NT and NCM ($0.07 \pm 0.07\%$ NT, $0.03 \pm 0.04\%$ NCM and $0.04 \pm 0.04\%$ dEV CM, vs $0.27 \pm 0.12\%$ ASC-CM, $0.25 \pm 0.1\%$ 1x EV and $0.22 \pm 0.1\%$ 3x EV) (Figure 2A). The EV groups also generated a greater level of collagen deposition after 30 days in stiff substrate gels compared to ASC CM ($0.04 \pm 0.05\%$ NT, $0.13 \pm 0.06\%$ NCM and $0.1 \pm 0.3\%$ dEV CM, vs $0.16 \pm 0.03\%$ ASC-CM, $0.23 \pm 0.09\%$ 1x EV and $0.31 \pm 0.03\%$ 3x EV) (Figure 2B).

Figure 2: Insoluble elastin and collagen generated by SMCs within stimulated stiff substrate fibrin gels.

There was no significant difference between ASC CM or EV groups and control groups regarding insoluble elastin deposition after 30 days in soft substrate gels ($0.23 \pm 0.14\%$ NT, $0.24 \pm 0.07\%$ NCM, and $0.29 \pm 0.26\%$ dEV CM, vs $1.25 \pm 2.72\%$ ASC-CM, $1.45 \pm 2.19\%$ 1x EV and $0.41 \pm 0.32\%$ 3x EV) (Figure 2A). Similarly, there was no significant difference between ASC CM or EV groups and control groups regarding collagen deposition after 30 days in soft substrate gels ($0.19 \pm 0.19\%$ NT, $0.2 \pm 0.06\%$ NCM and $0.2 \pm 0.15\%$ dEV CM vs $0.34 \pm 0.15\%$ ASC-CM, $0.3 \pm 0.1\%$ 1x EV and $0.28 \pm 0.12\%$ 3x EV) (Figure 2B).

Tensile testing of the same soft substrate gels following 30 days of culture revealed that the low elastic modulus of the gels was largely unchanged (Figure 3C). There is an apparent trend regarding high modulus whereby the EV groups display a greater high modulus compared to the remaining groups. However, the standard deviation is large across all examined parameters for the soft substrate gels ($0.05 \pm 0.3\text{kPa}$ NT, $0.1 \pm 0.04\text{kPa}$ NCM and $0.13 \pm 0.07\text{kPa}$ dEV CM vs $0.12 \pm 0.08\text{kPa}$ ASC-CM, 0.15 ± 0.16 1x EV and $0.21 \pm 0.24\text{kPa}$ 3x EV) (Figure 3D).

Figure 3: Insoluble elastin and collagen within stimulated soft substrate fibrin gels and mechanical properties of the gels.

DISCUSSION

Our analysis shows that stimulating SMCs with ASC derived EVs in fibrin gels plated on stiff substrates results in greater insoluble elastin and collagen deposition compared to NT, NCM and dEV CM. This demonstrates the potentially wide-ranging vascular extracellular matrix regenerative capabilities of ASC EVs.

Experiments conducted in soft substrate gels demonstrate larger standard deviations than stiff substrate gels, therefore limiting the conclusions that can be drawn regarding the mechanical functionality of EV stimulated elastin and collagen.

We conclude that ASC EV treatment of SMCs stimulates elastin and collagen deposition. This could potentially lead to an effective non-surgical regenerative therapy for treatment of AA. Future work will perform qPCR to examine SMC elastin chaperone protein transcription and gel imaging to examine fiber diameter and intersection density.

INTRODUCTION

The arterial wall intima is composed of endothelial cells and fenestrated elastic lamina adjacent to the smooth muscle cells of the tunica media. This intra-arterial barrier is subjected to the physical stresses imposed by the flowing blood. Biological cells can rearrange their cytoskeleton as they grow, divide and adapt to the physical environment. Actin filaments, microtubules and intermediate filaments are the major components of the cytoskeletal structure and play dominant roles in various cellular events, including cell proliferation, migration, differentiation and apoptosis. They also determinate the mechanical properties and shape stability of cells and contribute to cell-to-cell and cell-to- extracellular matrices physical interactions. The cell regulates the length and stability of its cytoskeletal filaments by converting information received through signaling pathways [1].

Many models have been developed in permeable supports in culture dishes, lacking the ability to disassemble the co-coculture complex for insertion in test chambers for mechanobiology studies. The knowledge of the mechano-behavior of the cells under physical forces can contribute to tissue engineering studies. For instance, the study of how different physical loads can contribute during cellular growth to successfully engineer artificial tissue and organs that mimic the *in vivo* biological characteristics and biophysical environment. It will also help to accelerate the development of three-dimensional (3D) tissue engineer techniques for pre-programming functional biological characteristics with mechanical viability. In addition, the development of *in vitro* platforms can replace human or animal experiments for basic studies and testing medications or hazardous materials.

We developed a multi-layer tissue-engineered model that mimics the inner *in vivo* architecture of the arterial intima to allow for *in vitro* mechanobiology studies. This model will be tested in flow systems that generate fluid flow wall shear stresses (WSS) on the endothelial

cells in order to explore the biological response to different physical environments.

METHODS

A co-culture of endothelial and smooth muscle cells has been developed on a collagen-coated Polytetrafluoroethylene (PTFE) synthetic membrane. We developed a custom-designed well equipped with a PTFE membrane that can be disassembled for insertion of the co-culture model in flow chambers. The collagen coated membrane was also coated with human fibronectin and then seeded with human umbilical arterial smooth muscle cells (HUASMC). After 24 hours we coated the HUASMC with collagen and seeded human umbilical vein endothelial cells (HUVEC). After one more day, the tissue engineered model was ready for application of WSS induced by steady flow. In addition, we also cultured a monolayer of HUVEC for evaluation of differences in cytoskeleton changes between HUVEC of monolayer and HUVEC on co-culture due to provocations of WSS. Immunofluorescent staining and confocal imaging were utilized to confirm that the *in vitro* model was composed of a multi-layer structure of HUVEC on top of HUASMC. We used antibodies that depicted the VE-cadherin of the HUVEC and the HUASMC actin.

The flow circuit for applying WSS on top of the HUVEC cells was composed of a flow chamber with a rectangular cross-section which can hold 6 well bottoms with the tissue-engineered vascular wall model and a peristaltic pump was used to generate steady uniform flow of medium [2]. Since the height ($h=1$ mm) of the flow chamber is much smaller than either its length ($l=100$ mm) or its width ($b=35$ mm), the fluid flow characteristics within the flow chamber can be described as a parallel plate flow. Thus, the WSS is given by,

$$\tau = \frac{-6\mu Q}{bh^2} \quad (1)$$

where μ is the fluid viscosity and Q is the fluid flow rate.

RESULTS

We generated a 3D *in vitro* model of HUVEC cultured on top of HUASMC similar to the *in vivo* organization of the arterial inner barrier. Confocal images of the *in vitro* model with the two layers of different cells is shown in Figure 1. This model was cultured in the custom-design wells and 90% confluency for both HUVEC and HUASMC was observed after 1 day of cultivation. The average height of the intra-arterial barrier 3D model was about 22 μm .

Figure 1: Confocal images of the arterial co-culture. The top row shows the HUVEC - positive for VE-cadherin (pink). The bottom row shows HUASMC - positive alpha-actin (red). At the middle Z-stack projection from the side. F-actin stained with phalloidin (green), and nuclei with DAPI(blue) ($n \geq 20$).

We carried out experiments in which steady flow WSS were applied on top of the HUVEC for 60 min. These *in vitro* experiments were conducted with a monolayer of HUVEC as well as with a co-culture of HUVEC on HUASMC. Confocal images of the HUVEC cytoskeletal components of the monolayer of HUVEC is depicted in Figure 2, for control without flow ($\tau=0$) and after exposure to WSS of $\tau=24 \text{ dyne/cm}^2$. The F-Actin in HUVEC cultured as monolayer was more visible in samples exposed to WSS than in the control. Moreover, the VE-cadherin appears to be more solid in the control than in the well under WSS. The confocal images for the HUVEC cultured on top of the HUASMC are depicted in Figure 3, for control without flow ($\tau=0$) and after exposure to WSS of $\tau=24 \text{ dyne/cm}^2$. In the samples with flow, HUVEC began to acquire an elongated shape as is well known that the endothelial cells align themselves with the flow.

Figure 2: Confocal images of monolayer of HUVEC – control and after exposure to WSS ($n \geq 5$). VE-cadherin (pink). F-actin stained with phalloidin (green) and nuclei with DAPI(blue) ($n \geq 20$).

Figure 3: Confocal images for *in vitro* co-culture model with and without WSS ($n \geq 5$). VE-cadherin (pink). F-actin stained with phalloidin (green), and nuclei with DAPI(blue) ($n \geq 20$).

DISCUSSION

A 3D *in vitro* model of the intra-arteria wall was developed in custom-wells and was exposed to different WSS. The HUVEC cells expressed more F-actin in models under strong WSS and the cells began to align themselves towards the flow direction. This new co-culture model of the arterial inner barrier will be useful to study the contribution of adjacent cell layers to the biological response to environmental physical provocations. The results can be useful for mechanobiology studies such as different flow types, static and dynamic pressures. Furthermore, examination with this *in vitro* model may be helpful in advanced studies of tissue engineering.

INTRODUCTION

Vascular calcification is the leading indicator of cardiovascular morbidity and mortality [1]. Recent studies have shown that vascular calcification is initiated through specific calcifying extracellular vesicles (EVs) released by cells in the vascular wall. Once released from cells, calcifying EVs aggregate and fuse to form microcalcifications, which serve as building blocks for larger calcifications [2]. Calcifying EV formation begins with endocytosis of caveolae, small invaginations in the cell membrane [3].

Caveolae endocytosis and intracellular trafficking integrates tissue non-specific alkaline phosphatase (TNAP) into smooth muscle cell-derived EVs. TNAP mediates atherosclerotic mineral deposition through hydrolysis of calcification inhibitors and generation of free phosphate ions [2]. Caveolae are also known mechanosensors that respond to changes in cell membrane tension; however, the relationship between cell mechanics and the formation of calcifying EVs remains unknown. Previous studies have shown that increased cell contraction is required for calcification [4], and increased contraction leads to elevated cell prestress according to tensegrity models [5]. We hypothesize that increased human coronary artery smooth muscle cell (HCASMC) contraction and prestress is required for the caveolae-dependent formation of calcifying EVs and pathological calcification.

METHODS

Glucose has been shown to increase cell contractility, and the stiffness of the extracellular environment resists cell contraction. HCASMCs were cultured under three glucose concentrations (0, 1.5 g/L, and 4.5 g/L) in two conditions: control media or media supplemented with pro-calcific (PC) reagents (0.1 mM L-ascorbic acid, 10 mM β -glycerophosphate, and 10 nM dexamethasone). Extracellular calcification was measured with alizarin red S staining. Phalloidin staining assessed actin filament length and cell area as a measure of HCASMC contractility. Nanoindentation was used to investigate changes in HCASMC stiffness (an indicator of tensegrity prestress). To study the effect of prestress on calcification, HCASMCs were treated with jasplakinolide (50nM), which promotes actin filament elongation.

To study the effect of growth substrate stiffness on vascular calcification, HCASMCs were cultured on two substrates with stiffness of 1 and 100 MPa and treated by either control (4.5 g/L glucose) or PC media for 21 days. Furthermore, to investigate the influence of cytoskeleton alterations, HCASMCs were treated for 21 days under control and PC media, where either actin filaments or microtubules were disrupted by cytochalasin D or nocodazole, respectively. After collecting conditioned media at day 14, EVs were isolated using ultracentrifugation at 100,000 \times g. TNAP activity colorimetric assay was performed to assess the activity level of this enzyme in released EVs.

RESULTS

The average surface area (Figure 1A) of phalloidin-stained HCASMCs cultured in 0g/L glucose, 1.5 g/L glucose, and 4.5 g/L glucose (Figure 1C) was determined using a custom MATLAB image analysis script. After 3 days in culture, 1.5 g/L glucose resulted in a 26% decrease in HCASMC area, and 4.5 g/L glucose treated HCASMCs exhibited a 42% decrease in area with short, thick actin stress fibers compared to cultures with 0 g/L glucose (Figure 1A, 1C). Relative to cultures with no glucose, 4.5 g/L glucose treatment for 3 days resulted in a 1.3-fold increase in HCASMC stiffness, and the addition of PC components increased HCASMC stiffness by 3.4-fold (Figure 1B). The decrease in HCASMC area correlated with a dose-dependent increase in calcification after 21 days in culture as shown by alizarin red S staining (Figure 1C, inset images). The addition of jasplakinolide inhibited the decrease in HCASMC area following 3 days in 4.5 g/L glucose media and mitigated calcification in these cultures after 21 days (Figure 1C). Our results suggest that glucose-mediated increases in HCASMC contractility and prestress is required for calcification.

Figure 1: (A) Average areas of HCASMCs in PC media with 0, 1.5, or 4.5 g/L glucose for 3 days; (B) Nanoindentation measurement of HCASMC stiffness in response to 4.5 g/L glucose in control and PC media compared to cultures with 0 g/L glucose; (C) Representative images of phalloidin-stained HCASMCs in PC media with 0, 1.5, 4.5 g/L glucose, and 4.5 g/L glucose Jasplakinolide treated for 3 days. Inset images of alizarin red S staining after 21 days.

Culturing HCASMCs on a lower stiffness substrate yielded a 1.8-fold increase in EV TNAP activity in control media compared to tissue culture plastic controls (Figure 2A). HCASMCs cultured in PC media on a lower stiffness substrate exhibited a 7.6-fold increase in EV TNAP activity compared to HCASMCs cultured in normal media on tissue culture plastic (Figure 2A). Disruption of actin filaments and microtubules led to a 30% and 10% decrease in EV TNAP activity, respectively (Figure 2B).

Figure 2: TNAP activity in EVs from (A) different ECM stiffness, and (B) cytoskeleton disruption.

DISCUSSION

The data indicate that elevated prestress or reduced substrate stiffness enhance the calcification potential of HCASMCs. Tensegrity models predict that either of these changes could lead to plasma membrane compression. This compression may induce caveolae endocytosis and the initiation of calcifying EV formation. Subsequent deposition of mineral stiffens the extracellular matrix, resisting the compression. Therefore, the mechanisms identified in this study may indicate caveolae trafficking as a rheostat that allows cells to sense and direct changes in extracellular stiffness. Future works will address this proposed mechanism and potential related therapeutic interventions for vascular calcification.

INTRODUCTION

Cells sense mechanical signals from their microenvironment and transduce them to the nucleus to regulate gene expression programs. To elucidate the physical mechanisms involved in this regulation, we developed an active chemo-mechanical model to describe the three-way feedback between the adhesions, the cytoskeleton, and the nucleus. The model shows how cell geometric constraints affect the three-way feedback and induce cytoskeleton-mediated alterations in the properties of the nucleus such as nuclear lamina softening, chromatin stiffening, nuclear lamina invaginations, increase in nuclear height and shrinkage of nuclear volume. We predict how the disruption of cytoskeletal components impacts the feedback and subsequently induce alterations in the properties of the nucleus. The predictions are experimentally validated by studying the properties of nuclei of fibroblasts on micropatterned substrates with different shapes and areas.

METHODS

We develop a chemo-mechanical model that accounts for all the key cellular components involved in the transmission of mechanical stimuli from the cell-matrix interface to the nucleus including (i) the cytoskeleton, (ii) the nucleus, and (iii) the focal adhesions.

The cytoskeletal model is composed of the myosin motors, the microtubule network, and the actin filament network [1]. We model the nuclear envelope (NE) as a filamentous network material which stiffens along the tensile principal axes of the stress tensor to capture the fact that lamin A,C increases with tension in NE. We combine our mechanical model with reaction-diffusion equations for the transport of epigenetic and transcription factors. With the average contractility at hand from our mechanical model simulations, the signaling model enables us to quantitatively predict the contractility dependent translocation of these factors such as HDAC3 and MKL.

RESULTS

NIH 3T3 mouse fibroblast cells are cultured on fibronectin-coated micropatterned substrates with two extreme geometries (Figs. 1A and 1B): a rectangle with an aspect ratio of 1:5 and a substrate surface area of 1600 μm^2 (large and elongated substrate geometry), and a circle with a substrate surface area of 500 μm^2 (small and circular substrate geometry). Cells on the rectangular substrate have higher and polarized contractility, cytoskeletal tension, and cytoskeletal stiffness leading to a flattened and elongated nuclear morphology (Fig. 1C). As a result, tension is generated in the nuclear envelope lamina of rectangular cells correlated with their higher levels of lamin A,C and nuclear envelope stiffness (Fig. 1D).

Figure 1: Cell geometric constraints regulate cell contractility, actin organization, and nuclear envelope lamina stiffness.

Next, fibroblasts are cultured on fibronectin-coated micropatterned substrates with the same substrate surface area of $1600 \mu\text{m}^2$ but various aspect ratios 1:1 (Fig. 2A), 1:3 (Fig. 2B), and 1:5 (Fig. 2C) [2]. Formations of apical and lateral stress fibers lead to flattening (Fig. 2E) and elongation (Fig. 2F) of the nucleus in the rectangular substrate geometries (1:3 and 1:5 aspect ratios) compared to the square substrate geometry (1:1 aspect ratio) as actomyosin contractility increases with anisotropy in tensile stresses (Fig. 2D). We also find that stress fibers (Fig. 2G) are formed in the direction of the maximum principal stress (Fig. 2H).

Figure 2. Substrate aspect ratio induces alterations in prenuclear actin organizations and nuclear morphology.

We next show that microtubules in large and elongated cells buckle without being able to significantly indent the nucleus as the MTOC is pushed toward the cell boundary by the nucleus (Figs. 3A and 3C). In contrast, cells on small and circular substrates exhibit crescent-shaped nuclear morphologies as the MTOC pushes against the nucleus and forms a local indentation in the nucleus (Figs. 3B and 3D). Similar to the circular cell, the nucleus is indented by the MTOC when actin filaments are depolymerized in the rectangular cell (Fig. 3E). We finally show that overexpression of lamin A,C rescues nuclear invagination in circular cells (Fig. 3F).

Figure 3. Nuclei with low levels of lamin A,C and round morphologies are indented by the MTOC.

We also report that the level of contractility regulates nucleo-cytoplasmic translocations of epigenetic and transcription factors (Fig. 4A) [3]. Cells on large and elongated substrates have higher contractility (compared to small and circular cells) and higher levels of polymerized F-actin (Fig. 4B). As G-actin is polymerized into F-actin, MKL unbinds from G-actin and shuttles to the nucleus leading to higher nuclear accumulations of MKL in large and elongated cells (Fig. 4C). On the other hand, decreasing contractility by constraining cells on smaller and unpolarized substrates (Fig. 4D) or by using actomyosin inhibitors (Figs. 4E-G) leads to translocation of HDAC to the nucleus and subsequently chromatin condensation.

Figure 4. Cell geometric constraints induce nuclear translocation of HDAC driven by decreases in actomyosin contractility.

DISCUSSION

Using a chemo-mechanical model, we showed how the physical properties of the microenvironment, including cell substrate area, shape, and stiffness, impact the properties of both cytoskeleton and nucleus by regulating the dynamic reciprocities between tension-dependent formation of focal adhesions, phosphorylation of myosin motors, polymerization of actin filaments, stiffening of the nuclear envelope lamina network, and nucleo-cytoplasmic shuttling of epigenetic factors. Given the predictive power of the model as illustrated by extensive experimental tests, it can potentially be used to describe abnormal nuclear morphology in diseases like progeria, cancer, fibrosis, and dilated cardiomyopathy.

INTRODUCTION

Endothelial cells respond both morphologically and biochemically to the mechanical environment. The cell response is highly complex, with protein expression, activation, and cellular localization changing as the cell responds to mechanical stimuli [1]. Current experimental techniques cannot simultaneously measure all of these factors in real time, even in simplistic 2D cell culture models. Therefore, computational models are needed to predict cell mechanobiology responses and thereby direct future experimental studies.

Computational cell models come in many forms. Mass action kinetic models require reaction kinetic parameters but can simulate the cell response over time. These models can also directly couple the mechanical environment, for example fluid flow, to mass transport and binding kinetics [2]. Stoichiometric models require less information since they rely on reaction stoichiometry. These models account for all genetic and biochemical components and their reactions (e.g., genome-scale); however, they are limited to steady state conditions [3].

In this study, we developed two computational models of endothelial cell response to fluid shear stress. First, we created a mass action kinetics model of endothelial growth factor binding in cells adapted to either static conditions or fluid flow. Second, we created a stoichiometric model of endothelial glucose metabolism and analyzed pathway changes associated with shear stress response. In both cases, the models were developed and validated with experimental data.

METHODS

Mass action kinetics model of growth factor binding in flow

The mass action kinetics model was created in Comsol for fibroblast growth factor-2 (FGF2) using Glycotech parallel plate flow chamber dimensions (6 cm long x 1 cm wide x 0.0127 cm high). The

fluid was defined as incompressible Newtonian fully developed laminar flow with no-slip boundary condition at the walls. The standard convection–diffusion mass balance equation was used to define FGF2 concentration with respect to location and time:

$$\frac{\partial [F]}{\partial t} + \nabla \cdot (-D \nabla [F] + [F] \vec{u}) = 0 \quad (1)$$

where $[F]$ is FGF2 concentration, D is the FGF2 diffusion coefficient and u is the velocity vector. Reactive species included FGF2, the FGF receptor (FGFR) and heparan sulfate proteoglycans (HSPG). Possible reactions are shown in Figure 1.

Figure 1: Model schematic showing species, reactions, and bound complexes. F = FGF2, R = FGFR, H = HSPG, FR = FGF2-FGFR, FH = FGF2-HSPG, FHR = FGF2-HSPG-FGFR. i indicates internalized species.

For example, FGF2-HSPG (FH) complexes were defined to change with time based on association, dissociation, and internalization rates:

$$\frac{d[FH]}{dt} = \alpha k_{on,FH}[F][H] - k_{off,FH}[FH] - k_{on,FHR}[R][FH] - k_{i,FH}[FH] \quad (2)$$

For experimental validation, endothelial cells were exposed to shear stress in a Glycotech flow chamber. After 24 hours, medium was changed to binding buffer with 0 or 10 ng/mL FGF2 for an additional two hours of flow. Cell surface HSPG-bound FGF2 was first extracted using a salt buffer, after which FGFR-bound FGF2 was extracted using an acid buffer. FGF2 was quantified in all extracts using an FGF ELISA.

Stoichiometric model of glucose metabolism in flow

The stoichiometric model was built using Recon3D, a genome-scale model that represents a human cell metabolic network [3]. In this model, the coefficients for metabolites and reactions were represented in a stoichiometric matrix, while fluxes were represented as the flux vector, which contained upper and lower flux bounds. The FASTCORE algorithm was then used to remove reactions that are not expressed in endothelial cells based on human endothelial gene arrays (ArrayExpress; E-GEOD-21212). The final model contained roughly 1000 unique metabolites and 1500 biochemical reactions.

The model was validated with $^{13}\text{C}_6$ -glucose mass spectrometry experimental data. Endothelial cells were exposed to either static culture or steady laminar flow (20 dynes/cm² shear stress) for 24 hours in a custom cone and plate device. Cells were then cultured with 5 mM $^{13}\text{C}_6$ -glucose for 24 hours to ensure steady state. Metabolites in cells and media were extracted using 80:20 methanol:water and analyzed using ultra high-performance liquid chromatography (UHPLC). The human metabolome database (HMDB) was used for metabolite identification.

RESULTS

Mass action kinetics model of growth factor binding in flow

We first experimentally measured FGF2 binding to endothelial cells adapted to shear stress. As shear stress increased from 0 to 20 dynes/cm², FGF2 binding to cell surface HSPG increased five times and then decreased 40 dynes/cm² shear stress. FGF2 binding to cell surface FGFR did not change with shear stress. Both flow rate and receptor effects were statistically significant, as was their interaction ($p < 0.001$).

We then used the computational model to predict what might contribute to biphasic FGF2 binding to cell surface HSPG under flow. The computational model run under varied flow rates did not reproduce the experimental results. Instead, FGF2 bound to cell surface HSPG remained constant at all shear stress levels, suggesting that it is not flow itself but cell adaptation to flow that alters FGF2 binding.

Figure 2: The computational model closely matched experimental data only when HSPG production was included along with availability and dissociation. [FGF2] = 10 ng/mL (5.56×10^{-5} μM); [HSPG] = 2.16×10^{-10} mol/m²; [FGFR] = 4.15×10^{-12} mol/m²

We therefore investigated cell changes that could increase or decrease cell surface HSPG binding. HSPG production rate and binding availability, both of which are suggested to change with flow, had large effects on FGF2-HSPG but not FGF2-HSPG-FGFR, suggesting that these are FGF2 storage rather than signaling complexes. FGF2

dissociation from HSPG, which has been proposed to demonstrate slip-bond characteristics, also had a large effect on FH complexes. We then estimated how HSPG production, availability and FGF2 dissociation would change with flow based on our prior data and the literature. When we added these flow-induced changes into our computational model, it matched our experimental data well (Figure 2) [4].

Stoichiometric model of glucose metabolism in flow

Since stoichiometric models do not have unique solutions, we first ran the model with an objective function of maximizing ATP production. Since endothelial cells primarily use aerobic glycolysis rather than the TCA cycle, we shuttled 98% of pyruvate to secreted lactate. The model successfully produced 2 ATP from glycolysis and 32 ATP from oxidative respiration.

We then simulated fluid flow in the model by blocking PFK1, a critical enzyme in glycolysis that has been shown to be decreased by increased KLF2 in laminar shear stress [5]. Interestingly, glycolysis blockade at this rate limiting enzyme did not affect ATP production. Instead, glucose proceeded through a glycolysis side branch, the pentose phosphate pathway, at the blockade and then rejoined glycolysis as glyceraldehyde 3-phosphate (Figure 3). These data show that metabolic inhibition is complicated by the high incidence of pathway side branches and re-entrant loops. Thus a computational model validated with experimental data is critical to understanding metabolic changes in endothelial cells adapted to fluid shear stress.

Figure 3: When glycolysis is inhibited in endothelial cells exposed to laminar shear stress, the cell uses the pentose phosphate pathway to bypass the blockade and produce ATP.

DISCUSSION

These two different models demonstrate the power of computational tools to integrate multiple data sets, generate of hypotheses by running experiments in silico, explore mechanisms to explain experimental results, and interpret high throughput/high dimensional data. These models can then be used to predict responses to other mechanical stimuli and inhibitors, include parenchymal cell interactions, and be incorporated into human organismal models.

PERLECAN DEFICIENCY IMPAIRS THE INTRACELLULAR CALCIUM SIGNALING IN MECHANICALLY LOADED BONE AND OSTEOCYTES

INTRODUCTION

Perlecan (*Hspg2*, a large linear proteoglycan) is found within the pericellular matrix of osteocytes [1]. It can serve as a critical component of the mechanosensing tethers in the lacunar-canalicular system [2], allowing osteocytes to sense and respond to mechanical signals [3]. Deficiency in perlecan is associated with profound musculoskeletal disorders, such as the Schwartz-Jampel syndrome with reduced stature and skeletal abnormalities [4]. Previously we demonstrated marked attenuation of bone formation under mechanical loading in a perlecan deficient mouse model [5]. However, the underlying molecular mechanisms remain unclear. Intracellular calcium is a ubiquitous messenger that controls numerous cellular processes, including proliferation, development, and differentiation [6]. Intracellular calcium peaks are one of the earliest cellular responses of osteocytes (within seconds) following mechanical stimulation in vitro and in situ [7,8]. In this study, we aimed to test the hypothesis that perlecan deficiency impairs the intracellular calcium signaling pathway in mechanically loaded bone and the encased osteocytes.

METHODS

(1) RNA sequencing: 19-week-old perlecan deficient mice (Hypo) and WT controls (C57BL/6J, n = 3 /genotype) were subjected to unilateral tibial loading for 7 days on the left tibia (5 min/day, 4Hz, 8.5N) [5]. The contralateral right tibia served as non-loaded control. Total RNA samples were collected from freshly isolated tibiae (with marrow) 24h after the last loading session, and sequenced similarly as [9]. Differentially expressed genes (DEGs: Hypo vs. WT) were identified (FDR < 0.05 and cutoff fold-change of 2) and submitted to DAVID (version 6.8) for enriched KEGG pathways analysis [10] (**Fig. 1 A**). (2) In situ osteocyte intracellular calcium imaging: 18-21-week-old male mice (8 WT; 4 Hypo) were used. Tibiae were harvested, incubated

for 2 h, loaded with Fluo-8 AM calcium indicator for 0.5 h, and imaged with a confocal microscope under cyclic loading as in our previous study [8] (**Fig. 1 B**). Student's t test and Mann-Whitney *U* tests were used to compare the percentage of responsive cells (with normal distribution) and the other measures (without normal distribution), respectively, between WT and Hypo, and the Chi-square test was used to compare the percentage of responsive cells with multiple peaks between WT and Hypo, with $p < 0.05$ as statistical significance.

RESULTS

(1) RNA sequencing: Regarding the calcium signaling pathway, relative to WT, Hypo mice showed 6 and 7 DEGs (all with decreased transcription levels), resulting in a trend ($p = 0.07$) and a significant ($p = 0.006$) enrichment of the pathway in the non-loaded and loaded tibiae, respectively. Detailed analysis of the loaded tibiae (**Fig. 2**) clearly demonstrated an overall down-regulation of the calcium signaling pathway, as seen in the 4-8 fold decrease in the transcripts of the L-type calcium channel (*Cacna1s*), ER Ca^{2+} releasing receptor (RYR/ *Ryr1*), ER Ca^{2+} refilling pump (SERCA/ *Atp2a1*), and some downstream genes (myosin light chain kinase 2/ *Mylk2*; myosin light chain kinase 4/ *Mylk4*; Troponin C/ *Tnnc2*; Phosphorylase Kinase Catalytic Subunit Gamma 1/ *Phkg1*). The decreasing fold changes of *Atp2a1* and *Ryr1* in Hypo vs. WT were also validated with RT-qPCR results. (2) Intracellular calcium response: Perlecan deficient mice showed more than 58% lower responding rate (% osteocytes with at least one calcium peak over the total number of cells: WT 15.7%; Hypo 6.6%, $p = 0.04$, **Fig. 3B**). The responding Hypo osteocytes, in average, exhibited fewer number of peaks (WT 2.4; Hypo 1.6, $p = 5 \times 10^{-6}$) and lower percentage of multiple responding peaks (1+ peaks, WT 53%; Hypo 25%, $p = 3 \times 10^{-6}$, **Fig. 3B**) during the 8-min recording. The dynamic measures of the first peaks in Hypo, relative to WT, showed a

trend of lower magnitude (WT 1.49; Hypo 1.41, $p = 0.09$), longer arising time (WT 7.88 sec, Hypo 8.70 sec, $p = 0.04$), and longer relaxation time (WT 5.34 sec, Hypo 7.15 sec, $p = 0.0004$, Fig. 3C). Pooling all the peaks together, similar differences were observed in Hypo relative to WT in the peak magnitude (-6.8%, $p = 0.001$) and relaxation time (+23%, $p = 0.0007$), but no change in arising time (+0.4%, $p = 0.5$, Fig. 3D). Overall, the calcium response in Hypo osteocytes was impaired with fewer responsive cells, lower peak magnitude, longer arising time, and delayed return to baseline from the peak.

DISCUSSION

Perlecan deficient mice showed downregulation of the calcium signaling pathway in RNA sequencing, which was validated with reduced intracellular responses under mechanical loading in situ. These results support our hypothesis and elucidate the mechanisms underlying the attenuated anabolic response to loading in Hypo [6].

A MODIFIED BIOREACTOR CONFIGURATION TO STUDY EFFECTS OF LOW INTENSITY PULSED ULTRASOUND TREATMENT

Abdolrasol Rahimi (1), Zach Pittz (1), Nicholas Weaver (1), Natasha Case (1)

(1) Biomedical Engineering Program
Saint Louis University
Saint Louis, MO 63103

INTRODUCTION

Long-term application of a low intensity pulsed ultrasound (LIPUS) regimen has been shown to enhance bone healing for a subset of patients with nonunions. Preclinical and *ini vitro* studies have suggested that LIPUS contributes to bone healing by stimulating early synthesis of extracellular matrix proteins and by activating bone formation pathways. For the clinical regimen, LIPUS is delivered as a pulsed signal (1.5MHz frequency with 20% duty cycle and pulse repetition frequency of 1KHz) for a treatment time of 20 m daily.

US bioreactors are common platforms that have been used in *ini vitro* studies to investigate effects of LIPUS treatment under well-controlled conditions. To more effectively interpret the results of *ini vitro* US experiments, a thorough understanding of US wave propagation and the acoustic pressure field in the bioreactor is needed, and this can be achieved by using computational modeling. Studying how changes in design parameters affect the acoustic pressure in US bioreactor experimentally is challenging and often impractical. However, computational modeling is a reliable and cost-effective approach to complement experimental data, enabling the assessment of how a change in a design parameter affects the acoustic pressure in various regions of the US bioreactor. A current complication of US bioreactors is the presence of an air interface, which results in high variability in the acoustic pressure field because of the near complete wave reflection at the interface. The first objective of this study was to analyze effects of an air interface and resulting wave reflections on the acoustic pressure in the US bioreactor. The distance that the US transducer is positioned above the dish surface where the cell monolayer is located is a major factor that determines the pressure magnitude delivered to cells. Therefore, the second objective was to determine the transducer position that would support development of the maximum pressure level at the cell layer.

METHODS

A multi-physics finite element model of the US bioreactor was developed (COMSOL, V5.3) and included the piezoelectric US transducer immersed in culture medium contained within a circular culture dish, water. The US transducer model was composed of a three-layered cylinder including a matching layer, a piezoelectric disk (25 mm diameter), and a backing layer surrounded by a stainless-steel casing. The bottom surface of the culture dish was either contacted by air or by a water layer coupled with a non-reflecting boundary that represented an acoustic absorbent material (Figure 1). The Helmholtz wave equation was developed to simulate wave propagation in the culture medium and water. Frequency domain simulations were conducted to evaluate the acoustic pressure within the US bioreactor and to estimate the acoustic pressure experienced by the cell layer. For pressure at the cell layer, the acoustic pressure in the fluid layer contacting the upper surface of the culture dish was spatially averaged over the center area of the dish (25 mm diameter) and will be referred to as the pressure at the dish surface. For direct pressure measurements, the transducer (25 mm active element diameter, Precision Acoustics) was placed in the center of the culture dish in contact with the medium to deliver US at 1.5 MHz center frequency, 30 mW/cm² spatial-average temporal-average intensity, and a pulse repetition frequency of 1KHz (Figure 1). A water layer bounded by an acoustic absorbent material (Precision Acoustics) was placed in contact with the bottom portion of the dish to remove the air interface. The acoustic pressure in the culture medium was measured by a needle hydrophone with an active element diameter of 400 μ m connected to a pre-amplifier. The output signal of hydrophone was collected by an oscilloscope.

The MC3T3-E1 cell line was used as a pre-osteoblast model. Cells were cultured in MEM with 10% FBS and 1% penicillin/streptomycin

and seeded at $40\text{--}50 \times 10^3$ cells/cm². After 2-3 days, cultures were incubated with medium containing 0.5% FBS overnight and LIPUS stimulation was applied the next day. Western blotting was performed on whole cell lysates of stimulated and control samples to evaluate phosphorylation levels of ERK1/2 Map kinase, P38 Map kinase, AKT kinase, and Focal Adhesion Kinase (FAK) followed by densitometry.

Figure 1. In-well ultrasonication configuration. The US transducer was placed in a cell culture dish in contact with the culture medium. To remove the air interface and minimize the reflection, a water layer and an acoustic absorbent material were added under the dish.

RESULTS

Simulations were conducted to both explore effects of the air interface at the lower dish surface on the acoustic pressure field and to determine the placement of the US transducer above the culture dish to deliver the maximum pressure. Thus, the thickness of the culture medium layer between the US transducer and the upper surface of culture dish (denoted t_{medium}) was varied from 1.5 to 4.5 mm and the acoustic pressure was evaluated (Figure 2.A). In the original in-well bioreactor configuration, the US waves travel from the transducer through each consecutive layer of the model until reaching the bottom surface of the culture dish in contact with air, where near complete reflection of the acoustic wave occurs (>99.9%). When the water layer and acoustic absorbent material are placed under the dish, US waves will travel into the water and eventually will be damped by the acoustic absorbent. As t_{medium} increased from 1.5 to 4.5 mm, the acoustic pressure at the dish surface experienced repetitive minimum and maximum pressures, observed in both configurations. This showed the importance of the US transducer distance from the upper dish surface. The averaged ratio between six consecutive maximum and minimum pressures was 5.3 when the air interface was present (Figure 2.A). This ratio dropped to 1.2 in the modified bioreactor configuration. Simulations showed that a 100 μm deviation in the transducer position away from a location where the pressure was maximum caused a 69% decrease in acoustic pressure if air contacted the lower dish surface, but only a 7% decrease with the modified configuration removing the air interface. To evaluate the acoustic pressure field in the culture medium, the volume average of the acoustic pressure in the medium was calculated. The volume-averaged acoustic pressure at maximum was 4.8- and 1.1-fold higher than minimum for the original and modified bioreactor configurations, respectively. These findings revealed that by making a simple modification of adding a water layer and an acoustic absorbent material, the pressure variability could be substantially decreased. This reduced pressure sensitivity to t_{medium} provided an experimental system that would support improved reproducibility across experiments.

When incoming and reflected waves interfere, the pressure amplitude at a given location can increase if constructive interference occurs or can decrease if destructive interference occurs. The higher level of wave reflections due to the presence of the air interface led to increased constructive and destructive interference, as demonstrated by

the maximum pressure in the presence of the air interface being 2.4-fold higher than the maximum pressure in the modified configuration (Figure 2.A). To validate the computational model, acoustic pressure at the dish center for both configurations was measured using a needle hydrophone (Figure 2.B). Results showed that acoustic pressure at the dish center when the air interface was present was 2.2-fold higher than the pressure when the air interface was removed by using the acoustic absorbent material. Overall, the normalized acoustic pressure from the hydrophone measurement was in close agreement with the computational modeling results.

Figure 2. (A) Normalized acoustic pressure at the dish surface as the culture medium layer thickness changed. Results are normalized to the maximum spatially averaged acoustic pressure at the dish surface. (B) Normalized acoustic pressure at the dish center using a needle hydrophone.

Cellular responses to the US treatment were studied using the modified bioreactor configuration. Cell monolayers were lysed after 20 min incubation following US treatment and western blotting analysis was performed. Densitometry analysis on immunoblot images indicated that signaling pathways were responsive to the stimulus of US waves in the modified bioreactor configuration. Results showed 2.5-, 2.3-, 1.7-, and 1.9-fold increase in phosphorylation level of FAK, AKT kinase, ERK1/2 Map kinase, and P38 Map kinase, respectively, in the stimulated cell monolayers compared to control untreated samples. This finding confirmed that this modified bioreactor configuration can be used effectively to conduct *in vitro* cellular experiments.

DISCUSSION

Using computational modeling, the effects of the air-dish interface on the acoustic pressure at the dish surface for ultrasonication within a culture dish were investigated. Including an acoustic absorbent layer to remove the reflection from the air interface decreased the pressure variability as the thickness of the culture medium varied. Moreover, simulations showed careful consideration should be given to the relative location of the US transducer from the dish. Experimental results showed that LIPUS applied using the modified bioreactor configuration with an acoustic absorbent layer could activate signaling pathways in MC3T3-E1 cells, consistent with previous studies using the original bioreactor configuration. These signaling pathways are known to be involved in bone fracture healing. Overall, this work demonstrated that computational modeling is a robust tool to characterize the acoustic pressure in US bioreactor and understand how changes in design parameters may affect the acoustic pressure. Although this study was limited to evaluations of the pressure field for a 2D *in vitro* experimental setup, future studies will investigate the acoustic pressure field for LIPUS applied to cell-seeded scaffolds.

DESIGN AND COMPUTATIONAL MODELING OF AN ULTRASOUND BIOREACTOR FOR STIMULATION OF CELL-SEEDED SCAFFOLDS

Jacob Crapps (1), Abdolrasol Rahimi (1), Natasha Case (1)

(1) Biomedical Engineering
Saint Louis University
St. Louis, MO, USA

INTRODUCTION

Daily application of a low intensity pulsed ultrasound (LIPUS) regimen has been shown to have positive effects on bone fracture healing [1]. However, the underlying mechanisms are not well understood. While most *in vitro* studies have focused on US stimulation of two-dimensional (2D) cell monolayers, a fracture site requires treatment of a three-dimensional (3D) volume and US propagation within such a space is complex. Therefore, *in vitro* studies using 3D models, such as cell-seeded scaffolds, are needed to investigate the bioeffects of LIPUS under well-controlled conditions. A limitation of commonly used US bioreactor designs is the presence of an air-liquid or air-solid interface in the direct path of US wave propagation, which causes wave reflections and formation of standing waves [2]. These effects increase variability in the pressure delivered to cells within the bioreactor, thereby reducing reproducibility across experiments. To provide a well-controlled environment for ultrasound stimulation of cell-seeded scaffolds, an ideal bioreactor configuration would eliminate air interfaces along the US wave transmission path and allow for the central positioning of the scaffold.

The purpose of this study was to develop and characterize a novel bioreactor configuration for US stimulation of cell-seeded scaffolds using a design that eliminated all air-fluid and air-solid interfaces intersecting the wave propagation path. In the bioreactor configuration, an enclosed sample holder filled with culture medium was combined with an acoustic absorbent (AA) material. The US transducer was submersed in water and positioned below the sample holder. The acoustic pressure in the fluid domains of the US bioreactor was evaluated by developing a finite element model and conducting multiphysics simulations in the frequency domain. Effects of individual configuration parameters, including thickness of the water layer, presence of the AA material, and radius of the inner well, on the

spatially-averaged acoustic pressure over the surface that a scaffold would occupy were analyzed.

METHODS

Figure 1: A bioreactor was developed for ultrasonication from below the sample, with 3D printed sample holder for containment of a cell-seeded scaffold, an ultrasound transducer submersed in water, and an acoustic absorbent material.

A novel sample holder was designed and fabricated (Figure 1) using a stereolithography technique (Form 2, Formlabs) with a durable resin. Two pieces were designed to screw together creating a central horizontal channel filled with culture medium through which US waves would pass and an outer vertical cylindrical channel to trap air bubbles. The base of the holder had a central inner well for positioning a scaffold at the center of the US pathway.

A model of the configuration was developed in COMSOL Multiphysics software (V5.3, COMSOL). A solid mechanics interface

was used to model the sample holder, transducer components, and AA material (Aptflex F28, Precision Acoustics) as isotropic, linear elastic materials. An electrostatics interface was used to model the charge distribution in the piezoelectric disc component of the transducer, and an acoustic pressure module was used to model the acoustic pressure in the water, air, and culture medium. The spatially-averaged acoustic pressure at the inner well surface was then analyzed under various conditions.

RESULTS

Figure 2. The spatially-averaged acoustic pressure at the inner well surface was analyzed with variation in the thickness of the water layer between the sample holder and transducer.

Simulations were conducted with either the AA material (solid line) or air (dashed line) contacting the top of the sample holder. All pressure values were normalized to the maximum acoustic pressure in the presence of AA.

A sample holder consisting of two solid components was designed and fabricated to eliminate the air-culture medium interface that would be present with the use of a standard tissue culture dish. Frequency domain simulations of the US bioreactor using this sample holder were conducted. As the thickness of the water layer beneath the sample holder was increased from 2 to 4 mm, the spatially-averaged pressure at the inner well surface varied in a repetitive pattern, moving first to a point of minimum pressure (node) and then to a point of maximum pressure (antinode). This repetitive pattern was observed when either the AA or air contacted the top of the sample holder, indicating that this variance was due in part to weak standing waves formed from reflections at sample holder-liquid interfaces (~5.6% reflection at each). The acoustic pressure increased 1.75-fold from the node (N) to antinode (AN) position with the AA layer present. This difference was increased with air contacting the top of the holder (2.72-fold from N to AN), due to the additional contribution of reflections at this air-solid interface on wave interactions within the bioreactor. To further investigate the importance of eliminating air-fluid boundaries in the US bioreactor, a similar simulation was conducted with the entire top portion of the sample holder modeled as air, which would be comparable to using a tissue culture dish for a sample holder. In this simulation, the average pressure at the well surface increased 4.19-fold from node to antinode position.

To assess the impact of the inner well on pressure developed within the bioreactor, a simulation was conducted to compare two inner well radii for effects on the radial pressure pattern at the inner well surface, and a water thickness corresponding to an AN position was used. In the original configuration with an inner well radius of 7.5 mm, the pressure pattern was irregular, with radial pressures being an average of 39% of the maximum pressure and dropping as low as 18% of the maximum. When the radius was increased to 15 mm to be larger than the active

element of the transducer, there was less radial variation, with pressure values being an average of 50% and dropping as low as 36% of its maximum pressure. However, the maximum pressure at the well surface was only 77% of the maximum with a radius of 7.5 mm. This simulation indicated a potential flaw in the original design of the sample holder, as the geometry of the smaller inner well produced a less uniform radial pressure pattern. Based upon the differences in radial pressure variation, the simulation in Figure 2 was repeated using an inner well radius of 15 mm. The results showed that the inner well radius had a minimal effect on wave interactions within the bioreactor, as the difference in pressure between the N and AN position was 1.74-fold with the AA layer and 2.49-fold with air.

Figure 3. Acoustic pressure across the surface of the inner well with simulations conducted for inner well radii of 7.5 mm and 15 mm and an AN position for the water layer thickness. All radial pressures were normalized to the maximum pressure for $r = 7.5$ mm.

DISCUSSION

Overall, this study showed that the proposed novel bioreactor design provided an environment with less experimental variability for the US treatment of a cell-seeded scaffold. It effectively removed all air-liquid interfaces using a uniquely designed sample holder and an acoustic absorbent material, which reduced wave reflections and resultant wave interference within the bioreactor. However, multiple solid-liquid boundaries in the bioreactor contributed to the formation of weak standing waves, with the positioning of the transducer below the sample holder being shown to be an important parameter influencing pressure developed at the inner well surface. Additionally, this study showed that the radius of the inner well of the sample holder influenced pressure variations in the region where cell-seeded scaffolds would be located. Future work will include the addition of scaffolds as porous solids to the computational model.

INTRODUCTION

Osteoporosis is a debilitating bone condition, affecting nearly 54 million Americans, in which the body loses excessive amounts of bone, produces too little bone, or both. This results in fragile bones that are at greater risk for fracture. Bone is sensitive to mechanical loads, and loss of mechanical load, such as in extended bed rest or microgravity, results in significant bone loss. Voltage sensitive calcium channels (VSCC) are the channels responsible for regulating the osteoblasts that secrete and mineralize the bone matrix. They are divided into two primary types: L-types and T-types. L-type VSCCs, or $Ca_v 1.2$ L-type channels are long lasting and require a higher voltage for activation whereas T-type VSCCs, or $Ca_v 3.1$ T-type channels/ $Ca_v 3.2$ T-type channels are activated with lower voltages and primarily open during membrane depolarization. The Duncan lab has previously shown that the in vitro and in vivo inhibition of LVSCC, and TVSCC in vitro, significantly reduces the mechanical response of bone at both the cellular and tissue levels. Although past research has shown that pulsed electromagnetic fields (PEMF) promote osteoblastic proliferation, exact mechanisms are unknown. I hypothesize that VSCCs can be stimulated by PEMF and in turn can stimulate bone formation.

METHODS

Osteoblast Cell Culture

MC3T3-E1 pre-osteoblasts (American Type Culture Collection) were cultured in Minimum Essential Medium Eagle Alpha Modification (MEM- α , Sigma-Aldrich) and supplemented with 10% Fetal Bovine Serum and 1% Penicillin and Streptomycin. Media was changed every 2-3 days and cells were passaged at 80% confluence with 0.25% Trypsin.

Creating a Pulsed Electromagnetic Field Generator

Equation 1, as shown below, is a derivation from the Biot-Savart law to define the magnitude of the uniform magnetic field between Helmholtz coils. It has been rearranged to solve for current, I , as shown in equation 2.

$$B = \frac{\frac{3}{42} \mu_0 \eta I}{R} \quad (1)$$

$$I = \frac{BR}{\frac{\frac{3}{42} \mu_0 \eta}{5}} \quad (2)$$

Where $\mu_0 = 4\pi \times 10^{-7} (T \cdot m/A)$
 η = # of turns of wire
 I = current of coil (A)
 R = radius of coil (m)

The PEMF generator was developed using a 33220A Arbitrary Waveform Generator from Agilent as a voltage source, a Lepai LP-2020A+ Hi-Fi Stereo Amplifier to amplify the source signal, and the Agilent Intuilink Waveform Editor application to create a pulsed square wave. A pair of 3B Scientific 51000611 Helmholtz coils were used to create the EMF, and a PCE MFM 3000 AC/DC Magnetic Meter from PCE instruments was used to measure the strength of the produced magnetic field. The pulsed waveform was designed to have a burst width of 5 ms, a pulse width of 0.2 ms, a pulse wait of 0.02 ms, and a burst wait of 15 ms repeated at 45 Hz. In order to produce a uniform magnetic field, the coils were placed away from each other at a distance equal to their radii. A base for the coils and the platform for the culture dishes was designed using Solidworks and machines out of acetel plastic in the College of Engineering Student Machine Shop.

Methods for Proliferation Studies of PEMF Exposed Osteoblasts

An MTS assay was used to determine cell proliferation. MC3T3-E1 cells were seeded on collagen I coated 96-well plates at a density of 2,500 cells/cm². Two rows of wells were treated with MEM- α media, two rows were treated with MEM- α with 5 μ M nifedipine, an L-VSCC inhibitor, and two rows were treated with MEM- α with 5 μ M NNC-55, a T-VSCC inhibitor. Media was changed just before cells were exposed to a PEMF at a magnitude of 2.2 ± 0.5 mT for two hours a day for four days. At 24, 48, 72, and 96 hours, the CellTiter96™ AQueous One Cell Proliferation assay was used, and absorbance values were then recorded using the Synergy™ H1 plate reader from Biotek.

Methods for Fluorescent Microscopy of Osteoblasts

MC3T3-E1 cells were seeded at a density of 4000 cells/mL on 35mm MatTek petri dishes with 14mm microwells. Two days later, the cells were incubated in a 25 μ M Quinacrine (QAC), a fluorophore that binds to ATP, for 30 minutes. Cells were then exposed to PEMF for 0, 1, 2, 3, 4, or 5 minutes and rinsed twice with Hank's Balanced Salt Solution with Calcium and Magnesium (HBSS with Ca²⁺ and Mg²⁺, Sigma-Aldrich). Then, 1mL of HBSS with Ca²⁺ and Mg²⁺ was added to each dish and imaged using an Axioscope (Zeiss).

RESULTS

MC3T3-E1 cells that were exposed to PEMF at 2.2 ± 0.5 mT showed significantly greater proliferation than the non-stimulated controls after two days of exposure. Cells treated with either L-VSCC or T-VSCC inhibitors showed significantly reduced proliferation, regardless of exposure to PEMF at 2.2 ± 0.5 mT, as shown in Figure 1.

Figure 1: Graph of the relative absorbance values with respect to the recorded baseline at Day 0. The MC3T3-E1 cells \pm PEMF exposure proliferation whereas those treated with VSCC inhibitors \pm PEMF exposure show reduced proliferation (n=16).

Preliminary data in figure 2 has shown that ATP is released from intracellular stores in MC3T3-E1 cells. The average fluorescent light intensity was measured and shown to drastically decrease once the cells were exposed to PEMF.

Figure 2: Graph of the fluorescence intensities of MC3T3-E1 osteoblast-like cells at several treatments including 0 minute exposure without Quinacrine, 0 minute exposure with Quinacrine, 1 minute exposure, 2 minute exposure, 3 minute exposure, and 5 minute exposure to PEMF.

DISCUSSION

We propose that PEMF stimulates osteogenesis through activation of L-VSCC and T-VSCC- previous data in our lab suggests this is through activation in the L-VSCC. The proliferation studies indicate that VSCCs may be activated by PEMF to further stimulate proliferation, as inhibition of these channels attenuates proliferation. The ATP studies indicate that ATP is stored within intracellular vesicles prior to PEMF exposure, and VSCCs are activated to release ATP their stores once exposed to PEMF. Future work includes: additional studies to determine the effects of PEMF on ATP release, testing other magnitudes of PEMF to determine the optimal field for osteogenesis, running apoptosis studies to determine if cells are dying or if they are phasing into a senescent stage, developing a small, wearable, cuff-like device to implement these tests in mice.

ACKNOWLEDGEMENTS

This work was supported by a grant from the National Institutes of Health (NIDCD DC014461). We would also like to thank the University of Delaware's Undergraduate Research Program for additional funding of this project, and Scott Nelson and Jeff Ricketts for assistance in the Student Machine Shop.

INTRODUCTION

In the human throat, the hypopharynx houses the larynx, which allows for vocal function. In certain instances, such as irreversible damage from laryngeal cancer or severe throat trauma, a laryngectomy may be necessitated. During a laryngectomy, the larynx may be completely or partially removed from the hypopharynx. Following surgical removal, a hole (stoma) is created in the throat to allow air to enter the lungs.

Post operation, individuals permanently breathe through the stoma. In the year 2018, about 13,150 new cases of laryngeal cancer were discovered, with ~50,000–60,000 laryngectomy patients (i.e. laryngectomees) currently living in the United States [1-2].

With the stoma being a direct passageway to the lungs, laryngectomees are at significantly higher risk of drowning through accidental submersion while around open bodies of water. This can deprive laryngectomees of participating in popular, water-based activities, an important part of social interaction and engagement, as 61.3% of Americans participate in swimming activities, 36.2% in boating activities, and 33.9% in fishing activities annually [3]. The inability to participate in social activities such as those listed can have severe psychological impacts, particularly for laryngectomees, as approximately 22.2% suffer from a psychiatric disorder after their operation [4]. Maintaining social contacts and participating in regular activities can help prevent the development of these disorders.

While two commercially-available products exist, which allow laryngectomees to safely swim, they are not comfortable for long term wear and, most importantly, require anticipation of submersion by the user. As such, they do not function for accidental/unanticipated water submersion as may occur while boating, fishing, etc. [5]. The purpose of this project is to develop a product which allows a laryngectomee to participate in aquatic activities, where accidental submersion is a risk, without risk of personal safety.

PRODUCT DESIGN

The stoma snorkel (Storkel) is designed to fulfill the following objectives: (1) passively occlude water from the stoma when submerged at any angle, (2) maintain comfortable respiratory function while above water, (3) allow for comfortable long-term usage of equipment and (4) enable uninterrupted speech while equipped. The three most common mechanisms of speech for a laryngectomee are tracheoesophageal (TEP), esophageal, and usage of an electrolarynx. While the Storkel will not interfere with esophageal and electrolarynx

speech, to use TEP speech it must be possible to temporarily occlude the stoma to redirect air from the trachea, through an implanted prosthesis, and into the esophagus.

Figure 1 displays the prototype. A stoma attachment (1) extends slightly into the stoma and provides an attachment point for the rest of the Storkel. A silicone pad interface (2) ensures that the attachment is comfortable, and an adhesive dressing (3) makes a water-tight seal around the stoma. A plastic junction (4) connects to the stoma attachment and splits into two directions. One downward to the drainage valve (5) to expel any water that may incidentally enter the system, and one to the flexible tubing (6). A small spring (7) and button valve (8) are embedded within the plastic junction and can be used to momentarily block the airway within the plastic junction, allowing for TEP speech (see inset). In order to keep the entire apparatus stable and more comfortable for long periods of use, a neck strap (9) and head band (10) hold the tubing firmly in place.

A float valve mechanism (13-16) is incorporated to occlude the airway during submersion, while automatically reopening upon surfacing. The float valve consists of a hollow shell, such that the positive buoyancy force produced during submersion due to the air pocket inside is the same magnitude as the opposing force due to gravity when not submerged. Figure 2 illustrates how, in an upright position, this causes the valve to remain open, but when submerged, the moment arm of the buoyancy force (X_B) is larger than that of the force of gravity (X_G) thereby lifting the weight and closing the airway.

Figure 1: Fully-assembled Storkel

Figure 2: Proof of float weight concept

In the inverted orientation, the gravitational force holds the valve closed regardless of whether it is submerged or not. To ensure that the float valve functions correctly regardless of the angle of submersion (i.e., such that the axis of rotation is normal to the water surface), a flotation ring (17) is added to the tubing. This flotation ring ensures the housing of the float valve is in a semi-upright position so that the float valve actuates properly. It is recommended that this product is used in conjunction with a life-jacket to minimize time submerged.

To ensure that the tubing will not restrict respiratory function, the pressure drop within the tube must be less than what the lungs can comfortably produce during normal respiration. This pressure drop is calculated through the energy equation in equation 1.

$$\left(\frac{\Delta p}{\rho g} + \alpha \frac{\Delta V^2}{2g} + \Delta z\right) = \left(\sum f_i \frac{L}{D} + \sum K_L\right) \frac{V^2}{2g} \quad (1)$$

where ρ is density, p is pressure, V mean velocity, g is gravity, and z is height. The right side of the equation accounts for the losses due to friction and bending in the tube. The tubing in the Storkel is smooth and the flow is laminar so a modified equation for friction losses can be used. The Storkel will have three 90-degree bends that will constitute the minor losses. The K value for a 90-degree bend is 0.3.

A person participating in moderate exercise produces an airflow rate around 75 L/min or 0.00125 m³/s [6]. Using that flow rate and a range of diameters from 0.01 m - 0.028 m the pressure drop can be calculated. During normal respiration the average lung pressure is 784 Pa [7]. Comparing the average lung pressure to the calculated pressure drops, the Storkel diameter must be greater than 0.02 m to enable sufficient airflow.

Prototype evaluation will be carried out to ensure the following: (1) the connection interface fits comfortably with the stoma, (2) the collar will provide sufficient stabilization, (3) the method of speech is not interrupted, and (4) the float valve actuates appropriately following submersion. The fitting test, comfort tests, and speech performance tests will be performed in conjunction with Utica, NY Laryngectomy support group. The float valve will be tested by submerging the apparatus in a multitude of scenarios, while varying multiple parameters such as angle of entry to surface and depth of submersion.

BUDGET & MARKET ANALYSIS

The target market for the Storkel is individuals with a stoma who desire a safe method of enjoying water activities. This market encompasses both laryngectomy and tracheostomy patients, both of whom utilize stomas. In addition to laryngectomees, there are upwards of 100,000 tracheostomies performed each year [8, 9], although many are temporary, performed during in-patient hospitalization. The combination of these populations will represent the core of potential consumers and will create a total market size estimated to be just over 110,000 individuals. Noting that not all may be interested in water

activities, market analysis indicates this will result in a more realistic market size currently estimated at 48,000.

The first year market share is conservatively predicted to be 3.0%, and to grow by 1.0% annually thereafter, until achieving a steady-state market capture of 7.0% in year 5.

The current Storkel prototype is projected to be produced at a per unit cost of \$27.96. The cost breakdown of each component is shown in Table 1. Most components will be produced in house with a 3D printer (Stratasys F270). The remaining parts (tubing, adhesive, neck strap and headband) can all be purchased directly from retailers. Including shipping costs, each unit is expected to cost a total of \$32.96. The projected sales price is \$110, yielding a per unit profit of \$77.04.

Expenses include the 3D printer, which will be purchased for \$20,000, as well as salary and benefits for one full-time employee (\$100,000.00). Overhead costs will be minimized by partnering with the Peyton Hall Incubator, associated with Clarkson University, which will function as the manufacturing and distribution facility as this space is available at no cost. A loan for \$45,000 at 5% interest rate for 60 months will be taken out to cover start-up costs (purchase of the 3-D printer) as well as marketing expenses and unanticipated costs in the first 5 years. In year 1, a net annual revenue is predicted to be \$-4,500. However, by year six the revenue will grow to \$153,800, ensuring a profitable endeavor.

Table 1: Parts List and Production Costs

Part Number	Part Name	Price (\$)
1	Stoma Attachment	\$0.06
2	Silicone Pad	\$0.08
3	Adhesive Dressing	\$1.00
4	Junction	\$0.39
5	Drainage Valve	\$0.08
6	Tubing	\$10.52
7	Spring	\$0.88
8	Button Valve	\$0.05
9	Neck Strap	\$9.80
10	Head Band	\$4.00
11	Clip 1	\$0.10
12	Clip 2	\$0.23
13	Float Casing	\$0.43
14	Float Weight	\$0.02
15	Float seal	\$0.01
16	Float Cover	\$0.17
17	Flotation Ring	\$0.14
Total		\$27.96

DYNAMIC TRACKING OF FLUORESCENTLY LABELED TYPE I COLLAGEN MOLECULES; DIRECT QUANTIFICATION OF MOLECULAR ASSOCIATION WITH NATIVE FIBRILS

Seyed Mohammad Siadat, Jeffrey W. Ruberti

Department of Bioengineering, Northeastern University, Boston, MA, USA

INTRODUCTION

Collagen is the most abundant protein in vertebrate animals, found in tissues that regularly experience tension, compression, and shear forces. Although connective tissue has been the subject of investigation for more than 100 years¹, there are currently no widely accepted mechanistic models of growth and remodeling of collagenous connective tissue. It has been suggested that fibril growth is the result of linear and lateral fusion of immature intermediate fibrils². It has also been shown that placement of collagen is a function of the local tissue micro-mechanical environment³, that fibroblast traction can rearrange collagen fibrils⁴, and in some cases, that actin filaments align with fibrilpositors and intracellular fibrils⁵. However, the detailed mechanism by which the actual collagen molecules (and microfibrils) are added (or subtracted) from the resident collagen fibrils is not known. It is highly probable that the mechanism that drives growth and remodeling will operate independently of the cell surface or at some nominal distance from it⁶. Unlike early development⁷, when connective tissues are highly-cellular, much of growth and remodeling occurs when the matrix-to-cell volume ratios are relatively high.

To explore the possible mechanisms that govern homeostasis at the fibril surface, it is important to be able to observe directly, the motion of individual collagen monomers entering and exiting the fibril. Our goal was to fluorescently label and track collagen monomers, while minimizing the effect of labelling on fibrillogenesis of collagen. Our approach was to achieve a labeling ratio of 2-3 fluorophores per collagen molecule to minimize disrupting the functionality of collagen, while still permitting us to determine the orientation of the tagged molecules on a fibril surface. Such a tool has the potential to not only track individual molecular associations in a complex biological system but also the directionality with respect to the fibril axis. This will permit us to determine if the associations are functional or non-specific.

METHODS

Collagen Labeling. Type I bovine collagen solution was diluted to 1 mg/ml using 10 mM hydrochloric acid, and then mixed 1:1 with 0.2 M sodium carbonate–bicarbonate buffer containing 1 M sodium chloride. Alexa Fluor 488 was dissolved in dimethyl sulfoxide to a concentration of 0.5 mg/mL and added to collagen solution to achieve 1-10 fluorophores per collagen molecule. The reaction mixtures were stirred for 3 hours at room temperature. (Figure 1)

Figure 1: Schematic of collagen molecule labeled with 2 fluorophores.

Molecular Association of Labeled Monomers with Native Fibrils Experiment. A glass bottom, ITO coated Delta-T dish and a perfusable coverglass lid were plasma cleaned and coated with 1% BSA at 4 °C overnight. The dish was placed on the microscope stage and 1 mL of sclera fibril suspension was added. Then 5 mL of 2 µg/mL labeled collagen was added at 1 ml/h to maintain constant concentration inside the chamber. The collagen concentration was kept at 2 µg/mL (sub-threshold for new fibril formation) to prevent self-assembly and formation of new fibrils. DIC and fluorescent images were taken every 10 minutes for 6 hours using 60x oil objective.

RESULTS

Labelling 100% of the collagen monomers with this small molecular weight probe affected the self-assembly kinetics for new fibrils (figure 2), but produced little discernible effect on assembled fibril morphology (D-banding) as confirmed by transmission electron microscopy. Reducing the relative number of labeled monomers to below 5% of the total number of monomers restored the self-assembly kinetics suggesting that the effect of the label can be taken into account via calibration.

Figure 2: Turbidity of 50 µg/mL labeled collagen at 37 °C. DOL is the degree of labelling.

We then exposed native, young bovine scleral collagen fibrils, extracted from 1-10 day old animals, to a small concentration of labeled monomers. The incorporation rate and total accumulation (to reach saturation) of labeled collagen into the scleral fibrils (predominantly type I collagen) was measured as 2.8 ± 1.2 and 4.0 ± 1.5 molecules/($\mu\text{m}^2 \cdot \text{minute}$) and 114.3 ± 26.8 and 207.1 ± 55.4 molecules/ μm^2 at 25 and 30 °C, respectively. The reaction of the monomers with the fibril surfaces produced a kinetic signature similar to *de novo* collagen assembly, with an activation energy of 12.6 kcal/mol. The results suggest that our labeled, exogenous collagen molecules dynamically associate with and incorporate into young native collagen fibrils (figure 3).

Figure 3: Incorporation of labeled collagen into native fibrils.

DISCUSSION

Part of the difficulty in establishing k_{on} and k_{off} is the insoluble nature of the collagen fibrils and the uncertainty of the nature of their association with soluble monomers/microfibrils. While estimation of the rate constants for collagen fibril surface erosion and adsorption requires relatively simple quantitative fluorescence microscopy, determining whether or not collagen monomers are incorporating functionally into extant fibrils is more difficult. The goal of this study was to develop methods which enable us to ask quantitative questions about the dynamics of molecular assembly and disassembly at the collagen fibril surface.

The activation energy of 12.6 kcal/mol calculated in the present study was lower than values reported in the literature for collagen assembly *in vitro* (27 – 58 kcal/mol)⁸⁻¹⁰, suggesting that the activation energy for growth of a native fibril is less than formation and growth of a reconstituted fibril *in vitro*. Moreover, it has been shown that proteoglycans can be removed from collagenous tissue by trypsin treatment^{11,12}. Therefore, the lateral growth of our proteoglycans-free scleral fibrils and the lower activation energy can be attributed to the absence of proteoglycans. Therefore, the presence of proteoglycans on the scleral fibrils in our study might inhibit the incorporation of collagen monomers and guide the equilibrium fibril diameter^{13,14}.

The lag time during initial fibrillogenesis (figure 2) is due to the lack of pre-existing nucleation sites that must be established. However, this is not the case in figure 3 where monomers are incorporating into the already extant native fibrils. The lag time we observe might be due to formation of microfibrils and their lateral association with the native fibrils. The plateau region of a turbidity experiment (figure 2) is partially due to consumption of the reactant, while our monomer/fibril association experiment (figure 3) had a constant supply of monomers. Saturation of scleral fibrils by labeled monomers shows that besides proteoglycans, there must be other inhibiting factors that arrest the fibril's growth. We suspect that collagen fibrils reside in a state of dynamic equilibrium with the local extracellular milieu and that this equilibrium can be altered by mechanical strain, shifting the molecular association rates, k_{on} and k_{off} , between fibrils and molecules.

INTRODUCTION

Every year, 475,000 cardiac arrests occur; 45% of out of hospital cardiac arrests lead to death due to failure in cardiopulmonary resuscitation (CPR) [1]. Less than 1 in 6 people can perform CPR properly [2]. To correct areas of common failure, such as depth of chest compression and rate of compressions, assistive CPR devices are being implemented among emergency medical staff (EMS). Regardless of innovations, assistive CPR devices provide no statistical increase in survival over manual CPR [3].

Clinical immersion through the Bioengineering Scholars Summer Program allowed undergraduate engineering and medical students hands-on discovery of medical problems [4]. A list of problems derived from recorded observations were filtered to find the most heavily weighted problem. Observations of a failed usage of an automatic CPR machine produced the following need statement: “There is a need to address CPR in out-of-hospital adult cardiac arrest patients, prior to EMS arrival that optimizes layperson compressions and reduces fatigue”.

The goal of this work is to develop a mechanically assistive CPR device to be used in home by family members of cardiac arrest victims prior to EMS arrival. The absolute design criteria is to be a mechanical device that optimizes bystander’s performance of CPR. Optional criteria would be to increase bystander reaction rates and reduce user fatigue. The majority of this work focused on need validation and preliminary design of a solution; solid specifications and manufacturability were not within the scope of this project.

NEED VALIDATION AND REQUIREMENTS

The defined need statement was validated through 50 surveys and 7 interviews of professionals varying from Rowan University EMS, Gloucester County EMS, and Cooper University Hospital. Here, surveys were flagged for statistics, uncommon problems and stories, and solidification to researched facts. This research is limited to locational trends; further research is required before implementing to other regions. Some major takeaways include: the importance of compression location and bystander CPR prior to EMS arrival. Improper compression location could result in puncturing the heart or lungs which significantly increases risk of death. Bystander CPR is often low quality due to fatigue and lack of training; it is also often not performed at all. The interviews confirmed the patient population as individuals who are in the age range of 40-60 years old [5]. Interviewees expressed lack of confidence in performing CPR on obese victims suggesting a solution be tailored towards larger body types.

Requirements were established through 3 primary resources: AHA and FDA standards, the surveys and interviews, and existing products. Functional requirements include: harnessing the victim in place and performing compressions. Performance requirements include: force application to the body between 100-125 pounds, minimum compression frequency of 100 beats per minute (BPM) with a depth of 2-2.5 inches [6, 7]. Depth may vary depending on the chest bust of the individual. Interface requirements include: compressions located between the sternum tip and the nipple line beginning at a maximum of 45-60 seconds after cardiac arrest begins [8].

PRODUCT DESIGN

The assistive CPR machine is comprised of an alignment harness, a dual linkage system for variable compression depth, and a crank handle.

To address an immense spectrum of possible body sizes, from 5th percentile female to 95th percentile male profiles, two harness sizes will need to be produced. These percentile dimensions were defined using published resources from NASA and the US Anthropometry Survey [9, 10]. The scope of this design focused on the 95th percentile male due to the comments on obesity from the surveys. To apply the harness, the victim must be lying down face up. The harness will be “forklifted” over the victim’s head and encompass the upper torso as shown in Figure 1. Compression straps will be used to deform the harness frame and fix itself to the victim’s body. A forklift approach reduces time by eliminating the need to roll the victim onto a compression tray.

The dual linkage system consists of a crank-rocker assembly and rocker-slider assembly. The crank is a hand powered input. The slider is a cylindrical, compressive piston. The two assemblies share the rocker linkage. Three variable pivot holes along the rocker linkage allow for adjustable compression depth. This variability is useful for larger patients who require a deeper compression to overcome additional chest bust. This linkage system is shown in Figure 2.

A custom written Excel-Visual Basic (VBA) code was used to parametrically alter linkage sizes to find possible permutations validated by the Grashof Condition [11]. These linkages were manually filtered by stroke length, by overall size, and with mechanical design intuition. Since the required compression force and frequency are given as requirements, these were used as inputs to solve for crank handle torque and angular velocity. The results of the VBA provided near instant insight on the performance of every linkage permutation.

Figure 1: Side view of harness and linkage system applied to laying victim. Compression straps not shown.

Figure 2: Front view of the dual linkage system. Link 1 is connected to the input crank handle. Link 2 and 4 are connecting links of the first and second assembly. Link 3 is the dual rocker linkage. Link 5 is the slider which acts as the compressive piston for CPR. Nodes A, B, and C are pivot point options.

Prior to EMS arrival, compression feedback will be given by use of a tachometer on the crank handle linkage. The machine will measure the compression frequency and alert the user of variance from the optimal frequency based on the performance requirements. Flashing LEDs will correspond to labels “Too Slow”, “Good”, or “Too Fast”.

BUDGET & MARKET ANALYSIS

Based on the need statement, the primary customers are individuals and families with a history of cardiac arrest or other heart-related health complications. Secondary customers are EMS personnel and other healthcare providers. The total estimated cost for developing a functional prototype is \$107 as compiled in Table 1.

Table 1: Primary component summary bill of materials to build functional prototype [12].

Part(s) per machine	Cost [\$]
Linkages	47.75
Crank Handle	13.00
Harness	46.25
Total	107.00

SUMMARY

There is a validated need for mechanically assistive CPR machine outside of the hospital for laypersons. This work has produced a design template for a harness, a variable linkage system, and crank handle.

Future work will include material simulations on the harness and linkage. The harness design will be solidified to ensure correct compression alignment. A verbal feedback system will be added to supplement the LEDs and include instructions of use. Instructions will include dialing 9-1-1, the harnessing the victim, and beginning compressions.

THERMAL ANALYSIS OF PARTIAL VITRIFICATION WITH APPLICATION TO LARGE-SIZE CRYOPRESERVATION

Purva Joshi and Yoed Rabin

Biothermal Technology Laboratory
Department of Mechanical Engineering
Carnegie Mellon University
Pittsburgh, PA, USA, 15213

INTRODUCTION

Despite advances in medicine and biotechnology, concurrently with an increased awareness of the benefits of organ donation and transplantation, an everlasting gap exists between organ demand and supply [1]. According to the Global Observatory on Donation and Transplantation, only 10% of the worldwide demand for organ transplantation is being met [2,3]. Organ cryopreservation is a promising technique which can successfully increase the availability of organs for transplant medicine by improving both logistics and outcomes of transplantation [3,4].

A typical cryopreservation protocol includes loading the specimen with a cryoprotective agent (CPA) solution, cooling to cryogenic temperatures, storage for an indefinite period of time, rewarming, and washing out the CPA, all while minimizing injury to cells and damage to the tissue structure. Vitrification is a cryopreservation protocol where the cooling and rewarming rates are rapid enough in order to prevent ice crystallization—the cornerstone of cryoinjury (*vitreous* in Latin means *glassy*). Given the virtually infinite combinations of parameters that affect cryopreservation success, it is prudent to precede experimental cryobiology by computer simulations of the process, in order to facilitate a robust analysis and optimization of the protocol, thereby preserving resources and potentially accelerating progress. Consistently, the current study focuses on adverse phase-change effects occurring in attempts to vitrify CPA solutions.

This study proposes a framework for thermal analysis of the partial vitrification in large specimens. This framework concerns a simplified scenario where the thermal field and the kinetics of crystallization are unidirectionally coupled, where the crystal formation is assumed to behave similarly to a quasi-steady phase-change process once a critical cooling rate is surpassed. Essentially, this study represents a practical, first-order approach, which is appropriate for high-concentration CPA

solutions, typical to whole organ vitrification. The computation framework represents an expansion of the so-called enthalpy approach [5], where the unique contribution of this study comes about. This computational framework is materialized with the finite elements analysis (FEA) commercial code ANSYS, while integrating recently developed differential scanning calorimetry (DSC) data on physical properties of relevant CPAs.

METHODS

The geometry analyzed in this study is of a cylindrical container, consisting of two subdomains: CPA solution and solid walls. No tissue sample is included in the current proof-of-concept analysis, which would be permeated with the same concentration CPA solution, and which may have similar properties [6]. Heat transfer in the container and the CPA undergoing vitrification is assumed solely by conduction while a combined convection and radiation heat transfer coefficient is assumed between the outer surfaces of the walls and the cooling chamber [7].

The enthalpy approach [5,8] is based on an effective specific heat, representing the combined effects the intrinsic specific heat and the temperature-dependent effect of latent heat:

$$h_{12} = \int_{T_1}^{T_2} C_{eff} dT = \int_{T_1}^{T_2} C_p dT + L_{12} \quad (1)$$

where, h_{12} is the enthalpy changes between the onset of crystallization at T_1 and the termination of crystallization at T_2 , C_{eff} is the effective specific heat, C_p is intrinsic specific heat, and L_{12} is the latent heat absorbed between the corresponding temperatures. Consistently, the thermal conductivity within the phase-transition temperature range is

temperature-dependent and calculated as a mixture of amorphous and crystallized materials [9].

RESULTS AND DISCUSSION

Cooling-Rate Effect: Figure 1 displays the crystallization amount and the temperature field for four representative cooling rates: 4.5°C/min, 7.5°C/min, 15°C/min and 30°C/min, where the former is below the critical cooling rate of 5°C/min. Data in Fig. 1. refers to the temperature below which significant phase-transition during cooling is negligible, -75°C, when the sample is cooled from an initial temperature of -25°C to a storage temperature of -120°C.

Figure 1: Crystallization amount and temperature field after completion of phase transition subject to the following cooling rate: (a) 30°C/min (t = 1060s), (b) 15°C/min (t = 1157s), (c) 7.5°C/min (t = 1308s), (d) 4.5°C/min (t = 1638s).

Unexpectedly, crystallization at the center of the container happens even when the outer surface is cooled at 30°C/min, Fig. 1(a)., which is higher than the critical cooling rate, due to the decay of heat transfer rate towards the center of the container. When the cooling rate at the outer surface is decreased to 15°C/min, Fig. 1(b)., the amount of vitrification close to the container wall decreases, but so is the portion of crystallization at the center of the container. However, this reduction in complete vitrification is merely 3% of the entire domain as compared to the change in the cooling rate which was reduced by half.

Only 3% of the entire domain vitrifies when the external cooling rate is set to 7.5°C/min, Fig. 1(c)., while the overall crystallization portions is 1%. This means that 96% of the domain is partially vitrified to a varying degree. The trend of crystallization described above is very difficult to trace from the temperature field alone, as displayed in the lower portion of Fig. 1., which signifies the importance of the proposed detailed analysis.

Counterintuitively, while complete crystallization is observed near

the container wall at a subcritical cooling rate, Fig. 1(d)., partial vitrification is also found near the center of the container. In fact, the lowest amount of crystallization is observed in the latter case near the center of the container, despite the lower external cooling rate. This can be explained by an accelerate cooling rate at the center of the domain when the so-called “thermal wave” reaches there. Here the speed of propagation of thermal information is proportional to the thermal diffusivity and inversely proportional to the specific heat of the material.

Initial Temperature Effect: To study the effect of initial temperature on crystallization, two temperature values were considered: 0°C and -25°C, while the cooling rate was kept constant at 7.5°C/min. Counterintuitively, the case with the highest initial temperature resulted in a lower portion of overall crystallization, which can be explained by the longer period of time available for the thermal wave to reach the center of the domain, before the entire domain reaches the phase transition temperature range.

Container Size Effect: The dimensions were increased by two folds to study the crystallization trends in a volume required for cryopreservation of a human kidney [9]. Keeping the initial temperature and storage temperature consistent with the other studied cases (-25°C and -120°C, respectively), cooling rates as high as 100°C/min did not result in partial vitrification at the center of the larger container.

CONCLUSIONS

This study proposes a simplified model and a computation framework to explore effects of partial crystallization in cryopreservation processes. This study focused on the effect of cooling rate, initial temperature and container size on the extent of vitrification obtained in the container. Results of this study demonstrate that the extent of vitrification obtained in the specimen is highly dependent on the initial temperature as well as the storage temperature. Results also suggest a non-linear relationship between the cooling rate at the outer surface of the domain and the vitrification potential. For example, doubling the cooling rate resulted in an increase in complete vitrification in only by 3% of the domain. Counterintuitively, cooling rates lower than the critical cooling rate do not always result in complete crystallization in the specimen. Lower cooling rates resulted in complete crystallization at the boundaries but only partial crystallization at the center. While increasing the cooling rate increases the extent of vitrification close to the container wall, it may have adverse effect on the extent of crystallization at the center of the domain, depending on the specific size of the container and thermal protocol. In a broader perspective, this study demonstrates the value of thermal design and analysis of cryopreservation protocols using computer simulations.

INTRODUCTION

Respiratory syncytial virus (RSV) is among the leading causes of pediatric death secondary to pneumonia worldwide and to date there is no effective vaccine available or antiviral therapy. Early and point-of-care (POC) diagnosis of RSV is critical to isolate infection reservoirs and inform treatment decisions. Current diagnostic methods for RSV detection, including laboratory-based tests such as polymerase chain reaction (PCR, i.e., respiratory panel for FILMARRAY multiplex PCR system, >\$1400 per test) or rapid diagnostic tests such as lateral flow immunoassay (LFI, i.e., Alere RDT), are either costly and time consuming or lack of sufficient sensitivity.

Colorimetric assay can detect intact viruses in a simple step, without the need of extracting and amplifying RNA. The antibody functionalized Gold nanoparticles (GNPs) are used to target the viruses surface protein. The adjacent plasmonic GNPs on the virus are coupled, leading to a color change (Figure 1A). However, one major limitation of the colorimetric detection is the large amount of coupled GNPs required to yield a substantial and detectable color change. Inspired by recent developments of digital assays ^[1-2], we report a novel digital nanobubble detection as a read-out method to significantly improve the limit of detection (LOD) of the colorimetric plasmonic coupling assay by 2-3 orders of magnitude. The sample-to-answer diagnosis can be achieved within 30 minutes by minimal additional time to the already rapid GNP-based aggregation assay. The proposed method is generally applicable to detect a broad range of viral infections.

METHODS

Antibody and GNP conjugation: Synagis (Palivizumab) was chosen as the RSV-specific monoclonal antibody. Synagis provides passive immunity against RSV by binding the RSV envelope fusion protein on the virus surface and blocking a critical step in the membrane

fusion process. GNPs (15 nm/30 nm/45 nm) were synthesized on the basis of the standard citrate reduction technique with slight modifications, and GNP concentration is calculated according to their optical properties. To conjugate Synagis onto GNPs surface, we tested passive absorption, PEGylated method, and DTSSP method reported earlier ^[3-5] to create GNP-Syn probes. The probes were characterized by dynamic light scattering (DLS) using Malvern Zetasizer Nano (Malvern Instruments Ltd., UK).

GNP aggregation assay: RSV and other closely related respiratory viruses such as Human metapneumovirus (hMPV), Parainfluenza viruses (PIV), and Influenza Virus A (IVA) were then incubated with GNP-Syn probes for at least 30 min at room temperature in the presence of 5% sucrose and cell debris in 1×PBS. The optical spectrum was measured using a Beckman Coulter UV-Vis spectrophotometer (model DU800), and the GNPs targeted viruses samples were observed by transmission electron microscopy (TEM JEOL JEM 2100). Each of the GNP samples was spotted onto a thin carbon film coated Cu grids (300 mesh, Pacific Grid Tech) and air-dried for TEM characterization.

Digital nanobubble detection: To selectively detect coupled GNPs, which indicate the presence of the RSV, ultrashort laser pulses were applied to activate the coupled GNPs and create transient cavitation bubbles, i.e. nanobubbles, at a laser intensity threshold well below the threshold required for single nanoparticle cavitation ^[6]. The nanobubbles can be readily detected due to the high refractive index mismatch and scattering (Figure 1B). Basically, a syringe pump is used to flow the sample (GNP-syn + RSV) through a simple micro-capillary channel (ID=400 µm). Then a short laser pulse (532 nm, pump laser) was applied while simultaneously monitoring with a continuous low-power probe laser beam (633 nm).

Figure 1: Schematic of (A) analog colorimetric detection and (B) digital nanobubble detection.

RESULTS

For analog detection, 45 nm GNP-Syn probe was first tested. GNP-Syn conjugation leads to plasmon resonance peak shift from 532 to 538 nm and hydrodynamic diameter increase by 23 nm (Figure 2A). Polyethylene glycol (PEG) has a nonspecific affinity to viruses and has been used to concentrate viruses. Thus, using PEG does not show the specific detection of viruses. Passive absorption has some limitations for long term storage of GNP-syn probes. We explore another decent method using DTSSP bifunctional crosslinker to modify GNPs surface and create more stable GNP-DTSSP-syn probes, which can distinguish crude stocks of RSV from other respiratory viruses (Figure 2B, C). This colorimetric detection results suggest that the LOD of the analog assay is about 10^4 ~ 10^5 PFU/mL, which is below the mean nasal viral load on day 1 of infection. RSV targeted by GNP-DTSSP-syn probes was confirmed by TEM imaging (Figure 2D).

For digital nanobubble detection, we have tested the nanobubble probability over a wide range of laser energy using 15 nm GNPs (Figure 3A). The results suggested that the presence of the viruses will lower the energy threshold for nanobubble generation. By analyzing the nanobubble probability versus the virus's titer at the laser fluence of 500 mJ/cm², we can differentiate RSV at the titer of 10^0 ~ 10^6 PFU/ml from the control group (Figure 3B).

DISCUSSION

In this study, we developed a novel digital nanobubble diagnosis technique based on the colorimetric immunosensor to detect RSV in a simple step. The results from analog detection assay suggest GNPs aggregation is a promising method in POC diagnosis of RSV. Digital nanobubble detection can provide about 2-3 orders of magnitude improvement in the limit of the detection (LOD) compared with the colorimetric detection. This work will have a broader impact on addressing the scientific challenge for rapid and ultrasensitive diagnosis in the biomedical community and contributing to infectious disease management which eventually reduced morbidity, mortality, and healthcare costs. Future work is needed to enhance the dynamic range and the sensitivity by optimizing the size or the concentration of the GNP probes.

SAFE DURATION OF A PERSON SOAKING INSIDE A HOT TUB: THEORETICAL PREDICTION OF TEMPERATURE ELEVATIONS IN HUMAN BODIES USING A WHOLE BODY HEAT TRANSFER MODEL

Myo Min Zaw, Manpreet Singh, Ronghui Ma, Liang Zhu

Department of Mechanical Engineering
University of Maryland Baltimore County
Baltimore, Maryland, USA

INTRODUCTION

Soaking in hot tubs has become a popular relaxation activity during all seasons. Unfortunately, hot tub related emergency visits increase in recent years. Based on a New York Times article, approximately more than 6000 emergency visits in 2007 are related to hot tube injury. Although most of the injuries were due to slips or falls, still more than 10% of those visits were heat stroke related. People often mistakenly assume a sense of safety since the head is typically not soaking inside the hot water. Understanding how high the body temperature especially the brain temperature will rise is crucial to educate the public to prevent heat stroke from happening when using hot tubs.¹

In this study, we first develop a whole body model based on measurements of a human body, with realistic boundary conditions incorporated before and after a person jumps into a hot tub. For the transient heat transfer simulation, the initial condition is the established steady state temperature field of the human body with appropriate clothing layer to ensure thermal equilibrium of the body with its surroundings. Once the person is inside a hot tub, the Pennes bioheat equation² is used to simulate the transient temperature elevations of the body, and the rising of the arterial blood temperature is solved by an energy balance equation modeling thermal exchange between body tissue and the blood in the body.³ The safe duration of soaking in hot tubs is then determined as affected by the hot tub water temperatures.

METHODS

A physical whole body model based on realistic measurements of a human body was generated. As shown in Figure 1, the body (81 kg, 1.82 m tall) consists of three components: the hemispherical brain, the rectangular column of the internal organ, and the muscle for the rest of the body. Each component has its own thermal and physiological properties. The Pennes bioheat equation² is used to model the transient temperature field of the body as

$$\rho_t c_t \frac{\partial T_t}{\partial t} = k_t \nabla^2 T_t + \omega_t \rho_b c_b (T_b(t) - T_t) + Q'''_{met,t} \quad (1)$$

where ρ is density, c is specific heat, k is thermal conductivity, ω is local blood perfusion rate, and Q'''_{met} is volumetric heat generations rate. Initially, the body is exposed to an ambient environment, and the thermal resistances due to clothing layers and convection/radiation with the air are lumped as an overall heat transfer coefficient U_{air} . Once the body is soaking inside a hot tub with water, the overall heat transfer coefficient is same for the head surface, however, a new overall heat transfer coefficient U_{water} is calculated based on free convection in water. The boundary condition can be written as

$$-k_t \left. \frac{\partial T_t}{\partial n} \right|_{\text{surface}} = U_{air,or,water} (T_t - T_{air,or,water}) \quad (2)$$

Figure 1: Schematic diagrams of the whole body model and its boundary conditions before and after the body inside a hot tub.

In Eq. 1, the arterial temperature T_a that is initially prescribed as 37°C rises with time. One can model the blood in the body as a lumped system that only varies with time.³ The increase or decrease in the arterial blood temperature is due to its heat exchange with the surrounding tissue in the body, described by the Pennes perfusion

source term in Eq. 1. The following equation is developed for determining the time-dependent arterial temperature $T_a(t)$ as

$$\rho_b c_b V_b \frac{dT_a(t)}{dt} = Q_{\text{tissue-blood}}(t) = \rho_b c_b \bar{\omega} V_{\text{body}} [\bar{T}_i(t) - T_a(t)] \quad (3)$$

where V_b is the blood volume and V_{body} is the body volume, $\bar{\omega}$ is the average blood perfusion rate, and $\bar{T}_i(t)$ is the weighted average tissue temperature of the body, they are defined as

$$\bar{\omega} = \frac{1}{V_{\text{body}}} \iiint \omega dV_{\text{body}}, \quad \bar{T}_i(t) = \frac{\iiint \omega T_i(x, y, z, t) dV_{\text{body}}}{\iiint \omega dV_{\text{body}}} \quad (4)$$

Eq. 1 and Eq. 3 are solved simultaneously to demonstrate thermal exchange between the arterial blood and tissue. Numerical simulations are carried out by ANSYS 19.2 Fluent.

RESULTS

Table 1 gives the physical and physiological parameters used in the heat transfer simulation. Note that the local blood perfusion rate of the internal organ region is adjusted so that the cardiac output of the body is equal to 5.5 liter/min, while the other two blood perfusion rates are obtained from literature.⁴ The overall heat transfer coefficient $U_{\text{air}} = 4.4 \text{ W/m}^2\text{K}$ is determined so that the body establishes a thermal equilibrium with the surrounding air before the person is inside the hot tub. U_{water} is calculated as $61.93 \text{ W/m}^2\text{K}$, however, its value would be much bigger if the water is actively stirred to move around. Three water temperatures (40°C, 43°C, and 46°C) are prescribed to evaluate the temperature elevations in the body.

Table 1 Physical and physiological properties⁴

	Brain	Internal organ	Muscle	Blood
$k, \text{W/mK}$	0.52	0.52	0.52	0.50
$\rho, \text{kg/m}^3$	1050	1050	1050	1050
$c, \text{J/kg K}$	3800	3800	3800	3800
$\omega, 1/\text{s}$	0.0087	0.0021	0.00052	-----
$Q'''_{\text{met}}, \text{W/m}^3$	9225	2198	554	-----

Figure 2: Contours of the temperature field of the body in a hot tub for 30 minutes, $T_{\text{water}} = 40^\circ\text{C}$.

Figure 2 shows the temperature contours of the body for the beginning, 15 min, and 30 min inside the hot tub. The initial temperature field is reasonable.⁵ Once the person is soaking inside a hot tub at 40°C, one can see the skin surface temperature rises from 35.5°C initially to that of the water, and the brain has the highest temperature in the body during the soaking from 37.2°C initially to 38.2°C after 30 min.

The weighted average tissue temperature (Eq. 4) and the arterial temperature T_a during the soaking are plotted in Figure 3. Initially they are the same as 37°C, due to the prescribed thermal equilibrium before the hot tub soaking. Once the body is immersed in hot water, heat conduction from the skin to the body tissue elevates the body temperature, making the right side of Eq. 3 positive, thus, resulting in an increase in the arterial blood temperature. The warmer arterial blood then further elevates the tissue temperature, shown in the perfusion source term in Eq. 1, continuing positive feedbacks between T_a and the weighted average tissue temperature. The shoulder by shoulder temperature rises in Figure 3 are consistent with our previous studies of a human body subject to harsh environment or during heavy

exercise.⁵ If one follows the recommendation of hot tub manufactures to soak in water at 40°C for up to 30 min, the maximal body temperature is less than 38.1°C. However, the threshold of body temperature at 38.5°C is reached after soaking for 25 or 18 min when T_{water} is 43°C or 46°C, respectively. Body temperature can rise to 39.4°C when staying in a 46°C hot tub for 30 min.

Figure 3: Temperature increases during soaking (red: weighted average tissue temperature, blue: T_a).

Table 1 lists temperatures of individual components in the body with time. Initially, the brain and internal organ have almost the same temperatures, which are higher than the muscle temperature. The brain maintains the highest temperature during most of the soaking time even if it is exposed to ambient air. However, the muscle temperature surpasses the temperature of the internal organ first, then the brain temperature once the soaking time is long. An increase in muscle temperature would divert more blood flow to the muscle region. If the cardiac output can't catch up, it may lead to reductions of the blood flow to vital organs, particular to the brain, and may also cause a decrease in systemic pressure to a dangerous level.

Table 1: Temperatures of individual components, °C

T_{water}		0 min	10 min	20 min	30 min
40°C	Brain	37.234	37.518	37.8704	38.204
	Internal organ	37.228	37.404	37.7297	38.071
	Muscle	36.684	37.357	37.7597	38.082
43°C	Brain	37.234	37.694	38.2664	38.809
	Internal Organ	37.228	37.511	38.0423	38.598
	Muscle	36.684	37.78	38.4348	38.951
46°C	Brain	37.234	37.862	38.6567	39.410
	Internal organ	37.228	37.611	38.3485	39.119
	Muscle	37.484	38.198	39.1055	39.832

SUMMARY

In this study, a whole body heat transfer model is developed to simulate temperature rises in individual body components when the body is soaking in hot water. The Pennes equation is coupled with an energy balance equation to determine both the temperature field of the body and the arterial temperature rises during the soaking. The recommended hot tub water of 40°C by manufactures is safe when the soaking time is less than 30 minutes. However, the soaking time should be limited to 25 minutes or 15 minutes when the hot water is 43°C or 46°C, respectively. Actively stirring the water in hot tubs would lead to shortening of the predicted soaking time, especially in adults with cardiac conditions.

INTRODUCTION

Cancer is a major public health problem worldwide and is the second leading cause of death in the United States. In 2018, 1,735,350 new cancer cases and 609,640 cancer deaths are estimated by the American Cancer Society [1]. Cancer progression ends in metastasis in critical organ such as the lungs, liver, bone and brain, which is the major cause of cancer death [2]. Therefore, early detection of the disease may result in the disparities in cancer survival if timely treatment is conducted. One of the major steps that cancer cells undertake to establish the metastatic tumor is that the primary cancer cells invade the surrounding parenchyma and intravasate into blood to circulate and spread [3]. These rare circulating tumor cells (CTCs) are considered to be a valuable target for early detection and characterization of cancers [4].

We developed a microfluidic device with distinct capture and flow zones (ZonesChip) for highly efficient antibody-based capture of CTCs from human blood. The cells are moved from the flow zone into the capture zone by applying an external force (dielectrophoresis or DEP force in this study). The flow speed in the capture zone is low, which not only facilitates the binding between CTCs and antibody on the microposts, but also reduces the possibility of the captured cells being washed away by the flow-induced force. Our results indicate that at high flow speed, this separation of the flow and capture zones can improve the efficiency of capturing spiked cancer cells from <1.5% to ~100% for devices without engineered flow and capture zones. In these devices, the injected cells stay dominantly in the flow zone, limiting their likelihood of being captured.

METHODS

Fabrication of microfluidic device. Photoresist SU-8 2025 (MicroChem, Westborough, MA, USA) was spin-coated on the surface of a 4-inch silicon wafer with a thickness of 100 μm . PDMS (Dow Corning, Midland, MI, United States) pre-polymer and its crosslinking agent

were poured over the photoresist mold, and cured at 72 °C for 3 h. Then, the PDMS surface modification with antibody was performed according to a previously reported method with slight modification.[5]

Experimental setup. As show in Fig. 1a, inlet 1 was connected to a syringe filled with DEP buffer (10% (w/v) sucrose and 0.3% (w/v) glucose in deionized water). Cells suspended in DEP buffer were introduced into the device via inlet 2 and collected from the outlet. The diameter of the microposts was 100 μm , and the gap between two adjacent microposts was 50 μm . The height of the channel was 100 μm . Electrodes 1 and 2, made of copper (Pololu, Las Vegas, NV United States), were inserted into the space between the sidewall and the microposts immediately next to the sidewall in the main channel on both sides of the device, for applying the patterned electric voltage on the device. The microcontroller was programmed to turn the switch on (for 3 s) and off (for 3, 3, 1, 0.5, 0.25 s when the flow rate was 0.1, 0.5, 1, 2, and 4 mL/hr, respectively).

RESULTS

Design of the ZonesChip with distinct capture and flow zones. The ZonesChip microfluidic device system (Fig. 1a) consists of two major components: (1) parallel patterned microposts modified with anti-EpCAM antibody for capturing the CTCs, and (2) electrodes placed against the inner sidewalls of the channel for generating DEP force that can move the cells and increase the cell-micropost contact frequency. More importantly, by taking advantage of the parallel design of the microposts (Fig. 1b), two distinct zones can be created in the main channel: (1) a capture zone (green in Fig. 1b) with low flow speed (< 0.2 mm/s, see Fig. 1c) for capturing cancer cells, and (2) a flow zone (yellow in Fig. 1b) with high flow speed (> 0.2 mm/s) (see Fig. 1c) for samples to flow through the microfluidic device. And cells will experience a positive DEP force, and be driven from the flow zone with low electric field towards the capture zone with strong electric field

(Fig. 1d). In a device without antibody modification, nearly all cells move in the flow zone in the absence of an electric field (i.e., switch off, Fig. 1e, left). When the switch is on, and an electric voltage ($V_p = 200$ V) is applied on the device (i.e., switch on), nearly all the cells are moved by the DEP force into the capture zone from the flow zone, and contact with the microposts (Fig. 1e, middle). When the switch is off again and the voltage is removed, nearly all the cells are dragged away from the capture zones and move back into the flow zones (Fig. 1e, right).

Figure 1: Microfluidic device with distinct capture and flow zones.

As shown in Fig. 3a, the captured PC-3 cells are all in the capture zone, and most of them are in the middle of the capture zone. This further confirms the aforementioned force and cell movement analyses. Typical high-magnification light and scanning electron microscopy (SEM) images of a captured PC-3 cell are shown in Fig. 3a and b, respectively. The capture efficiency of PC-3 cells spiked into the DEP medium is further quantified under various conditions to assess the importance of separating the capture and flow zones. As shown in Fig. 3c, with both DEP and surface modification with antibody, the capture efficiency reached ~100% at all the flow rates of 0.1, 0.5, and 1 mL/hr. Additionally, the capture efficiency of PC-3 cells spiked in DEP medium with both DEP and antibody modification at various flow rates (0.5-4 mL/hr) is shown in Fig. 3d. At the flow rate of 1 mL/hr, the capture efficiency can reach 98.1%, as the flow rate increases from 1 to

4 mL/hr, the capture efficiency decreases. To further test the universality of the ZonesChip for capturing EpCAM+ cancer cells, six types of cancer cells with positive EpCAM expression (PC-3, HCT-116, SK-MES-1, OVCAR-3, MCF-7, and CAPAN-2 cells) spiked in WBC suspensions (5×10^6 WBCs /mL) are studied and the data are shown in Fig. 3e. For all the cancer cells, the capture efficiency can reach more than 91%, suggesting this device works efficiently for all the EpCAM+ cancer cells. Furthermore, the capture of PC-3 cells spiked at various numbers in WBC suspensions is conducted, and the capture efficiency can be ~92% (i.e., the slope of the fitting line in Fig. 3f) on average when the spiked cell number is over a range of 2 to 1300 cells per mL (Fig. 3f). This data suggest this device has the capacity to work effectively over a large concentration range of cancer cells in blood samples.

Figure 2: Capture of cancer cells spiked in medium.

DISCUSSION

we developed an antibody-based microfluidic approach for CTC detection with distinct capture and flow zones to greatly enhance the throughput with high detection efficiency. This is achieved by minimizing the flow speed and thus flow-induced force in the capture zone even at flow speeds that are ~4 times higher than that commonly used in the literature, and by using DEP force to move cells from the flow zone into the capture zone. This idea of separating the flow zone from the capture zone has an immense potential to enhance microfluidics-based disease detection.

INTRODUCTION

Microchip electrophoresis provides a compact, rapid, and streamlined means for complete diagnostic workflow for disease detection, which is the essence of any point-of-care (POC) technology [1]. Capillary electrophoresis (CE) based microchips have been widely implemented for various analytical applications. We previously presented the first mass-producible, paper-based microchip electrophoresis (HemeChip) platform (Fig. 1) [2-4]. HemeChip is a point-of-care technology that uses a strip of cellulose acetate (CA) as the separation medium for the electrophoretic separation process. It performs electrophoretic separation of hemoglobins in whole blood and can detect, identify, and quantify the hemoglobin types present in a blood sample. In traditional microchip systems, extensive studies have been performed on system electrochemical behaviors such as ion migration, electrochemical reaction and pH change. However, this information is missing for paper-based microchip systems since they are mostly based on passive capillary flow or pressure driven flow instead of electric or electrochemical driving forces. This knowledge discrepancy may affect diagnosis accuracy and precision for paper-based microchip electrophoresis system, such as HemeChip. Because, hemoglobin separation in CA electrophoresis takes place based on charge to mass ratio, which can be affected by the pH. In this work, we present a method to investigate dynamic pH variation and gradient within paper-based microchips. A new electrophoresis buffer was developed to manifest run-time pH change based on colorimetric analysis (Fig. 2). Using an image analysis technique, spatial and

temporal change in pH was quantified in CA electrophoresis. The dynamic change in pH was quantified (Fig. 3) using calibrated digital time-lapse imaging.

Figure 1: HemeChip pH measurement: (A) HemeChip cartridge with separated hemoglobin bands. (B) Overview of run-time pH gradient during the electrophoresis process. (C) A representative illustration of the pH gradient along the CA paper after the HemeChip test is completed.

METHODS

The design and development of HemeChip technology as well as the HemeChip test process has been described previously [2, 3]. The HemeChip cartridge contains a strip of CA paper, which acts as the separation medium. For a standard HemeChip test, 10x concentrated

TBE (Tris/Borate/EDTA) buffer is diluted to 1x, pH 8.4, using ultrapure water. In this presented method of pH measurement, a modified TBE buffer solution was developed. The modified buffer is the 10x concentrated TBE buffer diluted to 1x buffer, using a 50:50 mixture of ultrapure water and pH-indicator solution (pH 4-10).

Figure 2: pH gradient across the CA paper strip during electrophoresis process. (A) A custom color map developed for the dynamic pH change tracking for the electrophoresis process. (B) A time lapse of the HemeChip test with the modified pH buffer. Time lapse shows the change in pH and its distribution across the CA strip.

Figure 3: Dynamic pH tracking along the length of the CA paper. The figure shows the change in pH along the length of the CA paper at different times during an electrophoresis test.

For the dynamic measurement of pH, the CA paper strip is soaked and the buffer pools are filled with the modified buffer and a HemeChip test is run (without blood sample) following the standard test protocol

[3]. The process is imaged using a Raspberry Pi 3B+ unit. A custom developed color map has been developed (Fig. 2A) using standard pH solutions in CA paper (pH: 5 - 11). The captured images (Fig. 2B) are later analyzed compared with the color map to quantify the dynamic pH change (Fig. 3).

RESULTS

The pH gradient in the CA paper can be obtained by fitting color change data into a customized pH-calibration curve. During the HemeChip electrophoresis process, electric potential was applied and color change, thus the pH gradient was observed. Through color calibrated time-lapse imaging, the change in average hue due to pH change was captured, and was converted into pH value (Fig. 3) based on the pH color dictionary that was derived using the same color calibration procedure (Fig 2A). Figure 2B shows a gradient of pH from both ends towards mid-section of the CA paper strip, which changes over time as the electrophoresis process is run. Figure 3 shows the pH across the CA paper strip in 0-5 minutes. As the time passes, the pH near the cathode end (left) of the CA increase, while the pH at anode end (right) does not change noticeably (Fig. 1C&3), while the pH at the mid-section of the CA paper shifts into acidic range (pH: 6.5).

DISCUSSION

We presented a dynamic pH change tracking method for measuring pH change within CA paper-based microchip electrophoresis system. Through color calibrated digital images, we quantified pH change within the separation medium and found it to be in the range of 6.5-8 (Fig. 3). This result suggests that instead of a uniform and constant pH value at 8.4 (TBE buffer), a pH gradient emerges and persists during electrophoresis process within CA paper. This pH gradient may lead to a hemoglobin charge to mass ratio variation during the separation process, which may lead to hemoglobin mobility affected temporally and spatially. This may affect separation efficiency, band resolution, and hence may impact detection accuracy. Future work will focus on minimizing pH gradient in CA electrophoresis through strategies, including electrode modification to control electrochemical reactions, and modification of the separation medium.

ROBUSTNESS OF CONVOLUTIONAL NEURAL NETWORKS FOR MALARIA PARASITE IDENTIFICATION IN THIN BLOOD SMEAR IMAGES WITH ADVERSARIAL IMAGE NOISE

INTRODUCTION

Malaria is a serious and sometimes fatal disease caused by a single-celled protozoan parasite in the *Plasmodium* genus, the most lethal of which is *P. falciparum*. The most common biological vector for the parasite is the female Anopheles mosquito. As the malaria parasites infect the red blood cells (RBCs), through blood transfusions, organ transplants, or contaminated needles, the disease can be spread from person to person. Thus, the prompt detection of malaria is essential for a patient to receive timely treatment and for preventive measures to be implemented to prevent further spread of infection from mosquitoes.

Two commonly used mechanisms of detecting malaria include rapid diagnostic tests (RDT), in which test kits are able to detect the presence of malarial antigens, and “blood smears,” where a drop of a patient’s blood is spread out on a microscope slide. This technique of microscopic diagnosis remains the gold standard for laboratory confirmation of malaria. However, the results depend on the quality of the staining reagents, the resolution and magnification of the microscope, and the experience of the laboratorian, all of which can be lacking tropical and sub-tropical regions where malaria is the most prevalent.

Convolutional neural networks (CNNs) are a type of deep neural networks that have achieved excellent performance in the field of computer vision. Studies have demonstrated that CNNs can be effectively used for malaria parasite identification. In particular, Rajaraman, *et al.* 2018¹ investigated the accuracy of six pre-trained CNNs, for example accuracy of 95.7% from the ResNet-50 was obtained, and developed a customized CNN which achieved an accuracy of 94.0%. These excellent results demonstrate the strong potential of CNNs for the clinical applications. Compared to the pre-trained CNNs, the customized CNN has a much smaller size, suitable to be used in mobile devices.

However, studies have shown that CNNs are not robust to small input perturbations, known as adversarial attacks², which work effectively on the images of a wide range of objects such as handwritten digits, animals, human faces, vehicles, and even traffic signs. A recent study³ shows that adversarial attacks can cause many state-of-art CNNs to make wrong classifications of medical images: by adding small perturbation to the input image, the output of a CNN could flip from the correct classification to a wrong one. Medical images often contain noises⁴ or artifacts⁵ from imaging process. Such noises and artifacts can be considered as perturbations on clean images, which could also cause CNNs to output wrong results. Until today, there does not exist a general solution to this robustness problem.

The objective of this study is to investigate and improve CNN robustness for the application of malaria parasite identification. We choose the customized CNN from the work of Rajaraman, *et al.*¹ as the base model, and new CNN models are derived from it by changing the structure and/or adding a constraint to the loss function. To add perturbations to images, the Fast Gradient Sign Attack (FGSA)⁶ algorithm was used. The experiments show that the new CNN models are very robust to FGSA perturbations, whereas the base model suffers significantly from the perturbations.

METHODS

In this study, we utilized the public dataset provided by Rajaraman, *et al.* 2018 of the NIH¹. The dataset consisted of Giemsa-stained thin blood smear slides from 150 de-identified *P. falciparum*-infected and 50 de-identified healthy patients. In total, there were 27,558 cell images with equal numbers of parasitized and uninfected cells. To evaluate the base and new models, the images were split randomly into a training set and a testing set at the patient level. The training set contains infected and uninfected images from 160 patients; the testing set contains the remaining images. Pixel values were normalized in the range of 0 to 1.

Data argumentation using random image rotation was applied to increase the amount of training data, reducing overfitting.

Figure 1. The base and new CNN models

Fig. 1 shows the structures of the base and new CNN models. The new model includes a sigmoid output layer, a 2D-dropout⁷ layer, and a channel-average layer which computes the average value of each feature channel. In addition to the binary cross entropy (BCE) loss, another loss term is added as a constraint on the magnitude of the derivative of BCE loss with respect to the input image⁸.

RESULTS

We performed evaluations on: the base model (CNN-B), base-model with the constraint (CNN-BC), the new model (CNN-N), and the new model with the constraint⁸ (CNN-NC). Fig. 2 shows the accuracies of the models on the testing set during the training epochs. The models were implemented using Pytorch. At the end of each epoch, FGSA perturbation noises (parameter $\epsilon=0.01$) were added to the testing images, and the accuracies were re-evaluated on the noisy data, shown in Fig. 3. Some examples are shown in Fig. 4. (More examples will be shown during the conference)

Figure 2: Accuracy vs Epoch for the CNNs on original data

Figure 3: Accuracy vs Epoch for the CNNs on noisy data

Figure 4: left panel: original images (CNN output), middle panel: noisy images (CNN output), and right panel: noise distribution.

DISCUSSIONS

The results show that all models have similar accuracies on the original testing data. But, the base model is not robust to noisy data, which suggests that it may not be safe to use it in clinical applications. The constraint⁸ was not very helpful for improving the robustness of the base model. The new model shows high robustness even without the constraint, which is attributed to the channel-average layer: averaging will remove noise. It may be noticed that the accuracy of the base model on the noisy data is relatively high during the early training stage, and then it decreased and oscillated, which may suggest overfitting. Thus, early stopping could be a simple strategy to maintain robustness. However, in practice, it is difficult to set up a criterion to determine at which epoch the training process should stop.

In our future work, we will explore more new structures and learning strategies. We will test the models against imaging noises, image artifacts, and all of the adversarial attack algorithms in the literature. We believe the robustness issue will be eventually resolved.

INTRODUCTION

Hepatocellular Carcinoma (HCC) has a 5-year survival rate of 11%. It is the 5th most common cause of cancer related death in men and the 8th in women [1]. Despite significant advances during the past two decades, high rates of tumor recurrence and disease progression following treatment of locally advanced liver cancer remain unresolved issues, urging the need for development of novel approaches. Transarterial Chemoembolization (TACE) exploits the preferential hepatic arterial blood supply of liver tumors to selectively deliver high concentrations of drugs via the intraarterial route [2,3,4]. Use of gradient magnetic fields and magnetic drug carriers (MDC) for TACE is a promising approach to improve drug targeting to the tumor and reduce systemic toxicity [2,3,4]. Previous approaches included a simple placement of an external magnet over the tumor location [2] and using an expensive MRI for vascular navigation of the MDC [3,4]. Herein we propose an external electromagnet to steer the MDC at the bifurcation using the patient images to create a robust, low-cost patient specific magnetic navigation system (Figure 1).

Figure 1: Illustration of using an electromagnet to direct microparticles through the hepatic artery.

This study investigated the possibilities of using an external magnet to navigate MDC to cancerous tissue in the liver. Using patient image-based vascular models, an optimum route for the drugs could be determined which would reduce systemic toxicity. Magnetic steering of the drugs requires drug-loaded magnetic microspheres and a device to generate a gradient magnetic field. To test these theories, a patient image-based computational fluid modeling approach was used in this study in addition to a simplified physical model to compare the results.

METHODS

Simulation: The first step in making this a patient specific treatment was to obtain an image of the hepatic artery and make it compatible with commercially available finite element simulation software. Once in the simulation software we were able to run flow simulations and input a concentration of particles into the flow. Pressure values were found from literature that could be inputted into the simulation to then calculate flow velocities. Below is a flow chart of these steps (Figure 2).

Figure 2: Schematic showing conversion of patient images to STL file and final geometry imported to simulation software.

We could then observe the effect of and applied magnetic field on the flow of magnetically sensitive particles. Due to the image having multiple flow pathways, we were able to determine the ideal distance of the magnet from the artery to direct most of the particles down the desired branch.

The modeling variables were determined using average pressure values at the inlet of the hepatic artery from literature and then calculating outlet pressures for each of the exit points using Poiseuille's Law:

$$Q = \frac{\pi \Delta P r^4}{8 \eta L} \quad (1)$$

Experiment: A physical flow model was made using a 3D printed bifurcation. This allowed us to get a general idea of how a magnet effects the flow of particles. It also helped us to determine inputs for our simulation model. Magnetic microspheres (12-00-304, Micromod, Rostock, Germany) were injected into a closed-loop circulating water network exposed to a magnetic field gradient at the bifurcation using an N52 neodymium permanent magnet (127 lb pulling force, 1.46 T magnetic flux density). The magnet was positioned at different intervals throughout the study. An open-source pixel counting software (ImageJ) was used to analyze images of the particles. The efficiency was found using these pixel counts from before and after the bifurcation.

Figure 3: A 3D-printed test piece and flow loop used to compare with our simulation results.

RESULTS

Simulation: Figure 3 below shows the results from the patient image-based model simulation. The highest efficiency (~72%) of directing particles into the desired branch was found at a magnetic flux density of 248 mT. Higher magnetic flux lead to an agglomeration of the particles to the vessel walls. The microparticles agglomerated to the walls of the model when subjected to a greater flux density, resulting in a lower efficiency. Due to the small strength of the magnet used, the position had to be very close (10 mm) to the bifurcation to direct the microparticles.

Figure 4: Plot shows the concentration of MDC's entering and leaving the target artery as a function of particle injection time.

Experiment: The experimental model was limited to a single 3D-printed bifurcation. The results from the experiments showed that a 248 mT flux density provided an efficiency of 78%, and the agglomeration on the walls of the vessel at higher flux densities was seen in this model as well as in the simulation.

Figure 5: Concentration of particles in the upper branch of the bifurcation (physical model).

DISCUSSION

The magnet was positioned at different intervals throughout the study to hone the steering of the microspheres into one branch of a bifurcation, while avoiding agglomeration near the walls of the vessel. Results show that there is a dependence on the magnetic field strength and geometrical characteristics as the effective magnetic force on the concentration of particles is sensitive to the governing magnetostatic equations. The steering efficiency of the concentration is therefore dependent on the magnet being used and an optimized position of a static magnetic field is to be found in the future as well as the introduction of an electromagnet.

Future studies should introduce an electromagnet in place of the permanent magnet, then design an electromagnet magnet with a larger spatial gradient to accommodate larger distances of operation. Another means of improvement would be to allow for movement of the magnet to 'follow' the particles and allow for more precise targeting.

THEORETICAL EVALUATION OF TEMPERATURE ELEVATION, THERMAL DAMAGE, TRANSPORT POROSITY ENHANCEMENT, AND MAGNETIC NANOPARTICLE MIGRATION IN TUMORS DURING LOCAL HEATING

Manpreet Singh, Ronghui Ma, Liang Zhu

INTRODUCTION

Recent microCT imaging study¹ has demonstrated different patterns of nanoparticle distribution by local heating. A much larger nanoparticle distribution volume in tumors after heating was observed than that in tumors without localized heating, suggesting possible nanoparticle redistribution/migration during heating. It is unclear what kinds of mechanisms resulted in the nanoparticle migration from high concentration region to low concentration region. It has been speculated that an increase in nanoparticle diffusion coefficient may play an important role here. It is possible that the intracellular solution is released from the dead cells after cell membrane ruptures. The relationship between diffusion coefficient and porosity of tumors suggest a 3.5 fold increase in nanoparticle diffusion coefficient if the porosity is elevated from 20% to 60%.

In this study, we develop a 1-D model to evaluate to what extent the enhanced nanoparticle diffusion coefficient leads to an increase in the nanoparticle distribution volume in tumors after local heating. The Pennes bioheat equation is used to simulate temperature elevations in a tumor with magnetic nanoparticle deposition, when it is subject to an alternating magnetic field. The blood perfusion rate and metabolism in tumors, and local tumor porosity are coupled with local thermal damage using the Arrhenius integral. Finally, the diffusion equation is implemented to simulate possible spreading of nanoparticle, providing a dynamic volumetric heat generation rate distribution in the heat transfer simulation. Results from the 1-D model may be extended to 3-D situations of nanoparticle redistribution in magnetic nanoparticle hyperthermia based on realistic microCT scans of tumors.

METHODS

A spherical tumor (10 mm in radius, initial porosity $\phi_0=0.2$) is proposed for this study. The tumor is exposed to a convection environment ($h=10$ W/m²K, $T_{air}=25^\circ\text{C}$), and magnetic nanoparticles

originally injected occupy a smaller spherical region (4 mm in radius) at the tumor center. The volumetric heat generation rate distribution Q'''_{MNH} was initially uniformly distributed in the small spherical region as 1.38×10^6 W/m³. The Pennes bioheat equation² in 1-D spherical coordinates used to simulate the transient temperature field during magnetic nanoparticle hyperthermia:

$$\rho c \frac{\partial T}{\partial t} = \frac{k}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial T}{\partial r} \right) + \frac{\omega_0}{e^\Omega} \rho_b c_b (37 - T) + \frac{Q'''_{m,0}}{e^\Omega} + Q'''_{MNH} \quad (1)$$

All the thermal properties in Eq. 1 such as density ρ (1000 kg/m³), specific heat c (3500 J/kgK), thermal conductivity k (0.64 W/mK), blood perfusion rate ω_0 (0.00083 1/s) and metabolism $Q'''_{m,0}$ (2708 W/m³) are the same as that in Lebrun et al.³ In Eq. 1, both the blood perfusion rate and metabolism decrease as the increase in the local thermal damage, defined by the Arrhenius integral Ω :

$$\Omega(r, t) = A \int_0^t \exp[-E_a/R_u T(r, \tau)] d\tau \quad (2)$$

Q'''_{MNH} in Eq. 1 is directly proportional to the local volume-averaged nanoparticle concentration C (mol per unit volume of tissue) as:

$$Q'''_{MNH}(r, t) = 2266.67 * C(r, t) \quad (3)$$

Thermal damage to tissue also results in an increase in the porosity ϕ from its original value ϕ_0 as:⁴

$$\phi(r, t) = \phi_0 + (100\% - \phi_0)(1 - e^{-\Omega(r, t)}) \quad (4)$$

The governing equation for nanoparticle diffusion is written as

$$\frac{\partial C}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} \left(\phi D_n r^2 \frac{\partial (C/\phi)}{\partial r} \right) \quad (5)$$

where the diffusion coefficient D_n is a function of the interstitial space fraction (porosity) ϕ :⁴

$$D_n = D_{n,f} [2\phi/(3-\phi)] \quad (6)$$

where $D_{n,f}$ is the nanoparticle diffusion coefficient in interstitial fluid.

The initial temperature field in the tumor is assumed uniform as 37°C, and the initial nanoparticle concentration C_0 in the small sphere is 608.899 mol/m³. Heating duration is set as 25 minutes (1500 seconds). The coupled equations (Eqs. 1-6) are solved simultaneously using COMSOL software.

RESULTS

Figure 1 shows temperature and thermal damage contours at various time instants during heating. The maximal temperature occurs at the tumor center and reaches 57°C after heating of 25 minutes. The thermal damage defined as $\Omega \geq 4$ with the dark red color. Thermal damage region occupies a sphere with a radius of 3.3 mm after 1000 seconds of heating. At the end of 1500 seconds of heating, tumor cell within a spherical region with a radius of 4.8 mm are permanently damaged.

Figure 1: Temperature distribution (left) and thermal damage region (right) in the tumor during heating

The results of the spatially and temporally varying porosity and nanoparticle diffusion coefficient are updated during the heating, shown in Figure 2. Initially, the porosity is uniform everywhere as 20%, and it gradually increases as thermal damage spreads from the tumor center to its periphery. After 1000 seconds of heating, the porosity at the center increases to 93%. At the end of the heating session the porosity of most tumor region is 100%, suggesting permanent thermal damage. The change of the effective nanoparticle diffusion coefficient due to increase in porosity follows a similar trend (Figure 3) and the diffusivity at center increases from its initial value of 9.57×10^{-12} to 6.59×10^{-11} (m²/s) after 1500 seconds of heating.

Figure 2: Tumor porosity distribution during heating

The nanoparticle distribution has been re-simulated based on the updated porosity and nanoparticle diffusion coefficient and the results are shown in Figure 4. The initial nanoparticle concentration profile is assumed as a quasi-step function. Once the thermal damage spreads towards the tumor periphery, significant nanoparticle diffusion occurs

in the region with the maximum concentration gradient. As a result, it is observed that nanoparticles have diffused to the tumor periphery, expanding the tumor region containing nanoparticles from a spherical regions with a radius of 4 mm ($t=0$) to that with a radius of 4.7 mm at the end of the heating session. If one defines the nanoparticle distribution volume as a region containing a nanoparticle concentration $\geq 5\%$ of the maximal nanoparticle concentration, a heating of 1500 seconds results in a nanoparticle distribution volume increase by approximately 62%.

Figure 3: Distribution of the enhanced nanoparticle diffusion coefficient during heating

Figure 4: Nanoparticle concentration redistribution due to change in the tumor structure during heating

SUMMARY

In this study, a theoretical framework is developed, consisting of a nanoparticle diffusion model and a heat transfer model to address possible nanoparticle redistribution. Their dynamic interactions during magnetic nanoparticle hyperthermia treatment are evaluated via modified tumor porosity and diffusion diffusivity of nanoparticle concentration in porous tumors. The simulation results have shown that thermal damage induced nanoparticle redistribution has increased the tumor volume containing nanoparticles by 62%. This study demonstrates the feasibility of enhancing nanoparticle dispersion from injection sites using targeted thermal damage.

INTRODUCTION

Cervical carcinoma is the second most prevalent cancer affecting women today. The human papilloma virus (HPV) is a common precursor to cervical carcinoma, and greatly increases a woman's risk of developing cervical cancer if contracted. The current state of the field relies heavily upon screening and pre-clinical testing to prevent cervical carcinoma and detect it as early as possible. When cervical cancer develops treatment is limited; patients undergo a hysterectomy followed by both local radiation and systemic chemotherapeutic treatment. Localized chemotherapeutic delivery greatly reduces adverse effects of chemotherapy and may be employed as radiation sensitizers are adjuvant therapies. For non-traditional therapy, aloe vera (*barbadensis miller*) is investigated for medicinal purposes: it is an antioxidant, beneficial for the natural vaginal biome, and promotes re-epithelization of the cervix. Alginate is studied as a drug delivery vehicle for its non-toxic cross-linking ability. The current study aims to develop an aloe/alginate hydrogel for the localized delivery of a chemotherapeutic to the cervix. It was hypothesized that the natural-based hydrogels will exhibit appropriate mechanical properties and anti-cancer biological activity based on antioxidant level [1,2, 3] and drug encapsulation and release.

METHODS

Aloe extraction

Aloe gel was harvested from aloe leaves. The gel within the aloe vera leaf was extracted by gentle scraping, then blended until homogenous using a standard blender, followed by lyophilization.

Aloe/alginate hydrogel fabrication and characterization

Three % (w/v) polymer hydrogels were formed from non-modified alginate, a 1:1 weight ratio of aloe and alginate, and a 2:1 weight ratio of aloe and alginate. The polymer solutions were placed in Teflon molds, then crosslinked using 0.5M CaCl₂ solution. Once formed, hydrogels were frozen at -80 °C and lyophilized. Hydrogels were chemically characterized via Fourier-transform infrared (FTIR) spectroscopy. Rheological data was collected using an AR2000 stress-controlled rheometer (TA Instruments). An oscillatory time sweep was

performed at 10 Hz and 1% strain at room temperature; storage moduli (G') were collected after the addition of 0.5M CaCl₂.

Swell ratio and degradation

Two groups of aloe-alginate were prepared, ratios of 1:1 and 2:1. Cylindrical hydrogel specimens (6mm x 3 mm) were formed via CaCl₂ crosslinking, frozen at -80 °C and then lyophilized. The dehydrated specimens were weighed, then placed in 500 µL of simulated vaginal fluid (SVF), consisting of: 3.51 g NaCl, 1.40 g KOH, 0.22 g Ca(OH)₂, 0.018 g bovine serum albumin, 2.00 g lactic acid, 1.00 g acetic acid, 0.16 g glycerol, 0.4 g urea, and 5.0 g glucose. [4] The pH was then adjusted to 4.2 using HCl. Samples were rehydrated for 24 hours at 37 °C in a shaker incubator. A wet weight of each sample was measured. Equilibrium water content was calculated as the percentage of wet weight divided by initial dry weight. The samples were lyophilized for 24 hours. The weight loss was calculated as the final mass subtracted from the initial mass, divided by the initial mass. To determine the polymer loss due to hydration and diffusion of non-crosslinked molecules, the mass of the dry sample after the crosslinking process was performed was measured.

Antioxidant assay

The reaction medium (7mM ABTS+ stock solution with 2.45 mM potassium persulfate (1/1, v/v)) was prepared, mixed overnight, then diluted with ethanol to an absorbance of 0.700 ± 0.05 at 734 nm. A photometric assay was conducted on 0.9 mL of ABTS+ solution and 0.1 mL of experimental samples (100 and 200 µg/mL of hydrogel eluent, i.e., SVF) and mixed for 45 seconds. The measurements were taken after 1 and 15 minutes at 734 nm. The antioxidant activity of the tested samples was determined by the decrease in absorbance at different concentrations. [2,3]

Drug encapsulation and release

A set of the 1:1 and 2:1 aloe:alginate solutions (10 mL) were mixed with 80 µL and 50 µL of 10% doxorubicin hydrochloride (DOX). The solutions were placed in molds and crosslinked. Six mm diameter hydrogel samples were suspended in 500 µL of SVF, and incubated at 37 °C. At 2, 4, 6, 8, 12, 24 h, and daily up to 7 days, 100 µL of SVF was

removed for analysis, and replaced with 100 μ L of fresh SVF to maintain the total volume. The samples were analyzed at 480 nm the values were compared to a standard curve DOX concentration was determined by using an absorbance assay and generating a standard curve. Cumulative DOX (μ g) release over time was calculated by adding the mass of DOX released at each time point per mass of the hydrogel samples.

RESULTS

The aloe:alginate hydrogels retained each component after crosslinking, verified via FTIR spectra (data not shown). The hydrogel exhibited appropriate stiffness and high swelling ratios, which maintained structural integrity while releasing chemotherapeutic. In addition, the degradation products from control aloe:alginate hydrogels demonstrated high antioxidant activity compared to the alginate control.

Figure 1. Storage moduli (G') of aloe:alginate hydrogels after crosslinking with 0.5M CaCl_2 . The hydrogels demonstrate appropriate integrity as an implantable hydrogel.

Figure 2. Swell ratio and weight loss of various weight ratios of aloe:alginate hydrogels after incubation in simulated vaginal fluid for 24 hours.

Figure 3. Antioxidant activity of various aloe:alginate hydrogel, with different weight ratios, compared to alginate controls. The assay was performed on the degradation products of the hydrogels after swelling in simulated vaginal fluid for 24 hours.

DISCUSSION

The anti-oxidant behavior of the aloe-alginate hydrogels may have applications in the treatment of cervical cancer exhibiting the ability to quench reactive oxygen species. Additionally, the gelation behavior and

sustained release a chemotherapeutic are also promising for a device for localized cervical drug delivery. The hydrogel exhibited structure integrity appropriate for adhesion to the vaginal canal, and the material also swelled, lost little weight, and sustained antioxidant properties in simulated vaginal fluid. In summary, the material will allow for a new form of treatment for cervical cancer, using a sustainable plant-based product further protecting healthy cervical tissue. One limitation of this study is the cross-linking techniques of CaCl_2 . However, there are other possibilities for crosslinking, either via pH or temperature, using various salts or chemically modified alginate. Furthermore, DOX was used in this study to reveal the kinetics of the drug release from the hydrogel, which was selected due to its solubility and detection via absorbance. This study demonstrates that aloe-vera has great potential to enhance cancer treatment and may also succeed in a multitude of applications related to women's health. For further investigation into the potential uses of the aloe:alginate drug delivery hydrogel ongoing *in vitro* study are investigating the cytotoxicity towards cervical carcinoma cells, in addition to the encapsulation of various pharmaceuticals.

Figure 4. DOX release from aloe:alginate hydrogels. Two concentrations of DOX were encapsulated in the hydrogels, and release took place in simulated vaginal fluid at 37 $^{\circ}\text{C}$.

MODELLING LYMPH PROPULSION IN A SERIES OF PUMPING LYMPHANGIONS

INTRODUCTION

The lymphatic system is a unidirectional vessel network maintaining the fluid balance by transporting the excess fluid from the interstitium and ultimately returning it to the venous circulation. Despite the adverse pressure gradient, lymph propulsion is possible due to the presence of the contracting collecting vessels that actively push the fluid forward and the valves which inhibit backflow. Impairment of the lymphatic transport leads to a variation of pathologies including lymphedema which is characterized by swelling of the limbs, high susceptibility to infection, and tissue fibrosis. Lack of a proper understanding about the mechanisms of fluid transport during lymphedema has in part lead to the absence of effective treatments.

Since the lymphatic system does not have a central pump, transport of lymph along the lymphatic system is mainly dependent on the synchronized contraction of the lymphangions, the small units that make up lymphatic collecting vessels. Most of the models describing the lymphatic system are either lumped or one-dimensional [1]. As far as we know, the only three-dimensional model of a lymphangion was the work of Rahbar and Moore [2] excluding the valves. The purpose of this study was to computationally model the propulsion of lymph in a series of lymphangions by means of active contraction of the lymphangions and one-way valve implementation.

METHODS

Our model describes a series of three pumping lymphangions immersed in the interstitium and was defined using COMSOL Multiphysics. The 2D axisymmetric geometry (500 μm by 3320 μm) includes 3 different domains being the inner volume of the collecting vessel (3 lymphangions each with a diameter of 100 μm and length of 1000 μm), the lymphatic vessel wall (10 μm thickness) and the interstitium (Figure 1). Lymph and interstitial fluid were modelled as a free fluid phase with a density of 997 kg/m^3 and a viscosity of 1.5 mPa.s. The lymphatic wall was considered as a linear elastic material. The valves were implemented as a porous medium, yet with a pressure dependent permeability ranging between 10^{-10} and 10^{-25} m^2 , which prevents lymph backflow whenever the pressure gradient over a valve is negative. At the boundaries of the interstitium, a sinusoidal pressure with a magnitude of 3.5 mmHg and a frequency of 0.4 Hz was chosen [3]. At the inlet and outlet of the vessel, open boundaries with zero pressure were imposed so that the lymph propulsion would be only the result of pumping lymphangions. At the vessel wall of each lymphangion, a boundary load, with the maximum magnitude of 5 N/m^2 , was applied with a contraction delay of 0.5 s between the lymphangions [4].

Figure 1: (a) Geometry and different domains of the model; (b) boundary conditions implemented in the model.

RESULTS

The results showed that we were able to model the simultaneous contraction along the length of the lymphangion leading to a maximum of $1.2 \mu\text{m}$ compression in radius (Figure 2c). With each contraction, the following lymphangion is initially expanded before its own contraction starts (Figure 2b). The graph of velocity magnitude in time (Figure 3) highlights the closed and open states of the valves. As each lymphangion contracts, its proximal valve closes while the distal valve stays open. Lymph velocity also proved to be very sensitive to the force applied at the vessel wall: changing the load from 5 N/m^2 to 10 N/m^2 lead to doubling of the maximal lymph velocity magnitude. Peak permeability of the valves was changed from 10^{-10} to 10^{-9} elevating both average lymph velocity magnitude and backflow. Altering the minimum permeability with a factor of 10 had no impact on the results.

Figure 2: Panel (a) presents the load applied as a boundary load at each lymphangion wall; (b) shows the spatial deformation of the vessel wall for two time points of 0 s (blue) and 1 s (green); (c) compares the deformation of the 3 lymphangions at different time points of 1.5 s (red), 1.9 s (grey), and 2.3 s (purple) when they have their maximum deformation.

Figure 3: Velocity magnitude (mm/s) of the lymph as it passes through the valves. In the instances where the valves are closed, velocity magnitude of lymph is recorded as zero mm/s.

DISCUSSION

These initial computational results illustrate the ability of our approach to model the unidirectional valves and the pumping mechanism of the lymphangions. Our model showed more sensitivity to the high value of valve permeability (10^{-10} ; minimum resistance) than to the low value of valve permeability (10^{-25} ; maximum resistance), similar to the behavior of the lumped parameter model of Jamalian et al. [5]. In the next steps, we will perform a parameter study, incorporate a poroelastic interstitium and increase the topological complexity to better match anatomical reality. To extend this model, we can also incorporate the initial lymphatics and study lymphatic uptake in multiple scales. We will also set up validation experiments in mice by which we will collect morphological and physiological data of the lymphatic system.

A 2D AXISYMMETRIC COMPUTATIONAL MODEL FOR THE STUDY OF MASS TRANSPORT INTO LYMPHATIC CAPILLARIES AND PRE-COLLECTOR VESSELS

Carlos A. Silvera Delgado (1), Ghazal A. Koudehi (1), Matthias V. Impe (1), Charlotte Debbaut (1), Patrick Segers (1)

INTRODUCTION

The lymphatic system is a unidirectional vessel network expanding throughout the body, evacuating interstitial fluid back into the circulation. Main components are lymphatic capillaries (initial or terminal lymphatics), collecting lymphatics and lymph nodes. Lymphatic capillaries, composed of a single layer of endothelial cells, are the sites where interstitial fluid (IF) enters the system, where it forms lymph. Primary one-way valves (endothelial flaps) along the length of the capillaries prevent retrograde flow towards the interstitium in normal physiological conditions. Lymphatic capillaries coalesce into the larger pre-collector and collector vessels and trunks. Lymph is returned to the central circulation both at lymph nodes and by the collecting lymphatics which propel the lymph by active contraction and external input from the surroundings. Impairment of lymph formation and evacuation can lead to lymphedema (swelling of extremities), high susceptibility to infection, and tissue fibrosis. The aim of this study was to develop a computer model for the study of lymph mass transport, particularly focusing on lymphatic clearance during lymphedema. Existing models of lymphatic capillaries are 2D models and do not include the pre-collector region. Furthermore, they most often focus on single valves, rather than the overall capillary function.

MATERIALS AND METHODS

A 2D axisymmetric model of a single capillary and a pre-collector is proposed. The model includes three the lymphatic capillary (80 μm diameter, length 310 μm), the tapering pre-collector (minimal diameter 80 μm , maximal diameter 120 μm , length 310 μm) and the interstitium (500x920 μm^2). The interstitium was considered as a poroelastic

Figure 1: 2D model geometry with applied BCs. The subpanel shows how wall permeability changes to mimic primary valves.

medium (which can thus change its volume). The vessel was assumed to be a linear elastic solid (Young's Module of 0.5 kPa) with a 10 μm thickness. The model geometry was designed to be consistent with values found in literature [1]. The lymph and interstitial fluid were assumed to have the same density (1000 kg/m³) and viscosity (1.5 cP) [2]. The fluid along the domains was assumed to be Newtonian. The

physiological values of the permeability and Young's Modulus of the interstitium were assumed to be $7.6 \times 10^{-14} \text{ m}^2$ and 5 kPa, respectively.

Primary lymphatic valve function was mimicked by implementing a wall permeability that depends upon the transendothelial pressure difference (see Figure 1). To mimic lymphedema, different combinations of wall permeability (from $1 \times 10^{-18} \text{ m}^2$ to $1 \times 10^{-27} \text{ m}^2$) and Young's Modulus for the interstitium (from 5 kPa to 10 kPa) were implemented. Computational simulations were performed using COMSOL Multiphysics® 5.4, Free and Porous Medium package. Since lymph formation is an unsteady mechanism, transient simulations have been performed.

I. Governing equations

The classical Biot theory of poroelasticity treats a porous material as a linear elastic solid governed by Hooke's law, while the flow inside the porous domain is described by Darcy's law. In this model, Brinkman's equations that are an extension of the Darcy's law have been applied. The equations ensure a continuous velocity and pressure field at the interface of the two domains (the endothelial layer and the lymph channel) because the equations are valid for low and high permeability values.

II. Fluid dynamics and solid mechanics boundary conditions (BCs)

As lymph formation relies on the cyclic nature of the interstitial pressure, a sinusoidal pressure (peak-to-peak from 3 to -1 mmHg; 1Hz) was applied at the external edges of the interstitium (Figure 1, red line) [3]. Pressure at the outlet of the pre-collector vessel was set to 0 mmHg. No slip conditions were applied elsewhere. The external edges of the interstitial space were free to move, but the lymphatic vessels were fixed (no active/passive contraction). These BCs lead to a time-dependent pressure difference between the interstitial space and the lymphatics and hence a pressure-dependent permeability of the wall (Figure 1).

III. Modelling lymphedema and pathology

Lymphedema was reproduced in two ways: first, an initial lymphatic obstruction was reproduced by decreasing the permeability of the lymphatic valves with constant values imposed for open and closed state (from $1 \times 10^{-18} \text{ m}^2$ to $1 \times 10^{-20} \text{ m}^2$); second, lymphatic leakage was modelled by increasing the permeability of the wall during the closed state (from $1 \times 10^{-27} \text{ m}^2$ to $1 \times 10^{-18} \text{ m}^2$) keeping the open state in the normal value ($1 \times 10^{-17} \text{ m}^2$). Modelling fibrotic conditions in lymphedema was done by increasing the Young's Modulus of the interstitium (from 5 kPa to 10 kPa).

RESULTS

Figure 2 shows the characteristic interstitial swelling (together with Von Mises stresses) when modeling lymphedema in response to lymphatic leakage. For the assumed parameter values, maximum swelling reached a 10% increase in volume compared to the resting condition. Increasing the Young's Modulus of the interstitium decreases the amount of fluid that enters the lymphatic capillary. Figure 3 illustrates how the flow rate of the capillary is critically dependent on the permeability, since a decrease of it reduce flow rates.

Figure 2: Interstitial swelling and Von Mises stress when mimicking secondary lymphedema.

Figure 4 displays the maximum backflow at the outlet when varying the permeability of the

wall, mimicking lymphatic leakage.

Figure 3: Flow rate at the outlet in case of lymphatic obstruction for three wall permeability values.

Figure 4: Maximum backflow in case of lymphatic leakage as a function of wall permeability. The values for the x-axis and y-axis have been presented in logarithmic scale.

DISCUSSION

Despite its geometric simplicity, this 3D computational model of the poroelastic interstitial space and initial and secondary lymphatics allowed us to replicate lymphedema in response to impaired lymphatic clearance, leading to an increase of interstitial fluid volume and swelling of the tissue (Figure 2). Lymphatic leakage (increased permeability) has two consequences: (i) fluid is being cleared from the tissue less efficiently than under normal physiological conditions; (ii) the presence of backflow provokes an imbalance in the water content of the interstitium, leading to tissue swelling.

We circumvented addressing primary valve malfunctioning at the level of the individual valves by modelling valve function via a pressure (and space) dependent wall permeability. Furthermore, the time dependent pressure boundary conditions imposed at the boundary of the interstitial domain lead to a pressure dependency of permeability and a functional pumping of the primary lymphatics (Figure 3). The computed flow rates are in good agreement with literature [2].

The novelty of our approach is that it is highly straightforward to represent different levels of impairment of the pre-collectors and the lymphatic capillaries, from a total obstructed capillary (zero wall permeability at all times) to a leaking one (high permeability at all times) and any intermediate situation (and this in space-dependent manner). Further research will focus on further extension of the model, coupling it to pumping lymphangions, and extensive validation.

INTRODUCTION

The ability of red blood cells (RBCs) to undergo extensive reversible deformation when passing through narrow blood vessels and capillaries is critical for the continual blood flow and adequate perfusion in microcirculation. However, within the context of various hematological disorders, such as malaria and sickle cell disease (SCD), obstruction of small blood vessels is frequently induced by abnormal RBCs due to their altered deformability. Here, we demonstrate a functional microfluidic device that is composed of a series of micropillar arrays embedded into the microchannel (Fig. 1A). We designed the microfluidic device such that abnormal RBCs with significantly reduced deformability are retained by the upstream micropillar arrays containing coarse constrictions, while those with moderately reduced deformability by the downstream micropillar arrays containing finer constrictions. We further report a new parameter, namely RBC Occlusion Index (RBI), computed based on the overall occlusions induced by abnormal RBCs within the device, correlated to subject-specific clinical phenotypes. Our results indicated that the developed microfluidic device and the measured RBI values may serve as a promising universal tool to assess deformability and associated microvascular occlusion risk of RBCs within the context of microcirculatory health and disease.

METHODS

The microfluidic platform was designed and produced using established polydimethylsiloxane casting protocols and bonded to microscope slides (Fig. 1B). The masters of PDMS channels were fabricated with silicon wafers using standard photolithography techniques and followed with 2-h surface passivation using fluorinated saline vapor.

Figure 1. The microfluidic device: design and fabrication. (A) Each microfluidic device is composed of 9 micropillar arrays containing narrow constrictions from 20 μm to 4 μm . Inset: SEM images showing the inspection of the fabricated PDMS micropillar arrays (all indicated dimensions are in microns). Scale bars represent a length of 100 μm and 10 μm , respectively. (B) Flow of the fabrication process of the device. (C) Macroscale view of the microfluidic device. Arrow indicates flow direction.

Prior to introducing RBC samples into the device, the channel was rinsed with pure ethanol and PBS, and then incubated with 2% BSA overnight to reduce non-specific cell adhesion. A 20%-hematocrit RBC suspension was injected into the microchannel at a constant inlet pressure of 60cm H₂O for 20 minutes (**Fig. 1C**). Non-retained RBCs were washed off with PBS. Serial quantitative evaluation of occlusions induced by abnormal RBCs and calculation of the corresponded RBI values were carried out under standardized protocols on 5 healthy subjects, 15 subjects with homozygous HbSS (SCD), and 5 cultured malaria (*Plasmodium falciparum*)-infected blood samples.

RESULTS

We observed significantly elevated numbers of occlusions in the channel induced by RBCs from SCD and malaria-infected samples, compared to RBCs from healthy subjects, as expected. To assess the extent to which individual RBC subpopulations induced vaso-occlusive events in capillary bed within different micropillar arrays, we defined and calculated the RBI of an individual sample based on the numbers of occlusions induced in each micropillar array ($RBI = \sum \text{Number of occlusions within the unit} \times \frac{\text{The unit number}}{4}$).

Our results (**Fig. 2**) show that the RBI was heterogeneous in blood from SCD subjects, varying between 271 and 16,310 (mean \pm standard error of the mean (SEM); $2,727.7 \pm 1,005.8$), which is significantly greater compared to healthy subjects (115.1 ± 24.4) (**Fig. 2**, $p=0.001$, Mann-Whitney U test). Additionally, the RBI of malaria-infected RBCs ranged between 1,906.5 and 6,487 ($3,232.7 \pm 838.6$), which is also significantly greater compared to healthy subjects (**Fig. 2**, $p=0.012$, Mann-Whitney U test). These results indicate that within the context of malaria and SCD, RBC deformability is significantly altered, which directly leads to increased microvascular occlusion risk.

Because the RBI scores of SCD subjects were very heterogeneous (271-16,310), the SCD subjects were categorized into two groups (RBI $<$ and $>$ 1,000 (**Fig. 3A**). The SCD subjects with RBIs $>$ 1,000 exhibited significantly higher white blood cell (WBC) counts (**Fig. 3B**, $p=0.032$, Mann-Whitney U test), lactate dehydrogenase (LDH) levels (**Fig. 3C**, $p=0.028$, one-way ANOVA), and reticulocyte counts (**Fig. 3D**, $p=0.023$, Mann-Whitney U test), but lower platelet counts (**Fig. 3E**, $p=0.043$, Mann-Whitney U test) and fetal hemoglobin (HbF) levels (**Fig. 3F**, $p=0.043$, Mann-Whitney U test).

DISCUSSION

We present a microfluidic approach that allows quantitative analysis of RBC deformability and microvascular occlusive risk within the context of malaria and SCD. We have shown that RBCs from subjects with SCD and malaria-infected samples are significantly less deformable compared to RBCs from healthy subjects, based on the size-dependent occlusions within our micropillar arrays. These subject-specific RBI values have been demonstrated to correlate with subjects' clinical phenotypes. When RBCs travel from arterioles through capillary bed to venules, the dimension of the blood vessels exhibit a wide range of variations from nearly 100 μm to 4 μm [1]. Therefore, our microfluidic device can be utilized to monitor RBC-capillary bed interactions and help in understanding the dynamic pathophysiology of various circulatory diseases.

INTRODUCTION

Vaso-occlusive crises (VOCs) are one of the most important pathophysiological manifestations of Sickle Cell Disease (SCD). Number of studies suggest that one of the key mechanisms which contribute to the VOCs is the adhesion of sickle RBCs to activated vascular endothelial cells in microvasculature [1, 2]. The essential reason for such abnormal adhesion to endothelial wall is the polymerization of abnormal hemoglobin molecule when deoxygenated, predisposing sickle RBCs to hemolysis [3]. In addition, emergence of anti-adhesive therapies targeting adhesion proteins on sickle RBCs claim reduction of the VOCs in vivo, supporting the hypothesis that adhesion of sickle RBCs is a key component in VOCs [4, 5]. Although the adhesion events are well studied, detachment of sickle RBCs, which might be key to understanding of survival of RBC adhesion under shear, is underexplored.

Our purpose was to experimentally examine the RBC detachment process using microchannels by gradually increasing the shear force acting on the adhered RBCs (Figure 1). We captured the sickle RBCs on a surface immobilized laminin-1 using technology described by Alapan *et al.*[6], then, collected videos of the adhered RBCs while gradually increasing the flow rate of buffer. Shear rate was ranged from 50 s^{-1} to 950 s^{-1} , such that it was kept in physiological range of capillary venules in microcirculation [7]. Timing of each RBC detachment was quantified by an image analysis algorithm that tracks the motion of RBCs in the video outputs. We described detachment characteristic of each blood sample tested by plotting ratio of number of adhered RBCs at time t to initial number of adhered RBCs by analyzing each RBC detachment event. Then we analyzed data further to understand survival rates of RBCs under different flow conditions.

Figure 1: Red blood cells are illustrated during their detachment from the protein surface.

METHODS

Microfluidic Chip Fabrication. The microchannels were fabricated by assembling a double sided adhesive (DSA) film on a rectangular polymethyl methacrylate (PMMA) piece and fixing the PMMA onto a APTS (3-aminopropyl triethoxysilane) functionalized microscope glass slide through the DSA. The microchannel height was determined by the DSA thickness, which was approximately 50 μm and which mimicked the scale of post capillary venules.

Surface functionalization. A cross-linker agent GMBS was used in order to covalently immobilize the proteins to the microchannel surfaces. After GMBS treatment and wash, 22.5 μL of protein working solutions ($100 \text{ mg} \times \mu\text{L}^{-1}$) were injected into the microchannels and

incubated for 1.5 hours at room temperature. Then, 30 μL of BSA solution was added into the microchannels, and held at 4°C overnight.

Blood processing and data acquisition. The microchannels were placed on an inverted motorized microscope stage for visualization and connected to a programmable syringe pump. Whole blood samples were tested within 24h after drawing. Blood flow rate was kept at 18.5 $\text{mg} \times \mu\text{L}^{-1}$ until residual BSA was completely removed. Afterwards, 15 μL of blood perfused at 1.85 $\text{mg} \times \mu\text{L}^{-1}$, corresponding to an approximate shear stress of 1 $\text{dyne} \times \text{cm}^{-2}$ throughout the microchannel. In order to wash the non-adherent cells off of the microchannel surfaces, wash buffer containing 1% BSA and 0.09% sodium azide was connected to the device and the buffer was pumped starting at a flow rate of 5 $\mu\text{L} \times \text{min}^{-1}$ for 100 μL to ensure that most of non-adherent cells were completely removed. Next, the flow rate of the wash buffer was increased gradually at linear rates while the videos of the microchannel surface were recorded at 10 fps and at 10X magnification. The duration of each video was set to be 20 minutes.

Analysis algorithm. A MATLAB© based code for automated processing of the experimental video data was developed. The pre-processing for identification of sickle RBCs adhered to functionalized surface was performed. This ensured the removal of spurious and non-specific adhesions that would interfere with the tracking algorithm. Then the pre-processed data was fed into the tracking algorithm specifically designed for microfluidic assays, to generate temporal detachment counts. The tracking kernel tackled issues like discarding mobile cells flowing into the frame of view, and being able to identify onset of rolling (as opposed to complete detachment). Trial runs tested against manual analysis yielded robust agreement.

RESULTS

Results are obtained through the tracking algorithm. Detachment events were recorded as the moment cells left their initial position. 17 blood samples were tested in these experiments at four different rates of gradual increase of shear force, which are defined as ‘shear rate ramps’ in this context. Fractions of initial population still attached at time t was represented by $S(t)$ and are presented in Figure 2 for each sample at different ramps.

Figure 2. Number of adhered sickle RBCs with time. At a force ramp rate of (a) 2.5 $\mu\text{L}/\text{min}^2$, (b) 3 $\mu\text{L}/\text{min}^2$, (c) 3.5 $\mu\text{L}/\text{min}^2$, (d) 4.5 $\mu\text{L}/\text{min}^2$. Each sample has the same color across plots.

Theoretically, area under the temporal detachment curve gives us average time to detachment, t_{avg} , of RBCs in that population which is calculated as;

$$t_{\text{avg}} = \int S(t) dt \quad (1)$$

Average time to detachment of samples of sickle RBCs under different ramp rates are depicted in Figure 3. Coefficient of variation decreases with the increasing force ramp rates.

Figure 3. Average time to detachment with corresponding ramp groups. Each sample has the same color across plots.

DISCUSSION

Observing and analyzing detachment of sickle RBCs unveiled many interesting features of sickle RBCs. One of these features is that both sickle RBCs and SCD itself, exhibits heterogeneous adhesion characteristics. $S(t)$ curves revealed that as the ramp rate increases, the average time to detachment of sickle RBCs gets shorter, however, considerable portion of sickle RBCs managed to stay at its initial position at even high flow rates giving a hint of underlying mechanism. Samples also showed considerably different $S(t)$ curves across different ramp rates. $S(t)$ curves at higher ramp rates are less dispersed than the curves at lower ramp rates. These new insights might play a key role in understanding and treating long and painful episodes of VOCs.

EFFECTS OF LEAKY TUMOR VASCULATURE ON TISSUE STRESS AND POROSITY IN A BIPHASIC MODEL OF BRAIN GLIOMA

INTRODUCTION

The mechanical forces present within a tumor and its surrounding normal tissue affect tumor progression and therapies. These forces can influence the growth and metastatic potential of cells directly or indirectly by compressing tumor blood vessels [1]. The resulting hypoxic conditions stimulate the formation of leaky vasculature that elevate interstitial fluid pressure and drive extracellular fluid out of tumors, posing a challenge for targeted drug delivery [1].

Past tumor mechanical models have focused on stresses resulting from tumor growth within host tissue and the role of extracellular matrix fibers [2] [3]. However fluid exuded by tumor blood vessels can also exert forces on cells and matrix components. A better understanding of how this can influence the stress state of tumors is needed, especially in brain gliomas given brain parenchyma lacks lymphatic vessels to clear away exudate. These tumors also tend to be softer than the surrounding normal tissue making their growth more difficult to explain.

Previous tumor models have used biphasic theory to account for the interplay of fluid and solid components in tissue [4]. In this study, a spherical biphasic finite element tumor model was developed to predict interstitial fluid and solid phase stresses caused by vascular exudation and its effect on tissue porosity. This is the foundation for future models with MRI-based geometries that account for blood vessel heterogeneity and collapse.

METHODS

A biphasic finite element model of a spherical tumor embedded within brain tissue was developed using the FEBio software suite [5]. In the biphasic formulation the solid phase includes cells and extracellular matrix while the fluid phase consists of the interstitial fluid. The leaky tumor vasculature was modeled as a distributed fluid source governed by Starling's law.

$$\dot{V}_f/V = L_p(p_v - p) \quad (1)$$

The left hand side is the ratio of fluid volume produced per unit time, \dot{V}_f , and tissue volume, V . This ratio varies directly with the difference between vascular pressure, p_v , and interstitial fluid pressure, p , where L_p is a vascular leakiness parameter.

The solid phases of both the tumor and host tissue were modeled as Neo-Hookean materials. The porosity of the solid phase, ϕ , was derived in terms of the Jacobian of deformation, J , and porosity in the reference configuration, ϕ_0 .

$$\phi = 1 - \frac{1}{J}(1 - \phi_0) \quad (2)$$

Interstitial fluid obeyed Darcy's law with hydraulic conductivity, k , which coupled to tissue deformation by a Holmes-Mow formulation

$$k = k_0 \left(\frac{J - (1 - \phi_0)}{\phi_0} \right)^\alpha e^{\frac{1}{2}M(J^2 - 1)} \quad (3)$$

where α and M are fitting parameters and k_0 is hydraulic conductivity in the reference configuration [6].

The modeled geometry consisted of a 3 mm radius tumor and surrounding host tissue that extended at least five radii beyond the tumor boundary. Because of spherical symmetry, only an octant of the sphere was considered while prescribing symmetry boundary conditions on the internal surfaces and free fluid flux through the tumor boundary. The model was implemented on a rectilinear mesh with 21,952 elements with elements becoming coarser with distance from the tumor boundary.

Tissue vascular leakiness, stiffness, porosity and hydraulic conductivity were assumed uniform within tumor and host tissue except a smoothly varying transition region at the tumor boundary. To achieve this smooth variation, material properties were assigned to the finite

element mesh on an element by element basis in a set of custom MATLAB scripts. Baseline material properties were estimated from previous studies in our labs.

RESULTS

Fluid exuding through leaky tumor vasculature resulted in elevated interstitial fluid pressure within the tumor and a steep pressure decline near the tumor boundary (Figure 1). The pressure field within the tumor generated the lowest fluid velocity near the tumor center and the highest velocity near its boundary.

Figure 1: Interstitial fluid pressure and velocity produced by fluid sources obeying Starling's law distributed within tumor tissue

Another consequence was an increase in tumor tissue volume that strained the solid matrix of the tumor and surrounding host tissue. The solid matrix of the host tissue experienced radial compression and hoop tension whereas that of the tumor experienced radial and hoop tension (Figure 2).

Figure 2: Radial and hoop stresses produced by fluid sources obeying Starling's law distributed within tumor tissue.

The increase in tumor tissue volume had the effect of increasing the porosity of the solid matrix. Beginning with a smoothly varying porosity curve in the reference configuration characterized by low porosity within the tumor because of elevated cell density, the deformed configuration predicted a reduction in porosity just beyond the tumor boundary (Figure 3).

Figure 3: Radial variation of tissue expansion and porosity

DISCUSSION

A biphasic finite element model of a spherical brain glioma was developed to study how fluid production by tumor vasculature affects the stress state and porous properties of tumor and host tissues. The fluid pressure and velocity magnitude were greatest in the center and rim of the tumor, respectively, in agreement with past theoretical and animal models [1] [4] [7]. The solid stress state of the surrounding host tissue was radial compression and hoop tension as is expected for growth induced stress, but stress in the tumor interior was radial and hoop tension which is opposite that induced by growth [2]. The tension in the tumor's solid phase balances the outwardly directed interstitial pressure drop produced by its leaky vasculature. The presence of leaking vessels could potentially alleviate compressive growth stresses and promote further growth since compression appears to inhibit cell proliferation [1].

Porosity measurements for rat gliomas taken with DCE-MRI have indicated slightly lower porosity within the tumor center and even lower porosity at its boundary relative to the host tissue [8]. The tissue deformation expected from fluid production transformed a uniformly low porosity within the tumor to a profile that matches more closely with these measurements [8]. The mechanical forces that accompany leaking vessels likely play an important role in the growth of brain gliomas given they appear to be softer than the surrounding tissue which is at odds with previous theoretical tissue stiffness predictions [9]. Future work will account for tumor growth to compare its contribution to the overall stress state with that of vascular leakiness.

MODELLING ADVECTION-BASED NANOPARTICLE DRUG DELIVERY TO THE LEFT VENTRICLE USING A SPLITTING METHOD FOR ADVECTION-DIFFUSION-KINETICS

Alexandra K. Diem (1), Kristian Valen-Sendstad (1)

(1) Department of Computational Physiology
Simula Research Laboratory
Fornebu, Norway

INTRODUCTION

The use of nanoparticles (NP) target drug delivery directly to the heart for treatment of diseases via nanoparticles (NP) has been a major goal of cardiovascular research since the early 2000s. Recently, such NP delivery systems based on non-invasive administration via inhalation have successfully been developed and shown to reduce heart failure in mice [1]. However, the transition of such innovative technology to larger animals and subsequently humans, requires careful optimisation of physico-chemical parameters of the NP, in order to achieve efficient distribution throughout the tissue.

We address this challenge by presenting a finite-element model of NP delivery via perfusion through the myocardium in the left ventricle (LV), which presents its own unique challenges: The discrepancy of scales between the size of the LV, blood vessels perfusing the LV, and NP requires the development of efficient averaging methods to effectively reduce simulation times. To achieve this, perfusion is represented by a three-compartment porous media continuum model based on Darcy's law [2], while NP delivery is approximated by splitting advection and diffusion kinetics across compartments.

Using these methods we demonstrate efficient simulation of NP delivery to the myocardium.

METHODS

We model the myocardium of the LV (domain Ω) as a three-compartment porous media continuum model, where a compartment represents artery, arteriole and capillary beds, respectively. Denoting different compartments using index i ,

$$-\nabla \cdot (\mathbf{K}_i \cdot \nabla p_i) + \sum_{k=1}^3 \beta_{i,k} (p_i - p_k) = s_i \quad \text{in } \Omega \quad (1)$$

with \mathbf{K} permeability of the porous medium, p pressure, and $\beta_{i,k}$ exchange coefficient between compartments i and k , and s source/sink terms. We use Neumann boundary conditions to model the inflow of blood from the coronary arteries via volumetric inflow

$$(-\mathbf{K}_i \cdot \nabla p_i) \cdot \mathbf{n} = \Psi_i \quad \text{on } \Gamma_N \quad (2)$$

on boundaries Γ_N .

NP distribution is modelled using standard advection-diffusion (AD) kinetics for each compartment i

$$\begin{aligned} \partial c_i / \partial t = & \nabla \cdot (D_i \nabla c_i) - \nabla \cdot (\mathbf{w}_i c_i) \\ & + \sum_{k=1}^3 \gamma_{i,k} c_k + s_i \quad \text{in } \Omega \quad (3) \end{aligned}$$

with c NP concentration, D diffusion coefficient, w advection velocity, $\gamma_{i,k}$ exchange coefficients between compartments i and k , and s source/sink terms.

Splitting Method for NP Deposition

Deposition of NP into myocardial tissue can only occur within the capillary bed. The non-linear advection-diffusion equation is time consuming to solve and thus we introduce the following splitting method: We model a *bolus of NP* as a collection of NP using Lagrangian particle tracking in the artery and arteriole bed (compartments 1 and 2)

$$\partial x_{1,2}/\partial t = w_{1,2} \quad (4),$$

while modelling diffusion in the capillary bed (compartment 3)

$$\partial c_3/\partial t = \nabla \cdot (D_3 \nabla c_3) + \gamma_{2,3} c_2 + s_3 \quad (5)$$

The equations are solved using the finite element Python package FEniCS [3]. Time discretisation is achieved using a Crank-Nicolson scheme.

RESULTS

The efficiency of the splitting method was tested on a unit square geometry over 3.0 s using a prescribed sinusoidal velocity profile (Figure 1) before application of the new method to a human LV geometry.

Figure 1: Velocity field in the unit square test geometry.

The equations were solved over 0.2 s on the test geometry with 5k, 20k, 40k and 80k dofs, respectively and a time step size of 0.005 s. Using the conventional AD equations the solution time increases exponentially from 26 s to 660 s, while the splitting method solves in 6 s to 66 s. Errors were measured by calculating the total mass over the geometry. In the case of the AD equations the error decreases linearly from 2.7×10^{-5} to 2.1×10^{-5} , while it stays roughly constant around 1.2×10^{-5} for the splitting method. Figure 2 shows an example solution over 3 s using the splitting method. An example solution for the human LV geometry using 10k dofs is shown in Figure 3.

Figure 2: Concentration in the capillary compartment of the test geometry with isocontours.

Figure 3: Concentration in the capillary compartment in the myocardium of a human LV geometry.

DISCUSSION

Interest in using NP for the non-invasive, targeted delivery of drugs to the heart tissue has been growing over the last twenty years. Experimental research currently focusses on rodents and simulations possess the potential to accelerate the transition of the technology to testing in large animals. However, the conventionally used advection-diffusion equations are computationally expensive. Here, we present an efficient method to track NP in the LV via a combination of Lagrangian particle tracking and diffusion. This method leads to a speedup of the simulations by reducing both the required mesh size and number of time steps.

COMPARISON OF PRINCIPAL COMPONENT ANALYSIS AND NON-NEGATIVE MATRIX FACTORIZATION IN PREDICTION OF UNMEASURED MUSCLE EXCITATIONS

INTRODUCTION

To drive the computational models of musculoskeletal systems to estimate muscle forces and joint moments during a variety of dynamic motor tasks, electromyography (EMG) signals have been traditionally focused on. Surface EMG signal is non-invasive to record. However, it is unable to reliably record activity of the deeply located muscles that highly contribute to the generation of joint moments. Even though intramuscular recording--as one alternative to surface EMG, is able to pick up less surrounding muscle activities and capture more accurate deep muscle excitation, there are still potential complications of patient discomfort and pain. Additionally, there is also the risk in having the EMG fine wire electrodes to penetrate pathological tissue. One example, which is one of the long-time interests of this study, is the tumor developed in the hip region of the pelvic sarcoma patients, and that iliopsoas muscle group cannot tolerate a fine wire.

One strategy for the neural motor system to interact with the highly complex environment and to accomplish the multidimensional dynamic motor tasks is to identify the operation regularities [2]. A common hypothesis is that muscle synergies that are extracted from muscle excitations may be able to represent these regularities in the motor system. The muscle synergies extracted from a group of muscle excitations have been shown to be able to reconstruct the excitations of the other muscles [3], which can also demonstrate the coordination of these muscle synergies underlying behaviors. Taking the advantages of extrapolative property of muscle synergies, we may rebuild the unmeasured muscle excitations by investigating of the control strategy of muscle synergies in measured muscles.

Matrix factorization algorithms have been widely used to decompose a large number of experimental EMG signals into a smaller number of time-varying synergy commands, along with time-invariant synergy weights. However, the performance of each algorithm can be affected by specific assumptions and signal processing methodologies [1, 4]. One of the intrinsic defects of EMG is the challenge in attaining true maximum local muscle excitation for normalization. As a popular matrix factorization and data compression algorithm, principal component analysis (PCA) can capture the most important features of the large dimensional dataset, which may not be as sensitive as non-negative matrix factorization (NMF) to scaling scheme of muscle excitations and may provide us benefits in finding quick, unique and reliable synergies without 'truly' normalizing the data. In this study, a comparison is presented between PCA and NMF to investigate the performance of each on reconstruction of the unnormalized measured muscle excitations and extrapolation to predict unnormalized unmeasured muscle excitations.

METHODS

In this study, we compared the performance of the synergies extracted from normalized measured EMG data by PCA and NMF in fitting unnormalized measured and unmeasured muscle excitations. Data from previously published work was used in which EMG of 16 muscle groups were recorded from a stroke patient walking at different speeds, including self-selected speed (0.5 m/s; 3 trials) [4]. To test our hypothesis, the EMG of iliopsoas, collected by fine wire electrodes, was taken out as 'unmeasured' EMG signal, and the remaining 15 EMG signals were assumed to be 'measured'. All the measured EMGs were processed by band-pass filtering, full-wave rectifying and low-pass filtering. The resulting linear envelopes were normalized with

Figure1. (A) The 15 reconstructed unnormalized measured muscle synergies (at 5 synergies); (B) The average VAF values at each number of synergies between experimental and reconstructed original unnormalized measured muscle excitations.

respect to the peak processed EMG values observed across the entire set of recorded trials. We applied NMF on normalized measured muscle excitations and PCA on the demeaned normalized measured muscle excitations to extract synergy excitation commands. The synergy weights corresponding to all unnormalized muscle excitations were found via linear algebra. The similarity in the shape and amplitude between experimental and reconstructed muscle excitations was quantified by Variance Account For (VAF) and Pearson correlation (r).

RESULTS

With the 5 synergies from PCA and NMF extracted from the 15-channel normalized measured muscle excitations (normalized to max values over all trials), the original unnormalized measured muscle excitations were reconstructed fairly accurately (Fig.1A). For both PCA and NMF, the VAF values showed a rising trend by increasing the number of synergies. However, across all selected number of synergies, the VAF values with PCA were higher than those with NMF (Fig.1B).

The ability in reconstruction of the unnormalized missing muscle excitation (iliopsoas) by the synergies extracted using PCA and NMF from normalized measured muscle excitations was also compared, as shown in Fig. 2A for 5 synergies. Except for 3 synergies, all the VAF values with PC were greater than those with NMF. For PCA, the VAF values reached above 95% with 4 synergies. Pearson correlation values r between the reconstructed excitation and experimental PCA were higher than those with NMF at all the numbers of synergies above four (Fig.2C).

DISCUSSION

By increasing the number of synergies, the synergies extracted from normalized measured muscle excitations with both PCA and NMF resulted in better fitting both unnormalized measured and unmeasured muscle excitations. In other words, by appropriately optimizing synergy vectors (e.g. via EMG-driven model based optimization [Meyer et al. or who?]), we can rebuild original unnormalized muscle excitations that agree with the experimental signals using the PCA or NMF synergies extracted from normalized measured muscle excitations. However, PCA did a noticeably better and more reliable job than did NMF.

PCA is a linear decomposition approach that leads to the unique solution of PCs instead of multiple solutions as in NMF, which may allow us to perform synergy extraction repeatedly on rescaled version of muscle excitations through optimization process. Another advantage of PCA is that the synergies extracted from the normalized muscle excitations-- to the maximum values across all trials in the current study--can be applied to predict the original unnormalized missing muscle excitation more accurately compared to NMF. Hence, PCA-based synergy analysis could be performed before the start of the calibration process of missing synergy vectors and muscle specific parameters, while NMF may need to perform on rescaled-muscle excitations over and over again through optimization. Finally, the issue with finding the true normalized muscle excitations to derive synergies would not exist anymore if PCA is applied.

VARIANCE IN SWIMMER SYMMETRY DUE TO EFFORT AND FATIGUE

C. Main, C. Goehler

INTRODUCTION

The current methods for quantifying human motion in swimmers are not as advanced as those implemented for other athletes. While runners have a variety of sensors that can be attached to their body to measure joint flexure and gait, it is increasingly difficult to measure parts of the swim stroke due to the lack of waterproof sensors, and some sensors that are waterproof tend to be invasive in that they affect the stroke of the swimmer. The most common method for evaluating swimmers is qualitative observation from the pool deck and timing with a stopwatch [1], which is heavily influenced by refraction of light from the water and very unreliable. Current quantitative methods of measuring the biomechanics of swimmers include the use of Computational Fluid Dynamics to measure drag coefficients [2], tether cords to measure force [3], waterproof EMGs for muscle activation [4] and inertial magnetic measurement units for joint flexion [5], and accelerometers [6] in wearable technology to count strokes and laps.

The main objective of this study was to use a minimally invasive sensor to analyze basic “gait” patterns of swimmers swimming the front crawl at various intervals of effort, and then measure the average path of the stroke throughout each trial and how each stroke varies from the average. By determining how much a swimmer can vary in their stroke while fatigued, it may be possible to determine a threshold of safety for swimmers. If swimmers spend too much time continuously swimming outside of a certain threshold of safety for position of stroke and variance in stroke, they will be more likely to be injured from the repetition of incorrect swimming mechanics. These injuries that stem from repetitive motions are often career-ending and can greatly affect athletes in their daily life outside of the pool, even with treatment. Understanding where this threshold of safety exists will then help coaches create more effective practices that can help their swimmers improve technique and efficiency in water without risking injury.

METHODS

A GaitUp Physilog®5 motion sensor was clipped to the back of the swimsuit on two female collegiate swimmers. These sensors measure acceleration in Cartesian coordinates along with gyration about each axis, pressure, and temperature. The swimmers then swam eight trials, the first four at 70% effort, 80% effort, 90% effort, and 100% effort respectively, and the last four in reverse order. The first swimmer, a sprinter, completed trials 100 yards in length, the other swimmer, a distance swimmer, completed trials that were 200 yards in length.

The data from these sensors was then uploaded to a program in MATLAB. In the program, the data was filtered, position was derived from acceleration using kinematic equations, and each stroke was averaged together to identify the average stroke pattern for each trial. Then, each stroke was compared to the average to determine the variance of each stroke and the total variance of every stroke in a trial compared to the average. Finally, three parameters were calculated. The variance per trial was calculated using Eq. (1), the average amplitude of each trial was calculated using Eq. (2), and the change in amplitude between right and left strokes was calculated using Eq. (3), where s signifies position in all three equations. These values were compared to the percent effort of each trial to see trends in how effort and fatigue may influence the symmetry and consistency of stroke.

$$variance = \Sigma(s_{stroke} - s_{average}) \quad (1)$$

$$average\ amp = \frac{1}{2} \left(\frac{\Sigma s_{max}}{\# strokes} - \frac{\Sigma s_{min}}{\# strokes} \right) \quad (2)$$

$$\Delta amp = \frac{\Sigma s_{max}}{\# strokes} + \frac{\Sigma s_{min}}{\# strokes} \quad (3)$$

RESULTS

Each swimmer's data was run through a MATLAB program that plotted the position vs. time of each of her strokes and determined her average stroke pattern as shown in Figure 1. This allowed qualitative observation of the variance in each stroke throughout the trial.

Figure 1: Each stroke swam by the sprinter in her 5th trial compared to her average stroke pattern.

The average amplitude of each stroke was determined by taking the absolute values of the maximums and minimums of each stroke and averaging them. Then, for each trial, all of the average amplitudes of the strokes are averaged together and plotted in Figure 2. In both swimmers, as effort increased to 100% in trials 4 and 5, the average amplitude of rotation actually decreased 33.3% and 21.7% in the sprinter and the distance swimmer respectively as compared to their first trial.

Figure 2. The change in the average amplitude of rotation of the sprinter for each trial.

The variance of each stroke was measured as each data point's distance from the average stroke line. The total variance of each trial was determined and plotted in Figure 3. In both swimmers, the variance tended to become less negative as effort increased.

Figure 3. The change in the stroke variance of the sprinter for each trial.

The change in amplitude between left and right strokes did not vary significantly based on effort in either the sprinter or distance swimmer. When the change in amplitude from side to side was divided by the average stroke amplitude to find percent change in symmetry, there was also no significant correlation with effort or fatigue.

DISCUSSION

The data shown aligns with qualitative data often reported by coaches. As swimmers become more fatigued they tend to swim "shorter" or with less length in each stroke and less rotation. This also follows intuition that as swimmers try to swim faster, they will move their arms faster, and have less time to rotate fully to the side for each stroke. The decrease in amplitude of rotation from Figure 2 depicts a "shorter" stroke in trials 4 and 5, which are both at an intensity of 100%.

However, the variance becoming less negative does not seem intuitive. As the swimmer goes faster, he or she will be paying less attention to stroke mechanics, so it may be thought that the variance would be greater. Contrarily, it seems that as the average amplitude gets smaller, there is less room for error from the swimmer, so the overall variance decreases.

Finally, the absence of significant change between left and right strokes shows that neither of these swimmers seem to favor one arm more when they are tired. If the swimmer favors one arm when she is swimming at a normal pace, fatigue does not greatly impact this habit.

Future work would investigate swimmers' amplitudes and variances for longer periods of time along with taking qualitative observations from the swimmers. This will allow for the beginnings of a threshold of safety to be created for symmetry, stroke position, and variance of swimmers in order to prevent future injuries.

JOINT STIFFNESS MODULATION OF GAIT VARIABILITY IN A STROKE PATIENT DURING GAIT

INTRODUCTION

Individuals who become hemiparetic post-stroke demonstrate higher-than-normal gait variability [1]. Increased gait variability impairs stability [2], elevates the risk of falling [3], and hence makes individuals post-stroke more prone to injury during walking. It is therefore important to understand how the gait variability is modulated in the stroke-affected individuals so that effective treatments can be designed to reduce gait variability and improve stability during walking.

Previous studies used either temporal (stride-to-stride time) or spatial (stride length and width) metrics to describe gait variability. This study used joint position variability to address the gait variability in both temporal and spatial sense. This study attempted to investigate whether the joint stiffness, defined as the elastic response created by actuating muscles at the joints to the changes in joint kinematic, had been the modulator of joint position variability.

METHODS

The subject for this study was a right-side paretic chronic stroke survivor. The subject walked on an instrumented treadmill while motion, force, and electromyography (EMG, for 16 leg muscles groups) were collected. The subject's self-selected walking speed was 0.5 m/s. A previous study built a musculoskeletal model of the subject and calibrated the model through an EMG-driven framework until the model-predicted joint moments matched well with those from inverse dynamics [4].

The muscle parameters and forces extracted from the calibrated model were substituted into an analytical formulation to solve for joint stiffness, defined as

$$k_j = -\frac{\partial M_j}{\partial \theta_j} = \sum_{i=1}^{n_M} \left(r_{ij}^2 \frac{\partial F_i^T}{\partial l_i^{MT}} - \frac{\partial r_{ij}}{\partial \theta_j} F_i^T \right) \quad (1)$$

where i represents the i^{th} muscle among the 35 muscles in the model, and j represents the j^{th} degree of freedom (DoF, used

interchangeably with joint) among the 6 DoFs in each leg: hip flexion-extension (Hip FE), hip abduction-adduction (Hip AA), hip rotation (Hip Rot), knee flexion-extension (Knee FE), ankle flexion-extension (Ankle FE), and subtalar inversion-eversion (Subtalar IE). r_{ij} is the moment arm for the i^{th} muscle about the j^{th} joint, F_i^T is the tendon force and l_i^{MT} is the length of the muscle-tendon unit for the i^{th} muscle.

In the calculation of the joint position variability, the time between two subsequent heel-strikes of the same foot was defined as a full gait cycle. There were 101 uniformly spaced time points within the gait cycle to represent each percentage of the gait cycle. A full gait cycle was divided into the following five phases: 1st double support (DS1), single support (SS), 2nd double support (DS2), initial-to-mid swing (SW1) and mid-to-terminal swing (SW2). The onset of each phase was determined by detecting foot lifting or landing events from the ground force data for each trial and taking the averages across a total of 10 trials for each leg. For each phase in the gait cycle, only the joint angle data at the center of the phase (removing the first and final 5 time points to avoid outlier data at the transition between two phases) were selected for the calculation of joint position variability (JPV). At each selected time points of the gait phases, the standard deviation of joint angles across different trials was defined as JPV and calculated.

For the same selected time points, the mean of joint stiffness at each point across different trials was also calculated. The Pearson correlation coefficient r between JPV and mean joint stiffness were computed to determine the relationship between JPV and mean joint stiffness.

RESULTS

The phases in each trial determined by the event detection were fairly consistent as the standard deviation of phase boundaries was typically between 2 – 3 % gait cycle. The paretic side had shorter DS1

but longer DS2 phases than the non-paretic side had (22.4 vs 27.4 for DS1 and 22.4 vs 25.5 for DS2), as shown in Table 1.

Table 1: The bound of gait phases expressed as mean (std) in gait cycle %, and selected data points for each phase

Non-paretic Side			Paretic Side	
Phase	Bound	Selected	Bound	Selected
DS1	27.4 (2.3)	5 – 22	22.4 (1.9)	5 – 17
SS	52.4 (2.2)	32 – 47	48.8 (1.7)	27 – 44
DS2	74.8 (3.1)	57 – 70	74.3 (2.1)	54 – 69
SW1	87.4 (2.1)	80 – 85	87.2 (2.0)	80 – 85
SW2	100.0 (0.0)	90 – 95	100.0 (0.0)	90 – 95

In general, JPV is lower and mean joint stiffness range was paretic side compared to the ones on the non-paretic side. Exceptions were the small stiffness range of Hip FE joint on the non-paretic side during SS phase and large JPV of Subtalar IE joint on the paretic side during SS and DS2 phase (Figure 1 and 2). JPV within SS and the DS2 phases were tightly controlled at most joints except at knee and subtalar joints.

Figure 1: JPV vs mean joint stiffness during SS phase

Figure 2: JPV vs mean joint stiffness during DS2 phase

A large proportion of Pearson correlation coefficients that measure linearity in the relationship between JPV and mean joint stiffness were either greater than 0.9 or less than -0.9 (bolded values in Table 2). This indicated that there was strong linear relationship between JPV and mean joint stiffness on during various phases of gait. Majority of the strong linear relationship could be observed on the non-paretic side.

Table 2: Correlation coefficient between JPV and joint stiffness

Non-paretic side at walking speed = 0.5 m/s						
Phase	Hip FE	Hip AA	Hip Rot	Knee FE	Ankle FE	Subtl. IE
DS1	-0.14	0.94	0.97	-0.99	-0.78	0.32
SS	0.75	-0.19	-0.99	0.76	0.96	0.51
DS2	-0.99	0.94	-0.95	-0.98	-0.95	-0.18
SW1	-0.77	0.74	0.96	0.95	-0.98	0.44
SW2	0.94	0.99	0.99	-0.97	-0.96	0.96
Paretic side at walking speed = 0.5 m/s						
Phase	Hip FE	Hip AA	Hip Rot	Knee FE	Ankle FE	Subtl. IE
DS1	0.10	-1.00	0.90	0.77	-0.82	0.32
SS	-0.98	-0.90	-0.13	-0.74	-0.75	0.51
DS2	-0.97	0.45	0.86	-0.98	0.92	-0.48
SW1	-0.98	-1.00	0.67	-0.96	1.00	-0.91
SW2	1.00	0.99	-0.99	1.00	0.43	-0.90

DISCUSSION

Joint stiffness could be considered as the response provided by muscles to modulate gait variability. Ideally, a strong negative linear relationship ($r < -0.9$) should be expected as it showed that joint stiffness was modulating gait variability effectively, i.e. decreased JPV when increasing joint stiffness. However, a positive linear relationship did not necessarily mean ineffective modulation of the gait variability. It could mean that the joint still maintained the required level of stability while allowing some freedom in motion. The key criteria in determining the effectiveness of the gait variability modulation should be how much variation was allowed. For instance, during the SS phase, the stiffness of knee and ankle on the non-paretic side increased, but the variability gained minimally (Figure 1, less than 0.5 degree). This could still be considered as effective modulation of joint position variability.

For the three joints (Hip FE, Knee FE and Ankle FE) that governed the motion in the sagittal plane, the ones on the non-paretic side demonstrated more effectiveness in modulating JPV than the ones on the paretic side during the SS phase (Figure 1) where most amount of stability was required and least amount of gait variability was desired. The joints on the non-paretic side operated in lower-stiffness region while allowing the same JPV as the joints on the paretic side did in the higher-stiffness region. The muscles on the paretic side had to exert more effort to generate higher joint stiffness to control the variability.

During the DS2 phase, the paretic side showed lower JPV in all joints except Subtalar IE than the non-paretic side did for same or higher mean joint stiffness (Figure 2). This could be due to that the joints in the paretic side had limited range of freedom. However, this result pointed out that the subject had sufficient stability in the paretic leg during double support stance. Treatment should focus on improving stability during other gait phases when stability was lacking.

The limitation of this analysis was the low number of walking trials (10 trials for each leg) used. Error in processing the data for one trial could cause the data to be out of sync with data from the other trials and distort variability. The single trial anomaly could be remedied by having large number of trials to minimize the distorting effect. However, calculating joint stiffness of large number of trials could be computationally expensive.

INTRODUCTION

Estimation of muscle forces during human movement could facilitate the development of improved interventions for disorders such as osteoarthritis, stroke, cerebral palsy, and Parkinson's disease [1]. Optimization methods have been often used to predict muscle forces. However, it is well known that these approaches lead to minimized antagonistic coactivation and therefore joint stiffness. During gait, the human body not only varies the forces generated by the lower limbs but also the limb stiffness to control stability or to absorb impacts [2]. While joint stiffness has been identified as a crucial factor in joint stability, many studies have discussed stiffness without clearly describing how to define it. Although many studies have defined stiffness as the slope of the joint moment-angle curve--quasi-stiffness, this quantity does not account for how the system is controlled, i.e., whether the moment is coming from a muscle-actuated or a torque-actuated system. While the majority of studies use quasi-stiffness, few studies have shed light on how to compute stiffness in a muscle-actuated system, e.g. [2], [3]. However, published studies do not provide the complete derivation of their joint stiffness equation.

This study 1) formulates muscle and joint stiffness analytically from musculotendon kinematics and kinetics, 2) verifies the analytical stiffness calculations with a numerical perturbation method, and 3) compares the analytic stiffnesses with the formulation used in previous studies [2], [3].

METHODS

This study used previously collected data from a male chronic stroke survivor with significant walking dysfunction. Motion, ground reaction, and electromyography (EMG; from 16 lower extremity muscles) data were collected simultaneously from the subject as he walked on an instrumented treadmill at 0.4, 0.5, 0.6, 0.7, and 0.8 m/s.

A modified OpenSim ([4]) model with 31 degrees of freedom (DoFs) and 35 muscles was used for the initial musculoskeletal analysis, including detailed scaling, inverse kinematics, and inverse dynamics. An EMG-driven framework was used to calibrate musculotendon parameters based on Meyer et al. [5].

Muscle stiffness was calculated analytically using a custom Hill muscle model with rigid tendon. The stiffness of each joint was calculated using analytical relationships derived from the muscle model. In brief, for any joint j possessing generalized coordinate θ_j and joint moment M_j , joint stiffness k_j was defined as

$$k_j = -\frac{\partial M_j}{\partial \theta_j} = \sum_{i=1}^{n_M} \left(r_i^2 \frac{\partial F_i^T}{\partial l_i^{MT}} - \frac{\partial r_{ij}}{\partial \theta_j} F_i^T \right) \quad (1)$$

where $r_{ij} = -\partial l_i^{MT} / \partial \theta_j$. In contrast, Refs. [2], [3] used the following joint stiffness formulation:

$$k_j = \sum_{i=1}^{n_M} \left(r_i^2 \frac{\partial F_i^T}{\partial l_i^{MT}} + \frac{\partial r_{ij}}{\partial \theta_j} F_i^T \right). \quad (2)$$

In both equations, r_{ij} is the moment arm for muscle i (from 1 to the total number of muscles n_M) about DoF j , F_i^T is the tendon force for muscle i , and l_i^{MT} is the length of the muscle-tendon unit.

For the numerical part, DoFs were perturbed one at a time at each walking joint angle θ_j for a small step of $-\delta\theta$ and $+\delta\theta$. Then the corresponding joint moments (M^- and M^+) were computed using the musculoskeletal equations. Next, using centered finite difference, numerical stiffness was computed as $k_j^{Num} = (M_j^+ - M_j^-) / 2\delta\theta$. Perturbation size (finite difference step size) was varied between 10^{-2} to 10^{-16} to assure finding accurate derivatives.

RESULTS

By decreasing the perturbation step size to $\delta\theta = 10^{-12}$, the analytical and numerical joint stiffnesses matched perfectly, as shown

Figure 1) Analytical (dashed black line) versus numerical perturbation (solid thick grey line) and literature (dashed grey line) joint stiffness for hip flexion, knee flexion and ankle dorsiflexion of the right (paretic) side

in Figure 1 for one trial of the patient's self-selected speed (0.5 m/s; as an example) for three representative DoFs: right (paretic) hip flexion, right knee flexion, and right ankle dorsiflexion. Further reduction of the perturbation step size led to jagged results due to truncation errors.

DISCUSSION

Although Pfeifer et al. [2] reported good agreement between their stiffness formulation and experimental joint stiffness data, our study showed that their results differ from the numerical perturbation method. Since our analytical formulation produced identical results to those from the perturbation method, future investigation is warranted to understand the source of the disagreement.

This study introduced an analytical muscle stiffness formulation. The analytical derivation of muscle stiffness was possible due to the use of a custom musculotendon model and parameterization of musculotendon length as a function of generalized coordinates. An analytical expression for muscle stiffness may be useful for many different human-centered applications, such as in biomechanics, rehabilitation, and human-robot interaction. Another benefit of this study's stiffness formulation is the ability to examine the stiffness contribution of individual muscles.

Prediction of muscle forces is crucial in the design of treatments, such as assistive devices and implants. Current biomechanical models result in minimized antagonistic coactivation and therefore joint stiffness levels. Joint stiffness could play an important role in computational algorithms of muscle force prediction. Antagonistic muscles could be recruited to change joint stiffness while the net muscle moment stayed the same. Furthermore, stiffness seems to be correlated with the stability of joints and overall human body movement. Therefore, correctly formulating muscle and joint stiffness may be valuable.

INTRODUCTION

Falls are common across a wide range of populations ranging from older adults to individuals with neurological impairments [1,2]. Each year falls lead to injuries in millions of people and accounts for 10-15% of all emergency department visits [3]. In the population of people over 65 years of age, falls are the underlying cause of more than 50% of injury-related hospitalizations and 40% of all nursing home admissions. The financial fallout is a major burden to the United States healthcare system, costing over \$31 billion in direct costs alone in 2015 and only expected to continue to increase [1]. Globally this problem is expected to grow significantly because by 2030 the number of people aged 65 and more will have tripled to 1.5 billion [4] and those suffering from neurological impairments will have exceeded 1 billion [5].

Finding effective methods capable of detecting a manifestation of impaired balance when there are no apparent signs of instability can thus improve the quality of life of billions of people while reducing the economic cost. One of the fundamental limitations is that postural instability is rarely identified before a fall occurs, and only then does a patient receive appropriate attention for improving balance control. While prior research has tried to address this by looking for subtle changes in postural sway, there is a lack of connection between these changes and their root cause. An ability to identify the mechanisms responsible for instability and in turn to provide personalized balance training would improve the efficiency of rehabilitation, ultimately reducing the substantial economic cost associated with falls.

To address these limitations Chagdes et al. [6] developed a method for identifying an oscillatory instability predicted by a mathematical model of upright balance when neurological delay is long. While this study successfully identified this instability in over half of the

individuals with neurological impairment, the method was unable to distinguish differences between the remaining individuals with neurological impairment and healthy control participants. Furthermore, the method was unable to identify a second instability predicted by the model resulting in a leaning posture when feedback gain was too low.

In this study, we present a novel approach for detecting manifestations of impaired balance and identify the likely mechanism of instability using topological data analysis (TDA) and the inverted pendulum model of Chagdes et al. [6]. TDA uses techniques from topology mathematics to provide a reduction in the dimensionality of datasets and is robust to noise. Using TDA we explore not only the region of oscillatory instability but also the regions of leaning instability and upright stable balance. This is accomplished through a data mapping technique where data is group based on proximities between the data generated by the mathematical model and experimental data of Chagdes et al. [6].

METHODS

Experimental Data: The experimental data consisted of the de-identified center of pressure (CoP) data used in Chagdes et al. [6] of 12 individuals with multiple sclerosis (MS), 12 age-matched healthy controls, and 12 healthy older adults. Participants completed three trials with their eyes-open and three trials with their eyes-closed. Data were collected at 50 Hz for 30 seconds.

Simulation Data: Time series realizations were generated by simulating the mathematical model of Chagdes et al. [6] for 1,500 different combinations of neuromuscular feedback gain and time delay equally spaced across the stability region shown in Figure 1. Time series realization were sampled at 50 Hz for a duration of 30 seconds.

Figure 1: Upright balance stability boundaries predicted by mathematical model showing (left) leaning instability region, (center) stable region, and (right) oscillatory instability region.

Data Transformation and Model Mapping: In their current states the data sets offer a low dimensional comparison in a TDA space as the only variable linking the simulated and experimental dataset was the anterior-posterior CoP. To increase the dimension of comparison we decomposed CoP using the continuous wavelet transform for 128-scales of the Mexican Hat wavelet. All except for the first four of the 128 vectors of wavelet coefficients were then used to create the model mapping between the simulated and experimental dataset. The first four scales were ignored as they were related to frequency ranges above 6.25 Hz beyond the capacity of upright quiet stance.

To accomplish the mapping process, two models were created using the Ayasdi workbench platform: (1) a mapping model, and (2) a classifier model. The mapping model was created using both simulated and experimental data to link experimental behavior to the mathematical model. The link between datasets was created by generating families of related simulation data points based on their proximity to their experimental counterparts. Following this linking, stability of experimental data was quantified by identifying occurrences of this data in the classifier model, which was created from only simulated data. All models were created using the neighborhood lens one and two, a resolution of 70, and a gain of two.

RESULTS

The classifier model (Figure 2) shows three distinct regions. The region highlighted in red corresponds to the stable region and the blue regions to the left and right correspond to the oscillatory instability and the leaning instability respectively.

Figure 2: Classifier model constructed from simulation data using the normalized correlation metric.

The subsequent mapping models (Figure 3) show the information density by coloration of the mapping a participant with MS and their healthy counterpart. Red nodes represent data nodes dominated by the subject's experimental data and blue nodes represent nodes saturated by the simulation data. Family grouping of simulation data points from the non-saturated nodes were constructed to map between the simulation and experimental data. These groupings were then mapped back to the original classifier model for both the MS subject (Figure 4) and their healthy counterpart (Figure 5). Classification of upright stability was indicated by coloration with red nodes indicating a large rate of occurrence in a region, blue a low rate, and grey if no occurrence.

Figure 3: Mapping model of (left) a participant with MS, and (right) a healthy MS control participant.

Upon mapping of the MS participant's data back to the classification model (Figure 4), we identified a high correlation to the oscillatory instability region as well as to the boundary between the stable and leaning states. Over all the trials, roughly 56% of this participant's mapped experimental data fell within the stable region, 30.5% fell within the oscillatory region, and 13.5% fell within the leaning region of our classification model.

Figure 4: Mapping of experimental data onto the classifier model for a participant with MS.

Similarly, mapping of the healthy MS control participant's data back to the classification model (Figure 5), we identified that the highest correlation was with the stable and leaning regions. Over all trials, about 54.1% of this participant's mapped experimental data fell within the stable region, 36.9% fell within the leaning region, and 9% fell within the oscillatory region of our classification model.

Figure 5: Mapping of experimental data onto the classifier model for a healthy MS control participant.

DISCUSSION

Our analysis shows that the MS participant had a larger amount of data correlated to the oscillatory instability region than their healthy counterpart indicating instances of impaired balance. Furthermore, the large percentage of the MS participant's data falling within the stable and oscillatory instability region supports the findings of Chagdes et al. [6] which identified intermittent instability in this participant.

A limitation of this work is the low number of participant data analyzed. While future studies will aim to analyze the entire data set of Chagdes et al. [6] the current study demonstrates the power of TDA in quantifying postural stability. The framework developed has the potential to not only quantifying postural stability but to identify progression toward impairment, to identify the mechanisms of instability, to provide insight into personalized rehabilitation plans, and to provide feedback on the effectiveness of rehabilitation.

INTRODUCTION

Cardiovascular medical devices such as blood pumps and blood contacting tubings are important life-saving devices, but are associated with blood damage, which occurs due to two mechanisms. In devices with high flow rates such as blood pumps, high fluid stresses lead to hemolysis and subsequently thrombosis [1], and on almost all artificial surfaces, protein adsorption occurs leading to foreign surface thrombosis reactions [2]. One of the methods recently proposed to decrease hemolysis risk is to reduce fluid shear stresses via surface drag reduction with superhydrophobic coatings [3]. Superhydrophobic surfaces trap a thin layer of air in a micro-/nano-structured surface to enable fluid slip, and is known to reduce drag forces of flowing liquids [4]. However, hydrophobic surfaces are more susceptible to protein adsorption [5], and this can remove the Cassie-Baxter state of the coating and remove slip-flow characteristics. Here, we propose a novel strategy to utilize superhydrophobic surfaces to reduce drag forces and at the same time ensure good functional durability via additional grafting of anti-adsorption material on the surface. To demonstrate the feasibility of this strategy, we grafted polyethylene glycol (PEG) onto PDMS surfaces with micro-patterns (obtained via micro-imprinting), and showed that the resulting surface could concurrently reduce drag and protein adsorption

METHODS

Micro-structured polydimethylsiloxane (PDMS) substrates were prepared using the micro-imprinting technique, at the Institute of Materials Research and Engineering, A*STAR, Singapore. The imprinted PDMS substrate had a regular surface pattern of micro-pillars which were 2 μm in length, width, height and gap spacing (denoted as PDMS μ). SEM images of these patterns are shown in Figure 1. Two methods were used to graft PEG onto the micro PDMS samples, namely, the plasma activation method and silanization

activation method. Both methods endowed functional groups (silanol for plasma activation, and epoxy group for silanization activation) on the otherwise inert PDMS surface to enable PEG molecule attachment. Comparing with the plasma activation method, the silanization method allows us to limit the activated area to the top of the pillars since it is difficult for aqueous solutions to penetrate the air pocket between the pillars.

Figure 1 SEM images of (a) top view and (b) side view of PDMS μ . (c) Schematic illustration of the modification of PDMS μ via silanization activation method, and oxygen plasma activation method.

RESULTS

The SEM images in Figure 2 shows the morphology of PDMS μ , and how the morphology evolves over time during incubation in PEG solution. For plasma activation method, the width and the height of the

pillar structures reduced as the PEG-reaction time increased due to PEG deposition at all locations on the surface, both on the pillar and in the depressions between pillars. As deposition advanced, the new pillar structures, composed of PEG alone, would gradually adopt narrower, sharper and shorter pillar shapes. With silanization activation on the other hand, PDMS could only be deposited on the tips of the pillar structures, since wet chemistry was employed for the deposition, and the water-based solutions could not get into the depressions between pillars due to the Cassie-Baxter state of the surface. To obtain more quantitative measurements of the morphology, AFM measurements were taken (Figure 2 c-d). The results showed that PDMS μ S had more uneven pillar tip surfaces, demonstrating PEG deposition. Figure 2e shows the contact angle characteristics for both PDMS μ S and PDMS μ P. With more advanced PEG deposition, PDMS μ S showed a small gradual reduction in contact angle. PDMS μ P on the other hand, demonstrated a drastic decrease initially, but regained higher contact angle with longer reaction times.

Figure 2 SEM images of oblique view of (a) PDMS μ P and (b) PDMS μ S after immersion in PEG solution for different durations; AFM images of (c) pristine PDMS μ , (d) PDMS μ S-24; (e) contact angle trend of PDMS μ P (blue line) and PDMS μ S (red line) after immersing for different reaction time.

To evaluate its anti-fouling ability and drag reduction performance, we did series of experiment. In Figure 3., protein adsorption on PDMS μ decreased by 25% compared to plain PDMS. This could be due to the smaller contact area between surface structures and the protein solution, due to the Cassie-Baxter state of PDMS μ . For PEG-modified PDMS μ surfaces, both activation methods decreased the protein adsorption dramatically, with over 80% decrease for the plasma activation method. PDMS μ P performed better than PDMS μ S most likely because it was more thoroughly coated with PEG. The results of the water jetting test are shown in Table 1. The PEG-modified flat PDMS (PDMS μ P) does not show an increase in drag force compared to flat PDMS, suggesting that no-slip flow condition was found in both, and either surface could be used as control. Comparing PDMS and PDMS μ , it can be seen that addition of microstructures to PDMS resulted in significant decrease of flow drag forces, which is consistent with the literature on how the Cassie-Baxter state can enable drag reduction, especially at lower jetting velocities. In the case of the PEG-coated samples, the drag reduction was observed as well, which shows that the surface maintains the Cassie-Baxter state even though hydrophilic polymer was deposited on the surface. At the higher jetting velocities, the dynamic pressures imposed by the jet increases fluid pressure on the sample surfaces, and could be suppressing the Cassie-Baxter state to reduce slip flow.

Table 1 Friction drag reduction percentage of pristine PDMS μ and modified PDMS μ under different water flow velocity.

flow rate(m/s)	PDMS μ P-24	Pristine PDMS μ	PDMS μ S-24	PDMS μ P-24
3.61	1%	16%	5%	7%
3.99	1%	9%	6%	10%
4.29	0%	7%	5%	9%
4.67	0%	11%	5%	9%
Average	0%	11%	5%	9%

Figure 3 Difference of the protein adsorption amount under static environments (immersing in 1mg/ml BSA solution for 4 hours). Significant differences compared to the plain PDMS surface ($p < 0.05$) are marked *.

DISCUSSION

Test results showed that both PEG grafted surfaces reduced protein adsorption compared to untreated PDMS surfaces, and both retained some drag reduction capabilities. Further, PDMS μ P was more successful than PDMS μ S at reducing flow drag and protein adsorption, and was more functionally durable when fouled with protein. Recently, there has been substantial interest in using superhydrophobic surfaces for medical tubings and conduits to tap into their drag reduction capabilities [6], and such tubings were observed to repel blood and reduce coagulation [7]. This approach can be used on medical conduits with low pressure, such as venous blood tubings, drug and saline tubings, and venous catheters, where there is an absence of high pressure to breach the Cassie-Baxter state. The PEG-modified PDMS microstructured surfaces in the current study will be very suitable for such applications as well, given their anti-fouling and drag-reduction properties. The present work thus validated the strategy of grafting anti-adsorption polymer to slip-flow material to retain benefits of both anti-fouling and drag reduction. However, the materials investigated were not yet optimized, and other anti-fouling polymers and substrates might be able to enhance the extent of anti-fouling and drag reduction. Future work to investigate and optimize this is thus much warranted.

INTRODUCTION

Each year, thousands of pediatric patients develop premature congestive heart failure (CHF) due to exposure to bacteria or viruses that attack the heart's muscle tissue or due to being born with congenital heart defects.^{1,2} Most severe cases require heart transplantation or the use of short or long-term mechanical circulatory support (MCS) systems, such as ventricular assist devices (VADs). VADs have demonstrated success as a bridge-to-transplant and bridge-to-recovery in a small number of pediatric patients.^{3,4} VADs specifically for children, continue to lag behind those developed for adults. In addition, there is no heart pump with the design innovation to support the dysfunctional states of heart failure and the range of the anatomic and physiological heterogeneity in pediatric patients from one stage of development to another. To address this unmet clinical need, the BioCirc Lab is developing a dual-configured mechanical pumping device that has an axial pump parallel in configuration with a centrifugal pump, as shown in **Figure 1** below.

This innovative new medical device will have the ability to switch from the axial pump to the centrifugal pump, as the patient ages or as the pressure/flow demands increase. The pumping system is being designed to be able to deliver flows of 1 - 5 L/min and pressure rises of 50 - 120 mmHg at 2,000 - 14,000 RPM. The impellers of these blood pumps are levitated using magnetic bearings and rotated by motor magnets. In this study, we focus our efforts on the initial design of the centrifugal and axial blood pumps for this new medical device.

METHODS

The design of the centrifugal pump was performed based on the Taguchi optimization method, which allowed us to find the optimal parameters. The axial pump was previously designed. Computational fluid dynamics simulations were conducted in order to find the optimal parameters for both an axial and a centrifugal pump. ANSYS CFX computational fluid dynamics software was used to generate the mesh and model for simulation. The axial pump is divided into the following sections: inducer, impeller, diffuser, and straightener. Each section was iteratively improved, while modifying the length, height, thickness, inlet and outlet angles, and twist angle. Grid independence and mesh quality studies were performed for each pump design. The axial pump was evaluated at operational speeds of 10,000 RPM to 14,000 RPM. The axial pump is being designed to generate 50-80 mmHg at 1 to 3 LPM for 10,000 to 14,000 RPM. The design goal was to meet the pressure-flow requirements for a pediatric patient, while also maintaining the scalar stress below 425 PA, radial force below 1 N, residence time below 600 ms, blood damage index below 2%, and axial force below 10 N. The centrifugal pump is being designed to generate 80-120 mmHg at 3 to 5 LPM for 2,500 to 3,500 RPM. The following centrifugal pump parameters and levels were considered for

**Figure 1: A. Orientation of the two pumps in a single housing.
B. Blood flow path within the VAD**

optimization; shroud clearance (0.15mm, 0.25mm, 0.35mm), blade number (4, 5, 6), twist angle (30°, 60°, 90°), and angle difference between the top and bottom of the blade at the trailing end (3°, 5°, 8°). Four parameters with 3 levels in each results in Taguchi matrix based on Equation 1 below.

$$N = 1 + \sum_{i=1}^{IndVar} (Levels(i) - 1) \quad (1)$$

IndVar represents the number of impeller parameters, Level represents how many values for each parameter are being considered, and N represents the minimum number of designs needed. The 9 centrifugal designs were then analyzed by simulation to predict pressure generation, scalar stress, axial and radial fluid forces on the surfaces of the impellers, fluid residence time, and blood damage levels.

RESULTS

The axial pump has an overall length of 50 mm. The impeller is designed to have 4 blades. Figure 2 shows that the axial pump is able to provide 50-80 mmHg for 1 to 3 LPM for operating speeds of 11,000 to 14,000 RPM.

Figure 2: Pressure generation profile of the axial pump

The scalar stress, blood damage indices, fluid residence time, radial and axial forces were all within the target limits for the axial pump. However, at the highest rotational speed and lowest flow rate, we did estimate a higher than expected scalar stress level. The optimal centrifugal design obtained through the Taguchi Optimization method has an overall diameter that is less than 50 mm with 6 blades, shroud clearance of 0.15mm, twist angle of 90°, and angle difference of 8°. Figure 3 illustrates that the centrifugal pump is able to provide 80-120 mmHg for 3 to 5 LPM while running at 2,500 to 3,500 RPM.

Figure 3: Pressure generation profile of the centrifugal pump

The average scalar stress, blood damage index, residence time, radial forces were all within the desired limits. For the axial pump the maximum axial and radial forces were 0.7N and 0.04N and for the centrifugal pump the maximum radial force was 0.75N. The resulting conceptual design of the axial and centrifugal pumps are shown in Figure 4. An axial and a centrifugal pump are positioned in parallel with respect to one another in a single housing.

Figure 4: Exploded view of the blood pump

DISCUSSION

The parameters and values chosen for the Taguchi Optimization Method led to a centrifugal pump design that met the target performance values required to support pediatric patients. The axial pump was iteratively improved until recirculation was virtually eliminated within the impeller and diffuser regions. The centered position of the impeller and the height of the blades for both the axial and the centrifugal pump lowered the axial and radial forces below the threshold values. For centrifugal pumps the distance between the shroud and blades added with the distance from the blade trailing end to the edge of the hub had a substantial impact on scalar stress and blood damage index. In case of the axial pump, the distance between the leading edge of the impeller blades and the straightener blades combined with the distance between the trailing edge of the impeller blades and diffuser blades had a significant impact on scalar stress and blood damage index. Scalar stress values of each blood particle were low in magnitude, thus maintaining the blood damage index near 2%. Results of the CFD studies shows that the Taguchi Optimization method is a beneficial tool for designing a blood pump for pediatric patients. All the computational simulations were conducted at steady state conditions. In order to better predict the performance of the pumps next stage would be to carry out further computational simulations using quasi-steady flow and transient flow. We also seek to experimentally verify through prototype testing using a water-glycerin mixture.

INTRODUCTION

Bifurcation lesions are the most frequent complex coronary lesion encountered in everyday interventional practice. Accounting for up to 20% of all coronary disease treated by percutaneous coronary intervention, they pose a significant challenge to present stenting techniques, resulting in lower success and higher complication rates compared to non-bifurcation lesions [1,2]. Current coronary artery bifurcation stenting techniques entail a high level of operative complexity as the main and side branches of the bifurcation must be treated separately. Further, certain contemporary techniques leave areas of the bifurcation exposed outside of the stent, creating a predisposition to turbulent flow and restenosis. Additional techniques utilize overlapping or adjoining stents, which can create a high amount of stress on the arterial wall leading to vascular neointimal growth and restenosis [3].

Current information on the flow and stresses that coronary artery stents are exposed to, especially in a bifurcation, is limited. This project aims to establish an experimental model of coronary stent implantation to advance optimal stent design through evaluation of post-deployed stent and lesion geometry, as well as provide an approach to produce input and validate future finite element modeling techniques. The overall goal is to determine the forces that stents encounter in the bifurcation along with providing indications for optimal stent designs to treat a bifurcation lesion using coronary intervention.

METHODS

To investigate the biomechanics of stented coronary arteries, experimental data from the Cardiovascular Biomechanics Laboratory at the University of Arkansas are summed into three major components: the artery, the stent and the balloon. The artery is evaluated at specific lesion geometries with a pre-defined Medina classification, consisting of the main branch, distal branch, and side branch with predetermined

divergent angles. Specific parameters are being investigated and will be ready for presentation at the 2019 SB³C conference. A novel method of creating tissue mimicking phantoms has been developed in collaboration with industry (Humimic Medical, Ft. Smith, AR).

Geometry data was gathered from a 2.25 mm diameter cobalt chromium Mini Vision Multi-link stents (Abbott Laboratories) using a Nikon XT H 225 ST μ CT system in both the crimped and deployed states. The deployed stent was expanded with 9 atmospheres of pressure using the polyethylene terephthalate balloon included with the device from the manufacturer.

RESULTS

A successful scanning of the stents was completed, and the acquired data was converted to a 3D Computer Aided Design model using a custom developed MATLAB script. The files were reconfigured and prepared for future use in a Finite Element Modeling simulation of a deployed stent in the bifurcation. Said scanned files are displayed in Figure 1.

Figure 1: 3D scans of a commercially available Multi-link stent in the crimped (left) and deployed (right) states

Provided a three-dimensional model of the coronary artery geometry, an artery exhibiting stenosis can be fabricated using the tissue mimicking gel. The tissue mimicking phantoms with

blood vessels can be utilized for in vitro testing of medical devices, such as coronary stents. (Fig 2).

Figure 2: Example of gel phantom containing an artery

The mechanical and acoustic properties of the human tissue mimicking gel and blood vessels can be closely matched to that of in vivo cardiac and surrounding tissues, including arteries. This provides an ideal in vitro model for validating future computational simulations, and will be used for the bifurcation lesion experimental setup. Three-dimensional models of the bifurcation exhibiting various degrees of stenosis were successfully created, two of which can be seen in Figures 3A and 3B. While deployed in the phantom, the crimped and deployed stents will be scanned using the μ CT machine as is shown in the exploded view of Figure 3C.

Figure 3: 3D models of bifurcation lesion phantoms at two different stenosis percentages (A & B); C) stenosis induced phantom with a Multi-link stent and a standard sized 10mm diameter balloon

DISCUSSION

Currently, stents used in treating bifurcations create a predisposition to high rates of in-stent-stenosis, thrombosis, and adverse clinical events. By clarifying the stresses and strains exerted on the stented vessel, this study can contribute to enhanced understanding of the unique therapeutic requirements for coronary bifurcation lesions.

Data from the crimped stent experiments will provide a parametrical basis and boundary conditions for future computational simulations, while the deployed stent will be used for validating these simulations. The results can provide a platform for the development of novel stent designs that will decrease stress on the arterial wall, thus reducing the risk of long-term complications. Additionally, the future framework of this study utilizing the Finite Element software will decrease development time and testing of superior stenting devices and procedures to reduce current efforts in optimizing stent design and pave the way for innovative technology to improve clinical outcomes for those suffering from coronary artery disease [4].

AGONIST / ANTAGONIST CONTROL COMBINING MIXED SENSITIVITY DESIGN AND ITERATIVE LEARNING

INTRODUCTION

Cadaveric experimentation provides orthopaedic researchers with the ability to make invasive measurements and apply multiple test conditions to the same specimen but is without active, internal actuation. Researchers have overcome this shortcoming by developing cadaveric testbeds known as joint motion simulators (JMSs). JMSs typically actuate a joint specimen by rigidly supporting one side of the specimen while leaving the other side free to be actuated by a motor driven, cable system that connects to muscle insertion sites along physiologic lines of action. Paralleling a joint's natural structure, a JMS's cable actuation often works in opposing agonist / antagonist (AA) arrangements.

JMS control is complicated by the uni-directional nature of cable actuation, geometric nonlinearities, specimen variation, and specimen degradation. An ideal JMS control system would be stable and have accurate joint position and tendon tension control with the potential for small cable tensions and without the need for specimen specific adjustments. Cable actuated AA systems, possessing all but the biological complications, have been studied in robotics and controlled with mixtures of position and tension control [1, 2]. Mixtures of position and tension control have also been applied in JMS control [3].

Our hypothesis is that the position / tension control paradigm can be extended with a combination of mixed sensitivity robust control, tendon tension source switching, and iterative learning control (ILC) to form an ideal JMS control system. Nonlinearities and specimen variation can be lumped into the uncertainty accounted for in the robust control framework which provides stability and decoupling. Tendon tension source switching allows small tendon tensions and prevents slack, alleviating many of the cable actuation complications. ILC, its prerequisites met by the robust closed loop system, adapts feedforward

inputs for each specimen to accurately track commanded joint position and tendon tension trajectories.

As a first step in validating this approach, this control combination was applied to a simple AA system consisting of a single degree of freedom (DOF) joint actuated by two opposing actuators (Figure 1).

Figure 1: Elbow flexion as an agonist / antagonist pair.

METHODS

The control approach was applied to and tested on an existing elbow JMS validated to have physiologic geometry [4]. The motors and pulleys designed to simulate the brachialis and triceps were connected to a mechanical elbow whose motion was restricted to flexion /

extension (FE) to form an AA system. A linear decoupling matrix, designed as a function of moment arms and stiffnesses in the middle of the elbow's FE range, was inserted prior to the brachialis and triceps velocity inputs giving approximate joint position and tendon tension decoupling. Using a stepped sign approach, transfer functions were identified at 60°, 90°, and 120° of flexion from inputs of joint position velocity and tendon tension velocity to outputs of joint position and tendon tension. A nominal model and uncertainty models were assembled from these identified transfer functions. A mixed sensitivity robust controller was designed using the nominal model, desired performance, input voltage limitations, and plant uncertainty [5]. If the original decoupling was not accurate, the robust design decoupled the system based on the identified transfer functions. Tendon source switching was accomplished with logic that closed the tension control loop with the smaller of the brachialis and triceps tensions. With the approximate decoupling of joint position and tendon tension control; independent, proportional ILCs were designed to generate and update tracking references for joint position and tendon tension [6].

The system was commanded to track a 90° flexion cycle in 5s. Antagonist tension was to be maintained at 3N. The ILC was iterated 20 times. The maximum and RMS joint position and tendon tension errors were calculated for each trial.

RESULTS

Over the course of 20 trials, maximum joint position error was reduced below 0.25° and RMS joint position error was reduced to 0.10° (Figure 2). Over the same trials, maximum tendon tension error was reduced to 0.50N and RMS tendon tension error was reduced to below 0.15N (Figure 3). All error reductions were approximately monotonic.

Figure 2: Max and RMS joint position error as a function of trial number.

Figure 3: Max and RMS tendon tension error as a function of trial number.

DISCUSSION

A combination of mixed sensitivity robust control, tendon tension source switching, and ILC successfully reduced joint position and tendon tension errors in an AA system performing a common motion in JMS related testing. Oscillations at the FE natural frequency of the system prevented further reductions in error. The work was limited in that it tested only a single degree of freedom system. Additionally, only one elbow specimen, a mechanical analog, was tested. Further work will extend the approach to 2 DOFs adding pronation / supination to FE as well as test the approach across a range of cadaveric elbows.

INTRODUCTION

Hydrogel based polymers are usually applied in tissue engineering and drug delivery applications, due to characteristics that include non-fouling behavior and tunable density. Microscale pressure sensors, based on whispering gallery mode, have been used to measure steady state and unsteady wall pressure in fluid mechanics and biomedical applications [1-3]. A microscale resonator, spherical, dome-shaped, and disk shape, made with polymer is embedded in soft materials [1-3]. What remains unknown is whether this type of sensor, embedded in soft materials, can be used to measure shock wave pressures caused by improvised explosive devices (IED). This study applies finite element methods to quantify the diametral deformation of microspherical resonators based whispering gallery mode (WGM) sensor, embedded in a soft material and subjected to shock wave impact. The diametral deformation can be correlated to the shift of optical resonances; the optical resonances shift is then correlated to the pressure variation. The sensing element is made with poly(ethylene glycol) diacrylate, known as PEGDA. The results of this work will provide design guidelines for manufacturing PEGDA sensors to measure dynamic pressure in soft materials and brain tissue.

METHODS

Finite element (FE) analysis of PEGDA embedded in polydimethylsiloxane (PDMS) was performed. The aim of this analysis is to quantify the diametral change of the PEGDA sensor embedded in PDMS during shock wave loading [4].

A hemispherical-shaped PDMS, simulating a simplified brain geometry, is used to study shock wave impact, while the geometry of the PEGDA sensor is spherical. The diameter of the hemispherical PDMS is 50 mm and the diameter of the spherical PEGDA sensor is 13 μm , which is 0.26% of the PDMS. Simplification of the FE simulation

was made by considering a small region around the spherical sensor. Thus, the geometry of the PDMS is a brick (Figure 1). The size of the bricked-shaped PDMS is $0.1 \times 0.1 \times 0.04 \text{ mm}^3$. However, future simulations will consider a larger brick dimension to determine the optimal brick size.

The spherical PEGDA sensor is halfway embedded into the PDMS and the two contact faces were set with a bonded boundary condition. The top-half surface of the spherical PEGDA sensor is a free surface, and the bottom-half are internal surfaces. For the brick-shaped PDMS, not all faces are free surfaces. Rather, the four edges of the PDMS shown in Figure 1 are fixed, which allow the deformation to be symmetric.

Figure 1: Geometry of spherical PEGDA sensor and PDMS brick in the FE simulation. Edge fixed support locations are depicted by the orange arrows. The pressure (red) applied to the top surface of the PEGDA sensor and PDMS are also shown.

Pressure load data was taken from shock tube experiments conducted in the laboratory. In these experiments, a pressure transducer

(PCB 113B22) was placed at the end of a custom-built shock tube to measure the pressure applied on the sample. This pressure was applied on the surfaces of the PEGDA and PDMS shown in Figure 1. The pressure measured from the dynamic pressure transducer is shown in Figure 2. To avoid conflict with the fixed support boundary condition placed on the PDMS, the pressure was not applied on the edge of the surface.

An isotropic elastic model was applied for both the brick-shaped PDMS and the PEGDA pressure sensor. The Young's modulus of PDMS is $3 \times 10^6 \text{ Pa}$, while the Young's modulus of PEGDA is $1 \times 10^5 \text{ Pa}$, which is much softer than PDMS [3, 4]. Poisson's ratio for both PDMS and PEGDA is 0.49, since an incompressible assumption was made. A tetrahedral mesh was applied. The total number of elements was 450,000, which was chosen after a mesh independence study.

Figure 2: The pressure captured with dynamic pressure sensor located at the end of shock tube.

RESULTS AND DISCUSSION

The radial deformation of the microp spherical PEGDA sensor can be correlated with the shift of the optical resonances through the equation $\Delta\lambda/\lambda = \Delta R/R + \Delta n/n$, where $\Delta\lambda$ is the optical shift, λ is the light wavelength in vacuum, ΔR is the radial variation of the microsphere, R is the radius of the microsphere, Δn is the refractive index variation of the microp spherical PEGDA material, and n is the index of refraction; $\Delta n/n$ can be neglected as showed in [1-3]. For a microsphere made with PEGDA ($n=1.46$) of a diameter of $13 \mu\text{m}$ and assuming a wavelength light of 600 nm , a free spectral range (FSR), which is the distance between optical modes of the same order, of $\sim 6 \text{ nm}$ is calculated.

The maximum deformation of the PEGDA pressure sensor is provided using the equivalent elastic strain result shown in Figure 3. The maximum strain location is near the interface of PEGDA and PDMS. Three locations (Figure 3) on the surface of the PEGDA sensor were chosen near the interface.

Figure 3: The equivalent elastic strain result on the surface.

Radial displacement results are shown in Figure 4, for the three locations considered. The maximum deformation ranges from $0.3 \mu\text{m}$ to $0.19 \mu\text{m}$. The maximum deformation is 14.6% of the diameter. Thus,

the maximum diameter decrease is 29.2% of the sensor diameter. The maximum deformation leads to a FSR of $\sim 8.7 \text{ nm}$. Therefore, a smaller PEGDA microsphere should be used (larger FSR) or a slightly stiffer hydrogel should be employed for the fabrication of the sensor. The FE simulation results show that a PEGDA sensor with a Young's modulus of $1 \times 10^5 \text{ Pa}$ will yield a maximum diameter change of 29.2%, when compared with the sensor's original diameter. Future studies will vary the stiffness of PEGDA and PDMS, to investigate the influence on diametral change.

Figure 4: The radial displacement at the three locations.

This study provides insight into the deformation of a soft pressure sensor embedded into soft materials, for quantifying the mechanical response of the soft material's surface following shock wave impact. Embedding rigid pressure transducers in PDMS will influence this soft materials' dynamic response to shock wave impact. However, utilizing micron-sized spherical PEGDA sensor is a viable solution to measure the dynamic pressure on the surface of PDMS, without affecting the deformation response. Manzo et al. [5] have encapsulated a dome shaped sensor made with mixture of Trimethylolpropane Tri(3-mercaptopropionate), commercial name THIOCURE and PEGDA into a 1:10 PDMS slab and it was used as pressure gauge sensor; the resolution exhibited was $\sim 50 \text{ kPa}$. In the future, shock wave experiments will be conducted on embedded PEGDA sensors on the surface of soft materials, to validate the FE results.

EXERCISE THERAPY AFFECTS GLENOHUMERAL JOINT STABILITY IN PATIENTS WITH ISOLATED SUPRASPINATUS TEARS

Luke T. Mattar (1), Camille C. Johnson (2), Tom H. Gale (2), Adam Popchak (3), James J. Irrgang (3,2), William J. Anderst (2), Volker Musahl (2,1), Richard E. Debski (1,2)

INTRODUCTION

Rotator cuff tears are a prevalent and serious clinical issue with an incidence as high as 20-30% in the general population^{1,2}. High treatment failure rates have been reported for non-operative treatment and can result in substantial pain and disability emphasizing the need to improve upon current treatment methods³. Current studies have observed poor kinematics and range of motion loss in rotator cuff tear patients during various activities^{4,5}. However, internal and external rotation at 90° of humerothoracic abduction is not well understood in-vivo, which is relevant for activities of daily living. Rotator cuff tears commonly occur in the supraspinatus tendon¹, an active compressor of the humeral head into the glenoid when performing external rotation in the abducted position. Thus, it is important to understand the effect an isolated supraspinatus tear has on the efficacy of the internal and external rotators of the rotator cuff to stabilize glenohumeral translations within the joint during this task. The objective of this study is to determine the effects of a 12-week exercise therapy program on glenohumeral kinematics in subjects with isolated supraspinatus tears during internal and external rotation at 90° of humerothoracic abduction.

METHODS

Ten subjects (mean age 58.7 ± 5.6 years, mean BMI 27.5 ± 3.8) with a symptomatic degenerative rotator cuff tear isolated to the supraspinatus tendon were recruited for the study after providing IRB-approved written informed consent. Exclusion criteria included asymptomatic tears, previous shoulder injury, or presence of severe capsule tightness. Each subject underwent computed tomography (CT) of the affected shoulder and the images were segmented to create a 3-dimensional (3D) subject specific surface model of the humerus and scapula using Mimics 20 software package. The glenohumeral joint was imaged using biplane radiography⁶. Three trials of the motion were captured over 2 seconds

per trial, starting in maximum internal rotation and ending after maximum external rotation was reached. The subjects were seated with their back straight and the affected arm at 90° of humerothoracic abduction for all trials. A stand was positioned at the distal end of the humerus to support the arm and to maintain the humerothoracic abduction angle. Digitally reconstructed radiographs from each subject and the captured biplane radiograph images were matched frame by frame using a custom model-based tracking technique (accuracy $\pm 0.4\text{mm}$ and $\pm 0.5^\circ$)⁶. Local coordinates systems for the humerus and scapula were based on a glenoid modified variation of the International Society of Biomechanics (ISB) standards⁷. Outcome measures included anterior/posterior (AP) and superior/inferior (SI) translation of the humerus with respect to the glenoid, contact center of the humerus on the glenoid, and maximum external rotation. AP and SI contact positions were normalized to glenoid width and height respectively. The normalization of the glenohumeral contact data results in the total contact path length normalized to glenoid size. Due to the variation in the amount of internal and external rotation between subjects, comparisons between pre- and post-therapy were made on an individual basis using the largest shared range of motion between data collection sessions. For all kinematic data, the trial containing the maximum external rotation angle was used for all analyses. Strength of the glenohumeral internal and external rotators were measured pre- and post- exercise therapy using a handheld dynamometer (Lafayette Manual Muscle Testing System). Paired sample t-tests were used to determine the difference in maximum external rotation, contact path length, and glenohumeral external rotation strength pre- and post-therapy with significance set as $p < 0.05$.

RESULTS

All subjects successfully completed the 12 weeks of exercise therapy. A significant reduction in contact path length of $12.6\% \pm 14.3\%$ of glenoid size occurred post-exercise therapy (Table 1, $p=0.02$). Eight subjects showed a decrease in contact path length with the largest decrease in contact path length being 38% (Table 1). A non-significant increase in maximum external rotation of $4.0^\circ \pm 9.2^\circ$ occurred post-exercise therapy (Table 1, $p=0.20$). Six subjects showed an increase in maximum external rotation, with the largest change being 18.1° (Table 1). Nine subjects experienced a significant increase in glenohumeral external rotation strength at 90° of humerothoracic abduction post-exercise therapy with an increase of $18.8\text{N} \pm 8.6\text{N}$ (Table 1, $p=0.001$). Glenohumeral external rotation strength post-exercise therapy was not obtained for Subject 2.

Table 1: Individual Differences in Kinematics Post-Exercise Therapy Program

Subject	Max. ER Angle ($^\circ$)	Contact Path Length (%glenoid size)	ER Strength (N)
1	-4.7	-4.2	5.6
2	13.6	-14.4	-
3	10.4	-13.4	26.5
4	-3.1	-38.0	29.4
5	-7.4	-19.6	12.4
6	18.1	-24.0	29.4
7	-7.1	13.7	12.1
8	10.3	-7.2	13.1
9	3.6	-19.4	18.0
10	5.9	0.6	22.6

Figure 1: Representative contact path kinematics for a single subject during the internal and external rotation task. a) Pre-exercise therapy and b) post-exercise therapy. The contact path is represented by the white line.

DISCUSSION

Our data shows that a structured exercise therapy program that focuses on restoring range of motion and strength overall successfully reduced the contact path length and increased glenohumeral external rotation strength and maximum external rotation range of motion (although only contact path length and strength were found to be significant). A significant decrease in contact path length post-therapy is indicative of greater joint stability during external rotation at 90° of humerothoracic abduction. The observed improvement in stability may be due to improvements in compensatory rotator cuff and scapular stabilizing muscles such as the force couple created by the infraspinatus and subscapularis post-therapy as shown by the improved measures of glenohumeral external rotation strength in clinic. A non-significant increase in maximum external rotation of $4.0^\circ \pm 9.2^\circ$ was observed. These findings were similar with ranges of 7.3° - 15.2° reported in other studies determining the efficacy of conservative treatment in patients with full-thickness rotator cuff tears^{8,9}. In the referenced studies, conservative treatment occurred for either 2 or 6 months and goniometers were used to measure external rotation ranges of motion. Other studies have tested the effects of exercise therapy in internal and external rotation with the arm by the side¹⁰. It was found that exercise therapy had no effects on the contact path length demonstrating that improvements in glenohumeral kinematics may be task dependent. These findings are clinically significant as specific exercise therapy programs may need to be developed to address task specific rehabilitation needs.

Limitations of the study include the lack of cartilage on the glenoid and humerus in the model tracking technique. This may lead to overestimation of contact path length. However, because the primary objective was to determine the effects of a 12-week exercise therapy program on glenohumeral kinematics within the same subject, lack of cartilage in the model should not have affected the quantitative comparisons.

Further studies should be done that analyze the effects of exercise therapy on glenohumeral kinematics longitudinally in subjects with isolated supraspinatus tears to determine if joint motion and stability is maintained over time. This may potentially be used to determine factors that lead to success or failure of structured exercise therapy programs and help to improve upon current treatment methods.

BICEPS VOLUNTARY ACTIVATION: METHOD TO CALCULATE PRE-STIMULUS MOMENT AFFECTS MAGNITUDE BUT NOT REPRODUCIBILITY

Thibault Roumengous (1), Paul A. Howell (1), Carrie L. Peterson (1)

(1) Department of Biomedical Engineering
Virginia Commonwealth University
Richmond, VA, USA

INTRODUCTION

The technique of superimposing electrical stimulation during a voluntary contraction, termed the interpolated twitch technique, has been used to assess voluntary activation (VA). VA quantifies the degree of voluntary drive to a muscle during maximal effort. Measured in the non-impaired elbow flexors, VA is reproducible within an individual from day to day [1]. VA may be beneficial for understanding changes in voluntary drive in patient populations due to injury or disease progression, or to assess the efficacy of rehabilitation. Towards our long-term goal to assess the reproducibility of VA of the biceps in individuals with spinal cord injury to direct rehabilitation, we first aim to standardize methods used to calculate VA.

In order to measure VA, participants must reach and maintain a perceived maximal effort until the superimposed stimulus is delivered [2]. The pre-stimulus moment is used to compute the amplitude of the interpolated twitch. The method to quantify the pre-stimulus moment varies across the literature, contributing to difficulties when comparing results [3]. Two main approaches can be identified: the mean moment of a short period before the stimulus onset [4-6], or the maximal moment reached any time prior to the stimulus onset [7]. Additionally, several studies do not report the exact method to determine the pre-stimulus moment. The objective of this study was to determine whether the method to calculate the pre-stimulus moment affects VA and/or the inter-session reproducibility of VA in non-impaired individuals.

METHODS

Experimental Set-up: Ten healthy participants (ages 19 to 27; 7 males, 3 females) were seated in a chair in an upright position with their dominant arm supinated in a cast attached to a force-moment transducer. The forearm was immobilized such that a 90° elbow angle was maintained during the experiment. After a short familiarization

phase and a warm-up, participants were instructed to perform a set of 3 maximum voluntary contractions (MVCs). Participants were provided visual feedback of their effort relative to their average MVC, and were asked to perform 10 additional MVCs during which they would receive two stimuli per trial; one stimulus superimposed during the maximum moment, and another stimulus at rest, five seconds after the MVC to elicit a potentiated twitch. A visual moment feedback and verbal encouragements were provided during effort. Each participant completed three sessions separated by at least a day.

Stimulation Parameters: Stimulation electrodes were positioned over the biceps (anode) and anterior face of the elbow joint (cathode). Optimal stimulation intensity was found by increasing the stimulus intensity until the moment response reached a plateau. 120% of this intensity was then used during the protocol to ensure that a supramaximal stimulus was delivered.

Moment Data Processing: For each trial, the pre-stimulus moment was computed with three different methods as follows:

- 1) The average moment maintained for 50 ms prior to the stimulus.
- 2) The instantaneous maximal moment within a 500 ms window prior to the stimulus after application of a 10 ms moving average smoothing filter.
- 3) The instantaneous maximal moment within a 500 ms window prior to the stimulus with a 50 ms moving average smoothing filter.

For each of the three methods, the twitch moment was computed for each trial as the difference between the maximum moment occurring within 150 ms after the superimposed stimulus and the pre-stimulus moment. The potentiated twitch occurring at rest was computed as the difference between the maximal moment within 200 ms after the

stimulus and the mean resting moment prior to stimulus. VA was calculated as a percentage given by equation (1).

$$\%VA = 1 - \left(\frac{\text{Superimposed twitch moment}}{\text{Potentiated twitch moment}} \right) \times 100 \quad (1)$$

Figure 1: MCV trial example. The three methods used to calculate the pre-stimulus moment are illustrated. In red; moment trace with arrows indicating electrical stimulation, first superimposed to MVC then at rest, potentiated.

Data and Statistical Analysis: VA was calculated for each trial with all three methods then averaged per subject. In order to test the null hypothesis that the mean estimates of VA are equal between the three methods, a one-way ANOVA was performed on the dataset. The Intraclass Correlation Coefficient in a two-way random effects model with repeated measures (ICC 2, k), following Shrout and Fleiss [8] was computed as a measure of the inter-session reproducibility. Here, the ICC is a reflection of the reproducibility of the average per-subject measure of VA across the entire set of three sessions.

RESULTS

For each of the three methods, we observed no differences in VA estimates between sessions. The following ICC (2,k) values (Shrout-Fleiss reliability; random set mean k scores) were calculated for each of the three methods: Method 1: 0.931; Method 2: 0.926; Method 3: 0.928. VA values estimated using Method 1 were significantly lower than Method 2: -2.804% with a 95% confidence interval of [-3.626% ; -1.981%] (P adj. < 0.0001) and Method 3: -2.581% with a 95% confidence interval of [-3.4038% ; -1.7585%] (P adj. < 0.0001). No statistical differences were found between VA calculated with Method 2 and 3 (P adj. = 0.8005) (Table 1).

Table 1: Average voluntary activation across subjects for each method of determining the pre-stimulus moment (mean ± standard deviation in percent).

	Method 1	Method 2	Method 3
Session 1	95.82 ± 4.62	98.62 ± 2.83	98.33 ± 3.24
Session 2	95.46 ± 4.25	98.45 ± 3.34	98.19 ± 3.52
Session 3	94.89 ± 4.44	98.03 ± 3.19	97.83 ± 3.28

DISCUSSION

We aimed to determine whether the method used to calculate the pre-stimulus moment affects VA and/or the inter-session reproducibility of VA. High ICCs calculated for all three methods suggest that regardless of method, VA is highly reproducible between sessions. In non-impaired subjects who are not fatigued, VA should theoretically approach 100% in most MVCs collected in proper experimental conditions [9]. We found that the more aggressive smoothing filtering of Method 3 had no effect on the estimation of VA compared to Method 2. Additionally, we found that measuring the pre-stimulus moment right before the onset of the superimposed stimulus (i.e., Method 1) leads to a slight but significant underestimation of VA compared to the other two methods. One possible explanation for this observation is that the subject might reach a higher moment output during their MVC that does not occur within the 50 ms window. In other words, the superimposed stimulus does not coincide with the maximum moment, which causes a larger twitch response. Despite familiarization, most subjects—especially those not physically trained—exhibit a moment drift after reaching maximal effort rather than maintaining a plateau. It is possible to mitigate this mismatch effect by measuring the maximal pre-stimulus moment after filtering the signal to discard moment spikes.

A limitation of the approach represented by Methods 2 and 3 is that it results in an indirect or delayed measure of the superimposed twitch. Specifically, the pre-stimulus moment subtracted from the twitch peak moment can be measured any time before the stimulus onset rather than directly at the base of the twitch as with Method 1. Therefore, Methods 2 and 3 rely on the assumption that VA can be estimated using a non-instantaneous measure of the superimposed twitch amplitude.

In conclusion, the method used to calculate the pre-stimulus moment does affect VA and should be taken into consideration when using the interpolated twitch technique; however, it does not alter the reproducibility of VA.

EFFECTIVENESS OF AN EXTENSIVELY ACTIVE AND AUTHENTIC LEARNING ENVIRONMENT IN AN UNDERGRADUATE BIOMEDICAL ENGINEERING MODULE – A CASE STUDY IN A SOUTH-EAST ASIAN COHORT

Vivek Vasudevan, Alberto Corrias, Martin L. Buist, Leo Hwa Liang, Choon-Hwai Yap

Department of Biomedical Engineering
National University of Singapore
Singapore

INTRODUCTION

There is extensive literature on the effectiveness of active learning in the context of engineering courses [1-2]. When students construct their own understanding of concepts through carefully designed activities, they assimilate the contents better, obtain better understanding and retain more lasting impressions of the concepts. Similar evidence for an authentic learning environment is found in literature [3], wherein learning based on authentic real-life scenarios elevates the status of class material from inconsequential textbook concepts to practical and useful real-world knowledge. This motivates students to learn, and engages them better. We designed an extensively active and authentic learning module in the context of South-East Asian biomedical engineering education and tested its effects on learning effectiveness and learning motivation on two consecutive years (Fall Semesters of 2017/18 and 2018/19).

METHODS

The course that was implemented was known as Engineering Principles and Practice, which is a foundational first year module that aims to equip students with fundamental engineering knowledge such as energy and mass balances, and foundational mechanics, as well as introduces them to engineering skills such as back-of-envelope calculations, block diagrams, and CAD drawings. The module was designed to have 25% lecture and 75% activity time. Lectures were conducted in the flipped classroom format, which prepared students for two 3-hour active learning sessions in the same week. Each active learning session involved a number of small groups of students (8 groups of 5 students), paired to a lecturer and two teaching assistants, for a more interactive instructional setting. The active learning sessions were carefully designed to scaffold students' learning, and involved an

elaborate new laboratory setup to enable this scaffolding. These sessions forced students to actively assimilate technical content by putting them into practical scenarios where they needed to use principles taught in the lectures to solve their problems. Time was spent on a selected real world scenario that exposed the students to an actual application of theory, thereby introducing an authentic learning paradigm to course design. For example, students investigated the working principles and technical issues involved in the use of a real-life Emergency Room (ER) medical device, namely, an extra-corporeal centrifugal blood pump. Activities involving actual centrifugal blood pumps of various designs were incorporated into the active learning sessions to enhance the authentic learning component. Additional authentic learning components were included by inviting industry experts to give talks to students on topics related to their class activities.

In the final form, the module was implemented with (1) extensive active and collaborative learning, (2) a highly authentic learning environment, (3) flipped classroom for most of the class. The module structure is summarized in Fig. 1.

Figure 1: Module Structure for BN1101

RESULTS

Efficacy of learning environment was assessed through triangulation of student's survey, two focus-group discussions, and assessments. The data is summarized in Figs. 2a – e based on the responses to students' survey, with scores between **Strongly Disagree** (0) to **Strongly Agree** (5). Data suggested that active learning approach led to a better engagement of students, enhanced learning and made deeper impressions of concepts taught (Fig. 2a). The collaborative learning approach increased peer-to-peer learning among students and efficiently utilized lecture time for a broader understanding of differing viewpoints (Fig. 2b). The authentic learning component helped correlate theoretical principles with real life applications and demonstrated the utility of concepts taught (Fig. 2c). The flipped components of the module (in the form of online video lectures) were found to be effective as the students' could learn the materials at their own customized pace (Fig. 2d). Finally, the module increased passion among the students toward their major, and facilitated a slight shift from emphasis on performance-orientated goals towards learning-oriented goals (Fig. 2e).

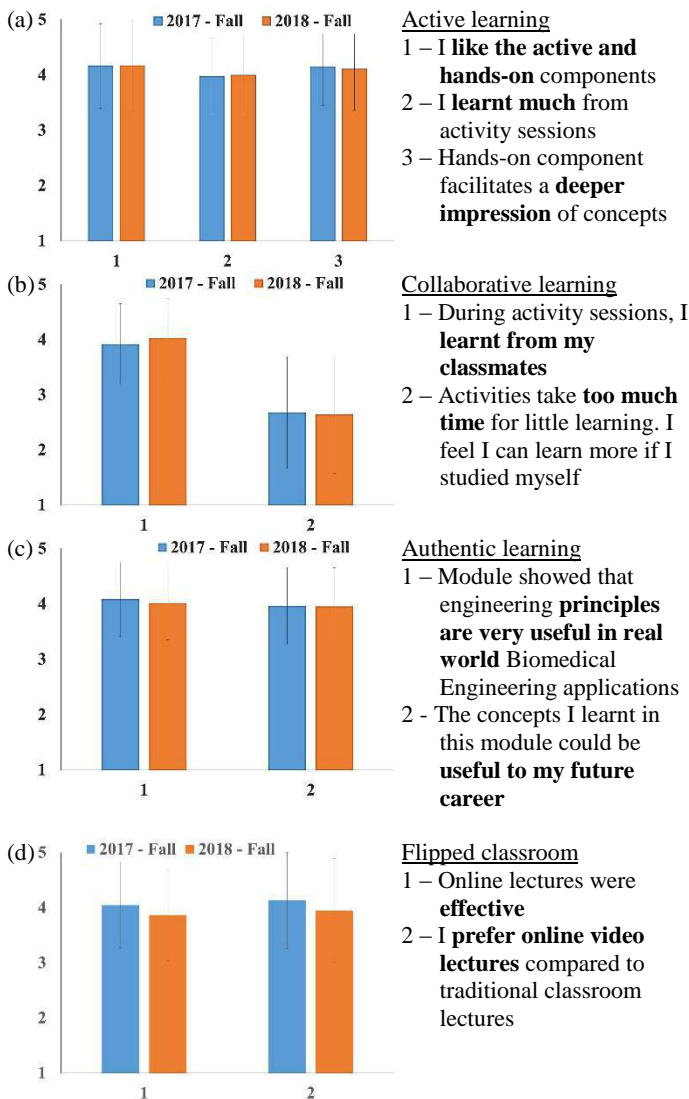

Figure 2: Summary of responses to students' survey for BN1101. (2017 – Fall: n = 131; 2018 – Fall: n = 138)

DISCUSSION

Although the profession of Biomedical Engineering has a relatively recent emergence of approximately 15 years ago, it has grown rapidly undergoing drastic changes, and has been projected to continue growing rapidly [4]. Such a dynamic environment requires enhanced pedagogy, to train students to be adaptable, flexible, and resourceful. An extensively active and authentic learning approach would therefore be appropriate to prepare students for this rapidly growing field.

Active learning brings about constructivist learning, with a better assimilation of technical content due to a practical need to use these knowledge to solve problems [1]. Our case study results demonstrated an agreement with literature, that this approach could lead to a deeper understanding and more lasting impression of concepts learnt [2, 5]. We believe that active learning must be supplemented with authentic learning, so that the enhanced learning effectiveness from active learning can be paired with improved learning motivation and student engagement. Authentic learning gives real-world relevance to class material so that students' perception of their value will be elevated [3]. Our results suggested that this design has been successful.

Apart from these outcome, there were also encouraging albeit moderate signs of improvement in students' interest for their course of study, as were their motivation for learning outside the classroom. This suggested a moderate shift in students' learning motivation away from one that over-prioritizes grades.

Other minor pedagogical enhancements included a flipped classroom and collaborative learning. Flipped classroom shifted the presence of the lecturer from a low cognitive phase of learning (during lecture) to a higher cognitive phase of learning (during problem solving activities) to enhance learning [6]. Our results demonstrated that most students welcomed this approach. They also liked the web videos as they conferred learning flexibility, allowing control over their own pace of learning. Finally, the extensive small group activities were found to enhance collaborative learning [7], and peer instruction [8], and most students were found to welcome this interaction.

INTRODUCTION

The majority of NFL injuries transpire to the foot and ankle region, accounting for 26% of all reported injuries [1], of which a significant but unknown number are related to excessive traction. Injuries related to foot traction are ubiquitous ranging from insufficient traction (slip and fall) to excessive traction (failure to release causing fracture or soft tissue damage). The existing literature on computational modeling of the footwear/ground interaction is limited and focused primarily on musculoskeletal dynamics simulation (i.e., the load transfer through the body) rather than on transfer into the body (through the ground/foot interface). Hence, there is opportunity to develop and/or enhance techniques for modeling footwear traction to reduce injury.

METHODS

The first part of this research was obtaining experimental data for comparison. In this case, three football studs were torqued to slip on artificial turf in a laboratory setting to provide validation data (see Figure 1). The studded assembly was turned at 1 degree per second in artificial grass alone, rubber infill alone, and grass+infill artificial turf on a servo hydraulic load frame for 60 seconds. The bench results were used to calibrate a discrete element model (DEM) of three studs. Subsequently, a series of simulations were run to determine the effects of stud geometry and pattern. The models applied 1 degree per second for 60 seconds or 2.58 meters per second for .4 seconds, as with

published literature [2, 3]. Each model evaluated the torque/rotation load history and the force/translation history in two directions. The three load scenarios were repeated on four common stud shapes and three unique stud patterns. Filtered torque, force, and kinetic energy were evaluated as indicators of stud grip. A third order Butterworth low pass filter with a cutoff frequency of 20 Hz was used on the collected data to assist in the reduction of noise.

Figure 1: Set up for Laboratory experiments.

RESULTS

Results for round studs within infill alone via a DEM simulation were within the expected range (see Figure 2). The load path mimicked experimental data. However, this was not true for round studs in grass+infill (see Figure 3). The grass+infill load path is only similar to experimental data for the first half second, at best. Thus, more research is required. Noting, once the experimental data was post-process it was clear artificial grass alone has a negligible effect on the studs. This was intuitive but was done for completeness.

Round, square and hex shape studs were compared via computer simulations in infill alone. Peak torque increased 17% and 0.9% for the square and hex stud compared to the round studs. Mean torque over time increased 22% and 0.4%, respectively.

Figure 2: Laboratory experiments compared to DEM simulations, infill alone.

Figure 3: Laboratory experiments compared to DEM simulations, grass+infill.

DISCUSSION

Admittedly, the grass+infill model is inapt and does not model the complexities associated with artificial turf. This was believed to be due to software limitations. Hence, a change to - what appears to be - a more feature rich software has been made. Research is still on-going in this area but appears promising

Stud geometry appears to play a significant role in torque generation in infill alone. Clinically, the results suggest that round studs may limit torque transfer and thus might reduce injury. However, the optimal balance between traction and release has not been established. Based on these preliminary results, the discrete element method appears to provide effective dynamic stud/turf interaction modeling and may be useful in a broader set of studies.

ACKNOWLEDGEMENTS

We would like to thank Nicolas Aumonier and FieldTurf for donating all the turf necessary for this research.

INTRODUCTION

Participation in exercise is important in all stages of life. Moderate exercise during pregnancy has shown to have positive consequences for the mother as well as the fetus [1-2]. Regular exercise during pregnancy for the mother is associated with improved maternal cardiovascular function, limited weight gain and fat retention, improved insulin resistance and metabolic control, preventing the onset of gestational diabetes mellitus, reduced delivery time, and decreased depressive symptoms after giving birth [1-2]. For the fetus, improved fetal stress tolerance, reduced neonatal fat mass, and advanced neurobehavior maturation have been shown through maternal exercise [1-2].

Previous research has reported that regular maternal aerobic exercise during pregnancy to be associated with lower fetal heart rate (HR) and higher heart rate variability (HRV) at 36 weeks gestation, and this trend continues to be seen in infants at one month of age [1-2]. HRV is the beat to beat variation in the duration of the R-R interval (RRi) and is a noninvasive tool able to assess cardiac autonomic function [1-4]. In developing fetuses and infants, HRV can demonstrate how well the central and peripheral nervous system are working together [1-2].

Metabolic equivalent (MET) value is a technique used by exercise experts to measure physical activity for a varied population [5]. One MET is the amount of oxygen required by the body in a resting state, which equals 3.5 ml O₂/kg/min [5]. Less than 3.0 METs is considered light exercise, between 3.0-6.0 METs is considered moderate exercise, and greater than 6.0 METs is considered vigorous exercise [5]. Based on the associations between HR and the intensity of maternal exercise and HRV and the duration of maternal exercise found in [1-2], this study aims to determine the impact of average MET values of the mother throughout the entire pregnancy on infant HR and HRV at 1 month of age. Infants born to mothers with higher MET values will have lower HR and higher HRV.

METHODS

The study population was comprised of infants born to women enrolled in a randomized, blinded, prospective study designed to determine how exercise affects the infant's health outcomes [1-2, 6]. Forty-seven mother-infant pairs were enrolled in this study. If participants met the specified requirements, they were randomly assigned to exercise intervention (aerobic, circuit, resistance) or no intervention (control).

A continuous ECG recording was obtained for infants at one month of age by using a Hexoskin Shirt-Junior's (Carre Technologies Inc, Montreal, QC). The recordings were taken when the infants were in a quiet but alert state. The software used to analyze the ECG signals and the RRi signals was Kubios HRV Premium (Kubios Oy, Kuopio, Finland). Before the files were processed through Kubios, two MATLAB (The MathWorks, Inc., Natick, MA) scripts were used. One extrapolated the RRi signal files between four and five minutes to five minutes, added 10 seconds to the beginning of each file, and converted the excel files into text files, an acceptable input file type for Kubios. The other script converted the wav files, which contain the ECG signal, into text files.

Five minutes is needed to calculate the time and frequency parameters of HRV. Files between four and five minutes were extrapolated to five minutes, but files less than 4 minutes were discarded. Two files were rejected for not having adequate time/RRi. Thirteen files were discarded due to the signal being more than half artifact/noise. In these files, the infants were either moving around or the electrodes became unattached. It should be noted that nine of the 47 infants had two recordings. This is done to verify the variability. The best file of the two recordings was used, and the other was discarded.

One file was loaded into Kubios at a time. Once the artifacts were removed, the file was saved to a .CSV batch file, which allowed all 32

files to be saved to one excel file. For statistical analysis, t-tests were used to compare infant HR, root mean square of successive differences (RMSSD), standard deviation of normal-to-normal intervals (SDNN), low frequency (LF), high frequency (HF), LF/HF ratio, and the MET values for the entire pregnancy between the exercise and control group.

RESULTS

Forty-seven participants were enrolled in the study. After exclusion criteria was met, the analysis included 32 participants: 15 aerobic exercisers, 4 resistance exercisers, 5 circuit exercisers, and 8 non-exercisers (control). A MET value of 6, 5.5, 8, and 3 was assigned to the groups list above, respectively, but the average MET was calculated by multiplying the compliance of the mother to her exercise regime to her assigned MET value. Due to the size of the resistance and circuit group, the three exercise groups were combined and referred to as the exercise group. Mothers whose compliance to her specified exercise regime was less than 75% ($n=5$) were not accounted for in Table 1 but were accounted for in Figure 1. The mean, standard deviation, and p value of HR, SDNN, RMSSD, LF, HF, and LF/HF ratio between the exercise and control group were displayed in Table 1.

Table 1: Results for Exercise vs. Control Group

	Mean \pm SD		p value
	Exercise (n=19)	Control (n=8)	
HR (bpm)	151 \pm 14.6	160 \pm 19.4	0.115
SDNN (ms)	24.2 \pm 9.36	21.1 \pm 5.71	0.151
RMSSD (ms)	14.9 \pm 10.2	11.4 \pm 5.26	0.132
LF (ms ²)	160 \pm 107	213 \pm 171	0.223
HF (ms ²)	78.8 \pm 77.1	60.8 \pm 60.0	0.261
LF/HF	3.16 \pm 2.08	4.82 \pm 4.67	0.181
MET	5.93 \pm 1.16	3 \pm 0.00	1.01E-09

Figure 1: SDNN vs. Average MET with a correlation coefficient of 0.202

No statistical significance was seen for the HR, SDNN, RMSSD, LF, HF, or LF/HF between the exercise and control group. Infant HR was lower (151 vs. 160 bpm, p value = 0.115) and overall HRV (SDNN) was higher (24.2 vs. 21.1 ms, p value = 0.151) in the exercise group when compared to the control group, but neither variable reached significance. Infant short term HRV (RMSSD) was higher (14.9 vs. 11.4 ms, p value = 0.132) and only HF was higher (LF; 160 vs. 213 ms², p value = 0.223) (HF; 78.8 vs. 60.8 ms², p value = 0.261) when comparing the exercise group to the control, but none of these variables reached significance either.

To find the correlation between the average MET and HRV, the average MET value was plotted against SDNN, and a linear regression line was used. SDNN was the chosen time domain parameter since SDNN assess overall HRV.

DISCUSSION

The results observed in this study for the exercise group compared to the control group corresponded closely to the findings in [1] for HR, SDNN, RMSSD, and HF but not for LF and LF/HF. In [1], the final sample size was 43 mother-infant pairs, 16 more participants than the current sample size of mothers compliant to their exercise regime ($n=27$). In [1], the HR was lower and SDNN was higher for infants exposed to maternal exercise compared to the control, but the HR and SDNN in did not reach statistical significance. The p values produced in this study for HR and SDNN were more statistically significant than the p values seen for HR and SDNN in [1].

For the RMSSD, LF, and HF in [1], statistical significance was found for each parameter, and the infants exposed to maternal exercise had higher RMSSD, LF, and HF than the control. But in this study, infant exposed to maternal exercise only had higher RMSSD and HF when compared to the control. The LF was higher for the control than the exercise group, and this contradicts the findings in [1-2]. The lower LF for the exercise group could be a result of the small sample size of this study or the software used to calculate HR and HRV.

A weak correlation was seen between the average MET and HRV. This can be attributed to the small sample size. Also, having all the control subjects assigned a MET of 3 could be skewing the results.

Overall, the results found in this study support the findings in [1] demonstrating that the effects of maternal exercise, lower HR and higher HRV, can be seen at one month of age. The findings support that maternal exercise produces positive, lasting effects on infant cardiac autonomic control. Regular maternal exercise, aerobic, circuit, or resistance, may be the earliest step available to improve cardiovascular health and outcomes in future generations.

In this study, the RRI signal was mainly used to calculate the HR and HRV. Further research will be done to compare the ECG signal results to the RRI signal results. Artifacts can be manually corrected when the ECG is uploaded. This will eliminate the risk of identifying normal beats as abnormal.

Two limitations are acknowledged for this study. First, a small sample size was used. Only 19 of the 24 exercise participants were in compliance with their specified exercise regime, and the control group consisted of eight participants. Second, potential correlations between pre/pregnancy activity/fitness level, maternal resting HR, maternal age, gestational weight gain, or infant sex were not considered.

INTRODUCTION

Many universities exclusively rely on student evaluations of teaching (SET) for assessment of teaching by faculty and use these ratings in tenure and promotion decisions. However, SET have significant systemic bias with respect to gender, race, and sexual orientation. Moreover, they are not a good measure of either teaching or learning in many contexts. These biases and limitations indicate that SET should not play a significant role in promotion processes or be used to revise instructional practices. Instead, detailed strategies for peer evaluation could improve formative feedback for faculty and assessment of engineering instruction.

LITERATURE REVIEW

Student feedback is a critical component of course and instructor evaluation. A common method of collecting feedback from students is via anonymous surveys on course and instructor demands, accessibility, and quality. The compiled numerical data is then used to evaluate the performance of faculty, staff and student instructors. Recent studies call this use of student evaluations of teaching (SET) into question. Multiple studies have shown that SET results are biased with respect to gender [1], to sexual orientation and gender identity [2], and to race [3]. Even purportedly objective metrics, such as how quickly homework are graded and returned, are affected by student understanding of gender [1]. Moreover, evidence has shown that numerical SET results do not reflect either the effectiveness of instruction or of learning [4,5]. As a result, changes to teaching practices in response to SET scores may not improve teaching or learning. For all of these reasons, SET are problematic when used in merit, tenure and promotion decisions.

Because they are an efficient way to gather student feedback, SET are unlikely to be eliminated on today's college campuses. Also, despite

their limitations, SET can yield useful information. For example, very poor evaluations can be indications of problems that must should be addressed [6]. In addition, SET can be used by individual instructors teaching the same course in subsequent years to track student response to instructional changes. Also, SET can be a useful tool to gather feedback on students' expectations [1] and the individual student comments from SET can guide course and instructor improvement.

RECOMMENDATIONS FOR USE OF SET

Stark and Freishtat [4] provide a set of recommendations on appropriate use of SET:

- effectiveness and value of courses should not be used as evaluation items,
- averages of scores should be de-emphasized while score distribution and number of responses should be reported,
- results from a low number of responses should not be used,
- comments from students should be considered only after understanding their limitations, and
- SET comparisons between different courses' content, types, sizes and areas of studies should be avoided - e.g., departments should not compare individual instructors against departmental averages

Regarding averages of scores in particular, disadvantages as compared to distributions include that:

- They presume the differences between values at the lower end of the scale (e.g., a 1 and a 2) is the same as that between values at the higher end of the scale (e.g., a 4 and a 5);
- They presume that the difference between numerical ratings (e.g., 3 and 4) mean the same to different students;

- They presume that a given numerical rating (e.g., 4) means the same thing to different students;
- They presume a rating of 5 balances a 3 to be equivalent to two ratings of 4; and
- At least half the faculty in any department will have average scores below the median average score.

In summary, the use of averages promotes simplistic judgement of a complex, nuanced activity.

PEER EVALUATION OF TEACHING

One frequently used tool for assessing teaching effectiveness is observation by peers [7]. In Peer Evaluation of Teaching, a peer of the instructor observes one or several classes and provides oral and written feedback. The systematic collection of peer evaluations of teaching are then documented in dossiers used for promotion and tenure decisions. One of the limitations of peer evaluation is that it takes a significant effort to obtain useful information. For example, [8] summarizes a set of recommended practices needed for effective peer evaluation. These include:

- Peers need to be trained for the effective use of the technique.
- A single class observation is not enough to obtain reliable indicators of teaching/learning effectiveness. At least three observations are recommended.
- Contextual information regarding the classroom activity, such as learning objectives, must be provided to the observer.
- A checklist must be provided to help the peer assess specific areas of the learning/teaching activity.
- The peer should be a strict observer. Participation of the peer in the teaching/learning activity – even their presence in the room – may distract the instructor or students from their activity.
- The peer should observe entire class periods.
- A written review should be provided right after the observed session.

SELF-ASSESSMENT

One opportunity for continuous improvement that is not typically included in evaluations of teaching is a formal self-assessment. Reflection is key to learning in many professional domains, including teaching [9]. As instructors become more experienced, self-assessment and self-reflection – for example through journaling, watching videos of themselves in the classroom or other evaluations – become useful forms of ongoing professional development [10]. To guide self-assessment and reflection in mathematics and science instruction, Wieman and Gilbert developed a Teaching Practices Inventory (TPI) [11]. The authors argue that teaching effectiveness can be measured by characterizing the use of best practices. In developing this inventory, Wieman and Gilbert sought to address the following objectives: validity—the result of the assessment must be strongly correlated with achievement; meaningful comparisons—the instructor should be able to be compare their performance against peers; fairness—the tool should be widely applicable and valid across curricula; practicality—implementation should be inexpensive for instructors and institutions; and improvement—the results could be used by instructor to improve their teaching. Currently, the TPI is available in multiple formats including an anonymous Qualtrics survey that takes ~10 min: www.cwsei.ubc.ca/resources/TeachingPracticesInventory.htm. Unlike a grading system in which 100 is the best and 0 is the worst, scores of 100% would indicate that all best-practices are used in a single course, which is not encouraged by the authors. In a single high-performing department, the distribution of scores ranged from 10 to 50 with a

median in the low 30s [6]. Indeed, the numerical score is not the emphasis; rather the value of this inventory is that the instructor reflects on their current practice and considers how best-practices may be incorporated to improve teaching and learning.

SUMMARY

Teaching and learning are complex activities. Thus, it is no surprise that they are difficult and time-consuming to assess properly. When gathering student feedback, SET are an alluring tool: there is an automated process for obtaining them and they can distill assessment of teaching to a single number. However, significant gender, race, and sexual orientation bias in SET and evidence that SET do not measure learning raise serious concerns about continued reliance on them for merit and promotion decisions. MacNell et al. [1], among other researchers, suggest that universities consider phasing out SET for tenure and promotion decisions “but still use them to get feedback on what students want and expect from their courses.”

Use of research-proven best practices for teaching should also be considered for promotion and tenure decisions given their correlation with teaching effectiveness [11].

We recommend that departments encourage their instructors, particularly probationary faculty, to take advantage of the wide range of institutional resources for improving teaching. Appropriate use of research-proven best practices will improve the quality of teaching and learning. It will also increase the success and job satisfaction of instructors.

INCORPORATING NATIONAL BIOMECHANICS DAY INTO BIOMECHANICAL ENGINEERING COURSES

Sara E. Wilson (1,2)

University of Kansas
Lawrence, Kansas 66045

(2) Bioengineering
University of Kansas
Lawrence, Kansas 66045

INTRODUCTION

National Biomechanics Day (NBD) was started in 2016 by Paul DeVita as past-president of the American Society of Biomechanics.¹ It has occurred in early April each year since 2016 and is scheduled for April 10, 2019. The primary goal of NBD is to introduce the field of biomechanics to K-12 students and their teachers, particularly those in high schools. Participating biomechanists come from institutions across the United States as well as internationally. International participants in 2018 came from 52 nations including Australia, Brazil, Chile, the Czech Republic, New Zealand, Portugal, Singapore, Iran, Pakistan, and the United Kingdom.² Participating biomechanists come from a variety of fields including engineering, kinesiology and sports science aligning with the membership of the American Society of Biomechanics. The topic areas that have been the focus of NBD include sport biomechanics, clinical biomechanics, animal biomechanics, human locomotion, modeling and robotics, imaging and material testing, and biomechanical technology, but the event is not restricted to these topics. Other areas of activity include an Art in Biomechanics competition, biomechanical interpretations of famous movies, and a two-minute video tweet competition. While participants are encouraged to schedule activities on the scheduled day, the event allows for alternate scheduling to accommodate needs.

NBD is an example of a service learning activity that can be used in a classroom setting. Service learning (a form of experiential learning) integrates meaningful community service

with instruction to enhance learning while strengthening communities and teaching civic responsibility.³ In service learning, the instructor becomes the facilitator of knowledge rather than the controller of knowledge.³ Effective service learning should include reflection on the experience in order to link knowledge and concepts to the service learning activities.³ Important in successful service learning projects is assessing partnerships to ensure that activities benefit both the learner and the community served.³

METHODS

Prior to NBD, my initial efforts at bringing a service learning component to my class involved having student teams participate in a locally run engineering expo. Engineering expo is hosted by the University of Kansas School of Engineering and brings K-12 children from around the region to campus for engineering demonstrations as well as K-12 engineering competitions including a Rube Goldberg, egg drop, and balsa wood bridge competitions. This event is hosted in the last week of February or first week of March, making it feasible only for Spring semester courses. The early timing during the semester also presented challenge in incorporating activities into the curriculum. The activities by the students typically involved demonstrating motion capture.

Because the early timing of this event proved to be a challenge, this project was changed to having students develop a demonstration for a subsequent year's engineering expo. While this allowed for greater development of learning objectives, the

students were not able to successfully utilize their efforts in a service learning environment.

In Spring 2019, we are working with a local elementary school to bring demonstrations to three kindergarten classrooms on National Biomechanics Day. This activity has been made possible by the formation of relationships with the teachers cultivated through community connections.

All of these projects have been done in teams of 3-5 students. I have also used several types of demonstration projects for these efforts that can be broadly divided into two classifications: open-ended and prescribed.

The prescribed projects, in the senior/graduate course ME 757 Biomechanical Systems, have involved the development of a computational and physical passive-dynamic walker and demonstration of passive-dynamic walking mechanics (Fig. 1). In this project, students were asked to work with provided MATLAB code to develop an animation of passive dynamic walking and to build a physical passive dynamic walker out of any materials.⁴ The physical walkers have been constructed out of a diverse range of materials including wood, PVC pipe, rubber bands, dowels, binder clips, and rapid prototyped parts. There is a wide array of videos and materials on the internet for students to use to support this effort and the project closely aligns with the course materials.

Open ended projects have been used in several courses including ME 757 Biomechanical Systems, ME 882 Advanced Control Systems and ME 758 Physiological Systems. In Spring 2019, the students have been assigned an open ended project for the NBD day presentations to kindergarteners. The guidelines for this project are that the teams need to identify one to two key concepts about an organ system (musculoskeletal, respiratory, cardiovascular, renal, etc.) and create a 10-minute demonstration that will convey that concept to kindergartners. The open ended nature of this type of project requires the students to figure out the key concepts rather than having those defined. It also leaves room for variability in the quality and extent of the work. To manage some of this variability, the project requirements include a proposal phase (in which teams identify three target demonstrations and receive feedback) and an early classroom demonstration and feedback one month prior to the kindergarten demonstration. Students will be evaluated by not only the instructor but also their teammates, classmates, the kindergarten teachers and the children. The teachers will be asked to evaluate the teams not only on the quality of the presentation but also the usefulness of the presentation for their students. The teachers are included in both the development of the specifications of the project as well as feedback on the overall exercise.

RESULTS

The past efforts to utilize the late February/Early March University of Kansas Engineering Expo date proved to be a challenge for incorporation of a meaningful experience into the curriculum. Projects in other courses that were developed, but never presented to children lacked the impact a true service learning project can have to both the engineering students and the community. National Biomechanics Day is well suited for

service learning due to its timing as well as the integration with an international biomechanics community. For the course described here, National Biomechanics Day is not a perfect match as much of NBD activities focus on sports and human motion while this activity is taking a broader view of biomechanics to include other physiological systems (respiratory, cardiovascular, renal, etc.). NBD has also been primarily focused on the high school level. We chose the elementary level due to community connections. Requiring the teams to present to kindergartners also requires they focus and simplify their presentation in ways that could be very powerful in reinforcing the concept with the engineering students. The elementary school selected is an ESL school with a diverse, multilingual student population with 62% participating in free/discounted lunch program (an indicator of low income diversity).

DISCUSSION

Service learning has the potential to not only reinforce classroom learning but to also provide benefit to the community at large. National Biomechanics Day is an opportunity to incorporate service learning projects into biomechanical engineering classrooms. The timing of NBD is well suited to a semester long project and allows for students to have covered much of the course before interacting with K-12 students. Prescribed projects have the advantage of clear education objectives and metrics, but open-ended projects can allow students to explore and develop ideas on their own and create a greater range of materials for the target K-12 students. Open-ended projects do require greater intermediate assessment and feedback to be successful.

INTRODUCTION

Infants with single ventricle physiology are born with a range of complex cardiac malformations resulting in an underdeveloped left or right ventricle. The incidence of these defects, including hypoplastic left heart syndrome, is approximately 2-4 per 10,000 births [1]. Patients undergo a series of palliative surgeries to reconfigure their anatomy, the first of which—the Norwood procedure—is completed within days after birth. In the Norwood, a systemic-pulmonary shunt is implanted to connect the functional ventricle to both circulations. This shunt remains in place until the second-stage procedure, completed at approximately 6 months of age [2]. Despite advancements in overall patient care, mortality rates have stagnated in recent years, remain the highest among congenital heart procedures, and remain elevated even after hospital discharge [3,4]. These rates indicate an inherent treatment issue.

The Norwood results in a circulation that mixes oxygenated and deoxygenated blood. This is adequate to sustain life given that the oxygenation ratio is properly balanced. Given that the shunt is solely responsible for the pulmonary perfusion, this balance is highly dependent on shunt conditions. Many variables can alter that balance during the months the shunt is in place, including normal developmental changes in vessel geometry, cardiac output, and pulmonary vascular resistance. Although some of these effects can be managed pharmacologically, a fixed shunt theoretically cannot maintain adequate blood oxygenation during the numerous changes during infancy.

The design of a new geometrically tunable hydrogel-based blood shunt would address the limitations of a static shunt, by adjusting in geometry in proportion to the patient's growth. This shunt (Figure 1) offers an innovative solution to balance the blood oxygenation ratio.

Computational fluid dynamics (CFD) has been shown to be valuable for patient-specific modeling, surgical planning, and is regularly incorporated into multiscale models where the anatomical

region of interest is coupled to a lumped parameter model. The overarching goal of this project is to create a multiscale model to be used in the design and development of the tunable shunt. This specific investigation lays the groundwork for that model, by developing and verifying the CFD component (Figure 2, left). This study is the first step in establishing that computational framework, and creates a valuable resource to complement the anticipated materials-based research.

Figure 1 The blood shunt with an inner lumen diameter expandable over time in proportion to growth.

METHODS

A model of the aortic arch region was developed from imaging data. The geometry was scaled to match typical neonatal dimensions and a Modified Blalock-Taussig Shunt (MBTS) was added based on surgical sketches. The MBTS was selected as the initial geometry for verification purposes, as it has a wide body of computational literature, and because the innovative shunt design would be arranged similarly.

Figure 2 The components of the multiscale model include CFD simulations of the aortic arch (developed in this study) coupled to lumped parameter models (LPM).

ANSYS was used to conduct the CFD studies under steady state conditions while varying shunt diameter, hematocrit, and cardiac output. Studies were performed to determine appropriate boundary conditions, to create a high-quality, grid-independent mesh, and to select an appropriate model of turbulence. Unless specified, blood was assumed to be Newtonian with a dynamic viscosity of 3.5 cP and density of 1050 kg/m³. The shunt diameter was varied over a range of diameters (3, 3.5, 4, and 5mm), the results of which would provide comparison to other literature. Cardiac output was varied as a measure of sensitivity to developmental changes, over a reasonable range expected clinically (0.5-1.5 LPM). The blood fluid physics was studied because blood is a non-Newtonian fluid. However, it is frequently assumed Newtonian in computational literature, an assumption safe to make when shear strain rates are above 100 s⁻¹[5]. A non-Newtonian model was implemented that covered the range of expected hematocrits (20-60%) [5].

The results of these simulations were used to select parameters in future modeling efforts and to verify its behavior. Streamlines were qualitatively assessed for vortices and eddies. The ratio of pulmonary-to-systemic flow, Qp/Qs, was calculated. The average and maximum velocities, shear rates, and shear stresses were gathered for further comparisons.

RESULTS

A grid-independent mesh was found to include approximately 6 million elements. The turbulence model comparison revealed the streamlines of the $\kappa - \omega$ model showed more complex flow patterns in the pulmonary arteries than the $\kappa - \epsilon$ model, so the $\kappa - \omega$ model was selected for all remaining studies. A baseline model was confirmed to have the desired Qp/Qs of 0.8, representing the non-ideal flow distribution typically observed in Norwood patients.

Larger shunt diameters allowed for larger pulmonary flow rates, increasing the Qp/Qs ratio and decreasing the average velocity in the shunt. The Qp/Qs ratios were found to vary between 0.6 with the 3mm shunt, to 2.6 with the 5mm shunt (Figure 3a). As the cardiac output increased, the Qp/Qs ratio decreased, demonstrating the rate limiting effect of the shunt diameter at increased inflow rates.

Three discrete hematocrits were implemented with the non-Newtonian model of blood physics: 20, 40 and 60%. The Qp/Qs ratio was found to decrease with increasing hematocrit, as an increasing percentage of blood was distributed to the descending aorta. The shear strain rates were found to be below 100 s⁻¹ at several locations in the model, including the ascending aorta, however, the entirety of the shunt was sufficiently above that threshold. Consequently, the dynamic viscosity was higher at the aortic inlet than in the shunt (Figure 3b).

Figure 3 (a) Shunt diameter increased the Qp/Qs ratio in agreement with literature [6] (b) At each hematocrit, the viscosity was higher at the aortic inlet than in the shunt.

DISCUSSION

The Qp/Qs ratios in the shunt diameter study were found to agree with the relationships and magnitudes widely reported, as compared in Figure 3a [6]. This agreement supports the validity of the fundamental ability of the model to reproduce basic relationships. The cardiac output study showed a rate-limiting effect of the shunt, as an increased amount of fluid flow to the system was not evenly distributed due to the resistance of the narrow diameter shunt. Even with relatively minor changes of 0.1 LPM resulted in sub-optimal changes to the Qp/Qs ratio. This analysis could be extended in future time-variant studies to further analyze the heart rate, a significant variable for the cardiac output.

The results of the fluid physics studies indicated a non-Newtonian model was successfully implemented. As seen in the difference in viscosity between the aortic inflow and the shunt, different viscosities were observed in regions with shear strain rates below 100 s⁻¹. Even though strain rates above that threshold were observed in the shunt, rates below the threshold were seen in the aortic arch, meaning that the non-Newtonian behavior of that fluid could have a downstream effect on the behavior in the shunt. While many use the Newtonian assumption, this data supported the use of the non-Newtonian model going forward [5]. However, this is just a single model of blood behavior, and it should be evaluated against the many others that exist in the literature.

Overall, the model developed was observed to be consistent with literature at precise steady-state conditions, providing evidence for the validity of these methods. These preliminary analyses are relevant to the overall goal. The effect of a diameter change will be impactful for the study of the degree to which the shunt geometry should be tuned, and the cardiac output study will inform the sensitivity of the ideal shunt diameter to day-to-day changes in heart rate or stroke volume. This model is the first major component in the creation of the computational platform to study the dynamic diameter changes for the tunable shunt. Future work will include the implementation of a lumped parameter model to be coupled with this work into a multiscale model. This model will serve as the foundation to inform and investigate many physiological hypotheses and design questions in the future of the design and development of this new innovative device.

INTRODUCTION

Congenital Heart Defects (CHD) occur in nearly 1% of all births per year in the United States [1]. Among these, Hypoplastic Left Heart Syndrome (HLHS) is responsible for about 9% [2]. HLHS is a complicated disease in which the left ventricle is underdeveloped. The common treatment for HLHS is a multistep postnatal surgical procedure which has a high mortality rate; even when it is successful, it leaves patients with lifetime complications. Therefore, there is a need for better and more successful treatment options.

To find better clinical interventions, we first need to get insight into the hemodynamics inside the heart; as numerous animal studies have shown that the intracardiac flow patterns in embryonic heart play a significant role in cardiovascular development [3]. This signifies the importance of understanding the relationship between blood flow (hemodynamics), structural development, and remodeling of the human fetal heart. Therefore, here, we quantify the hemodynamics during cardiac development in normal fetal hearts and fetuses diagnosed with HLHS to identify if a correlation exists between specific flow patterns and the heart malformations.

METHODS

We used Computational Fluid Dynamics (CFD) based on non-invasive patient-specific human fetal ultrasound scans to quantify intracardiac flow in the right ventricle in both normal and HLHS cases. 9 fetal hearts, including 4 normal (22-35 weeks of gestation) and 5 HLHS (22-37 weeks of gestation), were studied using 4D patient-specific spatio-temporal image correlation (STIC) ultrasound. Scans were collected using a RAB6 probe on a GE Voluson E10 system (GE Healthcare, USA). 4DView software (GE Healthcare, USA) was used to convert the 4D volume data to series of 2D images at multiple time points. These images were semi-automatically segmented using a lazy

snapping algorithm using a custom-written C++ code. Segmented slices were then converted to a 3D model using VMTK software. The surface of the reconstructed 3D geometries was smoothed using Geomagic software (3D Systems, Morrisville, NC). Ventricular wall motion was modeled using a Spherical Harmonic Transform algorithm created in MATLAB (MATLAB, Natick, MA) along with Doppler velocity waveform from ultrasound data, and measured volumes from the reconstructed 3D geometries using:

$$r_{model}(\theta, \phi, t) = \alpha(\theta, \phi)\Omega(t) + r_0(\theta, \phi) \quad (1)$$

where $\Omega(t)$ is the characteristic waveform which was obtained by taking the cube root of the ventricular volume over time, $\alpha(\theta, \phi)$ is amplitude of displacement waveform, and $r_0(\theta, \phi)$ is the initial radius. The wall motion was modeled as a function of volume at each time point of the cardiac cycle and radial displacement in θ and ϕ directions, where θ probes from 0 to 180 and ϕ probes from 0 to 360. The wall motion was incorporated into a user defined function (UDF) utilized in a computational fluid dynamics (CFD) simulation (ANSYS Inc., Canonsburg, PA). Hemodynamic parameters such as wall shear stress (WSS), transverse wall shear stress (transWSS), interventricular pressure gradient (IVPG), kinetic energy (KE), work done (Wd) and the energy loss were computed. Statistical analyses were performed using SAS software (SAS Institute Inc., Cary, NC, USA) between HLHS and normal groups, and between mid-stage and late-stage of development. Wilcoxon test was performed with 80% confidence interval at significance level (α) of 0.2.

RESULTS

Overall, the fetal heart rate decreases and CO increases with gestational age for all hearts, while all hemodynamic parameters, i.e.

CO, WSS, transWSS, and IVPG, are larger in HLHS cases relative to normal cases.

FIGURE 1: Kinetic energy in the control volume during systole and diastole at (A) mid-stage and (B) late-stage of cardiac development.

Fig. 1 shows the KE with systole shown during the first ~50% of the cardiac cycle and diastole for the second half of the cardiac cycle. KE in HLHS is about 3 times more than that of normal hearts. Trends further show that KE in the ejection phase is similar for normal and HLHS hearts. However, more KE is produced during the filling phase for HLHS. Correspondingly, we found that the right ventricle thicker and stiffer for HLHS cases.

The maximum systolic Wd in HLHS is higher than normal hearts by 40%, Fig.2. In HLHS the average energy loss is approximately 2.4 times more than the average energy loss in normal, demonstrating that HLHS hearts are less efficient than normal hearts.

DISCUSSION

Our CFD results provide unique and detailed insight into flow for a highly complex congenital heart malformation involving a single ventricle defect for the first time. With this effort, we can begin to identify changes in required effort from the right ventricle when the left ventricle loses any useful function.

Our results show that all studied hemodynamic parameters in HLHS were higher when compared with normal, which indicates the right ventricle in HLHS compensates for left ventricle dysfunction as an adaptive response to provide enough blood supply for the body. As a result, the HLHS right ventricle works harder to eject the blood out, with more energy loss, leading to inefficient pumping [4]. The high blood velocity in HLHS leads to the formation of strong vortices and high WSS, along with high transWSS. The increased effort from the right ventricle leads to a thicker, less compliant wall. Although, we can only correlate these results, it's likely that the thickened, stiff wall may demonstrate a hypertrophic cardiomyopathy that may pertain to an adaptive response to high pressure in HLHS, which can be sensed by myocardial cells through mechanotransduction [5].

The patterns of normal and HLHS cardiac development demonstrates that as fetuses grow, the filling phase of the ventricle for

HLHS results in a slightly higher KE than its ejecting phase, while in normal hearts, the ejecting phase becomes stronger than the filling phase to meet the increased demand as the body grows. It is likely that the HLHS right ventricle can't sufficiently compensate through the ejection phase, and therefore, the filling phase aids in the production of a necessary CO, possibly through increased atrial contraction. Also, HLHS diastolic KE is higher than normal by 7% at mid-stage, and changes to 2.3 times at late-stage. In the other words, the more HLHS fetus grows, the more the right ventricle loses its ability to eject the blood, and to meet the demand. The presence of a high blood flow velocity in HLHS at an early stage of development contributes to generation of high WSS and high flow momentum, and consequently production of a highly multidirectional flow which may be linked to HLHS.

FIGURE 2: Systolic work done by HLHS and normal right ventricle at (A) mid-stage and (B) late-stage of cardiac development.

This work provides insight into the blood flow hemodynamics in normal and diseased fetal hearts. It is a first step toward characterizing hemodynamics in a disease state to determine how to better correct congenital heart defects like HLHS. Additional work needs to be performed to uncover the potential treatments that have better outcomes.

INTRODUCTION

Bicuspid aortic valve (BAV) disease is the most common congenital anomaly of the heart valves and occurs in 2% of the population. BAV patients are predisposed to aortic dilations and dissections and abnormal secondary flow that results in elevated wall shear stress on the arterial wall. There are several types of BAV; the most common being fusion of the right and left coronary cusp (RL-BAV), and fusion of the right and non-coronary cusps (RN-BAV). These morphotypes contribute to the variation of hemodynamics in the ascending aorta. Blood flow in RL-BAV and RN-BAV aortas has been observed to be helical in nature (as compared with predominantly streamlined flow in healthy patients). Hope et al. [1] observed that the helical flow is markedly different in the two morphotypes; with the RL-BAV showing right-handed helical flows from right anterior flow jets, and the RN-BAVs showing left-handed helical flow from left posterior flow jets. Such changes in the hemodynamics of the aorta is expected to directly influence its biomechanical properties. This includes principally, the influence of helical flow on the arterial wall, resulting in elevated wall shear stress (WSS), and hence clinical complications.

The hemodynamics of BAV disease can be directly quantified using 4D-flow MRI measurements of the flow field in the ascending aorta [2]. Much of what is known about BAV hemodynamics comes from studies that involve 4D-flow MRI and tools such as computational fluid dynamics (CFD). Using such tools, Meierhofer et al. [3] and Saikrishnan et al. [4] compared the hemodynamics of healthy tricuspid aortic valves (TAV) with a set of BAV types to determine flow variations and resulting WSS. A prospective study showed that the cumulative net WSS and circulatory WSS were significantly increased in individuals with BAV compared with individuals with TAV in the mid-ascending aorta (main pulmonary artery level) [3]. However, the axial component of the WSS was significantly reduced in the BAV

patients compared with the TAVs. This led the researchers to conclude that flows in the ascending aorta of TAV individuals was mostly streamlined while those of BAV patients were helical in nature. Saikrishnan et al. [4] reinforce these findings in an *in vitro* study conducted using Particle Image Velocimetry (PIV) on both types of valves. The study included stenosed BAVs, as well as those with regurgitation. The researchers observed systolic jets in BAV patients. The structural setup of BAVs resulted in delayed vortex formation in early systole as opposed to the normal flow behaviour of TAV patients. This was also reported by Hope et al. [1], but in a cohort that did not include patients with stenosis or regurgitation.

BAVs confer a considerable burden of morbidity and mortality. Despite this, there is no clear mechanistic understanding of the abnormal flow behaviour associated with this condition. In this study, 4D-flow MRI imaging of the flow conditions generated by BAV cases (with normal valvular functions, and without concomitant stenosis or regurgitation) is used to generate realistic CFD models of flow and WSS. This approach is applied in healthy aortas in order to better understand the interplay between abnormal flow at the valve level in RL-BAV and RN-BAV compared with normal TAV flow.

METHODS

A cohort of five healthy ascending aortas was chosen to perform the analysis. Inlet flow boundary conditions were drawn from healthy TAV and three types of BAV pathologies, to be applied to the cohort. Participants provided written informed consent in accordance with the ethical guidelines of the respective institutional review boards. MRI scans were generated using a GE Medical Systems 3T 750W MRI scanner including MR angiographies and 4D-flow data. An in-house semi-automated segmentation to simulation pipeline was used to perform CFD analysis, using ANSYS CFX v18.2. Inlet velocity

boundary conditions were obtained from 4D-flow MRI measurements. To remove the influence of vessel shape, the five healthy TAV aortas were used as the common vessel wall boundaries for each type of BAV inlet case studied. Blood flow was assumed laminar and incompressible, with blood having a non-Newtonian viscosity governed by the Carreau-Yasuda (modified Cross) formulation [5]. The outlet flow boundary conditions were estimated using physiological flow division based on Murray's Law, and by a zero-gauge pressure outlet boundary at the descending aorta.

RESULTS

The average age of the cohort of normal aortas was about 50 years. The BAV inlet flows were drawn from patients that were age-matched with the healthy aortas. The WSS, Oscillatory Shear Index (OSI) and the velocity streamlines for the subject cohort were processed at peak systole in the sixth cardiac cycle to remove the effect of initial conditions. Figure 1 shows the velocity streamlines of a representative healthy aorta when the three different BAV inlet flow conditions are applied. The helical vortex development in the ascending aorta in the RN-BAV is significantly stronger than the other BAV morphotypes.

Figure 1. Velocity streamlines in a normal aorta with (a) TAV, (b) RN-BAV, (c) RL-BAV and (d) 0AP-BAV inflow conditions.

Figure 2 shows the WSS distribution within a representative healthy aorta when the three types of BAV inlet flow conditions are applied. The peak WSS is highest in the RN-BAV with a value of 25.9 Pa, as compared with the normal TAV aorta showing a peak WSS of 15.8 Pa. Figure 3 shows the OSI for the set of normal and BAV inlets on the healthy aorta.

DISCUSSION

This is the first known work on modeling healthy aortas by introducing pathology to propose a generalizable model for flow dysfunction in BAV patients. The aim of the study was to use 4D-flow MRI to apply measured flow fields of BAV and TAV subjects at the sinotubular junction and to use CFD to quantify hemodynamic parameters that will result in providing a comprehensive diagnostic model to predict complications in BAV patients.

As seen in Figure 1, the streamlines show the flow development to be markedly different in each of the three types of valve physiologies with the BAV inlet aortas showing strong helical vortices in the ascending aorta. The progression of the helical vortex has been deemed to be a significant biomarker in the assessment of risk for aortic dilatation and dissection. In addition, quantification of WSS as shown in Figure 2 will provide a basis for comparison of healthy TAV patients with those having aortic valve disease. The RN-BAV shows markedly

higher WSS and this is attributable to the high velocity systolic jets impinging on the aortic wall. These jets originating in the valve are dependent on the morphotypes. The flow in the ascending aorta with RN-BAV is right-hand helical and lasts spatially longer along the ascending aorta compared to a healthy TAV. The OSI, which is a hemodynamic parameter, does not show significant variation amongst the cases, indicating that it is more influenced by the geometry of the aorta which is controlled in this study. The use of 4D-flow MRI based CFD methods to quantify flow in aortic valve disease can provide valuable information to the clinician in the assessment of progression towards complications like aortic dilatation and dissections.

Figure 2. Distribution of WSS in a normal aorta with (a) TAV, (b) RN-BAV, (c) RL-BAV and (d) 0AP-BAV inflow conditions.

Figure 3. Distribution of OSI in a normal aorta with (a) TAV, (b) RN-BAV, (c) RL-BAV and (d) 0AP-BAV inflow conditions.

INTRODUCTION

Mitral regurgitation (MR) is quite prevalent, present in 1.7% of the general population and 9.3% of those age 75 and older [1]. Unfortunately, surgical treatment is not suitable for high-risk patients. Instead, transcatheter therapies can be used, such as Abbott's MitraClip NT, which can benefit symptomatic Degenerative MR (DMR) and functional MR patients with high MR grades and ventricles that aren't severely dilated [2,3,4]. One issue is sufficiently maintaining reduced MR while avoiding an elevated transmitral pressure gradient that creates mitral stenosis (MS), as patients with procedure related MS of pressure gradient > 5 mmHg have poorer long-term outcomes than those with residual MR [3,4]. This issue is more important when clinicians consider a second or third MitraClip when intra-procedural MR continues. Together, this leads to the question of when more than one MitraClip should be deployed, since more clips can further decrease MR but also cause pressure gradient to further increase [4]. The objective of this study is to understand how multiple MitraClips effects the hemodynamic performance of the mitral valve (MV) for various DMR severity levels, with a specific focus on increases in pressure gradient. The hypothesis of this study is that though MitraClip increases pressure gradient, the valve benefits by reducing regurgitation.

METHODS

Experiments were performed using an in vitro left heart simulator with full ventricular and atrial function. A custom MV chamber was designed to hold the valve, with a system to hold the papillary muscles (PMs) in place, as function is vital to valve competence. The working fluid was a 60-40 water-glycerin mixture to achieve the density (1060 kg/m^3) and kinematic viscosity of blood (3.88 cSt), and the valve in the aortic position was a 21 mm Medtronic Hancock II valve. The setup also allowed for high fidelity pressure and flow hemodynamic measurements of the valve to quantify parameters, including effective

orifice area (EOA), pressure gradient, and mitral regurgitant fraction (MRF) defined as the ratio of regurgitant volume to stroke volume.

A porcine mitral valve with septolateral and intercommissural dimensions of 20 mm and 32 mm was sutured to a plate, as shown in Figure 1A. The valve was modeled in native (unaltered) and pathophysiological states with MR severities defined as mild, moderate, and severe, with MRFs of < 0.30 , < 0.50 , and ≥ 0.50 , respectively [5,6]. This valve was tested under a systolic ventricular pressure of 120 mmHg and heart rate of 60 beats per minute, where systole composed one-third of the cardiac cycle. The cardiac output was set to 3 L/min appropriate for the valve size. 12 configurations were created, which included the number of clips (0, 1, and 2) and valve state (native and mild, moderate, and severe MR).

Figure 1: Mitral Valve and MitraClip

A MitraClip analog was created to mimic the footprint MitraClip has on the leaflets while allowing removal of the device such that the same valve can be assessed for all configurations. A comparison of the

analog with the MitraClip is shown in Figure 1B. For clipped cases, clips were sutured to the center of the leaflets (Figure 1C).

Severe DMR was induced via cutting all chordae tendineae connecting the posterior leaflet to the anterolateral PM, and moderate and mild MR was achieved via placing suture(s) to restore select connections (Figure 1C).

Flow and pressure were recorded for at least 50 cycles for each configuration. EOA, pressure gradient, and MRF were calculated and compared between each clip case for each valve state using Tukey tests.

RESULTS

Hemodynamic data for the native valve is shown in Figure 2.

For the native case, there was a statistically significant difference for each parameter between clipping configurations.

Figure 2: Native Valve Hemodynamics

Data for the mild and moderate MR cases are shown in Table 1 while that for the severe case is shown in Figure 3.

Table 1: Mild and Moderate MR Hemodynamics

	Configuration	EOA [cm ²]	Pressure Gradient [mmHg]	MRF
Mild	Unclipped	0.75	8.57	0.146
	One Clip	0.51	15.60	0.142
	Two Clips	0.50	16.04	0.139
Moderate	Unclipped	0.90	10.76	0.395
	One Clip	0.70	9.32	0.150
	Two Clips	0.46	19.58	0.150

For the mild case, there was a statistically significant difference for each parameter between clipping configurations ($p < 0.0001$, except MRF in unclipped vs one clip – $p < 0.001$).

Clipping the native and mild MR valve did not decrease MRF to a degree clinically relevant. However, EOA and pressure gradient were impaired.

For the moderate case, there was a statistically significant difference for each parameter ($p < 0.0001$), except for MRF in one vs two clips (NS). Clipping the moderate MR valve greatly improved MRF, reducing severity to mild. EOA and pressure gradient also decreased. However, the use of two clips instead of one gave no added benefit to MRF but continued to decrease EOA, while pressure gradient doubled.

For the severe case (see Figure 3), there was a statistically significant difference for each parameter between clipping configurations. MRF decreased drastically with clips for the severe case. The use of one clip decreased MR to moderate. However, EOA was halved to 0.54 cm² and pressure gradient almost doubled to 22.1 mmHg. Two clips decreased MR to mild, and EOA continued to

decrease to 0.42 cm² while pressure gradient continued to increase to 27.3 mmHg.

Figure 3: Severe MR Hemodynamics

DISCUSSION

MRF did not change in the native and mild cases, as MRF was not high enough for the clip to impact when restricting leaflet motion. These results were as expected, as the MitraClip is intended for treating higher grades of MR. As a result, the pressure gradient sufficiently increased to 20+ mmHg for the native case and 15+ mmHg for the mild case. A study by Katz et al [7] demonstrated a 50% decrease of the mitral valve area after the first clip and a further decrease of 30-40% after the second, which explains the elevated pressure gradients. This great elevation is harmful, especially because MRF was not reduced. Clipping the moderate valve decreased MR severity to mild. It is interesting to note the unexpected decrease of pressure gradient with one clip in the moderate case. This decrease may be attributed to the decrease of forward flow. Two clips being unable to further reducing MRF may be due to clip location, as the second centered clip was unable to impact MRF. A study by Magruder et al specified that multiple clips may only be efficient for a wide regurgitant jet of diameter exceeding 7.5 mm [8]. This shows that though lowering MR is the goal, adding clips can elevate pressure gradient and may not help MRF.

Clipping greatly reduced MRF for the severe case. One clip decreased severity to moderate while two decreased severity to mild. However, MRF did not significantly decrease with two clips compared to one but further impaired EOA and pressure gradient. Similar to the moderate case, MRF not further decreasing may be due to clip placement. Again, this shows that though MR can be further reduced to an even lower severity, pressure gradient can be further elevated.

This study shows that validated in vitro models can be used to explore the full effect of MitraClip. Ongoing studies are currently performed to optimize MitraClip usage.

INTRODUCTION

Subclinical leaflet thrombosis following transcatheter aortic valve (TAV) replacement (TAVR) and valve-in-valve (ViV) has been correlated in literature to neo-sinus and sinus flow stasis^{1, 2}. Therefore, it is possible to reduce the risk of leaflet thrombus if not eliminate it, if the washout in the sinus and neo-sinus regions tremendously improves. Recently, the bioprosthetic or native aortic scallop intentional laceration to prevent iatrogenic coronary artery obstruction also known as BASILICA has been introduced as a technique to help mitigating coronary obstruction through lacerating the bioprosthetic leaflet³. Despite being used in the context of solving potential coronary obstruction, BASILICA as previously explained, introduces a laceration to the leaflet that opens a narrow but direct flow pathway between the sinus and the neo-sinus, and thus potentially altering flow dynamics in both sinus and neo-sinus. The objective of this study is to assess neo-sinus and sinus flow washout with and without leaflet laceration in the context of leaflet thrombosis.

METHODS

A 23mm Edwards SAPIEN 3 and a 26mm Medtronic Evolut were deployed in a 23mm transparent surgical aortic valve model (See Figure 1) pre and post-leaflet laceration with and without coronary flow. The neo-sinus and sinus hemodynamic were evaluated under pulsatile flow conditions ensured by a left heart pulse duplicator yielding physiological flow and pressure curves and including a left coronary loop¹. Briefly, the left coronary flow is controlled by a Starling resistor that was collapsed or expanded during specific intervals to match the changes in coronary flow during myocardial contraction or relaxation respectively. Base hemodynamics for all conditions were maintained with a systolic to diastolic pressure of 120/80mmHg, 60 beats per minute heart rate, a systolic duration of 33% and a cardiac output of

5l/min. The working fluid in this study is a mixture of water-glycerin producing a density of 1080 Kg/m³ and a kinematic viscosity of 3.5 cSt similar to blood. Particle image velocimetry was performed in order to quantify sinus flow hemodynamics and leaflet washout.

Using Lagrangian particle tracking, sinus and neo-sinus washout was

Figure 1: Valve-in-valve deployment in a transparent surgical valve model with (a) Evolut and (c) SAPIEN 3 pre-leaflet laceration and (b) Evolut and (d) SAPIEN 3 post-laceration.

evaluated. Briefly, particles were seeded as a uniform grid of 0.0003mx0.0003m cell size over the sinus region at the beginning of the cardiac cycle. Each particle's trajectory was computed by integrating its velocity with respect to time based on:

$$\frac{d\vec{x}}{dt}(t) = \vec{u}((\vec{x}), t)) \quad (1)$$

With:

$$\vec{x}(t = 0) = \vec{x}_0 \quad (2)$$

After every cardiac cycle only the particles that remained in the sinus were re-seeded based on their last positions and their trajectory over the subsequent cardiac cycle was calculated. This process continued until

all particles exited. Once all the particles exited the sinus, a histogram of the time spent by the particles was generated and then converted to a cumulative distribution function representing the particles' survival probability as a function of time. This procedure is repeated over 6 cycles for every valve combination. The resulting curves represent the sinus washout characteristic for all cases.

RESULTS

Fig.2 shows the velocity fields of the sinuses without coronary flow. It is clear that higher velocities (expressed by larger vectors) exist at the interface between sinus and neo-sinus after BASILICA. Washout results in the neo-sinus are shown in Fig.3a.

Without coronary flow: Without coronary flow, total washout (0% particles remaining in the neo-sinus) with Evolut TAV laceration, total washout was achieved by the end of the first cardiac cycle. 65% of the particles exited by 0.5s. With a SAPIEN 3 TAV without coronary flow, total washout was achieved after 3.5s progressively with 90% of the particles exiting by the end of the second cardiac cycle. With leaflet laceration, total washout was achieved at 0.8s almost immediately.

With coronary flow: With coronary flow, total washout with Evolut was achieved after 2.75s, 80% before the end of the first cardiac cycle and the remaining 20% gradually over the remaining 2s. After leaflet laceration, total washout was achieved at 0.54s. With a SAPIEN 3 TAV

Figure 2: Vector fields in the sinuses without coronary flow.

without coronary flow, washout occurs progressively and total washout is completed after 3.5s. After leaflet laceration, total washout was achieved at 0.8s. With coronary flow, total washout with SAPIEN 3 was completed before the end of the 3rd cycle at 3.93s. 80.5% were washed out before the end of the 1st cycle. After leaflet laceration, total washout was achieved at 1.3s with 96.1% already washed out by 0.5s.

Fig.2b shows the washout in the sinus of the 8 different ViV combinations with and without coronary flow with Evolut and SAPIEN 3 TAVs.

Without coronary flow: total washout was achieved with Evolut ViV after 1.4s. Before the gradual decrease to 1.4s, 90% of the particles were already out of the sinus by 2/3rd of the first cycle. After leaflet laceration, total washout was completed at 0.8s. SAPIEN 3 ViV without coronary flow leads to a total gradual washout after 2.09s while after leaflet laceration, total washout was completed after 2s with steeper and less gradual phases.

With coronary flow: total washout with Evolut ViV was achieved after 0.79s while after leaflet laceration, total washout was immediately completed by 0.26s. SAPIEN 3 ViV with coronary flow yields a total washout by 0.85s, while after leaflet laceration total washout was completed at 0.99s.

DISCUSSION

Implementing a laceration to the leaflet of the surgical valve in ViV is simply allowing the flow to exit a cavity (neo-sinus) more freely from two sides now instead of one: forward and upward toward the sinus. Without laceration, the connection between sinus and neo-sinus is nonexistent directly. This "trans-leaflet" flow explains the increased velocity observed at the intersection of the sinus and the neo-sinus compared to the cases without leaflet laceration. In the presence of coronary flow, the influx from the neo-sinus is almost directly and fully

Figure 3: (a) Washout curves in the (a) neo-sinus and (b) the sinus.

absorbed by the coronary ostium. Leaflet laceration adds new flow features because of the new trans-leaflet flow and enhances the flow in the sinus particularly in the area towards the annulus where stagnation is most likely to occur^{4,5}. In addition, the presence of laceration alters the typical flow features in the sinus. The aortic sinus vortex is pushed further towards the sinotubular junction (STJ) and the flow is forced to exit the sinus faster with the new flow influx. Several studies have shown the impact of coronary flow on sinus hemodynamics in ViV^{1,4}. The results presented in this study show that leaflet laceration may provide the sinus (if it is non-coronary) the same advantage that coronary flow presents in terms of enhanced fluid motion and increased velocities in the sinus^{1,4}. Thrombosis occurs most likely in low flow regions characterized by longer particle or cell residence time⁶ and poor washout is believed to be one of the reasons that lead to bioprosthetic valve thrombosis^{7,8}. Allowing the flow to have more degrees of freedom and to stop being partially confined in the neo-sinus explains why washout was tremendously improved by at least a factor of two between pre and post-laceration. Washout in the sinus was also improved post-laceration only the differences were not as important as those obtained in the neo-sinus. The extra momentum brought into the sinus from the neo-sinus as previously explained creates vortices in the sinus back adjacent to the annulus side that help in pushing the fluid outside the sinus into the STJ side. With coronary flow, this mechanism is much more enhanced¹.

INTRODUCTION

Transcatheter aortic valve (TAV) replacement (TAVR) has emerged as an alternative to surgical aortic valve surgery¹. Recently, leaflet thrombosis – mainly recognized by reduced leaflet mobility - was identified as an adverse effect of TAVR². Leaflet thrombosis is sub-clinical thus cannot be identified with routine clinical tools, in addition to not being always accompanied by direct symptoms³. With the increasing number of TAVR procedures performed annually, the likelihood of adverse effects is also going to increase. Therefore there is a need to predict or identify the early onset of the occurrence of these adverse effects. Miniaturized pressure biosensors, if incorporated in the valve at different locations, can convey information once any abnormality in the valve function occurs⁴. In order to determine configuration of these biosensors to monitor various hemodynamic signals in the vicinity of the valve there is need to understand localized variations in pressure along the stent frame and distal to the valve with and without reduced leaflet mobility (RLM). The objective of this study is to identify the impact of RLM due to leaflet thrombosis on the pressure at different selected points on the TAV frame and distal to the frame.

METHODS

A 26mm Edwards SAPIEN 3 TAV was hemodynamically assessed in a pulse duplicator left heart simulator flow loop under physiological pressure and flow conditions (cardiac output = 5 L/min; heart rate = 60 beats per minutes; systolic to diastolic pressures = 120/80 mmHg). Reduced leaflet mobility was simulated by manually obstructing the leaflet (corresponding to point 5 in Figure 1) which prevented the leaflet from opening during systole. Pressure was recorded using a Millar catheter at various locations. Locations 1, 2 and 3 (shown in Figure 1) are at the sinotubular junction (STJ) plane and

locations 5, 6 and 4 are behind the valve leaflets in the order of locations 1, 2 and 3 respectively. In addition, measurements of pressure at different points in the outflow region (at valve leaflets, at STJ line and at 5 cm from the valve orifice) along with a measurement of the ventricular pressure were also performed. Figure 1 summarizes the locations of these points.

Figure 1: Measurements locations of the different pressure points.

One hundred consecutive cardiac cycles of pressure at each location, and flow rate data were recorded at a sampling rate of 100 Hz. Fluctuating pressure was obtained by subtracting the ensemble averaged pressures from the instantaneous pressures signals. Total and fluctuating pressure signal two point correlations as well as individual power spectral density functions were calculated to assess the impact of RLM on the local dynamics of the pressure field.

RESULTS

Figure 2 shows the ensemble averaged pressure over the cardiac cycle at the points indicated in Fig.1. The figure shows that there exists a pressure loss (Fig.2a, b and c) with RLM at all points distal to the valve and not necessarily only at the one point where the leaflet immobility is applied. The ventricular pressure does not show significant change in magnitudes with and without RLM (Fig. 2d). Figure 3 shows the power spectrum of the fluctuating pressure (i.e. instantaneous minus ensemble averaged) at pts. 1, 2, 3, 5, 6 and 4. The figure highlights pt.1 with RLM (dotted blue line) and pt. 5 (located behind 1) that show the lowest peaks at primary and all harmonic frequencies (1Hz, 2Hz, 3Hz etc). Table 1 shows the two point correlation coefficients between points 1, 2 and 3 for the different cases. When the valve is fully open, RLM increases the correlation coefficient between the points, keeping a lower value between 2 and 3. During all the cardiac cycle, correlation coefficients varied non-monotonically between the 3 points and between pre-RLM and post-RLM. Looking only at the fluctuating component of the pressure during all the cardiac cycle, RLM led to low correlation coefficients that subsequently decrease with the lowest being between 2 and 3. Also, the correlation coefficients were negative for some cases pre and post RLM showing that as the pressure at Pt 1 increases, that at Pt 2 and 3 decreases pre-RLM. The same applies between Pts 1 and 3 and 2 and 3 post-RLM.

Figure 2: Recorded pressure at points (a) 1, 2 and 3, (b) 5, 6 and 4, (c) along the longitudinal axis of the aorta and (d) in the ventricular side.

Correlation Coefficients		Pts 1 and 2	Pts 1 and 3	Pts 2 and 3
Open Valve Phase	Pre-RLM	0.944	0.944	0.935
	Post-RLM	0.978	0.972	0.952
All Cardiac Cycle	Pre-RLM	0.967	0.972	0.965
	Post-RLM	0.791	0.973	0.800
All cardiac cycle – fluctuating pressure	Pre-RLM	-0.180	-0.185	0.046
	Post-RLM	0.041	-0.045	-0.034

Table 1: Correlation coefficients between Pts 1, 2 and 3 pre- and post- RLM for different cases.

DISCUSSION

As expected reduced leaflet mobility has been shown to cause an increase in pressure gradient (additional ~15mmHg in this experiment) across the valve compared with healthy subjects [5]. Results of this study show a drop in the pressure at and around the outflow of the valve.

The severity of pressure gradient throughout the progression of leaflet thrombosis thus could be captured and identified with embedded pressure sensors. From the power spectrum analysis (Fig.3), the leaflet that was forced to stay closed during valve opening phase (pt.1 and pt.5 located behind 1 at the leaflet level) displayed the lowest power spectrum densities at both primary and harmonic frequencies compared with the other points, which made it easily identifiable. Therefore, the temporal pressure fluctuation behavior of the RLM subjected leaflet is not only different compared with the other leaflets but also could be predicted with a sufficiently high sampling frequency.

Because of probably the effect of pressure variation occurs mostly there, the results demonstrate that the correlation coefficients are higher between the point where RLM is induced and the other 2 points (1 and 2; 1 and 3) compared with the other points (2 and 3).

Figure 3: Power Spectrum of fluctuating component of pressure versus frequency in log-log scale for points (a) 1, 2 and 3 and (b) 5, 6 and 4. Insets show power spectrum for frequencies exceeding 1 Hz.

HEMODYNAMICS, IN ADDITION TO MORPHOLOGY, PREDICTS LONG-TERM OUTCOME OF INTRACRANIAL ANEURYSMS TREATED WITH FLOW DIVERTERS

INTRODUCTION

Flow diverters (FDs) have emerged as an alternative paradigm to traditional coil embolization for treatment of intracranial aneurysms (IAs), especially for wide-neck and fusiform aneurysm morphologies. [1] The densely woven mesh of FDs aim to induce flow stasis in the aneurysmal sac, while promoting thrombotic conditions and eventual occlusion of the IA. Despite its recent success in treatment of IAs, approximately 25% of FD-treated IAs fail to reach complete occlusion after 6 months of treatment. Patients with persistent residual filling in the aneurysm sac after FD-treatment are at risks of thromboembolic complications and aneurysm rupture. *A priori* assessment of FD-treatment outcome could aid the clinicians in treatment optimization and lead to better outcomes.

We recently developed a computational workflow that uses neural network to predict the 6-month clinical outcome of FD-treated aneurysms with 90% accuracy, as shown in Figure 1. [2] Our computational workflow includes aneurysmal morphology assessment, device modeling and CFD simulations to obtain relevant morphological, FD-related and pre- and post-treatment hemodynamic parameters (Figure 1). [3, 4] These parameters are imported into a machine-learning algorithm, which could predict the 6-month clinical outcome of FD-treated aneurysms. Although shown to be highly accurate in our preliminary testing, the computational analysis workflow involves

modeling the FD device and image-based CFD simulations, which are time consuming (~24 hours). This could make it difficult to be adopted into the clinical setting.

In this study, we investigated whether device modeling and subsequent hemodynamic analysis are truly necessary to make accurate FD-treatment outcome predictions. In particular, if morphology alone could provide similar prediction accuracy, this would drastically reduce the computational cost and make transition into the clinic more straightforward. To that end, we applied the computational workflow on FD-treated aneurysm patients to develop two predictive models using: (1) morphological parameters only and (2) both morphological and hemodynamic parameters.

METHODS

Patient Selection

Patients treated using the commercial FD—Pipeline embolization device (PED, Medtronic)—at the Gates Vascular Institute between 2009-2018 were retrospectively collected for this study. The inclusion criteria was: (1) sidewall aneurysm located at the internal carotid artery (ICA), (2) treated using a single PED, (3) availability of 6-month follow-up angiographic image and (4) pre-treatment 3D digital subtraction angiography (DSA) image. For cases that satisfied the inclusion criteria, 3D DSA images before treatment, clinical outcome at

6-months
and clinical
and

Figure 1: Schematic of the computational analysis workflow. The 3D DSA prior to treatment are taken as input, and computational analysis is performed that includes morphology analysis, device modeling and CFD simulations. These analyses provide the parameters/features for each case, which are used in a neural network to predict the 6-month occlusion outcome.

demographic data were collected. Based on their angiographic outcome at 6-month follow-up, aneurysms were divided into two groups: occluded (complete occlusion) or residual (contrast filling at the aneurysmal neck/dome). The 3D DSA images were segmented using the open-source software virtual modeling toolkit (www.vmtk.org).

Virtual Device Modeling and CFD Simulation Setup

We used an in-house virtual stenting workflow to model the clinical deployment of FDs in the 3D aneurysm models. [2] After virtual device deployment, we used STAR-CCM+ (v11.02, Siemens PLM, Plano, TX) to perform the volumetric meshing and subsequent CFD simulations. Pulsatile flow simulations were performed for each case, with blood assumed to be Newtonian and rigid wall assumption at the arterial walls. The density and dynamic viscosity was set as 1056 kg/m³ and 0.0035 Pa-s. For each aneurysm case, 2 simulations were performed: one untreated and one treated with the FD.

Parameters Quantified: Morphology and Hemodynamics

Based on the segmented 3D aneurysm model, and pre- and post-treatment CFD simulations, morphological and hemodynamic parameters were calculated. Morphological parameters included aneurysm size, neck diameter, size ratio, aspect ratio, neck ratio and ostium ratio. In terms of hemodynamics, pre- and post-treatment hemodynamic values of inflow rate, aneurysm averaged velocity, shear rate and turnover time were quantified. [2, 3] A total of 14 parameters were calculated for each FD-treated aneurysm case: 6 morphological and 8 hemodynamic parameters.

Training Neural Network Algorithm

Supervised machine algorithms with binary classification were used to train neural network (NN) algorithm, which is inspired by human brain that uses system of interconnected neuronal layers to generate non-intuitive combinations of input features to enhance the classification model for accurate predictions.

Model Training and Testing

Using NN algorithm, we trained two models on the same dataset: (1) using morphological features alone and (2) using both morphological and hemodynamic features. Before training the models, we randomly divided the database into training and testing cohorts roughly at a 3:1 ratio. The parameters were then normalized dataset to a zero mean and a standard deviation of 1. For each model, the training loss function was observed to enable the convergence of each trained model.

To quantify the training performance of each model, receiver operating characteristic (ROC) curves were plotted, and the area under the ROC curve (AUC) was

calculated. To quantify the predictive accuracy of each model, the correct predictions of both models on the independent testing samples was divided by the total number of testing samples.

Figure 2: Flowchart for training and testing neural network models. Two models were trained: (1) using morphological parameters only and (2) using morphological and hemodynamic parameters.

RESULTS

Patient Database

Based on the selection criteria, 84 aneurysms in 80 patients were included in this study. Based on the 6-month clinical outcome, 63 aneurysms were completely occluded (occlusion group) and 21 had residual contrast filling at neck/dome of the aneurysm (residual group).

Randomization of the data resulted in 64 cases (48 occluded, 16 residual) in the training cohort and 20 cases (15 occluded, 5 residual) in the testing cohort.

Training Performance and Testing Accuracy of Predictive Models

The ROC curves of the two trained models on the training data is shown in Figure 3. Model trained using both morphology and hemodynamic parameters (AUC=0.926, 95% CI: 0.685, 0.982) had better performance than morphology-only model (AUC=0.905, 95% CI: 0.797, 0.978).

Figure 4 shows accuracy of the two models on the independent testing cohort. Prediction model trained using both morphological and hemodynamic parameters outperformed the model trained using morphology by 20%.

Figure 4 shows accuracy of the two models on the independent testing cohort. Prediction model trained using both morphological and hemodynamic parameters outperformed the model trained using morphology by 20%.

DISCUSSION & CONCLUSIONS

Our results show that including hemodynamic features along with morphological features during training of the neural network model slightly improved the AUC, but the accuracy in testing cohort was drastically increased for predicting FD-treatment outcome. This suggests that model trained using morphology alone was overfitting to the training data. The importance of pre- and post-treatment hemodynamics in accurate predictions also suggest that hemodynamics might play a bigger role than morphology alone in the healing of FD-treated aneurysms. In future studies, we will train another model using clinical parameters to compare its performance with these models.

INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of mortality in the U.S. and leads to ~8M inpatient procedures annually. ~86M Americans have some form of CVD and a substantial portion suffer from coronary artery disease (CAD) [1]. Whether or not to treat a particular coronary stenosis is often debated among interventional cardiologists, with hemodynamic criteria from fractional flow reserve (FFR) [2] and its computational counterpart, (FFR_{CT}) [3], growing in popularity over image-based criteria. However, in cases of multiple stenoses in the left main coronary artery (LMCA) bifurcation, FFR may yield inaccuracies [4]. In practice, invasive FFR can be costly and requires potentially uncomfortable vasodilator agents. Park et al. offered an integrated FFR and IVUS method for better lesion classification [5]. However, the cost of implementation, procedural time and availability of trained personnel are potential limitations. FFR_{CT} also uses computational fluid dynamics (CFD) analysis with non-linear lumped parameter boundary conditions that require careful tuning under several applicable flow conditions [6].

A wave-free period in diastole when coronary resistance is constant and minimum affords the possibility of performing pressure-derived stenosis severity assessment without a pharmacological agent. The instantaneous wave-free ratio (iFR) is an index derived to quantify severity using this method. iFR is defined as the ratio of the mean instantaneous pressure distal to a coronary stenosis relative to that in the aorta during the wave-free period. iFR has been correlated to FFR with values from 0.83 to 0.92 reported as equivalent for FFR 0.8, which is the putative standard for percutaneous coronary intervention [7]–[9].

The computational counterpart of iFR (iFR_{CT}), derived from coronary CTA, is a strong tool for integrated evaluation of a coronary stenosis. However, in cases of multiple intermediate coronary stenoses near the LMCA bifurcation when the FFR is in its clinically important

range (0.6-0.9), the effect of downstream lesions on iFR is not clear. The objective of the current work is to computationally assess the accuracy of the current iFR threshold in an idealized case consisting of multiple lesions near the LMCA bifurcation and determine the correlation between iFR_{CT} and FFR_{CT}. The independency of iFR to hyperemia is also debated [8], which is further studied here.

METHODS

Computational model creation. Segmentation and model construction was performed using a normal CTA data set on the SimVascular website (Documentation, Coronary Normal). Models of stenoses in the LMCA, LAD, and LCX were then created. Clinically representative minimum lumen areas (MLA) of 6 and 4.5 mm² [2] for the LMCA and 4 and 3 mm² for the two branches [10] were compared to study the effect of multiple lesions on iFR and FFR (Figure 1).

Figure 1: Model creation, classification, integration, discretization

Simulations and boundary conditions. Parameters for CFD simulations were implemented using SimVascular (simtk.org). A five-element non-linear model was used at coronary outlets. The model consists of small artery resistance (R_a), micro-circulation resistance (R_m), venous resistance (R_v), arterial capacitance (C_a) and myocardial capacitance (C_m) [11]. The flow distribution to each coronary outlet was calculated based on a generalization of Murray's law (radius ratio to the 2.6 power) [12]. In the autoregulatory range (Figure 2), flow was assumed constant and 4% of cardiac output (CO) [13] at rest. Similarly, for the pharmacological stress condition, flow was assumed to be 7% of CO [14]. According to literature, CO of 5 and 8.6 L/min, systolic blood pressure (SBP) of 120 and 78 mmHg, diastolic blood pressure (DBP) of 80 and 56 mmHg and heart rate (HR) of 60 and 96 bpm were considered for rest and stress condition, respectively [15]. Depending on the severity of a coronary stenosis, hemodynamics may fall into the autoregulatory or maximum vasodilation range [16] (Figure 2).

Figure 2: Autoregulatory relation under rest and pharmacological stress conditions (i.e. 140 μ g/kg/min adenosine).

RESULTS

From rest to stress in the normal case, the cardiac cycle decreased from 1 to 0.625 s, the average coronary flow increased from 3.4 to 10.1 mL/s, and its range increased from 4.2 to 14.1 mL/s. In the stenoses models, the range of coronary flow decreased substantially with the severity of stenosis. The FFR_{CT} was between 0.68 and 0.98. In the stress condition, a significant drop in iFR_{CT} was observed yielding a value <0.7 for models with multiple lesions. During rest condition, however, it results in values above 0.94. For cases with two lesions the iFR_{CT} ranged from 0.94 to 0.97 suggesting significant epicardial pressure drop (Table 1) when related to FFR_{CT} .

Table 1: Computed FFR_{CT} and iFR_{CT} for all cases

Class	MLA [mm ²]		% of Stenosis		iFR_{CT}		FFR_{CT}
	LM	LAD	LM	LAD	Rest	Stress	
Normal	-	-	0	0	1.00	0.96	0.98
400	4.5	-	79	0	0.97	0.69	0.80
600	6	-	72	0	0.98	0.81	0.89
430	4.5	3	79	83	0.94	0.51	0.68
440	4.5	4	79	78	0.95	0.61	0.75
630	6	3	72	83	0.95	0.59	0.73
640	6	4	72	78	0.96	0.70	0.81

DISCUSSION

According to the results, during rest condition, an iFR_{CT} of 0.96 corresponds to FFR_{CT} 0.81 showing a correlation between lack of suggested treatment for iFR_{CT} and FFR_{CT} in the case of multiple stenoses. For multiple lesions, iFR_{CT} varies within a limited range and values of 0.94-0.95 suggest treatment when interpreted relative to FFR_{CT} . Results also suggest that the iFR_{CT} , which is independent to hyperemia by definition, does depend on pharmacological stress conditions. This fact is also reported in VERIFY clinical trial [8].

INTRODUCTION

The vascular wall consists of a layer of endothelial cells (VasEC) that are directly in contact with blood flow, and a sublayer of vascular smooth muscle cells (VasSMC). Vascular remodeling often involves paracrine signaling between VasECs and VasSMCs, and diseases such as atherosclerosis can result from improper communication between these cells.

Figure 1: Vascular Endothelial Cells (VasECs) and Vascular Smooth Muscle Cells (VasSMCs)

VasECs are known to respond to hemodynamic stimuli, and VasEC dysfunction in atherosclerosis occurs preferentially at regions exposed to oscillatory flow. Studies have demonstrated development of

cardiovascular tissues under dynamic environments such as flow, flexure, and stretch, in which have significant impact on cell phenotype [1]. In this regard, there may be a range of oscillations that maintains vascular tissue integrity. In the current study, we conditioned VasECs under various specific oscillatory flow profiles, which can be quantified by the oscillatory shear index (OSI) parameter. It is widely accepted that biomechanical cues are critical in maintaining vascular tissue homeostasis; however, oscillation dependent changes in cell communication and molecular regulation has not been thoroughly investigated. We therefore examined the paracrine signaling of biochemical end-products between VasEC and its sublayer, VasSMC, through the biochemical environment resulting from physiologically relevant oscillations.

METHODS

Oscillatory shear index (OSI; Equation 1) is a parameter that quantifies the change in direction and magnitude of wall shear stresses [2]. The following OSI magnitudes were applied to the VasECs: static (no flow), steady flow (OSI = 0), 0.25 OSI, and 0.5 OSI.

OSI is defined as:

$$OSI = \frac{1}{2} \left(1 - \frac{|\int_0^T \tau_w dt|}{\int_0^T |\tau_w| dt} \right) \quad (1)$$

Where τ_w = wall shear stress, T = duration of cycle, t = time

VasECs were seeded for 24 hours at 2.0×10^5 cells per channel in 24-well Bioflux plates, consisting of 8 microfluidic channels per plate (Fluxion Biosciences, San Francisco, CA). VasECs were later

conditioned for 48 hours using a shear stress cell assay system (Fluxion Biosciences) at a magnitude of 1 dyne/cm² [3].

Figure 2: Schematic of microfluidic channels

The conditioned media from VasECs for each flow group were collected. These media were subsequently used to culture VasSMCs for 48 hours using 8×10^5 cells in 6-cm dishes. After exposure to the conditioned media of the various flow groups, key phenotypic markers expressed by VasSMC were assessed using RT-qPCR at three replicates per target gene per flow sample group. Data from RT-qPCR consisted of cycle threshold, or C_T values, which were analyzed using the Livak method, $\Delta\Delta C_T$ [4], to compute fold change with the static (no flow) sample group as control.

RESULTS

Three VasSMC samples (n=3) at three replicates per target gene were analyzed. Higher expression of smooth muscle alpha-actin (alpha-SMA) was observed in VasSMCs exposed to non-static VasEC conditioned media compared to those exposed to the static media (Figure 3). Alpha-SMA expression was highest in VasSMCs exposed to steady flow (OSI = 0). Compared to the steady flow group, alpha-SMA expression decreased with increasing levels of OSI.

Figure 3: Expression of Alpha-SMA from Vascular Smooth Muscle Cells

DISCUSSION

We observed that various oscillatory flow profiles alter cell responses to its immediate environment via both cell-to-cell paracrine and autocrine communication. A higher expression of alpha-SMA from VasSMC in non-static groups of conditioned media may indicate that fluid motion promotes paracrine signaling for fibrotic development. As alpha-SMA is a marker for contractile phenotype of adult smooth

muscle cells, non-static flow groups experienced by VasEC may have led to the secretion of factors then enabled paracrine regulation of VasSMC phenotype.

It is known that VasSMCs exhibit a less proliferative and more contractile phenotype with abundant alpha-SMA [5]. The VasSMCs exposed to steady flow conditioned VasEC media expressed the highest level of alpha-SMA amongst all sample groups. As oscillatory flow was introduced to the system, the expression of alpha-SMA decreased. This supports previous observations of vascular remodeling in regions of oscillatory flow.

Previous studies have shown the role of disturbed flow in VasEC physiology and pathogenesis of vascular diseases. However, in this study, we have further verified that through OSI-initiated paracrine signaling, the biochemical end-products released from VasECs under disturbed flow is also transmitted to the sublayer cells, or the VasSMCs, thereby potentially affecting their phenotype.

NON-LINEAR CD31 EXPRESSION IN VASCULAR ENDOTHELIAL CELLS IN RESPONSE TO INCREASING OSCILLATORY FLOW CONDITIONS

Alexandra G. Tchir, Chia-Pei Hsu, Sharan Ramaswamy

Biomedical Engineering
Florida International University
Miami, Florida, USA

INTRODUCTION

Cardiovascular disease is one of the leading causes of death worldwide. As the overall population ages, rates of heart disease and stroke are continuing to rise at alarming rates. Proper function of vascular endothelial cells is a critical underlying factor in the prevention of arterial disease. Specifically, the vascular endothelium has several functions including maintaining hemostatic balance, regulating vascular tone and angiogenesis, initiating wound healing responses when needed as well as paracrine signaling with vascular smooth muscle cells [1]. The endothelial cells in the vascular system receive signals from both intrinsic and extrinsic factors and responds in different ways to maintain homeostasis [1]. Hemodynamic forces are a major regulator of the vascular endothelium. Endothelial cells have mechanoreceptors which sense the blood fluid-induced biomechanical signals which are then used to maintain the vascular phenotypic [2]. Pulsatile blood flow generates oscillatory patterns at different sites in the vascular system, resulting in oscillatory shear stresses. Many studies have shown the correlation between regions of oscillatory flow and atherosclerosis. A parameter used to quantify oscillatory flow is the oscillatory shear index (OSI). Oscillatory shear index is defined as [3]:

$$OSI = \frac{1}{2} \left(1 - \frac{\int_0^T \tau dt}{\int_0^T \text{abs}(\tau) dt} \right) \quad (\text{Eq. 1})$$

A zero OSI is indicative of unidirectional flow while 0.5 would represent maximum temporal oscillatory flow conditions [4]. High OSI is said to correspond with regions where atherosclerotic plaque will eventually form [5]. In the current investigation, we speculated that there is a specific range of OSIs that leads to pathology which is distinct

from an OSI range necessary to maintain arterial homeostasis. Hence, we exposed vascular endothelial cells to different oscillatory flow conditions in *in vitro* culture and subsequently assessed their phenotypic responses.

METHODS

Vascular endothelial cells were commercially obtained. The cells were plated to a size of 2×10^5 /channel for a total of 8 channels/experimental group in a commercially available shear stress cell assay system (Bioflux 200, Fluxion Biosciences, San Francisco, CA) in our laboratory. Three OSI profiles based on pulsatile flow waveforms (Fig. 1) were applied for a period of 48 hours as follows: 0 (steady flow), 0.25 and 0.5. An accompanying no flow control (static) group consisting of roughly 80,000 cells per channel was also cultured for the 48 hour period. Note that prior to cell-plating the microfluidic channels were pre-coated with gelatin for proper cell adhesion and were subsequently primed with fresh media. The time-averaged shear stress in the flow experiments was in the order of 1 dyne/cm², with the steady shear stress group set to a constant value of 1 dyne/cm². After 48 hours of culture, RNA was extracted from the cells using TRIzol (Invitrogen, Carlsbad, CA), and *Power* SYBR Green RNA to CT *1-step* kit (Applied Biosystems, Waltham, Massachusetts) utilized to perform RT-PCR (Applied Biosystems, Waltham, Massachusetts). Target genes were as follows: *B-actin* and *CD31*. Using the CT values from the RT-PCR, the normalized gene expression for each flow profile was performed using the $\Delta\Delta CT$ /Livak method [7].

Figure 1: The 0.25 and 0.5 OSI flow profiles.

RESULTS

The average cyclic threshold values for gene expression were summarized (Table 1) and were subsequently used to calculate fold changes between the groups. The Preliminary results showed substantial up-regulation of the CD31 gene under an OSI of 0.25 (Fig 2). On the other hand, the lowest expression of *CD31* was at the highest an OSI of 0.5 OSI.

Table 1: The average CT values of the four different flow profiles for the genes B-actin and CD31.

Gene	Static	Steady	0.25 OSI	0.5 OSI
B-actin	22.09	21.43	24.9	24.58
CD31	28.94	27.21	28.82	30.97

Figure 2: Gene expression from porcine valvular endothelial cells of the vascular endothelial phenotypic marker, CD31.

DISCUSSION

CD31 is a widely used endothelial cell marker, that is relatively sensitive and specific to endothelial cell differentiation [7]. Its upregulation at an OSI of 0.25 opposes conventional theory that higher OSI are adverse while steady flow conditions (OSI = 0) are ideal, in the context of atherosclerosis. The preliminary findings here point towards a non-linear, parabolic-type, rather than linear relationship between CD31 gene up-regulation and OSI, with a peak gene expression occurring at OSI = 0.25.

In conclusion, maintaining the shear stress magnitude while systematically modifying localized OSI conditions, may help towards delineating distinct ranges of oscillatory blood fluid-induced biomechanical stimuli that may play a critical role in normal versus abnormal vascular tissue remodeling. Further experimentation would thereby necessitate establishing greater resolution in OSI and its association with multiple healthy/diseased vascular endothelial cell gene markers.

INTRODUCTION

Transcatheter aortic valve (TAV) replacement (TAVR) has emerged as an alternative to surgical aortic valve surgery. The assessment of TAV function post-implantation is routinely performed using standard echocardiography¹. Another method of measurement of transvalvular pressure gradient is the cardiac catheterization¹. Both measurement techniques yield different results with the echo providing measurement at the vena contracta (VC) whereas catheterization provides measurement distally from the VC. Therefore, cardiac catheterization takes into consideration pressure recovery as well as true losses which are not reflected in the modified or simplified Bernoulli equation. Briefly, as the jet expands, its velocity decreases and pressure is recovered depending on several factors such as turbulence. In a retrospective study between January 2017 and March 2018 at the Ohio State University medical center, a total of 204 patients of which 86 had TAVR with SAPIEN TAV and 118 with Medtronic Evolut were studied. Transvalvular pressure gradients (PG) were measured by echocardiography and cardiac catheterization. The mean PG with SAPIEN TAVs was 12.3 and 3.9 with echo and catheterization respectively. The mean PG with Evolut TAVs was 9.1 and 3.6 mmHg with echo and catheterization respectively. It seems from this cohort of patient that SAPIEN yields higher pressure gradients with echo and higher pressure recovery compared to Evolut. Several studies demonstrated the contributions of the stent and valve cusps to flow acceleration inside the valve and total valve gradient of the Edwards SAPIEN valve². The objective of this study is to elucidate on the physical

mechanics behind the flow acceleration and recovery variations between the SAPIEN 3 and Evolut TAVs through the measurements of precise axial pressure profiles.

METHODS

A 26mm Edwards SAPIEN 3 TAV was hemodynamically assessed in a pulse duplicator left heart simulator flow loop under physiological pressure and flow conditions (cardiac output = 5 L/min; heart rate = 60 beats per minutes; systolic to diastolic pressures = 120/80 mmHg). Experiments on the Evolut TAV are currently ongoing. Pressure was recorded using a Millar catheter that was inserted longitudinally along the centerline of the aortic valve chamber. Measurements were obtained upstream of the valve (ventricular), at the entry of the valve stent, inside the valve and distal. Measurement were taken at intervals of 0.5cm. Position 0 corresponds to the upstream measurement, position 0.5 cm corresponds to the point at the valve entry, positions 2.0 to 3.5 cm correspond to locations inside the valve and 5.5 cm and above correspond to downstream of the valve. A hundred consecutive cardiac cycles pressure and flow rate data were recorded at a sampling rate of 100 Hz. Particle image velocimetry (PIV) was performed with the 26mm SAPIEN 3 along with a 26mm Evolut under the same hemodynamic conditions. Time-resolved PIV images were acquired with resulting spatial and temporal resolutions of 0.0723 mm per pixel and 1000 Hz, respectively. Phase locked measurements were recorded for 4 phases of the cardiac cycle (acceleration, peak,

deceleration, and diastole) repetitively 250 times with a spatial resolution of 0.0723 mm per pixel. Reynolds shear stress (RSS) was computed as follows:

$$RSS = \rho \sqrt{\left(\frac{u'u' - v'v'}{2}\right)^2 + (u'v')^2} \quad (1)$$

Where ρ is the blood density and u' and v' are the instantaneous velocity fluctuations in the x and y directions respectively.

RESULTS

Figure 1 shows the variations of pressure versus axial position along the centerline shown for every 50 ms for the full cardiac cycle. The valve is open (systole) from time 0 to 0.34 s. During systole, a highly non-monotonic pressure profile with respect to axial position can be appreciated. Localized adverse

Figure 1: Variation of ventricular pressure with distance downstream of the SAPIEN 3 valve.

pressure gradients are seen within the valve as well as beyond the 5.5 cm position corresponding to pressure recovery. During diastole (time > 0.34s), pressure downstream of the valve (beyond 3.0 cm) is higher than that upstream consistent with valve closure.

Figure 2 shows the principal Reynolds shear stresses at different phases in the cardiac cycle. Peak principal RSS was equal to 337.22Pa and 157.91Pa with the Evolut and SAPIEN respectively.

DISCUSSION

Two important physical mechanisms concerning flow acceleration within the valve and pressure recovery emerge from the results. With respect to flow acceleration, it can be appreciated that the pressure varies non-monotonically between locations corresponding to 2.0 to 3.5 cm with local adverse pressure gradients occurring inside the valve during acceleration as well as deceleration phases of systole. From a classical standpoint, the pressure is expected to simply decrease monotonically in this region. These adverse pressure gradients

may be attributed to the SAPIEN skirt particularly its dynamic effects (potentially local flow acceleration and separation within the valve). Based on a previous study highlighting a mechanism of flow separation at valve inflow due to obstruction of the inlet⁴, it seems that the SAPIEN 3 skirt may allow for this mechanism to happen thus influencing the variations in pressure inside the valve.

With respect to pressure recovery, Figure 1 illustrates pressure recovery seen from measurement locations 5.0 cm through 11 cm. In this region, there appears to be a phase dependent behavior of pressure recovery. Interestingly, during acceleration phases (time 0.05s, 0.10s, and 0.15s) the net pressure rise between $x=3.5$ cm and 11.0cm is negligible and even negative at earlier (e.g. at 0.05s). During deceleration phases (time 0.20s and 0.25s) there appears to be a clear pressure recovery signal. We anticipate this characteristic to be different for the Evolut TAV currently being characterized as evident from the starkly differing turbulence characteristics shown in the RSS fields (Figure 2).

Figure 2: Principal Reynolds shear stresses at different phases in the cardiac cycle.

RSS measures the shear stress (acting on the mean field) between fluid layers when fluid particles decelerate or accelerate while changing direction³. The higher the RSS magnitude the higher the turbulence, thus the overall pressure drop. The clinical results obtained with SAPIEN 3 showed a higher pressure drop at the VC yet a higher pressure recovery compared with the Evolut. The differences seen in turbulence levels (Figure 2) corroborate these clinical observations as more turbulence is obtained with Evolut (by almost a factor of two) than with SAPIEN. Clinical and in-vitro studies comparing these two valves are necessary to compare and evaluate pressure drop and recovery in both TAVs and are parts of currently ongoing studies.

INTRODUCTION

Aortic stenosis is a disease in which the aortic valve (AV) connecting the left ventricle and aorta narrows, resulting in restricted blood flow to the body and subsequent complications that can end in heart failure. The mortality rate is more than 50% at 2 years with untreated, symptomatic disease [1]. The incidence of aortic stenosis in the population rises with age to reach 10% of those in the 80s [2].

A leading cause of aortic stenosis in younger patients is bicuspid aortic valve, where two leaflets of the normal tricuspid valve are congenitally fused. Bicuspid AV occurs in 1-2% of the population. Other abnormalities usually accompany the defect, such as increased risk of aortic aneurysm and dissection (5-9 times the general population incidence), tissue changes in the aorta, and larger aortic root dimensions [3]. In an 11-year study of 932 sequential replacements for stenotic aortic valve without evidence of mitral stenosis, 49% had bicuspid valve, with an additional 5% unicuspid [4]. Patients with bicuspid AV typically have surgery for AV replacement at an earlier age [3].

The traditional surgical aortic valve replacement (SAVR) procedure involves sternotomy and bypass. A newer, minimally invasive procedure, transcatheter aortic valve replacement (TAVR), involves delivering an initially collapsed replacement valve by catheter. When expanded within the aortic root, it pushes the existing valve leaflets to the side without removing the existing valve. TAVR is approved for intermediate or high-risk surgical patients for standard valve replacement surgery, but not for bicuspid aortic valve, which involves higher risks of difficulty in the valve-in-valve insertion and variable aortic root anatomy, leading to improper seating and leakage.

The goal of this project was to create a tabletop flow loop modeling blood flow through the human aorta to allow testing of existing TAVR valves in bicuspid AV anatomy. The system was designed to reproduce

fluid flow rate, pressure, and timing across the AV (Fig. 1). It was also designed for insertion of interchangeable 3D-printed sections of human anatomy reconstructed from national databases of bicuspid defects that could then be implanted with a commercial valve, and for accessibility by ultrasound. This project began as a student design project with a funding cap. The requirements of ability to test in real patient anatomy and minimal cost preclude use of a commercial system. The long-term goal is to help determine the feasibility of TAVR in cases of bicuspid AV.

METHODS

The system was first modeled with the traditional 3-element Windkessel model, implemented in MATLAB and Simulink. The Windkessel model uses electrical analogies to represent fluid quantities: charge, current, and voltage for volume, volumetric flow rate, and pressure; electrical resistance for fluid resistance, and capacitance for system compliance. This analysis showed reasonable values for lumped resistance and compliance elements. The effects on the system of varying their magnitude was also clear: increasing the resistance shifted the entire pressure trace upward, while increasing the compliance increased the difference between systolic and diastolic pressures.

The fluid pump is a crucial element of the system. A piston pump was first designed and fabricated, but later discarded because of the difficulty in maintaining a tight piston seal while keeping friction at a manageable level. The piston pump was replaced by a bellows pump (Dynatest bellow, Thermiseal cover, 2" ID, 3" OD), with bellows collars fastened to custom aluminum blocks. Both pumps were driven by a custom cam-follower mechanism designed with MATLAB and Solidworks and analyzed with Working Model. The aluminum cams, manufactured in-house, reproduced a cycle of 40% contraction and 60% relaxation. A

motor (Leeson M1125004.00, 1/17 hp, 36 lb-in torque) and motor controller (Leeson Speedmaster 174308.00) drove the cam at a set rotation speed, representing heart rate. Separate cams produced stroke volumes of 60 mL, 70 mL, and 80 mL.

Figure 1: The target aortic pressure waveform (reproduced from [5]). Systolic pressures to 180 mmHg were achieved by Arduino-controllable ball valve, while the pulse pressure was controllable with fluid column and air pressure in the compliance tank.

Fluid was pumped within a closed system through valves, sensors, and lumped compliance and resistance elements (Fig. 2). Commercial check (one-way) valves regulated the intake and outtake of the pump, although the outtake valve was only used during design and testing to avoid damage to an expensive, implantable TAVR valve. The blood analog fluid was produced by adding glycerin to distilled water to reach 1.0501 specific gravity and 3.3 cSt viscosity. The fluid flowed through 3/8-in I.D. amber gum and copper tubing.

A compliance tank representing the lumped compliance of the aorta and peripheral circulation was inserted at the location shown (Fig. 2). In this position, it mainly reflects aortic compliance, defined as change in blood volume due to change in pressure. The compliance chamber is a sealed polycarbonate container with a fluid inlet and outlet. A column of fluid contained within the chamber rises and falls with the system pressure. The compliance was controlled by adjusting the air pressure above the fluid with an attached air bladder pump.

To reduce cost and keep the system user accessible, sensors were chosen that interfaced with an Arduino Uno board. An in-line, flow-rate sensor (Adafruit, Liquid Flow Meter - Plastic 1/2" NPS threaded) verified output from the pump. Pressure transducers were placed both before the 3D print with TAVR valve and after the compliance tank (Honeywell HSCDANT005PG2A5). A voltage-controlled ball valve (Belimo B218B+TR24-SR US) located downstream from the compliance chamber was Arduino-controlled to maintain system pressure as measured by the pressure transducer after the compliance tank.

A closed-loop PD feedback control system with user interface was implemented to control the system mean pressure. The control system gains were chosen to optimize the ball valve's response time based on the system beats per minute, pressure sensor sampling rate (nominally 30 Hz), operating speed of the ball valve's motor, and minimizing overshoot of the target pressure, all dependent on the compliance existing in the system. A GUI allowed the user to easily set the target system pressure and view a real-time pressure vs. time trace.

RESULTS

Replacing the piston pump with a bellows significantly reduced the motor power needed. System pressures of 80 – 180 mmHg and flow rates of 5 – 18 L/min could be obtained. An unwanted side effect was occasional warping of bellows path, later corrected with a sleeve. On start-up, the control system and ball valve required less than one minute

to reach desired pressure, and pressure was maintained within 2% afterward. The motor and controller were the most expensive part of the system, but the total of all purchased parts was less than \$1000. Investments not reflected in this total include in-house expertise (student, faculty, and technician) and existing materials.

The 3D-printed section is crucial in achieving the project goal. Prototypes were printed in transparent, flexible material (Agilus 30 or TangoPlus by Stratasys) and designed to include the aortic root and approximately 3–4 cm each of left ventricle and aorta on either side of the valve location. The sections achieved the desired result of water-tight interchangeability and ultrasound permeability.

Figure 2: Schematic of the cardiac flow loop designed to test replacement valves positioned in 3D-printed sections reproduced from bicuspid aortic valve anatomy.

DISCUSSION

Some important questions remain about the printed section geometry, such as the importance of mimicking the actual tissue elasticity, and how much of left ventricle and aorta need to be incorporated. Further experimentation will attempt to answer these questions.

This system provides an *in vitro* means to test valves designed for TAVR placement in anatomical models constructed from patients with bicuspid aortic valve. Aortic regurgitation is currently the bane of TAVR. Unlike SAVR, where the artificial valve is sutured in, minimizing the risk of leakage, TAVR can be complicated by aortic regurgitation around the valve prosthesis. Unfortunately, there is not a good tenable solution for treatment of aortic regurgitation. This problem is magnified in the cases of bicuspid aortic valve, where the valve leaflets are often asymmetrical, leading to an overall non-circular annulus, which leads to a greater chance of aortic regurgitation.

With respect to TAVR, there are several different kinds of prostheses available. These include balloon expandable valves, self-expandable valves, and mechanically expanded valve prostheses. Obviously, their expansion characteristics afford unique deployment mechanics rendering them useful in different valve morphologies and geometries. It remains unclear, which of these prostheses are most suitable for bicuspid valve anatomy. The system described here will help ascertain the degree of aortic valve regurgitation in a closely simulated condition, which will help with the choice of the valve in a real human being.

EFFECT OF LEAFLET OPENING GEOMETRY ON TURBULENT CHARACTERISTICS FOR PROSTHETIC AORTIC VALVE APPLICATIONS

Megan Heitkemper (1), Hoda Hatoum (1), Jun Kim (1), Lakshmi P Dasi (1)

INTRODUCTION

While thrombotic proclivity of heart valve prostheses is often related to material characteristics, thrombogenic potential is also highly dependent on flow conditions, which are significantly influenced by valve design. Increased turbulent stresses are associated with increased thrombogenic potential, and therefore it is important to investigate turbulent stresses in characterizing prosthetic valve function. Turbulent stress levels, and especially Reynolds shear stress, are well known to be an indirect measure of the shear stresses experienced by blood cells and platelets in a turbulent flow environment[1]. Therefore, an ideal prosthetic valve design would yield the least turbulent effects and decreased levels of Reynolds stress while exhibiting surface hemocompatibility. While the effect of geometric orifices on turbulent jet flows has been studied extensively, no study has investigated the

leaflet opening geometries modeled after known prostheses to determine how the leaflet geometry will affect flow turbulence and thus thrombogenic potential.

METHODS

Leaflet opening geometries modeled after commercially available valves (round) and a polymeric valve previously introduced (triskele-like) [3] of the same area were 3D printed. The 3D printed geometries were implanted in the aortic position of a pulse duplicator left heart flow simulator and hemodynamic performance was evaluated under physiological pressure (120/80 mmHg), heart rate (60 bpm), and cardiac output (5 L/min). A working fluid of 60/40 water to glycerin was used to provide density and kinematic viscosity comparable to blood, at 1060 kg/m³ and 3.5 · 10⁻⁶ m²/s respectively. Aortic and ventricular pressures as well as flow rates were collected at a sampling frequency of 100 Hz for 60 consecutive cardiac cycles. From these data, mean transvalvular pressure gradient (ΔP) and effective orifice area (EOA), were computed for each of the orifices.

Particle Image Velocimetry (PIV)

Particle image velocimetry (PIV) was performed to visualize and evaluate the flow velocity field through the leaflet opening geometries and to identify turbulence characteristics. Briefly, the flow of interest was seeded with fluorescent PMMA-Rhodamine B particles and illuminated by a thin laser sheet created with a double pulsed neodymium-doped yttrium lithium fluoride (Nd:YLF) solid state laser. Time-resolved recordings were acquired at spatial and temporal resolutions of 0.037 mm/pixel and 1000 Hz respectively. 250 repetitions of phase locked measurements were recorded for acceleration, peak systole, deceleration, and mid-diastole phases of the cardiac cycle.

Figure 1: Leaflet opening geometries

effect of prosthetic valve opening geometry on turbulent stress levels [2]. Previous studies have indicated that valve opening geometry can vary, especially in investigational valve designs with novel materials [3]. In this study, we aim to characterize in-vitro the hemodynamic function and turbulent flow characteristics of two distinct

DaVis PIV software (DaVis 7.2; Lavisision, Göttingen, Germany) was used for all image post processing.

Principal RSS is a statistical quantity that measures the shear stress between fluid layers when particles decelerate or accelerate while changing direction [4] and is calculated as:

$$RSS = \rho \sqrt{\left(\frac{u'u' - v'v'}{2}\right)^2 + (u'v')^2} \quad (1)$$

where ρ is the density of the working fluid (Kg/m^3) and u' and v' are the instantaneous velocity fluctuations in the x and y directions respectively (m/s). Equation (1) implicitly assumes no out-of-plane component of instantaneous velocity, w' , and can be considered as a 2D surrogate of the principle RSS [4].

RESULTS

Phase averaged velocity vector fields and corresponding vorticity contours for the two 3D printed leaflet opening geometries are shown in Figure 1 at four time points in the cardiac cycle, namely, acceleration, peak systole, deceleration and diastole, which are denoted by a red dot along the representative aortic flow curve. Bright red and blue contours represent the vorticity within the shear layers which correspond to the jet boundaries. The distance between the shear layers represent the width of the jet at a distance downstream from the valve.

Velocity Vector Field and Vorticity Contours

At peak systole, the triskele leaflet opening geometry produced lower velocities than the round leaflet opening geometry at the valve

Figure 1: Velocity profile in m/s; at the valve opening (P₁); at the STJ (P₂); at one diameter from the STJ (P₃); where y/D is the position indexed by the valve diameter

opening, the sinotubular junction (STJ), and one valve diameter from the STJ (Figure 1). For both geometries, peak velocity was approximately the same at the STJ as it was one valve diameter from

Figure 2: Phase averaged velocity vectors and vorticity contours throughout the cardiac cycle

the STJ, reaching a peak of approximately 1.4 m/s for the triskele geometry and 1.6 m/s for the round geometry. At peak systole, the shear layers are less pronounced with the triskele leaflet configuration compared to the round leaflet configuration, and attached to the aortic

chamber approximately 16 mm from the outlet. There is a significantly larger region of flow separation for the round leaflet configuration, with flow attachment not occurring until approximately 42 mm from the outlet. At the deceleration phase, the presence of shear layers has diminished for the triskele configuration, and only very slightly for the round configuration. In the triskele configuration, the shear layers are significantly diminished at approximately the STJ of the aortic root chamber, much before the shear layers are diminished for the round configuration.

Reynolds Shear Stress

Figure 2 shows the principal Reynolds shear stress (RSS) at acceleration, peak, deceleration and diastolic phases of the cardiac

Figure 3: Phase averaged Principal Reynolds shear stresses (RSS) throughout the cardiac cycle

cycle for each valve. For each leaflet opening geometry, the highest values of RSS were present at peak systole, with 11.3 Pa in the triskele leaflet configuration and 30.9 Pa in the round leaflet configuration. In comparison to the round leaflet opening geometry, the triskele had a significantly smaller region in which higher RSS values were present.

DISCUSSION

The decrease in vorticity fluctuation seen for the triskele leaflet opening geometry is indicative of a decrease in turbulence (and therefore energy loss). The decreased velocity and vorticity fluctuation during peak systole and deceleration phases as compared to the round configuration is likely due to the 3D curved surfaces that induce a radial and azimuthal velocity component of the flow as it exits the valve opening, leading to sooner flow reattachment. RSS magnitudes have an important role in determining the biocompatibility of a valve prosthesis because they can indicate regions of probable platelet activation from turbulent fluctuations of the blood velocity [2,5-6]. All current valve designs studied to date have mean turbulent shear stresses in excess of 20 Pa [7], which is comparable to the round leaflet opening geometry as expected. Therefore, while a round leaflet opening configuration for a valve prosthesis is often desirable, the results presented here show that it may not be the most optimal choice to limit turbulence. In order to mitigate the durability issues that are caused by blood damage, an appropriate leaflet opening geometry should be considered during the design and development of novel valve prostheses.

INTRODUCTION

Thoracic aortic aneurysms (TAA) occur in an estimated 6 per 100,000 person-years [1], and typically involve the aortic root or the ascending aorta. Complications associated with TAA include intramural hematoma, aortic dissection, and aortic rupture [2]. In order to prevent these complications, consensus guidelines recommend surgical correction for patients that meet necessary criteria. One of the surgical options for aortic root aneurysm includes aortic root replacement with a valved-conduit where both the aortic wall and valve are replaced.

Edwards Lifesciences recently developed a bioprosthetic valved conduit featuring a valve along with incorporated sinuses of Valsalva. The inclusion of sinuses of Valsalva has been postulated to be advantageous, as it more closely mimics patient anatomy (At the time of this writing, this product is not yet approved for human use). However, the hemodynamic and physiological benefits of this design are yet to be investigated. Hence, the purpose of this study was to characterize the *in vitro* flow characteristics the design of the KONECT™ RESILIA™ Aortic Valved Conduit (AVC), which features a sinus section. The performance of this AVC was compared with the same AVC model but without a sinus section (the control group) to show that there are improved hemodynamic effects to the function of the valve portion of the device associated with valve/graft interface.

METHODS

Test Section Flow Models.

There were two testing chambers used in this study. The KONECT RESILIA valved conduit (AVC_{Sinus}) was used as the test group, and the same aortic valved conduit model without a sinus section, AVC_{No sinus}, was used as the control group. Particle image velocimetry (PIV) experiments require optical access to the region of interest. Hence, transparent versions of the grafts (milled acrylic blocks) were used.

These chambers were designed to approximate the internal dimensions of an annular size 25 mm KONECT RESILIA aortic valved conduit that pressurized at 100 mmHg. The pressurized graft diameter was measured by laser micrometer.

Pulsatile Flow Loop.

These models were placed in pulsatile simulators for hemodynamic studies. The pulsatile experiments were conducted using the Georgia Tech left heart simulator at nominal hemodynamic conditions: cardiac output of 5 LPM, heart rate of 70 beats per minute, and a mean arterial pressure of 100 mmHg (120/80 mmHg). This experimental setup is described in detail in previous publication [2] and conforms to ISO 5840-2 testing guidelines for surgically implanted heart valves[3]. The working fluid used in these experiments was a water-glycerin mixture (36% glycerin), which was used to mimic the kinematic viscosity of blood.

Bulk Hemodynamic Characterization

Hemodynamic performance of the valves was evaluated using transvalvular pressure gradient (TVPG) and effective orifice area (EOA). TVPG values were calculated as the mean pressure gradient (ΔP_{mean}) across the valve during systole, while EOA values were calculated as the root mean square of the measured flow (Q_{rms}) per the following equation.

$$EOA = \frac{Q_{rms}}{51.6 \sqrt{\frac{\Delta P_{mean}}{\rho}}} \quad (1)$$

For calculating EOA, the positive systolic gradient period was used as the duration for Q_{rms} and ΔP_{mean} . All values were acquired over 50 cardiac cycles and then averaged to get representative data both for the rapid deployment and control valves.

Planar particle image velocimetry (PIV)

PIV was used to quantitatively assess flow field characteristics of the valves at acceleration (75 ms), peak systolic (175 ms), and deceleration (250 ms) phases of the cardiac cycle (856 ms). The flow was seeded with fluorescent particles, and a pulsed Nd:YAG laser source was used to create a thin laser sheet using appropriate optics in the center plane of the test sections (Figure 1). At each acquisition time point, 200 image pairs were acquired to enable averaging of flow fields. Details on these techniques have been described in a previous publication[4].

Figure 1: Acquisition plane for PIV testing

Statistical Analysis

All bulk hemodynamic data were analyzed for normality using Shapiro Wilk's test. Differences between groups were identified using independent samples t-test for normally distributed variables or Mann Whitney U-test for non-normally distributed variables. P values of 0.05 or below were considered significant.

RESULTS

A summary of hemodynamic results for the AVC models is given in Figure 2 for cardiac output of 5 liter per minute. Mean TVPG (mmHG), EOA (cm²), and closing volume (mL) increased with increasing cardiac output. AVCSinus showed lower mean TVPG than AVCSinus (Figure 2). A similar trend was seen in EOA; AVCSinus had a higher EOA than AVCSinus. No differences were found in valve closing volume between AVCSinus and AVCSinus.

Figure 2: Bulk hemodynamic comparison between the two AV conduit models, Bars: $p < 0.05$.

A comparison of PIV results for the AVC models is given in Figure 3. During the acceleration phase, the maximum velocity for AVCSinus was lower than AVCSinus. The maximum velocities observed for AVCSinus and AVCSinus were 1.62 m/s and 1.73 m/s, respectively. At peak systole, the maximum velocities observed for AVCSinus and AVCSinus were 2.26 m/s and 2.23 m/s, respectively.

During the deceleration phase, higher velocities were observed in the AVCSinus compared to the AVCSinus model. The maximum velocities observed were 1.42 m/s and 1.2 m/s for the test sections, respectively.

Figure 3: Velocity vector fields in Plane 1 under 5LPM cardiac output for the AV conduit with a sinus and without a sinus during the acceleration, peak systolic, deceleration, and diastolic phases

DISCUSSION

In this study, the *in vitro* flow characteristics of the KONECT RESILIA AVC were investigated to highlight the benefits of an AVC with a sinus of Valsalva compared to one without a sinus. Major findings included the following:

The AVC model with a sinus had lower pressure gradients and 10 percent higher EOA compared to the AVC without a sinus. This suggests that the presence of an additional amount of space and fluid behind the leaflets in AVCSinus contributed to less constraint on the AVC leaflets.

AVCSinus had lower velocities during the peak systolic phase of the cardiac cycle than AVCSinus. Due to the wider opening of the AVCSinus leaflets, at the same flow rate, lower velocities are expected.

Our particle image velocimetry results revealed a vortical structure hits the aortic wall during the acceleration phase. This phenomenon shows that when no Valsalva sinus is present, the fluid has insufficient space to retreat upon leaflet opening, potentially causing energy dissipation and momentum loss. In turn, a back pressure is generated on the leaflet that leads to lower EOA, and a higher transvalvular pressure gradient.

The KONECT RESILIA conduit reproduces the bulged section of the native aortic root corresponding to the sinuses of Valsalva. The importance of the sinuses of Valsalva in regulating aortic valve motion during the cardiac cycle has been extensively studied [5]. By using this Valsalva-type conduit, it was possible to obtain more physiologically accurate valve motion characteristics that leads to more durability for the valve. Furthermore, a drawback of excluding a sinus from AVC design could be reduced valve durability due to the non-physiologic flow characteristics of the valve.

AUTONOMOUS PUMPING IN A PHYSICAL MODEL OF A MULTI-LYMPHANGION SYSTEM

INTRODUCTION

The lymphatic system is responsible for managing the balance of interstitial fluid, but unlike blood flow that is driven by a central pump, the lymphatic system consists of a series of units called lymphangions that serve as both pump and conduit. Each lymphangion consists of a segment of vessel surrounded by lymphatic muscle cells with each end bounded by valves that limit backflow [1,2]. Lacking a central pacemaker like the heart, the lymphangions contract in response to mechanical and electrochemical signals from the fluid within and from neighboring lymphangions. In particular, Ca^{2+} ions and NO have been shown to affect the contraction and relaxation of the lymphatic muscle cells while their concentrations are influenced by the transmural pressure and fluid shear stress [3].

While much has been learned about the dynamics of lymphatic pumping from intravital microscopy, ex vivo preparations and computational modeling, networks of multiple lymphangions have been found to be particularly complex and challenging to study. As an adjunct to these existing approaches we have explored the use of a physical model that mimics many of the essential features of the living system. In earlier studies, we studied the dynamics of the system under pre-programmed pace-making patterns. The purpose of this study is to determine what conditions lead to autonomous pumping. That is, what combination of vessel wall stretch, fluid shear stress, cell signaling and valve behavior can trigger self-sustaining contractions without an artificial pace-maker?

METHODS

Our physical model of a multi-lymphangion system consists of three units constructed from a compliant ½ in. ID PVC tube inside a rigid chamber that can be pressurized by air admitted under computer control from a high pressure manifold (Fig. 1). As changes in the air

pressure are used to compress and relax the tubing, water flow is directed downstream by one-way valves at the end of each unit. Sensors are placed throughout the system to monitor pressure and flow. Matlab® programs and a National Instruments® interface manage the air flow (contraction and relaxation) and data collection. The lymphangion units can be assembled into a variety of series, parallel or tree-like configurations that can be oriented horizontally or vertically to introduce gravity effects. While the tubing is much larger than even the largest lymphatic vessels, we have found that the flow is dominated by the resistance of the valves and the compliance of the tubing with little evidence of significant inertial effects much like the situation in vivo. Measured values for the resistance and compliance of each element provide a scaling relationship between our physical model and its anatomical counterpart.

Figure 1. Schematic of the multi-lymphangion model. Bypass loops on check valves allow some backflow

In this study we introduced two features that support autonomous operation. First, we modified the control program to use feedback from the measured pressures and flow throughout the system to determine the next actions of each lymphangion (Fig. 2). The lymphangions were programmed to contract briefly when their internal pressure exceeded a fixed threshold, mimicking a stretch response. In addition, the duration of the interval between contractions could be extended during periods of high flow, mimicking a shear stress-NO response. The second modification was to add bypass loops around the one-way valves (Fig. 1). These loops permit a controlled amount of flow to leak backward between the lymphangions to simulate the bias toward being open that has been observed in real lymphatics [4].

Figure 2: Schematic of feedback controlled multi-lymphangion model.

RESULTS

We first programmed the system to retain the first lymphangion as a preprogrammed pace-maker with all downstream units programmed to react to the pressure and flow conditions within their respective units. The downstream units were programmed to contract after their internal pressure exceeded a pre-set threshold. Initially, we did not include bypass loops on the valves. In this configuration the downstream units followed the lead of the upstream unit. However, when the upstream unit was switched from programmed timing to the same reactive algorithm as the downstream units, all contractions soon stopped throughout the system. While many variations on this algorithm were tried, we found none that could sustain contractions.

We then added the bypass loops on the valves. The backflow in each loop could be adjusted independently. With the bypass loops open between the units we found that fully autonomous pumping could be readily sustained (Fig 3). An initial series of contractions needed to be programmed into the first unit, but once the downstream units were pumping the first unit could be switched to the same reactive algorithm and would continue pumping.

The effects of shear stress were introduced by programming the units to have a longer interval between contractions or a higher threshold for the transmural pressure necessary to trigger a contraction. When the flow rate and accompanying shear stress are sufficiently high, contractions can cease as would be advantageous when the vessels are oriented so that gravity assists flow.

DISCUSSION

The mechanism by which autonomous pumping occurs is as follows. When a downstream unit contracts, most of the flow is forced further downstream, but the bypass loops allow a small amount of fluid to move upstream. In doing so the pressure in the upstream unit will increase slightly, thus stretching the vessel wall making it more likely to contract. The resulting contraction of the upstream unit will then force

Figure 3: Self-sustained, autonomous contraction sequence of the first (blue), second (orange), and third (yellow) lymphangion units with backflow at each valve.

fluid downstream to initiate a new contraction downstream that can feed pressure back upstream and so on. Our results cannot rule out the possibility that other mechanism could support self-sustained pumping, but here we found that the leakage of fluid upstream between units was necessary. This result is consistent with the bias of lymphatic valves toward the open condition seen in vivo [4].

Careful examination of the contraction patterns in Fig. 3 shows that the sequence of contraction can be either retrograde or orthograde relative to the flow even though the time averaged flow remains downstream in all cases. This result is also consistent with observations in vivo [5].

We have found that our physical model is useful for studying the dynamics of complex pump-conduit systems similar to lymphatic vessels. While not a complete substitute for existing methods, our model provides a unique mix of visual, tactile, audible and quantitative feedback to the user.

INTRODUCTION

The lymphatic vessels perform vital transport functions, including return of excess fluid from the tissues to the circulatory system. Inadequate fluid transport can lead to edema, a common and debilitating condition in both the developed and developing world. Lymphatic transport relies on both intrinsic and extrinsic contractions, but the mechanoregulatory mechanisms responsible for intrinsic contraction are not fully understood. Lymphatic endothelial cells (LEC) likely play a role, being sensitive to local fluid shear stress (FSS) and the wall strain caused by contraction [1]. The effects of these mechanical forces have been studied extensively in vascular endothelial cells [2], but considerably less so for LEC [1]. Importantly, to our knowledge, no studies applied simultaneous FSS and stretching to LEC in vitro, through these occur concurrently in vivo.

We therefore developed a custom bioreactor to apply both types of forces (FSS and stretch) simultaneously to cultured LEC, attempting to verify the levels of FSS and strain through analytical, computational, and optical measurement techniques. Studies applying controlled levels of mechanical forces should help illuminate the endothelial role in mechanoregulatory mechanisms of intrinsic lymphatic contraction.

Maintaining cell attachment in such a bioreactor is nontrivial; in addition to moderate and widely varying levels of FSS, lymphatic vessels can experience high dynamic circumferential strains of >50%, compared to 5-10% in arteries [3]. We therefore conducted studies to determine which treatments most effectively promote LEC attachment to the silicone membranes we plan to use in the bioreactor, including under conditions involving FSS and high dynamic strain. Additionally, we used a fluorescence Live/Dead assay to investigate whether live cells were maintained in culture inside the experimental chamber.

METHODS

Bioreactor Design: Cells in the bioreactor are cultured on a flexible silicone membrane. The sealed culture module containing the membrane acts as a standalone culture system until the cells have reached sufficient confluency. The module contains viewing ports for transmitted-light imaging for easy monitoring of cell status. This chamber can then be integrated into the stretch and flow bioreactor without disrupting the cells. To achieve dynamic stretch, the membrane is stretched uniaxially in-plane over a pair of steel rollers; this is controlled by the movement of a step-motor-actuated shaft (Fig. 1).

Figure 1: Custom Flow-Stretch Bioreactor

FSS is applied by placing the cultured membrane in an adapted parallel-plate flow channel in a circulating flow loop with a pump circulating media at a given flow rate. Importantly, the FSS and stretching on the LEC are independently controlled, meaning any number of flow, stretch, or combined flow/stretch scenarios could be simulated in the same device. Computational Fluid Dynamics (CFD) studies in ANSYS Fluent were performed to calculate wall shear stress

at the cell culture region of interest using a custom meshed model of the chamber. Boundary conditions were flow rate at the channel input and pressure at the output. Materials for all potentially cell-contacting components of the device were selected for biocompatibility and autoclavability.

LEC Attachment Studies: Rat mesenteric LEC were cultured on silicone (PDMS) membranes treated with various substrates (gelatin, Poly-D-Lysine [PDL], fibronectin). Phase contrast images at 24 and 72 hr post-seeding were processed with ImageJ to identify and count cells in 3 different locations on each membrane, and the cell count was compared between treatments. In a second experiment, fibronectin-treated LEC-seeded membranes were stretched to 20% and back 3 times at 1%/sec. One membrane was exposed to FSS via an orbital rocker for 12 hr before testing. Phase contrast images pre-test and at 0 and 24 hr post-test were analyzed with ImageJ and compared as before. Finally, cell-seeded fibronectin-treated membranes were mounted into the custom parallel-plate flow chamber. Cells were exposed to ~5 dynes/cm² steady FSS for 16 hr. Phase contrast images pre- and post-test were analyzed with ImageJ and compared as before. Significance testing was Student's t-test (for FSS study) and ANOVA with Tukey HSD post-hoc testing.

Strain Measurement: A random dot pattern was applied to silicone membranes using spray paint. Mounted in the system, the membranes were stretched by manually inputting step values into the stepper motor. Images were taken via digital camera every 100 steps. The Digital Image Correlation (DIC) software GOM-Correlate was used to map the strain values on the membrane surface.

RESULTS

Bioreactor Design: In the assembled bioreactor, stretch and flow were applied at experimental rates without leakage or mechanical failure. Cells were cultured in the standalone culture module which was then able to be integrated into the stretch/flow system. The viewing ports included in the culture module allowed phase contrast images to be taken on an inverted microscope without disrupting the cells or unsealing the culture area (Fig. 2).

Figure 2: (Left) Culture module being imaged on inverted microscope. (Right) Phase contrast images of 3T3 fibroblasts imaged in the culture module

LEC Attachment Studies: Significantly more LEC were attached to the fibronectin-treated membranes than PDL after 72 hr. Fibronectin on silicone was the most effective treatment observed, providing attachment equal to or better than that seen on gelatin-treated glass controls. On silicone membranes stretched to 20%, there was a significant decrease in number of cells attached after 24 hours, but the decrease was not significant for a membrane exposed to FSS before stretching (Fig. 3, Left). Qualitative assessment of morphology suggested that morphology changed less after stretching for pre-stressed cells. In the FSS study, LEC-seeded membranes showed no significant decrease in number of cells attached after 16 hr at 5 dynes/cm² steady FSS (Fig. 3, Right).

Figure 3: (Left) LEC counted before and after dynamic stretch. (Right) Cell count before and after steady FSS.

Strain Measurement: Green Strain in the direction of stretch was averaged over the membrane cell culture region of interest (Fig. 4, error bars \pm SD). Within the range of movement of the motor, this reached 30-40% strain. A linear model assuming 0 strain at 0 motor steps found a slope of 3.74×10^{-5} strain units per motor step, with a correlation coefficient (R^2) of 0.94.

Figure 4: Steps vs. mean Green strain in the silicone membrane.

DISCUSSION

We have developed a custom bioreactor designed for novel in vitro studies with simultaneous stretching and FSS applied to LEC. Strain measurements on the membrane in the device indicate average strain values similar to those that could plausibly be encountered in vivo, with a highly linear relationship between motor movement and membrane strain. FSS levels on the cells cannot be directly measured, but can be calculated via CFD or analytically given the flow rate and various assumptions. However, validation of the FSS will require more future work, such as demonstrating the elicitation of known shear stress responses in the LEC (e.g. altered morphology and mRNA expression).

Preliminary results indicate that LEC can be cultured on the flexible silicone membranes to be used in future experiments, and remain attached under conditions of fluid shear stress and dynamic strain. Fibronectin has proven to be a useful substrate to facilitate cell attachment to the silicone. It appears attachment during a stretching experiment can be encouraged through application of FSS during culture as a pre-stress. Additionally, future validation will include Live/Dead analysis of cells cultured in the bioreactor.

The work presented here represents a proof of concept of the bioreactor, with the goal of facilitating experiments which will combine flow and stretch. By studying LEC response in a controlled environment to FSS and stretching, we aim to investigate how these forces and the LEC affect the mechanoregulation of intrinsic lymphatic pumping.

INTRODUCTION

Complications such as delayed cerebral ischemia, vasospasm and hydrocephalus account for the poor prognosis and death of many patients following subarachnoid hemorrhage (SAH)[1]. Primarily caused by ruptured aneurysms and trauma, SAH releases blood into the cerebrospinal fluid (CSF) exposing the surrounding tissue to inflammatory clotting byproducts[2]. Removal of blood via lumbar drain has been shown to positively impact clinical outcomes and the rapid removal of blood from the CSF is the target of a new device aimed at improving patient outcomes. The presented work outlines the assembly and testing of an in vitro platform (**Figure 1a**) modeling active clearance of SAH using a dual lumen catheter-based CSF Filtration device[3][4] (NeurapheresisTM System; Minnetronix Neuro, St. Paul, MN). This device introduces a flow loop aimed at improving particle clearance from the CSF. The resultant model allows parametric testing of therapies and devices such as Neurapheresis therapy that would otherwise be prohibitively difficult and costly to perform in vivo. Additionally, the in vitro model provides known boundary conditions that allow validation of computational analogs for iterative optimization schemes.

METHODS

A complete geometry of the craniospinal CSF system was constructed from our previously published spinal anatomy[5] and segmentation of additional high-resolution subject specific magnetic resonance imaging (MRI) of the complete cranial volume (**Figure 1b** and **c**). The highly complex geometry of cortical surface and ventricular CSF system was smoothed and simplified such that total cranial CSF volume remained congruent with the original model. This was achieved by offsetting the cranial arachnoid and pial surfaces by a uniform gap of ~2.0 mm. The falx cerebri and tentorium cerebelli were modeled as impermeable divisions between the left and right hemisphere as well as the cerebral and cerebellar compartments respectively. Additional geometry for access and flow ports was also added. Final digital geometry was submitted for stereolithographic 3D printing with a layer and in-plane resolution of 127 μm and 500 μm respectively for the cranial volume and 127 μm and 250 μm in the spinal column (**Figure 1**). The caudal end of the model was connected to a custom-built CSF flow pump imparting a waveform based on in vivo CSF flow waveform measured at C2/C3 via phase-contrast MRI (**Figure 2b**). The dual lumen neurapheresis catheter was inserted through an access port such that aspiration and return flow occurred at L2/L3 and T2/T3 respectively (**Figure 1d**). An aqueous solution of fluorescein sodium (15 μM) was used to fill the model initially and represented a uniform distribution of blood. In the case of Neurapheresis therapy, flowrates for aspiration of the fluorescein solution and return of clean deionized water (DIH_2O)

were set at 2.0 ml/min and 1.8 ml/min, respectively. A net volume of 0.2 ml/min was discarded, per design, by the system and replaced by an equal flowrate of DIH_2O into the lateral ventricles to maintain a constant system volume. For comparison, a lumbar drain was simulated with an aspiration rate of 0.2 ml/min at L2/L3 with ventricular production of DIH_2O at 0.2 ml/min. All experiments were conducted with the model at 30 degrees from horizontal. Time-lapse imaging was collected, and digital image subtraction of maximum and minimum background intensity images were applied to normalize the data and obtain spatial-temporal fluorescein concentration (**Figure 2a**).

Figure 1: (a) 3D printed Cranial CSF phantom with upper arachnoid shell removed showing cortical surface. (b) Digital reconstruction of the complete CSF system from MRI. (c) Cervical spine detail showing 3D printed nerve roots included in the spinal model. (d) T9 looking caudally, catheter insertion was posterior to the spinal cord.

RESULTS

The final model included realistic spinal nerve root detail and a subject specific ventricular system including the lateral, third and fourth ventricles, sylvian cisterns, cisterna magna, pontine cistern as well as foramen Monroe, Magendie, Luschka and Sylvian aqueduct. Final cranial and spinal volumes were 215.0 ml and 97.0 ml, respectively with a total CSF system volume of 312.0 ml. Spatial-temporal tracer concentration revealed Neurapheresis therapy to dramatically decreased tracer concentration compared to lumbar drain (**Figure 3**). The difference in concentration decrease was strongest within the upper thoracic spine. At 24 hours, tracer concentration 20 cm below the foramen magnum (FM) had decreased to 1.5% for Neurapheresis therapy and 8.5% for lumbar drain from the initial uniform distribution of 10%.

Figure 2: Schematic of the in vitro system. (a) CSF with tracer was removed at L2 and clean water returned at T2 and in the lateral ventricles. (b) Oscillatory CSF flow was delivered by a custom-built pump programmed with an idealized waveform measured with phase-contrast MRI at C2/C3.

DISCUSSION

The developed anthropomorphic in vitro model and imaging system allowed parametric evaluation of CSF tracer clearance for a subject specific geometry and physiologic conditions. In comparison to lumbar drain, Neurapheresis therapy at the flow rate analyzed increased tracer clearance to a greater degree at all time points after ~10 minutes (**Figure 3**). These changes were most pronounced within the dual-lumen catheter flow-loop region and also extended to the cortical subarachnoid space. Distribution of tracer concentration was relatively uniform around the spinal cord for the duration of the experiment. CSF production stemming from the 4th ventricle outlets decreased local tracer concentration near that region (cisterna magna).

Several anatomic simplifications were necessary in the cranial model due to limitations in 3D printing capabilities and MR image

resolution. These included cortical and ventricular surface smoothing and a rigid CSF space geometry (non-compliant) that resulted in a constant CSF flow rate throughout the model. CSF pulse was assumed to be cardiac related only with no impact from respiration. Digital imaging was obtained as a projection of the model (2D). Thus, it was not possible to obtain the exact 3D spatial distribution of tracer concentration over time. Lastly, CSF production, aspiration, and return rates resulted in a total CSF volume drift of <20 mL over the 24-hour period (<6%).

Figure 3: Time-lapse photography was used to track spatial temporal tracer distribution. (a) Experiment conducted with neurapheresis therapy set to an aspiration rate of 2 ml/min, return rate of 1.8 ml/min, and ventricular CSF production rate of 0.2 ml/min. (b) Experiment conducted with a lumbar drain rate of 0.2 ml/min and ventricular production of 0.2 ml/min.

INTRODUCTION

Subarachnoid hemorrhage (SAH) is a severe and often-fatal event [1] in which blood is released into the cerebrospinal fluid (CSF) due to intracranial insult, ruptured intracranial aneurysm, and/or other head trauma. It has been hypothesized that early and rapid filtration of blood and blood breakdown byproducts (e.g., hemoglobin and other inflammatory mediators) post-SAH may reduce the incidence of stroke, cerebral vasospasm [2] and hydrocephalus, and shorten hospital stay. A computational model of CSF filtration could help understand blood clearance from the CSF system. The present study objective was to formulate such a model to evaluate the Neurapheresis™ System (Minnetronix Neuro, St. Paul, MN), which consists of a dual-lumen intrathecal catheter, a filtration assembly, and a controller (Figure 1a) [3] designed to accelerate blood clearance from the subarachnoid space. In brief, Neurapheresis therapy involves aspiration of CSF from the lumbar spinal subarachnoid space (SSS), filtration of blood and/or other pathogens specific to the malady, and then return of filtered CSF to the SSS at the thoracic spine, via redundant fenestrations (to avoid clogging or blockages) in the dual-lumen catheter. The impact of the Neurapheresis system on CSF flow velocities, steady-streaming, and subarachnoid blood clearance was investigated by comparing it to a case with lumbar drain only.

METHODS

A multiphase computational fluid dynamic (CFD) model of the SSS was built using ANSYS Fluent 19.1 (ANSYS Inc., version 19.1, Canonsburg, PA, USA). Model geometry was defined by our previously developed anatomically realistic open-source 3D intrathecal space [4-6]. A dual-lumen catheter geometry was added to the posterior SSS at the T2-L2 level and positioned at the midline (Figure 1b). The final computational mesh comprised 14.8 M cells. Flow boundary conditions

Figure 1: (a) Schematic of the Neurapheresis system catheter. (b) Overview of 3D CFD model. (b1-b4) Magnified view of the Neurapheresis catheter return and aspiration ports, surface mesh, and flow direction. (c) Subject-specific CSF flow along the SSS.

reproduced subject-specific non-uniform CSF flow along the spine (Figure 1c) by imposing non-uniform dura deformation [4, 5]. CSF was considered to be incompressible with a density of 993.8 kg/m³ and Newtonian with a viscosity of 0.693 mPa·s. Velocity results were obtained for the second flow cycle with a time-step size of 0.01 s (total cardiac cycle = 0.85 s) [4]. CSF flow was quantified in terms of axial distribution of Reynolds number and CSF velocity contours. To visualize steady-streaming along the spinal axis due to convective

acceleration of oscillatory flow within an eccentric annulus, the cyclic mean sagittal velocity, $U_{z\text{-mean}}$, at each node was calculated. This steady-streaming velocity field [7] was then held constant (“frozen flow field”) to compute hemorrhage clearance. Blood was modeled as a passive species advected in the bulk fluid phase (CSF). An initial uniform blood concentration of 10% was assumed. Neurapheresis system aspiration flow was set at 2.0 ml/min and return to 1.8 ml/min, for retentate of 0.2 ml/min (**Figure 1a**). Simulated blood concentration was plotted spatially and temporally at multiple spinal levels over 24 hours for Neurapheresis therapy and a lumbar drain with 0.2 ml/min CSF removal.

Figure 2: (a) Reynolds number distribution computed along the spine. (b) Sagittal visualization of cyclic mean velocity, $U_{z\text{-mean}}$, and (c) Sagittal visualization of CSF velocity magnitude profiles. (c1-c2) Magnified coronal view of the return and aspiration ports.

RESULTS

Maximum Re was 180 and located within the cervical spine (**Figure 2a**). The sagittal $U_{z\text{-mean}}$ velocity profiles showed a region of caudally directed (\downarrow) steady-streaming in the posterior SSS in the middle thoracic spine and in the anterior SSS in the cervical spine (**Figure 2b**). Average steady-streaming velocity for Neurapheresis therapy and lumbar drain was 0.19 and 0.09 (mm/s), respectively. Visualization of unsteady CSF velocity contours in the sagittal plane showed that peak CSF velocities occurred in the cervical spine (**Figure 2c**). CSF velocity profiles near the aspiration and return ports showed that most of the flow into and out of the domain originated from the first two holes at the return and the aspiration port (**Figure 2c1-2**).

Blood concentration contours demonstrated that the lumbar and thoracic SSS were largely cleared of blood after 24 hours of Neurapheresis therapy (**Figure 3a-b**). The average blood concentration plots showed relatively rapid removal of blood from the thoracic SSS after 1 hr of filtration (**Figure 3b**). 24 hours after Neurapheresis therapy, less than 10% of the initial blood concentration remained in the lumbar and thoracic spine and more than 70% was cleared from the cervical spine (**Figure 3c**). In comparison, lumbar drain had a much

lower impact on blood concentration reduction. After 24-hours of lumbar drain, blood concentration in the thoracic spine decreased to ~7% compared to <1% under neurapheresis therapy (**Figure 3c**).

DISCUSSION

Neurapheresis therapy was found to have little impact on CSF velocities in comparison to normal cardiac-induced physiologic CSF movement. Therefore, it is not expected that these alterations to CSF velocities would, on their own, have ramifications to the normal physiology. Previous research has shown that peak cardiac-induced CSF velocities in healthy people range from 2-4 cm/s within the intrathecal space [8]. Our findings show that Neurapheresis therapy-induced CSF velocities ($U_{z\text{-mean}}$) do not exceed 0.08 cm/s for Neurapheresis flow of 2.0 ml/min (**Figure 2**).

The Neurapheresis therapy drastically reduced blood concentration within the intrathecal space within a relatively short period of time in comparison to a lumbar drain with a typical CSF removal rate of 0.2 ml/min. The reduction in blood concentration was most evident within the flow-loop region introduced by the dual-lumen catheter.

TOWARDS PHYSIOLOGICALLY-RELEVANT VOCAL FOLD MODELS FOR VOICED-SPEECH INVESTIGATIONS

Mohsen Motie-Shirazi (1), Natalie I. Jagelski (1), Byron D. Erath (1)

(1) Department of Mechanical and Aeronautical Engineering

INTRODUCTION

Human voice is produced as air is driven from the lungs through the larynx, producing self-sustained oscillation of the vocal folds (VFs). Oscillations are achieved due to a combination of geometry and material properties of the VF structure. Due to their relative inaccessibility, in vivo VF investigations focused on the diagnosis and remediation of VF pathologies are severely limited. As such, synthetic models that replicate the anatomical, aerodynamic and acoustic properties of voice production show significant promise as VF surrogates.

Initial attempts at reproducing synthetic VF oscillations were achieved with simplistic single-layer, homogeneous, isotropic models that utilized a generalized VF geometry;¹ a significant simplification of the complex layered structure of the VFs that is comprised of the thyroarytenoid muscle, lamina propria, and epithelium.² Subsequent attempts at developing synthetic VF models have produced more realistic VF dynamics through the implementation of multi-layered approaches.³ Nevertheless, shortcomings that prevent broader deployment of these models still exist, including; (1) unnaturally high onset pressure (the minimum pressure at which the VFs oscillate), (2) abnormally low closed quotient (CQ) (the ratio of closed phase to oscillation period), and (3) the lack of a robust mucosal wave, which is a hallmark of healthy and normal vocal fold oscillations.

The objective of this work is to revisit the underlying assumptions related to synthetic VF model development to develop more physiological VF surrogates that address current shortcomings and, as such, provide a viable alternative platform for performing scientific investigations of voiced speech.

METHODS

The VFs are commonly modeled as a three-layer structure consisting of a body, cover, and epithelium. To overcome existing

model shortcomings, histological images of the VFs² (Fig.1) were revisited to identify key features that have been neglected in prior modeling attempts. These include: (1) an undercut on the superior surface, (2) inclusion of a layer of adipose tissue (AT) that fills the paraglottic space⁴ (the space between VF and thyroid cartilage), (3) a ligament membrane within the VF (the conus elasticus), and (4) a longer medial contact length. Including the undercut is expected to reduce the onset pressure as the structure will have less support under the superior edge, while also creating a more pronounced divergent state that leads to a better mucosal wave. AT provides a more flexible substrate for the VF and is also expected to lower the onset pressure due to the added mass, but may also lead to increased abnormal motion in the inferior-superior direction. However, the inclusion of a thin and stiff conus elasticus layer should counteract this unwanted motion by increasing the stiffness in the inferior-superior direction.⁵ In addition, extending the medial length should result in better VF closure and improve both the CQ and the robustness of the mucosal wave.

The reported dimensions for an excised human VF are the basis for the peripheral geometry in the anterior-posterior cross section of the newly-developed models used in this study (Fig.2).⁵ Furthermore, by

Figure 1: Coronal section of the vocal folds showing the Undercut (UC), Medial Length (ML), Conus elasticus (CE), and Paraglottic space (PS)

Figure 2: Vocal fold shape and geometry a) Anterior-Posterior cross section, b) 3D view

using histological images, the geometry and dimensions of the inner layers are estimated. As can be seen in Fig.2(a), the newly proposed model consists of 5 layers: (1) an AT layer that separates the VF from the thyroid cartilage, (2) a body layer, (3) the conus elasticus, (4) the cover layer, and (5) the epithelium.

Synthetic models are manufactured using Smooth-OnEcoflex 00-30™ and Dragon Skin™ 10 silicone rubber and adding different ratios of silicone thinner to create the desired stiffness. A mold is created for each layer and the models are fabricated by sequentially adding and curing each layer of silicone. The modulus of elasticity for each silicone ratio is found by performing dynamic mechanical analysis, to ensure physiological relevance. Table.1 lists the range of physiological values for the corresponding in vivo VF tissues layers.

Table 1: Model and physiological stiffness values for the different layers of the vocal folds

Layer	Physiological Stiffness Range (kPa)
Adipose Tissue	1 – 10
Body	7 – 30
Cover	2 – 8

The model variables (see Fig. 2) were parametrically varied to assess their impact on the model VF dynamics; namely, (1) adipose tissue thickness (A), (2) adipose tissue stiffness, (3) superior surface undercut radius (R), (4), length of the medial surface (M), (5) thickness of the cover (T), (6) anterior-posterior length (L), and (7) the amount of static contact pressure along the medial surface.

The self-oscillatory dynamics of each model is tested in a laryngeal flow facility. The facility consists of a large plenum supplied by regulated, compressed air, with a 15 cm long, 2.89 cm² cross-section area exiting it, which represents the lung volume and tracheal airway, respectively. Synthetic VFs are mounted into two opposing brackets, and positioned such that the medial surfaces are in contact. The amount of compression between the models can be adjusted, and is recorded. In this manner, air passes from the lung chamber, through the tracheal tube, and then through the VF models, driving the models into self-oscillation. The mean flow rate is measured by a Dwyer flow meter that is positioned before the plenum. A Dwyer manometer, which is connected to static pressure tap, measures the mean subglottal pressure, while the unsteady pressure is recorded with a Kulite XCS-063 pressure transducer. A Photron high-speed camera records the VF vibration at frame rates of 20 kHz.

For each test, the kinematics of the model VF oscillations are acquired from the high-speed video. The glottal area (the space between the VFs) is determined by defining a threshold filter such that the VF boundaries are detected. A known reference length in the images, the VF length, is used to calibrate the images. By computing the glottal area, it is possible to then compute the CQ as well as the lag between the inferior and superior edges of the VFs, which provides a benchmark for

evaluating the robustness of the mucosal wave. In addition to the video acquisitions, the onset pressure, flow rate, and fundamental oscillation frequency are recorded and compared to physiological measures. The experimental procedure includes changing one parameter each time and studying its effect on the VF motion to achieve a model that best conforms to the aforementioned physiological characteristics.

RESULTS

For each investigation, the medial compression pressure was held constant by using shims between the mounting brackets that hold the VF models. Adding the AT layer reduced the onset pressure, which is one of the major shortcomings of synthetic VF models, with optimal results found at the lower limit of AT stiffness. At this lower limit of AT stiffness, the effect of the superior undercut was studied by changing its radius. The undercut had a significant effect on reducing the onset pressure and creating a more pronounced convergent-divergent motion (increase inferior-superior phase lag) in the mucosal wave. For short lengths of the medial VF surface, complete closure of the VFs was rarely achieved, and the oscillation mode resembled that of falsetto, as opposed to normal, or chest-register motion. Increasing the length increased the phase lag between the inferior and superior margins of the VFs, which enhanced the mucosal wave quality, but increased the onset pressure as well. Hence, there is a trade-off between achieving a lower onset pressure and increased convergent-divergent glottal motion, indicative of a more pronounced mucosal wave. For this reason, the shortest medial length that lies within the physiological range was chosen for subsequent investigations. With the cross sectional geometry specified, the effect of thickness and stiffness of the various tissue layers was investigated, where it was found that the stiffness of the cover layer had the greatest influence on the frequency of oscillation, onset pressure, and CQ. Finally, the role of medial compression was studied. Low medial compression resulted in the inability to achieve good VF closure and a healthy mucosal wave, while excessively high compression deformed the VF and produced irregular oscillations.

DISCUSSION AND CONCLUSIONS

It was shown that the shape and material properties of each layer play an important role in synthetic VF vibration dynamics. In this study, the geometry, stiffness, and medial compression of synthetic VF models were methodically improved to generate a physiologically-relevant surrogate for VF investigations. The synthetic model was shown to generate a more robust mucosal wave with a CQ that is similar to physiological measures while keeping the glottal area, fundamental frequency, and onset pressure within an acceptable range.

Synthetic VF model investigations are highly repeatable and provide a low-cost approach. Moreover, the ability to tune them to match particular phonatory behaviors (e.g. model pathologies) is highly attractive. The new model proposed in this study was found to be a valuable tool for experimental VF modeling approaches that show very good agreement with generalized clinical measures of aerodynamic and kinematic VF performance.

INTRODUCTION

Chiari malformation type 1 (CMI) is a structural abnormality of cerebellum at the craniospinal junction, the part of brain which is primarily responsible for motor control. This malformation was radiologically described in 1985 by Aboulezz et al.[1] as a greater than 5 mm caudal displacement of the cerebellar tonsils below the foramen magnum (FM). However, cerebellar tonsillar position (CTP) does not always correlate with the symptom severity. The conundrum arises because some individuals who meet the MR imaging criteria are asymptomatic, while individuals with less than 5 mm CTP have CMI symptoms[2]. Hence, researchers have been seeking different measurement parameters to quantify CMI severity.

An alternative method to quantify the impact of CTP is longitudinal impedance (LI), a scalar parameter used to quantify impedance or fluid flow blockage per unit length of a conduit such as the spinal canal. In this study we used LI as a parameter to determine the cerebrospinal fluid (CSF) flow blockage at the foramen magnum (FM). CMI patients report different types of symptoms and these symptoms have been shown to be related to the percentage change in CSF stroke volume [3]. We hypothesized that LI will also be different for specific and nonspecific symptomatic CMI patients.

METHODS

Thirteen symptomatic CMI patients with a mean age of 38.6 ± 6.7 years and CTP greater than 5 mm were studied. Two board-certified neurosurgeons with more than fifteen years of experience in Chiari developed a grading scale for symptom severity and divided patients into two groups blinded to MR images: 1) Nonspecific CMI (NS-CMI) (5/13) – CMI patients with nonspecific symptoms like non-coughing-related or mild occasional cough-related headache, neck pain, dizziness, paresthesia, and/or dysphagia. 2) Specific-CMI (S-CMI) (8/13) – CMI

patients with symptoms like severe cough-related headache, myelopathy, syringomyelia, and muscle atrophy, as described in a previous study [3].

The cervical spine of each patient was imaged with 3D T2-weighted MR imaging on a 3T scanner [Achieva; Philips Healthcare, Best, the Netherlands]. A semi-automatic active contour segmentation aka “Snake”[4] was used to segment the inner and outer boundaries of cervical spinal subarachnoid space (SAS) between FM and 6 cm caudal to FM using ITK-SNAP [UPenn, PA]. The boundaries were smoothed and reconstructed by two commercial software MeshLab [ISTI-CNR, Pisa, Italy] and Maya 2018 [Autodesk Inc, San Rafael, CA] and both ends (FM & caudal end) of the 3D model was extruded 4 cm to allow the flow to be nearly fully developed inside the model.

An unstructured tetrahedral mesh was created using two different Tetra/Mixed mesh methods (Robust {Octree} & Quick {Delaunay}) for computational fluid dynamics (CFD) using ICEM 18.2 [Ansys Inc, Canonsburg, PA]. Finite volume solver software Fluent [Ansys Inc, Canonsburg, PA] was utilized to run the fluid simulation, modelling CSF as water at 37 °C, 1.0 g/cm³, and $\mu = 0.001$ P. The 3D segmented model outer and inner surfaces were assumed to be a rigid wall with no slip condition applied. The caudal end of the model was treated as the INLET with an unsteady velocity inlet boundary condition (IBC), which represented cardiac cycle and CSF flow. The cranial end was treated as the OUTLET with a constant pressure boundary condition (CPBC). Each case was evaluated using two cycles to avoid cycle independency. Figure 1 shows the 3D model construction steps of the cervical spinal SAS.

The unsteady average pressure change with respect to time was evaluated as the difference between pressure at FM and 2.5 cm below the FM. The resulting pressure drop waveform and the flow waveform were used to calculate LI at each waveform harmonic for all subjects.

Figure 1: 3D model construction steps of cervical spinal SAS (a1-MR Image, a2-3D segmented model, a3-3D model with extensions)

Each frequency component of the pressure and flow waveforms were extracted using fast Fourier transform. Next, LI was integrated from 1 to 8 Hz to obtain a characteristic value to compare each case (Equation 1). Statistical significance was evaluated as $p < 0.05$.

$$LI = \int_{1\text{ Hz}}^{8\text{ Hz}} \left| \frac{fft(\Delta P)}{fft(Q)} \right| df \quad (1)$$

RESULTS

Mean average values of integrated LI and CTP for S-CMI and NS-CMI subjects are listed in Table 1.

Table 1: Mean Average Integrated LI and CTP

	S-CMI	NS-CMI
Integrated LI (dynes/cm⁵)	1056.7 ± 599.2	645.7 ± 484.6
Average CTP (mm)	17.5 ± 7.4	12.2 ± 6.2

Although statistical analysis revealed no significant difference between integrated LI magnitude for S-CMI and NS-CMI patients, the mean average values of S-CMI patients was 64% larger than NS-CMI patients (1056.7 ± 599.2 and 645.7 ± 484.6, $p = 0.2$ respectively).

Integrated LI is plotted as a function of CTP in Figure 2. NS-CMI patients have lower average integrated LI compared to S-CMI, and integrated LI for NS-CMI increased in a linear fashion with respect to CTP ($r = 0.99$, $p = 0.001$). However, the integrated LI for S-CMI patients is scattered and is not significantly correlated with CTP ($r = -0.11$, $p = 0.80$).

Figure 2: Integrated LI as a function of CTP

DISCUSSION

In this study, we evaluated integrated LI for two groups of symptomatic CMI patients. We found out that the average integrated LI for CMI patients with specific symptoms and objective finding, that is more severe disease, was 64% larger than those with nonspecific symptoms. However, it was not statistically significant. This might be due to small sample size and large standard deviation. In addition, Figure 2 shows an exception where the NS-CMI patient with CTP of 24 mm had an integrated LI magnitude of 1470 dyne/cm⁵, which is larger than the average integrated LI for S-CMI.

Furthermore, Figure 2 implies that larger CTP does not always follow the trend of greater resistance to flow. For example, the largest integrated LI (2323 dyne/cm⁵) was measured for a S-CMI patient, who had a CTP of 10 mm. On the other hand, two S-CMI patients with the largest CTP of 27 mm had almost 3 times smaller integrated LI magnitudes (973 and 799 dyne/cm⁵). Therefore, it indicates that the CTP may be a poor indicator of CSF flow impedance, which was also shown by Shaffer et al.[5]. This is expected since Bezuidenhout et al.[3] found no statistically significant relationship between CMI severity and anatomical measurements.

Several limitations were present in our study. First, the small sample size restricts us from recommending our method as an objective evaluation for disease severity in CMI until further patient data are collected in a larger study. However, this small group demonstrated statistically different LI values for the two groups (S-CMI and NS-CMI patients) and shows potential as a metric to assess CMI patients. Second, due to small sample size, the patients were only divided into two groups as was done by a previous study[3]. However, due to a wide range of symptoms and clinical findings, it would be better to divide the patients into more groups based on symptoms. If this methodology is to be used in future studies, these limitations must be considered and improved.

In conclusion, this study shows that LI appears to be a useful geometric parameter in quantifying CMI symptom severity by comparing S-CMI and NS-CMI patients. While these results support the prior studies that CTP may not be related neurological symptoms[3,5], these results also show that CTP does not necessarily have a linear relationship with CSF flow blockage. A larger and more controlled study population is needed to fully understand the clinical relevance, if any, of LI.

INTRODUCTION

Shear-thinning hydrogels are interesting materials because they can be used as injectable cellular and drug delivery platforms. Their unique chemistry often produces materials that self-heal and re-gel after removal of shear stress. In addition to being used to deliver biological molecules and cells within a bulk gel via injection [1–3], shear-thinning droplets have been proposed to be used in tissue engineering and multi-stage drug delivery applications [4–6].

Despite the fact that there are many microfluidic droplet studies and a significant focus on shear-thinning hydrogels in biological systems [7], the fluid dynamical mechanisms of non-Newtonian shear-thinning droplet formation have not been fully determined. Davidson and Cooper-white [8] studied the dynamics of shear-thinning pendant drop formation in air from a circular orifice. Qiue et al. [9] numerically studied formation of Newtonian droplets from an aperture in the continuous phase of a shear-thinning fluid. Ren et al. [10] numerically studied Newtonian droplet generation in a continuous phase of shear-thinning fluid in a co-flow device. These studies concluded that the viscosity of a shear-thinning fluid has a significant impact on the control of droplet size. Additional studies innovated on the computational methods used to study droplet formation in T-junctions using the Lattice Boltzmann Method (LBM) [11,12].

Whereas, much progress has been made in understanding droplet formation in T-junctions, there is a significant lack of understanding on the mechanisms of droplet formation of shear-thinning fluids in flow-focusing geometries. The flow focusing droplet generators are used to generate smaller droplets with higher control of size and frequency of droplet generation compared to two other passive methods of droplet generation including co-flows and cross-flow (T-junction) [13]. Furthermore, most of the investigations to date have examined droplet formation in systems with a non-Newtonian continuous phase rather

than a shear-thinning dispersed phase. In the current study, we focus on the formation of shear-thinning droplets in a Newtonian continuous phase using a passive flow-focusing droplet generator. We modeled a shear-thinning hydrogel with a Power-law model and studied the effects of flow behavior index, flow consistency index and interfacial tension on the mechanism and mode of droplet generation.

METHODS

The VoF (Volume of Fluid) in ANSYS FLUENT 19.0 was used for simulation of multiphase flow of shear-thinning flow-focusing droplet generator shown in Fig. 1. Droplets were generated in silico using a flow focusing geometry and a Newtonian continuous phase (HFE-7500 oil) and non-Newtonian dispersed phase (shear-thinning hydrogel), Figure 1.

Figure 1: Flow focusing droplet generator

A Power-law model (equation 1) was used to describe the non-Newtonian shear-thinning hydrogel.

$$\tau = K(\dot{\gamma})^n \quad (1)$$

Where τ , $\dot{\gamma}$, K and n are shear stress, shear rate, flow consistency and flow behavior indices, respectively. The flow behavior index (n), is less than 1 for a shear-thinning fluid.

The continuum surface force (CSF) model developed by Brackbill et al. [14] was used to model the interfacial tension (σ). The interfacial

tension term was added as a source term to the momentum equation (equation 2).

$$\bar{F}_{Vol} = \sigma \left(\frac{\rho_d \kappa_d \nabla \alpha_d}{1/2 (\rho_d + \rho_c)} \right) \quad (2)$$

Where α_d , ρ_d , ρ_c are the volume fraction of dispersed phase, density of dispersed phase and density of continuous phase, respectively. The surface curvature, κ_d , of the droplet defined as divergence of unit normal \bar{n}_d , given by equation 3.

$$\kappa_d = \nabla \cdot (\bar{n}_d) \quad (3)$$

Wall adhesion effects were considered by adjusting the surface curvature near the wall using Youngs method [15]. The boundary value for the inlets of continuous and dispersed phases were constant velocity and outflow. It is assumed that there is a no-slip condition at the walls.

RESULTS

We studied the effects of flow behavior index, flow consistency index and interfacial tension on the mechanism and mode of droplet generation (Table 1, 2 and 3, respectively). All simulation variables are held constant across these in silico studies except the parameter that is studied.

Table 1: Effect of n ($K=0.01$, $\sigma=0.03$ N/m)

n	Contour of multiphase flow	n	Contour of multiphase flow
0.75		0.85	
0.8		0.9	

Table 2: Effect of K ($n=0.9$, $\sigma=0.03$ N/m)

K	Contour of multiphase flow	K	Contour of multiphase flow
0.005		0.015	
0.01		0.02	

Table 3: Effect of interfacial tension ($K=0.01$, $n=0.9$)

σ (N/m)	Contour of multiphase flow	σ (N/m)	Contour of multiphase flow
0.02		0.04	
0.03		0.05	

DISCUSSION

We investigated the role of the flow behavior index (n), the flow consistency index (K) and the role of interfacial tension (σ) on droplet formation of a shear-thinning fluid in computational multiphase fluid dynamics studies. It is observable from Table 1 that at a fixed operating condition, the droplet generation mode changes from the bimodal (pairs of droplets with different sizes for $n = 0.75$ and 0.8) to monodispersed ($n = 0.85$ and 0.9) with increasing flow behavior index (n). Increasing this parameter also decreases droplet size; however, the mechanism of droplet formation is insensitive to n as for all values tested, a dripping

mode of droplet formation was observed. In contrast, when the flow consistency index was varied, significant changes to the droplet generation mechanism and size polydispersity were observed. At low K , droplets are formed via dripping in a monodisperse size range, but at larger K , droplet generation is unstable, shifting to a polydisperse population owing to a change in droplet formation mechanism due to a shift into a jetting mode. Likewise, droplet size decreases with increasing K .

Alterations in the interfacial surface tension, σ , in our model have primary effects on the jetting to dripping transition and thus the overall polydispersity and mode (e.g. bimodal, monodisperse, etc). Low σ results in jetting of the shear-thinning material into the continuous oil phase with minimal droplets formed. When the interfacial tension is increased to the 0.03 N/m, then the droplet generation mechanism and mode are changed to dripping and monodispersed. Interestingly, when the interfacial tension is increased (0.04 N/m), the droplet generation mode is changed to dripping-bi-modal. Further increases in σ (0.05 N/m), result in occasional plug flow of the droplet within the channel in a non-periodic manner due to an instability in droplet generation due to a consequent pressure drop. The droplet generation is shown to be very sensitive to the interfacial tension. Whereas we haven't included the addition of surfactants as are commonly used in these systems, these data do highlight the non-intuitive results of including surfactants in shear-thinning dispersed phase systems to prevent coalescence and aggregation of dispersed phase droplets. Surfactant use, which lowers interfacial surface tension, should be carefully used as lowering σ , can result in an unstable dripping-to-jetting transition and a polydispersed droplet population in shear-thinning droplet generators.

INTRODUCTION

The current literature associates bending failure of a long bone with butterfly fracture, in which fracture initiates transversely at the tensile side of a bent bone and branches in a Y-shape as it propagates toward the compression side, resulting in a wedge fragment known as a tension wedge [1]. Thus, the orientation of the resulting wedge fragment is often considered diagnostic of impact direction [2]. However, numerous experimental studies indicate that bending of a long bone does not always produce butterfly fracture, and the produced wedge fragments also vary in tension or compression. Martens et al. [3] report that 4-point bending of posterior-loaded human femora produces compression wedge fracture in 85% specimens and oblique fracture in 15% specimens. In 3-point bending experiments using ovine femora, Reber and Simmons [4] report butterfly fractures in approximately half the sample, in which 60% are tension wedges and 40% are compression wedges. Recently, a study from our laboratory using 3-point bending on unembalmed human femora shows the complete fracture types being transverse, oblique, and comminuted fractures, with patterns of the incomplete fracture being comparable to a tension wedge [5].

While long bone fractures are a common injury in adults as well as in the pediatric population and the rate of loading has also been shown to significantly influence fracture morphology [6], the effects of age and rate of loading on failure patterns of long bone fracture due to bending remain largely unknown. In addition, the application of the standard 3-point bending configuration commonly used in studies investigating bending failure of a long bone may put restrictions on the evaluation of fracture data due to potential local stress concentrations that may form under the central loading point, decreasing the overall bending strength of the bone [3].

The purpose of the current study was to perform controlled, concentrated 4-point bending (similar to that of Martens et al. [3]) impact experiments on skeletally immature and mature fresh ovine femora with two different rates of loading. It was hypothesized that fracture patterns, as well as mechanical failure parameters, would be different between the two age groups and between the two rates of loading.

METHODS

Skeletally immature (1-7 days old, n=20) and mature (1-2 years old, n=20) ovine femora were collected from animals that died of natural causes in a local farm. An approved IACUC exemption was obtained for the current study. The whole femoral bone was dissected, cleaned of soft tissues, wrapped in saline-soaked gauze, and frozen at -20°C. The femoral specimens were thawed overnight at room temperature prior to testing. All tests were performed within 24 hours of thawing.

Figure 1: Experimental setup with a femur in 4-point bending.

A custom-built bending fixture was utilized to load the specimen in a servo-hydraulic testing machine (Instron, Norwood, MA). Concentrated 4-point bending, similar to that used in Martens et al. [3], was applied to specimens through a pin-supported fulcrum that uniformly loaded the asymmetric bone surface throughout failure (Figure 1). The two inner supports were set to 10% of the femoral length, while the outer supports were set to 60% of the length. All femora were loaded posteriorly, assuming no difference in fracture patterns between anterior and posterior impacts [5]. The anterior surface of the femur was rested on free-rolling pin supports.

In each age group, unpaired specimens were randomly separated into a low rate group (test in 2 Hz or 0.25 s to peak, n=10) and a high rate group (test in 10 Hz or 0.05 s to peak, n=10). After a preload of 20 N was applied for 5 s, bending impacts were performed in displacement-control, with a maximum displacement set to 5 mm. For each impact the force-displacement data were collected by a personal computer via a load cell (Interface, Scottsdale, AZ). Failure force of each specimen was documented and the slope of the force-displacement curve was defined as the bending stiffness. Following impact, bone fragments were collected and any remaining adhering soft tissues were removed using heat maceration techniques. Each specimen was subsequently reconstructed from its constituent bone fragments to allow for photographic documentation of fracture outlines. Medial and lateral views were recorded to account for potential asymmetry.

Two-way ANOVA with Tukey post hoc test in Minitab (State College, PA) was used to compare the differences in failure force and bending stiffness between the immature and mature specimens (factor one) and between low and high rates of loading (factor two), with $p < 0.05$ considered significant.

RESULTS

Force-displacement curves showed a linear response of each bone with a sudden drop in load indicating an abrupt fracture in all cases. While failure forces in the low rate tests were not statistically different from those in the high rate tests for either the immature (585.1 ± 187.7 N versus 586.8 ± 117.7 N, respectively, $p = 0.995$) or the mature bones (4376.4 ± 1169.0 N versus 3909.1 ± 1348.8 N, respectively, $p = 0.958$), it required significantly higher force to fracture the mature bone than that required to fracture the immature bone in either rate of loading ($p < 0.001$). Similarly, bending stiffness was significantly higher ($p < 0.001$) in the mature bones than that in the immature ones for either rate of loading (1892.0 ± 333.4 N/mm versus 180.2 ± 97.2 N/mm for the low rate and 1843.0 ± 692.5 N/mm versus 208.3 ± 66.6 N/mm for the high rate of loading). No statistical differences in bending stiffness were observed between the low and high rate of loading for either age group.

Upon visual inspection of the gross fracture patterns of the femora in both the medial (M) and lateral (L) views, it became clear that the fracture patterns under a concentrated 4-point bending scenario were dependent on both the age of development and the loading rate. Specifically, the immature bone produced transverse (4/10 (40% M), 8/10 (80% L)) and partial butterfly fractures (2/10 (20% M), 2/10 (20% L)) at the low loading rate (Figure 2, left), while the mature bone produced compression wedges (15/20 (75% M), 15/20 (75% L)) and oblique fractures (3/20 (15% M), 2/20 (10% L)) of the proximal third of the bone at both low and high rates of loading (Figure 2, right). Interestingly, the immature bones at the high loading rate produced variant fractures (6/10 (60% M), 6/10 (60% L)) that transitioned from a partial tension wedge to a partial compression wedge, or a combined tension and compression wedge (Figure 2, left). In mature specimens loaded at the high rate, a unique 2-tailed

compression wedge pattern was observed (3/10 (30% M), 1/10 (10% L)) (Figure 2, bottom right).

Figure 2: Typical fracture patterns in the immature (left) and mature (bottom right) bones, and oblique fractures (top right).

DISCUSSION

The results of the current study demonstrated that for the mature femora, compression wedge fracture can be generated consistently under a concentrated 4-point bending configuration, further supporting the findings of Martens et al. [3] where a compression wedge is produced in 85% adult human femora due to 4-point bending. It is therefore suggested that the traditionally accepted determination of impact direction in a long bone based on the orientation of the produced wedge fragment, i.e. tension versus compression wedge, may be questionable. The concentrated 4-point bending configuration used in the current study, in addition to being more appropriate than a 3-point bending configuration from a mechanics point of view [3], may also be more forensically relevant, as impacts involving car bumpers or even flat plates with proper dimensions might be more accurately simulated by this 4-point than the traditional 3-point loading configuration. This may also explain the variations in long bone fracture patterns observed in various experimental studies using the traditional 3-point bending configuration [4,5].

While in the current study the effect of loading rate on the mechanical failure parameters (failure force and bending stiffness) was not found to be significant, the results on fracture patterns showed that the immature femora were rate sensitive. At the low loading rate, immature femora primarily failed in transverse fractures and partial tension wedge fractures, while at the high rate of loading a combined tension and compression wedge fracture emerged in immature bones.

The current study has shown that age and rate of loading can play important roles in the ovine femoral fracture patterns. The forensic community and medicolegal professionals should take cautions in interpreting impact direction from long bone fracture patterns.

INTRODUCTION

Forensic evaluations of blunt force trauma to the human head have traditionally relied on investigator experience and comparisons with case studies, rather than on controlled experimental data. Experimental and computational head impact research typically focuses on fracture tolerance, skull force-deflection response under quasi-static and dynamic loads, and the effects of blunt head trauma on the tissues of the brain, while the patterns of cranial fracture resulting from head trauma have yet to be investigated in depth [1-3].

Recent research from our group has investigated the influence of multiple extrinsic impact variables on initiation and propagation of cranial fracture, such as impactor geometry, energy of impact, number of impacts, and location of impact [4]. While the results generally indicate that extrinsic factors play a significant role in determining the final fracture pattern, they unfortunately do not fully explain the variability between skulls. These types of studies do not account for the potential significance of the skull's intrinsic properties, i.e. skull morphology, on the resulting fracture pattern.

The objective of the current study was to investigate the comparative contribution of intrinsic skull properties, such as skull morphology, and extrinsic impact properties, such as impactor geometry, to the prediction of remote fracture site initiation. It was hypothesized that areas of remote high tensile stress would correspond to locations of remote fracture initiation observed experimentally, and that the magnitude and pattern of tensile stress contours would be affected by skull morphology.

METHODS

Thirty-three unembalmed, adult male human crania were included in this study. Twenty-four impacts were administered laterally towards the anterior/posterior center of the parietal bone,

superior to the temporoparietal suture, while nine impacts were administered superiorolaterally towards the geometric center of the parietal bone. Impacting implements included a flat 3-inch diameter implement, a flat 1-inch diameter implement, a cylindrical curved 2.5-inch diameter implement, a 2-inch diameter hemisphere implement, and a 1-inch edge length square implement. A high-speed 10,000 fps camera captured video of fracture initiation and propagation throughout each impact test.

Each specimen underwent a pre-impact high-resolution computed tomography (CT) scan (GE 750HD; 120 kVp; 125 mAs; 0.625-mm slice thickness; 0.49 mm pixels; 512x512 matrix), from which 3D finite element models of the specimens were created. Wrapping operations were performed to eliminate cancellous cavities between the interior and exterior cortical layers of the skull cranium. A thickness analysis was performed to evaluate the average thickness of each specimen in the region enclosed by the sphenoid to the coronal suture, sagittal suture, occipital suture, and the region superior to the mastoid, external auditory meatus, and zygomatic arch on the ipsilateral side of impact.

Three specimens, representing a wide range of average skull thicknesses (thin, average, and thick) were meshed using tetrahedral elements. Cortical bone material properties were assigned to the elements using a linear elastic material law. Laterally applied dynamic impacts were simulated for each specimen using the cylindrical 2.5-inch diameter, flat 3-inch diameter, and flat 1-inch diameter implements. The speed, mass, and orientation of the impacting implement with respect to the anatomical features of the skull were held constant in each simulation. The impacting mass was 6.349 kg and the impacting velocity was 6.455 m/s for all simulations. Signed von Mises stresses at maximum impactor engagement were generated and compared for each test setup to the experimental results.

Figure 1: (a) Fracture initiation during experimental impact, (b) Resulting fracture pattern after experimental impact, (c) Thickness map of specimen, (d) Impactor orientation in computational simulation, (e) Peak signed von Mises stress distribution in computational simulation.

RESULTS

Thickness analyses on all thirty-three specimens yielded a maximum average thickness of 9.6 mm, a mean average thickness of 7.0 mm (SD \pm 0.9 mm), and a minimum average thickness of 5.1 mm. The thickest specimen contained a significant defect on the contralateral side of the skull, and was excluded from being chosen for mesh model creation in favor of the second thickest specimen (8.6 mm). Specimens 16-3817, 17-4813, and 18-3930 represent the thickest, average, and thinnest computational models used in the simulation, respectively. Thickness maps of the computational models are shown in Figure 1c.

Impactor orientation and results of selected dynamic simulations are shown in Figure 1d and 1e. Red shaded areas represent regions under tensile stress, while blue shaded areas represent regions under compressive stress (Figure 1e). Peak tensile stress concentrations remote to the origin of impact on the exterior of the skull tended to occur in the area of the sphenoid near the zygoma in all specimens, independent of impacting implement. Extension of this peak tensile stress region occurred posteriorly superior to the zygomatic arch, external auditory meatus, and mastoid. The magnitude and span of stress in these regions tended to increase as the overall thickness of the skull decreased. Peak tensile stress concentrations remote to the origin of impact on the interior of the skull tended to occur in the area of the petrous ridge.

High-speed camera footage of the experimental fracture data confirmed the identified high tensile stress concentration regions on the exterior of the skull as common sites of remote fracture initiation, as shown in Figure 1a. The resulting fracture pattern for each specimen is shown in Figure 1b.

DISCUSSION

The hypothesis that localized geometric features of the skull contribute to the generation of remote peak tensile stress concentrations was confirmed. Independent of impacting implement, peak tensile stresses remote to the location of impact occurred in regions of geometric transition or discontinuity. Gross skull morphologies, such as the transition from the convex frontal, parietal, and squamous temporal bone to the concavity of the sphenozygomatic suture, the relative reduced thickness in the sphenozygomatic region, the presence of a hole in the external auditory meatus, and the transition from an area of increased thickness near the mastoid to an area of reduced thickness superior in the temporal squama, are thought to be responsible for these peak tensile stresses concentrations on the exterior of the skull. Similarly, the crease geometry of the petrous ridge is thought to be responsible for peak tensile stresses on the interior of the skull.

While the magnitude and span of the tensile stress concentrations on the exterior of the skull tended to increase as the thickness of the skull decreased, the magnitude and span of the tensile stresses on the interior of the skull did not follow this trend. The magnitude and span of the tensile stress on the petrous ridge of the thinnest specimen appeared to be smaller than those of the thickest specimen. One possible explanation for this is the geometric prominence of the petrous ridge, which appears less prominent in the thin specimen as compared to the thick specimen.

Results of these analyses indicate that, in the absence of additional fracture pattern information near the identified or suspected location of impact, impacting implement identification may be difficult to achieve given that intrinsic skull morphology tends to drive the initiation sites of remote fractures. This study identifies the likely locations of remote fracture initiation based on skull morphology, but does not guarantee fracture will occur in that location, especially if fracture initiation occurs local to the point of impact. Experimental results have demonstrated initiation and propagation of fracture from the location of impact in some cases.

Limitations of the current model include the absence of varying properties for the three-layer composition of the skull, and consideration of the subject-specific intrinsic density distribution in the CT scans. Further refinements of the computational model may be required to explain the differences in fracture patterns observed experimentally local to the point of impact due to extrinsic impactor shape properties. Failure criteria and transient response of the computational model to developing fractures are necessary to continue to model the development of fracture patterns after initiation.

ACKNOWLEDGEMENTS

The study was supported by an NIH grant 2015-DN-BX-K013 and Explico Engineering Company. The authors thank Mr. Clifford Beckett for technical assistance in the experiments.

INTRODUCTION

The available kinematic and kinetic data with respect to low speed rear-end collisions are limited to volunteer, cadaver, and anthropomorphic test device (ATD) tests. Biomechanical analyses involving these collisions can be made more robust through the consideration of the occupant's specific anthropometry, interior vehicle geometry, and occupant position. The MATHematical Dynamic Modeling (MADYMO) software suite can be utilized to conduct such subject-specific analyses. MADYMO is widely used in automotive safety, research, and forensic engineering for evaluating occupant dynamics utilizing multi-body, finite element, and computational fluid dynamic solvers.

To demonstrate the presented methods, a belted, female occupant involved in a rear-end collision while driving a 2004 Toyota Highlander was evaluated. Specifically, the collision was evaluated to determine the potential for biomechanically causing intervertebral disc herniations. Previous biomechanical studies have demonstrated that axial compression is imperative to the causation of, or significant contribution to, a traumatic disc herniation [1,2]. Therefore, the objective of the current study was to outline a methodology for conducting a subject-specific analysis of a low speed rear-end collision in the evaluation of spinal compression. It was predicted that the results from the current study would be consistent with previously published rear-end crash data.

METHODS

The Event Data Recorder (EDR) of the Toyota was imaged from the Airbag Control Module (ACM) directly through the Diagnostic Link Controller (DLC) utilizing Bosch's Crash Data Retrieval (CDR) software. One event was recovered during retrieval, and was determined to be consistent with the subject collision. The EDR

reported a maximum longitudinal change in velocity (Delta-V) of 9.0 kph (5.6 mph) with a peak acceleration of 3.5 g's over a pulse duration of approximately 120 ms (Figure 1).

Figure 1: Collision pulse downloaded from the subject vehicle

The subject driver, demonstrating her body positioning in the driver seat of the subject vehicle, was imaged using a Faro Focus 3D laser scanner. The MADYMO seat model was created using a series of ellipsoids connected by joints to geometrically match the 3D laser scan data (Figure 2). The contact stiffness characteristics and seatback joint rotational characteristics were applied based on prior data from static tests on mechanical car seats [3]. MADYMO provides ellipsoid dummy models that have the ability to be scaled to specified

anthropometry. For the subject analysis, a Hybrid III 5th percentile dummy was scaled based on the height and weight of the subject female driver. The scaled dummy was aligned with the 3D laser scan data to match the position demonstrated by the subject, and belted using a three-point harness utilizing multi-body elements positioned to correspond with the 3D laser scan data (Figure 2).

The collision pulse retrieved from the EDR of the subject vehicle was applied to the vehicle system in MADYMO. For the subject analysis, linear head acceleration, upper cervical spine compression, and lower lumbar spine compression were recorded and filtered according to SAE J211 specifications.

For comparison, an analysis was conducted utilizing previously published volunteer and dummy low speed rear-end crash data evaluating the variables of interest. The Delta-V's in these tests ranged from 1 to 24.4 kph (0.6 – 15 mph). A linear interpolation of the datasets was performed to determine generalized results applicable to the subject collision [4-9]. Interpolated spinal loads were appropriately scaled to the occupants weight and added to static loads determined from anthropomorphic databases and simulation software (MICH3DSSP).

Figure 2: (A) 3D scan data of seat and subject, (B) model built to match 3D scan data, and (C) final model.

RESULTS

The occupant kinematics of the subject simulation were consistent with kinematics demonstrated in previously conducted volunteer, cadaver, and dummy tests (Figure 3). Specifically, the occupant remained stationary as the seat was accelerated forward. The occupant therefore moved rearward relative to the seat into the seatback and head restraint. The peak linear head acceleration was 8.4 g's, the peak cervical spine compression was 71.2 N, and the peak lumbar spine compression was 457.9 N.

A correlation analysis of 43 volunteer tests and 8 dummy tests indicated a strong linear relationship between Delta-V and linear head acceleration ($R^2 = 0.87$). Furthermore, select dummy tests exhibited correlation between Delta-V and both cervical spine compression ($R^2 = 0.95$) and lumbar spine compression ($R^2 = 0.79$). Based on the linear interpolations the subject Delta-V would produce a linear head acceleration of 8.4 g's, a cervical spine compression of 69.0 N, and a lumbar spine compression of 547.3 N.

Figure 3: Occupant position (A) pre-impact, (B) impact, and (C) rebound.

DISCUSSION

The results from the present study indicate that MADYMO can be utilized to evaluate collisions with a subject-specific analysis. The results from the simulation were consistent with previously conducted low speed rear-end crash test data. These data indicated that the use of a subject-specific model accurately predicted results of a generalized rear-end collision. Furthermore, the effects of occupant and vehicle specific geometries did not have a significant effect on the metrics evaluated, i.e. spinal compression and linear head acceleration. This indicates that MADYMO is a useful tool when predicting results of real-world collisions. These data also provide the methodological framework for evaluating real-world collisions that may be less characteristic of generalized testing performed for collinear rear-end collisions with a normally seated driver.

The present study evaluated a Hybrid III 5th percentile dummy scaled using anthropomorphic databases. Scaling can be improved through scaling factors specific to the occupant in place of the scaling algorithms determined through the anthropomorphic databases. Additionally, MADYMO offers scalable human models in conjunction with the scalable dummy models used in the present study. The MADYMO manual indicates that the human models have improved biofidelity in comparison to the dummy models and can be utilized in a wider range of loading conditions [10]. Future work will utilize the human body models and evaluate in comparison with the dummy models. Furthermore, these outlined methodologies will continue to be developed to analyze a wide range of occupant anthropometries, body positions, and interior vehicle geometry.

INTRODUCTION

Airway obstruction and compromise is the second leading cause of preventable battlefield death (77 out of 976 preventable battlefield deaths studied) [1], a fact attributed to unavailability of sufficiently powerful portable suction systems, insufficient training of combat medics, and improper use of airway securement devices, among others [2]. As such, airway securement is one of the foremost challenges for combat medics responding to traumatic injury [3]. This lifesaving intervention involves quickly assessing the severity of airway injury, which is immediately followed by insertion of a suction catheter in the oropharyngeal area to evacuate any accumulated obstacles, which may include saliva, vomit, and blood. Process improvements directed toward pre-hospital care can improve survival rate from combat injury. Emergency care facilities and field hospitals are equipped with powerful suction systems which are non-portable, bulky, and heavy to carry manually. As a combat medic's kit routinely weighs in excess of 45 kg, this is not a practical device for them to manage [4]. There are different types of portable suction devices available on the market, including both manually powered and automatic systems. The former is frequently unable to remove sufficient material in a timely manner, while the latter are more powerful, but too cumbersome for the combat medic to carry in their kits [4]. Also, these devices are orientation dependent i.e. these will stop working if they are put upside down or in sideways as the hydrophobic filter inside will get clogged by the back flow of liquid [5]. Market assessments and surveys conducted by this

group have demonstrated that combat medics require a light weight, compact, efficient, and reliable portable suction alternative for the battlefield [6, 7]. Discussion with emergency physicians and combat medics revealed the design specifications i.e. size (30 x 10 x 10 cm), weight (<1 kg), vacuum pressure (450-550 mmHg), fluid flowrate (16 ml/s) etc. Also, the device should work independent of its position on the ground. This research describes the initial design, fabrication, and characterization of a suction platform focused on bridging this gap in combat casualty care. Characterization experiments include flowrate testing, solid particle lift tests, comparative analysis of the flowrate between commercially available suction tips, and evaluation of design criteria for maximum flowrate and minimum obstruction resistance at a given vacuum pressure.

METHODS

The prototype was designed and fabricated in line with the derived specifications. This orientation independent prototype includes three major sections: a compact, rectangular, and durable housing, a canister, and a suction pipe with catheter. The housing stores the diaphragm type Parker suction pump which is connected to the cylindrical canister (1L) by a hydrophobic filter (0.2 micron) to protect the pump from getting contaminated by the backflow of liquid. The canister is supported by 2 sets of ball bearing at two ends for rotating freely irrespective of the position of the device on the ground. The other end of the canister is connected to the suction pipe (10 mm inner diameter) and catheter (Yankauer suction tip, model#298, Busse Hospital

Disposables, Hauppauge, NY). The Arduino Uno circuit board was used to control the pump-motor. The user can regulate the motor speed as per requirement through a potentiometer attached to the main housing. An overdrive switch has also been integrated with the assembly to run the pump at full capacity whenever necessary. The rechargeable 12 V battery can provide power for approximately 3 h of continuous use. This device was utilized to evaluate the maximum vacuum pressure and flowrate while evacuating simulated vomitus liquid prepared by mixing 1L of distilled water with 10g Xanthan gum and 100 g of 1 mm diameter glass beads. Then five different commercially available suction catheters: Yankauer (4 mm inlet diameter), Wide Yank (11 mm), Flange (3.8 mm), Argyle (3.2 mm), and Poole (3 mm) were compared in terms of suction flowrate while evacuating water (baseline), blood phantom, and simulated vomit. The blood phantom solution was prepared by mixing 276 ml of glycerol into 1224 ml of distilled water [8]. The dynamic viscosity of water, blood phantom, and vomitus solution was measured as 0.89, 3.68, 22.71 mPa.s respectively at room temperature of 22°C (viscosity measured with DV1 digital viscometer, AMETEK Brookfield, Middleborough, MA). Finally, a solid particle lift test was carried out using the 10 mm diameter suction pipe only without the catheter. The device was used to lift three sets of stainless steel spheres (set 1: 6 mm diameter, 0.9 g; set 2: 8 mm diameter, 2.7g, set 3: 14 mm diameter, 11.3g) submerged in the water.

RESULTS

Figure 1.A depicts the orientation independent design which is 30 x 15 x 15 cm and weighs 1.2 kg with a 1L waste canister and 10 mm (inner diameter) suction tube. Performance tests revealed the device generated a maximum of 560 and 650 mmHg vacuum pressure with and without the hydrophobic filter, respectively. The suction flow rate of vomituous solution without the filter was 13.5 ml/sec, while inclusion of the filter reduced this to 11.7 ml/sec. In next test, the Wide Yank demonstrated higher flow rates than Yankauer, whereas the Poole demonstrated lower flow rates than Yankauer for each of the fluid solutions which revealed that bigger diameter suction catheter without sharp bends generate higher suction flowrate. Solid particles lift test demonstrated that the device could evacuate submerged metal spheres of set 1 and set 2. The third set of spheres (14 mm diameter, 11.3 g) were larger than the tubing's diameter (10 mm). However, the tubing could lift the largest spheres while they were submerged, but released once being lifted into the air.

DISCUSSION

Structurally, the present airway suction device achieves a smaller footprint than commercially available devices, such as Laerdal Compact Suction Unit® 4 (LCSU4, 800 ml) that measures 24 x 20 x 24 cm and weighs 1.95 kg [5]. The max vacuum pressure, and flowrate test of simulated vomit also support its achievement of clinical reliability and durability. The drop in maximum vacuum pressure and flowrate observed during the test can be reduced in the future through replacing the

0.2 µm filter, which is more restrictive than necessary, with a larger pore size alternative. Another solution would be utilization of a liquid compatible vacuum pump, eliminating the need for the filter altogether. Future work will focus on carrying out a drop test of the device to evaluate the durability and utilizing alternate design to minimize the footprint while enhancing the maximum vacuum pressure.

FINITE ELEMENT MODEL OF NEONATAL BRACHIAL PLEXUS AND SPINAL CORD

Christian D'Andrea (1), Anita Singh (2), Sriram Balasubramanian (1),

Sciences and Health Systems
Drexel University
Philadelphia, PA, USA

(2) Department of Biomedical Engineering
Widener University
Chester, PA, USA

INTRODUCTION

Limitations with studying birth-related brachial plexus (BP) injuries in humans warrant the use of highly biofidelic (human-like) physical surrogates or computational models. Such models can help develop preventative strategies in complicated birthing scenarios. Very few models exist with none having the ability to report spinal cord (SC) responses to BP stretch. In this aim, we propose to develop a 3D Finite Element Model (3D FEM) of the neonatal SC and BP complex.

METHODS

Geometry and Mesh Development: Using average dimensions for the individual structures of the SC-BP complex obtained from 110 fetuses (Wozniak 2012), a precise 3D unilateral geometric model of the SC-BP complex with dura was created (Figure 1). This model also includes spinal nerve roots of C5-T1. The extracted geometries were meshed to generate high-quality tetrahedral solid elements (total 420,799 elements) using Hypermesh v.11 (Altair Inc, MI) and ICEM CFD v.14.5 (ANSYS, Canonsburg, PA).

Biomechanical Properties: The elastic moduli (E) for the BP complex were based on in vitro tensile tests performed on neonatal BP structures (Singh et al., 2018). Additionally, we tested a total of six spinal cord (with dura) samples obtained from neonatal (3-5 days old) piglets (Figure 2). The maximum failure load for SC was found to be 6.5 ± 2.2 N at a failure strain of $31.7 \pm 7.2\%$ with an elastic modulus of 1.1 MPa. These

biomechanical data were used in the neonate 3D FEM of the SC-BP complex.

Boundary / Loading Conditions and Simulations: The superior and inferior ends of the spinal cord were fixed, and a load of 1 N and 3.5 N were applied to the end of the C5 BP nerve segment at 10 mm/sec. Simulations were run on ANSYS v.18 (ANSYS, Canonsburg, PA), and the maximum principal stress and maximum principal strain values were recorded at the SC-BP junction (i.e. at rootlets) at all levels.

Figure 1: FE models of spinal cord and brachial plexus complex

Figure 2: In vitro mechanical testing of neonatal spinal cord

RESULTS & DISCUSSION

For a 1 N applied force, a maximum principal stress of 25.4 MPa and maximum principal strain of 19.3% was observed at the SC-rootlet junction at the C5 level (Figure 3). The 3.5 N traction force resulted in approximately 300 MPa max principal stress and 32% max principal strain at the rootlets at the C5 level. Based on preliminary in vitro testing performed on SC-BP complex with similar boundary and loading conditions, a failure at the rootlets at approximately 3.5 N was observed. However, it is unknown if the stresses from the simulation are similar to those experienced during failure during the in vitro experiment.

Figure 3: Simulation results from 1 N traction force applied to the C5 nerve segment (a) Maximum principal stress distribution, and (b) Maximum principal strain distribution.

CONCLUSION

This is the first reported 3D FEM of the neonatal SC-BP complex with a simulation of in vivo loading. Such 3D FEMs may serve as useful tools that provide quantitative metrics for the assessment of BP and concomitant SC injury.

INTRODUCTION

According to the CDC, head injury is one of the leading causes of death and disability among the population of the United States [1]. Mild TBI (mTBI) accounts for most of the head injuries sustained each year, and until recently the clinical impact of mTBI on function and quality of life has been thought to be low [2]. However, a multitude of recent studies have shown that mTBI is not only difficult to detect using current diagnostic imaging modalities [3,4,5] but is also linked to negative neurological outcomes [6,7,8]. The mechanics and biological sciences communities have approached the TBI problem from different perspectives for some time now without any significant bridge between the fields. The mechanics community focuses on the macro level mechanics of the head upon impact by using human headforms equipped with high sampling frequency accelerometers that yield accurate acceleration measurements [9,10]. However, these models do not allow for study of damage to tissue or microvasculature nor do they allow for following neurological outcomes post-injury. Biological science fields that utilize animal models enable such benefits, but these studies are focused predominately on the cellular level processes that occur downstream of the mechanical injury itself [11]. The separation between these fields leaves an open question regarding whether the mechanical parameters of an impact are linked to a patient's outcome post-injury. This project is novel in that it utilizes a customized visual tracking analysis method in conjunction with a new animal model of TBI. This combination of techniques allows for kinematic analysis of a living subject being exposed to an impact scenario and allows for the animals to be followed post-impact and tested for impairment.

METHODS

This study used a closed-head animal model that was optimized in parallel with the development of the tracking technique. Previously, TBI literature has been dominated by open-head injury models. In these

models the animal's head is held still while damage is induced directly on the brain tissue [12]. This eradicates the affects of the kinematic interactions likely at play in acceleration/deceleration dominated TBI scenarios, which make up the majority of human TBIs treated in emergency departments every year [1]. This new model, adapted from the Shohami model [13], more accurately mimics injuries humans experience in the field.

In this study, rats and mice sustained controlled head impacts using a drop tower style test rig [9,10]. In this model the animals are initially suspended over a catch-box by support material. Upon impact, the animal is forced through the support material, falls and lands on a layer of foam lining the bottom of the catch-box. A single view of the impacts (side view) is filmed. The rat and mouse impacts for this study were filmed at 60 and 240 frames per second (fps) respectively. The impact videos are uploaded to an opensource motion analysis tool, Tracker. The videos are calibrated within Tracker and then an anatomical feature on the animal (usually the eye) is traced through each frame of the video (fig. 1). Tracker takes the position data of the tracers to calculate the linear and angular acceleration of the animal's head during impact using the finite difference method.

RESULTS

Repeatability of Tracking:

Tracking features on the animals in the impact videos by-eye introduced some error to the method. The repeatability of the method was analyzed by tracking a cohort of rat impact videos (n=4) three times each. The peak linear and angular

Figure 1 : Tracer placement through rat impact video

accelerations were compared between the three tracks for each animal (table 1). The standard deviations of the peak accelerations were all found to be under ten percent of the mean values for the animals. The animal with the highest standard deviation also had the largest amount of out-of-plane (toward the viewer) motion during impact, which was not accounted for with the current method.

Table 1 : Linear (m/s^2) and Angular (rad/s^2) Acceleration Repeatability Data for Rat Cohort Filmed at 60fps

Animal ID	Linear [mean±SD(%)]	Angular [mean±SD(%)]
S1	70.51±2.49(3.53)	2366.17±174.95(7.39)
S3	49.86±2.51(5.04)	1354.92±71.46(5.27)
S4	41.12±4.03(9.79)	1276.02±99.49(7.80)
S5	48.89±1.89(3.86)	1331.88±34.26(2.57)

Sensitivity to Camera Capture Rate: The technique was developed as the animal model was being optimized on different species so several cameras were used to film impacts. During analysis the capture rate of the camera became a limiting factor. This was most obvious between the rat cohort discussed above and filmed at 60fps and a mouse cohort (n=4) filmed at 240fps (fig. 2).

Figure 2 : Linear acceleration traces for rats (red) filmed at 60fps and mice (black) filmed at 240fps

The average peak linear acceleration of the mouse impacts was 6.8 times higher than that of the rats, even though the rats were struck at a higher impact velocity to compensate for their larger size. The average time over impact for the mouse impacts was also much lower, 33ms compared to 120ms, and approached what has been previously reported for times over impact [14]. There were also noticeable dips in the linear acceleration traces filmed at 60fps that were not characteristic of previously reported impact acceleration traces recorded using accelerometers [9,14].

Comparative Ability between Animals: Each of the animals in the rat cohort that has been described were exposed to the same impact parameters (drop height:85cm, impactor weight:120g). However, their trajectories and landings varied, and this was identifiable in the acceleration traces (fig.3) of the animals after the video analysis. Animal S1 experienced a typical impact and subsequent fall through the support material and landing in the catch-box. In comparison, animal S3 landed in a position that caused whipping of the head, which was reflected by multiple secondary acceleration peaks in the trace of linear acceleration where the animal's head contacted the foam lining the bottom of the catch-box multiple times. Animal S5 landed directly on its head and neck and came to an abrupt stop, which was reflected in the sharp secondary acceleration peak for that animal that then dropped to zero acceleration.

Normally animals land on their backs and bounce slightly before coming to rest. Also note that animal S4 experienced the most out-of-plane motion, which is reflected by the amount of noise in the animal's acceleration trace.

The animals in the mouse cohort

were also exposed to the same impact parameters (60cm, 100g), however animal 3A-1 experienced an atypical flip. The animal turned 360 degrees after impact before contacting the foam lining the catch-box. This case was especially interesting because this animal's peak acceleration was noticeably higher than the other animals in the cohort (fig. 2) and upon sacrifice this animal had a skull fracture and brain bleed while the other animals did not display these findings.

DISCUSSION

The results from this early testing showed that the tracking method is sensitive to capture rate, and that by-eye tracking of the videos were repeatable and provided valuable comparisons between animals even at this low-fidelity stage. The current method was able to be developed and tuned quickly and cost-efficiently as the impact experiments were being optimized, however the accuracy of acceleration magnitudes suffered due to low capture speed of the camera equipment used. The effects described between capture rates were likely due to a type of aliasing: the camera was not capturing frames quickly enough to accurately capture the motion of the head during impact at lower frame rates. This would explain why the traces for the videos filmed at 240fps have a more characteristic shape and the peak acceleration values are approaching those previously reported in human headform testing using accelerometers at similar impact velocities [9]. Increasing the capture rate of the camera to mimic those used in some previous related studies should increase the accuracy of the acceleration results, however, will come at a cost, both monetarily and in labor. The current method could also be improved by adding another camera view to each impact video to account for out-of-plane movement of the animal after impact.

INTRODUCTION

Within the U.S. Military, approximately 25% of injuries during recent conflicts were craniomaxillofacial (CMF) in nature [1]. To predict injury risk and evaluate potential countermeasures, the Facial and Ocular Countermeasures Safety (FOCUS) headform was developed with segmented facial regions for measuring facial and ocular insults [2]. The biofidelity of a headform is essential for this purpose, and the FOCUS headform has been shown to respond similarly to cadaveric subjects for anterior-posterior (A-P) blunt impacts to the frontal bone, nasal bone, and maxilla [3]. For mandibular A-P impacts, however, large displacements of the unrestrained mandible prohibited the appropriate evaluation of the FOCUS headform mandible [4].

Recently, a method was developed to evaluate the mandible under a restrained jaw condition that more realistically mimics the response of a helmeted individual [5]. The current study used this method to determine the cadaveric response of the restrained jaw to A-P blunt impacts and assess the biofidelic response of the FOCUS headform.

METHODS

Impacts to the cadaveric mandible and mandible region of the FOCUS headform were performed using a gravity-driven guided cylindrical impactor with a 6.45 cm² surface area and 3.2 kg mass to remain consistent with previous investigations [3-5].

The impactor was instrumented with a load cell (Model 53; Honeywell) directly behind the impact surface and an accelerometer atop the impactor mass (Model 7264C; Endevco). Data were collected using a Synergy Data Acquisition System (Hi-Techniques Inc.) at 1 MHz and filtered in MATLAB (Mathworks) using a 4th order low-pass Butterworth filter with a 500 Hz cutoff frequency [4,6]. Tests were

recorded using a high-speed camera (Vision Research Inc.) at 10,000 frames per second.

Cadaver Test Series. Twenty-five fresh-frozen male post-mortem human surrogate (PMHS) heads were used. All specimens were handled in accordance with institutional standard operating procedures and U.S. Army Policy for Use of Human Cadavers [7]. Specimens were secured in a potting fixture using polyurethane resin (Golden West Manufacturing) with the Frankfort plane vertical. Strain gauges were attached to the skull and acoustic emission sensors were secured at the angle of the mandible (bilaterally) to assist with fracture detection.

The impactor was centered on the symphysis of the mandible with the edge of the impactor below the alveolar process (Figure 1). A restraint fixture was used to prevent the jaw from opening during impact [5]. Impacts were repeated in 5 J increments until fracture was detected through review of sensor data and comparison to baseline assessment impacts (5 J).

Figure 1. Schematic of the specimen mounted in the test fixture with the impactor positioned above the mandible.

FOCUS Test Series. The FOCUS headform was attached to a Hybrid III neck and mounted to the test device. Five impacts were conducted at each of 5, 10, 15, and 20 J energy levels. The internal mandible load cell data were collected and filtered in the same manner as the impactor data [4,6].

Analysis. Mandible force-displacement response was computed from the time of initial impactor contact (defined as 10N of contact force) to 90% of the peak force. Impactor accelerometer data was double integrated to obtain position data. The cadaveric response was defined using the characteristic average and corridors calculated using methods described by Lessley et al. [8].

RESULTS

Cadaver Test Series. Sixty-five tests were performed on 25 mandibles and used to determine the PMHS biomechanical response. Impact velocity ranged from 1.7 to 4.4 m/s, corresponding to impact energies from 4.5 to 31.4 J. Maximum force and displacement increased with increasing impact energy (Table 1). Force-displacement data for all impact energies were used to obtain the PMHS characteristic average and corridors (Figure 2).

Table 1. Average peak force and displacement by impact energy.

Energy (J)	PMHS		FOCUS	
	Force (N)	Disp (mm)	Force (N)	Disp (mm)
5	1795 ± 315	6.5 ± 1.3	990 ± 3.5	7.7 ± 0.1
10	2320 ± 296	8.0 ± 2.0	1403 ± 6.3	10.1 ± 0.6
15	2779 ± 550	9.8 ± 2.7	1768 ± 8.1	11.4 ± 0.4
20	3465 ± 758	12.0 ± 3.5	2117 ± 10.9	12.7 ± 0.1
25	4167 ± 947	14.7 ± 2.1	—	—
Overall	2476 ± 837	8.6 ± 3.0	—	—

Data given as mean ± standard deviation. Disp: displacement.

Figure 2. PMHS characteristic average and corridors for all tests.

FOCUS Test Series. Twenty A-P impacts on the FOCUS headform were performed at four energy levels. The headform produced repeatable loading responses. The peak force and displacement were dependent on the impact energy but the overall stiffness was independent of energy (Table 1; Figure 3).

Figure 3. FOCUS headform average response by impact energy overlaid with the average response from Cormier [4].

The PMHS showed a bilinear response with initial (0-20% peak force) and secondary (20-80% peak force) stiffnesses of 152.3 and 324.6

N/mm, respectively. The FOCUS headform response was linear and fell within the PMHS response corridors (Figure 4).

Figure 4. Average PMHS response and corridors overlaid with the average FOCUS headform responses at each energy.

DISCUSSION

When overlaid, the PMHS corridors from Cormier [4] fall within the PMHS corridors from the current study (Figure 5). Our tests exhibited much larger reaction forces than Cormier [4] due to the restrained chin condition. Cormier [4] observed more jaw motion, lower forces, and fewer mandible fractures. The differences in secondary stiffness could be attributed to their lower forces that did not cause fracture and perhaps indicate that their data reflect the initial PMHS response.

Figure 5. Average PMHS response and corridors overlaid with the corresponding response and corridors from Cormier [4].

The FOCUS headform response was consistent with the results of A-P impact testing performed by Cormier [4], whose impact energies ranged from 12.7 to 15.7 J (Figure 3). Thus, the FOCUS headform gives a consistent mechanical response that is biofidelic and useable in evaluating facial insults to the mandible.

INTRODUCTION

Traumatic brain injury (TBI), including sports-related concussion that occurs in 1.6 to 3.8 million athletes a year, is a major health problem in the United States (1). This necessitates accurate and reliable prediction of brain injury. In the past, head impact kinematics including peak magnitudes of linear or rotational accelerations have been extensively used as injury predictors. Lately, efforts to employ finite element (FE) models of the human head are increasing. These models translate impacts into tissue strains thought to cause injury and are generally believed to potentially improve the prediction performance.

Numerous efforts exist to improve FE models of the human head, including optimizing brain material properties, enhancing the quality of brain meshes, etc. Still, a significant disparity between the various human head injury models is the different simulation packages. This may preclude a meaningful comparison between simulation results and injury analyses using different head injury models.

Abaqus and LS-DYNA that are the most common choices in TBI impact simulations. In this study, we converted our latest anisotropic Worcester Head Injury Model (WHIM) developed in Abaqus into LS-DYNA format. This conversion process allowed us to understand the differences between the two most commonly used software packages in brain injury studies. This would facilitate the comparisons between models developed in these two packages in the future.

METHODS

The latest WHIM served as a baseline for model conversion. The model uses a re-meshed brain (202.8 k high-quality hexahedral elements of the brain (2)) and implements brain material property anisotropy in Abaqus using the HGO hyperelastic model coupled with viscoelasticity (3). It was successfully validated against both high-rate cadaveric head impacts and *in vivo* head rotation. Unfortunately, LS-

DYNA currently does not have an equivalent anisotropic material. Therefore, a material optimization scheme was conducted to convert the Abaqus HGO anisotropic material model into an isotropic model in LS-DYNA while minimizing differences between model simulation responses. It was necessary to model the gray matter (GM) and white matter (WM) separately in order to preserve their response differences arising from brain material anisotropy.

The 50 deep white matter regions of interest (ROIs) were localized in the WHIM by registering the JHU-ICBM-DTI 81 WM atlas with the T1-weight MRI used to develop the baseline WHIM (3). Similarly, a GM neuroimaging atlas (4) was used to identify 54 cerebral GM regions within the WHIM space. A recorded loss of consciousness impact (5) was simulated to aid the model conversion.

Specifically, we started with the baseline WHIM based on a full integration element with incompatible modes (C3D8I) in Abaqus. This type of element often serves as a benchmark in simulation that is free from shear locking, immune to hourglass deformation, and with minimal volumetric locking (2, 6). However, this element is computationally rather expensive. Therefore, we first converted the model into reduced integrated elements (C3D8R) using relax stiffness hourglass control (HG) with a high scaling factor (SF) of 200 for GM and 100 for WM to maximize model simulation efficiency.

Next, an Ogden isotropic hyperelastic model was selected to approximate the previous anisotropic response. The initial shear modulus, G_0 , was determined *via* iterative adjustment so that a linear regression slope between the peak maximum principal strains in the GM and WM regions obtained from the two models was within 1.00 ± 0.05 .

With the same G_0 value for the entire brain as a new starting point, the G_0 values for the GM and WM were further iteratively adjusted so that the linear regression slope between GM regions, as well as that for the WM regions, were both within 1.00 ± 0.05 .

Next, the two isotropic GM and WM material models were directly converted into LS-DYNA format without alteration. As there were quite some different integration schemes available in LS-DYNA, we sought to identify the best option to maximize the match between simulation results with respect to that from Abaqus. Specifically, we examined the selectively reduced integration (S/R; element types 2, -1, and -2) and all of the reduced integration schemes in LS-DYNA, enumerating each HG type with three hourglass coefficients (QM) (0.01, 0.1 (default), and 1), with a maximum QM of 1 to avoid unstable simulations.

Table 1 summarizes the overall procedure of this study, including the type of material properties and element types used in each step.

Table 1: Summary of six simulation steps to convert the baseline WHIM using anisotropic brain material properties in Abaqus into LS-DYNA counterpart with isotropic properties.

Step	Software	Hourglass Control (HG)	Elm. Type	Material
1	Abaqus	Not needed	C3D8I	Anisotropic
2	Abaqus	Relaxed stiffness WM SF of 100 GM SF of 200	C3D8R	ibid.
3	Abaqus	Relaxed stiffness WM SF of 100 GM SF of 200	C3D8R	Isotropic (same for GM/WM)
4	Abaqus	Relaxed stiffness WM SF of 100 GM SF of 200	C3D8R	Isotropic (with GM/WM heterogeneity)
5	LS-DYNA	Not needed for S/R	{2, -1, -2}	ibid.
6	LS-DYNA	Type 1 to 10, excluding 8/QM of 0.01, 0.1, 1	1	ibid.

RESULTS

After converting the baseline WHIM (step 1 in Table 1) into isotropic and heterogeneous GM/WM with C3D8R (step 4 in Table 1), element-wise comparisons led to the following linear regression slopes (k) and Pearson correlation coefficients (r): $k_{WM} = 0.91$ and $r_{WM} = 0.71$ for the 50 WM ROIs; $k_{GM} = 0.96$ and $r_{GM} = 0.86$ for the 54 GM ROIs. Step-wise comparisons are reported in Table 2. Converting anisotropy into isotropy mostly affected the WM (a low r_{WM} of 0.78), as expected. These results suggested that the reduced integration scheme was able to preserve the simulation accuracy while maximizing computational efficiency (2h 24 min versus 38 min on a computer cluster: 15 CPUs + 2 GPUs). **Fig.1** (a, b, c) compares their fringe plots of accumulated maximum principal strain.

Table 2: Summary of the results from the experiments.

Reference	Target	54 GM ROIs		50 WM ROIs	
		k_{GM}	r_{GM}	k_{WM}	r_{WM}
Anisotropic/C3D8I	Anisotropic/C3D8R	0.97	0.92	0.93	0.95
Anisotropic/C3D8R	Isotropic/C3D8R	0.99	0.92	0.98	0.78
Isotropic/C3D8R	LS-DYNA HG = 1	0.93	0.88	0.98	0.85
Anisotropic/C3D8I	LS-DYNA HG = 1	0.90	0.87	0.89	0.64

When further converting into LS-DYNA, results from the S/R integration (element types 2, -1, -2; step 4 in Table 1) did not match the

Abaqus counterpart (e.g., $k_{WM} = 1.32$, $r_{WM} = 0.72$ and $k_{GM} = 1.12$, $r_{GM} = 0.42$ with element type 2). The closest response was obtained using reduced integration with HG types 1, 2, or 3 with the default QM of 0.1 (e.g., step 6 in Table 1; **Fig. 1d**). A QM of 1 led to unstable simulations in most cases. Results from HG type 6, 9 and 10 were always unstable regardless of the QM (type 8 for shell elements was not applicable here).

These findings were further re-confirmed by simulating a separate impact case (self-reported concussion case (5)). This suggested that the observations may be applicable more broadly in other impacts as well.

DISCUSSION AND CONCLUSION

In this study, we used the benchmark element type, C3D8I (full integration element with incompatible modes), as the baseline to convert the latest WHIM into LS-DYNA format step-by-step. Our results suggested that reduced integration with HG types 1, 2, and 3 coupled with the default QM of 0.01 produced the most similar results relative to the Abaqus baseline. S/R did not yield comparable results.

However, even with the most similar results (**Fig. 1d**), significant differences were apparent in both strain magnitude (underestimated by ~10% w.r.t. C3D8I baseline) and distribution. While the magnitude may be compensated for *via* scaling, the distribution disparity was likely a result of the two different material properties used in the two WHIM variants. Nevertheless, this study enhances our understanding of the differences between Abaqus and LS-DYNA in impact simulation.

Fig. 1: Cumulative maximum principal strain from C3D8I with an anisotropic material model (a), same anisotropic material with C3D8R and high SFs (b), optimized isotropic material with GM/WM heterogeneity using C3D8R and high SFs (c), and same isotropic materials converted into LS-DYNA (d).

QUASI-LINEAR VISCOELASTIC FITTING OF THORACIC TISSUES AND BALLISTICS GEL FOR MODELING BEHIND ARMOR BLUNT TRAUMA

Madelyn A. K. Eaton (1), Robert S. Salzar (1)

(1) Center for Applied Biomechanics
University of Virginia
Charlottesville, VA, USA

INTRODUCTION

Injuries resulting from the non-penetrating energy dispersion of a projectile missile into body armor is a phenomenon known as behind armor blunt trauma (BABT). Characterized as an emerging problem in the military and law enforcement,¹ BABT occurs when the body armor stops the projectile without penetration but deforms into the body of the wearer. This back-face deformation (BFD) results in blunt-type injuries ranging in severity to include death. BABT has been shown to result in numerous thoracic injuries, the most lethal being rib fractures and injuries to the cardiac and pulmonary tissues.²⁻⁴

The pass/fail of body armor is almost solely dependent on its BFD. The official measuring of BFD comes from the National Institute of Justice (NIJ), and uses an oil-based clay (Roma Plastilina No.1) as a backing material and measuring standard. The passing limit of the armor is set at 44 mm: the BFD cannot exceed 44 mm in more than 20% of the hits with a confidence of 95%, and the armor fails if BFD reaches 50 mm or higher.⁵ However, this method for testing armor, specifically using a single measure of BFD, has never been correlated with injury risk or severity. The clay used in NIJ standard testing was picked for its close material response to that of 20% ballistics gel. 20% ballistics gel was the first medium used to measure the effects of BABT, but was replaced with clay to lower cost, omit the need of high speed cameras, and to be able to utilize a reusable material. The 44 mm BFD limit was picked based on data from a .38 caliber round and for soft body armor, and has no proven relevance to higher velocity rounds.⁶

Since the clay standard was chosen for its closeness to 20% ballistics gel, many studies have turned to using gels as a backing material since its progress can be tracked with video.⁷⁻⁹ The goal of this study is to find the material properties associated with the lungs and heart at certain strain rates and compare their responses to those of the 20% ballistic gel (comparable to the clay standard). In order to further

the knowledge of the response of these organs under BABT the data will be processed for future use in a finite element model (FEM). The intermediate step between experimental findings and modeling will be through quasi-linear viscoelastic (QLV) fitting, which will allow the data to be implemented into the FEM. Furthermore, the elastic (Young's) modulus of lung tissue has not been thoroughly discussed in the literature, so this study attempts to bridge the gap by reporting the elastic moduli for the tested strain levels.

METHODS

The tissue samples tested were acquired from whole porcine organs ~1 hour after death and were never frozen. The porcine lungs were sectioned into 4 cylindrical samples (2 left, 2 right), and the heart into 6 cylindrical samples: 4 from the ventricles (2 left, 2 right) and 2 from the atriums (1 left, 1 right). The gel was from standard 20% clear ballistics gelatin, and was also sectioned into cylindrical samples. The samples' radii were such that when the 1/8 inch (3.175 mm) cylindrical indenter was used for compression, the infinite plane scenario was maintained. The samples were placed on an aluminum mounting plate and uniaxially compressed using a displacement/force driven bench-top test machine (ElectroForce® 3100, Bose Corporation – ElectroForce, Eden Prairie, MN). A 1000 g load cell was used and velocity was set to 1 m/s. On each compression sample, four strain levels were achieved in a step-hold fashion: 10% strain, 20% strain, 35% strain, and 45% strain. The strain level was held for 30 s, and between each strain level the sample was decompressed and allowed to relax until the load cell read zero. The strain levels went in ascending order: a sample was first tested at 10% strain, held for 30 s, allowed to relax, then tested at 20% strain, etc.

The testing resulted in force/displacement time histories, and the force response to an arbitrary displacement input, $\delta = \delta(t)$, was modeled using a quasi-linear viscoelastic (QLV) mathematical framework:

$$F(\delta, t) = \int_0^t G_{red}(t - t') \frac{dF^e(\delta)}{d\delta} \frac{d\delta}{dt'} dt' \quad (1)$$

where $F^e(\delta)$ is the instantaneous elastic response modeled with:

$$F^e(\delta) = A[e^{B\delta} - 1] \quad (2)$$

and $G_{red}(t)$ is the reduced relaxation function:

$$G_{red}(t) = G_{\infty} + \sum_{n=1}^5 G_n e^{-t/\tau_n} \quad (3)$$

The reduced relaxation function has been normalized so that $0 \leq G_{red}(t) \leq 1$. The elastic coefficients, A and B, and the viscoelastic coefficients, G_n , were determined by minimizing the sum squared error (SSE) between the experimental data set and the predicted model fitting (Excel Solver®, Microsoft®, Redmond, WA). The time constants, τ_n , were set as decades to simplify and improve stability: $\tau_1 = 0.001$, $\tau_2 = 0.01$, $\tau_3 = 0.1$, $\tau_4 = 1$, $\tau_5 = 10$.

RESULTS

All samples were tested successfully for all strain levels; engineering stress vs. strain curves were found and no sample had any obvious failure of material. Elastic (Young's) moduli were found based on the engineering stress-strain curves, and the strain rates were found to be consistent among samples for the same strain levels (Table 1). The force and displacement data for each set of samples (tissues/gel) was averaged within the separate strain levels, so that each material tested had one data set per level of strain.

Table 1: The right column details the tested strain levels, while the table depicts the elastic moduli of lung, heart ventricles, heart atriums, 20% ballistics gel in kPa, and the strain rates in %/ms

	E, Lung	E, Heart-V	E, Heart-A	E, BGel	Strain Rate
10%	0.28	2.11	0.97	2.95	0.9
20%	0.56	2.96	1.03	3.38	1.9
35%	0.70	6.06	1.16	5.11	3.2
45%	0.77	7.52	1.19	5.08	4.0

For the QLV fitting of the experimental force, all data for each material was modeled together; the average curves for each strain level were fit all as one. In this way, there is one set of coefficients for each material that predict a model that fits all strain levels (Figure 1).

Figure 1: QLV results at strain level 35% for a.) lung, b.) heart ventricles, c.) heart atriums, and d.) 20% ballistics gel. Experimental data is shown in black, the model fit is shown in red.

DISCUSSION

As expected, the results of the 20% ballistics gel didn't match either the lungs or the heart completely, a large factor being that the three materials are very different in density and material structure. However, it could be said that the ballistics gel has too high of an elastic modulus to compare with inner organs, yet way too low to compare with bone; it is close to cardiac muscle in magnitude, but the relaxation curve is more similar to lung. This could account for the discrepancies found when the 20% ballistics gel or clay standard is compared with human surrogates (animal, FEM, etc.).^{6,8,10}

As for the constitutive modeling of the materials, a QLV fit was found readily for all materials for all strain levels. The r^2 values, for the experimental force and the fitted model force, were: 0.997 for lung, 0.997 for heart ventricles, 0.996 for heart atriums, and 0.998 for 20% ballistics gel.

Future courses of action include using the QLV data obtained from these materials at these strain rates, and improving FE models of organs to improve current methods of determining risks and injuries associated with BABT.

INTRODUCTION

Chronic pain is a debilitating disorder affecting nearly 1/3 of American adults [1]. The cervical nerve root is a common source of pain from its compression during neck trauma and/or disc disease [2]. Nerve root compression (NRC) induces a host of inflammatory mediators, including pro-inflammatory cytokines, prostaglandins, in the spinal cord that initiate and maintain neuronal hyperexcitability and pain [3-5]. NRC induces persistent pain within 1 day [6]. Spinal glial activation and cytokine upregulation also occur early after a painful insult [3,7], which directly and indirectly induce and modulate spinal neuronal hyperexcitability [4,8]. Although hyperexcitability of spinal neurons is evident at later times after NRC when pain persists and is attenuated by neuromodulatory drugs that provide pain relief [8,9], it is unknown if spinal neuronal hyperexcitability is established as early as day 1.

Spinal phospholipase A₂ (sPLA₂) has been implicated in painful NRC [7]. sPLA₂ is an enzyme that releases arachidonic acid from cell membranes and is involved in production of inflammatory mediators like prostaglandins [10]. sPLA₂ has been implicated as an early pain mediator in inflammation and neural injury [10,11]; it modulates neuronal regulation of nociception, excitotoxicity, and excitatory signaling [12,13]. Yet, its involvement and/or its effects on spinal neuronal changes that lead to early central sensitization after painful root injury are not known. This study investigated whether inhibiting spinal sPLA₂ modulates pain, spinal neuron hyperexcitability, and/or spinal genes involved in glutamate signaling early after NRC injury. At day 1 after NRC, with or without sPLA₂ inhibitor, behavioral sensitivity and extracellular potentials in the spinal cord were measured to assess onset of pain and spinal neuronal activity. Because glutamate signaling has a role in synaptic plasticity and central sensitization [14], RT-PCR probed genes in glutamate regulation [15-17]: a metabotropic glutamate

receptor (mGluR5), a subunit of the NMDA glutamate receptor (NR1), and a transporter involved in glutamate uptake (GLT-1).

METHODS

All procedures were IACUC-approved. Male Holtzman rats underwent a unilateral C7 dorsal nerve root compression (NRC) by a 10-gf clip [8]. Immediately after root compression, rats received the sPLA₂ inhibitor thioetheramide-PC (Cayman) dissolved in PBS (0.25mg/kg) intrathecally by lumbar puncture (40-60µL) (NRC+TXT; n=4) [12]. Additional groups of rats underwent root compression only (NRC; n=3) or a sham surgical procedure (SHAM; n=3) with the C7 nerve root exposed but not compressed. Behavioral sensitivity was measured as the ipsilateral paw withdrawal threshold (PWT) to a series of von Frey filaments with increasing weight before (baseline) and 1 day after surgery [8]. PWTs were normalized to baseline and compared between groups by a two-way ANOVA with Tukey's HSD test.

One day after behavioral testing, electrophysiology recordings measured spinal extracellular potentials [8]. Rats were anesthetized with sodium pentobarbital (45mg/kg; i.p.). A recording electrode was lowered in the C6/C7 dorsal horn on the same side as surgery [8]. After identifying mechanosensitive neurons, nonnoxious and noxious von Frey filaments (1.4g, 4g, 10g, 26g) were applied for 5 consecutive 1s-intervals [8]. Voltage potentials were measured during each stimulation, spike-sorted and counted using Spike2 software (CED). Evoked responses were compared between groups by an ANOVA with Tukey's HSD test. Each neuron was classified [8]: wide dynamic range (WDR) neurons respond in a graded manner, low-threshold mechano-receptive (LTM) neurons respond more to nonnoxious stimuli, and nociceptive specific (NS) neurons respond only to noxious stimuli. A Pearson's chi-squared test compared the proportion of neuron types across groups. After recording, rats were transcardially perfused with PBS. The

ipsilateral C6 spinal cord was collected and homogenized in Trizol for RT-PCR. Total RNA was extracted and reverse-transcribed into cDNA [3]. RT-PCR was carried out in duplicate with primers specific to mGluR5, GLT-1, NR1, and CyA (Table 1) [3,15-17]. Genes were normalized to CyA and calculated as fold-changes over normal levels. Quantification was performed by the comparative $\Delta\Delta C_t$ method [3] and levels for each gene were compared between groups using ANOVAs.

Table 1: Primer Sequences for Genes Probed.

Gene	Sequence
mGluR5	F: 5'-GTAACCAAGACCAACCG-3'
	R: 5'-CGCATAGAACGTCGCA-3'
GLT-1	F: 5'-AACCGAGGGTGCCACAA-3'
	R: 5'-AAGCAGCCGCCACATAC-3'
NR1	F: 5'-AGATGGCCCTGTCACTGTGT-3'
	R: 5'-GTGAAGTGGCTGTTGGGAGT-3'
CyA	F: 5'-TATCTGCACTGCCAAGACTGAGTG-3'
	R: 5'-CTTCTTGCTGGTCTTGCCATCC-3'

RESULTS

Inhibiting spinal sPLA₂ at NRC prevents pain at day 1, with normalized PWT (0.78 ± 0.30) significantly higher ($p < 0.01$) than NRC (0.17 ± 0.10). The PWT after treatment is not different from sham (0.85 ± 0.29) at day 1. Although NRC significantly reduces ($p < 0.01$) the PWT at day 1 from baseline, the withdrawal thresholds for NRC+TXT at day 1 (0.78 ± 0.30) are not different from its baseline (1.0 ± 0.33).

Neuronal activity in the dorsal horn is also reduced by inhibitor treatment (Fig. 1). Recordings were made at a depth of $533 \pm 238 \mu m$ below the pial surface, with no difference in recording depth between groups. At day 1 after NRC (20 neurons), neuronal activity evoked by all stimuli increases over normal (16 neurons) levels ($p < 0.04$), and sham (34 neurons) levels ($p < 0.02$) for all filaments except the nonnoxious 1.4g filament (Fig. 1). However, NRC with sPLA₂ inhibitor treatment (37 neurons) decreases neuron firing for all stimuli, with significant reductions ($p < 0.04$) for the 4g, 10g, and 26g filaments.

Fig. 1: (A) Representative recordings for the 26g filament stimulus (STIM). (B) Evoked firing increases ($p < 0.04$) after NRC over normal levels for all filaments and is higher than SHAM ($p < 0.02$) and NRC+TXT ($p < 0.04$) for the 4g, 10g, and 26g filaments.

Inhibiting spinal sPLA₂ with NRC also rescues the shift in neuronal phenotype distribution that occurs with NRC (Fig. 2). After NRC, the majority (78%) of neurons are classified as WDR, which is higher ($p < 0.04$) than in normal (33%) and sham (38%) rats. In those control groups, the majority of neurons are LTM (53.3% NORM; 52.9% SHAM) (Fig. 2). However, with inhibitor treatment, the phenotypic distribution resembles that in SHAM, with 49% of neurons classified as LTM and 43% as WDR (Fig. 2). The distribution for NRC+TXT is significantly different ($p < 0.05$) from that of NRC alone.

Fig. 2: The distribution of neurons after NRC is different ($p < 0.05$) from that of normal, sham, and NRC+TXT.

All genes (mGluR5, GLT-1, NR1) were detected in the ipsilateral spinal cord in all groups (Fig. 3). Although expression of mGluR5 mRNA at day 1 after NRC is higher than SHAM and NRC+TXT, the difference is only significant ($p < 0.05$) for NRC+TXT which is not different from SHAM (Fig. 3). GLT-1 mRNA is significantly lower ($p < 0.04$) than SHAM after both treated and untreated NRC, which are not different from each other (Fig. 3). NR1 mRNA is not different between groups and more variable in the NRC groups (Fig. 3).

Fig. 3: Spinal mGluR5 mRNA is higher ($p < 0.05$) after NRC than NRC+TXT. GLT-1 mRNA is greater ($p < 0.04$) after SHAM than both NRC and NRC+TXT. NR1 mRNA is unchanged.

DISCUSSION

sPLA₂ inhibition at the time of nerve root compression prevents the early development of pain and spinal neuron hyperexcitability (Fig. 1) [7,8]. It also prevents upregulation of mRNA for mGluR5 at that time (Fig. 3). These data suggest spinal sPLA₂ may directly modulate neuron activity early after painful NRC. The apparent reversal of neuronal phenotypic changes (Fig. 2) is consistent with other reports of neuromodulatory drugs preventing the shift to WDR neurons [8,9]. However, the downregulation of GLT-1 mRNA that is observed after painful root injury is *not* reversed with sPLA₂ inhibition (Fig. 3). Since mGluR5 is expressed on both neurons and astrocytes and GLT-1 is expressed *only* on astrocytes [4,8], and spinal astrocytic activation occurs later after painful NRC [7], the differences observed here may be due to the early time point and direct relationship between neuronal hyperexcitability and the genes probed in this study. The variability between the RT-PCR and electrophysiology results (Figs. 1-3) also may be due to differences in the assays themselves. RT-PCR was performed on *whole* C6 spinal cord tissue but recordings were made only from the dorsal horn but at both C6 and C7 levels. Studies at later times, of protein, and of additional regulators are needed. Also, glutamate levels were not measured directly but genes for receptors and transporters *do* provide a proxy measure of signaling [16,17]. Nevertheless, the fact that its inhibition prevents pain and neuronal hyperexcitability after NRC suggests that sPLA₂ has a role in early nociceptive transmission and central sensitization for painful injury.

INTRODUCTION

In recent years, there has been an escalation of blast-induced traumatic brain injuries (bTBI) caused by improvised explosive devices (IEDs) during global conflict. Blast injuries are attributed to the blast wave and has the capability to cause life-threatening injuries and fatalities. However, the mechanical behavior of brains subjected to shock wave impact is still unknown. Thus, hindering improved countermeasure development to mitigate bTBI. This study aims to understand the viscoelastic response of shock wave impacted brain tissue. *Postmortem* porcine brain tissue was subjected to shock wave impact, prior to unconfined compression experiments at a linear rate of 5 and 50 mm/min to a strain of 20%. The shock wave impacted tissue was allowed to relax for two minutes, after being compressed to 20% strain. Coefficients of the fractional Zener (FZ) constitutive model was optimized to obtain the viscoelastic material properties of the brain tissue.

METHODS

Porcine brains, chosen due to availability and anatomical similarity to human brains [1], were extracted from the skull immediately after the porcine was harvested. Afterwards, the freshly extracted brains were subjected to shock wave impact using a 0.177 cal Crosman Pumpmaster Classic air pistol. The pistol was pumped five (5) times before firing a single shock of air at the temporal region of the brain to achieve a reflected pressure of 138 kPa (20 psi). A pellet was not used with the air pistol. After the shock wave impact, each brain was prepared for unconfined compression tests by coring both the left and right cerebral hemisphere (Figure 1). Due to the brain's heterogeneous and anisotropic properties, care was taken to core a sample with a consistent composition [2].

Cored brains, with an average height of 12 mm, were subjected to stress relaxation using unconfined compression experiments (Figure 2). Unconfined compression occurred at a linear rate of either 5 or 50 mm/min to a strain of 20%, at which the strain was held constant for two minutes. Brain samples that were unimpacted by a shock wave were also subjected to unconfined compression experiments, for comparison. All porcine brains were tested less than 8 hours *postmortem*.

Figure 1. The black circle, overlaid on the right hemisphere of the porcine brain, illustrates the region and diameter cored.

Figure 2. Schematic diagram of test setup.

The viscoelastic brain was described using the fractional Zener (FZ) constitutive model. The FZ coefficients were optimized by fitting the FZ model with the experimental data, using a nonlinear least squares

method in the software MATLAB [3]. Equation 1 describes the FZ viscoelastic model, where the coefficients are composed of E_∞ , the long-term modulus of the tissue; E_0 , the brain's instantaneous modulus; τ_0 , the relaxation time; and α , representing the brain tissue's location on the viscoelastic spectrum. $\alpha = 0$ represents an elastic (Hookean) solid and $\alpha = 1$ describes a Newtonian fluid.

$$(1) \quad \sigma(t) + \tau_0^\alpha D^\alpha \sigma(t) = E_\infty \epsilon(t) + E_0 \tau_0^\alpha D^\alpha \epsilon(t),$$

where σ is stress and D is a differentiation/integration operator from fractional calculus [4].

The FZ model coefficients, describing the material properties of both shock wave impacted and unimpacted brain tissue, were quantitatively compared using a standard least squares regression that was fit to a linear fixed effect model. The statistical software JMP [5] was applied for the standard least squares regression analysis. The linear fixed effect model was used to understand the relationship between independent variables, such as shock wave impact and compressive loading rate, on the dependent variables (i.e. FZ coefficients). An analysis of variance (ANOVA) was then used to identify the FZ coefficients that were significantly dependent on the shock wave impact and/or the compressive rate. The significance level (p-value) was 0.05. As a result, p-values less than 0.05 were considered significant.

RESULTS

Fresh porcine brains, less than 8 hours *postmortem*, have a lower average instantaneous modulus (Figure 3) and lower average long-term modulus (Figure 4) after shock wave impact.

Figure 3. Average instantaneous modulus E_0 for brain unimpacted and impacted by a shock wave, at compressive rates of 5 mm/min and 50 mm/min.

Figure 4. Average long-term modulus E_∞ for brain unimpacted and impacted by a shock wave, at compressive rates of 5 mm/min and 50 mm/min.

Coefficient values describing the relaxation time τ_0 and fractional order α were statistically influenced by the independent variables (i.e. whether or not the brains were subjected to a shock wave impact and also the applied compressive rate). The instantaneous modulus E_0 and long-term modulus E_∞ of the tissue was not statistically dependent on

the compressive rate applied or whether or not the brain samples were impacted by a shock wave. Table 1 summarizes the results from the ANOVA.

Table 1: Influence of shock wave impact and compressive rate on the FZ coefficients. A p-value < 0.05 is statistically significant.

Linear Fixed Effects Model Parameters	Fractional Zener Coefficients			
	E_∞	E_0	τ_0	α
Shock wave Impact	0.3805	0.0978	0.0374	0.0114
Compressive Rate	0.5005	0.4024	<0.0001	<0.0001

DISCUSSION

In this paper, whole porcine brains were impacted by a shock wave, as would occur during a blast impact, to investigate the viscoelastic properties of the brain after a bTBI. The coefficients of a fractional Zener constitutive model were used to describe the viscoelastic response of shock wave impacted brain tissue. The brain tissue is softer after shock wave impact, as evidenced by lower average elastic modulus values (i.e. E_0 and E_∞). Additionally, the coefficients for the relaxation time and fractional order statistically depend on the compressive rate considered and whether or not the brain was impacted by a shock wave. Coefficients for the elastic modulus were not statistically influenced by shock wave impact status of the brain or compressive rate. This may due to variance in the distribution of gray and white matter of the cored inhomogeneous brain sample, even though the samples were extracted from the same region of the brain to achieve a consistent anatomical structure.

Previous study by Bentil et al. [4] and Davis et al. [6] also considered the fractional Zener model to characterize the brain's material response following unconfined compression experiments. However, this is the first study the authors are aware of that examined the mechanical response of brain tissue after a simulated blast-induced TBI. Thus, the results of this study will advance the knowledge of the brain's material properties due to bTBI.

INTRODUCTION

Kendo, Japanese fencing, is a modern martial art, which descended from swordsmanship, and is widely practiced in Japan, Korea, U.S. and many other countries today. In order to get points and win matches, each player tries to hit one of the four target areas on opponent's body with a bamboo sword.

Many audiometric studies have shown that kendo training over many years often causes sensorineural hearing loss at 2000 Hz and/or 4000 Hz. Although the risk of kendo-associated hearing loss has long been known, its mechanism is still unclear.

Our hypothesis is that the cause of hearing loss by kendo may possibly be related to accumulation of small concussions in the human head by the excessive impact-induced bone conduction. We evaluated this hypothesis by a simplified impact experiments and Finite Element (FE) simulation using a skull bone and a kendo helmet models.

METHODS

1) Impact experiments

As shown in Figure 1(a), impact experiments were performed using a skull bone model (BONELike™, 3B Scientific), which has similar mechanical properties of the human skull bone. Strain gauges (KFG120Ω2, KYOWA) were then attached at 9 points of the skull model. Time history responses of strain at each points to impact by a bamboo sword were measured. Frequency responses were also analyzed based on time history data.

2) Bone conduction simulation

We introduced a computational approach to simulate bone conduction using a newly constructed FE model of a human head. The head model contains the skull, brain, soft tissue, cartilage and auditory peripheries, including the middle ear, cochlea and semicircular canals. In order to validate the newly constructed model, an impulse force,

which were the same as the impact experiments, were applied only on FE skull model directly as shown in Fig. 1(b) and amplitude of bone conduction were calculated.

2) Kendo helmet model

A newly constructed FE model of kendo helmet is shown in Fig. 2. Kendo helmet consists of anterior and side parts and made by Titanium alloy and thick cotton fabric, respectively. Time history of impact distribution was simulated by applying impulse force on the impact area, which is surrounded by white dashed line in Fig. 2.

Simulation of bone conduction and impact simulation using FE models were performed by COMSOL Multiphysics.

Figure 1: Experimental and computational approaches for evaluating bone conduction by kendo impact. (a) Experimental setup for bone conduction map using a skull bone model. Impact force was applied by a device with miniature shinai (bamboo sword) and strain at each points were measured. (b) Simulation of bone conduction using FE skull model. An impulse force was applied on the forehead area and velocity amplitude was calculated.

RESULTS AND DISCUSSION

Figure 3(a) shows frequency characteristics of the strain amplitude at impact area, ear area and back of head area. At the impact area, impact by shinai causes bone conduction, which consists of frequency domains of 10, 100, and 200 Hz. Curves of ear area and back of the head are also showed that frequency components of bone conduction around 100 Hz are dominant.

Figure 3(b) is frequency response of velocity amplitude by FE skull model. Frequency component of bone conduction is approximately 100 Hz, which is correspond to that in experiments using the skull model. These results therefore indicate that an excessive bone conduction may possibly affect physical damages on brain and auditory peripheries.

Impact simulation using FE model of kendo helmet showed that excessive impact propagates to especially side part of kendo helmet, which may cause damage on brain and auditory system.

CONCLUSIONS

An excessive bone conduction may possibly affect physical damages on brain and auditory peripheries and frequency components around 100 Hz are dominant. Further simulation of bone conduction using a coupled model of human head and men are needed in order to evaluate relationship between bone conduction of 100 Hz and previously reported hearing loss at 2000 and/or 4000 Hz.

INTRODUCTION

The grey matter neocortex contains most of the brain's neuronal cell bodies and plays an important role in the causation of traumatic brain injury (TBI). The function of grey matter (GM) includes muscle control, sensory perception, as well as information storage and cognitive abilities. The grey matter consists of six layers of neuronal tissue with different histological constitution. Brodmann [1] and Vogt [2] first described and mapped the cyto- and myeloarchitecture of neocortical grey matter (GM) in different regions, identifying at least six distinct histological layers of the GM neocortex. In their computational models, investigators have used a single layer representing the grey matter which would lead to inaccuracy in their TBI analyses [3]. As several studies have shown [4], [5], the resulting mechanical strains in the brain, induced by a head injury, are responsible for the injury of the brain tissue at the microscale. The detailed material properties of each layer of the grey matter as they relate to the outcomes of TBI have not been investigated yet.

The objectives of this study are to identify the six distinct layer of the gray matter and to determine the elastic and viscoelastic properties of each layer. It is further the goal of this study is to investigate the inaccuracy (error) in the computational TBI models when considering the grey matter as one uniform layer versus six distinct layers.

METHODS

Microscopy: A brain cadaver from a 67-year-old male was obtained from the anatomy lab of CUNY School of Medicine. A cubic cut-out segment was extracted with a scalpel from the cortex of the right hemisphere, containing GM neocortex and a significant amount of white matter, from the region of Brodmann's area 9 [1] of the superior frontal cortex, as shown in Fig. 1. After immersing into paraffin wax

(Histoplast LP) using the tissue processor Leica ASP 300S, slices of 1.5 μm thickness were produced using the microtome Leica RM 2265 for microscopic analysis, and one 12 μm thick slice for indentation. The obtained slices were laid on a conventional glass plate and washed out from paraffin wax. The microscopic slices were stained with hematoxylin-eosin (H&E) and hermetically covered with a transparent thin covering plate, thus prepared for microscopic analysis. The thicker slice determined for indentation analysis was also washed out from paraffin and put into filtered water for storage, at 15 °C temperature.

The microscopic sample was examined under a ZEISS Axiocam HRc microscope using 10x and 20x zoom, and the tissue structure was visually analyzed, after post-processing (AxioVision), shown in Fig.2

Fig.1: Location of the extraction of the sample

Fig.2: stained cross-section of the neocortical specimen showing the six layers of the grey matter from layer I adjacent to the pia matter

Indentation: The instrumented AFM nanoindenter MFP-3D™ (Asylum Research, Inc, USA) was utilized to conduct experiments on the 12 μm specimen slice. A silicon cantilever type SICONG-TL-SIO2-D5 (Applied NanoStructures, Inc, USA) with a spherical silica glass tip

was installed into the cantilever holder. The apparent radius was measured visually with the AFM instrument and was found to be $R = 19 \mu\text{m}$. After calibration of the instrument, the spring constant of the actual cantilever was measured $k = 0.28 \text{ N/m}$. After finding the different layers based on the microscopic analysis, measurements were conducted across the entire GM cross-section, to obtain data from all layers of the neocortex. One series of measurements across the thickness of GM was declared as one sample. Six different sample regions were defined on the specimen containing several measurements in each layer. Elastic moduli from force-displacement curves were yielded by defining the contact stiffness [6] and using the Oliver-Pharr method [7].

The AFM nanoindenter was then utilized to create relaxation curves at all sample positions, by applying a pre-set displacement ($1 \mu\text{m}$) of the cantilever tip held for 10 s, followed by an unloading phase. The apparent force (Fig 3) was registered for all measurements and analyzed using the software Igor Pro 6.37 (WaveMetrics, Inc.). The force decays were fitted by a two-term exponential function and a Prony-series representation of viscoelasticity was established for each layer by conversion to shear values [8] and building layer averages.

Fig. 3: Time dependent force plot (AFM), relaxation experiments

RESULTS

The microscopic image on Fig. 2 shows a cross-section of the obtained specimen from the superior frontal cortex. With the combination of Harris hematoxylin and eosin, the neural cell nuclei, colored dark purple, could be distinguished from the network of axons and dendrites having light pink colors. Thus, different cell types and densities became apparent based on which the six different layers after Brodmann [1] were identified (Fig.2). The specimen was examined for its material properties with AFM nanoindentation, focusing on the differences in the outcomes of material properties between the layers. The elastic moduli and viscoelastic properties of the six layers of the gray matter were determined and are shown in Figs. 4 and 5, respectively.

Fig. 4 Elastic modulus E[kPa] of the six layers (I to VI)

DISCUSSION

This study reveals difference ($p=0.14$) between the elastic modulus of layer III and layer I of the GM. The calculated average value $E=1.78$

lies close to the value $1.389 \text{ kPa} \pm 0.289 \text{ kPa}$ found by Budday et al. [9], strengthening the feasibility of the measurements in this study.

Fig. 5 Dimensionless average viscoelastic functions of the layers

The disparity of E among the layers can be connected to variations in the cytoarchitecture and the presence of pyramidal neurons in a dense fibrous network in layer III, while they are completely absent in layer I, as well as very scarcely populated in layers II and IV [1].

The analyses of the average viscoelastic properties of the GM reveal a sharp relaxation with a fast decay in layers III and V, indicating a more elastic, fibrous material, while layers I and II demonstrate a comparably slower decay implying more viscous characteristics than III and V. Regarding the comprising Prony-parameters, it was apparent that the overall average across all layers for parameters g_1 (0.2003) and g_2 (0.1983) yields almost the same values. The two relaxation times τ_1 and τ_2 were different in every layer with 2 orders of magnitude (avg. values 0.069 and 2.17) and could be associated with the viscous and the porous nature of brain tissue [10].

We have also used the results of this study in our FE head model and determined the inaccuracy (error) in the computational TBI models when considering the gray matter as one uniform layer versus six layers. The significant application of this study is to provide the ability to analyze the specification of TBI, i.e. the strain in each layer that is associated with specific dysfunction of the brain such as muscle control and sensory perceptions.

INTRODUCTION

It is known in biomechanical and clinical literatures that angular kinematics play a major role in traumatic brain injuries¹. Contact loading to the head may be a necessary condition to achieve the levels of angular kinematics required to produce brain injuries². Sporting events such as American football, at the professional or collegiate level, have shown that contact loading to helmeted athletes can result in mild traumatic injuries, termed as mTBI or concussion^{3,4}. This is also true in the military⁵. To determine helmet injury mitigating capability, helmet test standards use drop techniques that do not include the neck structure, which would enable the angular motions of the head-helmet system. The overall objectives of the present study are to develop a test methodology using a hybrid helmeted-head-neck system, and to determine the linear and angular kinematics under impact loads delivered at four distinct sites, around the head circumference.

METHODS

Specimen preparation: The study was conducted using a hybrid helmeted-head-neck system. The anthropomorphic neck surrogate from the widely used Hybrid III test device in automotive environments was attached to the Facial and Ocular Countermeasures for Safety (FOCUS) headform, with an army combat helmet. This headform is used for evaluating head and facial loads⁶. The helmet was donned to the head with straps per Army guidelines (TM 10-8470-211-10, active 08/01/2015). Care was taken to ensure that the helmet was placed horizontally when viewed from the sagittal plane and with bilateral symmetry from the coronal plane. The helmeted-head-neck system was attached to a load cell at the base of the neck and fixed to the custom platform of a mini-sled (Figure 1). The Frankfort plane of the head-helmet system was maintained horizontal in all tests. This was ensured with a laser beam. A velocity gate was used to measure the impact

velocity, and a light sensor was used to trigger the high-speed camera and data acquisition system simultaneously.

Impact sites and loading: Four sites were chosen to apply the impact loading to the helmeted-head-neck system: front, rear, left side, and left nape. These sites corresponded to the current locations for evaluating helmets and obtaining head linear accelerations from drop tests. Repeat tests were done at each of the four sites. The target impact velocity was 3 m/s, also according to the current standards in the military⁹. Sufficient time was allowed between tests to permit full relaxation of the viscoelastic components in the system: the neck and helmet.

Figure 1: Left: mini-sled test device. Right: four impact sites with the helmeted-head-neck system, and the impactor is also shown.

Instrumentation: A triaxial accelerometer (Endevco 7264B-2000, San Juan Capistrano, CA) was attached to the center of gravity of the head, and a triaxial angular velocity sensor was also attached to the same

block. An accelerometer placed at the base of the neck was used to record the applied acceleration. All data was gathered according to the Society of Automotive Engineers J211 specifications: at a sampling rate of 20,000 Hz and filtering using SAE class 1000 filter⁷.

RESULTS

Figure 2 shows a representative set of linear acceleration and angular velocity profiles from repeat tests for the side impact case. The maximum anteroposterior (X) and superior-to-inferior vertical accelerations (Z) for the rear impact tests were 33.0 ± 1.5 g and 11.7 ± 0.02 g. For the frontal impact tests, they were 27.3 ± 2.1 g and 10.2 ± 0.7 g, respectively, and the lateral accelerations (Y) were the minimal off-axis components. In contrast, for the side impact tests the anteroposterior accelerations were off-axis and minimal, while the lateral and vertical accelerations were 28.5 ± 1.2 g and 8.2 ± 0.05 g, respectively. All 3 components were comparable for the nape impact tests. Table 1 shows the peak data from all tests. Figure 3 compares the peak angular velocities from all tests. Standard deviations are shown in red bars for each impact site in the figure.

Figure 2: Linear acceleration (g, top) and angular velocity (deg/sec, bottom) for the side impact. Data are from repeated tests.

Table 1: Mean peak linear acceleration magnitudes from all tests. Off-axis values are not shown.

Impact Site	Values	Linear acceleration (g)		
		X	Y	Z
Rear	Mean	33.03	Off-axis	-11.67
	SD	1.50	Off-axis	0.02
Front	Mean	-27.34	Off-axis	10.18
	SD	2.15	Off-axis	0.75
Side	Mean	Off-axis	28.49	-8.22
	SD	Off-axis	1.22	0.05
Nape	Mean	29.36	16.72	-14.46
	SD	0.50	0.66	0.69

DISCUSSION

The linear and angular kinematics of the helmeted-head-neck system, as demonstrated by the morphologies of the time histories, were very repeatable for all impact sites. Further, both kinematic histories were confined to the principal plane in all cases except the nape site, which is to be expected as this location is off-principal planes. The coefficients of variations were low, less than 8% in all cases for both types of peak kinematics. This shows that the developed protocols for donning the helmet, maintaining the fit within the FOCUS headform,

and the testing methodology using the mini-sled are appropriate for evaluating the combat helmet to assess its injury mitigating characteristics and traumatic brain injuries from impact loading. It should be noted this method is novel, and it is not in the current military standards. Further, greater magnitudes of the angular kinematics from the present hybrid system shows the importance of including the neck to induce angular motions, paralleling a recent analysis albeit using a different model¹⁰.

Figure 3: Angular velocities from all tests.

The presently used 3 m/s impact velocity was based on the isolated helmet drop tests that includes a headform used in the automotive standards, FMVSS 218, for motorcycle helmets. The FOCUS headform used in this study was designed to have realistic ears, chin, and nape for proper mounting of spectacles and helmets, and it attaches to a standard Hybrid III neck. Other details of the headform are given elsewhere⁶. The present helmeted-head-neck preparation is therefore, applicable to the military, and it also uses biofidelic head and neck surrogates. This hybrid system can be used for other conditions such as those simulating parachute drops and determine the linear and angular kinematics⁸. The present data and results can also be used to exercise finite element models to compute regional and local brain metrics such as cumulative strain damage measures and brain injury criteria, BrIC¹¹.

In summary, this study has provided a methodology for testing military helmets using military-developed headform to induce angular kinematics and reported a set of metrics that are traditionally correlated with brain injuries, hitherto not considered in helmet evaluations in this discipline. The military helmet-FOCUS headform together with the widely used biofidelic neck can be used to conduct additional tests for evaluating the helmet performance and mitigation of brain injuries, as applied to this important group of our populations.

INVESTIGATE THE VARIATIONS OF THE HEAD IMPACT RESPONSE IN A RODENT HEAD IMPACT ACCELERATION MODEL BY FINITE ELEMENT MODELING

Runzhou Zhou, Liying Zhang

Biomedical Engineering
Wayne State University
Detroit, MI, USA

INTRODUCTION

Diffuse axonal injury (DAI) is a severe form of traumatic brain injury (TBI) and often induced by direct external forces as in motor vehicle accidents. DAI is generally associated with mechanical disruption of innumerable axons throughout the brain i.e. in the cerebral hemispheres (subcortical white matter) as well as focal lesions in the corpus callosum and in the dorsolateral quadrants of the rostral brainstem [1]. There were many in vivo models proposed to study DAI. Marmarou head impact acceleration model [2] is the most widely used. This model can reliably produce axonal changes in a closed head injury in rodents. However, this model suffers large variations of the injury results [3]. Recently, the impact device/system was modified to improve the consistency and repeatability of the impact energy [4,5]. Furthermore an in-house made miniature sensor was added to the rat head to monitor the real-time rat head motion in response to each impact. In addition, the degradation characteristics and reusability of foam after repeated was quantified to assure the consistent support offered by the foam bed during impact. Even by precisely control the impact velocity, the material properties of the foam bed [4], the variations of the head impact kinematics and subsequent brain injuries were still observed. This study was aimed to utilize a Finite Element (FE) model of a rat head/body to investigate the potential factors, e.g. the initial inclination angle of the helmet on the rat skull, the variation of the skull properties which could influence the impact energy transferring to the head. Therefore, it could affect the resulting head kinematics and its resulting injury severity in this rodent head impact model.

METHODS

FE rat head model development and validation: A detailed FE rat head model was developed based on the MRI, micro CT and atlas data.

The skull was meshed with three-layer solid elements with various thicknesses. The brain mesh included all essential anatomical structures i.e. cerebral white matter, gray matter, olfactory bulb, corpus callosum, hippocampus, cerebellum, brainstem with pyramidal tract (py), medial lemniscus (ml) and medial lemniscus fasciculus (mlf), ventricles, CSF, pia, arachnoid and dural mater (**Error! Reference source not found.**). The mass of the brain and head was 1.9g and 36g, respectively. The FE rat head model consists of over 722,000 elements of which 310,000 being the brain.

The white matters structures e.g. corpus callosum and brainstem consisting of highly aligned axonal fibers were assigned with transversely-isotropic material. The rest of the brain were assigned as linear viscoelastic. A simplified rat body were also modeled to provided realistic boundary to the head at the spine-medulla junction.

Three sets of experimental data including dynamic cortical deformation (DCD), brain scar length from head rotation, and impact acceleration kinematics [6-8] were simulated to validate rat model.

Figure 1 A FE rat head and brain model

Effect of the helmet angle, skull stiffness and impact: The validated rat head FE model along with a simplified rat body was applied to

simulate the rat head impact experiments using the modified Marmarou model reported previously [4,9]. Briefly, the rat was placed on the foam bed in prone position where the top surface of the helmet (stainless disc) glued to the skull was aligned with the horizontal plane. The flat end of the cylindrical impactor impacted to the helmet at 6.5m/s causing a downward head excursion first followed by the entire body pressing into the foam bed until the foam returned to its original height. The experimentally measured head kinematics showed large variations. A several factors might influence the test results. The helmet surface inclination angle might vary from test to test (Figure 2). The skull stiffness between the rats could vary and therefore the local deformation may vary. In order to understand the effect of the initial contact condition and the skull property on the resulting head motion, we conducted two studies. For helmet surface inclination effect: the helmet was inclined backward (Rb), forward (Rf) and sideward (Rs) by 2-5 degrees, respectively and compared to the helmet inclined at 0 degree (baseline) (Figure 2D,E). For the skull property effect, the skull elastic modulus was increased/decreased by 25% of the baseline value and also as rigid material (simulate no skull deformation). The resulting head kinematics and brain strain in the corpus callosum (cc) and pyramidal tract (py) of the brainstem, were compared.

Figure 2: Simulation setup to investigate the effects of the helmet surface inclination angles and variations of the skull stiffness on the resulting head kinematics in a closed head injury model

RESULTS

Rat head model validation: The DCD validation results showed that both the pia-arachnoid material property and the contact interface defined between the brain and skull had effects on resulting brain displacement profile under DCD loadings. The viscoelastic pia-arachnoid material along with the auto-tiedbreak matched not only to the peak but also the temporal patterns of the displacements measured from experiments (Figure 3) achieving CORA rating score of 0.74.

The brain scar length validation was aimed to validate the deeper brain responses due to head rotation. Explicitly modeling the pin was found to be essential to match the brain movement as measured by the pin. At the 2 mm below the brain surface, the model predicted strain scar length of 0.64 mm which matched well to tests (0.6±0.06mm).

For the validation of rat head kinematics, the model predicted the peak and patterns of the head linear acceleration and rotational velocity-histories matched to the typical experimental curves characteristics. The excursion of rat head into the foam and its displacement was also matched quite well with the experimental data.

Figure 3 DCD brain displacement validation results

Effect of the helmet surface inclination angle: At a given impact energy, by changing inclination angle of the helmet surface from 0 to 2 degrees anteriorly, laterally or posteriorly, respectively, the head linear acceleration varied by 2-8% but increased to 8-31% at 5-degree inclination angle (Table 1). The change in rotational velocity was inversely related to the change in linear acceleration in all cases.

Table 1 Head kinematics affected by helmet inclination

Linear acceleration changes							
	Baseline(Flat)	Rb-2D	Rb-5D	Rf-2D	Rf-5D	Rs-2D	Rs-5D
Acceleration		4%	8%	-8%	-31%	-2%	-11%
Rotational velocity changes (* (p): positive value; (n): negative value)							
	Baseline(Flat)	Rb-2D	Rb-5D	Rf-2D	Rf-5D	Rs-2D	Rs-5D
R-y (p)		0%	1%	-1%	-4%	0%	0%
R-y (n)		-7%	-19%	7%	14%	0%	-2%
Ry (p+n)		-4%	-9%	3%	5%	0%	-1%

Effect of the skull stiffness: By changing the skull' Young's modulus either increase or decrease by 25%, it was observed only 3% changes in head linear acceleration and velocity was unaffected (<1%). The brain MPS responses in the cc were unaffected. But for brainstem, MPS in the py near caudal end was increased by 10% as a result of softer skull. As the skull was defined as rigid, linear acceleration and rotational velocity were both increased by 8% suggesting that the skull deformation could have absorb some impact energy. The MPS in the cc and py were increased by 16% and 29%, respectively.

DISCUSSION AND CONCLUSIONS

The FE models of impact head injury once validated can assist in exploring various biomechanical factors influencing the head impact response and subsequently the internal brain response such as occurred in this rodent closed head impact TBI model. Identification of these variables may help explain the variability of injury severities observed between the samples from an injury model and across different labs.

For Marmarou's rodent head impact TBI model, in addition to improve the repeatability and consistence of the impact device by engineering design, the changes in initial boundary conditions from the helmet surface angle have shown to have impact on the head kinematics following the impact. The current study has shown that the helmet inclination angles could affect the head kinematics up to 19% and with more effect on the brain strain in terms of spatial pattern and magnitude. This may explain the variations of the head kinematics reported and DAI severities in our previous studies [3,7].

For the biomechanical responses within the brain, the MPS in the brainstem was affected by the local skull deformation but cc was not. The MPS in the cc was affected by the head rotation. The MPS in the brainstem was affected by the combined head kinematics (linear and rotation), local skull deformation and head-neck position. The ongoing analysis focuses on the correlation of the biomechanical response map in the FE rat brain model to the DAI injury map and ultimately to establish the tissue level thresholds for predicting white matter injury.

INTRODUCTION

Injury risk curves (IRCs) are needed to quantify human tolerance and develop countermeasures to advance safety in environments such as automotive, military, and aviation [1]. Historical developments have focused on binary regression methods such as the Weibull, logistic, and probit models. These models cannot account for censored data that are typical in impact biomechanics. More recent developments in the field include non-parametric and parametric survival regression methods. The International Standards Organization has recommended procedures to perform survival analysis for developing IRCs [2]. This process has been adopted in a variety of loading scenarios and applied to automotive and military disciplines [3-4]. This study presents a semi-parametric Bayesian technique for survival analysis, novel in the context of IRCs and impact biomechanics. Its effectiveness is demonstrated using tests with Post Mortem Human Subject lower leg-foot-ankle complexes.

METHODS

A published dataset was used from the senior authors [5]. It consisted of delivering axial impacts applied to the plantar surface of the foot to the below knee-foot preparations. The experimental test design included repeated tests on the same specimen resulting in injury and non-injury data points for each specimen. In some cases, only one test was conducted yielding a single injury or non-injury data point. Thus, the dataset consisted of a combination of interval censored, right censored, and left censored observations. The axial force was treated as the response variable. The IRC was developed using a semi-parametric Bayesian survival model, termed B-IRC. The transformed Bernstein polynomial prior was used [6]. Mathematical representation of the chosen technique is as follows.

$$\begin{aligned} S_0(\cdot) \mid \alpha, \theta &\sim TBP_L(\alpha, S_\theta(\cdot)) \\ \alpha &\sim \Gamma(a_0, b_0) \\ \theta &\sim N_2(\theta_0, V_0), \end{aligned} \quad (1)$$

where $S_0(\cdot)$ is a non-parametric baseline survival function, α and θ are prior parameters, a_0 , b_0 , θ_0 , and V_0 are prior hyperparameters, and $S_\theta(\cdot)$ is a parametric family of survival functions. The transformed Bernstein polynomial prior is given as

$$\begin{aligned} S_0(t) &= \sum_{j=1}^L w_j I(S_{\theta_j}(t) \mid j, L - j + 1) \\ w_L &\sim \text{Dirichlet}(\alpha, \dots, \alpha), \end{aligned} \quad (2)$$

where $I(\cdot \mid a, b)$ is the cumulative distribution function for a beta random variable with parameters a and b . The 95% credible intervals (CIs) were calculated with this method and were also used to calculate the Normalized Confidence/Credible Interval Size (NCIS) at a few levels of injury risk. This resultant B-IRC was compared to the IRCs developed using the standard parametric survival approach, denoted PS-IRCs, using Weibull (WB), lognormal (LN), and loglogistic (LL) distributions. Appropriate 95% confidence intervals (also noted CIs) were constructed and were used to calculate corresponding NCIS values.

RESULTS

The B-IRC and PS-IRCs are presented in Figure 1. Forces of 2.9 kN, 2.6 kN, 2.4 kN, and 2.3 kN were associated with 10% risk injury for the Bayesian, PS-LL, PS-LN, and PS-WB IRCs, respectively. Figure 2 shows difference between the PS-IRCs and the B-IRC for pre-chosen risk levels. The maximum change occurred at lower risk levels ($<LD_{50}$) with the PS-LL IRC and at higher risk levels with the PS-WB IRC. Figure 3 shows the NCIS values for the pre-chosen risk levels for each IRC. The NCIS values were the lowest for the B-IRC (0.55), and this was followed by PS-LL (0.91), PS-WB (0.93), and PS-LN (0.94),

at the same level of injury probability. The NCIS data are shown in Figure 3, for other risk levels.

Figure 1: IRCs

Figure 2: % Change from B-IRC

Figure 3: NCIS

DISCUSSION

Injury risk curves in recent years have been derived using parametric survival methods. In the absence of covariates, this involves estimating two scalar parameters of a chosen parametric distribution, typically labeled shape and scale, which would define the entire curve. This dependence on just two parameters puts strong constraints on the shape of the IRC. Even in the presence of three typical distributional choices for PS (Weibull, lognormal, loglogistic), the constraints may not allow enough flexibility to unbiasedly estimate the true underlying IRC. An entirely new paradigm for estimating IRCs is by using semi-parametric Bayesian survival methods, which are gaining increasing

acceptance in the statistical literature, owing to their flexibility. The semi-parametric Bayesian model presented in the present study is equivalent to estimating an IRC with an infinite number of parameters, allowing much greater flexibility compared to PS models. The flexibility is achieved through the prior, specified in equations (1) and (2).

All the PS-IRCs were relatively similar to the B-IRC around the LD₅₀ level risk of injury. The PS-IRC based on the Weibull distribution showed the greatest deviation from the B-IRC in general, especially at higher risk levels with a 37% increase compared to the B-IRC in force required for 95% risk of injury. The PS-IRC based on the lognormal distribution generally had a higher force required while that based on loglogistic was generally lower at lower risk values and higher at higher risk values. These are therefore dependent on the distribution, e.g., lognormal versus Weibull.

In constructing an IRC, it is intuitive that there should exist greater variability in the middle (LD₅₀ level) and less at the extreme ends (low/high force), as a very low force magnitude should have a very low probability of injury. Thus, the NCIS should be generally smaller at the extreme ends and larger in the middle region. The B-IRC showed this pattern, while the PS-IRCs did not demonstrate this level of association (Figure 3). In fact, the PS-IRCs showed the opposite pattern, with greater variability at the extreme ends and less towards the middle. These results, while derived for one set of experimental data, shows that the Bayesian method may be the more appropriate technique to construct IRCs that are a more robust estimate of the true risk curve.

The novel approach presented here not only allows greater flexibility in estimating IRCs but uses a methodology, Bayesian, that is growing in popularity in the statistics community. As such it is a rich area for future development, resulting in even more benefits over typical PS-IRCs. The Bayesian technique presented in this study has the potential to replace or confirm the validity of the PS methods that have been used for IRCs in impact biomechanics and safety engineering applications.

INTRODUCTION

Approximately 1.6 million to 3.8 million sport-related mild traumatic brain injuries (mTBI) occur in the United States each year [1]. Of particular concern is football, which not only has one of the highest rates of concussion but also the largest participation [2]. Between 2012-2014 NFL regular seasons, there were 292 reported concussions in 480 games giving an average concussion per game ratio of 0.61 [3]. There is also now evidence linking long-term neurodegenerative mechanisms such as Chronic Traumatic Encephalopathy (CTE) in former NFL players with repeated concussions [4].

These worrisome statistics in football led to many rule changes and emphasis on tackling form [5], as well as emphasis on novel helmet technologies [6]. There are three typical methods used for football helmet testing: a linear impactor [7], a drop tester [8] and an impact pendulum [9]. The NFL ranks helmets every year based on linear impactor tests and drop tests at speeds varying from 25.37 mph to 44.07 mph (11.34 m/s to 19.7 m/s). They look at peak rotational acceleration as well their own severity index values [10]. For the purpose of this study, we designed an impact pendulum that would mimic the mechanics of a football impact at speeds reaching up to 6.4 m/s. We constructed the impact pendulum and installed all of the supplemental pieces to match the previously stated NFL testing standards so we can research, design and test the different concussion prevention helmet accessories.

METHODS

This section will go into detail on the design and implementation of all of the supplemental components. The parameters of the impact pendulum were based on Virginia Tech's custom impact pendulum [9]. These components include: a scissor lift/slider assembly, an electromagnet lifting mechanism, four accelerometers and an

inclinometer. The scissor lift assembly consists of two motorcycle hand-crank lifts with a 30" x 5" x 0.5" steel plate welded between. The scissor lifts are bolted to the floor and the slider is bolted to the metal plate (Figure 1). The slider includes an attachment for the Hybrid-III 50th Male head form that includes the capability to change the angular orientation of the head form. The scissor lift allows for a wide range of impact heights on the Hybrid-III 50th Male head form depending on the helmet that is being used during testing.

Figure 1: Scissor Lift/ Slider/ Hybrid-III 50th Male Head Form and Neck Assembly

For the lift/release mechanism, an electromagnet was implemented into the supplemental design of the pendulum. An electric hoist, which is connected to the top horizontal frame of the pendulum, draws power from a ceiling outlet through an extension cord and is controlled by the yellow toggle switch. Connected to the hoist is the electromagnet which draws power from the electrical cart through a retractable extension cord and an on/off switch. The electrical cart is the hub of the controls for the

pendulum as it draws power from a wall outlet and allows for easy access to the drop mechanism when conducting impact tests. When the electromagnet is on, it connects to a u-bracket that is bolted to the pendulum arm, this connection allows for a safe lifting mechanism (Figure 2). Furthermore, an inclinometer will be attached to the pendulum arm and its display will be attached to the pendulum frame directly under the hoist control and near the electrical cart so the user can see the drop angle as the arm is being lifted.

Figure 2: Electromagnet Connection to Hoist and Electrical Cart

Finally, the impact data would be obtained by DTS sensors placed in the center of mass of the Hybrid-III 50th Male head form. These sensors include one tri-axial accelerometer (ACC3 PRO) and three uniaxial accelerometers (ARS PRO-8K 2000 Hz) placed into a mounting block. Figure 3 below shows the wiring diagram for the sensors while Figure 4 shows a wiring diagram for all of the electrical components connected to the cart. Initial drop test data was done with the sensors through the provided user interface, SLICEWare (Seal beach, CA, USA).

Figure 3: DTS Sensor Wiring Diagram

Figure 4: Electrical Cart Wiring Diagram

The pendulum frame is 11' 2" x 5' 4" x 8' and is made of hollow square steel tubing. The pendulum arm consists of three hollow square aluminum tubes, two being 2' 11" long, weighing 9.37 lbs. (4.25 kg) each and the third being 6' 3" long, weighing 20.11 lbs. (9.12 kg). The arm is connected to an aluminum cylinder at the top of the frame that is 3' 8" long and 4" in diameter. At the end of the arm is a steel hammer head form that is 5" in diameter and can fit six 4.5" diameter steel disks allowing for a maximum hammer weight of 40.79 lbs. (18.5 kg). These discs are removable allowing for weight variation during testing. In total the arm and hammer weigh 79.63 lbs. (36.12 kg) and carries an inertia of $3.51 \times 10^5 \text{ lbs. in}^2$ (102.72 kg m²).

The size and weight of the pendulum arm and hammer were designed to replicate the inertia of the average NFL player's torso [9]. The maximum pendulum starting angle is about 90 degrees from vertical and can reach a maximum impact speed of 14.32 mph (6.4 m/s).

RESULTS

We have conducted six impact tests at 90 degrees and measured the impact speed of the pendulum arm right at the contact point of the Hybrid-III 50th Male head form through a photogate sensor (ENFTG137). The impact speeds resulted in 14.32 +/- 0.67 mph (6.4 +/- 0.3 m/s), confirming our initial estimates about the system.

DISCUSSION

The future direction of this project is to use the pendulum to test the capabilities of different helmets and helmet accessories that are still in the design phase. This includes but is not limited a neck webbing design to prevent whiplash type concussions [11] and an electrical system to prevent direct impact type concussions [12].

ACKNOWLEDGEMENTS

Thank you to Metal Supermarket for assistance in building the impact pendulum frame and the scissor lift assembly.

HEAD IMPACT CHARACTERIZATION IN MEN'S AND WOMEN'S COLLEGIATE RUGBY

Emily E. Kieffer, Grace Pierce, Chase Vaillancourt, Steven Rowson

Biomedical Engineering and Mechanics
Virginia Tech
Blacksburg, VA, US

INTRODUCTION

Concussion is a serious concern in sports, especially those that are full-contact sports, such as rugby [1]. Worldwide, rugby is the most popular team sport, and its physicality and competitiveness leads to a high concussion rate [1]. It has been reported that 13-17% of rugby players will sustain a concussion in a season, depending on style of play [2]. Players sometimes choose to wear mouthguards and soft-shelled headgear while playing [3]. Headgear use is limited, as the design is not optimized to the type of head impacts sustained during play [4]. Effective headgear would reduce accelerations during real-world events, but there is need to characterize the types of head impacts rugby players experience. The objective of this study was to quantify and characterize head impacts experienced by collegiate rugby players in attempts to understand mechanism of head injury.

METHODS

The study was approved by and conducted according to the ethical guidelines of the Virginia Tech Institutional Review Board (IRB). During the fall of 2018, athletes were recruited from the Virginia Tech club women's and men's rugby teams. There were 35 women and 38 men enrolled in the study. Written informed consent was obtained from each participant after explaining the purpose, associated benefits, and risks of the

study. All participants were identified with a unique study ID to maintain confidentiality of study measures. The athletes were studied over the course of six weeks, in the middle of their fall season. Video was recorded for each game and practice for the purpose of visual identification of head impacts. A head impact was recorded if a player's head impacted another player, the ground, or another object on the field. Two research personnel identified each head impact in the videos, and their reports were compared and finalized to quantify head impact frequency. The categories differentiated the object the athlete's head was impacting: another head, a body, the ground, or equipment (the goal post or the ball). The two analyses were compared and disparities were reconciled by reviewing video clips to determine the presence and category of a head impact.

RESULTS

Over the six week span, there were 587 video-identified head impacts. The men's team sustained 403 of those impacts, while the women's team accounted for the other 184 (Table 1). More than 71% of the women and 92% of the men who were enrolled in the study sustained a head impact.

The women's team had three games in the six week period, with head impacts occurring at a rate of 3.04 ± 2.09 impacts/player/game. Their games were played in weeks four, eight, and nine. During practices, the impact rate was 1.0 ± 0.54

impacts/player/practice. The men's team played a game each week in the six weeks and sustained impacts at a rate of 2.95 ± 1.59 impacts/player/game. The impact rate for practices was 1.53 ± 0.78 impacts/player/practice. The number of head impacts per player varied by week and by team (Figure 1).

Table 1: Cumulative number of head impacts sustained each of the six weeks for each rugby team. Data collection started 4 weeks into the women's season and 3 weeks in to the men's season. The men's team experienced head impacts each week, while the women played two weeks without head impacts.

	Women	Men
Week 3	N/A	122
Week 4	66	85
Week 5	0	44
Week 6	5	37
Week 7	0	53
Week 8	39	62
Week 9	74	N/A
Total	184	403

Figure 1: Box plots of head impacts sustained for the female and male athletes over course of six weeks in-season. Data collection started 4 weeks into the women's season and 3 weeks in to the men's season. On average, the athletes sustained less than five impacts per week, but some outliers experienced many more.

The majority of head impacts the women's team sustained were head to body (82.6%), with the remaining impacts to the ground (17.4%). Head to body was the most common impact scenario for the men's team (84.9%), followed by head to ground (13.2%), head to head (1.7%), and head to equipment (0.25%).

DISCUSSION

The objective of this study was to quantify and characterize head impacts in men's and women's collegiate rugby players. Number of head impacts sustained varied by team, player, and week. The men's team experienced more head impacts than the women's team, but this could be due to style of play and the semester schedule. The women only had three games in the six week study period, but the men had a game each week (six in total). There were no clinically diagnosed concussions in the study period.

For both teams, head to body was the most common mechanism of a head impact. Rugby players are taught to tackle by driving their shoulder into the ball carrier's leg, wrapping their arms around the opponent's thighs, and bringing them down with momentum. The head should not be involved, but the speed and physicality of the sport can result in tackles in which the tackler's head, instead of the shoulder, makes contact first. Head to ground was the second most common mechanism for both sexes. The most frequent scenario for this impact is the ball carrier being tackled and thrown back to the ground with enough force that he or she cannot stop the momentum, and their head impacts the ground. A vast majority of head impacts were sustained during games compared to those sustained at practice. This disparity is likely because neither team had many full-contact practices. When they did include contract drills, head impacts were still infrequent because the pace was slower and they focused on tackling form, making it less likely that a player tackled with their head first.

The main limitation of this study is the use of researchers to video identify head impacts. At some points of play, obstructions on the field, video angle, and camera resolution made it difficult to identify a head impact. We attempted to minimize this error by using the two independent video observers. This study does not take into consideration the attrition on either teams; players who were enrolled but quit mid-way through the season were still included in the analysis.

The purpose of this study was to quantify and characterize head impacts sustained by collegiate rugby players. The frequency and characterization are similar for both men and women. Understanding how rugby players sustain head impacts could provide insight into mechanisms of injury and strategies on methods of reducing injury risk and improving clinical management of concussions.

ACKNOWLEDGEMENTS

INTRODUCTION

In an effort to design safer products and study the underlying mechanisms of brain injury, there has been a significant push to develop biofidelic finite element (FE) models of the human head. At this time, a number of FE brain studies have specifically focused on the prediction of DAI. Using a variety of methods, these models predict axonal strains, which are then compared with functional and mechanical tissue thresholds. While these studies are extremely useful, they have been restricted to simulating separate isolated events with elastic material properties. At this time, there is no accepted method to account for the accumulated damage that is caused by multiple head trauma events. In order to overcome this issue, this study is focused on the design, implementation and experimental validation of tract level damage models that provides a first step towards realizing history-dependent brain modeling. In this study, we present mechanisms of stress softening, fatigue damage, fiber rupture damage and a healing model that can be used together to understand the effect of successive loading on the axonal bundles. Here, we develop our damage models at the tract level so that we can compare predicted axonal fiber damage with experimentally observed diffusion tensor imaging disruption. Our ultimate vision is that these models will enable personalized computational-enabled brain medicine in the future.

METHODS

Damage accumulation is subdivided into different mechanisms commonly observed in brain tissue. There are some mechanisms where more experimental data is available. For example, material parameters for stress rupture in brain tissue are reported, but parameters for modeling brain tissue fatigue are not found to be abundant. Our approach was to conduct a thorough literature search on material models

for brain models, as well as other soft tissues, then employ the mechanisms that we identified.

In previous studies [1], brain tissue has been observed to experience significant **stress softening**, also called **the Mullins effect**, after the initial loading cycle. This stress softening behavior has been successfully modeled for brain tissue [2] using the pseudo-elasticity theory [3]. The material softens after the initial loading cycle and the degree of softening depends on the previous strain history. However, the degree of softening is unaffected by the number of loading cycles. To represent this mechanism, we employ a scalar damage variable η , which ranges from 0 to 1 to soften the Cauchy stress response of the fibers as follows:

$$\sigma_{fiber} = \eta \left[\frac{2\mu}{\alpha} \left(\lambda^\alpha - \lambda^{-\frac{\alpha}{2}} \right) \right] \quad (1)$$

Where μ and α are material constants and λ is the fiber stretch computed using the embedded finite element method as we have previously developed [4].

In order to introduce cycle-dependent degradation and finite life, we have also implemented a **fatigue-induced stress softening model**. At this time, the functional and mechanical fatigue properties of brain tissue have not yet been experimentally studied. However, based on the prevalence of fatigue damage in other soft biological tissues, we assume that brain tissue also experiences this mechanism. We calculate a damage parameter and update using the following linear damage accumulation model:

$$D_f = \sum_{n=1}^{N_{cycles}} \frac{1}{n_{tot}} \quad (2)$$

where n_{tot} is the number of cycles to failure. This damage parameter is then applied to the fiber elements which gives us the following stress response:

$$\sigma_{fiber} = (1 - D_f) \left[\eta \left(\frac{2\mu}{\alpha} \left(\lambda^\alpha - \lambda^{-\alpha/2} \right) \right) \right] \quad (3)$$

The next mechanism we implemented is for **tissue rupture**. In both the previous models, information from the initial loading cycle is used alter the response of the second loading cycle. These methods progressively degrade the tissue but cannot predict complete failure from a single cycle tissue tensile test to rupture. Interestingly, it seems that the most experimental data is available for this damage mechanism, even though it is the least relevant for mTBI (i.e., complete separation of tissue is severe). To remain brief, we do not present the damage equation for this mechanism since it is less relevant. We assume a linear evolution of fiber rupture damage, based on the fiber stretch history. The total fiber damage, D_{tot} , which ranges from 0 to 1, is then calculated for each fiber as the sum of the fatigue and fiber rupture damage parameters:

$$D_{tot} = D_f + D_r \quad (4)$$

and the stress becomes

$$\sigma_{fiber} = (1 - D_{tot})[\eta(\frac{2\mu}{\alpha}(\lambda^\alpha - \lambda^{-\alpha/2}))] \quad (5)$$

Finally, we have provided a mechanism to account for the **healing process between two successive events**. When the next simulation is initialized, a healing duration can be specified, which then partially or completely reverses the accumulated damage in each fiber element. Due to the lack of experimental data, a constant healing rate is typically assumed. In addition, we have assumed exponential recovery functions. It is important to recognize that healing is an extremely complex remodeling process that involves many interacting biochemical and biomechanical processes. It is also important to note that damage modeling is concerned with mechanical behavior and structural integrity, while most recovery studies are concerned with patient symptoms and functional restoration. Therefore, in order to accurately model damage recovery, future research is needed to understand how mechanical damage recovers over time.

RESULTS:

Our vision requires us to carry out simulations on head models with the entire fiber tractography included. Fig 1(a) shows one such test head model that highlights the fiber tractography. This tractography was obtained from an open source database at <http://brain.labsolver.org>; it has been constructed using diffusion MRI data of 842 subjects.

Figure 1: (a) Model showing the fiber tractography; the color of each fiber is a combination of red, green and blue where left-right is red, anterior-posterior is green and superior-inferior is blue (b) Entire fiber tractography (c) Damage evolution in a small fiber section.

Fig 1(c) shows preliminary results for a small section of brain tissue near the corpus callosum. It consists of multiple curves representing the Cauchy stress over time (or cycles) with and without including the healing function. Consider that the fiber tracts have been damaged in a previous event that was also simulated and the damage data has been stored. If further damage is experienced due to exposure from cyclic loads, the damage parameter continues from previous damage level (in this case, the red curve). However, if we consider some time has passed between both simulations and we enable healing, the effect of damage is reduced (the blue curve). It can be observed that as more cycles of load are applied, the damage increases and the stress carrying capacity of the fibers reduces. Therefore, by introducing damage, we are now able to view the consequence of successive impacts.

DISCUSSION:

In this study we designed, implemented and tested a modeling framework for computing the history-dependent mechanical damage of axonal fiber tracts in the brain. In its current form, the proposed framework should be regarded as a first step in a necessary direction of tracking neurotrauma over time. While we are able to validate some of the mechanisms to experimental data (e.g. tissue rupture), validation remains a challenge for other mechanisms (e.g. cyclic fatigue) due to the lack of experimental data. Continuing efforts from our research group seek to validate the predicted disruption in fiber tractography with diffusion tensor imaging. Preliminary results are expected for the meeting.

The implication of this work is that it further motivates the need for new measurements in experimental brain tissue mechanics that is critical for the modeling framework. A new metric (i.e., inelastic damage) that captures both the magnitude and frequency of successive fiber tract strains would be a significant advance in computational brain biomechanics.

INTRODUCTION

Previous experimental biomechanical studies using Post Mortem Human Subjects and animal models have shown that the chest deflection correlates well with thoracic and abdominal injuries¹⁻². The normalized peak chest deflection (C_{max}), velocity of compression (V_{max}), and viscous criterion (VC_{max}) are derived from deflections. They serve as injury criteria in frontal and side impacts³⁻⁴. Anthropomorphic test devices (also known as crash test dummies) are used as human surrogates to assess crashworthiness of vehicles, design restraint systems, and improve safety¹. The Test Device for Human Occupant Restraint (THOR) is shown to be an appropriate dummy for far-side occupant protection⁶. This dummy can record rib deflections using internal Infrared Telescope Rods for Assessment of Chest Compression (IR-TRACC). The aims of this study are to determine whether the IR-TRACCs location accurately measure the injury metrics, C_{max} , V_{max} , and VC_{max} in pure lateral and oblique far-side impact using sled test results.

METHODS

The 3-point belt restrained mid-size male THOR dummy was seated upright in a sled buck consisting of a rigid flat seat, simulated center console, dash board, far-side side door structure, and an armrest, and they were covered with energy absorbing materials. A center-mounted airbag was mounted to the right side of the seat, and two chestbands were routed around the circumference at the level of the third rib and sixth ribs. Oblique and pure lateral tests with and without airbags were conducted at a velocity of 8.3 m/s. An accelerator sled was used to deliver the impact to the dummy in the right far-side mode. The temporal contours were processed using custom software to determine the maximum chest deflections from three methods. The first method paralleled the computations of deflections from Post Mortem Human

Subject (PMHS) studies⁷. The second method used the actual anchor point location and actual alignment of the IR-TRACC to compute the deflections. The third method used the same anchor location at the rear of the internal sensor but, determined the location of the peak chest deflection on the contour and confining to the aspect (right or left) of the sensor to compute the deflections. These were termed as the SD, ID, and TD metrics, respectively (Figure 1).

Figure 1: Chest deflection calculation methods, SD, ID, and TD. A and B refer to the origin in the undeformed and deformed contours. The peak deflection is the difference between vectors AA1 and BB1.

The C metric was obtained by normalizing the compression of the respective widths. The C corresponding to the SD metric used the one-half of spine-sternum distance. The C corresponding to the ID metric used the initial length between the points of attachment (origin to the tip), physically corresponding to the location of the sensors. The C corresponding to the TD metric used the distance between the origin (physical attachment of the sensors inside the dummy rear) and the transformed location of the peak deflection (identified in the deformed contour) on the undeformed contour. The V metric was obtained by differentiating the deflection signal, and VC_{max} was obtained as the peak of the product of the C and V signals in the time domain. The peak

magnitudes of the metrics were obtained for the three methods, and an evaluation of the accuracy was made based on the SD method.

RESULTS

Briefly, the average SD-based C_{max} , for the upper and lower chest levels were 0.124 and 0.173, the V_{max} were 5.31 m/s and 1.75 m/s, and VC_{max} were 0.24 m/s and 0.15 m/s, respectively. Other data are given (Figure 2-4) for all metrics at the two levels of the thorax. Consistently, the peak metrics were the lowest for the ID method, and this was true regardless of the aspect, right or left side. In contrast, the SD method produced the greatest magnitudes of the metrics. The VC_{max} had the greatest percentage difference between ID or TD and SD (normalized based on SD) among all the three metrics.

Figure 2: Averaged C_{max} metric for the different methods

Figure 3: Averaged V_{max} for the different methods

Figure 4: Averaged VC_{max} metric for the different methods

DISCUSSION

Using the processed chestband contours at two levels, this study determined different types of deflection measures from the THOR dummy. While the data from the actual IR-TRACC sensors were not obtained, they were calculated using the contours (ID method). The effectiveness or accuracy of the 'sensor-predicted' C_{max} , V_{max} , and VC_{max} injury metrics were evaluated. It was based on the chestband deflection contours that paralleled procedures used in the PMHS tests, i.e., SD method^{7,8}. The underlying hypothesis is that the sensor-predicted deflection represents a lower bound estimate of the true deflections, and it is also true for the derived metrics, i.e., C_{max} , V_{max} , and VC_{max} . This is because the actual location of the peak deflections on the dummy ribs depends on factors such as the obliquity of the impact vector, interaction with the airbag, and belt restraint conditions. The *a priori* locations of the anchor point (origin) that is inside the ribcage (mounting) and the tip of the sensor that is attached to the inner surface of the ribs are fixed in the ID measures. Because of this, it is expected that all the three derived injury metrics would be lower than the SD method. This was proved in the present study as SD metrics were consistently greater than ID deflections in all cases, i.e., upper and lower thorax levels, lateral and oblique impacts, and presence and absence of airbags.

The TD method, instead, relaxed one assumption, i.e., the tip of the sensor was changed from the *a priori* location to the actual point where the deflection was found to be the maximum. This also produced lower deflections than the SD method in all cases. Thus, the hierarchical sequence was SD (actual true deflections and derived metrics), followed by the TD and ID methods, for all metrics. In addition, the VC_{max} was found to be more sensitive than the other two metrics, C_{max} and V_{max} .

Under the conditions tested in the present study, the computational chestband contour-based results indicate that the *a priori* placement of IR-TRACC sensors under predicts chest deflection-related parameters, and the viscous criterion is the least reliable metric (among the three metrics) in lateral and oblique far-side impacts. While additional studies are needed to reinforce these observations, these results lay a foundation to investigate other methods such as optical tracking for a better prediction of deflection metrics that describe human chest response to injury in far-side impact scenarios⁹. Such systems may prove to be more efficacious for improved assessments of crashworthiness and far-side occupant protection.

INTRODUCTION

In 2012, the pedestrian fatalities increased up to 14%, compared with 11% in 2003, in the United States^[1]. At the same time, 22% of children aged 5-15 who died in traffic accidents were pedestrians. The traffic accidents were the second-leading cause of death for children aged 4-7 in U.S in 2015^[2]. Therefore, the protection for child deserves further researches.

Nowadays, computational simulations such as finite element modeling (FE), multi-body modeling, are among the most important ways to investigate injury mechanism. In 2003, Okamoto^[3] developed a six-year-old child pedestrian lower extremity model based on MRI scans, but the model was not a full-scale model. The 10-year-old occupant and pedestrian human body FE models (CHARM-10) with detailed anatomical structures were constructed and validated by Shen Ming^[4]. Recently, a 6-year-old 6YO-PS FE model was developed by scaling and morphing the GHBM adult pedestrian model^[5]. However, child is not a scaled adult due to their anatomical differences, and some detailed anatomical structures such as abdominal organs, growth plates, should be constructed in the FE models.

The aim of this study was to investigate pediatric injury mechanisms by using of the 6-year-old occupant and pedestrian child human body finite element models with high-biofidelity and accurate anatomical characteristic.

METHODS

The human body 6YO-TUST FE models of pediatric pedestrian and occupant contained 858,190 nodes/801,926 elements and 767,475 nodes/732,595 elements respectively (Figure 1). The stature/weight of the pediatric pedestrian and occupant is 1135mm/26.8kg and 845.0mm/28kg, respectively.

Definition of 6-year-old pediatric occupant Impact Simulation

Figure 1: The 6YO-TUST FE models of 6-year-old pedestrian and occupant. (a) Pediatric pedestrian (b) Pediatric occupant

In Figure 2, the 6-year-old occupant FE model was seated using the CRS with forward-facing car seat and the booster. The parameters of restriction system were referred from the Hybrid III dummy simulation by Tanya Kapoor^[6]. The simulation was setup according to ECER44 regulation. The initial speed of all the models was set as 50km/h.

Figure 2: Simulation setup of occupant 6YO-TUST FE models with different CRS (a) Forward-facing car seat (b) Booster seat.

Definition of Car-to-Pedestrian Impact Simulation

A validated Ford Taurus sedan FE model from National Crash Analysis Center (NCAC) was applied in this simulation. The child FE model was positioned laterally 4mm offset from the vehicle's centerline in a midstance gait posture (Figure 3). The developed 6YO-TUST FE model was impacted laterally by the vehicle model moving at a 40 km/h initial velocity.

Figure 3: The initial position of the pedestrian 6YO-TUST model relative to the sedan vehicle.

RESULTS

Figure 4 showed the kinematics and dynamic response of the child occupant restricted by two different CRS system.

Figure 4: Kinematics of pediatric 6YO-TUST occupant FE models restricted by forward-facing car seat and booster seat

Figure 5 showed the whole-body kinematics of 6-year-old pedestrian during the impact.

Figure 5: Pedestrian Kinematic during Car-to-Pedestrian Impact simulation

DISCUSSION

Figure 6 showed the maximum first principal strain of internal organs in two occupant restraint systems. It can also be seen that the maximum first principal strain of internal organs restricted with 5-point seatbelt is usually lower than that of 3-point seatbelt, which means that the forward facing child safety seat usually has a better protection to child than the booster.

Figure 6: Maximum first principal strain of internal organs under two occupant restraint systems

The results suggested in the E-NCAP Technical Bulletin of Pedestrian Human Model Certification were output. As figure 7, the first peak of contact force occurs at 3ms and then decreases because of the free moving of upper limb. When the upper limb contacts the thigh muscle at 7ms, the contact force increases again along with the compression of thigh muscles. Then the contact force increases sharply to 3.47kN at 13ms when the thigh muscles are compressed to the limit. The maximum force is up to 4.23kN at 15ms, which leads to the fracture of femur (Figure 8).

Figure 7: The contact force history during the car-pedestrian crash

Figure 8: The fracture of femur at 15ms

The Z-direction acceleration rises sharply at 54ms, which means that the head hits the engine hood (Figure 9). The maximum contact force between head and engine is 1.54kN at 55ms. The maximum acceleration of head is 164g. The head hits the hood reinforcement panel at 61ms. There's a second peak acceleration at 61ms, leading to the HIC 1339, which means that the head has a high risk of injury. Figure 10 showed the trajectory of head COG, T1 and T12. It can be shown that the child pedestrian moves slightly upward during the impact. According to the definition of Head Impact Time (HIT), the HIT is 53ms. The WAD of head impact location is 1062mm, .

INTRODUCTION

Even though computational models provide significant insights into the impact mechanics of the brain, correlating this mechanical response to biological outcomes is not straightforward. Here, we implemented an *in vitro* model mimicking the various myelination levels observed in the pediatric brain, and the different anisotropy levels observed in white and gray matter in order to examine their response to mechanical compression tests under different loading conditions. Despite the fact that true organ function cannot be recreated *in vitro*, we seeded oligodendrocyte progenitor cells in co-culture with DRG neurons as well as on one of the most biofidelic scaffolds known, namely a 3D-fiber matrix, in order to render the culturing environment as physiological as possible. Mechanically testing such samples will allow us to obtain the mechanical thresholds for inducing axonal damage and microtubule rupture for age and brain-region specific cellular model systems, as well as to study the variations occurring in cell physiology at sub damage-inducing rates.

METHODS

DRG neurons were isolated following a well-established protocol [1] and either dissociated or directly plated as explants on electrospun 3D-PCL scaffolds. Neurons were allowed to extend axons for 2-3 weeks in either anisotropic (highly aligned axons in DRG explants) or isotropic (non-aligned axons in dissociated DRG neurons) patterns prior to their use in myelinating co-culture experiments. Primary oligodendrocyte progenitor cells (OPC) were purified from mixed glial cultures of postnatal day 1 rat cerebral cortices using immunopanning [1, 2]. Freshly purified OPC (Ran2-, A2B5+) were seeded directly onto X-micron thick network of DRG neurons for co-cultures or onto 3D-PCL scaffolds (50-100,000 cells). OPC alone cultures were maintained in Sato media with 10 ng/ml PDGF and 10 ng/ml

bFGF for proliferation, or induced to differentiate into mature oligodendrocytes (OL) in Sato containing T3 (30 ng/ml) for 1-3 days. All animal work was with IACUC regulations and under approved animal protocols.

The OPC proliferation, survival and differentiation were evaluated by staining in order with Ki-67, caspase 3, and MBP over the course of 1 week [1, 2]. We also used immunostaining for PDGFR α (immature OPC), Olig2 (immature and mature OL), CC1 (mature OL), NeuN (for mature neurons) β -III tubulin (Tuj1) or neurofilament (NF) to follow axon development.

Myelination was induced by changing DRG-OL co-cultures to MEM media containing 10% FBS, 2 mM L-glutamine, and 4 mg/mL glucose. Cultures were fixed at different time points (3, 7, 14 and 21 days) and confocal microscopy was used to check for the extent of myelination using antibodies to myelin basic protein (MBP), in combination with Olig2, NeuN and NF.

Electrospun fiber alignment and axonal directionality were assessed based on calculations of 3D directional variance from confocal Z-stacks as reported in [3]. This approach provided us with easy and powerful metrics to correlate variations in the stress-strain response curve of 3D cell culture samples with variations in the structural organization of tissue at the microscale.

We performed atomic force microscopy (AFM) indentations coupled with live cell imaging using SiR-Tubulin, SiR-Actin (Cytoskeleton) and/or FluoromyelinTM (Invitrogen) to enable visualization of the cellular structures and number of myelin segments. 4 experimental groups were established, 2 of which (Group III and IV) were used for AFM experiments as shown in Table 1. These include isotropic and anisotropic samples, which are prepared by using dissociated DRG neurons (isotropic) and DRG explants (anisotropic). Different myelination levels are observed by increasing

varying culturing times. We hypothesized that the microstructural variation within the tissue will manifest as mechanical differences in elasticity modulus and viscoelastic relaxation at microscales.

Table 1: Experimental groups for AFM indentations		
Myelination level	Low	High
Fiber alignment		
Isotropic	Group I	Group II
Anisotropic	Group III	Group IV

RESULTS

DRG/Oligodendrocyte co-culture

A reproducible method for the controlled myelination of primary DRGs in oligodendrocyte co-cultures was established [1, 2]. Cultures analyzed at different time points reveal a clear pattern of myelination, as indicated by the increased immunofluorescent signal for myelin basic protein (MBP). Markers such as Olig2 and neurofilament (NF) recognize cells of the OL lineage (mature and immature) and axons respectively. An increase in the number of myelin segments with time in culture is clearly observed (Fig. 1).

Figure 1: DRG-OL co-cultures displaying different myelination levels *in vitro*: Representative images showing the increase in CNS myelin formation over time in organotypic OL-DRG co-cultures grown in Matrigel. (Red: myelin basic protein. Blue: neurofilaments. Green: Olig2).

At the same time, a variation of the protocol (seeding whole DRG explants as well as dissociated DRG neurons) allowed to control the degree of axonal alignment: axon bundles in organotypic cultures displayed axons tightly packed in anisotropic bundles, while dissociated cultures showed thinner axon bundles arranged in a more isotropic pattern. Despite similar numbers of OLs, as shown by staining with Olig2+ (red) more myelin segments (green) were observed in organotypic compared to dissociated cultures (see Fig. 2).

Figure 2: Aligned vs. random DRG/OL co-cultures. Representative images of 18 days-old myelinating OL-DRG cocultures showing the differences in the extent of myelination (red: MBP stain) and axonal alignment (blue: neurofilament stain) in organotypic vs. dissociated cultures despite similar number of OL (green).

AFM indentation of DRG-OL co-cultures for mechanical characterization

Samples from different myelination levels for co-cultures with DRG explants (Group III and Group IV) were

imaged with an AFM to obtain stiffness measurements. Group IV (higher myelination) had significantly higher stiffness values (1.58 ± 1.1594 kPa, $p<0.05$) than Group III (lower myelination, 0.959 ± 0.51 kPa).

Figure 3: a) Stiffness map of anisotropic fiber alignment with low level myelination (Group III) sample obtained through AFM. b) Modulus map of anisotropic fiber alignment with high level myelination (Group IV) sample obtained through AFM. c) Comparison of stiffness values between Group III and Group IV.

Oligodendrocyte culture on electrospun scaffolds

Primary rat OL were seeded on a network of randomly aligned, electrospun polycaprolactone (PCL) fibers (cf. Fig. 4). The good adhesion and cell viability observed after 7 days in culture indicate the feasibility of the approach.

DISCUSSION

Our preliminary results confirm the strong link between myelin content and mechanical stiffness in neuronal tissues, as consistent with prior literature [4].

The measured samples were prepared using co-cultures prepared with DRG explants, yielding highly aligned hence anisotropic samples. Moving on, to obtain different degrees of anisotropy and isotropy, we will perform AFM analysis on co-cultures prepared with dissociated DRG neurons planted on PCL-scaffolds (Fig. 4). The purpose here is to mimic the differing levels of anisotropy in the human brain.

Figure 4: Primary rat oligodendrocytes growing on PCL electrospun scaffold. 7 DIV rat OL (green: phalloidin-actin) align and extend processes over a network on electrospun PCL fibers (red). Blue: DAPI.

AN ATLAS-BASED FINITE ELEMENT MODEL OF MOUSE BRAIN FOR CONTROLLED CORTICAL IMPACT

Changxin Lai , Suhao Qiu, Yuan Feng

School of Biomedical Engineering
Shanghai Jiao Tong University
Shanghai, China

INTRODUCTION

Traumatic brain injury (TBI) is one of the leading causes of death and injuries affecting millions of people [1]. To understand process and mechanism of the injury, many experimental work has been carried out [1-3]. However, human experiment can only be conducted in the non-injury level. Therefore, animal model is indispensable for injury-level studies. Although animal experiments could provide important data and insights, computational models could help guide the experiment and are crucial for translational studies.

Typical finite element (FE) models for animal studies include mouse [4], rat [5], and pig [6]. Among them, mouse could provide various genotypes, is easy to handle and is ideal for translational study. However, most of the computational studies of the mouse brain had simplified geometries of the brain structure. An accurate model with anatomically accurate geometry could improve the computational results.

Although there are many different ways to induce injury, controlled cortical impact (CCI) is able to provide well-controlled injury and is widely used for mouse model. In this study, we constructed an atlas-based model of mouse brain for CCI. The anatomically accurate FE model will provide helpful insights into the injury process.

METHODS

FE Mesh: The FE mesh was constructed from a set of probability MR images of mouse brain (UCLA Brain Mapping Center, CA) [7]. Custom written MATLAB (Mathworks, Natick, MA) codes were used for segmentation of images and generation of FE meshes. Mask images labelling different tissues were first generated. Each voxel was labelled as either white matter (WM) or gray matter (GM) with greater probability. The volumetric mesh was generated based on the generated mask image. The mesh composed of a total of 577,824 hexahedral solid elements, where GM had 484,647 elements and WM had 93,177

elements. The element size was 0.1 mm isotropic. The mesh was imported to ABAQUS 6.17 (SIMULIA, Providence, RI) for simulation.

Material Properties: A neo-Hookean material model was adopted for the brain tissue. Prony series were adapted to describe the viscoelastic behavior of the brain tissue.

$$G(t) = G_0 \left(1 - \sum_{i=1}^N \bar{g}_i^p (1 - e^{-t/\tau_i}) \right) \quad (1)$$

where $G(t)$ is the time-dependent shear relaxation modulus, G_0 is the instantaneous shear modulus, τ_i is the characteristic relaxation time, and \bar{g}_i^p is the Prony series coefficients. The relationship between long-term shear modulus G_∞ and the instantaneous shear modulus G_0 is

$$G_\infty = G_0 \left(1 - \sum_{k=1}^N \bar{g}_k^p \right) \quad (2)$$

We adopted the viscoelastic properties of the brain tissues from MacManus et al. (2017) [2], where GM ($G_\infty=1533\text{Pa}$, $\bar{g}_1^p=0.568$, $\tau_1=13\text{ms}$, $\bar{g}_2^p=0.264$, $\tau_2=184\text{ms}$) and WM ($G_\infty=1834\text{Pa}$, $\bar{g}_1^p=0.578$, $\tau_1=11\text{ms}$, $\bar{g}_2^p=0.267$, $\tau_2=176\text{ms}$) were separated based on the cortex and pons regions.

Figure 1. A sagittal view of the FE model.

CCI Simulation: To simulate the CCI process, a cylindrical impactor with a diameter of 3 mm were used to induce injury to the brain. Three different velocities (0.6 m/s, 0.8 m/s, and 1.0 m/s) were applied. The impact process was simulated as follows. First, the impactor hit the brain with a constant velocity, and held still for 0.001s at a maximum depth of 2mm. Then, the impactor retracted with the same velocity. The impactor was treated as a rigid body. A frictionless general contact mode was adopted for the interaction between the impactor and brain. The impact process was simulated with ABAQUS/Explicit.

RESULTS

Simulation results from different impact depths and velocities are shown in Figure 2. In all cases, the maximum stresses and strains were observed at the region of brain tissue that in contact with the impactor. For the impact velocity of 1.0 m/s, the brain tissue had the highest average von Mises stress and logarithmic strain.

Figure 2. (a) Von Mises stress and (b) logarithmic strain of the brain from different impact depths and velocities.

A clear wave propagation of stress was observed (Figure 3). When the impactor reached its maximum depth, the stress kept propagating throughout time due to the viscoelastic properties of the tissue.

Figure 3. Propagation of von Mises stress (a) when the impactor moved from 1mm to 2mm, and (b) when the impactor reached its maximum depth of 2 mm.

A plot of maximum principal stress over depth showed a similar pattern from different impact velocities (Figure 4). However, the stress propagation after the impactor reached its maximum depth differs from each other.

Figure 4. Maximum principal stress in brain tissue. The multiple “2”s of the depth axis refer to different time points when the impactor reached maximum depth of 2 mm.

DISCUSSION

In this study, an anatomically detailed FE mouse brain model was developed for CCI simulation. Using image-based modeling, the anatomical structure of the brain was preserved. We noticed that it was crucial to use viscoelastic material property for simulating dynamic responses of the brain. A clear time-dependent stress propagation pattern was observed. Sullivan et al. (2015) used an Ogden material model with 2nd order Prony series for the piglet brain [6]. In our case, a neo-Hookean material model with 2nd order Prony series was also used.

For CCI, the impact velocities could alter the biomechanical responses of the brain tissue. A larger velocity will introduce a larger distribution of stress and strain with the same impact depth. The simulation results are consistent with that from Sutton et al. (1993), where they found a greater velocity led to a greater contusion volume [8]. In addition, our observation of the biomechanical responses is also consistent with that by Mao et al. [5]. Future work includes animal experiments to validate this model. Also, influences of different impact configurations will be analyzed.

In summary, we developed a protocol to construct an image-based FE model of mouse brain. The simulation results are consistent with experimental observations and showed a clear time-dependent behavior of the brain tissue during CCI.

INTRODUCTION

The pia arachnoid complex (PAC) is a cerebrospinal fluid-filled tissue that surrounds the brain and spinal cord. Within the PAC, arachnoid trabeculae (AT) fibers, AT sheets, and blood vessels span the space between the arachnoid and pial surfaces. These microstructures help hold the delicate central nervous system tissue in place [1]. Due to its structural role, alterations to the biomechanical properties of the PAC caused by sub-concussive hits could impact stresses acting on the brain during traumatic brain injury (TBI). Relatively few studies have investigated PAC biomechanics [2-4]. However, relatively little is known about PAC biomechanical properties causing a gap in knowledge making it difficult to accurately model TBI using finite element modeling (FEM) [5, 6]. The aim of this study was to quantify the mechanical and structural properties of ovine PAC.

METHODS

Ovine brain samples (n=10) were harvested from the University of Idaho Vandal Brand Meats. All samples were removed from the skull within 30 minutes post-mortem. To access the brain tissue, skulls were split medially. To expose the base of the skull, the lower jaw was removed. A shearing knife was used to make clean proximal cuts through the buccal tissue. Once all connective tissue was cut, the lower mandible was removed and discarded. Subsequently, the skull was positioned with the hard and soft pallet of the mouth exposed. The hard and soft pallets were completely separated medially. A similar procedure was employed to split the top of the skull from the occipital region down to the nose. The skull was flipped, and the lower skull cavity was split. Final separation was achieved by breaking the occipital portion of the skull with the halves being carefully separated so as not to damage the brain. Using flat head forceps and a scalpel the brain was removed from the skull. A ~25x40x3 mm template was placed on the frontal right (FR), frontal left (FL), occipital right (OR), and occipital left (OL) region of the brain surface (**Figure 1b**). Each section was cut and removed using a disposable surgical scalpel and bent flat head tweezers. During removal, the brain was kept moist with artificial cerebrospinal fluid (aCSF). Immediately following the removal, each specimen was submerged in aCSF inside a 50 mL conical centrifugal tube and kept on ice. At <2-hours post-mortem all samples were taken back to the laboratory. Upon arrival, each PAC sample was removed and tested separately. It was necessary to remove the PAC from the underlying brain tissue. To do this, the sample was submerged in aCSF (~25ml) with the soft brain matter facing up. Using a scalpel and flat-head tweezers the brain matter was removed until all that was left was the clear PAC. The PAC was then placed in a C-shaped template made

of thick paper (10 mm opening) and glued shut (**Figure 2a**). KimwipesTM were soaked with aCSF and placed in the bottom of 50ml tubes and the PAC samples were gently placed inside and set on ice until testing. The prepared sample was then placed in the bioreactor system developed by Raveling et. al [7] (**Figure 2b**). Once clamped inside the rig, the samples were pulled in uniaxial tension at 2 mm/s until failure. The force and displacement data were acquired at 100 Hz using LabVIEW. To evaluate the stress and strain values, the length and width of the specimens were measured from photographs using ImageJ. PAC thickness was measured using a micrometer (Model 293-340-30 Mitutoyo, Japan). Each sample was measured three times. An Olympus Fluoview 1000 confocal/multiphoton microscope, with second harmonic imaging (860 nm excitation wavelength) was used to visualize collagen microstructure including sheets, pillars, and blood vessel walls. 4,6-diamidino-2-phenylindole (DAPI) was used to visualize cell nuclei.

Figure 1: (a) Sheep head with lower mandible removed showing order of cranial cuts (1-4). (b) Location of PAC specimen removal sites.

Figure 2: (a) C-shaped template used to mount into the bioreactor (10 mm opening). (b) Bioreactor apparatus with mounted sample prior to testing.

RESULTS

All data collected from the bioreactor was read into and analyzed with MATLAB to generate stress-strain curves. **Figure 3** shows the stress-strain behavior of the PAC samples, when subjected to uniaxial tension at an average strain rate of 0.59 s^{-1} . A Mooney-Rivlin model (Eq.1) was fit to the average stress-strain curve (Eq.1) with stretch ratio $\lambda = \varepsilon + 1$.

$$\sigma_{unaxial}^{eng} = 2C_{10}\left(\lambda - \frac{1}{\lambda^2}\right) + 2C_{01}\left(\lambda - \frac{1}{\lambda^3}\right) + 4C_{20}\left(\lambda - \frac{1}{\lambda^2}\right)\left(\lambda^2 + \frac{2}{\lambda} - 3\right) \quad (\text{Eq.1})$$

The nonlinear least-squares fit for the Mooney-Rivlin constants were estimated to be 1, -1.004 and 0.629 MPa for C_{10} , C_{01} , C_{20} respectively (SSE = 0.6552, $R^2 = 0.985$). The linear region Young's modulus (E), of the stress-strain curves was found to be $7.68 \pm 3.0 \text{ MPa}$. The mean ultimate stress and strain were found to be $2.69 \pm 0.76 \text{ MPa}$ and 0.60 ± 0.13 , respectively. The limited samples collected did not reveal significant differences across sample locations. Mean PAC thickness was found to be $69.7 \pm 29.7 \mu\text{m}$. Using SHG imaging, trabecular fibers and sheets were found to range from ~ 5 to $30 \mu\text{m}$ in thickness and showed both straight and crimp-like morphology (**Figure 4**). Cell nuclei appeared to be organized along blood vessel lumens traversing the PAC.

Figure 3. Stress/strain curves for n=10 ovine brain samples with a superimposed curve fit using the Mooney-Rivlin model.

DISCUSSION

To our knowledge, this preliminary study represents the first biomechanical characterization of ovine PAC tissue. Brain sample harvesting and uniaxial tension testing methods of fresh ovine PAC specimens (n=10 animals) were successfully developed. These methods required a detailed series of preparation steps to secure the samples in place for mechanical testing. Our results collected at a strain rate of 0.59 s^{-1} reasonably agree to those found by Jin et al., [3] with a Young's modulus of 11.33 MPa and ultimate stress of 1.44 MPa . We did not observe significant differences in Young's modulus with location on the brain surface. These properties can be used as input data in finite element models of the brain during TBI simulations. Albeit, the strain rate analyzed was relatively slow compared to those often seen in TBI-related circumstances. Future studies should clarify if the stress-strain

behavior of PAC tissue depends on strain rate or cyclic loading, representing repeated TBI scenarios.

Collagen folding was visible on SHG imaging, albeit, to a lesser degree than in many other biologic tissues. We found the PAC tissue to be pre-stressed on the surface of the brain. To our knowledge, pre-stress of PAC on the brain surface has not been previously reported in the literature. Upon removal from the surface of the brain from the PAC, the tissue contracted in length and became flaccid making it difficult to determine the physiological zero-strain state. For our testing, a threshold of 0.05 N was defined to determine the zero stress/strain state. Specimen length was found to change by as much as 63% between its pre-stressed condition situated on the brain, to its unstressed condition situated in a C-shaped template. This resulted in significant variation when calculating Young's Modulus. However, the ultimate stress/strain (failure point) of each sample under uniaxial tension were similar between cases.

INTRODUCTION

Virtual representations of the musculoskeletal extremities that faithfully replicate the behavior of tissue's surface mechanics would advance simulation-based surgical assessment, medical training, and prototyping of protective gear. The musculoskeletal extremities, consisting of the upper leg, lower leg, upper arm, and lower arm, are of particular interest because they account for more combat wounds than any other region of the body [1]. This study aims to develop template models for these regions that can accommodate simulations of indentation and other surface interactions, which are necessary for haptic feedback in virtual training.

METHODS

Finite element representations of cadaver arm and leg regions were generated for one male and one female donor (Table 1). The specimens were put through a series of experiments which tested the loads observed on an ultrasound probe during indentation trials [2]. Computed tomography (CT) images of these specimens were also collected at a resolution of 0.5 mm x 0.5 mm x 0.6 mm.

Table 1: Specifications of donors.

Sex	Age (years)	Weight (kg)	Height (m)	BMI (kg/m ²)
Male	65	77.1	1.778	24
Female	62	68.0	1.803	21

Anatomy of eight regional models was reconstructed from manual segmentation of the CT images using 3D Slicer [https://www.slicer.org]. Surface representations for both the lumped flesh and the bone were created by Poisson surface reconstruction on

the 3D Slicer output using Meshlab [http://www.meshlab.net]. The surface meshes were then parameterized, remeshed, and smoothed to improve mesh quality.

A three-dimensional scan of a Siemens 9L4 transducer, the ultrasound probe used during tissue indentation experiments, was generated to replicate its geometry for simulations. The ultrasound probe and the bone were both assumed to be rigid bodies and were modeled as 3 node triangular shell elements. The flesh volume was meshed with 10-node quadratic tetrahedral elements using Gmsh [gmsh.info]. The flesh component was modeled using an uncoupled Neo-Hookean constitutive model, with C_1 set to 0.01 MPa, based on a literature based effective Young's modulus [3]. K was set to 10 MPa to enforce near incompressibility, i.e., K was 1000 times larger than C_1 . The model was then assembled for simulation in FEBio [https://febio.org].

Contact between the ultrasound probe and the flesh was modeled with a frictionless, penalty-based, sliding-elastic contact formulation. The ultrasound probe was positioned based on the initial point of the experimental data and was given a prescribed displacement based on the displacement vector between the initial and end position during the indentation trials. Simulations were performed in FEBio v2.8.0 on the high performance computing cluster at the Cleveland Clinic. Figure 1 shows the basic setup of the upper leg models at the start of the simulation, as well as the flesh and bone components for the other six regions.

Prior to running simulations reproducing experimental conditions, a mesh sensitivity study was performed on the female donor's upper leg to determine the appropriate remeshing sampling rate. Convergence was considered reached after simulated reaction forces did not vary by more than 5% in consecutive densities. For these simulations the probe was displaced 15 mm and the material

parameters were set as C_1 at 0.0018 MPa and K at 1.795 MPa. These values were used as an approximation of material properties early in the model development process. Material properties are not expected to influence the mesh convergence results obtained (Table 2).

Figure 1: A. Layout of the probe, bone, and flesh components for the female and male upper leg models. B. Bone and flesh components for the remaining six models.

RESULTS

Table 2 shows the results of the mesh sensitivity study, highlighting the converged mesh, which had a remeshing sample rate of 5.

Table 2: Mesh sensitivity of female upper leg model. The bold row highlights the converged mesh density (remeshing sample rate 5).

Node Count	Predicted Reaction Force (N)	Percent Difference
44968	20.8	-
72904	19.9	-4.3
113836	18.1	-9.1
173068	17.5	-3.0
244551	17.6	0.3

Table 3 compares the experimental force data against predictions from simulations conducted with literature based material properties.

Table 3: Experimental vs. simulation predicted probe reaction forces.

Model Region	Experimental (N)	Predicted (N)
Male Upper Leg	13.1	25.7
Male Lower Leg	13.3	15.8
Male Upper Arm	9.6	24.9
Male Lower Arm	14.4	22.5
Female Upper Leg	9.9	13.4
Female Lower Leg	6.1	12.7
Female Upper Arm	7.9	20.1
Female Lower Arm	6.6	23.8

Figure 2 shows the effective stress distribution for the female upper leg model at the end of indentation. Other field metrics such as Lagrange strain and contact pressures are also available.

Figure 2: Effective stress (MPa) distributed across the surface of the flesh of the female upper leg model at full indentation.

DISCUSSION

Lumped tissue models for the musculoskeletal extremities were built and simulated with probe indentation for prediction of surface mechanics. While the reaction forces obtained from simulation do not match closely with experimental data, a close match was not expected at this point. Soft tissue material properties are known to differ based on a variety of factors, including gender and body region [4]. The literature based effective Young's modulus does not attempt to control for either of these variables and resulted in a simulated reaction force that is consistently an overestimation, by a factor ranging from 1.18 to 3.61. The variability in overestimation highlights the need to assign each flesh component its own material properties to obtain more representative surface mechanics.

Future work will include calibration of these models through inverse finite element analysis, where each model's material parameters will be determined based on the force-displacement data obtained from experimentation. This step will improve the accuracy of the representation of surface mechanics for each model. Once calibrated, these models may serve as the basis for individualized surgical simulation tools.

Beyond calibration of the lumped tissue models, additional model development is planned as a part of this project. Models that explicitly represent the skin, fat, muscle, and the interactions between these layers are currently under development. Additional model features such as gravity compensation and model incorporation with haptic feedback devices are also planned.

All models, data, and scripts that were used in this study are available online, in the source code repository at <https://simtk.org/projects/multis>. A more detailed set of modeling specifications is also available on this website's wiki. The open availability of this data through public dissemination aims to reduce the barrier of entry for other researchers to adapt these models to their own work.

INTRODUCTION

Subchondral bone cysts (SBCs) are frequently diagnosed in young horses bred for racing. They occur most often in the medial femoral condyle (MFC). SBCs can result in lameness and cause secondary injuries such as meniscal and cartilage damage. Traditional treatments of SBCs aim to reduce local inflammation and promote bone healing by use of anti-inflammatory agents, cyst debridement and/or regenerative substances [1]. Reported success rates vary greatly and reflect short-term lameness reduction only. Radiographic healing rates of SBC after treatment are rarely reported, and when they occur, are described as a reduction in SBC size rather than complete healing [2].

A recently developed treatment which places a transcondylar lag screw across the void has shown high success rates in both lameness resolution and radiographic healing [3], and recent work in our laboratory indicates the mechanism of healing is increased bone stress stimulus combined with reorientation of the compressive principal stresses. However, these results were obtained using a single 2 cm³ void. As such, it is of clinical interest to study the effectiveness of the standard screw placement for several different cyst sizes.

In this study, finite element analysis was utilized to quantify the bone remodeling stimulus with a proximodistal oblique transcondylar lag screw through an equine MFC with SBC voids of varying proximal-distal height, medial-lateral width, and anterior-posterior depth. We hypothesized that the lag screw treatment strategy stimulates bone formation in cysts where the screw passes through the cysts, but not for small cysts that the screw does not penetrate.

METHODS

Previous work by our lab developed a finite element model of an equine stifle joint in extension with a 2 cm³ void in the MFC under joint

loading to simulate stall confinement, hand walking and light exercise [4]. The present study used this model with an added sclerotic region of bone of thickness 5 mm (as seen clinically) outside of the SBC. The sclerotic density was assumed to be 1.0 g/cm³ and given a corresponding modulus of 3770 MPa using

$$E = 3770 \rho^3 \quad (1)$$

for the density-modulus relationship [5]. The remaining bone tissue was assigned properties using the same relationship. Cartilage material properties were lowered from our previous study to better represent the tissue response at lower loads and strain rates experienced in a post-operative environment ($E = 8$ MPa, $\nu = 0.45$).

Criteria for Effectiveness: To evaluate the efficacy of various surgical treatment strategies, Beaupre, Orr, and Carter's theory of bone remodeling was adopted [6, 7]. The standard tissue stimulus (Ψ) was calculated to predict bone resorption, apposition, or no net change,

$$\Psi = \left(\sum_{day} n_i \sigma_{b_i}^m \right)^{\frac{1}{m}} \quad (2)$$

where n_i is the number of cycles per day (for a given load), σ_{b_i} is a bone tissue-level effective stress based on strain energy density, and m is an empirical constant assumed to be 6 for the horse [8]. We assumed the standard attractor state (ideal reference stimulus) of 50 MPa and a "dead zone" of $\pm 20\%$ (i.e. 40-60 MPa). Thus, values of $\Psi > 60$ MPa predict bone apposition, and values of $\Psi < 40$ MPa predict bone resorption.

General Boundary Conditions and Analysis Procedures: A 900 N load was applied as uniform pressure on the proximal femur to simulate stall-confinement loading that occurs for the first few weeks post-surgery. The quadriceps tensile force on the superior aspect of the patella to prevent unrealistic femoral anterior translation was scaled down from our previous study to 100 N [5]. The proximal aspect of the

femur was constrained in varus-valgus (0°) and flexion/extension rotations (155°). The tibia was fully constrained, and all femoral translations and internal rotation were allowed. Frictionless contact was defined between all articulating surfaces using general contact in ABAQUS. Stimulus, Ψ , was calculated on the interior surface elements of the SCL, and the percentage of the available cyst surface area exceeding 60 MPa, bone formation area (BFA), was calculated.

For all models, a simplified screw (40 mm length and 4.5 mm diameter cylinder, $E = 200$ GPa) was constructed with a 6 mm head and tapered at the axial end. The head was constrained by contact with the outside of the bone and the tip was tied to the bone. Screw compression of 300 N was applied axially to simulate tightening. The screw was placed from abaxial to axial in the MFC (i.e. from medial surface toward central femur), to simulate the clinical proximodistal oblique transcondylar screw placement, such that the screw passes through larger SBC voids. The number of steps, cycles per day (cpd) or n_i in Equation 2, was chosen as 3000 cpd for the applied joint load of 900 N.

Parametric Study Design: Each spatial dimension of the cyst was varied between 3 different levels that represent the minimum, median, and maximum lengths observed clinically [9]. The proximal-distal height of the SBC void was 2 mm, 14 mm, or 26 mm. The medial-lateral width of the SBC void was 2 mm, 8 mm, or 14 mm. The anterior-posterior depth of the SBC void was 2 mm, 10 mm, or 20 mm. The study design was a full 3^k ($k=3$) factorial evaluation of all 27 combinations. Previous work has shown that at 900 N load, a neutral screw with 0 N of compression does not differ from using no screw at all. Therefore, the models were run with 0 N of compression and then again with 300 N compression. The change in BFA was calculated to demonstrate the effectiveness of the compression on the lag screw.

RESULTS

The results clearly show that the size of the cyst is the primary predictor of the increase in bone formation area (BFA) caused by the screw (Table 1). For all cysts with a 2 mm height, the BFA increased a negligible 0-3 %. For cysts with a 14 mm height, the BFA increased by 6-31%. For cysts with a 26 mm height, the BFA increased 5-34%. In particular, the height of the cyst had the largest effect. Regression analysis showed that the cyst height alone accounts for 56% of the variation (increase) in the BFA, followed by cyst depth (12%) and cyst width (negligible). For small height cysts (Figure 1A), the screw does not penetrate the cyst, but simply goes over the top of it, producing little stress stimulus for bone formation. For cysts with a 14 mm height, the screw penetrates and crosses the top of the cyst. Depending on the cyst width and depth (Table 1), the screw increased the bone stimulus and BFA substantially.

Figure 1. Bone tissue stress stimulus in the medial femoral condyle region of interest 900 N joint load, 300 N stainless lag screw compression, and 3000 cpd for three different sizes of cyst.

- A) 2 mm height, 2 mm width, 2 mm depth
B) 14 mm height, 8 mm width, 10 mm depth
C) 26 mm height, 14 mm width, 20 mm depth

DISCUSSION

The BFA is affected by the screw position in the cyst, and the PDO screw position is constrained by the regional anatomy, as the screw head

cannot contact the cartilage or meniscus. Given that limitation, the cyst height is the most important factor affecting the increase in BFA provided by the screw. While the 14 mm cyst height did see substantial increases in BFA with the screw (Figure 1 and Table 1), this cyst height may be near the minimum for the screw to be effective using the standard screw placement. When the screw goes above the cyst, it has little effect on the BFA (Figure 1A).

Table 1: Predicted bone formation area (BFA) increase as a percent of void surface area with a 900 N joint load, 300 N screw compression, and 3000 daily cycles (steps).

Height	Depth	Width	BFA % Increase
14	10	2	12
14	10	8	15
14	10	14	27
14	20	2	10
14	20	8	20
14	20	14	31
26	10	2	34
26	10	8	28
26	10	14	24
26	20	2	34
26	20	8	22
26	20	14	29

Cyst depth (anterio-posterior) had a moderate impact on BFA and the impact of cyst width was minor. Because the screw goes primarily medial-lateral and proximal-distal, a larger depth is important so that the screw will pass through the cyst. Thus, the secondary factor affecting the increase in BFA is cyst depth. But if the cyst is high enough and deep enough, it will pass through a cyst regardless of the medial-lateral width. In order to reach lower cysts, a lower and more horizontal screw would be required, but the screw head would interfere with the medial meniscus. It may be possible to reach and stimulate bone formation in such cysts with a dual pitch headless screw, if enough compression can be achieved across the cyst.

There are a number of limitations to this study. All configurations tested were variations of a single finite element model based on a single healthy stifle joint. The SBC shape and the sclerotic region were idealized to match what is commonly observed clinically. The joint loading was estimated, as there are no kinetic data for the equine stifle. Also, the bone remodeling theory framework is based on limited samples that do not include equine data. While absolute values may be questioned, the relative values of stress stimulus clearly indicate the relative effectiveness of the lag screw for various sized cysts.

INTRODUCTION

Understanding *in vivo* motion of orthopaedic implants is an important part of evaluating performance. Simulation of these situations is often done via multi-axis mechanical simulators. As with any mechanical testing, the compliance of the machine and associated fixtures are sources of uncertainty in acquiring kinematic data. Compliance is often compensated for in 1 degree of freedom (DOF) applications with an extensometer (e.g. Instron machine for tensile testing). The extensometer, measures movement without the influence of machine deformation and thus provides a more accurate displacement measurement compared to the output of the machine itself. In this study, motion capture was used as a 6-DOF extensometer to eliminate machine compliance in the kinematic data during testing of orthopaedic implants. The aim of this study was to understand the kinematic differences in implant motion when reported by the testing machine vs. the motion capture system.

METHODS

A single knee implant was tested using a robotic musculoskeletal simulator that consisted of a pedestal base, ATI Omega 85 load cell, total knee replacement, and a Kuka KR300 robot. An active motion tracking sensor was mounted to the femur and tibia implants so as to be seen by the NDI Optotrak Certus stereoscopic motion tracking camera (**Figure 1**). Femur and tibia component coordinate systems were created relative to the robot, load cell, and motion tracking sensor by digitizing the implants, load cell, and robot. The relative relationship of the femur and tibia coordinate systems was defined by the Grood and Suntay knee joint coordinate system (JCS) [1]. The implant was then biomechanically tested using simVITRO® software by applying various motions and loads specified by a standard gait profile (ISO

14243-1) and constraint test (ASTM F1223) [2, 3]. The two versions of JCS kinematic data (i.e. measured by the motion tracking sensors and the robot) were collected throughout the tests and analyzed.

Figure 1: simVITRO Robotic Test System

RESULTS

Differences between JCS kinematics from motion capture and robot data were identified. The measurement noise was more favorable using robot data (60-800 μ m, 5-40 μ m noise range for motion tracking and robot respectively). Robot data accuracy decreased with increasing forces, as the differences in measurement was a function of force, and therefore due to system compliance (**Figure 2**). Compliance was identified in several degrees of freedom, however the difference between the motion capture and robot data was greatest in the inferior-superior direction (877 N/mm), and likely due to large applied compression forces. At high loads, the robot data suggested ~3 mm of reported penetration of the femur into the tibia (**Figure 3**).

Figure 2: Compression Force vs Kinematic Error

Figure 3: Incorrect (Orange) Penetration of Components

DISCUSSION

While the robot kinematic data was considerably more precise than motion capture, it was found to suffer from compliance induced accuracy problems. The linear relationship with force is likely due to machine and fixture compliance (**Figure 2**). When utilizing this data for kinematic control of biomechanical simulations, wear testing systems, or computational model validation, the machine compliance inaccuracies will degrade the kinematic integrity of the results. **Figure 3** shows the non-linear contact relationship between implant

components and how model reconstructions of the kinematic data can produce inaccurate results if using machine kinematic data only. Wear testing, for example, is performed by applying the same kinetic/kinematic profile to implants millions of times to characterize how the component changes. Kinematic controlled testing assumes the desired and actual kinematics match. If they don't, then the forces applied to the component will change, and introduce uncertainty in the results. However, motion tracking based kinematic measurement and control is no panacea and possesses two major pitfalls to be aware of: visibility and noise.

Each rigid body motion tracking sensor is made up of 3 or more 3D markers which can be combined together through a least-squares fit algorithm to determine the position and orientation of the rigid body. Occlusion of one or more markers so that there is less than 3 visible will result in no knowledge of rigid body location. In addition, occlusion of any one of the markers can affect the least squares fit result. Also, each of the markers has some stochastic noise associated with the measurement. This measurement (i.e. sensor location) is then transformed to the femur and tibia to calculate the JCS. Depending on the spatial relationship of the sensor and bone, this process can amplify noise and visibility uncertainty in the resulting JCS kinematics. Lastly, kinematic control of a testing machine using an external measurement of position (e.g. motion capture) is difficult due to these measurement uncertainties as well as other issues regarding control communication rates and robustness to noise and data dropouts.

Neither the robot or motion capture based kinematics are ideal, but each have beneficial properties. In the future, a potential solution for remedying the shortcomings of robot kinematic data and lessening the pitfalls of motion capture systems lies in a hybrid algorithm that combines data from both sensors in real-time.

In conclusion, the compliance of mechanical testing machines can generate incorrect kinematic data which when coupled to wear testing, superposition testing, or mathematical modeling can lead to incorrect conclusions about implant performance. By utilizing motion capture and accounting for its limitations, improved accuracy in testing results can be achieved thus providing meaningful research that can be more directly translated to patient care in any mechanical testing system in which compliance exists.

EFFECT OF PELVIS AND LIMB POSITION ON RADIOGRAPHIC LEG LENGTH DISCREPANCY MEASUREMENT: A SAWBONES MODEL

Chicago, IL, USA

INTRODUCTION

Leg length discrepancy (LLD) after total hip arthroplasty is a challenging problem which can result in nerve palsy, abnormal gait and hip instability among other complications.¹⁻³ Measuring LLD on pelvis radiographs can be challenging, especially because the obliquity of the pelvis and position of the corresponding limb can affect the measured leg length. A perfect pelvis x-ray with a level pelvis and neutral femur abduction is not always available or attainable. We sought to determine how varying pelvis and limb position would affect LLD measurement and devise a method to estimate true leg length discrepancy.

METHODS

A size large pelvis and bilateral femur sawbones model with equal leg lengths and a high resolution radiopaque cortical shell was utilized with fluoroscopy. Leg lengths were measured with a medical imaging software from the acetabular tear drop to the tip of the lesser trochanter, as is established in clinical practice.² Leg length discrepancy was measured with intentional malpositioning of pelvic obliquity 0°, 5°, 10° and 15° and femur malpositioning from 15° adduction to 15° abduction in 5° increments. We then calculated the LLD measurement error resulting from all combinations of pelvic obliquity and femur malpositioning.

RESULTS

Pelvic obliquity changes of 5° or less typically result in LLD measurement error <1 cm. As pelvic obliquity increases to 10°, resultant LLD measurements errors are <1cm if the femora remain neutral. At pelvic obliquity of 10° and 15°, even minor limb malposition results in clinically significant measurement errors >1cm. Greatest LLD measurement error occurs when femur on high side of obliquity is adducted and low side femur is adducted.

Figure 1: Measurement error in centimeters seen at varying limb positions when the pelvic is set at

0 degrees obliquity. The legend explains a negative ME implies a longer right side and positive ME implies longer left side

Figure 2: Measurement error in centimeters seen at varying limb positions when the pelvic is set at 5 degrees obliquity. The legend explains a negative ME implies a longer right side and positive ME implies longer left side.

Figure 3: Measurement error in centimeters seen at varying limb positions when the pelvic is set at 10 degrees obliquity. The legend explains a negative ME implies a longer right side and positive ME implies longer left side.

Figure 4: Measurement error in centimeters seen at varying limb positions when the pelvic is set at 15 degrees obliquity. The legend explains a negative ME implies a longer right side and positive ME implies longer left side.

DISCUSSION

LLD after total hip arthroplasty is a challenging problem for patient and surgeon alike and careful leg length measurement on pelvis radiographs is critical. Pelvic obliquity greater than 10° can lead to significant LLD measurement errors >1cm even with minor limb malposition.⁴ Error is increased in lower limb positions typically seen in a standing radiograph with pelvic obliquity where one femur is adducted and the other abducted. Accurate LLD measurement is critical but perfect radiographs are not always attainable. We offer methods to estimate true LLD using simple geometric calculations or correction tables obtained from our results.

The findings of our study are clinically relevant, as up until now CT, MRI, and X-ray scanograms have been shown to have more validity and reliability than AP radiographs.^{5,6} However, our method of measurement correction allows the use of quickly obtainable, cheap, AP radiographs to similar accuracy levels of the previously mentioned modalities.

CLINICAL REPRESENTATION OF JOINT COORDINATE SYSTEM FORCES

Callan Gillespie (1), Tara Nagle (1), Robb Colbrunn (1)

(1) BioRobotics Lab
Cleveland Clinic
Cleveland, Ohio, US

INTRODUCTION

There is currently no standard way of describing knee joint kinetics unlike kinematics, in the field of biomechanics. Practically, this means that two identical tests can produce different kinetic results because the results are displayed in different coordinate systems (CS). Three common ways to report knee loads are in the JCS reference frame, the tibia reference frame, and a third hybrid approach.

In the knee JCS a single translation and rotation is applied starting at the local femur CS followed by a second translation and rotation, and a third, as seen in the left of Figure 1. The JCS is a non-orthogonal CS, meaning that its axes, specifically the first and third do not have to be perpendicular [1, 2]. This knee JCS definition by Grood & Suntay was standardized by the International Society of Biomechanics and is now the accepted method to describe clinically meaningful representations of motion [2]. Alignment of the kinetic and kinematic CSs provides a direct mapping between kinetics and kinematics. However, JCS kinetics are non-orthogonal which creates the possibility of loads being overstated if components of the force aligns with multiple axes, or being understated if components are not aligned with any of the JCS axes. For normal knee motion these amounts may not be clinically significant, but they are real.

For this reason, kinetics are often described in an orthogonal tibia based CS where there is no possibility of under- or overstating loads. The downside is that anatomical loads and kinematic directions do not match. For example, if a patient is sitting on an exam table and the tibia is internally rotated 20 degrees, then when the clinician sitting across from the patient pulls the tibia towards them, it is clinically considered an anterior translation. However, the forces, as represented in the tibia

reference frame, include components of anterior and lateral loads (figure 1, right).

Figure 1: Knee Joint Coordinate System

Left: Knee JCS, Right: Knee JCS with Anterior Drawer Force

The third approach in literature is reporting orthogonal forces in the tibial reference frame, and projecting the torques onto the non-orthogonal JCS axes. This provides some benefits, retains some of the original limitations, and introduces a new limitation. Typically torques are projected onto the JCS without taking into account moment arms [3]. In the example described above, an anterior pull will create an extension torque about the flexion axis of the JCS (figure 1, right). However, if kinetics are initially computed in the orthogonal tibial plateau reference frame and then projected into the JCS, there will be a smaller torque because the calculations only include the moment arm

from the application of force to the tibial plateau, and not the femur flexion axis. To overcome the limitation of this approach, the moment arms from the orthogonal CS to each link of the JCS would need to be taken into account when calculating JCS moments.

The goals of this study were to understand the effect using different kinetic reference frames has on reported loads and to convey the importance of properly reporting kinetic reference frames.

METHODS

Freely available data from the Open Knees project was examined to determine the effect of different kinetic CSs [4]. Open Knees was a research project conducted at the Cleveland Clinic using a simVITRO® universal musculoskeletal simulator (Cleveland Clinic, Cleveland, OH) to apply forces and torques to cadaveric knee joints. The tests were performed by controlling kinetics in the tibial reference frame. Data collected from specimen oks008 was utilized. Combined loading states were applied to the knee joint yielding 27 different kinetic states at 90 degrees of flexion (Table 1).

Condition	Loads
Lateral Drawer Force	0 N
Anterior Drawer Force	100, 0, -100 N
Distraction Force	-20 N
Extension Torque	0 Nm
Varus Torque	10, 0, -10 Nm
External Rotation Torque	5, 0, -5 Nm

Table 1: Open Knees Combined Loading Conditions

Kinetics were considered in the native tibia reference frame, the projected reference frame (by projecting moments to the JCS reference frame (Eqn. 1)), and the JCS reference frame (by transforming forces and moments to the JCS reference frame (Eqn. 2-3)).

$$\bar{M}_i = \bar{M} \cdot \bar{e}_i \quad (1)$$

$$\bar{F}_i = \bar{F} \cdot \bar{e}_i \quad (2)$$

$$\bar{M}_i = \bar{M} \cdot \bar{e}_i + (\bar{r}_i \otimes \bar{F}) \cdot \bar{e}_i \quad (3)$$

In the above equations, \bar{M} is the moment vector and \bar{F} is the force vector represented on the orthogonal tibia CS of the knee. \bar{M}_i and \bar{F}_i are the kinetics about or along the i th JCS axis. \bar{r}_i is the moment arm vector between the origin of the tibia reference frame and the i th JCS axis of interest. Similarly, \bar{e}_i is the unit vector of the i th JCS axis represented in the tibia CS.

RESULTS

Tables 2 and 3 present the average difference between kinetics represented by either the tibial reference frame, or projected reference frame, compared to the JCS reference frame.

	Mediolateral JCS Force	Ant/Post JCS Force	Distraction Force	Resultant JCS Force
Tibia	33%	12%	0%	2%

Table 2: Average Force Differences per DOF

	JCS Extension Torque	JCS Varus Torque	JCS I/E Torque	Resultant JCS Force
Tibia	31%	12%	0%	5%
Projection	6%	1%	0%	4%

Table 3: Average Torque Differences per DOF

Distraction forces and external rotation torques were identical between all kinetic reference frames because the internal rotation axes were the same in all cases. For all other loads, differences were observed between the JCS reference frame and the tibia and projected reference frames. The alignment of JCS coordinate axes is demonstrated by the differences in resultant force and torque between JCS and tibial plateau kinetics.

DISCUSSION

Forces

The anterior and lateral forces were different in the JCS as opposed to the tibia and projected reference frames. These differences, can be attributed to internal/external rotation altering the anterior direction between the tibia and JCS reference frames. Large applied anterior forces between 100 and -100 N in the tibia reference frame are partly distributed as a medial/lateral force in the JCS reference frame when the tibia is rotated. Lateral force differences can be attributed to alignment between compression and mediolateral axes. Varus rotation causes the compression axis to be partially aligned with the mediolateral axis resulting in tibia compression creating mediolateral force.

Torques

Similar to the force, there was a trend of increasing kinetic differences when moving up the kinematic chain. Varus torques in the tibia were redistributed as varus and extension torques in the JCS, as a function of internal rotation. External rotation torques in the tibia were reported as extension torque of the JCS, due to alignment between the mediolateral and compression axes.

Table 3 demonstrates the relationship between tibial forces and moment arms applied to the different JCS axis. Including moment arms in torque calculations does produce noticeable differences as can be seen in the bottom of table 2. The Open Knees Protocol prescribes a tibia component ML force of 0. If this were higher differences would most likely be greater in both tables.

In conclusion, it can be convenient to describe kinetics in an orthogonal coordinate system especially when experimental methods obtain kinetics there directly [5]. However, this study shows there are significant differences between kinetics reported in these coordinate systems and the JCS reference frame. Kinetics possess more clinical meaning when described in the JCS and moment arms should be included in calculations so that the contribution of forces to JCS torques is captured. For studies where knee loads are controlled and kinematics are reported using the ISB Standards it is recommended to use the same JCS reference frame to control kinetics.

INTRODUCTION

Anterior cervical discectomy and fusion (ACDF) is the current established surgical treatment for cervical disk disease, such as herniated discs or stenosis. ACDF removes the damaged intervertebral disc and employs an anterior plate for cervical spine fusion to reduce graft-related complications. A common problem with cervical plates is the fixed spaced of rigid plate design, which was thought to promote bone fixation and healing, but has been shown to have a tendency to detach from the bone [1-4]. Recent designs utilize dynamic plates, which allow screws to glide between bone anchor points during early graft settling. In this study, we compare the load transmission between vertebral bodies and cages of the self-correcting feature of stand-alone cages (SAC) to conventional anterior plate-cage configuration (APC). Specifically, we aim at evaluating the biomechanical safety and efficacy of a 3 level construct from C3 to C6 using a SAC compared to an APC.

METHODS

Cadaver cervical spines from T1 – C2 were DEXA scanned for general bone density evaluation. Five non-osteoporotic spines were chosen. All soft tissues were removed except for ligaments and joint capsules. All spines were stored frozen and thawed on the day of the surgical procedures for testing at room temperature. The C2 level was held in a fixture that allows translations in the sagittal plane and rotations in 3 planes at each

level. The C7 and T1 levels were potted and fixed to the testing bench. Mechanical tests were performed via a servo-hydraulic testing system MTS 858 Mini Bionix II (MTS Systems Corp., Eden Prairie, MN, USA). The mount at C2 was preloaded posteriorly and the MTS applied a compression load anteriorly through a linear bearing system that followed the movement of C2 as the spine cycled from 1 Nm extension to 1 Nm flexion while range of motion (ROM) of each level was recorded by fluoroscopy (OEC 6600 Mini C-arm) in the sagittal plane, see Figure 1. Each spine had a discectomy performed at 3 levels. A SAC was applied at each level with a Tekscan 6900CR (Tekscan, Inc Boston, MA) pressure map placed between the inferior end plate and the cage, and a 1 cm wide strip of X-ray film (shim) was placed between the superior end plate and the cage. This construct was repeated at all 3 levels of the spine. After the first mechanical loading regimens and recordings were complete, the shims, 0.18 mm thick, were removed to simulate minor bone resorption in early healing, and the loading regimen and all recordings were repeated. After that testing with the SAC was complete, an anterior plate and cages (APC) were applied with the same construct of pressure maps and shims. The whole battery of loading regimens and recordings were repeated before and after removal of the shims with the APC construct. Peak pressures, average pressures, center of pressure movements, contact areas and forces were calculated for each pressure map at critical points of the cycle loading and for each condition tested. Analysis from the fluoroscopic images provided

measures of the ROM in sagittal plane for each motion segment unit.

Figure 1 – Experimental setup: the location of the pressure transducer and the orientation of the fluoroscope, as well as the loading conditions are shown

RESULTS

The ROM of the SAC and APC constructs were not significantly different. Comparison with vs. without shims showed no change in ROM for SAC, but there was a significantly larger ROM in extension for APC after shim removal ($p < 0.05$). Since the plated construct tends to create more compression on the cage in extension (plate in tension band mode) than in flexion, and the stand-alone cage is the opposite, we focused on analysis of the constructs in both extreme positions. None of the investigated levels of the spine lost significant contact area or average pressure with removal of the shim in the SAC constructs in both flexion and extension. There was significant loss of contact area and average pressure at 2 of 3 levels in the APC constructs in flexion and at 1 of 3 levels in extension. The combined losses at all 3 levels for SAC were not significant ($p > 0.05$). In contrast, for the APC constructs, the combined losses were statistically significant ($p < 0.05$), see Figure 2.

DISCUSSION

The ROM measures suggested that the rigidity of SAC was at least as good as APC constructs in flexion-extension despite the simulated loss of bone. Resorption of bone in early healing has been blamed for lack of healing with APC constructs [5].

It was impossible to measure the whole foot print of the cage-endplate interface. The contact area was variable since the cage's flat surface contacted a non-flat end plate surface. So we made the assumption that the measured area on each construct was a reasonable representation of the whole contact surface.

Moreover, the main goal of the study was to measure the change associated with the simulated loss of a thin layer of bone expected in early phases of healing, and those changes were consistent, reinforcing our assumption.

Overall, the results indicate that SAC provides an alternative construct that can “adjust” to the early loss of bone at the interfaces, without compromising the rigidity of a 3-level construct.

Figure 2 – Contact pressure measurements: (a) Loss of contact area; (b) average pressure. Data are reported at maximum extension and maximum flexion. Statistically significant changes only occurred for APC.

INTRODUCTION

Current US Federal Motor Vehicle Safety Standards in frontal impacts regulate occupant safety criteria for the head acceleration, neck loads, and thorax compression [1]. To date, human tolerances have not been similarly defined for the lumbar spine as the mechanisms of injury are not well understood. Several epidemiology studies have reported on lumbar spine injuries in motor vehicle accidents. One study examined crashes from 1993-2010 using National Automotive Sampling System-Crashworthiness Data System (NHTSA NASS-CDS) and Crash Injury Research Engineering Network (CIREN) databases and found an increasing trend in the number of occupants with lumbar spine fractures and vehicle model year [2]. Injuries were observed at all levels with the majority occurring at L1 and L5. A similar study was performed using the same databases and found 2.5 times increase in frontal crash occupants with major compression lumbar spine fractures in newer model vehicles compared to occupants of vehicles from the previous decade [3]. Likewise, burst fractures were mainly observed at L1 and L5. Both studies reported the occurrence of lumbar spine burst fractures in purely horizontal impacts indicating compression of the spine without a direct vertical input to the vehicle. Determining the tolerance of the lumbar spine to complex loading will help delineate the mechanisms of injury and establish new occupant safety thresholds. The aim of the current study is to simulate combined loading of the lumbar spine by conducting compression tests on isolated post mortem human surrogates in a flexed posture using a custom designed fixture.

METHODS

Nine specimens were procured and isolated from T12 to sacrum. The inferior end of the spine was potted in polymethyl-methacrylate (PMMA) such that the L5/S1 disc was free and the top surface of the PMMA was parallel to the S1 endplate in the sagittal plane. Superior

end of the spine was fixed in PMMA such T12/L1 joint was unconstrained. Six-axis load cells were mounted proximal to the superior PMMA and distal to the inferior PMMA. Sets of three non-collinear retroreflective targets were placed into the anterior vertebral body at L1-L5. Additionally, three targets were mounted on the anterior surface of the inferior and superior PMMA. A set of CT scans were obtained following instrumentation.

The superior end of the upper load cell was attached to a single-axis electro-hydraulic piston which applied a rostral to caudal compressive load to spine. The inferior end of the lower load cell was fixed to a spinal position device (SPD) which consisted of 3-axis translation platform and a dual axis rotation mechanism (Figure 1).

Figure 1: Spinal position device showing three axis translation (anterior/posterior, left/right, and superior/inferior) and dual axis rotation (flexion/extension, axial rotation) components.

Flexed posture of the spine was achieved by using the SPD to rotate the distal PMMA in the sagittal plane and translate it forward to minimize sacral slope. Height of the sacrum was adjusted so that vertical preload was approximately zero. Figure 2 shows radiographs of a specimen in its unstressed or natural position and pre-test position

Figure 2: Unstressed alignment of lumbar spine (left) and pre-test position (right).

Superior end of the specimen was compressed at a rate of 1 m/s for 30 mm. Piston displacement and linear acceleration, and upper and lower loadcells were collected at 20 kHz. Specimen preloads were accurately recorded and incorporated into load-time history curves by measuring the sensor offsets in an unloaded condition. Three-dimensional motion of the vertebral markers was recorded at 1 kHz using a six-camera motion capture system. Marker data was combined with anatomic information collected from pre-test CT's to calculate three-dimensional kinematics of each vertebral level. Posttest CT's and radiographs were obtained, and specimens were dissected to determine injury.

RESULTS

Injuries from the nine specimens are summarized in Table 1. Posttest CT is shown in Figure 2.

Table 1: Injuries

PMHS	Injuries
1	Vertebral body fractures at T12 and L2
2	Disc disruption L2-3, L3-4, L4-5, and L5-S1
3	L5 and S1 spinous process fractures, S1 body fracture
4	L5-S1 fracture dislocation; L5 vertebral body fracture
5	L1 compression fracture; L2 superior endplate fracture
6	T12 inferior end plate fracture; L1 superior end plate fracture; T12-L1 disc disruption
7	Transverse fracture S1
8	L1-2-disc disruption with herniation; L1 and L2 compression fracture
9	T12 inferior end plate fracture, T12-L1 disc disruption

Average peak failure was 5068 ± 2370 N and 347 ± 112 Nm for force and moment.

Figure 3: Posttest CT showing L2 vertebral body fracture

DISCUSSION

Design of the current study was to examine the effect of posture on the compression failure tolerance of the lumbar spine. Results from the CIREN studies revealed the occurrence of lumbar spine fractures in pure-horizontal frontal motor vehicle accidents. These studies hypothesized that compressive loading to the occupant was from the seat bottom or restraints and later in the event when the lumbar spine is in a flexed posture. Injuries from the current study were generally at the distal and proximal segments of the lumbar spinal column and agree with field observations.

One published study from two isolated lumbar spines reported higher peak compressive failure force, (5460 vs 5069 N) but lower peak flexion moment (201 vs 347 Nm) [4] compared to the current study. This may be due to differences in test setup and posture. In the previous study, specimens were isolated from T12-L5 and the distal end was potted at a 15-degree angle in the sagittal plane to represent the orientation of the spine in an upright seated position. The current study included the L5-S1 joint and placed the spine in a more flexed posture which may explain the differences in peak injury loads.

Data from this study has been used to derive preliminary injury risk curves (although not reported herein due to page constraints) using survival analysis for force, moment and interactive force-moment (N_{ij} -type). This methodology may assist in the development of human tolerance to advance vehicle crashworthiness and tolerance criteria hitherto not available to this region of the spine. With increasing advancement toward automated vehicles and autonomous driving, the present results may assist future safety standards.

3D SURFACE KINEMATICS OF THE LUMBAR FACET CAPSULAR LIGAMENT DURING INFLATION TESTING

INTRODUCTION

The facet joints articulate between the superior and inferior articular processes of adjacent vertebrae of the spine. The facet capsular ligament (FCL) encloses a facet joint with a capsule and encases the lubricating synovial fluid in the joint space between¹. The FCL contains a region of highly aligned collagen fibers on the outer (posterior) portion and is innervated with nociceptors that can trigger pain signals under stress¹. These structural and mechanosensory characteristics present the FCL as a likely culprit for low back pain (LBP)¹, a debilitating disease that affects 70 to 85% of Americans at some point in their lives². Among these patients, 90% are diagnosed with non-specific LBP, and treatment is often unsatisfactory. To provide better patient care, we must first understand how the various components of the lumbar spine work together in a healthy state and then extend this model to the diseased state. Specifically, this work seeks to define the relationship between the FCL ligament and the joint pressure.

Very little is known about the mechanics of the synovial fluid and how the inner capsular pressure changes with spinal motion. Defining the underlying mechanics of the synovial fluid will further our understanding of ligament-fluid interaction. An inflation test, where the specimen is injected with a known volume of solution and the subsequent change in pressure is recorded, can help provide this insight. Coupling the inflation test with 3D strain tracking of the FCL surface allows us to determine differences in the mechanical behavior of the FCL under load³. We can extend this experiment to record changes in pressures and strains to determine ligament-fluid interactions under prescribed spinal motions such as flexion or extension. We can also further expand this study to observe regional mechanical adaptations of the FCL in a diseased spinal state and increase our understanding of how FCL degeneration changes ligament loading.

In the current study, we conducted an inflation test while simultaneously recording 3D ligament surface kinematics on porcine lumbar spines. We hypothesized that we would observe higher stresses in the ligament that spans across the facet joint space as more solution is injected into the joint space.

METHODS

Sample Preparation

Three porcine lumbar spines were obtained from the Visible Heart Lab at the University of Minnesota. The samples were dissected to expose the posterior surface of the FCLs, and a total of 14 FCLs were viable for testing. These samples were then speckled by airbrushing for stereo imaging analysis.

Inflation Test

Pressure within the facet capsular space was measured using a pressure transducer (Harvard Apparatus) while saline was injected by a syringe pump. The pump injected 250 μ L of 1% PBS at a rate of 1,000 μ L/min into the joint space between facet joint pairs. The pressure transducer was zeroed by recording the voltage with the needle near the point of injection but not piercing the tissue. The needle was then pierced through the FCL such that the needle tip was within the facet joint space for interstitial pressure recording. All subsequent pressure recordings were determined by normalized the initial baseline pressure.

3D Strain Tracking

Concurrently with the inflation test, strain tracking was done on the speckled surface of the FCL using stereo imaging analysis. A two-camera system was utilized to obtain stereo images of the surface as it deformed during the inflation test. Surface displacements and strains were calculated using MultiDIC⁴.

Data Analysis

Data for four of the 14 samples were discarded because damage during set-up led to significant joint leakage. The pressure data from the remaining 10 FCL samples were analyzed (Fig 1). Tissue compliance β was defined as the slope of the linear portion of the pressure-volume curve, as given by equation 1 where V is capsule volume (μL) and P is pressure (mmHg):

$$\beta = \frac{dV}{dP} \quad (1)$$

Compliance was determined using four samples that displayed similar pressure-volume behavior. Average pressure and standard deviation were calculated using all ten samples.

The curvature for a single sample was obtained from the results of MultiDIC (Fig 3A). Using the locations of the speckles in 3D space, we are able to obtain two principal radii of curvature (R_1 and R_2) and approximate the facet capsule as an ellipsoid. R_1 is the radial direction and R_2 is in the longitudinal direction. Positions of the speckles were obtained from MultiDIC and a surface map of the underformed and deformed FCL was analyzed using MATLAB R2018a (Fig 3B-C). Displacements of the speckles were obtained from MultiDIC (Fig. 3D-F).

RESULTS

Pressure-volume curves for each sample and the mean are shown in Figure 1. The compliance was $0.776 \mu\text{L}/\text{mmHg}$, 95% CI [0.757, 0.794]. In some cases, the pressure begins to decrease due to ligament failure. This trend is observed after injecting 150 μL or more of saline.

Figure 1: The solid red line is the average pressure of all individual sample pressure-volume relationships (dashed blue). The black line is FCL compliance.

A function of the radii of curvature with respect to injection volume is shown in Figure 2. R_1 is smaller than R_2 at all volumes of injected saline. This denotes a higher degree of curvature in the radial direction. An increase in R_1 near 200 μL may be due to ligament failure.

Figure 2: The principal radii of curvature (A.) R_1 and (B.) R_2 .

Figure 3A outlines the region of interest on the FCL for analysis and we observe the highest speckle displacement after inflation in the y-direction (Fig 3B-F).

Figure 3: (A.) 3D surface outline on the sample where S=superior, I=inferior, M=medial and L=lateral. Surface map in XZ plane with color denoting Y of the (B.) reference and (C.) deformed sample. Speckle displacement (mm) in the (D.) x, (E.) y, and (F.) z direction.

DISCUSSION

We used inflation testing and 3D strain tracking to determine ligament-fluid interaction of a porcine FCL. Specifically, the pressure-volume response remained linear unless ligament failure occurs (Fig 1). We observed similar pressure-volume relationships for almost half of our samples despite differences in the vertebral levels of the FCLs. Concurrently with inflation, speckle displacements showed swelling of the facet capsule (Fig 3B-F). We conclude that the stress induced from facet capsule swelling will be similar across all lumbar levels.

Interestingly, we observe a lower radius of curvature in the radial, or bone-to-bone, direction (Fig 2). In this direction, the ligament is bounded on either end by facet joint. As the sample is inflated, the ligament displaces up and out (Fig 3E). The curvature along the radial direction increases at a higher rate than the curvature in the longitudinal direction. This trend is significant because it denotes a higher ligament strain in the bone-to-bone direction, which is believed to be the direction of primary fiber alignment in the collagen layer.

The results of this study further our understanding the relationship between interstitial fluid pressure and the FCL. We found that as the ligament swelled, the degree of curvature in the radial direction increased. This may lead to higher stresses along the primary fiber orientation and excess stretch of the nerves within the ligament, causing LBP.

DORSAL SUBLUXATION OF THE FIRST METACARPAL AT THE BASILAR THUMB JOINT DURING KEY PINCH: COMPARISON TO OSTEOARTHRITIS GRADING SYSTEMS

INTRODUCTION

The basilar thumb joint, also known as the trapeziometacarpal (TMC) joint, is commonly affected by osteoarthritis (OA). The standard imaging views used for radiographic evaluation of the hand are posterior-anterior (PA) or anterior-posterior (AP), lateral, and oblique. Special positioning techniques are also used to image the TMC joint. The PA view of the hand approximates a lateral view of the TMC joint.

Instability of the joint has been believed to be a factor in the development and progression of OA [1, 2]. Eaton and Littler first proposed a stress radiograph in 1973 to characterize laxity (instability) of the stabilizing ligaments, measuring metacarpal lateral subluxation [1]. A recent study reported that the basilar thumb joint experienced greater instability during key pinch than other functional tasks [3]. Thus, key pinch stress radiographs may be clinically useful.

The role of subluxation in diagnosing OA or evaluating OA risk in the TMC joint has been debated. The TMC joint lacks substantial geometric constraint and relies on muscles, ligaments and other soft tissue for stability. The palmar anterior oblique ligament (AOL) and the dorsoradial ligament (DRL) are thought to be most important in preventing dorsoradial translation of the metacarpal with respect to the trapezium [2]. Increased metacarpal dorsoradial translation has been reported increased arthritic wear in the TMC joint [2]. But, studies have reported poor agreement between radiographic and arthroscopic/visual measures of TMC joint OA, such as the Outerbridge system and International Cartilage Repair Society (ICRS) system [4].

The first objective of this study was to determine the imaging angle that best measures lateral subluxation during key pinch. The second objective was to compare the lateral subluxation of the metacarpal during key pinch with the Eaton-Littler radiographic OA grade and the visual OA grades from the Outerbridge and ICRS systems. The third

objective was to determine the effect that opening the joint capsule and cutting the AOL had on the lateral subluxation of the metacarpal during key pinch. We hypothesized that the percent of subluxation would significantly correlate with the radiographic and arthroscopic/visual classifications and that sectioning the capsule and/or the AOL would significantly increase the amount of lateral subluxation.

METHODS

Eleven frozen cadaveric forearms (10 males, 1 female, mean age at death 72 years, 54-88 years) were obtained with no known history of connective tissue disease. The mid-forearm was dissected to isolate tendons for the extensor pollicis longus (EPL), flexor pollicis longus (FPL), and abductor pollicis longus (APL). The hand was dissected to isolate and elevate the origins of the abductor pollicis brevis (APB) along with the radial portion of the flexor pollicis brevis (FPB) as one group. The adductor pollicis (ADP) along with the ulnar portion of the FPB were also isolated as a group [2]. The forearm was fixed in a neutral rotation. Kirschner wires were used to fix the wrist in 30° of extension, the thumb metacarpophalangeal (MP) joint in 20° of flexion, and the index finger MP joint at 90°. Krackow suture loops secured the end of each tendon/muscle group to for loading through a pulley system using weights. The loads applied followed Pellegrini et al. and were 0.8 N, 4.2 N, 5.0 N, 8.4 N, and 13.4 N for the EPL, ADP group, APB group, FPL, and APL, respectively, to simulate static key pinch [2].

During load application, a mobile C-Arm unit (OrthoScan HD model 1000-0004) was used to acquire three sets of radiographs. Images were recorded from 0° (the hand AP view) with the top of the C-arm rotated by 5° increments towards the ulnar aspect of the arm up to 60°. The first set of images was recorded with an intact TMC joint capsule. The best angle to measure lateral subluxation for subsequent analyses

was determined from the first set of images. The joint capsule was opened between the AOL and the APL, and another set of key pinch images was recorded. The AOL was sharply transected, and the final set of images was recorded. Specimen tissues were kept moist by saline mist. Grading of the specimens was performed by an orthopedic resident using the Eaton-Littler scale as a radiographic grading system, and the Outerbridge and ICRS systems for arthroscopic/visual grades.

Percent lateral subluxation of the metacarpal base was measured in Adobe Photoshop 6.0 (Figure 1-Left). Maximum subluxation was used to normalize subluxations from the other image views to reduce the effect of inter-specimen variability. A frequency analysis of the maximum normalized subluxation by image angle was performed. Further, we evaluated percent errors in the normalized maximum subluxation measurements for every angle and each specimen. The imaging angle that most frequently captured maximum subluxation and with smallest percent error was used for all further comparisons. Regression was used to evaluate the relationship between subluxation for each specimen and OA grades. Repeated measures ANOVA with Brown-Forsythe post-hoc analysis was used to evaluate differences between the subluxation measurements for the intact joint capsule, the open joint capsule, and the transected AOL. Statistical significance was set at $p < 0.05$.

RESULTS

Because lateral subluxation could not be consistently measured for image angles greater than 25° , only data from 0° (AP view) to 25° were used for analysis of the imaging angle (Figure 1). The most common view that displayed the maximum subluxation was the AP (0°) view (Figure 2-L). The mean percent difference from the measured maximum subluxation was also smallest for the AP view. Mean subluxation error increased as the imaging angle increased (Figure 2-R).

Figure 1: Left: Percent subluxation during key pinch calculated as lateral subluxation (LS) divided by the metacarpal articular width (AW). Red lines parallel to the metacarpal long axis. Mid: Typical AP (0°) X-ray. Right: Typical X-ray 25° supination.

Visual OA grades indicated the majority of the specimens had cartilage fragmentation or erosion to the bone. The remaining specimens had superficial fissures or lesions less than 50% of the cartilage depth. Only one specimen was found to be Grade 1 (cartilage swelling and softness). There was no correlation between lateral subluxation and the ICRS or Outerbridge classifications.

For the Eaton-Littler radiographic classification system three specimens were Stage I, three were Stage II, three were Stage III, and two were Stage IV. There was a significant correlation between lateral subluxation and the Eaton-Littler stage ($p = 0.0003$, $R^2 = 0.779$).

No significant difference was found between subluxation with an intact joint capsule, with the joint capsule opened, or with the AOL cut.

For the Eaton-Littler radiographic classification system three specimens were Stage I, three were Stage II, three were Stage III, and two were Stage IV. There was a significant correlation between lateral subluxation and the Eaton-Littler stage ($p = 0.0003$, $R^2 = 0.779$).

No significant difference was found between subluxation with an intact joint capsule, with the joint capsule opened, or with the AOL cut.

Figure 2: Left: For the majority of specimens, the maximum subluxation was measured in the AP view. Right: The AP view had the lowest mean error (7%) for specimens whose maximum subluxation was measured at a different angle.

DISCUSSION

Stress view radiographs provide insight that can help quantify the instability of the joint noted during physical examinations. Few studies have focused on subluxation of the first metacarpal during key pinch. Our study sought to verify the best view for subluxation analysis for future studies like these. The oblique orientation of the basilar thumb joint created some difficulties when attempting to analyze subluxation in the images due to its position and overlap between other osseous structures. Still, our findings suggest that the AP view provides the best assessment of lateral subluxation during key pinch.

While we did find a significant correlation between Eaton-Littler stage and lateral subluxation, this was expected, as the Eaton-Littler stage uses subluxation (during a different stress view) as one of the factors affecting the classification. Our results are consistent with other studies that have found poor agreement between subluxation and either pain or visual classification. While subluxation may not be as accurate for OA classification, we believe it is useful as a measure of the risk of developing OA.

That we found no significant difference in maximum subluxation with sectioning the capsule or AOL appears to support more recent studies indicating that the AOL may play a lesser role in the prevention of dorsal subluxation of the metacarpal [5]. However, the older age of our specimens and generally advanced arthritic states could have influenced the subluxation results [2]. Also, stability of the joint during simulated key pinch may be supported by (simulated) muscular activity.

This study has several limitations. Both visual and radiographic OA grades were assigned by only one investigator. An increased number of investigators grading the joints could produce more accurate averaged OA grades. Subluxation was also measured by only one of the investigators. Most cadaveric specimens were quite old and were kept frozen before the experiments and moist during the experiments. Only one specimen was female so no analysis of gender effects was possible.

INTRODUCTION

Full time manual wheelchair users rely entirely on their upper extremities for essential activities of daily living, including propulsion and transfers. Upper extremity pain and injury are highly prevalent among manual wheelchair users due to the repetitive movements and stresses associated with these activities [1, 2]. Previous studies have shown that between 30-70% of manual wheelchair users experience shoulder pain [3, 4], including pain related to wheelchair propulsion [5]. Moreover, manual wheelchair users must be able to navigate different terrain conditions that require differences in propulsion effort, including smooth level surfaces, indoor/outdoor carpets and sloped surfaces such as ramps [3,6]. Ramp propulsion specifically increases the biomechanical risk factors associated with wrist and shoulder injuries and pain [7]. When ascending a ramp, recovery time decreases while cadence increases, increasing the risk for carpal tunnel syndrome [6, 8]. Forward trunk flexion increases as the ramp incline becomes steeper to move the center of mass forward to prevent the wheelchair from tipping [9]. Forward lean of the trunk increases shoulder flexion, which can lead to shoulder pain/injury [10]. The combination of these factors makes ramped propulsion an activity with increased risk for upper extremity injury and pain.

Although clinical practice guidelines with specific recommendations concerning wheelchair setup and propulsion techniques have been published related to preserving upper limb function, the guidelines were based on research collected during level ground propulsion. It is therefore unclear if they are applicable to other types of mobility tasks on non-level surfaces [11]. On level ground, studies have collectively shown that positioning the seat more posterior with respect to the rear wheels reduces the biomechanical risk factors for upper limb injuries by lowering forces, lessening cadence, increasing the push angle, and reducing muscular effort. However, this

configuration is not ideal for ramps as the CoG shifts rearward due to the effects of gravity resulting in a compensatory forward lean to bring the CoG ahead of the rear wheels to prevent tipping. Additionally, posterior forces and internal rotation moments at the shoulder are higher with a more posterior seat during ramped propulsion [12]. A wheelchair configuration that helps to support better trunk and arm positioning on ramps may help mitigate the joint forces during ramp propulsion and preserve upper limb function.

A wheelchair that could enable the user to modify their configuration in real time depending on the terrain may reduce overall effort and promote biomechanically favorable propulsion patterns. Potential modifiable configuration parameters include the positioning of the footrest and seat relative to the rear wheel axle, respectively known as the footprint and seat position. The aim of this study was to compare joint range of motion (ROM) at the shoulder, elbow, wrist and trunk between four different wheelchair configurations over three different inclines. We hypothesized that a more stable configuration, with an elongated footprint and a more posterior rear axle would increase the ranges of motion at the shoulders, elbows and wrists and trunk during ramped propulsion.

METHODS

This study was approved by the VA Pittsburgh Healthcare System's Institutional Review Board. Six participants were recruited and signed informed consent forms prior to study procedures. In order to participate in the study, individuals had to have had a spinal cord injury, be at least one-year post injury or diagnosis, primarily use a manual wheelchair for mobility (over 40 hours/week), and had to be over 18 years in age. Participants were excluded from the study if they had upper limb pain or injury that interferes with the ability to propel,

had cardiopulmonary disease, were unable to be fitted in the ICON test wheelchair, or were women who self-reported to be pregnant.

Data Collection

Measurements of participants' personal wheelchairs were taken by the investigators and used to make the customizable ICON A1® chair (ICON Wheelchairs) as close to their personal wheelchair as possible by adjusting features such as seat height, wheel camber, backrest height, and seat width. Kinematic data were collected using a ten-camera Vicon motion capture system (Version 1.8). Passive reflective markers were placed on bony landmarks of the chest, back and non-dominant side upper extremity including the third metacarpophalangeal joint, radial styloid, ulnar styloid, lateral epicondyle and acromion. Markers were also placed on the wheel hubs. Data was collected at 100 Hz.

The configurations evaluated in the order of most stable to least stable were: anterior long (AL), anterior short (AS), posterior long (PL), posterior short (PS). Each of these configurations was tested on 3 inclines at controlled speeds: level at 1 m/s, 3 degrees at 0.8 m/s, and 6 degrees at 0.6 m/s. Participants were fitted to a harness on the Computer Assisted Rehabilitation Environment (CAREN) platform, which was attached to a four-point tie down system. The CAREN is an integrated system consisting of a platform with 6 degrees of freedom, a custom dual belt treadmill (each of which are 2m long and 0.5m wide), and embedded force plate. They performed a 2-3-minute warm-up followed by 1 minute of data collection in each configuration and incline.

Data Analysis

Data was post processed in the Vicon software to fill gaps in markers. The post processed data was then analyzed using a custom Matlab 2018a code to calculate joint angle ranges. Nine consecutive strokes from steady state data from the middle of the trials were analyzed and the average range is reported. Missing data due to Vicon marker drop out (less than 10%) were handled by group mean imputation. A two-way repeated measures ANOVA with Bonferroni post-hoc correction using SPSS (Version 25, IBM) was performed on the data with a significance level of 0.05.

RESULTS

The level ground trials showed the smallest ROM in lateral trunk bending compared to both the three-degree incline ($p=0.035$) and the six-degree incline ($p=0.022$). In addition, level ground trials showed the least ROM in trunk flexion and axial rotation compared to the three-degree ($p=0.041$ and $p<0.001$ respectively) and six-degree ($p=0.049$ and $p=0.022$ respectively) inclines. No significant differences were seen in trunk angles between wheelchair configurations.

The AL configuration had more ROM at the shoulder in adduction and abduction compared to PS ($p=0.029$). The AL and AS configuration both had larger ROM than the PS configuration ($p=0.009$ and $p=0.017$ respectively) in internal/external rotation of the shoulder. Elbow flexion showed that there was an interaction between wheelchair configuration and incline, wherein the AL and PS configurations had a larger ROM with the 6-degree incline in contrast to the AS and PL configurations showing a decrease at 6 degrees ($p=0.02$).

DISCUSSION

A smaller ROM at the trunk, as seen with level trials, is associated with increased trunk stability. Individuals had more stability on level ground because they had to be less concerned with the chair tipping backwards during propulsion. For the shoulder angles, it is ideal to have a larger ROM because a larger ROM will make it more likely for individuals to use a biomechanically favorable stroke pattern due to the increased time in which they have contact with the pushrim. The increased ROM in the

AL and AS configurations allows individuals to grip the pushrim at more locations, thus increasing the amount of time their hands stay on the pushrim. Elbow flexion ROM is dependent on both footprint and incline, as the forward lean of the trunk to compensate for the shift in CoG in the AL and PS configurations on inclines changes the nature of elbow flexion and results in increased ROM.

In contrast to studies showing posterior seat positioning as more beneficial for level ground propulsion [12], the anterior seat position seems to have greater biomechanical consequences on wheelchair propulsion on various inclines. Additional analyses may shed insight into the benefits of adjustable seating configuration during level and ramped wheelchair propulsion.

AN ALTERNATIVE METHOD TO CHARACTERIZE POROELASTIC MATERIAL PROPERTIES OF MURINE ARTICULAR CARTILAGE

Alexander Kotelsky (1), Joseph S. Carrier (1), Mark R. Buckley (1)

(1) Department of Biomedical Engineering
University of Rochester
Rochester, NY, USA

INTRODUCTION

Articular cartilage (AC) is a load-bearing tissue that covers bones in synovial joints. Due to its unique biphasic/poroelastic mechanical properties, AC serves as a shock absorber and attenuates contact forces that are transmitted across joints. Alterations in these mechanical properties can indicate functional loss and degradation of AC in the form of osteoarthritis (OA). For example, when proteoglycan loss occurs in the AC of degraded joints, the equilibrium Young's modulus (E) and hydraulic permeability (k) – measures of intrinsic stiffness and the ability of water to flow in and out of the tissue – are reduced and elevated, respectively [1]. Since OA can be easily induced through genetic or surgical means, murine models provide a valuable, low-cost research platform to study AC degradation. However, alterations in the mechanical properties of murine articular cartilage are challenging to measure due to its small size (thickness $\sim 50\ \mu\text{m}$). Only a few research groups have quantified the mechanical properties of murine cartilage through nano- and micro-indentation techniques [1, 2]. Though effective, these indentation techniques provide characterization of local mechanical properties and may overlook the overall mechanical response of AC, especially when it is focally damaged. Building off our previously described method for measuring the static mechanical properties of articular cartilage [3], here we describe an alternative method to measure the *biphasic* mechanical properties (k , E) of large regions of intact murine AC under compression through inverse finite element modeling and confocal microscope-based 3D stretch mapping.

METHODS

All experiments were conducted using our previously established custom microscope-mounted mechanical testing device (Fig. 1a) [3, 4]. Briefly, carefully dissected, fully intact cartilage-on-bone specimens from 8-10 week-old BALB/c female mice were placed onto the cover glass slide of the testing device and loaded with a prescribed force F on

top of the specimen such that the cartilage on the distal femoral condyles was compressed against the cover glass (Fig. 1a). Fluorescence micrographs of the articular surface and 3D z-stacks of AC were obtained using either an inverted epifluorescence microscope or an inverted confocal laser scanning microscope, respectively. Specimens were hydrated at room temperature in Hank's Balanced Salt Solution (HBSS) at 302 mOsm and a pH of 7.4 throughout the experiment.

Biphasic material properties (E , k) were characterized using a combination of experimental and computational methods (Fig. 1b). These methods and their sequence are as follows: 1) establishment of the correlation between cell death area across the articular surface and the peak cartilage compressive deformation; 2) characterization of transient cartilage deformation (boundary displacements) using the correlation established in step 1; 3) implementation of inverse finite element analysis (iFEA) based on the boundary displacement at equilibrium and the measured condylar boundary force to characterize E ; 4) implementation of iFEA based on the transient boundary displacements and the contact boundary force to characterize k of AC with a pre-determined E .

Figure 1: Schematic representation of (a) the testing platform and (b) the experimental methods.

1. Correlation between tissue compressive deformation and cell death. While slow acquisition of confocal z-stacks allows for

characterization of tissue deformation at equilibrium [3], it is virtually impossible to quantify transient boundary displacements during poroelastic creep of murine AC. Thus, transient tissue deformation was characterized by determining the extent of cell death at different loading times (quantified in step 2) and converting to deformation using the correlation between peak tissue compressive deformation and the extent of cell death. To first establish this correlation, in step 1, areas of chondrocyte death were induced on articular surfaces of proximal humeri and distal femurs through application of different load magnitudes (0.1N, 0.5N, or 1N, $n = 5/\text{group}$) on top of the specimens for 5 min. The specimens were vitally stained with calcein AM (an indicator of live cells) at baseline and with propidium iodide (PI) (an indicator of dead cells) after the load was removed and prior to imaging under fluorescent illumination. Cells that lost calcein fluorescence (green) and became PI-positive (red) were considered to be dead (Fig. 2a). Radii of cell death ($r_{\text{cell death}}$) were quantified assuming the areas were circles.

After assessment of cell vulnerability, the specimens were stored at -20°C for 1-2 weeks and then used to quantify the peak tissue deformation induced by each prescribed load. Specimens were then thawed, and the AC was fluorescently stained with 5'-DTAF to enable visualization of the extracellular matrix (ECM). AC on the lateral femoral condyles and on the humeral heads was imaged with a 40X dry lens on a laser scanning confocal microscope. 3D image stacks were obtained before compression and 5 min after the application of the corresponding load (Fig. 2b-c). From the acquired z-stacks, spatially varying tissue stretch (λ_z) was quantified by normalizing 2D thickness maps of compressed specimens by the corresponding thickness maps obtained at the baseline using custom MATLAB algorithms (Fig. 2d). Note that lower stretch means more compression. Therefore, the peak tissue compression (i.e., minimal value of λ_z (λ_z^{\min})) was correlated to the corresponding $r_{\text{cell death}}$ using a Pearson correlation (Fig. 2e).

2. Characterization of transient cartilage deformation during poroelastic creep. Distal femurs vitally stained with calcein AM were subjected to 1 N statically applied for 0, 5, 10, 30, 60, 300, and 900 s ($n = 5-6/\text{group}$), and $r_{\text{cell death}}$ on lateral femoral condyles was analyzed as a function of loading duration (Fig. 2f). The transient apical boundary displacement (i.e., λ_z^{\min}) was obtained using the equation from step 1 relating $r_{\text{cell death}}$ to λ_z^{\min} (Fig. 2e, g). Specimens that did not exhibit cell death on lateral femoral condyles were discarded since λ_z^{\min} could not be quantified.

Figure 2: (a) Representative fluorescent micrographs of viable/non-viable cells after the compression of AC. (b, c) Representative (side-view) confocal micrographs of murine AC on the lateral femoral condyle (b) before and (c) after specimen compression. (d) The resultant compressive stretch (λ_z) map for the specimen shown in (b-c). (e) Correlation between λ_z^{\min} and $r_{\text{cell death}}$. (f) $r_{\text{cell death}}$ as a function of load duration (mean \pm SD). (g) A creep curve estimated based on $r_{\text{cell death}}$ (mean \pm SD).

3. iFEA to determine E. A 3D finite element model (FEM) of murine

cartilage on the lateral femoral condyle was constructed using the FEBio software suite [5] (Fig. 3a). To account for inter-specimen variability in geometry, a specimen-specific radius of curvature and thickness were measured from confocal z-stacks of specimens ($n = 5$) exposed to a 1 N load in step 1 (Fig. 2b). The cartilage was approximated as an ideal hemispherical shell with a measured outer radius ($877.8 \pm 48.4 \mu\text{m}$) and a uniform thickness ($30.13 \pm 1.67 \mu\text{m}$). The top surface (cartilage-bone interface) was constrained to be stationary, and a rigid platen on the bottom surface (cartilage-glass interface) compressed the cartilage in the z-direction with a prescribed λ_z^{\min} determined from the equilibrium of the creep curve at 900 s generated in step 2 (Fig. 2g). The solid matrix was taken to be a neo-Hookean hyperelastic material with a previously determined Poisson ratio (ν) of 0.25 [3]. To estimate E, an iterative optimization algorithm implemented in FEBio was used to match the boundary force of 0.43 N exerted on the lateral femoral condyle corresponding to the 1 N load applied on top of the specimen [3].

4. iFEA to determine k. Poroelastic FEMs with specimen-specific geometry and corresponding E from step 3 were used to estimate k. Under a constant prescribed force of 0.43 N, an iterative optimization algorithm was used to match temporally varying mean λ_z^{\min} (Fig. 3b), also determined in step 3.

RESULTS

With the pre-determined ν of 0.25 [3], the mean E and k of mouse AC were measured to be 17.54 MPa and $0.86 \times 10^{-16} \text{ m}^4/\text{N}\cdot\text{s}$, respectively (Fig. 3 c-d).

Figure 3: (a) Representative FEM of murine AC used to estimate k and E. (b) A creep curve response from step 2 with the corresponding curve fit from FEA (mean \pm SD). (c, d) Measured poroelastic material properties of murine AC (mean \pm SD).

DISCUSSION

In this study, we developed an alternative method to characterize poroelastic material properties (E and k) of murine AC. Assuming a previously determined ν , the method involves fitting one parameter at a time by first focusing on AC equilibrium behavior to determine E, and then fitting the entire creep curve to determine k using iFEA. The measured k in this study ($0.86 \times 10^{-16} \text{ m}^4/\text{N}\cdot\text{s}$) is consistent with the value reported in literature ($k = 1.1 \pm 0.4 \times 10^{-16} \text{ m}^4/\text{N}\cdot\text{s}$) determined from micro-indentation [2]. However, E was not previously assessed for applied loads as high as the 0.43 N. As expected, due to the non-linear mechanical behavior of AC, E was found to be higher than the values reported in literature for lower applied loads [1-3].

We also established a strong relationship between AC deformation and cell vulnerability (Fig. 2e). This relationship may depend on mouse strain, age and/or gender. However, once this relationship is established, future studies using this method can bypass step 1 (the only step that requires the use of a confocal microscope), thereby reducing the cost and time associated with the characterization of E and k. Hence, $r_{\text{cell death}}$ quantification is the only requirement to determine E and k.

Future studies will expand the method to assess non-linearity of murine AC and will apply this method to assess how different stages of experimentally-induced OA alter k and E.

COMPARISON OF THE EFFECTS OF BOUNDARY LUBRICANTS ON THE TRIBOLOGICAL REHYDRATION OF ARTICULAR CARTILAGE

Margot S. Farnham (1), David L. Burris (2), Christopher Price (1,2)

INTRODUCTION

Articular cartilage is unique in that it retains exceptionally low frictional properties through the millions of articulation cycles we expose it to yearly. Healthy cartilage is composed of ~80% water, with the remaining ~20% consisting mostly of a deformable matrix of collagen and negatively charged proteoglycans¹, and it is thought that cartilage's unique tribomechanical properties stem from this biphasic composition. A major goal of the field has been to understand how this soft biological material can maintain phenomenally low friction values ($\mu < 0.02$) under usage conditions that can be considered extreme²⁻⁸. Recently, our team rediscovered an *ex vivo* cartilage testing configuration, the convergent stationary contact area (cSCA), that helps to shed light on these mechanisms due to its unique ability to promote and sustain physiologically-consistent levels of cartilage strain, deformation recovery, hydration, and lubricity over unprecedentedly-long time scales (hours). The cSCA configuration uses large ($\varnothing 19$ mm) articular cartilage explants that retain the joint's natural radius of curvature thought necessary for promoting hydrodynamically-driven interfacial behaviors when explants are slid again a counterface. These hydrodynamic forces, through a mechanism termed 'tribological rehydration'⁸⁻¹⁰, can 'pump' fluid exuded from cartilage during compression back into the tissue during sliding, enabling the recovery of interstitial fluid pressures and fluid-load support needed to maintain interstitial lubrication and physiologically low friction coefficients.

Previous cSCA studies have used 1X phosphate buffered saline (PBS) as the hydrating/lubricating solution, representing a 'worst-case' lubrication condition. Despite this, we have consistently observed remarkable tribological rehydration-driven strain recovery and frictional outcomes. However, the effect of other bathing solutions containing lubricants such as synovial fluid (SF), hyaluronic acid (HA), bovine serum albumin (BSA), or culture media, on tribological

rehydration have not been fully explored. The *goal of this study was to investigate the effect of boundary lubricants on tribological rehydration and tribomechanical outcomes in the cSCA configuration*. Four 'lubricants' were chosen for their presence *in vivo* (SF), and as common additives to articular cartilage testing (HA) and explant culture solutions (BSA, media). We hypothesized that the more viscous lubricants, HA and SF, would increase both the effectiveness of tribological rehydration and lubrication in articular cartilage by enhancing fluid uptake (strain recovery) and reducing friction over sustained bouts of sliding. We also wished to ask the question of *whether low viscosity PBS and standard chondrogenic culture media are suitable bathing solutions for ex vivo tribology studies or if boundary lubricants should be added to produce physiological 'safe' frictional responses*.

METHODS

Tissue Specimens and Tribological Testing: $\varnothing 19$ mm osteochondral cores were removed from the femoral condyles of mature bovine stifle joints (procured from Bowman's Butcher Shop, Churchville, MD)¹⁰. Cores were trimmed to ~12mm in height and the *in vivo* sliding direction noted¹¹. Following extraction, explants were stored in PBS + protease inhibitors (referred to herein as PBS) at 4°C¹². Explants were tested in a custom-built reciprocating materials device (a.k.a. tribometer)⁸ in which explants were compressed and slid against a reciprocating slide.

Boundary Lubricants: Four different boundary lubricants were tested in this study: SF, PBS+HA, PBS+BSA, and chondrogenic culture media. SF was extracted from healthy equine stifle joints within 2 hrs of euthanasia and stored at -20°C. PBS+HA was prepared by dissolving high-molecular weight (1350 kDa, 5mg/mL) hyaluronan in PBS. PBS+BSA was prepared at 3% wt/vol. Chondrogenic culture media was prepared using DMEM supplemented with 1% ITS+Premix (Corning), 20 μ g/mL ascorbic acid, 1% pen-strep, and 1% amphotericin-B.

Figure 1. A) Overlaid traces from a random SF explant show increased strain recovery and lower friction after addition of lubricant. Collated data shows B) sliding-induced strain recovery (i.e. tribological rehydration) is greater, and C) sliding equilibrium friction coefficient is lower in the samples treated with the more viscous lubrication solutions (SF, HA).

Testing Protocols: Prior to testing, each sample was inspected for surface damage using India Ink and a stereomicroscope; visible damage was an exclusionary criterion. Samples then underwent a diagnostic test consisting of 10min compression at 7N (~0.25MPa), followed by 2min of reciprocal sliding at 80mm/s (~walking speed) to identify if samples exhibited adequate tribological rehydration for inclusion in the study, i.e. friction coefficients $\mu < 0.2$, and sliding-induced recovery/reversal of deformation ($< 10\%$ of samples were excluded in this manner). Samples were then assigned to one of four lubricant study arms.

A tribological rehydration characterization scheme, with a repeated-measures design, was used for each lubricant testing group. This protocol started with 30min of static compression at 7N, followed by 30min of reciprocal sliding at 80mm/s under 7N compression¹¹. Characterization was first performed in the presence of a *PBS-only* bath, followed by a 1-hr free-swelling period in PBS. Next, characterization was repeated with the PBS bath replaced by one of the four lubricant baths immediately prior to sliding. After these *PBS+lubricant* tests, each explant was free-swelled in lubricant bath for 1-hr before a final characterization in the presence of *lubricant only*. Repeated-measures testing was utilized to improve statistical power and to determine if brief lubricant application or extensive lubricant soaking differentially influenced tribomechanical outcomes in the cSCA. After testing, explants were again assessed for damage using stereomicroscopy, and then bisected to measure cartilage thickness (h).

Data Analysis: Deformation (δ), normal force (F_N), and friction coefficients (μ) recorded and analyzed using MATLAB¹¹. Tissue strain ($\epsilon = \delta/h$) and friction magnitudes were analyzed at the beginning and end of active sliding, and strain recovery (i.e. tribological rehydration) during sliding was calculated. Friedman's Test, a nonparametric test with replication, was used to identify statistically significant changes between the repeated *PBS-only*, *PBS+lubricant*, and *lubricant-only* tests. Kruskal-Wallis' test was used to identify differences among the *PBS-only* test groups and the *lubricant-only* test groups.

RESULTS

The most pronounced changes occurred in samples where SF and HA were present (representative SF deformation and friction traces shown

in **Fig. 1A**); BSA and culture media did not meaningfully affect the tribomechanical behavior of explants. In the repeated tests, strain recovery increased when SF ($p=0.011$) and HA ($p=0.011$) were added as lubricants (**Fig. 1B**). Friction coefficients at the end-of-sliding (i.e. sliding equilibrium) were, relatively speaking, quite low for all groups (on average < 0.04), but high-viscosity lubricants (SF and HA) drove a significant reduction in sliding equilibrium friction ($\mu = 0.03$ to 0.003 , $p=0.033$ & 0.009 , respectively; **Fig. 1C**). There were no significant changes in strain recovery or end-of-sliding friction for the samples lubricated with BSA or chondrogenic media.

When comparing across lubricant testing groups, no significant differences in strain recovery magnitude (i.e. tribological rehydration) or rate of strain recovery were observed either prior to the addition of lubricant (*PBS-only* tests) or following the addition of the lubricants (*PBS+lubricant* or *lubricant-only*). However, the presence of both SF and HA led to, on average, significantly reduced end-of-sliding and time averaged friction compared to PBS, BSA, and culture media (BSA and culture media outcomes were no different from PBS outcomes). Start-of-sliding strain, end-of-sliding strain, time-average strain, start-of-sliding friction, and deformational time-constants were also investigated (data not shown), and showed similar results to strain recovery and end-of-sliding friction, with the majority of changes occurring when SF and HA were present as lubricants.

DISCUSSION

These results illustrate that viscous lubricants, e.g. SF and HA, create an environment that enhances tribological rehydration and lubrication during high-speed sliding in the cSCA. This was reflected in increased overall strain recovery and reduced sliding equilibrium friction when compared to the BSA, chondrogenic media, and PBS-lubricated groups. These findings suggest that SF and HA may aid cartilage function through two distinct, but complementary mechanisms. First, as traditionally-understood boundary-mode lubricants¹, and second, as viscous bathing solutions that enhance fluid pressurization (and thus tribological rehydration) within the convergent contacts (e.g. the cSCA) by purely hydrodynamic means. Enhanced tribological rehydration supports both the recovery of tissue deformation (i.e. strain recovery) and the promotion of very-low friction coefficients via the maintenance and replenishment of interstitial lubrication. Lastly, we have seen that even PBS and chondrogenic media can mediate, under high-speed sliding in the cSCA, equilibrium friction outcomes ($\mu < 0.03$) that are below those previously shown to induce chondrocyte 'dysfunction' ($\mu < 0.1$)¹³. Together, these findings suggest that highly-viscous solutions like HA and SF *enhance* the lubrication of articular cartilage *ex vivo*, however these *lubricants are not necessary for maintaining physiologically-consistent and safe tribomechanical behavior in the cSCA*. When possible, we recommend adding lubricants to bathing solutions, however due to increased cost of these solutions, lubrication with PBS and media is sufficient.

INTRODUCTION — Articular cartilage comprises the load-bearing region of synovial joints and, in the absence of injury or degradation, is able to support smooth articulation over decades of repetitive use. Cartilage's multiphasic structure, consisting of ~80% fluid and ~20% solid collagen and proteoglycan matrix, allows for its exceptionally low coefficient of friction ($\mu < 0.02$) and high wear resistance.¹⁻⁸ The fluid phase in particular is key to the tissue's phenomenal lubrication properties because it can support large fractions of contact stress while also shielding the solid matrix from excessive shear. In previous studies, our team has characterized usage of an *ex vivo* testing configuration known as the convergent stationary wedge (cSCA) that allows assessment of cartilage biomechanics under sustained, physiologically-consistent values of cartilage strain, strain recovery, hydration, and lubricity over multiple hours of testing.⁶ In the cSCA configuration, glass counterfaces are slid against large ($\varnothing 19$ mm) articular cartilage explants, which retain the cartilage's natural radius of curvature and allow hydro-dynamically driven fluid flow from the bathing solution into the tissue during sliding. Through a mechanism we have termed 'tribological rehydration,' hydro-dynamically driven fluid flow during sliding competes with, and often exceeds, the rate of load-induced fluid exudation associated with stationary compression. As a result, high interstitial fluid pressure is retained in the tissue during sliding and provides sufficient load support for sustaining cartilage hydration and low coefficients of friction over the duration of active sliding.⁸

In our previous cSCA-based studies, only one type of glass counterface, standard glass microscope slides was used. In order to further characterize the biomechanical response of cartilage under the cSCA configuration, *the goal of this study was to investigate the effect of glass counterfaces of different surface roughnesses on tribological rehydration and resultant cartilage tribomechanical outcomes.*

Specifically, counterfaces of three asperity heights were investigated, including super-polished quartz slides, plain microscope slides (those used in our previous investigations), and frosted microscope slides.

METHODS

Tissue Specimens and Tribological Testing: $\varnothing 19$ mm osteochondral cores were removed from the femoral condyle centerline of thawed, mature bovine stifle joints (procured frozen from Bowman's Butcher Shop, Churchville, MD)¹⁰. Cores were trimmed to ~12mm in height and the *in vivo* sliding direction noted¹¹. Following extraction, explants were stored in PBS + protease inhibitors (referred to herein as PBS) at 4°C¹². Explants were tested using a custom-built reciprocating materials device ('tribometer')⁸ in which explants were compressed and slid against a reciprocating glass slide. Glass Surfaces: Glass surfaces of three different different asperity heights were tested in this study: super-polished quartz microscope slides of roughness ~2 nm (SPI Supplies, West Chester, PA), plain microscope slides of roughness ~200 nm (Fisher Scientific), and frosted microscope slides of roughness >200 nm (Fisher). Testing Protocols: Prior to testing, each sample was inspected for surface damage using India Ink and a stereomicroscope; visible damage was an exclusionary criterion. Samples then underwent a diagnostic test: 10 min compression at 7N, followed by 2 min of reciprocal sliding at 80 mm/s (~walking speed) to identify if samples exhibited adequate tribological rehydration for inclusion in the study, i.e. friction coefficients $\mu < 0.2$, and sliding-induced recovery/reversal of deformation (<10% of samples were excluded in this manner).

A tribological rehydration characterization scheme, with a repeated-measures design, was used for each lubricant testing group. This protocol started with 30 min of static compression at 7N (~0.25 MPa), followed by 30 min of reciprocal sliding at 80 mm/s (~walking speed)

under 7N compression¹¹. Characterization was first performed sliding against a plain microscope slide, followed by two hours of free swelling in PBS. Characterization was then repeated with polished, plain, and frosted slides. Between each sliding test, each explant free-swelled in PBS for two hours. After testing, explants were again assessed for damage using stereomicroscopy, and then bisected to measure cartilage thickness (h). **Data Analysis:** Deformation (δ), normal force (F_N), and friction coefficients (μ) recorded by the tribometer were analyzed using MATLAB.¹¹ Measures of tissue strain ($\epsilon = \delta/h$) were calculated, and strain and friction magnitudes were analyzed at the beginning and end of active sliding, and strain recovery (i.e. tribological rehydration) during sliding was calculated. Characteristic deformation rates were obtained from linear regression fits of the time-dependent deformation data. Negative deformation rates are representative of recovery of compressive deformation (i.e., tribological rehydration), while positive deformation rates are representative of pure compression-induced deformation (during static loading) or continued compressive deformation, and thus, compromised tribological rehydration (during sliding). Friedman's Test, a nonparametric test with replication, was used to identify statistically significant changes between the repeated surface roughness tests

RESULTS — The deformation and friction responses were similar with sliding against regular glass slides and polished slides and strain recovery (i.e., tribological rehydration) was observed under both of these conditions ($p=0.97$). The most pronounced changes occurred when explants were tested against the rough glass counterface, under which strain recovery (i.e., tribological rehydration) did not occur. Under sliding against the rough counterface, strain recovery was significantly impaired relative to regular and polished surfaces ($p<0.0001$), as was deformation recovery. For regular and polished glass surfaces, explants recovered an average of 14.5 and 17.6 μm , respectively, while explants had not recovered any deformation at the end of 30 minutes of sliding against the rough glass, and instead compressed an additional 64.5 μm on average. Friction coefficients at the end of sliding (i.e., sliding equilibrium, were similar for all three surfaces ($\mu = 0.04 - 0.07$). However, there was a significant difference in start of sliding friction coefficient for sliding against rough glass ($\mu = 0.5288$, $p<0.0001$) compared to regular and rough surfaces ($\mu = 0.288$ and 0.289 , respectively; $p=0.9996$).

Surface roughness had no effect on the static deformation time constant ($p>0.1$); however, increased surface roughness had a significant effect on the sliding deformation time constant relative to regular and polished glass surfaces ($p<0.0001$), consistent with the lack of strain recovery observed under this condition.

DISCUSSION — The results of this study illustrate that decreasing surface roughness of the glass counterface has no appreciable effect on the tribomechanical response of articular cartilage under the cSCA testing configuration. This was reflected in similar values of strain recovery, deformation recovery, and start- and end-of-sliding friction coefficients for both regular glass and polished glass. These findings suggest that regular microscope slides are of sufficient frictional properties to assess the tribological behavior of articular cartilage under the cSCA and ultrapolished glass is not necessary for these experiments. Conversely, the use of frosted glass, which is of a greater asperity height, and thus, surface roughness, prevents cartilage from sustaining tribological rehydration under reciprocal sliding in the cSCA configuration. Under this condition of increased microscale porosity of the counterface surface, reciprocal sliding leads to wearing of the cartilage surface, and as the uppermost layer of cartilage matrix is being removed, lubrication is not actively occurring. This is

reflected in an overall increase in deformation during sliding for the rough surface, whereas a recovery of deformation is seen for polished and regular glass, meaning that tribological rehydration is not occurring when cartilage is slid against rough glass. In addition, increased surface roughness (i.e., increased nanoscale porosity) leads to a greater number of fluid flow pathways, thereby increasing compression-induced exudation and preventing tribological rehydration during reciprocal sliding.

These findings suggest that ultrapolished glass is not necessary for creating physiologically analogous behavior under the cSCA configuration and that plain microscope slides provide a sufficient surface roughness to sustain tribological rehydration in these experiments, while increasing counterface surface roughness defeats the tissue's ability to recover compressive deformation under sliding.

Figure 1. A) Overlaid traces from a representative explant show similar strain and friction behavior for regular and polished glass, and continued compressive deformation during sliding for rough glass. **B)** Sliding-induced strain recovery occurs with both polished and regular, but not rough glass (top row); the static compression time constants were similar for polished and regular glass while explants reached characteristic deformation faster when compressed against rough glass; end-of-sliding deformation time constants show that strain recovery occurred for polished and regular glass while sliding against rough glass resulted in continued deformation (bottom row).

MAINTAINING CARTILAGE HYDRATION DURING SLIDING PART I: THE EFFECT OF MIGRATION LENGTH

INTRODUCTION

The remarkable fact that cartilage can withstand contact stresses (0.5-10 MPa) that exceed its modulus (0.1-1 MPa) with minimal strains (5-20 %) and friction coefficients (0.001-0.05) is attributed to load support through interstitial fluid pressurization. The maximum fluid load fraction (F'_{max}) varies for cartilage but is typically between 70 and 99%, depending largely on the tensile stiffness of the matrix. Sustaining high interstitial pressure is necessary to sufficiently maintain the mechanical and lubrication functions of the joint.

Because interstitial pressure drives exudation, fluid load support subsides temporally during static loading. Fortunately, as both theory and experiments have shown, cartilage achieves and maintains maximum fluid load support if the contact migrates across the cartilage surface faster than the interstitial fluid can escape. According to the literature, maximum fluid load support is achieved when $Pe \gg 1$, which corresponds to sliding speeds exceeding 100 nm/s in a typical human joint. Thus, there is a school of thought that even “fidgeting” ($Pe \gg 1$) during nominally static loading can be sufficient to sustain interstitial fluid pressure.

While the role of migration speed on fluid load support is well-studied, the theory, experiments and discussions have only considered migration paths that greatly exceed the characteristic size of the contact. Clearly, maximum fluid load support cannot be sustained when a portion of the contact area remains in a stationary contact—which occurs whenever the path length falls below the characteristic size of the contact. Furthermore, full range of motion for most joints in vivo is comparable to the size of the contact area. This transitional response in migration length has yet to be studied in a systematic way and the literature provides little insight into how load, contact area, contact stress and limited ranges of motion affect fluid load support and joint function. This experimental study was designed to quantify these migration length effects and elucidate their possible contributions to joint dysfunction and disease.

METHODS

Materials: Adult bovine stifles were obtained from a local abattoir. Full thickness $\phi 19$ mm osteochondral plugs ($n=5$) were extracted along the centerline of the medial and femoral condyles from

3 joints. Samples were rinsed in phosphate buffered saline (PBS) and stored in protease inhibitor solution at 4°C. The samples were CNC-milled, mounted into a custom tribometer, and lubricated in a 1X PBS bath. Borosilicate glass spheres (ϕ 2.4, 3.9, 6.4mm) were used as the counter-body. The material properties of each sample were quantified before and after tribological testing. All tests were completed within 24hr of extraction to minimize the risk of enzymatic digestion-induced changes in material properties.

In-situ characterization: Normal force and indentation depth were quantified during sliding in the migrating contact area (MCA) configuration. Our previous in-situ observations with cartilage [1] showed that the contact geometry is best described by Hertzian mechanics, which we used to relate the contact radius (a) to the known probe radius (R) and the measured indentation depth (δ_s) with Eq. (1).

$$a = \sqrt{\delta_s \cdot R} \quad (1)$$

The effective contact modulus (E_c), which depends on the material properties and sliding speed among other variables, is quantified experimentally with measured/known values of load (F), equilibrium tissue deformation (δ_s), and probe radius (R), as described in Eq. (2):

$$E_c = \frac{3}{4} \frac{F}{R^{0.5} \delta_s^{1.5}} \quad (2)$$

At equilibrium under static contact conditions, load is supported entirely by osmotic pressure. With Eq. (2), the equilibrium contact modulus (E_{c0}) can be quantified by the force or deformation response during **static equilibrium** contact. During sliding, interstitial pressurization increases E_c and reduces friction. At **dynamic equilibrium**, interstitial pressure, the fluid load fraction, the effective contact modulus, and the friction coefficient depend on material properties and the sliding conditions. We quantify the magnitude of fluid load support using the fluid load fraction (F'), which varies between 0 and maximum fluid load fraction (F'_{max}). As we have shown in a previous paper [2], the fluid load support can be quantified experimentally based on E_c and E_{c0} using Eq. (3):

$$F' = \frac{E_c - E_{c0}}{E_c} \quad (3)$$

Tribological Testing: Each sample was first indented with a borosilicate glass sphere to a target load under static conditions until reaching equilibrium (<0.3 $\mu\text{m/min}$), as shown in Figure 1A.

Following equilibration, the next minute of data was used with Eq. (2) to determine the mean and standard deviation of the equilibrium modulus. Immediately following static equilibration, a lateral stage began reciprocating at 1.5 mm/s ($Pe > 100$) over a maximum track length ($S = 7$ mm) to establish the large Pe number and long track length baseline (F'_{max}). Following equilibrium ($< 0.3 \mu\text{m/min}$), the next minute of data was used to determine the mean and standard deviation in the maximum effective contact modulus and then the maximum fluid load fraction using Eqs. (2) and (3), respectively.

Figure 1: (A) Definition of measured variables and illustration of the indentation measurement. Force is quantified with deflection of a pre-calibrated spring and indentation depth is quantified with spring deflection and stage position. (B) Definition of path length (S) and migration length ($S^* = S/2a$).

The track length was then reduced to 4 mm and the system re-equilibrated to determine the corresponding fluid load fraction. This procedure was repeated for 2, 1, 0.5, 0.2, 0.1, and 0.05 mm track lengths in that order. Following the final equilibration, sliding was terminated, the probe retracted, and the sample left to free-swell in the PBS bath for 10 min before being subjected to another indentation measurement to establish the variability in the equilibrium response. Each sample was subjected to each of the three target loads (5, 20, and 100 mN) and probe sizes (ϕ 2.4, 3.9, 6.4 mm) in random order to test for load, area, and stress effects on the transition response.

Analysis: The fluid load fraction in an MCA of an infinite track depends on F'_{max} —which depends on sample-specific elastic properties, and the Pe number—which depends on speed [3], as follows in Eq. (4):

$$F'_{inf} = F'_{max} \cdot \left[\frac{Pe}{Pe+1} \right] \quad (4)$$

When $Pe > 100$ (1.5 mm/s), F'_{inf} is within 1% of F'_{max} . Therefore, the 7 mm baseline measurement, which is many times the contact diameter, provides a reliable measurement of F'_{max} . To isolate path effects from material effects, each variable path-length measurement of F' is normalized by its 7 mm (effectively infinite) path length counterpart (F'_{max}). Given the similarities in the physical effects of speed and migration length, we propose that the normalized fluid load fraction ($F^* = F'/F'_{max}$) varies between 0 and 1 as a sigmoidal function of the migration length ($S^* = \text{path length normalized by contact diameter}$, Figure 1B) and reaches 0.5 at a critical migration length (S^*_c), as described in Eq. (5):

$$F^* = \frac{F'}{F'_{max}} = \frac{S^*}{S^* + S^*_c} \quad (5)$$

The results were used to determine (1) if track length affects fluid load support, (2) the quantitative relationship between the two variables, (3) the necessary migration length for an effectively infinite track, (4) S^*_c , and (5) the directional effects of load, probe size, contact stress, and contact size on S^*_c .

RESULTS

The normalized fluid load fraction (F^*) is plotted against the migration length (S^*) for $N=5$ independent samples at all 7 track conditions, at all 9 combinations of load and probe radius in Figure 2A. We observed no significant reduction in fluid load support when the track length was an order of magnitude longer than the contact diameter ($S^* > 10$). The fluid load fraction decreased with decreased track length below this threshold. On average, the fluid load fraction

only decreased by $\sim 20\%$ when the track length matched the contact diameter ($S^*=1$). The fit to the entire dataset gave $S^*_c = 0.12$.

To determine if and how the critical migration length varied with probe diameter, load, contact area, and contact stress, we first binned the results into low, medium, and high groups within each category. Then, we determined the mean critical migration length and its statistical uncertainty by fitting each group within each category using Eq. (5). The dependence of the critical length on each variable is shown in Figure 2B. The critical migration length (the length needed to maintain 50% of F'_{max}), increased with decreased probe diameter ($p > 0.05$), increased load ($p < 0.05$), increased contact area ($p < 0.05$), and increased stress ($p < 0.05$).

Figure 2: (A) Plot of $N=5$ for entire dataset—varied load, track length and probe size. (B) Transition migration length (S^*_c) for each variable—*denotes significance of $p < 0.05$.

DISCUSSION

The results of this study demonstrate that restricted ranges of motion defeat interstitial hydration, pressure, and lubrication. Previous studies have hinted at this effect [4, 5]. Our results show that Eq. (5) yields a reasonable estimate of the fluid load fraction with $S^*_c = 0.12$ over a fairly broad range of tested conditions. For small-scale MCA conditions typical of cartilage friction studies, it seems safe to assume that a migration length of $S^* = 10$ results in full fluid load support. However, the results also suggest that the transition response varies significantly with changes in contact conditions. Unfortunately, the variables are inter-dependent, which makes it difficult to tease out the dominant contributor. For example, a non-significant probe radius effect might be best explained by its effect on stress (at fixed load). Our results are consistent with stress as the dominant variable; this explanation is also intuitive since stress drives exudation.

The clinical implications of these results are fairly obvious but it's important to establish without ambiguity: full or near full range of motion appears necessary to fully disrupt exudation and its functional consequences. On the joint level, these results dismiss the possibility that small-scale fidgeting preserves interstitial hydration even if $Pe \gg 1$. While these data cannot be used to predict the transition behavior of joints with any certainty, extrapolating the stress trend suggests that $S^*_c \sim 0.20$ – 1.2 for contact stresses between 1 and 5 MPa. This analysis reinforces the suggestion that full range-of-motion movements are important for maximizing tissue hydration and function. These results also suggest that the heaviest and least active populations are more likely to experience tissue and joint dysfunction.

Finally, these results leave little doubt that joints lose interstitial fluid in the absence of intentional activity, which composes only about 5–10% of a typical day. Part 2 of this paper considers the mechanisms and competitive rates of fluid recovery following static exudation.

INTRODUCTION

Ligaments are collagenous structures that connect the bones of the body and form the joints which are critical to overall foot function, including the ankle joint complex and the medial arch of the foot. Understanding the material properties of the ligaments supporting some of these key joints will help to predict how the structures of the foot respond to external loads and locomotion. Mechanical testing of soft tissues can provide these material properties; however, the small size and unique shape of the foot and ankle ligaments makes determining these properties technically challenging. One such challenge is that it is often difficult to load irregularly-shaped ligaments in their anatomic orientation, yielding material properties that are not representative of *in vivo* loading [1]. Additionally, the process of maintaining environmental conditions while running precise mechanical tests is exacting, demanding work that is subject to errors. The following is a presentation of methods developed to determine the viscoelastic properties of foot and ankle ligaments. These methods address a way to maintain anatomical alignment of a neutrally flexed foot, estimate the length of a small irregularly shaped ligaments, and maintain the specimen environmental conditions while partially automating the mechanical testing procedure.

METHODS

The calcaneofibular, anterior tibiofibular, calcaneonavicular, tibiocalcaneal, and interosseous ligament between the talus and calcaneus will be tested from eight fresh-frozen cadaveric specimens. The ligament viscoelastic response will be characterized at a range of loading frequencies (0.5, 1, 2, 5, 10 Hz) at several non-destructive strain targets using a mechanical testing machine (ElectroPuls 3000, Instron, Norwood MA), followed by a stress relaxation test, and concluding with a load to failure test. A 10-minute rest interval is prescribed between

each of these tests. Pilot ligaments were used to develop further experimental methods.

Specimen Length Estimate

In preparing the ligaments for mechanical testing, the soft tissues surrounding the ligaments are removed and the foot is placed in a custom radiotransparent acrylic loading jig where the foot is loaded through the tibia to approximately 50 lbs. of body weight. The foot and loading jig are then scanned using cone beam computed tomography (CT) (PedCAT, Curvebeam, Hatfield PA; 0.37 mm isotropic volume). The relevant bones and each ligament of the resulting DICOM images are segmented in Mimics (Materialise, Leuven Belgium) and imported as point clouds into a custom Matlab program.

In that program, two surfaces are created from the intersection of the ligament and bone point clouds at both insertion sites. The linear distance between the centers of each surface defines a rough ligament length. The line between these points is adjusted to intersect the cross-sectional center of the ligament at 10% intervals along the line's length. This process iterates bi-directionally until the length of the ligament changes by less than 5% (Figure 1).

Specimen Preparation

To maintain *in vivo* pose, a rigid wooden brace is fixed to each bony insertion with several 1mm wires while the ankle is flexed to ~90 degrees (Figure 2). Once secured with a polyurethane adhesive (Gorilla glue, Cincinnati OH.), the externally fixed bone-ligament-bone sample is excised using a surgical saw (Stryker, Kalamazoo MI.).

An alignment jig was used to visually align the ligament and external fixation in the potting and the rigid wooden brace are cut once the ligament has been positioned in the mechanical testing machine.

To compare the strain applied by the actuator to the true ligament orientation, fiducial marker clusters are placed on the potted ends. The potted bone-ligament-bone specimen complete with external fixation and fiducial marker clusters are CT scanned a second time. The relative positions of the bone-ligament surface centroids in relation to fiducial marker clusters can be used to relate the origin and insertion to actuator position and therefore applied strain to anatomical strain.

Figure 1: CT point cloud of a representative tibio calcaneal ligament (grey) with last 3 length estimates.

Maintain Environmental Conditions

A custom-made insulated chamber is used to enclose potted ligaments during mechanical testing. The chamber is fitted with a ceramic heating element and a saline sprayer system. A data acquisition system (National Instruments BNC 2090, Austin TX) was used to control the environmental temperature, saline spray, record and trigger high-speed cameras (Phantom v641, Vision Research, Wayne NJ.), download high-speed video, and record analog signals from mechanical testing equipment. Temperature from 6 thermistors surrounding the ligament was recorded and compiled with mechanical testing data.

Figure 2: (a) Example of a calcaneofibular and tibiofibular external fixation before and (b) after removal with fixation maintaining *in vivo* ligament pose.

Semi-Automated Mechanical Testing

A mechanical testing sequence with randomized loading frequencies and increasing strain targets is programed in testing software (Wavematrix, Norwood MA). During testing, a custom LabView program integrates the materials testing machine, cameras, sprayers, heater and data acquisition system. As each test in the sequence begins, the program interrupts the sprayers and starts the cameras. At the conclusion of each test, the program saves the displacement, force, and video data maintaining consistent naming conventions. The program inputs the next test parameters into the materials testing system, and this process repeats until all tests have been completed. The calibrated video data collected by the high-speed cameras will be used to perform 2d digital image correlation and to track proximal and distal marker clusters

RESULTS

Visual comparison of the intact and potted ligaments show that pose was maintained after ligament was excised.

After a total of 3 1-hour long pilot tests, the semi-automated mechanical testing system successfully performed sets of 5 loading frequencies followed by ramp and hold tests. The resulting video data, loadcell data, displacement data, and temperature data were successfully saved, and each next test was input and ran without user interaction. During this 3-hour long session temperatures were maintained within (37 ± 2.21 °C) while the specimens were kept constantly moist.

DISCUSSION

Length estimation is dependent on high contrast CT scan data, reliable feature detection, point cloud density, and operator variability. Removing soft tissues surrounding the bone and ligament produces CT images with high contrast since contrast is dependent on changes in relative density. To improve point cloud density, a surface subdivision routine can be applied to interpolate between points. Poor point cloud density and subsequent mesh resolution can cause inaccuracies in cross-section definition resulting in poor length estimations or an inability to converge to a final length after multiple bidirectional iterations.

The ability to maintain pose with external fixation requires healthy bone. If the bone is osteoporotic, the wire base may not stay in place while the bone is cut. While the comparison between the pose and the potted ligaments showed good alignment, a method is needed to determine the optimal potting orientation that best represents the common directions of *in vivo* tensile loading. Finally, the irregular shapes of these ligaments can make visual alignment during potting a challenge which can cause inconsistencies in ligament loading directions between specimens.

Ligament mechanical properties are sensitive to changes in temperature and moisture during long testing sessions which can fluctuate within an environmental chamber. The presented semi-automated testing methodology successfully maintained constant hydration and temperature during a long testing series.

The methods outlined here are now being applied to establish material properties for a series of ligaments from eight cadaveric specimens, this work is ongoing.

INTRODUCTION

Fatigue failure occurs with repetitive loading and, in baseball pitchers, such cyclic loads are applied at the elbow as a result of repeated pitches thrown. During the cocking phase of pitching, a large valgus torque is generated that can potentially damage the medial ulnar collateral ligament (mUCL). In that the mUCL is the primary stabilizer to valgus loading [1], the threat of injury to the ligament as a result of the repeated application of these valgus loads is evidenced by the growing number of mUCL surgeries.

The effect of fatigue has been studied in regard to human and animal ligaments. Lipps et al. [2] experimentally simulated cyclic pivot landings on knee joints and showed that the anterior cruciate ligament is indeed susceptible to failure by fatigue. Thornton et al. [3] showed that the degree of modulus reduction resulting from fatigue is more severe, as compared to creep, when studying rabbit medial collateral ligaments.

The current study seeks to introduce and test a custom designed fatigue testing machine to study the fatigue properties of the mUCL. In previous work, the ligament was instrumented in three distinct bands, posterior, middle and anterior, and strain data obtained with application of load. To study fatigue failure, strain data from cyclic testing can be compared to the quasistatic testing results and to any known failure values. The purpose of the current work was to perform initial testing of a valgus loading cyclic test machine for the mUCL so that the subsequent analyses could be performed. The basic hypotheses were that the custom device could impose failure loads and that strains would quantitatively match the quasistatically obtained values before failure.

METHODS

Three cadaveric elbows were prepared for testing by stripping away all muscle, nerve and soft tissue except the mUCL and that part of the lateral ligament complex lateral to the radial head. The humerus and ulna with the radius were each set within a PVC container and polyester resin was poured into the PVC and allowed to harden, securing the two bones. Screws were placed through the PVC and bone to ensure that the specimen could not rotate within the PVC. Optical markers were placed along the length of the mUCL in three equally-spaced columns, posterior to anterior.

Each elbow was mounted in the testing device (Figure 1). The device accommodates a variable flexion angle but the first tests were performed at a single fixed angle. The PVC containers were then placed inside two custom designed metal sleeves and loaded into the fatigue tester at 90° of elbow flexion. Each sleeve was connected to a shaft. The shaft with the humerus was held stationary and the shaft with the ulnar was connected to a torsional load cell that was driven by a 10:1 gear reducer. The gear reducer included an encoder to quantify angular motion and was driven by a servomotor. The axis of the shaft connected to the driving motor was positioned to align with the center of the capitellum in order to rotate the ulna/radius construct around the natural axis of valgus motion. The housing holding the PVC sleeves could translate along the swing arm attached to the drive shaft in order to minimize binding. For the current tests, internal-external rotation was completely constrained, although complete rotational freedom could have been allowed. With the specimen in place, two high-resolution cameras were calibrated and testing begun.

Figure 1: Fatigue Testing Apparatus; the lower expanded view shows the elbow housings attached to shafts with a load cell in line with the v-v axis

Testing began with an initial load-controlled valgus rotation of 2 Nm of torque. Three slow cycles were followed by a fourth cycle during which torque, angular displacement and ligament displacements were recorded. The recorded cycle was followed by one-hundred fast cycles and a final recorded slow cycle. This procedure was repeated for increments of 2 Nm of valgus torque, until failure of the ligament. A test length of 100 cycles was chosen because that number is the current expectation for the number of pitches thrown in a game.

The recorded camera footage was used to quantify the longitudinal displacement of the length of the mUCL. The ligament lengths at the beginning of each load cycle were used as the reference lengths in the strain calculations of each band.

RESULTS

Each of the three tested specimens ruptured completely in valgus loading. The failure torques were 50 Nm, 20Nm and 30Nm for specimens 1, 2 and 3, respectively. Specimens 1 and 3 failed with posterior band avulsion at the ulnar joint line and subsequent tearing to the mid-substance; specimen 2 failed by complete ulnar sided avulsion. Figure (2) shows the maximum strain in each band, for each specimen, at the start of the cyclic load step just before the cyclic load step where failure occurred. The maximum valgus loads for these cycles were 48 Nm, 18 Nm and 28 Nm. Except for the posterior band of specimen 1, the strain in each band at the end of the load step was larger than the strain at the beginning of the load step.

DISCUSSION

The fatigue tester successfully carried valgus testing to failure after multiple steps of loading. The device integrated features that allowed for adjustability of the specimen position, which kept the radial head pivoting on the capitellum. The valgus loads were able to be applied repeatedly for a prescribed number of cycles, consistent with what a major league baseball pitcher may perform during a single game.

The different torques at which each specimen experienced failure was a testament to the variability in the geometric and mechanical properties between the specimens. The specimen which failed at 50 Nm had significantly greater thickness than the other two specimens. This showed that these geometric attributes do affect the fatigue life of the mUCL.

Figure 2: Maximum Strain for each Band during the Start of the Cycle before Failure

The three failure modes were similar in the origination of failure at the posterior insertion on the ulna. For specimens 1 and 3, the failure was observed to originate at the posterior band near the mid-substance of the ligament. This was evident from the complete rupture of the posterior band fibers, which proceeded across the mid-substance of the ligament toward the anterior band, which had a few fibers still intact. The failure of specimen 2 originated at the posterior band near the ulnar end of the ligament. The initiation of the failure at the posterior band seemed to agree with the strain results of Figures (2), which show the posterior band strain to be approximately equal to, if not greater than, the strain in the middle and anterior bands.

The difference in failure location with one specimen could be a result of the variation of the ligament properties between specimens, as well as the valgus rotation angle. Because the test was load-controlled, the angular valgus displacement could have been different for each specimen at any particular magnitude of valgus torque. More tests need to be performed to determine the consistency of the observed failure nature.

Figure (2), showing the maximum strain for the cyclic load step just before the failure load step showed an indicator of stiffness reduction in the bands of the mUCL. The maximum strain was greater at the end of the cycle than at the beginning of the cycle for eight of the nine bands. This meant that, for the same value of valgus load, a higher amount of deformation was achieved. This showed that, due to cyclic loading, the stiffness of the mUCL was gradually reduced over the course of the cyclic load step. This stiffness, or modulus, reduction is a criterion that has been used to show the presence of damage accumulation within a solid body [3]. Viscoelastic deformation could also be the source of this additional stretch.

Similar to the results presented in the previous studies [2-3] on ligament fatigue of the human ACL and rabbit MCL, fatigue seemed to play a definite role in the degradation of the mechanical properties of the bands of the human mUCL as well. This degradation effect continued up until the ultimate failure of the ligament. Further experimental and computational modeling will seek to implement these fatigue results in an effort to predict injury, relating to baseball pitchers who regularly experience these types of loadings.

INTRODUCTION

During embryonic and neonatal development, there is a rapid change in tendon structure and mechanics. Previous studies demonstrate that the tendon tensile modulus and ultimate strength dramatically increase as the collagen fibrils grow in diameter and length.^{1,2,3} Additionally, there is a substantial decrease in the cellular volume fraction as more extracellular matrix is deposited.² These developmental changes are critical for the establishment of the load-bearing capacity of mature tendon. However, how tenocytes carefully orchestrate and regulate this process is unknown. Since tenocytes are sensitive to mechanical stimuli,^{4,5} there is likely a feedback loop between tenocyte behavior and the changes in their mechanical microenvironment that drives tendon development.^{5,6} Identifying the nature of this feedback loop and the role of cellular mechanotransduction in producing functional tendons will provide insight into the nature of tenogenesis and new opportunities for regenerative medicine.

A first step in identifying the interplay between tissue mechanics and cell behavior during tendon development is to determine the local tissue strains that cells experience in embryonic tissue. Previous studies only examined the macroscale mechanical properties of embryonic tendons.^{2,3,6} However, the observed macroscale tendon behavior likely does not reflect the local microscale mechanics. Recent studies investigating the multiscale mechanics of rat tail tendon fascicles reported that the microscale tissue strains are significantly less than those applied at the tissue level, which can be explained by relative sliding between collagen fibrils.^{7,8} However, it is unclear if the same phenomenon occurs within embryonic tissue and to what degree. Possible changes in fibril strains and sliding during development may have important implications for the mechanobiological pathways that are activated during tenogenesis.

The objective of this study is to measure the multiscale mechanics of embryonic tendons. We hypothesize that the fibril strains will be less than the applied tissue strains, suggesting that the fibrils are discontinuous and exhibit interfibrillar sliding under tensile load.

METHODS

Four digitorum longus tendons (n=4) were isolated from the tarsometatarsal region of the hindlimbs from white Leghorn day 20 (E20) chicken embryos. Samples were stained with DTAF at 10 ug/ml and secured in the grips of a tensile testing device mounted on a confocal microscope with a 5 mm reference length (**Fig. 1**).

Prior to testing, the samples were rotated in order to image the major and minor diameters, which were used to calculate the cross-sectional area. Samples were then untwisted and preconditioned to 1% strain for 5 cycles at 0.03 Hz. Three sets of photobleached lines (PBL) (4 lines, 125 μ m apart) were bleached at the sample center and ± 2 mm from the center. Samples were then loaded

Figure 1: Experimental setup for multiscale tension testing. (A) Uniaxial tension device mounted atop a confocal microscope. (B,C) Representative image of the photobleached lines at 15% strain and their corresponding microscale strains. Scale bar = 100 μ m.

to 20% grip-to-grip strain in 5% increments at 10%/min followed by a 15 min stress relaxation. At the end of the relaxation, z-stack images were acquired at all three PBL locations and the stage positions were recorded.

All images were processed utilizing a series of custom MATLAB scripts to precisely track the photobleached lines and quantify the microscale fibril strains and interfibrillar sliding (Fig. 1B-C).⁵ Additionally, a MATLAB code was utilized to optically quantify the macroscale strain by tracking the spatial displacement of the peripheral PBL sets relative to one another (PBL-to-PBL strain). The coefficient of variance for the ratio between the fibril and PBL-to-PBL tissue strains was calculated across the three PBL locations for each sample.

The applied load was collected during the entire ramp and stress relaxation period. The load during the last 30 seconds of the relaxation was averaged to determine the quasi-static stress at each incremental strain. The macroscale tissue modulus was calculated using a linear regression fit to the quasi-static stress versus both the grip-to-grip and PBL-to-PBL strains.

The fibril:tissue strain ratio was averaged across all strain increments and a Student's t-test was used to determine if the value was different from one. A linear regression was used to determine if the values were dependent on the applied tissue strain. Similar statistical tests were used for the interfibrillar sliding, except t-tests were used to determine if the average value was different from zero. Significance for all tests was set at $p < 0.05$.

RESULTS

The fibril:tissue strain ratio had an average coefficient of variance of 0.139 across the tendon length. The fibril strains were significantly lower than the applied tissue strain ($p < 0.01$) but were not significantly different with increasing strain ($p = 0.43$) (Fig. 2A). The interfibrillar sliding was significantly greater than zero ($p < 0.05$) and there was an increase in fibril sliding observed with increasing strain ($p < 0.01$) (Fig. 2B).

Figure 2: Multiscale behavior of embryonic day 20 chick tendon. (A) Fibril:tissue strain ratio and (B) interfibrillar sliding as a function of the applied grip-to-grip strain.

Figure 3: Plots and linear regressions of the quasi-static tendon behavior as a function of both the grip-to-grip and optical (PBL-to-PBL) strains.

Linear regressions of the quasi-static stress versus the PBL-to-PBL ($p < 0.01$) and grip-to-grip ($p < 0.02$) tissue strains indicated an average quasi-static modulus of 85.3 MPa and 31.7 MPa respectively (Fig. 3).

DISCUSSION

This study provides the first measurement of the local microscale tissue strains that cells are exposed to during embryonic development. Consistent with our hypothesis, the microscale strains were less than the applied macroscale tissue strains (Fig. 2A). Together with the observed non-zero interfibrillar sliding measurements (Fig. 2B), this suggests that the fibrils are discontinuous in E20 tissue and that they slide relative to each other during tendon elongation. While previous studies reported that discontinuous fibrils could not be extracted in tendons from chicken embryos beyond E17,¹ our current data are consistent with previous testing of mature rat tail tendons.⁵ However, in contrast to mature tendon, the fibril:tissue strain ratio was unaffected by increasing tissue strain and remained high with an average of 0.84 ± 0.04 . This suggests that a different mechanism governing interfibrillar sliding may exist in embryonic versus mature tendon; however, additional work needs to be conducted to investigate this phenomenon further.

It is worth noting that there was a large discrepancy between the tendon behavior depending on whether the grip-to-grip or optical (PBL-to-PBL) strains were considered. In general, the optical strain measurements were less than 50% of the grip-to-grip strains, suggesting that the bulk of the strain occurred near the grips. This resulted in a nearly three-fold difference between our calculated modulus values. While our modulus values calculated from the grip-to-grip strains are comparable to previous tests of late embryonic chick tendons,² our optical strain data suggest that prior studies may underestimate the stiffness of embryonic tendon. It may be useful to develop alternative grip designs that transmit more of the applied tensile strains to the central portion of the sample. Nevertheless, our results suggest that cells are exposed to complex mechanical stimuli in developing tendons. Future work will be conducted across additional developmental time points to determine how changes in local tissue mechanics influence cell behavior and subsequent tendon development.

ACKNOWLEDGEMENTS

FEMORAL TUNNEL LOCATION AFFECTS ACL EXCURSION DURING KNEE FLEXION

INTRODUCTION

Anterior cruciate ligament (ACL) rupture is a common sports injury, and active patients often undergo surgical reconstruction using a tendon graft. Isometry in the graft placement would reduce the chances of graft damage, but the existence of isometric points for graft insertion is far from certain due to the complex motion patterns of the knee. Isometric placement is technically demanding when it is possible [1]. Anatomic placement of a graft would seem to have an intuitive advantage, but the tension in the native ACL is known to vary considerably. A small deviation from the native location may offer stability and isometry, potentially reducing risk of post-operative graft rupture. Existing studies have compared ACL excursion for proposed isometric tunnel locations [2] and have determined that transtibial reconstructions are more isometric than anatomic reconstructions [3]. While previous authors' works have examined tunnel placement, this work investigated ACL excursion for different pairings of femoral and tibial tunnels spaced evenly in and around the native ACL footprint in the same knee. Additionally, the knee flexion angle of minimum ACL excursion was determined.

METHODS

Nine cadaveric knee specimens, mid femur to mid shank, were dissected, removing skin, adipose tissue, and muscle tissue. The patella and patellar tendon were also removed. Care was taken to preserve all ligamentous structures of the knee. The ACL was transected and six tunnels were drilled centered around the ACL's femoral footprint and five tunnels were drilled around and in the middle of the ACL's tibial footprint (Figure 1). The center of the femoral footprint was identified as a point 50% of the distance from proximal to distal on the femoral footprint and 8mm anterior to the posterior articular margin of the lateral femoral condyle. Additional

tunnels were drilled 5mm proximal and distal to this point, and 3 additional tunnels 5mm anterior to the first 3 tunnels. The center of the tibial footprint was identified as 9mm posterior to the posterior edge of the intermeniscal ligament and exactly midway between the tibial spines. Additional tunnels were placed 5mm anterior, lateral, posterior, and medial to the central tunnel.

Figure 1: Tibial (left) and femoral (right) tunnel locations.

Each knee was mounted in a horizontal plane in a custom test fixture that maintained knee flexion with the knee's lateral side up. The fixture held the femur rigidly and allowed the shank to move freely. A swingarm connected to an incremental encoder rotated with the shank, measuring knee flexion. A string potentiometer was mounted to the fixture. Near the knee, the potentiometer's string was routed from the lateral side of the femur, into the intra-articular space, out through the medial side of the tibia, and clamped.

The knee was moved through ten flexion cycles from full extension to at least 120°. The first five cycles were treated as preconditioning, the next three cycles were used for analysis, and the last two cycles were not used. The ACL excursion was calculated as the difference between minimum and maximum string potentiometer excursion seen during the three analysis cycles. Data was analyzed for flexion angles between 20° and 120° to ensure all knees were analyzed over the same range of motion. Additionally, the flexion angle between 20° and 120° of smallest ACL excursion for each knee was recorded.

Two separate two-way repeated measures ANOVAs were performed. The first ANOVA compared ACL excursions across 20° to 120° of knee flexion with factors of femoral tunnel location (6 levels, A-F) and tibial tunnel location (5 levels, A-E). The second ANOVA compared flexion angles of minimum ACL excursion with the same factors and across the same flexion angles as the first ANOVA. Significance was determined by a p-value below 0.05. In the case of significance, Tukey's Test was used for post hoc comparisons.

RESULTS

Femoral tunnel location significantly affected both ACL excursion between 20° and 120° of knee flexion ($p < 0.01$) and flexion angle of minimum ACL excursion ($p < 0.01$). Femoral tunnels D and B had the smallest average ACL excursions, 3.7 ± 1.5 mm and 4.0 ± 1.7 mm, respectively (Figure 2). ACL excursion for femoral tunnel D was significantly smaller than at all other locations except B and ACL excursion for femoral tunnel B was significantly smaller than at locations C, A, and F. The smallest ACL excursion, 3.4 ± 1.9 mm, resulted from femoral tunnel D and tibial tunnel C (Figure 3). Femoral tunnel locations D ($79.4 \pm 38.9^\circ$) and B ($83.4 \pm 26.7^\circ$) had knee flexion angles with the smallest ACL excursion significantly different than the other femoral tunnel locations as well (Figure 4).

Tibial tunnel location had no significant effect on either ACL excursion or flexion angle of minimum ACL excursion.

Figure 2: ACL excursion as a function of femoral tunnel location.

Figure 3: The five smallest ACL excursions.

Figure 4: Knee flexion angle of smallest ACL excursion as a function of femoral tunnel location.

DISCUSSION

This work found femoral tunnel location significantly affected both ACL excursion over the knee flexion range of 20° and 120° and the flexion angle of minimum ACL excursion over the same knee flexion range.

Zavras et al. [2] compared tunnel locations that have been suggested throughout the literature for isometric graft behavior. They found ACL excursions as large as 6 mm for geometrically placed tunnels and 3 mm for anatomically placed tunnels. They found several tunnel locations that had less than 1 mm total ACL excursion. The smallest ACL excursion found in our study was 3.4 ± 1.9 mm for femoral tunnel D and tibial tunnel C.

Lubowitz [3] compared anatomic and transtibial ACL reconstructions and found approximately 7.3 mm and 5 mm excursions, respectively, when the current method, ACL excursion as the difference between maximum and minimum change in ACL length across the knee's flexion range, was applied to his data. Both measurements are within the range of what was found in our study, although he included data to full knee extension.

Both Zavras et al. (full extension to 140°) and Lubowitz (full extension to 120°) used larger knee flexion ranges than our study which may have affected our flexion angle of minimum excursion because some minima were found to be at 120° of flexion.

Another consideration in a cadaveric study is the effect of muscular structures on knee stability. Only ligamentous structures were maintained during this study, and we cannot account for the complex patterns of musculotendinous units in the stabilization of the knee joint in vivo.

Finally, the motion measured in this study was limited to flexion and extension, and did not include imposed rotatory motion. Many prior works have demonstrated the importance of a reconstructed ACL to withstand a pivot shift type motion, and femoral tunnels drilled trans-tibially are more likely to result in grafts that fail to prevent this pathologic motion. Thus, less excursion of the graft during flexion and extension should not be inferred as clinically superior. Our results may explain the roughly 5% rate of post-operative rupture with anatomic reconstruction given the forces on the graft.

INTRODUCTION

Ultrasound is a non-invasive, reliable and cost-effective tool often used by clinicians to diagnose musculoskeletal injuries (ie. tendon and ligament injuries). Currently, evaluation of tissue quality based on ultrasound images is mostly qualitative and depends on the user. Acoustic Radiation Force Impulse (ARFI) imaging is an ultrasound technique that generates a localized force onto the tissue of interest at a precise location and the resulting tissue displacement is measured. Information about the resulting tissue displacement could lead to insights about tissue quality. ARFI imaging is primarily utilized for compliant, isotropic biological tissues such as the breast and liver, where tissue displacement measurements are $<10\mu\text{m}$. The utility of ARFI imaging is not well understood for stiff, anisotropic biological tissues such as a tendon (tendon modulus: $\sim 100\text{s of MPa}$ in long axis and $\sim 1\text{MPa}$ in transverse axis vs breast/liver $\sim \text{kPa}$), where tissue displacements may be too small to differentiate between un-injured and injured tendons. Conventional ultrasound imaging (full-frame imaging) utilizes narrow beams for better image resolution. However, utilizing narrow beams limits the acoustic radiation force applied to the tissue. Multi-foci beamforming is an imaging technique that allows for a more powerful and focused beam of acoustic radiation force by dividing the ultrasound transducer into multiple sub-apertures and programming each sub-aperture to focus at a specific axial and lateral position [4]. Therefore, the objective of this study was to assess the ability of the multi-foci and full-frame approach to push onto the tendons. It was hypothesized that tendon displacement will increase compared to full-frame ARFI imaging.

METHODS

Four fresh-frozen porcine knees were dissected, and the extensor tendons were harvested and prepared for tensile testing and ARFI

imaging of the tendon midsubstance. The cross-sectional area of the tendon midsubstance was determined using a laser scanner (Next Engine, Desktop 3D Scanner, Santa Monica, CA, USA).

Mechanical Testing: Each tendon underwent a uniaxial tensile testing protocol (Preload = 1N, Preconditioning = 1-10N for 10 cycles, Load to 100N) to determine its modulus in the linear region. The ends of the tendon were clamped with custom soft tissue clamps and aligned for tensile loading in the materials testing machine (Instron, Model 5965, Norwood, MA, USA). The midsubstance strain in the tendon was

Figure 1: Control images of the regions of excitation (bright areas) for a (A) full-frame and (B) multi-foci ARFI push in a homogeneous gelatin phantom. Multi-foci imaging focuses the acoustic radiation force to a precise location. (C) ARFI displacement within the stiff tendon is less compared to the surrounding softer muscle after a full-frame ARFI push.

measured with an optical tracking system (DMAS, Spica Technology, Kihei, HI, USA).

ARFI Imaging: Each tendon was wrapped with a layer of muscle and loaded into a custom tensioning jig immersed in distilled water to more closely mimic physiologic conditions. The tendon was loaded to five different stress levels (0.1, 0.25, 0.5, 0.75 and 1.0 MPa), where 3 full-frame and 3 multi-foci ARFI images were acquired at each stress level using a research ultrasound platform (Verasonics, VDAS V-1 Model, Redmond, WA, USA) and commercial linear array transducer (ATL L7-4). The average tendon displacement across the 3 images for both the full-frame and multi-foci approach was used for analysis.

For full-frame ARFI imaging, an ARFI push across the entire width of the transducer aperture was generated using a localized radiation force (spatial resolution = 148 μm) at the tendon midsubstance located at the elevation focus of the transducer (25 mm) for 1000 cycles at 5.2 MHz (duration = 192 μs). For multi-foci ARFI imaging, a multi-foci push is generated using the same parameters as full-frame ARFI imaging (spatial resolution = 298 μm). That is, the ultrasound transducer aperture is divided into 3 focused beams (foci), which all focus at the elevation focus and in the center of the transducer simultaneously (Figure 1B). ARFI tendon displacement was measured from post-ARFI push images and measured by manually selecting a region of interest at the center area of the tendon to minimize boundary effects (Figure 1C).

Mechanical Damaged Protocol: Cyclic compressive loading (40 cycles from 1-100N) was applied to the tendon midsubstance to damage the collagen fibers and injure the tendon. Loading conditions were determined based on preliminary tests that resulted in a decrease in the modulus of the linear region by ~40%. After injury, the same mechanical testing and ARFI imaging protocol performed for the uninjured tendon was repeated.

Statistics: A related samples Wilcoxon signed rank test was performed to assess the effect of ARFI technique (full-frame vs multi-foci) on ARFI tendon displacement. Significance was set at $p < 0.05$.

RESULTS

Multi-foci ARFI imaging resulted in significantly more tendon displacement compared to full-frame ARFI imaging (Figure 2). Across both tendon injury states and stress levels tested, multi-foci ARFI imaging was on average 2.7 times larger than the tendon displacement measured using full-frame ARFI imaging (multi-foci = $1.6 \pm 0.4 \mu\text{m}$ and

full-frame = $0.6 \pm 0.3 \mu\text{m}$, $p < 0.01$). The average linear region modulus for the 4 un-injured tendons was $347.0 \pm 100.7 \text{ MPa}$. Following the mechanical testing damage protocol, the modulus of the linear region dropped by an average of 43% (injured tendons = $195.4 \pm 47.8 \text{ MPa}$). The average difference of ARFI tendon displacement between un-injured and injured tendons was 0.2 μm when using the multi-foci approach (Figure 2). For the full-frame approach, the average difference in ARFI tendon displacement between un-injured and injured tendons across all stress levels was $< 0.1 \mu\text{m}$ (Figure 2).

DISCUSSION

The results of this study demonstrate the utility of multi-foci ARFI imaging to generate larger tendon displacement compared to full-frame ARFI imaging. On average across all stress levels, multi-foci ARFI imaging generated nearly 3 times more tendon displacement (Table 1), which was expected since the multi-foci ARFI imaging approach divided the transducer into 3 focused beams to push onto the tendon at a precise location. Our study shows that both full-frame and multi-foci ARFI imaging can displace the tendon enough to be measured, though lower than the magnitude of displacement reported for breast and abdominal tissues (up to 10 μm) [1-3].

Different ultrasound techniques such as shear wave elastography have been used by researchers to better understand tendon health [5]. The advantage of ARFI imaging is that it provides local information while shear wave elastography provides averaged information over the region where shear wave speed was taken. Previous studies have used ARFI imaging to identify the presence of tumors, by detecting changes in ARFI displacement to indicate a change in the tissue stiffness [1,2]. Our study establishes a novel methodology for ARFI imaging by focusing the ultrasound beams to a precise location (Figure 1B) and at a higher force. Developing a method that generates more force is important since tendons are much stiffer than tissues traditionally used for ARFI imaging (tendon modulus: ~100s of MPa vs breast/liver ~kPa).

In addition, the larger magnitude displacement using the multi-foci may be beneficial to differentiating the degree of injury or degeneration in tendons. Our results also show that distinguishing differences in tendon mechanical properties might be possible. At certain stress levels, differences greater than the repeatability (0.2 μm) of ARFI displacements measurements were found when using the multi-foci approach (Figure 2). With further development, multi-foci ARFI imaging may be a viable approach to target specific locations where a musculoskeletal soft tissue may be damaged and evaluate mechanical properties non-invasively.

INTRODUCTION

The glenohumeral joint is the most commonly dislocated joint, usually by an anterior shoulder dislocation [1]. This type of injury can result in non-recoverable strain of the glenohumeral capsule, increasing the chances of recurrent shoulder instability [2]. In order to minimize the risk of recurrent shoulder instability, a common surgical procedure is to plicate the capsule, reducing its size [3]. Currently, how the capsule is plicated depends on the surgeon's personal experience rather than taking into account the magnitude or location of non-recoverable strain in the capsule. Previous work has looked at non-recoverable strain in the glenohumeral capsule following multiple shoulder subluxations, while this study will examine non-recoverable strain following multiple severe anterior shoulder dislocations, with a severe dislocation being defined as the humeral head crossing the entire width of the glenoid. Optical tracking was used to measure non-recoverable strain, which allows non-recoverable strain in all directions to be accounted for, unlike other methods, such as strain gauges, which only allow strain to be measured along one axis. The objective of this study is to determine if performing 10 severe anterior shoulder dislocations without tearing the joint capsule is possible, as well as develop a method that utilizes optical tracking to calculate the magnitude and location of non-recoverable strain in the glenohumeral capsule following multiple severe anterior shoulder dislocations.

METHODS

Experimental Setup: Healthy cadaveric shoulders were dissected of all soft tissue except for the glenohumeral capsule. A 7x11 grid of black strain markers were glued to the inferior side of the capsule

Figure 1: Specimen mounted in the FRS2010 robotic testing system

spanning from the anterior band to the posterior band of the IGHL. The scapula and humerus were potted in epoxy putty and then mounted in the FRS2010 6 degree of freedom robotic testing system (Chino, Japan) (**Figure 1**).

The capsule was inflated to 0.7 psi and 0.9 psi at five different joint positions to determine at which position the capsule had the fewest wrinkles and folds. The joint positions that were tested were 60 degrees of abduction and 0, 5, and 10 degrees of internal and external rotation. Four cameras were clamped to the robot and captured the movement of the markers, and the coordinates of the strain markers at each of these positions were recorded

using a motion capture software, DMAS7 (Spicatek, HI). The joint position that had the least average marker movement between 0.7 and

Figure 2: Strain distributions after 1, 2, and 3 severe anterior shoulder dislocations shown on a right shoulder. The posterior side of the capsule is on the right, and the anterior side of the capsule is on the left.

0.9 psi was the joint position used for all following dislocations. The marker position of the intact joint at 0.9 psi was used as the reference position for calculating non-recoverable strain.

Data Acquisition: The specimen underwent 1, 2, 3, 4, 5, and 10 dislocations performed by the FRS2010. After each of these dislocations, the capsule was given 30 minutes of recovery time to account for the viscoelasticity of the tissue and was then inflated to 0.9 psi. The marker position at 0.9 psi was recorded by the four cameras and served as the strained state after each dislocation. Non-recoverable strain was defined as the maximum principal strain calculated from the marker configurations of the reference state and of the strained state.

Data Analysis: The marker coordinates from each of these states were used in ABAQUS (ABAQUS/CAE Student Version 6.4; Simulia, Providence RI) to generate strain maps. The 7x11 grid of markers produces a 6x10 grid of 60 elements. The capsule was split into six sub-regions, for each of which the average magnitude of maximum principal strain were calculated. The six regions were the glenoid side of the anterior band, the humeral side of the anterior band, the glenoid side of the axillary pouch, the humeral side of the axillary pouch, the glenoid side of the posterior band, and the humeral side of the posterior band.

RESULTS

Preliminary testing was performed on 4 specimens. The joint capsules of two of the four specimens tore following the third dislocation, making collection of data for dislocations 4-10 not possible for those two trials. 10 dislocations were successfully performed on the other two specimens. Non-recoverable strain was calculated at the centroid of each element, and the average non-recoverable strain of each sub-region of the capsule was recorded. Strain maps were generated for each dislocation to show non-recoverable strain distribution (**Figure 2**). Repeatability between specimens was calculated using one-way ANOVA to be 45.8%. A large increase in non-recoverable strain was observed in one specimen from the second to third dislocation on the posterior side of the capsule. The non-recoverable strain increased from 4.3% and 4.1% to 22.5% and 21.9% on the glenoid and humeral side of the posterior band, respectively.

DISCUSSION

This study was motivated by a need to quantify non-recoverable strain in the glenohumeral capsule following multiple severe anterior shoulder dislocations. Preliminary testing has proven that performing ten severe anterior shoulder dislocations without tearing the joint capsule is possible. The large increase in non-recoverable strain in one specimen suggests a possible error made when collecting data, such as a camera being moved after calibration. Any slight movement of the cameras after calibration greatly affected recording of the marker coordinates and created inaccurate strain readings when the data was processed in ABAQUS. The repeatability was calculated to be 45.8% and indicates unreliability in the data collected. Preliminary testing will continue with a focus on camera stability to ensure accurate data collection. More specimens will be tested on to determine the magnitude and location of non-recoverable strain in the glenohumeral capsule following multiple severe anterior shoulder dislocations.

3D STRAIN COMPONENTS AND THEIR VISCOELASTIC BEHAVIOR FOR KNEE MENISCUS TISSUE IN CIRCUMFERENTIAL TENSION UNDER STRESS RELAXATION AND CREEP

INTRODUCTION

The knee meniscus supports 3D loads in vivo and exhibits time-dependent (viscoelastic) material properties. The circumferential (x) direction is loaded in tension. This tensile hoop stress serves to restrain tibial translation. The radial (y) direction is loaded in a mix of moderate tension and compression, and the axial (z) direction is loaded in compression. The meniscus is also fluid-saturated. Accordingly, in joint-scale FEA simulations, the meniscus is typically modeled as a transversely isotropic, poroelastic material [1]. Compression in the z-axis is well-studied. However, key aspects of the meniscus' tensile properties remain unknown. In tensile tests, meniscus strain has only been measured in the plane of the specimen, not in 3D. The z-strain and hence volume change are not known. Volume change is a fundamental aspect of a poroelastic material's behavior because it sets the amount of fluid flux. Furthermore, although tensile viscoelasticity has been investigated using stress relaxation tests and attributed to poroelasticity [2], tests of the other tensile viscoelastic limiting case—creep—have not been performed, and it is unknown if results obtained from tensile stress relaxation generalize to tensile creep. In addition, the recoverability of tensile viscoelastic changes is not known, and is needed to distinguish normal mechanical function from damage. This study was designed to provide this missing fundamental data by testing the meniscus in circumferential tension, with test segments of both stress relaxation and creep and with continuous measurement of 3D strain in x, y, and z. Specifically, we sought to answer the following questions: (a) Does the meniscus' volume change under tension? (b) Is the 3D strain consistent with transversely isotropic material symmetry? (c) Do stress relaxation and creep differ in their effects on y-strain, z-strain, and volume? (d) Are volume changes during a loaded hold faster than during unloaded recovery?

METHODS

Tensile test specimens ($n = 3$) were cut from fresh-frozen adult bovine meniscus in the circumferential–radial plane. Cross-sectional area was measured using a laser interferometer. Specimens were cut in the expanded tab shape [3]. Midsubstance width (y, radial) = 8 mm and thickness (z, axial) = 2 mm. Specimens were mounted on an Instron 5943 with a grip-to-grip length (x) of 16 mm for circumferential uniaxial tensile testing, matching the direction of physiologic tension.

The test protocol consisted of preload to 20 kPa, preconditioning, stress relaxation at $\lambda_x = 1.08$ for 10 minutes, unloaded recovery for 30 minutes, creep for 10 minutes at the σ_{xx} value reached by a ramp to $\lambda_x = 1.07$, unloaded recovery for 30 minutes, and a repeat stress relaxation. The repeat stress relaxation verified that the specimen's properties did not change during the test. Preconditioning consisted of 30 minutes unloaded swelling followed by an identical stress relaxation at $\lambda_x = 1.08$. All ramps were done at 0.1 mm/s. Throughout the entire test, the x–y face of the specimen was videoed using a Basler a102f CCD camera (1392×1000 px, 1 fps) and the y–z side of the specimen was videoed using a Canon T7i (6016×4010 px, 1/30 fps). Tests were done in PBS.

λ_x was measured using grip-to-grip displacement. (There was no significant grip slip.) λ_y was measured using Vic-2D (Correlated Solutions, Inc.) to track the edge-to-edge width of the specimen in the CCD images at the midpoint between the two grips. λ_z was measured by manually tracing the specimen edges in each DSLR photo and calculating the median edge-to-edge thickness. Strain was referenced to the last value in the unloaded hold segment immediately prior to stress relaxation/creep. Volumetric strain was measured as $J = \lambda_x \cdot \lambda_y \cdot \lambda_z$.

Statistical analysis was performed using the initial and final strain values of each strain ratio in each loaded hold (stress relaxation, creep) and each unloaded recovery (Figure 1). The rapidity of change for each strain component was quantified as $t_{\Delta 63\%}$, the time to change by 63% of

final – initial. (The time dependency was often not exponential, so exponential decay fits were not used.) Null hypothesis significance tests were done using repeated measures ANOVAs for objectives a, b, and d and paired t-tests for objective c. Significance was set as $p < 0.05$ and trends as $p < 0.10$. In figures, * $\neq 1$, $p < 0.05$; • $\neq 1$, $p < 0.1$; — $p < 0.05$ between groups; - - $p < 0.1$ between groups.

RESULTS

In both stress relaxation and creep, volume increased during the ramp loading segment to $J = 1.02 \pm 0.01$ ($J \neq 1$, $p < 0.05$), then decreased significantly by a greater amount during the loaded hold segment, such that final $J = 0.98 \pm 0.02$ ($\Delta J \neq 0$, $p < 0.05$; final $J \neq 1$, $p = 0.06$) (Figs 1 and 2). Volume decrease during the hold was mediated by both λ_y and λ_z , which were ≤ 1 throughout, and exhibited further contraction during the loaded hold. This further contraction was sufficient to overcome the initial volumetric expansion caused by the applied x-extension and, by the end of the loaded hold, to produce overall volumetric contraction.

During unloaded recovery following stress relaxation and creep, volume increased significantly to a final $J = 1.007 \pm 0.006$ ($J \neq 1$, $p < 0.05$), indicating a final volume slightly greater than when the ramp to the loaded hold began (Fig 3). λ_y and λ_z also increased during recovery to final $\lambda_y = 1.004 \pm 0.004$ ($\lambda_y \neq 1$, $p < 0.05$) and final $\lambda_z = 1.003 \pm 0.003$ ($\lambda_z \neq 1$, $p < 0.10$).

Asymmetry was observed between the y and z axes. The final λ_z value in the loaded hold for both stress relaxation and creep was significantly less than the final λ_y value (Fig 2). During unloaded recovery after stress relaxation and creep, λ_z increased significantly more than λ_y ($p < 0.05$), such that both had a final value ≈ 1.0035 at the end of recovery. The kinetics of λ_y and λ_z also differed. As quantified by $t_{\Delta 63\%}$, λ_y tended to change faster than λ_z during the loaded hold ($p < 0.10$) and slower during the unloaded recovery ($p < 0.05$) (Fig 4).

Stress relaxation and creep overall produced similar changes in J , λ_y , and λ_z , with only two slight differences. In the loaded holds, J tended to be slightly smaller (more contracted) at the end of stress relaxation than at the end of creep ($p < 0.10$, paired t-test) (Fig 2). In unloaded recovery, $t_{\Delta 63\%}$ for λ_y was slightly shorter for stress relaxation than for creep ($p < 0.05$, paired t-test) (Fig 4).

Kinetics for J and λ_y differed greatly between loaded hold and unloaded recovery (Fig 4), with a much shorter $t_{\Delta 63\%}$ (faster change) during the loaded hold ($p < 0.05$). λ_z displayed a similar pattern, but the difference in $t_{\Delta 63\%}$ between loaded hold and unloaded recovery was small and not statistically significant.

DISCUSSION

Measured volume was found to significantly increase during the circumferential tensile ramps and decrease during the loaded holds, which is a new finding. This implies that the meniscus takes up fluid during rapid circumferential extension and loses fluid under static loading. Cycling of synovial fluid may benefit the meniscus by increasing exchange of metabolic or signaling factors. Fluid exudation from the meniscus during static loading may also serve, in the knee joint, to pressurize fluid in the cartilage–meniscus contact and force fluid into the cartilage.

Concerning symmetry, λ_y and λ_z were not equal, suggesting that the meniscus may not be transversely isotropic. Since the meniscus functions under 3D constraints in vivo, even slight asymmetry may meaningfully alter its internal stresses and limits of safe function.

Stress relaxation and creep produced similar changes in strain at similar rates, indicating that it is plausible to treat both as the consequence of the same viscoelastic mechanism. Strain and volume recovered much slower during unloaded recovery than they changed during stress relaxation/creep, taking almost 10 minutes to recover by 63%. This recovery is too slow to be useful in vivo for restoration of volume and fluid content; load-induced fluid pumping mechanisms are likely to be more relevant physiologically.

The observations made here of (a) a switch between volumetric dilation to contraction, (b) y/z asymmetry, (c) similarity between stress

relaxation and creep, and (d) slow unloaded recovery compared to relaxation/creep are all new findings and fill a fundamental gap pertaining to meniscus tensile mechanics and poroelasticity. This data provides a foundation for future work to understand meniscus function in native 3D joint loading.

INTRAMUSCULAR PRESSURE AND SHEAR MODULUS OF LOWER-LEG MUSCLES ARE CORRELATED

INTRODUCTION

Intramuscular pressure (IMP) is the hydrostatic regional stress in a muscle [1]. IMP is linearly correlated to muscle force during isometric, concentric and eccentric muscle contractions, as well as dynamic exercises such as running and walking [2]. Therefore, IMP is a good estimator of individual muscle force. Shear wave elastography (SWE) is an ultrasound-based imaging technique developed to non-invasively provide information about the shear modulus of soft tissues [3]. The shear modulus of the muscles is linearly correlated to force during isometric contraction [4] over the full range of 0–100% of maximum voluntary contraction. This similarity between IMP and shear modulus strongly suggest that these parameters are related. The objective of this study was to quantify the dependency of shear modulus within the lower-leg muscles on IMP in healthy individuals. This dependency is important to improve interpretation of ultrasound elastograms and to potentially use it as a biomarker for more accurate diagnosis of pathologies related to increased IMP.

METHODS

Nineteen healthy participants (eight males and eleven females; Mean age \pm SD, 23.84 \pm 6.64; Mean BMI \pm SD, 23.00 \pm 2.89) were recruited in this study. An initial SWE measurement was performed within the lower leg muscles (Tibialis Anterior, TA; Peroneus Longus, PL). The IMP of TA and PL was then increased using a blood pressure cuff placed around the thigh and inflated to 40, 80 and 120 mmHg (Figure 1 (a)). Elastography measurements were taken at each cuff pressure level (40, 80 or 120 mmHg). Additionally, one of the legs was elevated using a leg holder and the knee and hip joints were flexed to 90° and SWE was performed (Figure 1(b)). To directly measure the IMP corresponding to each cuff pressure level, an intramuscular pressure system was used (Figure 1(c)). For the statistical analysis, a linear mixed effects model was used, with the cuff pressure condition, muscle type and gender as fixed variables, while the shear modulus was used as the dependent

variable. The spearman's rank correlation coefficient was applied to analyze the correlation between the TA muscle shear modulus and IMP.

RESULTS

The change in shear modulus relative to the shear modulus at zero pressure (median and interquartile range) at elevated leg, 40 mmHg, 80 mmHg and 120 mmHg cuff pressure was -2.35 (4.08) kPa, 1.22 (2.09) kPa, 3.02 (4.94) kPa and 5.10 (5.02) kPa, respectively, for the TA muscle; and -1.06 (1.15) kPa, 1.12 (1.64) kPa, 3.02 (3.74) kPa and 3.22 (4.96) kPa for the PL muscle. From the linear mixed effects model, it was observed that muscle and cuff pressure had a significant effect on muscle shear modulus ($P < 0.01$ and $P < 0.01$, respectively), while gender did not. Figure 2 and 3 show representative shear modulus maps of the TA and PL muscles at each cuff pressure level. Additionally, the shear modulus for both the TA and PL muscles were found to increase as a function of IMP (Figure 4 and 5). Specifically, there were significant positive correlations found between the median shear modulus and IMP for the TA muscle ($\rho = 0.99$, $p < 0.01$), and

Figure 1: Setup for: (a) elastography while the TA muscle was pressurized, (b) elastography while leg was elevated and (c) IMP measurement.

the PL muscle ($\rho = 0.99$, $p < 0.01$).

Figure 2: The shear modulus maps of the TA muscle at each cuff pressure level: (a) 0 (b) 40 mmHg (c) 80 mmHg and (d) 120 mmHg.

Figure 3: The shear modulus maps of the PL muscle at each cuff pressure level: (a) 0 (b) 40 mmHg (c) 80 mmHg and (d) 120 mmHg.

DISCUSSION

The results from this study suggest that there is a linear correlation between shear modulus and IMP. This correlation is significant because IMP is an important parameter for evaluating function of muscle as well as some pathological conditions. IMP changes linearly during concentric and eccentric contraction. Therefore, IMP has been used to predict force during these type of muscle actions. The linear correlation shown here suggests that shear modulus can also be used to predict individual muscle force in the same way as IMP. So far, muscle shear modulus has been shown to correlate to force in isometric contraction only. However, the relationship to IMP suggests that shear modulus can potentially be used to measure individual muscle force during concentric and eccentric muscle contractions as well. Our results may also have several potential clinical applications. Shear modulus may also help clinicians diagnose or monitor the recovery process of compartment syndrome disease. Methods to measure IMP, such as needle manometry, suffer from significant variability depending on the depth of needle insertion, amount of fluid introduced, and soft tissue occlusion of the needle. The blood pressure cuff inflation around the thigh may also be used to simulate compartment syndrome with reversible neuromuscular dysfunction. Therefore, the results of this study may be beneficial for practitioners to consider the contribution of shear modulus changes on the diagnosis of compartment syndrome using ultrasound SWE.

The contact pressure between the transducer and the skin has been shown to affect the shear modulus of muscles. Kot et al. [5] evaluated the shear modulus of the rectus femoris muscle when different transducer pressures were applied to the muscle, reporting an increase in shear modulus from 13.33 kPa to 18.88 kPa when transducer's pressure increased from light to high. These results are in line with our observations. The pressure applied with the transducer may change the IMP and consequently the shear modulus measured.

Leg position is also an important factor affecting the shear modulus of lower leg muscles. Dubois et al. [6] quantified the shear modulus of the anterior and posterior lower limb muscles at rest and during passive stretching postures using a protocol that involved different body positions. They reported that shear modulus was significantly higher when muscle was stretched compared to rest posture. Results of our study showed that the elevated leg decreased shear modulus of the TA and PL muscles' due to the reduction in IMP. These observations can help giving a proper interpretation to changes in shear modulus in evaluation of protocols that use limb or body positions with changes in elevation.

Several studies evaluated effect of interstitial pressure on the shear modulus of soft tissues. Millonig et al. [7] studied the relationship between intravenous hydrostatic pressure and liver shear modulus in the isolated pig liver, reporting that the stepwise increase of intravenous pressure to 3.5 kPa linearly and reversibly increased liver shear modulus to the upper detection limit of 75 kPa. Nguyen et al. [8] evaluated the influence of the intraocular pressure on the elasticity of cornea in an ex vivo porcine model, reporting an increase in shear modulus of cornea with an increase in intraocular pressure. Gennisson et al. [9] measured elasticity of renal compartments at the baseline and urinary pressure levels from 5 to 40 mmHg in in-vivo pig kidney, reporting that the increase in shear modulus of renal compartments is linearly correlated to the increased urinary pressure. In this study, we revealed a similar relationship between IMP and shear modulus of lower-leg muscles using SWE. The limitation of this study was that the majority of the subjects recruited were under age 30. Consequently, it is unknown if the observed relationship is affected by age. In conclusion, this preliminary study suggest that changes in shear modulus could serve as a surrogate non-invasive measurement of IMP levels.

Figure 4: The shear modulus of TA increased as function of IMP (median, interquartile range) ($p < 0.01$).

Figure 5: The shear modulus of PL increased as function of IMP (median, interquartile range) ($p < 0.01$).

INTRODUCTION

Up to 20-30% of women over the age of 20 may suffer from pelvic floor disorders and up to 50% of women over the age of 50.¹ Furthermore, injuries as a result of childbirth can lead to varying types of incontinence, pelvic organ prolapse (POP), and avulsions^{2,3}. A strong association has been found between parity (the number of times a woman has carried pregnancies to a viable gestational age) and developing pelvic organ prolapse (POP).⁴ Given the strong evidence for injury during childbirth leading to later prolapse and recent developments in biomechanical understanding of the female pelvic floor, better understanding of the mechanical properties of the muscles are required to improve risk assessment for child birth induced injury. As pelvic floor muscle is an anisotropic material, mechanical characterisation requires multi-axial testing. Pelvic floor sample sizes are small (<20mm) and expected forces are low (<15N).

Many commercially available machines can be large and expensive, designed to apply relatively high loads to structural materials. The aim of this project is to develop a displacement-controlled multi-axial stretching device for characterising mechanical properties of female pelvic floor tissue.

METHODS

A low cost, desktop radial stretching device was developed, based on an open source design by Schausberger et al⁵, with adaptations to make it suitable for soft tissue testing. Specific adaptations include modifying grips for smaller soft-tissue samples, digital image correlation (DIC), and an environmental chamber for biological tissue testing. Samples can be clamped onto 18 arms to create a radial stretch during testing (Figures 1 & 2).

Figure 1 – Radial Stretch Tester

Figure 2 – Radial Stretch Tester Assembly

The radial stretch tester has been fitted with a 20N load cell (FSJ03829, Futek Inc., USA) to obtain load data and modified to incorporate smaller samples sizes and DIC to obtain strain data (Figure 3). Initial tests have been carried out using a sample of VersaflexTM CL2000X (Polyone Corporation). A displacement rate of 12mm/min was used for all tests. Uniaxial tests were carried out on a Lloyds instruments (Company info?) uniaxial tester with a 50 N load cell and repeated in the radial stretch tester in both uniaxial and radial mode. Grip-to-grip displacement was used to calculate strain in the Lloyd test while DIC was carried out to record strain for the radial stretch tests and Labview (National Instruments Corp., UK) was used to analyse data from the load cell. Further tests have been carried out comparing clamping systems using a sample of ChronopreneTM 40A (Dunn Industries, Manchester). Uniaxial tests repeated in the radial stretch tester using hooked clamps and Velcro clamps.

Figure 3 – Radial Stretch Tester with DIC

(Figure 4a,b). The radial stretch test with DIC was repeated in radial mode using the hook clamps (Figure 4c).

Figure 4 - uniaxial with hooks (a) uniaxial with velcro clamps(b),and (c) radial with hooks (all with speckle for DIC)

RESULTS

True stress results from the uniaxial tests in the rig were slightly higher than in the Lloyd test (Figure 5) due to friction in the rig which is being rectified. The true stress increased significantly for the radial sample compared with uniaxial testing as expected (Figure 5).

Figure 5 –True stress vs engineering strain data for three tests of Versaflex™ CL2000X

Similar results were found using the radial stretch tester in a uniaxial format for both the hooks and velcro clamps and the Lloyd test (Figure 6). However, the sample began to tear at the hooks before a strain of 0.4 in the uniaxial test and just after a strain of 0.3 in the radial test.

Figure 6 –True stress vs engineering strain data for three tests of Chronoprene™ 40A

DISCUSSION

Results verify basic functionality of the radial stretcher in both uniaxial and radial modes. Initial tests with soft tissue are now being carried out, incorporating adjustments in the form of a temperature controlled bath to incorporate an environmental chamber (Figure 7). Ovine pelvic floor tissue samples will be used as it is readily available and has many similar anatomical and ultrastructural anatomies to the human pelvic floor.⁶

Figure 7 – Environmental chamber for sample

Due to tearing at the hooks, peak strains are below reported maximum strains of 70–100% from analogous multiaxial tests in the literature^{7,8} and clamps are being redesigned to achieve higher stretch ratios before tearing. Additionally, alternatives to a load cell on each of the arms are being investigated to reduce costs of obtaining load data in multiple directions for anisotropic samples. Standard tension-to-failure and stress relaxation testing of pelvic floor tissue will be carried out following satisfactory performance in all verification tests.

BODY POSITION EFFECTS ON THIGH SOFT TISSUE PROPERTIES

Justin Scott, Sheng Chen, Sara Roccabianca PhD, and Tamara Reid Bush PhD

Mechanical Engineering, Michigan State University, East Lansing, MI, USA

INTRODUCTION

Seating interface design has significant impacts on the everyday lives of people, particularly those in wheelchairs. This is due to the fact that well designed interfaces distribute pressures, reducing pressure concentrations. For populations who spend the majority of their time in a seated position, such as wheelchair users or the elderly, the ability of seating interface to distribute pressure well can reduce the likelihood of tissue damage due to prolonged sitting [1]. The ability of seating interfaces to distribute pressure is often evaluated by finite element models. These models rely on accurate tissue properties to obtain realistic outcomes. Yet there is limited data on human soft tissue available for use in these models.

Current finite element models of human buttocks and thigh regions use material properties determined from animal tests of soft tissue and limited data from human tissue [2,3]. Current data is limited in that the material properties obtained from human thigh have been determined from studies where the participants were in a supine or prone position, not the seated position that is being modeled [4]. Second, these data sets come from only two points of deflection. There is a dearth of information on the mechanical properties of the human thigh while in the seated position as well as a need for data at multiple points of deflection. Models that simulate people sitting need representative properties of the thigh soft tissue while seated, through the full range of deflection to accurately represent body responses. *Thus, the goal of this study was to determine if differences occurred in the thigh material properties with changes in body posture.* The seated, quadruped, and prone postures were evaluated.

METHODS

Ten males and ten females volunteered for our study with Institutional Review Board approvals. A custom indenting tool with an

embedded load cell was used to obtain force and deflection measurements on three regions of the thigh. To obtain deflection measures, a linear potentiometer was attached to the indenter to track its location.

All participants wore snug fitting, stretchy athletic attire for all test positions. For the seated position, a section of the chair with a opening more than 3 times the size of the indenter head was removed to permit access of the indenter without inducing tissue tensions in the region (Figure 1). The indenting tool was held perpendicular to each test location. The thigh was indented using a constant load rate until a physiological barrier (ie. the femur) was felt, at which point the load was removed. This indentation process was followed for the proximal, middle, and distal thigh regions.

Figure 1. Indentation test set up in the seated (left), quadruped (middle), and prone (right) positions.

After a five minute period to permit tissue recovery, the participants moved to the quadruped position (Figure 1). In that position, the chest and legs were supported with the hips and knees flexed at 90°. The same three thigh regions were tested as in the seated position. After five minutes, the participants laid in the prone position with their hips and knees extended at 180° (Figure 1). The same

indentation process was followed in the prone position as for the other two.

Force and deflection data were converted into stress and stretch data which were then used to optimize the parameters of an Ogden based material model [5]. Stress data were obtained by dividing the indentation force by the cross sectional area of the indenting surface (25 cm²). Deflection was converted into stretch using a relationship between the thigh circumference and tissue thickness between the femur and posterior surface of the thigh. The strain energy density of the Ogden model is described by equation 1.

$$W(\lambda) = \frac{\mu}{\alpha}(\lambda_1^\alpha + \lambda_2^\alpha + \lambda_3^\alpha - 3) \quad (1)$$

In this equation, λ_1 , λ_2 , and λ_3 are the stretches in the principal directions. μ is a stiffness parameter with units of Pascals, and α is a unit-less nonlinearity parameter. Two conditions placed on this model were that of transverse isotropy and incompressibility, meaning that stress in the loaded direction is described by equation 2.

$$\sigma = \mu(\lambda^\alpha - \lambda^{-\frac{\alpha}{2}}) \quad (2)$$

In this equation λ is the stretch in the loaded direction. Stress and stretch data from each of the three thigh regions was used to determine μ and α parameter values so that comparisons could be made.

RESULTS

Average μ and α parameter values for each region and body position were reported for each sex (Tables 1 and 2). In all regions, for both males and females, the μ parameter values for the prone position were significantly smaller than the values in the seated and quadruped positions. The α values in the prone position, for both males and females, were significantly higher than those in the seated and quadruped positions. Higher stresses were consistently needed in the prone position to produce the same amount of stretch as the seated and quadruped positions (Figure 2).

Figure 2. Predicted stress and stretch values for the average middle thigh region in males and females.

Quadruped	5.72	4.72	3.84	5.53	3.61	3.26
Prone	10.2	11.11	13.38	9.71	11.17	13.26

DISCUSSION

The motivation for this work was to determine if body posture had any effect of the material properties of thigh tissue. To this end, force and deflection data were collected from the proximal, middle, and distal regions of the thigh while in the seated, quadruped, and prone postures. Parameters of an Ogden material model were then optimized to fit the soft tissue in the each region of the thigh while participants were in these three postures. The results of the model fitting indicated that all three thigh regions were stiffer in the prone position as compared to the seated and quadruped positions. *Thus, the body position does affect the material stiffness, indicating that the soft tissue in the thighs of finite element models used to simulate sitting should be represented by material properties obtained from thighs in the seated position.* The thighs and buttocks experience large external pressures while seated, making them sites of tissue damage. Accurately representing the tissues will change the internal stresses predicted in models to better predict the likelihood of tissue damage.

Material properties were also obtained for the thigh while in the quadruped position because the lower body joint articulations in that position were similar to those of the seated position. As such, the quadruped position produced parameters that were similar to the seated position. The adaptation of a quadruped position for the determination of material properties of the thigh will allow the collection of data to expand to those who use wheelchairs. While our results indicating body position matters when determining soft tissue properties can inform cushion design for able bodied individuals, another concern is the health of wheelchair users. Tissue damage is a costly issue, and cushions designed to prevent damage are a common solution. Expanding this work to obtain material properties that represent wheelchair users can inform that design process as well.

INTRODUCTION

Rotator cuff tears are common, affecting more than 50% of patients over the age of 65 and resulting in pain and loss of shoulder function [1]. Rotator cuff surgical repair is one of the most common shoulder procedures performed clinically. Unfortunately, healing after rotator cuff repair is a well-known clinical challenge, with reported failure rates as high as 94% [2]. In the current standard double-row suture bridge repair, the suture punctures through bone and tendon at only two anchor points, thus leading to high concentrated forces being transferred from tendon to bone, in shear at these two points (Fig. 1B) [3]. In the current study, we propose a new approach for tendon-to-bone repair inspired by the remarkable grasping ability of python teeth on their prey. Unlike shark teeth, which are triangular and function to cut their prey, python teeth have a curvature that grasps prey, prevents escape, and enables ingestion of entire, intact animals. To test the hypothesis that tooth shape drives the balance between cutting and grasping, finite element models and experiments were performed to quantify the interaction between tendon and seven different tooth designs, ranging from shark-like to python-like (Fig. 1A).

METHODS

Finite Element Model (FEM): 2D and 3D models of a frictionless tooth in a homogeneous tendon were studied using Abaqus (Dassault Systems). Images and microCT scans were used to determine the radii of python moluris teeth. 7 different tooth geometries were examined in 2D, as defined by

the dimensionless ratio w'/w , which ranged from 0.5 to 3.5 (Fig. 1A). A hard contact interaction was applied in the normal direction between the tooth and the tissue surfaces. Load was applied as a displacement of the tendon boundaries; periodic boundary conditions were applied to model an infinite row of teeth. The mesh was refined at the (rounded) tip of the tooth until convergence was reached. The maximum principal stress

concentration, the contact area beneath the tooth (Fig. 2A), and the average tissue/gum contact pressure were estimated.

Experimental Model: A modified single lap shear test was developed to test the grasping capacity of a tooth in bovine deep digital flexor tendon (3.9" x 2.4" x 0.125", N = 14). Each fixture contained one 3D printed tooth (EDEN 260VS, Stratasys LTD) made with VeroWhitePlus™, a rigid and durable material with a modulus of elasticity of 2500 MPa. Each 3D printed tooth shape (N = 6) was inserted into the precut tendon block so that the entire tooth was fully within the tendon. A uniaxial tension test was then performed at 0.05 mm/sec for up to 10 mm of displacement (TA instruments, ElectroForce). From the force elongation curves, peak force for 5 mm elongation, stiffness, and energy to yield were determined. Tooth engagement with the tendon was determined by visual inspection and verified through video captured during testing. Groups were compared using ANOVA with a threshold for statistical significance defined at $p < 0.05$.

RESULTS

FEM results showed that the contact area between the tooth and the tendon increased with increasing w'/w , consistent with the hypothesis that python-shaped teeth are designed for grasping (Fig. 2B). The maximum principal stress concentration remained constant for tooth shapes of $w'/w = 1, 1.5, 2$, and 2.5 and decreased for $w'/w = 3$ and 3.5 . There was a significant increase in maximum force with increasing w'/w (Fig. 3B, * $p < 0.05$, when compared to $w'/w = 0.5$). There was a dramatic decrease in the number of teeth that completely disengaged from the tendon with increasing w'/w (Fig. 3C). There was no significant difference between groups for stiffness and energy to yield.

Figure 2. (A) Representative FEM result of the interaction between a python tooth and tendon showing stress (color map), contact area (white line) and average stress in the downward direction (orange lines). (B) Normalized contact area graph for tooth geometries of $w'/w = 1-3.5$.

DISCUSSION

FEM and experimental results revealed a strong non-linear relationship between tooth curvature and tendon grasping, implying an optimal tooth shape for the design of a tooth array device for tendon-to-bone repair. An optimal tooth shape maximizes contact area without increasing the maximum principal stress concentration. From the modelling results, a shape with $w'/w = 2.5$ was optimal, as contact area did not increase with further increases in curvature. This shape was supported by experimental results, where the maximum force through 5 mm of displacement increased through $w'/w = 2.5$. In addition, as evidenced by the force-displacement curves and the visual determination of tooth engagement, the tooth completely disengaged from the tendon at low values of w'/w . Ultimately, the device for enhanced tendon-to-bone repair will include an array of teeth, as shown in Fig. 1C. The particular arrangement of these teeth will require optimization as well to effectively solve the tissue-level shear lag problem inherent to tendon-to-bone repair. To successfully translate this theoretical and experimental work into a clinically relevant device for tendon to bone repair, future studies will test an array of teeth in a cadaver rotator cuff repair model.

Figure 3. (A) Representative force-displacement curves for two tooth geometries ($w'/w = 0.5$ and 2.5). (B) Peak force for up to 5 mm of tendon elongation (* $p < 0.05$, when compared to $w'/w = 0.5$). (C) Percentage of teeth engaging vs. disengaging from tendon.

SIGNIFICANCE

The bioinspired tendon fixation system designed, analyzed, and tested here may have a significant effect on healing and functional recovery following rotator cuff repair, and holds potential the high post-surgery rupture rates.

OPTIMIZING NON-LINEAR MECHANICAL BEHAVIOR OF SOFT TISSUES IN FINITE ELEMENT MODEL OF HUMAN THIGH

Eli Broemer (1), Sheng Chen (1), Justin Scott (1), Tamara R. Bush (1), Sara Roccabianca (1)

(1) Mechanical Engineering
Michigan State University
East Lansing, MI, USA

INTRODUCTION

Pressure ulcers (PUs) are a soft tissue injury caused by sustained pressure and/or shear near a bony prominence, more commonly in the thigh and buttocks area [1]. The injury most commonly develops in those with reduced mobility such as hospitalized patients and wheelchair users. Formation of PUs can lead to pain, infection, and even death. A recent 10-year study found that PUs are prevalent in 9% to 13% of patients in health care facilities in the United States [2].

The clinical setting is also lacking effective prediction methods for PUs [1]. Specifically, an interpretive scoring evaluation is the widely recommended tool for assessing PU risk. And there is not strong evidence showing that scoring tools are more effective at reducing the risk of PUs when compared to a medical practitioner's judgement alone.

Finite element methods estimating pressure distributions in soft tissues surrounding bony prominences may be used as a novel PU prevention tool for patients in the future. Such models have been previously developed in literature ranging from 2D linear models with 34 nodes [3] to detailed 3D non-linear models with over 250,000 nodes [4]. These commonly focus on the thigh and buttock region, so that the material properties of the bulk soft tissue in the area may be estimated.

A significant limitation to most of these thigh-buttock studies is lack of validation and error estimation, or the use of only two data points to validate highly non-linear material models (i.e. an unloaded and a body weight-bearing configuration) [4, 5].

This preliminary study aims to find the best fitting material parameters using a finite element model of a thigh whose geometry is generated from subject-specific MRI scans. The innovation is that the material parameters are estimated by comparing the model prediction with *in vivo* indentation tests at multiple load configurations. The goal of the model is to study the material behavior of soft tissues in seated

individuals. Further research may investigate the material behavior as it relates to the prevention of PUs in wheelchair users.

METHODS

Experimental Setup. A single subject (Male, 185 lbs., 73 in.) participated for the purposes of this pilot study.

Force-deflection measurements were collected by indentation tests performed on the subject's thigh. Since it is difficult to collect indentation data from the posterior thigh of a seated individual, a quadruped posture was adopted for this procedure. The quadruped position has the same hip and knee flexion as the sitting position with the advantage of access to the thigh for indentation tests.

To setup the quadruped posture, the subject kneeled on both legs behind a small panel placed to constrain the forward movement of the thigh. The panel height was short of the subject's anterior superior iliac spine allowing them to lean forward, and a table in front of the panel supported their chest and head. The table was adjusted such that the subject's knee and hip angles were ~ 90° to mimic the seated position.

Indentation tests gave force-deflection measurements of the thigh via a six-axis load cell and a linear potentiometer respectively. The deformation was applied manually at a constant rate, and the system was calibrated to have zero force and deflection when the indenter was flush with the undeformed thigh [6]. Three locations on the posterior thigh were tested (i.e., proximal, middle, and distal), and between 60 N and 100 N of force was applied before the indenter was removed.

Geometry Generation. MRI scans of the subject in a supine position provided cross-sectional data for the thigh geometry. The images were segmented with Photoshop CS6 (Adobe – 2012) in order to obtain cross-sections of the bone, muscle, and fat. **Figure 1** shows 3D geometry for the three tissues, which was generated by interpolating the cross-sections in NX 12.0 (Siemens – 2017).

Figure 1: Geometry of subject's left thigh. Leftmost plane is just after buttocks and rightmost plane is just before the kneecap.

Finite Element Model. The model was meshed in HyperMesh (Altair – 2017) with second order tetrahedral elements. The mesh had 58,848 elements and 85,272 nodes. The model was setup and solved with the FEBio suite [7].

A previous study by our research group showed that the first order Ogden material model can accurately represent the non-linear mechanical behavior of these soft tissues *in vivo*. **Equation 1** shows the first order strain energy function for an Ogden material, where λ_i are the principle stretches, μ is a parameter with units of Pascals, and α is a unit-less parameter. Initial material parameters for the muscle and fat were taken from literature [4]. Soft tissues were assumed nearly incompressible (i.e., $\nu = 0.485$) [5]. The femur was assumed to be a rigid body.

$$W(\lambda_1, \lambda_2, \lambda_3) = \frac{\mu}{\alpha} (\lambda_1^\alpha + \lambda_2^\alpha + \lambda_3^\alpha - 3) \quad (1)$$

Four boundary conditions constrained the model solution: 1) the femur was fixed in all directions and rotations; 2) a no-slip constraint on all material contact surfaces; 3) the left and right planes in **Figure 1** were fixed in their normal axis; 4) nodes with forces applied, at the three testing locations, had their movement constrained to the anterior - posterior axis (i.e. the direction of the force). Three load conditions were applied to model the mechanical test performed *in vivo*.

Optimization. The goal of the optimization protocol was to minimize the difference between the model force-deflection curves and the experimental data for each of the three test locations. A simplex search function (i.e., `fminsearch`) in MATLAB (MathWorks – 2018) minimized the objective function by adjusting material parameters μ and α and then re-solving the model in FEBio at each iteration.

Equation 2 shows the objective function where $NRMSD_{prx}$, $NRMSD_{mid}$, and $NRMSD_{dis}$ are the normalized root mean square deviations estimated for each of the three test locations.

$$e = NRMSD_{prx} + NRMSD_{mid} + NRMSD_{dis} \quad (2)$$

RESULTS

Optimized material parameters were estimated by fitting the model to the *in vivo* experimental data (**Table 1**). The values of the material parameters are in reasonable agreement with recent studies investigating the same tissue behavior [4]. The first order Ogden model fit the experimental data well. Error, measured as the normalized root mean square deviations between the model and *in vivo* data, was 5.47%, 1.48%, and 9.96% for proximal, middle, and distal locations respectively (**Figure 2**).

DISCUSSION

This pilot study investigates the mechanical properties of fat and muscle tissues in the human thigh. An anatomically detailed FE model was used to determine optimized material parameters. This model represents the first attempt to inform a finite element thigh model by precise tissue geometry and non-linear *in vivo* experimental data.

Figure 2: Simulated material behavior (continuous lines) fitted to non-linear *in vivo* indenter data (markers) for proximal, middle, and distal locations on the thigh.

Bulk material properties found in this study are limited to the thigh in a quadruped position. Model error was smallest in the middle thigh. Larger error at proximal and distal thigh locations may be due to the close proximity to fixed boundaries. Material contact surfaces assumed to have no slip could also affect the accuracy of this model, however there is sparse literature on this material interaction.

The optimization and model approach in this pilot study is useful to others interested in non-linear soft tissue mechanical behavior modeling.

Table 1: Initial and optimized material parameters for this model

Material Parameter		μ (kPa)	α
Muscle	Initial	1.91	4.6
	Optimized	1.43	6.16
Fat	Initial	1.17	16.2
	Optimized	1.01	14.54

DESIGN OF A NOVEL BIAXIAL MECHANICAL TESTING SYSTEM AND PROTOCOLS FOR ANALYSIS OF BIOLOGIC TISSUES AND TISSUE-ENGINEERED CONSTRUCTS

INTRODUCTION

Recent advances in tissue engineering include the ability to “tune” the mechanical properties of engineered tissues. In the current paradigm, it is common to assess how well an engineered tissue mimics the mechanical behavior of its native counterpart by performing uniaxial mechanical tests designed to produce stiffness and/or strength measures. This type of material testing is founded in linear elasticity theory, however biologic tissues are generally non-linear viscoelastic inhomogeneous anisotropic materials that are subjected to large deformations and complex loading conditions, i.e. they violate every premise of linear elasticity theory. Nevertheless, there is some utility in using concepts from linear elasticity when attempting to engineer a tissue. The stiffness and strength parameters represent physically meaningful design targets. The challenge is to develop a theoretical framework that captures a more comprehensive set of the mechanical characteristics observed in biologic tissues and incorporates physically meaningful parameters in so doing. Conventional non-linear elasticity theories produce indeterminate equations that employ constants that are purely mathematical. Such models have utility for analysis applications (e.g. computational modeling), but offer little insight for synthesis applications, i.e. they lack physically meaningful parameters that might serve as design targets in tissue engineering applications. This work is focused on the development of experimental tools, methods, and protocols for the mechanical characterization of biologic tissues based on a novel theoretical framework that has been used to produce a 2D constitutive, or membrane model, that incorporates physically meaningful parameters [1].

The development of the new theoretical framework has required the development of a novel biaxial testing system and protocols. The

membrane model describes deformation based on three stress-strain conjugate pairs. The results in three unique physically meaningful parameters: dilation, squeeze, and shear. Thus, a biaxial system must facilitate testing of biologic tissues in a manner that allows determination of these three parameters.

When conducting mechanical tests on biologic tissues other practical concerns arise. First, an appropriate method for fixing the material in the testing system must be developed. Clamping has been widely employed in mechanical testing of soft tissues from animal/human skin, connective tissues to ligaments and tendons [2,3]. It ensures a continuous and uniform lateral load distribution at the junction of the clamp and the sample by constraining all the clamped edges of the sample; however, soft tissues pose a concern. The central difficulty arises from the low friction between the surface of the clamping device and the soft biological tissue specimen, leading to slippage.

In addition to the challenges related to clamping or fixing a material in the mechanical testing system, strain measurement is also a practical challenge that must be addressed. A number of strain measurement techniques have been developed for soft tissues [4,5]. Most of the research has been focused on only one side of the tissue (usually the side with less connective tissues and cleaner). But what happened to the other side? Considering the complexity of biological tissues, it might be necessary to take into consideration deformation of both sides.

METHODS

Biaxial System Design: It consists of four motorized linear actuators, each driven by a servo motor. All linear actuators and the

bioreactor are rigidly affixed to a breadboard table to alleviate vibration. A camera is mounted above the specimen to record the markers' movement on the specimen. The system incorporates a custom four-axis controller that will employ a centroid control algorithm to enable load and displacement control on each axis. The versatile system can be configured to conduct conventional uniaxial, equi-biaxial, general biaxial, and shear tests.

Figure 1: Novel clamping design.

Novel Clamping Design: After reviewing the successes and failures of alternatives, we present a novel clamp design. This design combines serrated clamps with needles. A schematic drawing of the clamps is shown in Figure 1. It was validated by 45 uniaxial tensile tests performed on rat abdominal wall muscles at 1% per second or 10% per second stretch rate. Dog-bone specimens were obtained from fresh and frozen samples. Load and displacement data were acquired at the grips. The clamping area was marked by India ink to check the slippage.

Strain Measurement from Both Sides: Rectangular specimens were cut out from rat abdominal skin specimens. A total of 20 uniaxial tests with 30% stretch were conducted. 14 tests showed no slippage. A custom-written program was used to calculate the strain. Strain at the inner side (the side connected to inner connective tissues) and outer side (the side open to the air) of the specimens were measured and compared.

Figure 2: Biaxial system setup.

RESULTS

Biaxial System: An experimental apparatus was designed with the intention of performing both biaxial and simple shear tests. The testing platform is shown in Figure 2. A number of mechanical considerations were taken into account in the design of this setup. Proof-Of-Principle tests have been conducted to evaluate this system.

Novel Clamping Design: The 3D printed clamps with needles attached demonstrate their overall reliability in fixing rat abdominal wall tissues in this study. Additionally, it is quite easy to operate and could be used in a wide array of testing environments (for example, a

Figure 3: Clamping validation test (specimen tested under 10%/s strain rate)

37° degree C saline bath), compared with freezing clamps. The effects of loading rate, anisotropy, and freezing on mechanical properties of rat abdominal wall

muscles are also studied. The test result of specimens under 10% per second stretch rate is shown in Figure 3.

Strain Measurement from Both Sides: This work shows that by measuring and comparing the strain of the inner surface and outer surface of rat skin specimens, we noticed that even when skin specimens are very thin, the strains are not always the same under the same loading condition. Thus it might be necessary to take into consideration the deformation of the inner side of soft tissues when trying to characterize their mechanical properties. One of the test result is shown in Figures 4~6.

Figure 4: Green strain (Exx) measurement for outer surface (left) and inner surface (right)

Figure 5: Green strain (Exy) measurement for outer surface (left) and inner surface (right)

Figure 6: Green strain (Eyy) measurement for outer surface (left) and inner surface (right)

DISCUSSION

The results from future work with this system could lead to a better understanding of the mechanical properties of soft tissues under complex loading environments. It may also provide tissue engineers with additional practical design information in the form of physically meaningful parameters that could enable the engineering of a more comprehensive set of the mechanical properties of the native tissue counterpart. We suspect that the needles employed in the clamping system help fix the center core to prevent slippage. However, this potential effect was not quantified in the current study. The specimens were cut along the cranial-caudal direction directly. In the future study, the fiber orientation of the sample will be determined prior to testing. This might help understand potential shear behavior in tests.

INTRODUCTION

Functional materials include metallic, intermetallic, ceramic or polymers in nature. Fabrication of an integrated material system from such a diverse subset of materials has created challenges to produce an engineered material that is able to act upon the exposed environments [1]. For example, in order to produce a prosthetic implant system, mechanical and electrochemical properties must be considered. The greater fatigue strength of the bearing element and higher corrosion resistance at the modular interfaces in total joint replacements (TJR) are the most important characteristics of the constituents. Therefore, it is necessary to design a functional implant material that possess a good resistivity against fatigue, wear, and corrosion [2].

Metallic implant materials have fascinated with a desirable combination of superior strength and ductility as summarized in Table 1. For example, the greater stiffness and strengths of CoCrMo would be suitable for the load bearing component of modular total joint replacements. The stable oxide layer of Ti6Al4V successfully protects implants from corrosion damage. However, the higher elastic modulus of metals compared to the bone tissue leads to bone loss and ultimately fails integrity at the implant-tissue interface, known as stress-shielding [3, 4]. Therefore, the ideal structural response of implants would be an optimum combination of superior mechanical strength and chemical inertness with lower stiffness. Consequently, the current study aims to utilize linear friction welding (LFW) technology to develop a bi-metallic Ti6Al4V-CoCrMo functional implant material to achieve the desirable properties.

Traditional fusion welding utilizes high energy input to produce weld pool mixing and solidify. Generally, the fusion welded metals result in defects including porosity, hot cracking and segregation. However, LFW is a solid-state joining process that utilizes friction heat to soften the workpieces and bonding by applied pressure [5]. It is a

significant advantage of LFW in nature as the solid-state and forging plasticized materials remove surface oxides and other impurities.

Therefore, in this report, bi-metallic Ti6Al4V-CoCrMo joints were manufactured using linear friction welding process and analyzed the weldability and bonding strength.

Table 1. Mechanical Properties of Metallic Implant Materials

Materials	Yield Strength (MPa)	Ultimate Strength (MPa)	Elastic Modulus (GPa)
Ti6Al4V (F136)	924	1000	116
CoCrMo (F1537)	958	1338	210
TiMo-β (F2066)	483	690	78
Ti45Nb	480	546	62
Human cortical bone	-	-	25.8 [4]

METHODS

Ti6Al4V and CoCrMo cylinders were manufactured to a standard size of tensile specimens and cut into two identical pieces. The surfaces to be welded were polished and cleaned before performing welding.

Figure 1. LFW of dissimilar components

CoCrMo cylinder was oscillated and Ti6Al4V cylinder was pushed to obtain axial shortening. A representative diagram of process parameters are summarized in Figure 2. Pressures were administered at 62 MPa to apply initial friction force and at 110 MPa to join the plasticized workpieces. An additional burn-off was applied to investigate the effect of the burn-off on bonding strength. A series of quasi-static tensile tests were performed on the dissimilar LFW CoCrMo-Ti6Al4V specimens to measure the bonding strength.

Figure 2. Measured burn-off (1.85 mm, 2.70 mm, and 3.75 mm) and forging pressure (110 MPa).

A mathematical transient heat transfer model was developed for the bi-metallic LFW process in order to obtain the temperature variation in the workpieces over time. Figure 4 (a) shows a schematic of heat transfer paths including conduction, convection and radiation. Straight arrows indicate conduction heat transfer paths and curved arrows indicate convection and radiation heat transfer paths.

The energy balance method was used to determine the temperature variation of the bi-metallic joint over time, which was based on subdividing the medium into a sufficient number of volumetric elements and then applying energy balance for each [6]. Conduction, convection, and radiation heat transfer were considered for each metal. The transient heat transfer equation is given by:

$$\rho V c_p \frac{dT}{dt} = h A_s (T_s - T_\infty) + \varepsilon \sigma A_s (T_s^4 - T_{surr}^4) + k A_c \frac{(T_s - T_{contact})}{L} \quad (1)$$

where σ is Stefan-Boltzmann constant, c_p is the heat capacity of the each material, ρ is metal density, and V is metal volume, ε is the emissivity of the metal surface, k is thermal conductivity of the metal, T_∞ is the room temperature, and T_{surr} is the temperature of the surroundings to which the element radiates.

Figure 3. Tensile test result with variable burn-off

RESULTS

The visual inspection illustrated the produced flash was from plasticized Ti6Al4V. According to the phase transformation diagram Ti6Al4V, β -transus temperature is below 1000°C and therefore softened Ti6Al4V produced the flash [7]. However, CoCrMo phase diagram illustrated phase transformation barely takes place at the welding temperature. It implies that the majority of plasticization would occur on Ti6Al4V. The forged Ti6Al4V surrounds the joint area and then solidified. This prevents two materials from mixing to form strong

bond. Tensile test results presented in Figure 3 describes a large scale plastic strain and catastrophic failure of the weldment.

The results of the thermal modeling for the joint are shown in Figure 5, which illustrate that the model predicted the thermal profile of the friction process when compared to thermography with $\pm 10\%$ error.

DISCUSSION

Mechanical bonding of the two biomedical implant materials were not successfully formed. The high temperature properties are critical to obtain mixing of two alloys. It is suggested to use different process parameters to induce a slow temperature gradient and lower shortening pressure. Having an interlayer may improve alloying and mixture of the elements to create strong bonding.

INTRODUCTION

Fibrous constituents of the extracellular matrix (ECM), such as collagen and elastic fibers, are essential for imparting tensile strength to biological tissues. Moreover, the mechanical properties of the tissue are dependent on the organization of such fibers. Tissues such as tendons and ligaments with strongly aligned collagen have high tensile strength along the direction of the fibers [1], whereas tissues with more randomly oriented fibers, such as skin, have reduced mechanical anisotropy in comparison [2]. In addition to dictating tissue mechanics, fiber topography has also been shown to affect the behavior of resident cells within the ECM [3-5]. Therefore, the ability to quantify fiber organization in biological tissues is a valuable tool with applications across a breadth of biomedical research.

Open-source programs to quantify fiber orientations in two-dimensional (2D) images are widespread throughout the literature, with options such as the FibrilTool and OrientationJ plugins in ImageJ [6,7], CT-FIRE [8], and CytoSpectre [9]. However, analyzing three-dimensional (3D) tissues in 2D has limitations: the results are dependent on the location and orientation of the imaging plane and low-density fiber networks are not readily visible in a single plane. While 3D orientation estimation is superior to analysis in 2D, options in 3D are limited and often constrained to particular imaging modalities [10-12]. To address this gap, we developed a novel 3D fiber orientation estimation technique for use on images with distinguishable fibers or fiber-like structures.

METHODS

A MATLAB script was written to calculate fiber orientations at each non-zero voxel in 3D image stacks. On a voxel-wise basis, a spherical window is generated around each voxel of interest by including all voxels at a distance less than a given radius from the voxel

of interest. Within the window, all non-zero voxels which are not connected to the voxel of interest are set to zero. A line is fit to the remaining voxels in the spherical window such that the sum of the squared perpendicular distances from the line to each non-zero voxel, weighted by the intensity of the voxel, is minimized (Fig 1). This process is defined in Eq. (1), where \mathbf{x}_α is the vector defining the intersection of the fit line with the surface of the spherical window, \mathbf{v} is the vector defining the orientation of the fit line, \mathbf{x}_i is the vector defining the location of each non-zero voxel in 3D space relative to the voxel of interest, w_i is the weight of that point, and n is the number of non-zero voxels in the reduced spherical window.

$$\min_{\mathbf{x}_\alpha, \mathbf{v}} \sum_{i=1}^n w_i |(\mathbf{x}_\alpha - \mathbf{x}_i) \times (\mathbf{x}_\alpha + \mathbf{v} - \mathbf{x}_i)|^2 \quad \text{such that} \quad \begin{cases} |\mathbf{x}_\alpha| = \text{window radius} \\ |\mathbf{v}| = 1 \end{cases} \quad (1)$$

Figure 1: Pictorial demonstration of orientation finding algorithm. (a) A spherical window is generated around a voxel of interest. (b) Non-zero voxels are represented as points in 3D space weighted by the intensity of the voxel. (c) A line within the spherical window is defined by the vectors \mathbf{x}_α and \mathbf{v} . (d) The line is fit to the points through minimization of the sum of the squared and weighted perpendicular distances from each point to the line.

The technique was validated on a complex image phantom comprised of forty fibers following periodically rotating sine waves

with randomly assigned orientations, amplitudes (range: 0-30 voxels), periods (range: 50-200 voxels), diameters (range: 2-12 voxels), and maximum intensities (range: 0.4-1.0 a.u.). Where fibers intersected within the phantom, the actual orientation of the voxel was set to the mean orientation of the fibers passing through the voxel weighted by fiber diameter and intensity. The phantom stack was analyzed using different window radii (4-16 voxels) to evaluate the accuracy of the technique and determine the effect of window radius on performance.

Following validation of the technique, the orientation quantification technique was demonstrated on biological images. The superficial digital flexor tendon and a patch of skin were harvested from a bovine hind limb. The fresh tendon was flash frozen in optimal cutting temperature (OCT) compound and sectioned longitudinally to a thickness of 100 μm . The dermis of the skin was exposed and imaged without freezing or sectioning. Both samples were imaged using label-free two-photon microscopy: collagen was visualized using second-harmonic generation (excitation: 840nm, emission: 420-460nm) and elastin was visualized using two-photon excited autofluorescence (excitation: 840nm, emission: 495-540nm). The elastin channel images were background subtracted and thresholded to fully isolate the elastic fibers within the image for analysis. Orientation distributions were determined for the elastic fibers (not collagen) using the algorithm described above and visually represented with spherical histograms.

RESULTS

The algorithm performed well on the complex image stack with randomized fibers (Fig 2(a)). With the window radius set to eight, the median and mean error of the orientation estimation were 0.720° and 4.782° , respectively. The distribution of errors was highly skewed to the right, with more than 61% of voxels having orientation errors less than 1° (Fig 2(b)). Voxels with greater errors were located in regions near the edge of the phantom, near fiber intersections, or in regions of high fiber curvature. Using a small window radius increased error due to fewer available voxels within the window for line fitting. Increasing the window radius from eight voxels also increased the error of orientation estimates because more voxels became affected by fiber intersections and regions of high curvature. Therefore, the algorithm achieved the best performance when the window radius was approximately equal to the average fiber diameter of the image being analyzed. Still, even with a broad range of window sizes, the median error remained below 2.5° , demonstrating the robust nature of the algorithm.

Figure 2: (a) Complex phantom image with forty randomized, curved fibers. (b) Histogram of errors from the orientation-finding algorithm with the window radius set to eight. The y-axis was broken to help visualize lower frequency bins and bin width = 1° . (c) Effect of window radius on algorithm performance on a complex phantom. Data are shown as median and interquartile range.

Application of the orientation algorithm was demonstrated on bovine tendon and dermis. The collagen fibers in the tendon displayed a strongly aligned and crimped structure, while the elastic fibers were sparsely distributed yet aligned with the collagen network: this alignment was represented in the sharply bipolar distribution determined by the algorithm (Fig 3(a-c)). In contrast to the tendon, both the collagen and elastic fibers in the dermis were found in a range of orientations within the plane of the skin (Fig 3(d-f)). The distinct

topographies of these tissues are directly related to the mechanical loads they are typically subjected to *in vivo*.

Figure 3: (a) Image stack of collagen (red) and elastin (green) in bovine superficial digital flexor tendon. (b) Isolated elastin channel from (a). (c) Spherical histogram representing the bipolar orientation distribution of elastic fibers in the tendon. (d) Image stack of collagen (red) and elastin (green) in bovine dermis. (e) Isolated elastin channel from (d). (f) Spherical histogram representing the orientation distribution of elastic fibers in the dermis. The peaks of the distribution are aligned within the plane parallel to the surface of the dermis.

DISCUSSION

We have presented and demonstrated a novel technique to find the voxel-wise orientation of fibers in three dimensions. While fiber intersections and regions with high curvature mildly impact the performance of the algorithm, a median error less than 1° was still achieved on a highly complex phantom image stack, exemplifying the high accuracy achievable with the algorithm. This technique is not dependent on imaging modality; however, it is limited to images with distinguishable fibers or fiber-like structures and may require minimal image post-processing prior to analysis. With these minor limitations, the algorithm still has potential applications across a large breadth of biomedical research including studying structure-function relationships in various tissues and in investigating fiber topography-dependent cell-ECM relationships. Further work extracting quantitative parameters describing the orientation distribution within single images or sets of images could augment the orientation algorithm by providing a simple measure to compare between study groups for statistical analysis.

INTRODUCTION

Bone is composed of 65 wt% mineral surrounded by hydrated proteins and aqueous body fluid[1]. The mineral provides mechanical strength to the bone in addition to acting as an ionic reservoir. Despite composing a majority of bone mass, bone mineral continues to be misidentified as, and assigned the properties of geological hydroxyapatite. Instead, bone mineral is carbonate-substituted, hydroxyl and calcium depleted apatite that forms nano-crystals of yet unknown properties. Studies have shown that chemical changes in composition, specifically the addition of carbonate, significantly affect mineral crystal size, atomic structure, and solubility. Recent *in silico* studies have indicated that the moduli of bone apatite should decrease with increased carbonate content[2].

In addition to the changes in mineral composition, it has been suggested that the aqueous environment present in bone may also serve to give bone mineral unique properties. Bone apatite in the presence of water has been shown to form a hydrated surface layer that resembles amorphous calcium phosphate (ACP)[3]. This layer appears to disappear with dehydration in air. The presence of this amorphous surface layer would be expected to modify many of the crystals chemical and mechanical properties.

Despite theoretical and structural data indicating that the mechanical properties of bone apatite are different from those of geological hydroxyapatite, it has been difficult to experimentally probe the modulus of bone-like mineral due to its nanometer-scale size. Here, we have employed X-ray Diffraction (XRD) in conjunction with fluid-mediated hydrostatic loading to measure the effects of composition and hydration on the mechanical properties of apatite.

METHODS

Aqueous precipitation methods were used to create five carbonated apatite powders. Powders were precipitated from NaHCO₃, Ca(NO₃)₂,

and NaH₂PO₄ in water at a pH of 9 and a temperature of 60°C. Carbonate content was confirmed via Carbon-Hydrogen-Nitrogen analysis to be 3.6, 9.2, 11.3, 13.6 and 17.8 wt% for the 5 samples. Powders were maintained and prepared in a dry glove box to minimize effect of environmental humidity. X-ray Diffraction and Raman Spectroscopy confirmed that the 5 samples were apatitic[2].

High Energy XRD and fluid-mediated hydrostatic loading were used to measure the deformation of these powders at P07 materials science beamline of Petra III synchrotron (DESY, Hamburg, DE) as previously described[4]. Powders were packed into a 7 mm² sample chamber with two flexible, x-ray-transparent kapton windows. The chamber was then filled with one of three liquids: phosphate buffered saline (PBS), ethanol (EtOH), or a 50/50 PBS/EtOH mixture (MIX) and sealed. The loaded sample holders were mounted into a custom made pressure chamber [4, 5] into which water was introduced and pressurized to hydrostatically compress the powders. Powders were gradually compressed in increments of ~100 GPa up to ~370 MPa.

The pressure chamber was aligned such that a collimated X-ray beam passed through pairs of diamond kapton windows, interacting with the pressurized powder thereafter exiting towards the detector. The x-ray beam had an energy of 60 or 71.8 keV with a 1x1 mm cross-section. XRD data was captured following each load increment on a 2048x2048 pixel Si detector with an acquisition time of 5x10sec. At each load both apatite (002) and (310) peaks were fully visible.

The full width at half maximum of the (002) and (310) diffraction rings were measured from the FWHM of the pseudo-Voigt fit peaks. The peak FWHM is inversely proportional to the atomic order of the crystals. The radial position of the (002) and (310) diffraction ring, R , was determined from the location of the center of the pseudo-Voigt fit for the peaks. The strains in the mineral, ϵ , were calculated from $\epsilon = R - R_0/R_0$, where R_0 is the radial position for the unstrained mineral. C-axis

strain was determined from the (002) peak while a-axis strain was determined from the (310) peak at each load.

The experimental results provide a direct measure of strain along the a and c-axes; however, due to the hydrostatic loading the compliance of the powders had to be found via optimization. From the strain measured and the load applied, we are able to calculate the bulk modulus, K, and the ratio η , which are related to the elastic constants C_{11} , C_{12} , C_{13} , and C_{33} according to the following equations:

$$K = \frac{\sigma}{\left(\frac{\Delta V}{V}\right)} = \frac{\sigma}{2\varepsilon_1 + \varepsilon_3} = \frac{[(C_{11} + C_{12})C_{33}] - 2C_{13}^2}{C_{11} + C_{12} + 2C_{33} - 4C_{13}} \quad (1)$$

$$\eta = \frac{\varepsilon_1}{\varepsilon_3} = \frac{C_{33} - C_{13}}{C_{11} + C_{12} - 2C_{13}} \quad (2)$$

With these known values, the elastic constants were optimized such that (1) the calculated K and η matched the experimental values and (2) that the residual sum of squares differences between the optimized and guessed values of C_{xx} were minimized. Preliminary guesses (seed values) for the elastic constants as a function of carbonate content were obtained from molecular dynamics (MD) data previously reported for carbonated apatite[2]. To account for variability in the original guess, the MD results were interpolated across all CO₃ values. The experimental results were similarly interpolated and used to run the optimization 10,000 times to determine the spread in the calculated constants. The Young's moduli could then be calculated:

$$E_{11} = \frac{[C_{33}(C_{11} + C_{12}) - 2C_{13}^2](C_{11} - C_{12})}{C_{11}C_{33} - C_{13}^2} \quad (3)$$

$$E_{33} = \frac{C_{33}(C_{11} + C_{12}) - 2C_{13}^2}{C_{11} + C_{12}} \quad (4)$$

The true experimental values were averaged for the results reported here.

Figure 1: Effect of composition and hydration on E₁₁

RESULTS

The Young's moduli of the carbonated apatites were significantly decreased ($p < 0.05$) with increasing carbonate content. Irrespective of the surrounding fluid, both the E_{11} and E_{33} exhibited a decrease with increasing carbonate concentration. The FWHM of both the (002) and (310) peaks increased significantly with increasing carbonate content. This indicates that there is greater atomic disorder in the more highly substituted samples. The bulk modulus, K, of the mineral powders exhibited no significant change as a function of carbonate content.

Overall, fluid composition in the loading chamber had no significant effects on the Young's moduli of the powders. The FWHM of the (002) peak does exhibit a trend towards a decrease in FWHM with increasing water content in the fluid. All compositions except that with the highest carbonate content (17.8 wt% CO₃) exhibited a significant decrease in (002) FWHM in PBS compared to EtOH. The bulk modulus showed no change with fluid composition.

Figure 2: Effect of composition and hydration on FWHM

DISCUSSION

The Young's modulus of geological hydroxyapatite, 114 GPa [6], is often used in bone modelling. However, our XRD results present the first direct evidence that the composition of the bone mineral can reduce mineral particle stiffness by 20% or more. Thus, small % changes in carbonate composition must be accounted for in determining its elastic properties. The addition of carbonate to the atomic lattice of hydroxyapatite causes a significant decrease in the longitudinal and axial Young's modulus of the crystals. Considering that the carbonate content of bone apatite ranges from 2-8 wt% in mammals, this suggests that E_{11} could vary from ~88-105 GPa and ~100-140 GPa for E_{33} . These are very different results than the commonly used isotropic 114 GPa. This stiffness change is likely caused by a decrease in atomic order associated with the carbonate substitution. The FWHM results clearly show that higher carbonate content is associated with an increase in atomic disorder.

It has been previously suggested that bone mineral forms an amorphous surface layer in the presence of water[3]. If such a layer was present, we would expect that the FWHM of the crystals would increase with additional hydration. However, the FWHM data indicates that the atomic order of the crystals actually increases in PBS as compared to EtOH at most carbonate contents. It is unclear whether this indicates that PBS acts to increase the atomic order of the crystals or if EtOH has some unknown interaction with the apatite that would cause a decrease in crystallinity. It has been reported that ethanol can better stabilize ACP as compared to aqueous media[7]. This stabilizing effect may cause ACP to remain present in the crystals in the presence of EtOH while it may recrystallize in PBS. Regardless of this change in atomic order, it appears to negligibly affect the mechanical properties of the crystals. The main change in elastic moduli of the crystals was due to carbonate composition and not by changes in the surrounding fluid.

INTRODUCTION

Unlike conventional inanimate composites, biological tissue composites contain dynamic inclusions: biological cells that actively generate contractile forces that act on the surrounding matrix.^[1] Non-destructive determination of these active internal stresses is necessary to build and validate accurate constitutive models. Micro-Raman spectroscopy (μ Raman) has been applied to non-destructively determine residual stresses and strains in ceramics previously.^[2-3] Here, we apply μ Raman to characterize the effect of applied stress on polyacrylamide (PA) hydrogels as a first step toward characterization of engineered tissues. μ Raman was performed on PA with increasing tension, and various features of the resulting spectra were compared to determine changes under strain.

METHODS

Fabrication of PA on Silicone Substrates. Silicone sheets (~250 μ m thick, HT-6240, Stockwell Elastomerics) were cut into approximately 42 mm \times 42 mm strips. PA gels were polymerized and attached to a silicone handle layer using benzophenone as previously reported.^[4] Briefly, a 5 mL prepolymer solution of 10% w/v acrylamide (99% pure, Bio-Rad), 1% w/v bisacrylamide (molecular grade, Promega Corporation), ammonium persulfate (0.1 g/ml, Bio-Rad), tetramethylethylenediamine (1:2000 vol/vol, Bio-Rad) and deionized water were mixed, and 100 μ l of this solution was pipetted onto benzophenone-functionalized silicone, covered with a 12 mm diameter coverslip, and exposed to UV (10.8 J/ cm^2 , λ = 383 nm) for 263 seconds. Subsequently, the coverslip was removed and phosphate buffered saline (PBS, pH 7.4) was used to rehydrate the gel for more than 10 min at room temperature. This formulation resulted in a gel with an effective

modulus of ~100 kPa as determined by millimeter-scale indentation on a custom cantilever-based system.^[5]

μ Raman Spectroscopy. Raman spectroscopy was performed with a 532nm argon-ion laser at 50 mW (Renishaw InVia). The spectra were recorded with a spatial resolution of approximately 1 μ m (20 \times objective, 200 \times total magnification). Spectra were obtained from 300 cm^{-1} to 4000 cm^{-1} with a resolution less than 0.1 cm^{-1} . Measurements were performed at room temperature, and 30 scans were acquired at each location. Thermal effects such as heating were neglected under the assumption that the hydrogel dissipated heat rapidly, as water would. Using a custom LabVIEW program (National Instruments), the 30 scans at each location were averaged and fit with Lorentzian distribution curves to determine peak locations.

Applied Strain. The PA gel was mounted into a “micro-vice” holder (S.T. Japan) via the silicone handle. Stress was applied by turning the drive screws by hand and calculating the resulting strain between edges of vice clamps. Previous calibration of the

PA-co-silicone system demonstrates full strain transfer from the silicone layer to the PA surface.^[4] Spectra were acquired from the approximate center of the sample at 0 and 44 kPa estimated stress.

RESULTS AND DISCUSSION

The goal of this study was to determine the effect of controlled stresses on peak wavenumber shifts with the overarching goal to correlate shifts to stress states in this material. At baseline, the peak wavenumbers we identified matched reasonably with published data from Gupta et al., who validated their simulations with PA in solution and cross-linked with bis-acrylamide^[6] (see Table 1). Under applied stress, the wave number and relative intensity of multiple peaks changed. For example, we observed that the 486 cm⁻¹ peak associated with skeletal bending shifted to a higher wavenumber and higher Raman intensity, while the 1430 cm⁻¹ peak associated with C-N stretching shifted to a lower wavenumber (Figure 2). While up-shifting of wavenumbers typically indicate bonds under tension and down-shifting of wavenumbers indicates bonds in compression, the physical interpretation of these data is still being clarified.

These findings suggest that uniaxial stress induces changes in molecular conformation that can be detected by μ Raman spectroscopy, but additional characterization and analysis is warranted. Namely, experimental determination of stress-strain curves for PA will help us correlate applied strains to internal stresses in necessary detail. Additional analysis and comparison of Raman spectra across gel formulations will build a foundation for applying μ Raman spectroscopy to cell-laden biomaterials for non-invasive or non-destructive evaluation of contractile stress, with the ultimate goal of improving computational models to support active inclusions.

INTRODUCTION

Natural to man-made supporting structures, such as the cytoskeleton of cells to the transmission towers in the power grid, consist of intricate arrangements of slender filaments. The deformation physics of these structures are largely governed by the bending of the slender members, which being a low-resistance deformation mode, is quickly tipped into the nonlinear conformations and large deflections even as the overall strains and forces remain small. While the physics of shear-free nonlinear bending has been described since the 18 century, discretized simulations of arbitrary filamentous media have relied on the linear and jointed approximations to the Euler bending equations. These approximations decouple the proportionality between bending mechanics and conformation inherent in the theory. The systematic error due to the de-coupling has not been investigated. We present the String-of-Continuous-Beams approach to modeling slender elements in 3D, which prevents the decoupling by retaining the nonlinear contour/mechanics terms without approximations as primary variables. The approach reproduces Euler bending mechanics and geometry with high accuracy for less computational cost, and is easily extendable to buckling scenarios with mother and daughter strands such as that occurring in dendritic actin meshes.

METHODS

In classic Euler theory for shear-free beam bending (Eq. 1, 2), the mechanics variables (i.e., bending force F and moment M) are directly proportional to the geometric variables (i.e., curvature $d\theta(s)/ds$ and its differential $d^2\theta(s)/ds^2$). They are coupled in that solving one, directly gives the other. However in modeling filamentous networks, it is common to approximate the curvature as small-strain or 'jointed' (i.e., hinged straight rods) (Eq. 3) to make the geometric variables tenable

for rectangular coordinates [1]. $\theta(s)$ is the in-plane bending angles along contour s .

$$M(s) = EI \frac{d\theta(s)}{ds} \quad (1)$$

$$F(s) = -EI \frac{d^2\theta(s)}{ds^2} \quad (2)$$

$$\frac{d\theta}{ds} = \frac{d^2y}{dx^2} \approx \frac{1}{L} \Delta \left[\frac{dy}{dx} \right] = \frac{1}{L} \Delta[\theta] \quad (3)$$

To avoid the approximation, the String of Continuous Beams (SOCB) approach retains the contour angle and its differentials as primary variables (does not express in terms of displacements), and instead fits the angle contour to a fifth-order polynomial in s . The displacements are then determined by numerically-integrating the angle polynomial as part of a mass or length conservation equation, which is solved simultaneously with the mechanics equations. The solution is generalized to arbitrary filament conformations by aligning the bending line with an in-plane x' axis, at where the filament shadow on each axis of the x' - y' - z' frame becomes the moment arm of the x' , y' , and z' components of the in-plane, out-plane, and axial forces [2]. An axial force at the end of a flexed filament can cause the filament to fold inwards or outwards, in both in- and out-plane directions. In-plane moment arms have to be compressed by the cos projection to compensate for an artificial increase brought about by the rotation.

RESULTS

Fidelity in capture Euler buckling mechanics: During axial buckling, the segment contour, forces, and moment arms undergo large changes and reverse direction, thereby serving as a good test case for stringently validating a generalized bending model (Fig. 1A). A filament can resist axial compressive force with stable axial bending

until a tipping configuration is reached. Beyond this configuration, filament buckles, passing through low-resistance states till tension in the opposite direction resists the compressive force (Fig. 1B). The SOCB model is able to capture the segment contours during the course of buckling (Figs. 1B and C) and the magnitude of the tipping force (scaled for filament length and EI) with <10% error using only 4 nodes, and with < 1% error by 8 nodes (Fig. 1C).[3] The jointed approach over-predicts the tipping force with >100% error with 4 nodes; the error stabilizes to 5% beyond 40 nodes.

Figure 1: Axial application of force (A) produces a tipping force beyond which the filament buckles. The SOCB approach captures the geometry and forces of buckling (B and D) with high fidelity. Approximated Euler beam mechanics in jointed approaches over-predicts the buckling force (C).

Buckling in dendritic actin unit-mesh: In a buckling filament, the resistance-force increases linearly as long as stable bending occurs, but at the tipping force it takes a gradual downturn and decreases rapidly (Fig. 1D). However when a dendritic actin mesh that is outgrown from an AFM probe is compressed, the linear force region (constant elasticity) is followed by a nonlinear force increase and a sharp downturn that is reversible. The dendritic mesh consists of ‘daughter’ filaments off-shooting from pre-existing mother filaments at 70° angle. Can simulating Euler bending mechanics for the simplest unit of a dendritic actin mesh (mother filament with a cross branch added at 70° angle) reproduce the nonlinear reversible-collapse observed in experiments? Since the geometry variables in the Euler equation are retained, force transfers in crosslinks between mother and daughter strands can be easily imposed (i.e., internal shear and moment continuity for the two interconnecting mother filaments, overall force continuity between all interconnecting filaments in Fig. 2B). The compression of a single mother filament with a daughter appendage-filament produced an initial region of low-force development followed by a nonlinear increase and a sharp downturn (Fig. 2A). The force increase occurs because the bending of the mother filament is resisted by the daughter appendage. The force downturn occurs as the mother

filament buckles when the daughter filament is no longer able to prop the mother filament. The force collapse is reversible.

Figure 2: Force profile and configurations (A) of a buckling strand when cross-linked with an appendage strand (B).

DISCUSSION

We present a technique for capturing the non-linear 3D bending of filaments within arbitrary meshes. Single or two-jointed rods are typically used to simulate bending filaments in semiflexible and structural networks. Fig. 1C suggests that insufficient joints will over-predict the buckling force. Since buckling is a tipping event (i.e., crossing a force threshold produces disproportionately large deformations), modest errors in estimated the tipping force can produce large errors in the perceived compliance and rearrangements of the network. The SOCB approach can accommodate complex force transfer between filaments in a crosslinks, compared to the oft-used pin-joint idealization used in semiflexible networks modeling. By attaching a daughter strand as an appendage to a mother-filament, the force vs. deflection of buckling filaments changes from gradual increase and gentle turnover (Fig. 1D) to nonlinear increase and sharp turnover (Fig. 2A). The nonlinear force increase occurs without the filaments being in classic tension. Compared to Fig. 1D, the buckling force in Fig. 2B is increased by the presence of a branch support. However the compressive strain at which buckling occurs is considerably lowered, possibly because the filament contour is constrained at the branch point.

INTRODUCTION

Plasmonic nanoparticles including gold nanoparticles (AuNPs) have created a tremendous impact on broad areas of research such as optics^[1], catalysis^[2] and biomedicine^[3], due to their superior optical properties. The interaction between AuNP and light, due to the resonant oscillation of light and free electrons in gold, results in numerous interesting phenomenon. Particularly, short laser pulses (femtosecond (fs) to nanosecond (ns)) irradiation makes AuNPs undergo various morphology changes including reshaping, fragmentation and welding^[4].

Two distinctive models have been proposed to explain the single AuNP fragmentation caused by short laser pulses^[5]. The Coulomb explosion model, as a non-thermal effect, interprets that the fission is caused by the charge repulsion within the AuNP due to the ejection of electrons. On the other hand, the photothermal evaporation model suggests that laser plasmonic heating of gold brings the AuNP temperature to melting even boiling point to cause the fragmentation of AuNP thermally. Interestingly, dominance of these two mechanisms is highly dependent on laser duration, *i.e.* Coulomb explosion for fs laser irradiation, while photothermal evaporation usually prevails in ns laser case. Previous theoretical study suggests that both mechanisms are possible in ps laser excitation^[5]. It remains unclear which mechanism dominates AuNP fragmentation under picosecond (ps) laser pulse.

Here, we experimentally studied the AuNP fragmentation induced by both ns and ps laser pulses. By systematically analyzing the extinction spectra change of AuNP before and after single laser pulse irradiation, we developed a method to determine the fragmentation threshold of AuNP which is highly size dependent for single ns laser pulse. This spectrum analysis further confirmed transmission electron microscope (TEM) imaging. Furthermore, we observed that the laser fragmentation behavior for ps laser irradiation is independent on size of AuNPs, suggesting a Coulomb explosion mechanism from ns laser

scenario. Further experiments and modeling will be required to better understand the mechanism of ps laser induced AuNP morphology change. This study is an important step for understanding the plasmonic processing of AuNP by ultrashort laser pulses.

METHODS

AuNP with different sizes were synthesized following the modified Frens' method^[6] and seed growth method. AuNP solutions (optical density @532 nm < 0.1) were loaded in 96 well plate with 115 μ L/well. Single ns pulsed laser (full width half maximum FWHM = 6 ns) or ps pulsed laser (FWHM = 28 ps) was used to irradiate AuNP solution in each well. Wavelengths for both lasers were set at 532 nm. After single pulse irradiation, AuNP solution was transferred in to a 384 well plate to measure the extinction spectra (400 - 800 nm). The control group are AuNPs without laser irradiation. The data was processed with MATLAB 2018a. We firstly calculated the wavelength ratio matrix [R] by the following equation.

$$R_{ijk} = A_{ik}/A_{jk} \quad (1)$$

Where, A_{ik} and A_{jk} are absorbances of AuNP at i nm and j nm respectively, k represents laser fluence applied on the sample. We then normalized [R] for the same wavelength ratio with following equation.

$$R_{ijk}^{Norm.} = \frac{(R_{ijk} - R_{ij}^{Min.})}{(R_{ij}^{Max.} - R_{ij}^{Min.})} \quad (2)$$

Where, $R_{ij}^{Min.}$ and $R_{ij}^{Max.}$ are minimum and maximum ratio value for all laser fluences when wavelengths were fixed. We then compared the normalized R for the laser irradiation and control groups and selected the ratio that changes most with increasing of laser fluence.

TEM imaging was used to confirm the AuNP fragmentation after laser. 10 μ L AuNP solution was added on a copper mesh, and air dried

overnight. Images were taken on TEM-JEOL 1400+ microscope (100 keV).

RESULTS AND DISCUSSION

Firstly, we observed that single ns laser pulse induces AuNP deformation and fragmentation. We checked the AuNP morphology by TEM imaging. As shown in Fig. 1A, AuNPs (15 nm diameter) remain spherical shape after laser irradiation at low fluence range (17, 65 mJ/cm²). The normalized wavelength ratio of AuNP (450nm/500 nm) indicates that the ratio change is very small when the laser fluence is below 130 mJ/cm², while it increases dramatically above 130 mJ/cm² (Fig. 1B). This result agrees with what we observed in TEM images (Fig. 1A), in which fragmentations start appearing when laser fluence is higher than 128 mJ/cm². Interestingly, fragmented parts appear as twisted strings or horns on particle surface. This can be interpreted by the model of photothermal evaporation of AuNPs. Laser plasmonic heating of the AuNP causes the formation of gold vapor and boiling bubbles on the gold surface which were later cooled down by surrounding medium and formed the fragmentation around the AuNP. We then tested the fragmentation damage thresholds of AuNPs with different sizes. Larger particles can generate more heat during laser irradiation due to their larger absorption cross section area. Consequently, it is easier for large AuNPs to reach boiling point than small particles. This is evidenced by experimental results that larger particle has lower threshold for fragmentation induced by single ns laser pulse (Fig. 1C).

Figure 1. Nanosecond (ns) laser pulse induced AuNP fragmentation. A) TEM images for AuNP (diameter 15 nm) after single ns laser pulse irradiation. B) The normalized absorbance ratio (R_{ijk}^{Norm} , $i = 450, j = 500$) indicates the fragmentation fluence threshold for AuNP (15 nm) C) The normalized absorbance ratio for different AuNP size. Larger particle has lower fragmentation threshold.

Next, we investigated the AuNP fragmentation induced by single ps laser pulse. Here we examined TEM imaging for two different sizes (5 and 100 nm). In both cases, irradiation at low (0.5 mJ/cm²) and high (25 mJ/cm²) laser pulse energies lead to particle fragmentation (Fig. 2A-L). Different from ns laser pulse irradiation, ps laser pulse leads to formation of small particles, for instance 2 nm population from 5 nm AuNP and 10 nm population from 100 nm AuNP. As laser pulse energy

increases, the population of small particle also increases (Fig 2D-E, J-L). Further examination suggests that the absorbance ratio change is independent of AuNP sizes (Fig. 2M). This bimodal size distribution and AuNP size-independent fragmentation strongly indicate a different mechanism, possibly by Coulomb explosion for ps laser induced fragmentation, different from the photothermal evaporation in ns laser fragmentation.

Figure 2. Picosecond (ps) laser pulse induced AuNP fragmentation. A-C) TEM images for AuNP (diameter 5 nm). D-F) Size distribution of AuNP in TEM images. G-I) TEM images for AuNP (d=100 nm) before and after laser. J-L) Size distribution in TEM images. The insert in L is TEM image for background of I which shows small particles. M) The normalized absorbance ratio (R_{ijk}^{Norm}) for different size AuNP.

In conclusion, we demonstrated that the ns laser and ps laser single pulse can both lead to AuNP fragmentation. However, the fragmentation behaviors of AuNP for these two cases are different and can be attributed to distinctive mechanisms (photothermal evaporation vs. Coulomb explosion). Further computational modeling and experiments are required to validate this finding.

INTRODUCTION

Approximately 40% of astronauts exposed to microgravity during long-duration space flight experience ocular changes, including change in visual acuity, in a condition known as space flight-associated neuro-ocular syndrome (SANS). The pathophysiology of SANS is poorly understood. However, the preponderance of evidence points to an important role of alterations in cerebrospinal fluid (CSF) pressure resulting from exposure to microgravity [1]. The optic nerve is surrounded by the subarachnoid space, which is filled with CSF, and the subarachnoid space is in turn encased in the optic nerve sheath (ONS), an anatomical extension of the dura mater. It has been reported that the elevated CSF pressure induces expansion of ONS [2], and that ONS tension can lead to significant mechanical insult to the optic nerve head (ONH) [3] where sight-influencing pathologies likely occur.

To explore the effects of microgravity and the possible effects of elevated CSF pressure on ocular function, it is useful to know the material properties of the ONS, e.g. to investigate ONS deformation and its effect on neighboring ocular tissues such as the ONH and optic nerve axons. Studies have measured the response of the ONS *ex vivo* [3-6]. However, to the best of our knowledge, there has been no effort to estimate the material properties of human ONS *in vivo*. In this study, we attempt to measure human ONS stiffness *in vivo* using MRI scans acquired during supine and head-down-tilt (HDT) postures, coupled with an inverse finite element approach.

METHODS

We acquired high-resolution MR scans of each eye in 4 healthy human subjects (7 eyes; 1 eye's scan had technical issues) in the supine position, followed by an identical scan during 15-degree HDT. The acute change in CSF pressure at the level of the eye associated with this postural change was estimated based on the hydrostatic indifference

level and a typical subject height ($\Delta p = 569.5$ Pa). The MR scans in both supine and HDT positions were then segmented using semi-automated tools to extract cross-sectional profiles of the inner surface of the dura mater as 3D point clouds. Segmented ONS contours from the MR scan in the supine position were used to reconstruct the outer ONS surface in the intraorbital region using open-source software (MeshLab). A typical dural thickness of $t = 0.4$ mm was specified to create a 3D finite element model (Fig.1), which was meshed using hexahedral finite elements (ICEM CFD). The increased CSF pressure due to postural change from supine to HDT was then applied as a loading condition to the inner surface of the dura in the finite element model, allowing dura expansion due to elevated CSF pressure to be computationally simulated. We also applied boundary conditions at the

Figure 1: Finite element model of optic nerve sheath (ONS) attachment to the ONH with boundary conditions.

anterior margin of the ONS (where it joins to the posterior globe) and at the optic foramen, as follows. At the anterior margin, a displacement (rotational) boundary condition was applied by computing the measured gaze angle change ($\Delta\phi_{LG}$, $\Delta\phi_{VG}$; Fig. 1) during position change from supine to HDT, as extracted from MR scans. At the foramen, the ONS was fixed, since its movement is tightly constrained at this location *in vivo*. In some cases, we were unable to segment the entire intraorbital length of the ONS due to artefacts in the MRI scans and scan resolution limitations; in such situations, we extended the length of ONS FE model by extruding the posterior margin of the segmented ONS to the location of the optic foramen and applied the fixed condition to the extended margin to reduce end effects. The dura mater was modelled as an incompressible, hyperelastic, neo-Hookean material assuming uniform material property along the entire ONS length. We computed the cross-sectional area of the ONS in HDT as a function of axial position. The FEM and MRI results were aligned using the most bulbous cross-section of the ONS as a reference location. Using an inverse FEM technique with the surrogate optimization algorithm (Matlab), we determined ONS stiffness (Young's modulus, E) that minimized the difference between computed and measured cross-sectional areas, evaluated using an objective function defined as the sum of root mean square differences calculated at uniformly sampled axial locations along the optic nerve axis.

RESULTS

Figure 2 shows a representative FEM result and comparison with HDT MRI data. Increased CSF pressure resulted in expansion of the ONS cross-sectional area during posture change from supine (black line) to HDT (red line), as measured by MRI. The FEM result (blue line) shows good agreement (RMS difference in cross-sectional area = 1.27 mm²) with the result measured from MRI data (red line). The estimated ONS stiffness for all 7 eyes was 96.26 ± 49.10 kPa (mean \pm SD; Fig. 3). Inter-individual differences in ONS stiffness (40-127 kPa) were larger than intra-individual differences (left vs. right eyes in a subject; 22-36 kPa; Fig. 3(b)).

DISCUSSION

We noninvasively estimated *in vivo* human ONS stiffness using an inverse FEM approach. Direct comparison of the estimated ONS stiffness to other published references is difficult because there is no information about *in vivo* measurement of human ONS stiffness, although there are *ex vivo* studies using animal eyes (porcine, bovine,

Figure 2: Experimentally measured ONS inner cross-sectional area as a function of axial position along the optic nerve in supine (black) and HDT (red) postures, and computed HDT values (blue).

ovine, and rat eye; [3-6]) and tensile testing. These studies report much larger stiffness (order 1 MPa) than our estimation; this difference may be due in part to the *ex vivo* conditions creating a reference stress state in the ONS differing markedly from that of the *in vivo* environment.

This work is subject to certain limitations. First, our preliminary research revealed that a more complex material model (collagen fibers embedded in ground substance) did not give significantly better agreement between experimental and computed results (up to 3% difference between fiber model and neo-Hookean model), likely due to resolution limitations in the MR scans. Therefore, in this study we simply used a neo-Hookean model to characterize the behavior of the ONS. Second, we assumed an identical CSF pressure increase, Δp , for all subjects as a loading condition. The use of individual-specific conditions based on the height of each subject could improve the accuracy of estimates. Third, in this study, the sex and age of the subjects were not considered as factors, which may contribute to the large inter-individual differences we observed. Fourth, we note that since the ONS was modeled as a hollow cylinder-like structure with uniform thickness, the stiffness that we extracted is an effective value ("structural stiffness"), which: (i) lumps together the effects of the dura mater and the arachnoid trabeculae, and (ii) does not account for subject-specific variations in dura mater thickness. However, the tension exerted on the ONH tissues during microgravity will depend primarily on exactly this structural stiffness, and thus this may be a suitable outcome measure for use in the future study exploring the complete pathophysiology of SANS.

Figure 3: Estimated ONS stiffnesses. (a) Box plot for all eyes (N = 7). The bottom and top of the box represent the 1st and 3rd quartiles, respectively. The line inside the box represents the median. The bottom and top bars represent the minimum and maximum values, respectively. (b) Scatter plot showing stiffness values in left and right eyes. Connected points are from the same subject.

INTRODUCTION

Idiopathic intracranial hypertension (IIH), which is related to pseudotumour cerebri (PTC), is a state of increased intracranial pressure (ICP) with unknown cause. Common symptoms of IIH are headache, pulsatile tinnitus, nausea, transitory visual obscurations, diplopia and blurred vision. Signs of intracranial hypertension (IH) on magnetic resonance (MR) images of the eye include flattening of the posterior globe and inward protrusion of the optic nerve head. Optic nerve head protrusion, i.e. peripapillary deformation (PD), is mostly due to papilledema, which reflects swelling of the retinal ganglion cells that form the optic nerve due to axoplasmic stasis. However, there may also be a mechanical component related to the inverted 'U' shape that peripapillary Bruch's membrane takes in states of high ICP [1]. In this work, we performed a finite element (FE) analysis to investigate the important parameters that affect the mechanical response of the posterior globe. Furthermore, we used the FE model in order to determine mechanical properties of ocular tissues as well as IOP and ICP pressures, which might facilitate the observed nerve protrusion in patients with idiopathic intracranial hypertension.

METHODS

The geometry of the posterior globe and intra-orbital optic nerve, Figure 1, was created from the available information in the literature [2-4]. The ANSYS APDL was used for conducting the finite element (FE) analysis. In the FE model, nodes on the axis of symmetry were constrained to deform such that they remain on the symmetry axis. In addition, because of anterior-posterior restraint of the extraocular muscles, nodes on the equator were constrained to radial deformation. Finally, since the degree to which the optic nerve is constrained is not fully known, a spring with normalized spring constant k was defined at the posterior ends of the dura mater and optic nerve, Figure 1.

Figure 1: A schematic showing the computational model of the posterior globe. The model is radially symmetric and linear springs are used for end boundary conditions.

In order to assign the material parameters of the numerical model, a mid-axial MR image at the level of the optic nerve head was identified and measures of posterior eye NP (measured at the posterior scleral boundary) were obtained. The selection of a patient with high resolution MR imaging was done retrospectively based on the review of patients seen in the neuro-ophthalmology division at Byers Eye Institute at Stanford. This work followed the tenets of the Declaration of Helsinki and is approved by an institutional review board at Stanford University with a waiver of informed consent.

In order to relate the results of the MR image and the FE simulation, we used the angle-distance analysis technique [5] for characterizing the amount of PD. In this method, the actual boundary of the optic nerve head was considered in the MR image (shown by green color in Figure 2) and the displacement of peripheral nodes on the

inner retinal surface from the center of the eye globe was plotted versus the angle θ . The same analysis was done for the finite element model, in which the model parameters were changed until the results matched those obtained from the MR image.

Figure 2: An MR image from a patient with high intracranial pressure. The outer boundary of the MR image is determined and was used for the angle-distance analysis.

RESULTS

Figure 3 shows the angle-distance graph obtained from the FE model matched very well with the curve obtained for a typical MR image shown in Figure 2. The numerical model showed that the amount of IOP and ICP and the material properties of lamina cribrosa, optic nerve, retina and pia mater were the most important parameters causing PD, i.e. the values of these parameters were significantly different than their default values. Furthermore, it was found that the end boundary conditions, modelled by linear springs, significantly influenced the amount of peripapillary deformation, Figure 4.

Figure 3: The Angle-Distance analysis of the finite element simulation of the MR image shown in Figure 2. The finite element results are obtained with IOP = 30 mm-Hg, and ICO = 70 mm-Hg. Furthermore, the modulus of pia mater, lamina cribrosa, optic nerve, and retina was 250, 25, 5, and 10 KPa, respectively.

DISCUSSION

Numerical models allow the isolation of mechanical from biological processes as well as enable researchers to manipulate parameters and measure outputs that cannot be accessed experimentally. Through manipulation of material properties, very good agreement was achieved

between the numerical results and the MR image analysis of a patient with IH. These results supported the strength and suitability of developed characterization angle-distance technique for quantitative characterization of the contributing factors to the PD. Furthermore, it suggested that the proposed numerical model can be used in future studies to analyze MR images of patients with IH in order to estimate the average changes in the mechanical properties of tissues surrounding the ONH. Though it has been proposed that biological changes in the optic nerve head contributes significantly to nerve protrusion seen on MR images, the present numerical analysis suggests that there may exist a mechanical contribution as well. In other words, material properties as well as increased pressure loads could play a critical role in susceptibility to PD. This could occur due to either an individual's congenital variation in material properties of ocular tissues or acquired variation caused by tissue remodeling. The boundary conditions used at the bottom of the optic nerve and the dura mater were found important to the mechanical response of the globe.

Figure 4: The effect of end boundary conditions on the amount of PD. The fixed boundary condition is obtained when the value of the spring constant is high. Except the spring constant, all other model parameters were the same as those used in Figure 3.

$$\text{Percentage of protrusion is } \frac{\Delta y}{R} \times 100.$$

INTRODUCTION

In angle-closure glaucoma, the anterior chamber angle (i.e., the angle between the iris and cornea) is closed or narrowed. Such a closure may lead to an increase in the intraocular pressure (IOP) due to the blockage of the aqueous humor outflow pathway. Laser peripheral iridotomy (LPI) is a common treatment method for angle closure [1]. In this procedure, a hole is made across the iris to redirect the aqueous humor flow and open the anterior chamber angle. However, LPI may not always be a successful treatment. IOP increases have been observed in patients undergone LPI, requiring additional interventions [2, 3]. In fact, the success rate of LPI may be as low as 24% [4, 5].

In our previous study, we showed that patients who continued to suffer from occludable angles post-LPI had stiffer irides [6]. While iris mechanical properties are important factors, the size and location of the LPI on the iris could also affect the surgical outcomes [7]. Although no gold standard exists, some clinicians have advocated for a hole size of at least 150-200 μm in diameter for the LPI candidates [8]. Such diameters, however, could change because of light-induced iris deformations. Using a computational approach we examined how the LPI hole size and location, as well as its deformation due to pupil dilation affect the pressure difference across the iris (i.e., between the anterior and posterior chambers of the eye).

METHODS

A three-dimensional finite element model of the iris similar to our previous two-dimensional axisymmetric model [6] was constructed using geometry obtained from an anterior segment optical coherence tomography image. Similar to our previous work [6], the iris was modeled as a neo-Hookean solid governed by the stress balance equations. A dilator region of 0.2 mm was manually identified in which the dilator stress was applied to simulate pupillary dilation. Holes with

diameters of 200 μm and 400 μm were made in the iris to simulate LPI. Three different case studies were conducted:

- To examine the effect of the hole location on the pressure difference, holes were placed in the iris at locations adjacent to the pupil, near the iris mid-periphery, and near the periphery of the iris (Figure 1).
- To examine the role of the hole size on the pressure difference, hole sizes with diameters of 200 μm and 400 μm were used.
- To examine the potential effect of iris compressibility on the pressure difference, Poisson's ratios of 0.35 and 0.49 were used for the iris model.

The geometry of the hole before and after dilation was imported into SolidWorks (Dassault Systèmes, Vélizy-Villacoublay, France) and a flow simulation was performed using Flow Simulation add-in in SolidWorks. Pressure difference across the two ends of the hole before and after dilation was calculated. For boundary conditions, the inlet surface of the hole had a volumetric flow rate Q of 3.0 $\mu\text{L}/\text{min}$ ($5 \times 10^{-11} \text{ m}^3/\text{s}$) [9] and the outlet surface had a known predefined pressure (P_o) (Figure 2).

Figure 1: Holes with a diameter of 400 μm placed (A) near the pupil, (B) near the iris mid-periphery, and (C) near the periphery of the iris.

Figure 2: Geometry and corresponding boundary conditions of (A) an undeformed and (B) a deformed hole for CFD analysis.

Reynolds number was calculated to be 0.32; hence, the flow was considered laminar. Using the simulated values (e.g., see Figure 3), the pressure difference (ΔP) required to drive the flow through the hole was calculated for each of the abovementioned case studies.

RESULTS

In the presence of a 200 μm hole, the pressure difference between the posterior and anterior chambers were 0.85 Pa, 0.80 Pa, and 0.92 Pa when the hole was placed near the pupil, at the iris mid-periphery, and near the iris periphery, respectively. These predictions were consistent with published simulated data by Dvoriashyna and Repetto [7].

Following pupil dilation, the pressure difference increased in all cases (Table 1). For the compressible model, the pressure increased by 4.70%, 63.75%, and 52.17% near the pupil, at the iris mid-periphery, and near the iris periphery, respectively. For the nearly incompressible model, the pressure increased by 7.06%, 51.25%, and 55.43% near the pupil, at the iris mid-periphery, and near the iris periphery, respectively. The pressure differences for the 400 μm diameter hole were extremely smaller compared to the 200 μm diameter hole, both before and following dilation (Table 2).

Table 1: Pressure difference between the posterior and anterior chambers of the eye using a LPI hole size of 200 μm .

Hole location	ΔP (Pa) before dilation	ΔP (Pa) following dilation for a compressible iris	ΔP (Pa) following dilation for a nearly incompressible iris
Pupillary Region	0.85	0.89	0.91
Mid-periphery	0.80	1.31	1.21
Periphery	0.92	1.40	1.43

Table 2: Pressure difference between the posterior and anterior chambers of the eye using a LPI hole size of 400 μm

Hole location	ΔP (Pa) before dilation	ΔP (Pa) following dilation for a compressible iris	ΔP (Pa) following dilation for a nearly incompressible iris
Pupillary Region	0.05	0.05	0.05
Mid-periphery	0.05	0.07	0.08
Periphery	0.06	0.08	0.09

Figure 3: Relative pressure difference across the hole ends and the flow profile for a presentative simulated case following dilation-induced deformation.

DISCUSSION

The increased pressure difference between the anterior and posterior chambers as a result of changes in the LPI hole size following dilation could be a potential reason as why the angle does not always open following LPI. The main purpose of LPI is to release the excessive pressure in the posterior chamber and move the iris more towards the posterior. The higher pressure difference following dilation may inadvertently lead to more anterior apposition of the iris periphery and thus blocking the outflow pathway.

Our study showed that the LPI hole size/location has a pronounced effect in both compressible and nearly incompressible irides. To determine the reason behind variations in pressure difference among different locations, the thickness of the iris was also calculated. Not surprisingly, we found that the pressure difference was directly proportional to the thickness. Therefore, the iris thickness should also be taken into consideration when performing LPI. In other words, thicker irides may require larger hole sizes to achieve the same pressure difference.

We also observed that holes that are larger in diameter provide better results in terms of pressure differences following dilation-induced iris deformations. While a tempting idea, increasing the size of the hole could generate a *second* pupil and negatively affects the optics of the eye. Similar argument is valid for the holes closer to the pupil: while their diameters do not change significantly with the pupil dilation, close proximity of the LPI hole to the pupillary margin could negatively affect the vision.

INTRODUCTION

Glaucoma is the leading cause of irreversible blindness worldwide. Loss of vision occurs due to progressive damage and eventual death of retinal ganglion cells, responsible for transmitting visual information from the eye to the brain. Although glaucoma can occur at any level of intraocular pressure (IOP), elevated IOP is a known risk factor [1]. Moreover, all current glaucoma treatments seek to reduce IOP, since sustained and significant IOP reduction is the only treatment that is known to slow or halt vision loss [1].

IOP is largely determined by the hydrodynamic resistance of the trabecular meshwork (TM), a porous, connective tissue through which aqueous humor fluid drains from the eye. The fluid conductance of this tissue (mathematical inverse of resistance) is referred to as the outflow facility, and is the most important measure of TM function. There is thus significant clinical and research benefit to knowing outflow facility, yet it is difficult to determine. Existing measurement techniques are either highly invasive, or are inaccurate, difficult to carry out, and time consuming; accordingly they are almost never used clinically.

We have recently shown that aqueous outflow facility and trabecular meshwork stiffness are closely correlated in both mouse and human eyes [2, 3], implying that TM stiffness may be a useful indirect measure of TM function and outflow facility. However, most previous work, including ours, has used invasive techniques on post mortem eyes to determine TM stiffness. Exceptions include the imaging-based studies of Pant et al. [4] and Johnson et al. [5]. To clinically exploit the link between TM stiffness and outflow facility, a non-invasive method of measuring TM stiffness is needed. Here our goals are to: (i) describe a minimally-invasive technique for optical coherence tomography (OCT)-based measurements of TM stiffness that overcomes many of the simplifying assumptions used in previous studies, and (ii) apply it to living mouse eyes.

METHODS

We used adult C57BL/6 mice for all studies due to well-documented structural and functional similarities between TMs in mice and humans. Studies were conducted with two cohorts of animals: one group received peri-ocular injections of dexamethasone (DEX)-containing nanoparticles, while the second group received vehicle-loaded nanoparticles (control). DEX is a glucocorticoid that causes a form of glaucoma similar to the most common form of human glaucoma, and thus DEX-treated mice are a good model of human disease. Methods are described in more detail in reference [6].

The TM and surrounding tissues were imaged using an Envisu R2200 high-resolution spectral domain (SD)-OCT system (Bioptigen). Images were acquired at a series of IOP steps (10, 12, 15, 17 and 20 mmHg), set by direct ocular cannulation with a glass micropipette attached to a reservoir.

A finite element model of a typical cross-section through the anterior eye was created and used to simulate the deformation of the TM as IOP was varied, quantified through the change in cross-sectional area of Schlemm's canal (SC), a fluid-containing vessel immediately adjacent to the TM (Figure 1A). We carried out an inverse FEM study, varying Young's modulus of the TM to match computed SC cross-sectional areas with values extracted from OCT images (Figure 1A). Due to the limited resolution of OCT images, we simply treated all tissues as linearly elastic, isotropic and incompressible, with TM modulus varied parametrically in the range 20-240 kPa and the moduli of other tissues taken from literature values [6]. Within the model, pressure loads were applied to surfaces exposed to aqueous humor, including an estimated pressure within the lumen of Schlemm's canal [6]. It was important to account for the biomechanical effects of the iris

and cornea through specification of forces and moments at the virtual cut plane corresponding to the edge of the OCT image (Figure 1B).

RESULTS

Simulations predicted significant iris deformations, matching the OCT images reasonably well (Figure 1C). The inclusion of iridial forces and moments at the virtual cut plane was critical to match computed predictions and experimental measurements of SC collapse, emphasizing the importance of properly accounting for complex iris-TM mechanical interactions in the mouse eye. The TM in DEX-treated eyes was predicted by inverse FEM to be approximately twice as stiff as in control eyes (69 kPa vs. 29 kPa; Figure 1D), a ratio generally consistent with reported effects of DEX on TM stiffness in rabbit [7] and mouse [3], obtained via ex vivo measurements.

DISCUSSION

The determination of TM stiffness in mice is feasible using a combination of OCT imaging and inverse FEM. Technical issues include the small size of the outflow tissues in the mouse eye and the deformation delivered to the TM/SC by iris-TM interactions. Such effects are expected to be less influential in human eyes, and thus this non-destructive approach to monitoring TM stiffness in vivo shows potential for both mouse and human studies. These data strongly motivate further studies to compare TM stiffness measured as described above with direct measurements in mouse and human eyes.

A COMPARISON OF TWO CONTINUUM MODELING APPROACHES FOR CORNEAL STROMA MECHANICAL RESPONSE

Shuolun Wang, Hamed Hatami-Marbini

Department of Mechanical and Industrial Engineering
University of Illinois at Chicago
Chicago, Illinois, USA
Email: hatami@uic.edu

INTRODUCTION

The cornea tissue covers the front of the eye and plays an important role in its proper function. For example, it is essential for protecting the inner contents of the eyeball. The precise shape and strength of the cornea are provided by mechanical properties of its extracellular matrix, which is composed of collagen fibers embedded in a proteoglycan matrix [1]. Experimental evidence shows that the collagen fibers in the corneal stroma are distributed with dispersion [2-3]. The mechanical contribution of these fibers into the mechanical behavior of the cornea tissue can be primarily captured via two different computational techniques, i.e. angular integration (AI) and generalized structure tensor methods. The angular integration method is based on the addition of the contribution of infinitesimal fractions of fibers oriented in different directions [4]. On the other hand, the GST method uses a generalized structure tensor for approximating the contribution of collagen fibers in order to avoid the required tedious angular integrations of AI approaches [5-6]. Although the GST approach is extremely friendly in terms of numerical implementation and computational cost, it is believed that its predictions include approximation and may produce unrealistic results. The primary objective of this study is to conduct a critical comparison between the GST and AI methods. Both methods are first implemented numerically in a commercial finite element software Abaqus/Standard by writing user-defined material subroutines (UMAT). They are then compared side by side by numerically simulating the experimental measurements conducted on the cornea [7].

METHODS

Both GST and AI approaches are implemented in Abaqus/Standard by writing user-defined material subroutines. The required energy functions are obtained from previous studies in the literature [4-5].

GST approach

The Total free energy could be decomposed into: 1) contributions from the soft matrix, and 2) contributions from N families of collagen fibers. In particular, the total free energy ψ_R is written as [5-6]

$$\psi_R = \psi_R^m(\bar{I}_1, J) + \sum_{\alpha=1}^N \psi_R^{f(\alpha)}(\bar{I}_1, \mathbf{A}_0^{(\alpha)}), \quad (1)$$

where ψ_R^m and $\psi_R^{f(\alpha)}$ are free energies of the matrix and of the collagen fibers, respectively. The structure tensor $\mathbf{A}_0^{(\alpha)}$ for α 's family of fibers is given by

$$\mathbf{A}_0 = \kappa \mathbf{1} + (1 - 3\kappa) \mathbf{a}_0 \otimes \mathbf{a}_0, \quad (2)$$

with κ denotes the dispersion parameter, and \mathbf{a}_0 denotes the referential unit vector pointing in the preferred fibers' orientation. For the derivation of κ , refer to Gasser et al. [6]. The nearly-incompressible Neo-Hookean model is used to describe the free energy of the matrix material,

$$\psi_R^m = \frac{1}{2} G_0 (\bar{I}_1 - 3) + K (\ln J)^2, \quad (3)$$

where \bar{I}_1 denotes the distortional part of the first invariant, J is the determinant of the deformation gradient, G_0 denotes the shear modulus, and K denotes the bulk modulus.

As for the fibers' free energy form, collagen fibers found in the cornea fall into type I category and are unable to withstand significant amount of compression; thus, the free energy is written as

$$\psi_R^f = \begin{cases} \frac{k_1}{k_2} (e^{k_2(\bar{I}_4)^2} - 1) & \text{if } \bar{I}_4 \geq 1 \\ 0 & \text{otherwise} \end{cases} \quad (4)$$

with \bar{I}_4 is the distortional part of the fourth invariant for α 's family, and k_1 and k_2 denote the model parameters.

AI approach

Compared to the GST approach, AI methods take into account more detailed information about the cornea architecture. The free energy of stroma per its unit un-deformed volume is given by

$$\psi_R^{stroma} = \psi_R^m + \frac{1}{m} \int_0^\pi \rho(\theta, \phi) \psi_R^f d\omega, \quad (5)$$

where $\rho(\theta, \phi)$ denotes the PDF of fibers' orientations, and $d\omega$ denotes the differential solid angle. Figure 1 shows the 3-D scatter plot of $\rho(\theta, \phi)$ at three different cornea depths, i.e. the AI approach is able to capture the variation in fiber orientation through the thickness of the cornea extracellular matrix.

Figure 1: 3-D scatter plots of the PDFs for AI approach. PDFs are demonstrated at three different normalized depths of a) $s = 0$, b) $s=0.5$, and c) $s = 0.9$.

RESULTS

In simple tension tests, both approaches are capable of capturing the anisotropic behavior of the cornea. For both simple shear and torsional shear tests, which are designed to probe the in-depth properties of the cornea, AI approach is a clear winner. Both approaches are able to capture the apical rise-IOP curve (shown in Figure 2), but the difference in Von-Mises distribution between two approaches (shown in Figure 3) suggests that the internal architecture within the cornea plays an important role in terms of the mechanical response.

DISCUSSION

The simulated experimental results confirm that both approaches have their merits and disadvantages. For example, the AI approach is able to capture more realistic features of the cornea – variation of in-depth properties, but extremely expensive in terms of numerical simulation time. On the other hand, the GST approach requires no numerical integration of complex PDFs over the unit sphere at each material point, which makes it relatively cheap numerically, but due to

fact that it is only an approximation of the true integral, the results it provides include some levels of inaccuracy.

Figure 2: The apical displacement - IOP curves obtained from the GST and AI approaches are compared with that of a previous study [5].

Figure 3: The simulated contours of the maximum principal stress (MPa) for both approaches at an internal pressure of 100 mmHg. a) The GST approach, and b) The AI approach.

MICROSTRUCTURAL CHANGES AT THE VITREORETINAL INTERFACE WITH REGION AND AGE IN HUMAN EYES

Christopher J. Creveling (1), Yousef M Alsanea (1), Brittany Coats (1)

(1) Department of Mechanical Engineering
University of Utah
Salt Lake City, Utah, USA

INTRODUCTION

Vitreoretinal adhesion plays an integral role in trauma and disease. In trauma, adhesion between the vitreous and retina dictates the distribution of loading to the retina. In disease, vitreoretinal traction and adhesion can modulate clinical outcomes [1]. Despite its importance, very little is known about the mechanisms and mechanics of the vitreoretinal interface. Recently, we measured changes in vitreoretinal adhesion with age and in different regions of the eye [2]. We found disruption to the inner limiting membrane (ILM) due to vitreoretinal separation was not dictated by strong adhesive force, but rather by the mechanism of adhesion. We hypothesize that collagen interaction with the ILM, including orientation and density, dictate the mechanics and failure mechanism of vitreoretinal adhesion. The objective of this study was to test this hypothesis by quantifying the collagen density, orientation, and ILM thickness at the vitreoretinal interface and identify relationships with vitreoretinal adhesive strength and failure. If correlated, collagen structure may provide insight into those at greatest risk for lingering adhesion and inform strategies to modulate adhesion to affect disease outcomes.

METHODS

Previously, we measured the adhesive strength between the vitreous and retina in sheep (n=43) and human (n=17) eyes [2]. The sheep eyes were used to evaluate adhesion differences between immature (infant to young child) and mature (young adult) eyes. A sheep model was selected because they have well-defined retinal structure and holangiotic vasculature, and vitreous composition similar to human eyes [3].

Following the rotational peel test described in [2], 2x2 mm specimens were collected from an unpeeled retinal region immediately adjacent to the peeled retina. These specimens were placed in a 1%

buffered formaldehyde and 1.25% glutaraldehyde solution, and processed as described in [2]. After embedding, 70 nm sections were cut and put on 150 copper mesh grids using a microtome (Leica UC6 Ultramicrotome, Leica Microsystems, Wetzlar, Germany). Sections were coated with uranyl acetate and lead citrate and were imaged on a 120kV FEI Tecnai T12 Spirit TEM. The magnification was set to 6500x with a beam size of 4 for optimal contrast and an exposure time of 0.5 seconds on the Gatan digital micrograph charge-coupled device. Approximately 25-35 TEM images were taken of each specimen. Specimens were obtained from the posterior pole and equator regions of each eye. A representative TEM image is shown in Figure 1.

Figure 1: TEM image of a human vitreoretinal interface from the equator of a 69-year old donor. Collagen fibers (C) can be seen running parallel to the ILM (I).

DEVELOPMENT OF A FINITE ELEMENT SIMULATION TO ESTIMATE CORNEAL ELASTICITY

INTRODUCTION

Cornea elasticity plays an central role in the proper function of the eye, yet it is not well understood. Therefore, the development of approaches to characterize ocular mechanical properties will impact numerous eye disorders. For example, Keratoconus (KC) is a progressive corneal ectatic disorder caused by degeneration of the collagen fibril network. Changes in the corneal stroma leads to topographic changes which results in a distinct bulging shape unique to patients with KC.¹ Due to the lack of proper stiffness measurements in vivo, KC can only be clinically diagnosed by detecting the bulging shape.

Keratoconus is halted using a procedure known as corneal crosslinking (CXL). The current FDA approved procedure (KXL) utilizes a potentially damaging ultraviolet light at 365 nm wavelength which can damage the endothelium layer leading to a corneal transplant.² Beginning with these observations, we initiated a long-term study which involves conducting mechanical testing on *ex vivo* corneas crosslinked at shorter UV wavelengths which are safer for the endothelium.

Unique to this study is the utilization of nanoindentation (NI) as a non-destructive, local mechanical measurement of corneal stiffness. This allows for repeated measurements on the same cornea, including before and after treatment and depth profiling.

Building upon the ability to stiffen corneas with UV, we have created an in vitro experimental platform where corneal stiffness, thickness and intraocular pressure can be measured and manipulated on a single human cornea. There are, however, no established methods of extracting the mechanical properties of a pressurized membrane with the nanoindenter. Thus, the creation of a model, which takes into account both the bending and compression components, is required.

The purpose of the current work is to create a reliable model to estimate the mechanical properties of a pressurized thin wall shell. In order to complete this task, a finite element simulation of the experimental setup was constructed. To fine tune the model, complimentary experiments were conducted with silicone elastomer membrane with varied stiffness and thickness either laid on a rigid support or mounted on an artificial anterior chamber which enables the controlled simulation of intraocular pressure.

METHODS

A finite element simulation was constructed on COMSOL Multiphysics, utilizing the Structural Mechanics Module. The model consists of geometry and boundary conditions such as a flat punch indenter tip with a 500 μm diameter and loading stages to mimic the Hysitron Triboindenter (Bruker) setup. To gauge

the efficacy of the simulation and evaluate candidate models for estimating elastic modulus, the computational model is currently being evaluated with a tunable elastomer, polydimethylsiloxane (PDMS). PDMS is an ideal elastic tissue mimic because the material properties can be easily manipulated such as thickness and crosslink density.

PDMS was purchased from Dow Corning Corporation. The samples were prepared by first mixing the base and crosslink components at a 10:1 ratio. The two components were then manually mixed for 15 minutes and poured onto petri glass dishes. The samples were then placed in a vacuum pump to remove air bubbles and were then cured in the oven at 65 °C for 24 hours.

The Young's Modulus and Poisson's ratio from the samples PDMS were measured using the nanoindenter and subsequently entered into the COMSOL program. Before introducing pressure, a rigid compression experiment was conducted, and the displacement for specific applied forces in the computational model was compared to the experimental results.

RESULTS

To interpret data from the indenter, a force versus displacement graph is plotted, displaying a line following the loading, hold and unloading stages of the indentation, shown in Figure 1. The slope of the unloading stage (S), the contact area of the tip (A), and the Poisson's ratio, ν , are then used to compute the compressive elastic modulus (Eq. 1). 0.49 was used as Poisson's ratio for the incompressible tissue.³

$$E_{Comp} = (1 - \nu)^2 \frac{S \cdot \sqrt{\pi}}{2 \cdot \sqrt{A}} \quad (1)$$

Figure 1: Raw data from nanoindenter

The force versus displacement data collected by the nanoindenter can be compared to the COMSOL model displacement field shown in Figure 2. From Equation 1, the data can then be converted to Young's Modulus. Experimental Young's modulus was calculated as 188 kPa while the COMSOL modulus is 130.5 kPa.

Force (µN)	Experimental (µm)	COMSOL (µm)	% Difference
120	1.88	1.37	29.3
100	1.753	1.14	34.9

Table 1: Linear elastic material model

Figure 2: COMSOL displacement field for rigid compression

DISCUSSION

The current finite element model deviates approximately 30% from the empirical result indicating that a linear elastic model does not completely replicate the experimental setup. In an effort to improve the model, we hypothesize that a hyperelastic material model will more accurately simulate the properties of PDMS as it is subjected to large deformations. By shifting to a hyperelastic material model, data from other modes of deformation such as uniaxial testing will provide a more accurate material behavior of PDMS for the finite element simulation. The aim of this study is to extract the material properties of a pressurized membrane through nanoindentation methods. After rigid compression has been accurately replicated, pressurized boundary conditions replicating fluidic intraocular pressure will be introduced and the combined bending and compression response will be analyzed. The proposed comprehensive model will greatly improve ophthalmic diagnosis of various ocular disorders by utilizing patient-specific cornea properties and may lead to new diagnostic instruments.

INTRODUCTION

Thrombus material is a critically important tissue component that has the essential role of preventing blood loss in the human organism. Thrombus or blood clots can form through various pathways in vivo; due to insufficient blood flow (stasis), very high shear flow conditions or as a result of exposed tissue factor coming in contact with flowing blood due to a vascular injury [1]. Many life-threatening conditions are associated with abnormal clotting, such as acute ischemic stroke (AIS), which accounts for 85% of all strokes [2].

Mechanical thrombectomy has been firmly established as the new standard of care for the treatment of AIS [3]. In-vitro thrombus analogs are very useful in the pre-clinical testing of devices intended for use in thrombectomy, where amongst other things they can be used to evaluate the number of attempts required to remove the thrombus and the risk of embolization [3]–[5]. Some key determinants for success of the thrombectomy procedure are the mechanical properties of the clot.

The mechanical properties of clots are influenced by the composition of the clot, the arrangement of these components in the clot and internal contractile forces. Clot contraction/retraction is the tightening and shrinking of the clot network. It occurs as activated platelets rearrange within the clot structure, pulling on the fibrin threads, thus causing the fibrin network to contract and reduce in volume. This helps to create an impermeable seal at the site of vessel injury to prevent bleeding. It has also been found that the extent of clot contraction is hematocrit-dependent [6].

The aim of this study is to investigate the effect of clot contraction on the microstructure of clot analogs with varying hematocrit levels, and to determine how this impacts the mechanical behavior of the material.

METHODS

Sample Preparation

Venous blood was collected from sheep for the preparation of the clot analogs, and a 3.2% sodium citrate anticoagulant solution was added. All clots were prepared within 5 hours of blood collection.

Two types of clot analogs were produced – non-contracted and platelet contracted. Non-contracted clots were produced by mixing platelet poor plasma (PPP) with red blood cells in controlled ratios to represent clots with a low, medium and high red blood cell composition; the quantity of red blood cell used in the blood mixtures were: 0% hematocrit (plasma only), 5% hematocrit and 40% hematocrit. Similarly, platelet contracted clots formed from blood mixtures with the same hematocrit levels were formed by mixing red blood cells with platelet rich plasma (PRP).

Once the various blood mixtures were produced, coagulation was initiated by the addition of a 2.06% calcium chloride solution to the blood mixture in a 1:9 ratio. The clots were allowed to mature overnight at 37°C. The samples were formed in cylindrical shaped vessels and cut to an appropriate height for testing. The samples were placed in PBS for 30 minutes prior to mechanical testing.

Clot Weight

The weight of the clots was measured after contraction and expressed as a percentage of the mass of the original blood mixture/non-contracted clot.

Compression Testing

Unconfined compression was used to determine the material behavior of the clot samples. The testing was performed on a Zwick uniaxial tensile machine (Zwick Z2.5, Ulm, Germany), with the samples

tested in PBS. The samples were placed between two platens and the crosshead position of the machine was adjusted so that the top platen was slightly touching the top of the sample at the beginning of the test. The clot specimens were loaded to a compressive nominal strain of 30% at a strain rate of 10% per second and then unloaded to their initial configuration at the same rate (n=5 for each group).

DMA testing

DMA (Q800; TA Instruments, New Castle, Delaware), which was carried out at UMASS, was also used to investigate the mechanical properties of the clot analogs. The test was carried out using a submersion compression clamp in the controlled force mode, in saline at 37°C. The samples were cut to have an approximate height of 3mm and a calipers was used to measure the diameter. The samples (n=5 for each group) were first subjected to a preload force of 0.01N followed by a compression force ramp to 15N at a rate of 0.5N/min, according to [5].

Histology

Sections of both the contracted and non-contracted clot analogs were fixed in a 10% buffered formalin solution after removal from the incubator, and left for 48 hours. The samples were then embedded in a paraffin wax and cut into 5µm sections. The section were the dewaxed and hydrated with distilled water in preparation for staining. MSB staining was selected as an appropriate method to stain for fibrin and erythrocytes [3], [4].

SEM

The analog samples were fixed with 2.5% glutaraldehyde and dehydrated in a series of ethanol concentrations up to 100%. The samples were frozen in liquid nitrogen and fractured so that the interior surface of the clot analogs could be examined. The samples were then critical-point dried, mounted and sputter-coated with iridium.

RESULTS

The results for the DMA testing are shown in Figure 1. The contracted clots were found to be stiffer than the non-contracted clots across all 3 hematocrits. The contracted clots were found to fall within the range of behavior the human red emboli.

Figure 1: Stress-strain plot for the DMA testing comparing the contracted and non-contracted clot analogs, with varying hematocrit, with human red emboli tested by Chueh et al. [4] shown in red.

Figure 2 compares SEM images from both non-contracted and contracted clots with a 40% hematocrit. The microstructure of the two clot analogs were found to vary significantly.

Figure 2: SEM images of non-contracted (left) and contracted clots (right) with a 40% hematocrit, with fibrin shown in yellow and RBCs in red.

DISCUSSION

Overall, the contracted clot analogs were found to be stiffer in compression than the non-contracted analogs across all hematocrits. The contracted clot analogs were also found to fall within the range of behavior of the human red emboli, previously tested by Chueh et al. [4] following the same protocol.

Importantly the histological study determined that there was little difference in the fibrin and RBC content when comparing the contracted and non-contracted groups at the same hematocrit levels. However, the SEM images show that the microstructure of both groups varied significantly. Taken together, the significant difference in mechanical properties and microstructure but without an appreciable difference in histology, implies that examination of the histology of explanted human clots alone may not prove to be predictive of the mechanical behavior of the clots in thrombectomy.

The extent of clot contraction was found to depend on the hematocrit, as clots with a greater hematocrit were found to exhibit less mass loss than clots with a lower hematocrit. The RBCs were found to be compacted into the core in all analogs, with the redistribution of platelets and fibrin to the outside of the clot [7]. The non-contracted clots were found to consist of a loose fibrin mesh with typical biconcave-shaped RBCs throughout, whereas the contracted clots consisted of compressed fibrin structures, compacted around polyhedrocyte-shaped RBCs [6]. The remarkable packing and reorganization of red blood cells into polyhedrocytes from there typical bi-concave discoid shape clearly demonstrates the internal contractility of clots brought about by platelets pulling on the fibrin matrix. Polyhedrocyte-shaped RBCs have previously been observed in cardiac-originating human thrombi [7] and it is hypothesized that this shape allows for more efficient packing of RBCs within the clots, thus creating an impermeable seal at the site of vessel injury to prevent bleeding.

In conclusion, it was found that platelet contraction significantly effects the clot microstructure, which in turn can cause an increase in clot stiffness. As this can also affect the clot permeability, it is hypothesized that this may impact the effectiveness of stroke treatments such as thrombolysis and mechanical thrombectomy respectively. We hope to investigate this further in future work.

ARTERIAL STIFFNESS COMPARED ACROSS SCALES: FROM CELLS TO EXTRACELLULAR MATRIX TO VESSELS

INTRODUCTION

The importance of increased arterial stiffness in human disease, although anticipated at the turn of the 20th century, was confirmed in a seminal clinical study that revealed that an increased pulse wave velocity (PWV) is an initiator and indicator of all-cause mortality [1]. There is increasingly greater interest in measuring and understanding arterial stiffness both in basic science studies and clinical assessments. Therefore, in this study, we examine and contrast different methods that have been used to measure and interpret arterial stiffness.

METHODS

Atomic Force Microscopy. Atomic force microscopy (AFM) uses a laser to detect small deflections of a cantilever probe as it interacts with the surface of a specimen. Associated data consist primarily of the applied force (f) and the imposed motion of the probe, often the depth of penetration into the surface (δ). f - δ data are often interpreted using a Hertz solution for the localized indentation of a semi-infinite half-space that exhibits a linearly elastic and isotropic material behavior under small strains and rotations [2]. This yields a Young's modulus E , a measure of the intrinsic compressive material stiffness for this specialized class of material behaviors. The Hertz solution assumes that the half-space is unloaded prior to indentation, a condition that is neither met in vivo (arteries are axially stretched, and distended due to blood pressure) nor ex vivo (loading in cell or organ culture). In particular, the f - δ relationship, and thus the inferred stiffness, depends strongly on the pre-existing state of stress in the material [3, 4].

Biaxial Biomechanical Testing. In biaxial testing, arteries are subjected to axial as well as circumferential tensile loads, thus mimicking in vivo loading. Associated pressure-diameter and axial

force-length data provide direct insight into the structural stiffness of these vessels. A global equilibrium solution reveals that the loads measured during standard biaxial tests on excised cylindrical samples can be related to principal components of the Cauchy stress [5]. Constitutive behavior is typically captured by fitting a strain energy function W to the measured data, from which a linearized spatial material stiffness obtained using the theory of small deformations superimposed on large deformations can be computed, namely:

$$\mathbb{C}_{ijkl} = 2\delta_{ik}F_{iA}^o F_{jB}^o \frac{\partial W}{\partial C_{AB}} + 2\delta_{jk}F_{iA}^o F_{lB}^o \frac{\partial W}{\partial C_{AB}} + 4F_{iA}^o F_{jB}^o F_{kP}^o F_{lQ}^o \frac{\partial^2 W}{\partial C_{AB} \partial C_{PQ}} \bigg|_o, \quad (1)$$

where δ_{ij} is the Kronecker delta and a superscript or subscript o denotes a quantity that is associated with an original finite deformation about which the small superimposed deformation occurs.

Pulse Wave Velocity and Distensibility. Whereas AFM, biaxial testing, and similar methods are used in vitro on excised samples, which generally enables significant experimental control, clinical studies necessarily require less invasive in vivo methods and measurements. The current clinical gold standard measure of arterial stiffness is the carotid-to-femoral PWV [6]. This metric of stiffness is best measured by dividing the centerline distance between two recording sites by the time that it takes the pressure pulse wave to travel between these sites. Nevertheless, intuitive understanding of the PWV often comes from the Moens-Korteweg equation, $PWV = \sqrt{Eh/2\rho a}$, where E is an intrinsic (linear) material stiffness, h is wall thickness, a is luminal radius, and ρ is the mass density of the fluid. Understood in this way, we see that PWV depends on both the intrinsic material stiffness and geometry of the wall, hence rendering it an integrated measure of structural, not material, stiffness. There are,

in addition, other local metrics of structural stiffness that are used clinically. One such metric is the so-called distensibility

$$D = (d_{\text{sys}}^n - d_{\text{dias}}^n) / d_{\text{dias}}^n (P_{\text{sys}} - P_{\text{dias}}), \quad (2)$$

where d is luminal diameter and P is pressure, with sys and dias denoting values at systole and diastole, respectively. The parameter $n = 1$ or 2 , yielding D values that numerically differ by approximately a factor of 2. Note that the Bramwell-Hill form of PWV can be written

$$\text{PWV} = \sqrt{1/\rho D} \quad (3)$$

for $n = 2$, hence localizing the value of the PWV.

Quantitative Comparison of Methods. To illustrate the effect of different loading regimens of AFM and biaxial testing, we proceeded as follows. First, we assessed the difference in compressive vs. tensile stress-strain behavior by simulating isochoric uniaxial compression in the radial direction (traction-free circumferentially and axially) as well as equibiaxial stretching in the circumferential and axial directions (traction-free radially) of rabbit thoracic aorta described by Fung strain energy functions specifically parameterized under compressive and tensile conditions [7, 8]. Second, we simulated inflation and axial extension of a cylindrical tube consisting of a Fung material [8] to illustrate effects of axial stretching on circumferential linearized stiffness (biaxial coupling; Eq. 1). Third, we simulated the effect of in-plane equibiaxial stretching of an isotropic Fung material (parameterized by minimizing the circumferential and axial Cauchy stress difference to simulated anisotropic data [8]) on out-of-plane compression tests [3]. Fourth, we quantitatively compared literature values for these metrics.

RESULTS

Compressive and Tensile behaviors Intrinsically Differ.

10% uniaxial compression ($\lambda_r = 0.90$) leads to a compressive Cauchy stress of 19.9 kPa, whereas 10% equibiaxial tension ($\lambda_\theta = \lambda_z = 1.10$) yields much lower stresses of 3.36 kPa (circumferentially) and 1.41 kPa (axially).

Circumferential Material Stiffness Depends on Axial Stretch. At a physiological luminal pressure of 120 mmHg, increasing axial stretch from 1.0 to 1.7 causes $C_{\theta\theta\theta\theta}$ (Eq. 1) to increase from 1.13 MPa to 1.95 MPa.

In-plane Pre-stretch Has a Dramatic Effect on Out-of-plane Indentation Stiffness. With an increase in equibiaxial in-plane stretch from $\lambda_\theta = \lambda_z = 1.0$ to 1.7 (i.e., from an unloaded to a physiologically stretched state), indentation stiffness increases 152-fold, from 0.095 kN/m to 14.41 kN/m.

Stiffness Values Reported in Literature for the Same Species and Vessel Show Large Dispersion. Results are shown in Table 1. Note the vast difference in material stiffness values derived from AFM (~20 kPa) and biaxial testing (~2 MPa). As PWV is a structural stiffness metric, PWV values cannot be directly compared to material stiffness metrics.

DISCUSSION

The many different metrics of arterial stiffness reported in the literature have different theoretical underpinnings and thus different meanings. Values of stiffness reported in literature (some compressive, some shear, most tensile) differ by orders of magnitude. In this study, we show that these differences can indeed be expected for highly nonlinear material behaviors when assessed relative to different configurations, ranging from otherwise unloaded to in vivo relevant. Caution is thus warranted when comparing values of stiffness across studies and interpreting fundamental implications of a particular metric.

REVIEW OF HYPERELASTIC MODELING OF BRAIN TISSUE

Kristen M. Cirincione and Joshua H. Smith

Department of Mechanical Engineering
Lafayette College
Easton, PA, USA

INTRODUCTION

Efforts to determine the mechanical behavior of brain tissue have occurred over the past several decades. Brain tissue was initially modeled as a linearly elastic material, with efforts limited to measuring a Young's modulus and shear modulus. However, researchers quickly determined that the behavior was more complex, with nonlinear stress-strain and time-dependent responses being observed in experiments. In addition, brain tissue is porous, and flow through the tissue has been connected to the physiology of the tissue and to diseases and their treatments. This has motivated researchers to model brain tissue as either single phase or biphasic and to model the mechanical behavior as hyperelastic and/or viscoelastic. In addition, researchers have considered the effect of the species, age of the tissue (i.e., infant vs. adult), region of the brain, homogeneity and directionality of extracted samples, and other experimental parameters such as how the tissue is preserved.

Despite a long history of experimental studies, there continues to be new contributions each year, with limited consistency amongst the results. Therefore, in order to make further progress in the field of brain tissue modeling, it is necessary to investigate the differences in modeling choices that arise among research groups. We focus our efforts on the modeling of the nonlinear mechanical behavior through the use of hyperelastic strain energy functions.

METHODS

Due to our interest in modeling the medical procedure convection-enhanced delivery [1] and the disease of hydrocephalus [2], we were familiar with a multitude of studies that

report on the mechanical behavior of brain tissue. However, for completeness, we conducted a literature review using the search engine Web of Science on the following keywords: brain hyperelastic, brain compression testing, brain tension testing, brain shear testing, and brain indentation testing. Additionally, we conducted a cited reference search on each of the previously identified articles to find any other articles that were not found through the keyword search.

RESULTS

Through our literature review, we found a total of 41 articles that reported on the hyperelastic material properties of brain tissue, with the earliest article dating from 1997. While there are many other articles on the mechanical behavior of brain tissue, they focus on viscoelasticity or report experimental stress-strain or stress-relaxation data without any mathematical characterization. In the articles that report hyperelastic parameter fittings, the strain energy functions include, but are not limited to, the Fung, Gent, hyperfoam, Maxwell, Mooney-Rivlin, Neo-Hookean, Ogden, and polynomial. Of these, the Ogden strain energy function was the most used (Table 1), so we focus the remainder of this abstract on that one function.

The most commonly used expression of the Ogden strain energy function for incompressible tissue is

$$W = \sum_{i=1}^N \frac{\mu_i}{\alpha_i^2} (\lambda_1^{\alpha_i} + \lambda_2^{\alpha_i} + \lambda_3^{\alpha_i} - 3), \quad (1)$$

where λ_i are the principal stretch ratios, α_i govern the shape of the stretch-stress curve, and μ_i relate to the infinitesimal shear modulus.

Table 1. Number of articles that report hyperelastic material properties for brain tissue. Some articles considered more than one function.

	Min	Max	
Compression	−1.8	−1.9	[7]
	−15.5	−22.8	[15]
	−25.71	−50.0	[16]
	−12.67	−19.54	[17]
Tension	−26.6	−43.6	[15]
	−0.01	−0.16	[16]
	+4.52	+15.54	[17]
Shear	−21.7	−25.6	[15]
	−19.13	−28.74	[16]
Multiple Modes	−18.7	−25.3	[15]
	−20.47	−30.64	[16]
	−21.27	−28.41	[19]

While some researchers fit this Ogden strain energy function to a single loading mode [3–17], others fit it simultaneously to multiple loading modes [15, 16, 18, 19]. Each of the studies that fit data from a single loading mode used a single term in the Ogden function (i.e., $N = 1$). While three studies fit multiple loadings using a single term [15, 16, 19], one used multiple terms [18].

Focusing on studies that modeled brain tissue with the one-term Ogden function, values for the parameter α_1 in Equation 1 varied quite extensively in terms of both value and sign (see Table 2 for representative values for human brain tissue). Some researchers found α_1 to be negative [4, 7, 11, 15, 16, 19], others found it to be positive [3, 5, 6, 8–10, 12–14], and some found it could be either [17]. Even among studies from the same research group, the sign of α_1 was not always found to be consistent [10, 11].

DISCUSSION

The parameter values associated with the Ogden strain energy function vary quite extensively, most likely due to differences in experimental testing protocols. At least for human brain tissue, fitting parameter values to multiple loading modes showed more consistency across different studies than did fitting a single mode (Table 2).

While Equation 1 is the most commonly used form of the Ogden strain energy function, other researchers (for example, [20–23]) have utilized a compressible form based on the deviatoric stretch ratios $\bar{\lambda}_i$,

$$W = \sum_{i=1}^N \frac{2\mu_i}{\alpha_i^2} \left(\bar{\lambda}_1^{\alpha_i} + \bar{\lambda}_2^{\alpha_i} + \bar{\lambda}_3^{\alpha_i} - 3 \right) - \sum_{i=1}^N \frac{1}{D_i} (J - 1)^{2i}, \quad (2)$$

that is found in the finite-element solver ABAQUS. While Equation 2 reduces to Equation 1 under the assumption of incompressibility, modelers adopting parameter values from literature must be careful to use values that are consistent with the form of the Ogden function that they have selected.

INTRODUCTION

Lung disease is the third leading cause of death in the United States, following cancer and heart disease, and costs over \$50 billion annually [1]. Lung mechanics is still in its nascency; the escalating number of fatalities accentuates the importance of understanding pulmonary structure and function, and how disease alters tissue properties. Characterization of bronchial material response is practically nonexistent while fundamental for the creation of future technological and bioengineering tools capable of improving diagnosis and personalizing therapies. To address this need, here we explore the mechanical viscoelasticity of the lung.

One unique feature of the lung is the regulation of each breath: inhalation can be short or fast and deep or shallow in response to stimulus or conscious control. Investigating the temporal loading of this organ can produce a potential biomarker and clinical metric to contrast healthy and diseased states. However, only one other viscoelastic airway study has been conducted to date; and it was limited to the trachea, whereas distal intra-parenchymal airways are the site of chronic lung disease. Viscoelastic aspects of the lung, experimentally measured from proximal and distal airways, are analyzed in this study. Notable hysteresis and preconditioning effects are observed. Multiple discrete rheological element models are proposed to evaluate airway stress relaxation. Anisotropic and heterogeneous trends are examined with respect to recent microstructural and tissue composition results.

METHODS

Samples were obtained from five fresh pig lungs and collected from three regions (trachea, large bronchi, and small bronchi) and two directions per region (axial and circumferential) with $N > 20$ per category (circumferential trachea, large bronchi, small bronchi: CT, CLB, CSB; axial trachea, large bronchi, small bronchi: AT, ALB, ASB). Uniaxial

tensile tests were conducted (Instron 5848 Microtester, 10N load cell), with samples preconditioned five times to 35% elongation at a strain rate of 1%/sec (Fig. 1A) [2]. Energy dissipation (kPa/kPa) was defined as the hysteresis area (region between loading and unloading stress-strain curves) normalized by the cycle stress range (Fig. 1B). The effect of preconditioning between the first and fifth cycles was compared. The sixth loading curve held for 300s informed stress relaxation response per tissue category.

Figure 1: (A) Representative hysteresis area for 1st and 5th cycle of loading and unloading; (B) Energy dissipation per region and orientation.

Discrete rheological element models, including Maxwell, Kelvin-Voigt, Standard Linear Solid (SLS) and Standard Linear Fluid, were used to describe the tissue relaxation modulus E_{relax} (diminishing stress normalized by fixed strain). Amongst these models, SLS was most appropriate yet unable to capture the initial stress reduction (Figure 2A). Better representative of biological tissues with varying sequentially engaged molecular segments are the Maxwell-Weichert (MW) and the fractional order derivative SLS (FSLs) models (Table 1). The latter model defined a merged spring-dashpot with power α , which behaved between a pure elastic ($\alpha=0$) and viscous material ($\alpha=1$) [3]. Linear

viscoelastic models were only considered as tracheal soft connective tissue was previously documented as insignificantly nonlinear [4]. MATLAB's non-linear least squares algorithm, *lsqnonlin*, was used to minimize the difference between the model stress and experimentally measured stress. The averaged correlation coefficient R^2 and residuals determined the best fit model. All results were subject to a Box-Cox transformation, followed by one-way ANOVA and Bonferroni post-hoc analysis with significance set at $p < 0.05$ (MATLAB Statistics Toolbox, Mathworks Inc.). Results presented as mean \pm standard error, and *denotes $p < 0.001$.

RESULTS

Preconditioning effects were notable between the first and fifth hysteresis samples (Fig. 1A). Circumferential samples were more subject to the effects of preconditioning than axial tissues: hysteresis area was seen to narrow and stress range decreased. Trachea samples required more preconditioning than large or small bronchi samples reproducibly behave. As preconditioning effects mirrored that of energy loss, results are not shown.

Energy dissipation was significantly higher in circumferential specimens compared to axial counterparts (Fig. 1B, $p < 0.001$). Amongst regions (combined axial and circumferential response), the trachea displayed significantly greater energy dissipation compared to large and small bronchi ($p < 0.001$).

Table 1 summarized model schematics, fit performances, and $E_{relax}(t)$. Of the three select models, all performed reasonably well with R^2 greater than 0.90. FLSL demonstrated superior fit to experimental stress relaxation data ($R^2 = 0.994$) and replicated the initial stress decay and asymptotic response the best, all with fewer parameters than MW.

The FLSL α parameter significantly differed for various regions and orientations (Fig. 2B). Anisotropy was only observed between circumferential and axial samples of the trachea and large bronchi ($p < 0.001$), not amongst small bronchi specimens. Trachea samples exhibited heterogeneity with significantly greater α than either the large or small bronchi ($p < 0.001$).

DISCUSSION

Energy dissipation is found to be associated with glycosaminoglycan (GAG) content. Previous studies reveal GAG degradation results in reduced energy efficiency [5]; additionally, GAG

bronchial heterogeneity uniformly increases from the trachea to the small bronchi [6]. These past studies speculate the energy inefficiency of the trachea; our viscoelastic study substantiates these inferences, finding energy dissipation and GAG are directly and inversely related.

Figure 2: (A) SLS, MW, and FLSL fit to experimental data; (B) FLSL α parameter per region and orientation.

Measures of GAG content combine circumferential and axial behavior, however, the reduction of axial energy dissipation indicates the engagement of collagen and elastin fibers (Fig. 1B). The potential energy efficiency of these axially aligned elastic components drastically reduces the energy loss seen in axial tension [2].

Conversely, amongst the various regions of axial specimens, small bronchi are observed to have the greatest energy loss despite exhibiting greatest GAG content. Fiber architecture could potentially explain the counterintuitive results: small bronchi have taut and straightened fibers, whereas crimped fibers in the trachea need to be unwound before conducting stress [6]. Therefore, the reversed hysteresis trends axially can be due to taut fibers in small bronchi extending beyond their ideal physiological elastic regime and becoming inefficient.

Similar to parenchymal indentation tests with comparable α values, fits indicate pulmonary tissue relaxation is better represented by the FLSL power law than exponential decay [3]. α 's are likewise more elastic (closer to 0) than viscous [3]. Regional α dependencies could possibly stem from thicker fibers in larger proximal airways, with increased viscous cross-links causing greater fluidic response; regional histology images substantiating this speculation are lacking in the literature but would elucidate the potential role of microstructure in mechanics. Energy efficiency heterogeneity is echoed in α , but overarching tissue anisotropy is insignificant; this suggests behavioral partitioning, where other discrete elements harbor the anisotropic response (indeed E_1 and η_1 present distinct direction-dependency).

This first assessment of proximal and distal bronchi viscoelasticity highlights significant anisotropy and heterogeneity, and establishes a novel relationship between tissue microstructure and energy dissipation. The intra-parenchymal results emphasize notable regional dependency, limiting extrapolation of tracheal mechanics to distal bronchi. Rheological models of bronchial viscoelasticity have the potential to yield novel diagnostic metrics of lung disease, as seen for breast tumors [3]; future studies, including dynamic viscoelasticity to represent the active breathing cycle, along with characterization and simulation of asthmatic and bronchitis human pulmonary tissue, can hold the same promise for advancements in pulmonary research.

DOES THE RANDOM GENERATION ALGORITHM AFFECT THE RESULTS OF NUMERICAL MODELS FOR MECHANICAL RESPONSE OF FILAMENTOUS NETWORKS?

INTRODUCTION

Fibrous protein networks are the building blocks of many different biological systems such as the extracellular matrix of soft tissues. There have been different numerical and experimental studies in order to better understand the unique mechanical response of fiber networks [1-2]. It is found that the mechanical response of these networks is a function of mechanical properties of individual fibers and their arrangement with respect to each other. Furthermore, it is known that the mechanical behavior of fibrous structures is non-affine, which means that displacement gradients measured locally are different from the uniform applied far-field strains.

In numerical simulations, the microstructure of these networks is often represented by the Mikado algorithm [3-4]. This algorithm is based on depositing randomly oriented filaments of a given length into a simulation domain. However, the Mikado model may not properly represent the microstructure of all natural systems as there exist fibrous structures whose microstructure is clearly different from than the one obtained from the Mikado algorithm [5-7]. For example, extracellular matrix is created from the assembly and growth of collagen monomers from many nucleation sites. The microstructure of these networks cannot be represented by the Mikado algorithm.

Here, we create random fiber networks by growing filaments from randomly positioned nucleation sites as well by using the Mikado algorithm. We will then conduct numerical simulations and characterize the mechanical response of these fiber networks in order to determine the similarities and differences in the behavior of networks constructed by these two different generation algorithms.

METHODS

Two-dimensional (2D) random fiber networks are created by two different algorithms. In the first method, fibers of length L_0 are deposited in a square domain in random directions. Rigid crosslinks are defined at the intersection of two fibers. The coordination number of these networks is about four as two fibers cross each other at crosslinks. Note that the presence of dangling ends, which will be deleted later because they do not contribute to the elastic energy, will slightly reduce the actual coordination number.

We also generate another type of 2D fiber networks by first distributing a given number of seed points into a square domain. Fibers are grown at a constant rate from each of these seed points in random directions. We stop the growth of a filament when it reaches another fiber or the boundary of the simulation domain. The coordination number of these networks will be three, which is lower than that of the networks created by the Mikado algorithm.

We write the total free energy of the structures in terms of the bending and axial energy of their constituting filaments, i.e.

$$U = \frac{1}{2} \sum \int (\eta u'^2 + \kappa \phi'^2) ds$$

In the above equation, the filaments are represented as cylindrical rods with axial stiffness η and bending stiffness κ . Furthermore, ϕ' and u' are the curvature and axial strain of the filaments, respectively. The networks are subjected to displacement boundary conditions and their deformation field is obtained from an energy minimization procedure.

The mechanical behavior of these networks will be a function of fiber density and the ratio of bending stiffness and axial stiffness of the filaments. The fiber density is a measure of how many fibers exist in the simulation box. The ratio of bending stiffness and axial stiffness represents the amount of flexibility of the filaments, i.e. the lower this ratio is, the more flexible the filaments are. Here, we use numerical simulations in order to characterize the effects of these parameters on the mechanical response of the Mikado fiber networks and the networks that are created by growing filaments from nucleation sites.

Figure 1: Typical random fiber networks created by different generation algorithm. The network shown on the right is created by the Mikado algorithm and the one on the left is created from the growth of random lines from nucleation sites.

RESULTS

The normalized Young's modulus of the fiber networks created by the Mikado algorithm and the growing one, as a function of the fiber density, is shown in Figure 2. The fiber density represents the amount of filaments per unit area in each structure. It is seen that the elasticity of both network types increases with increasing the fiber density and gets closer to its affine estimate. The affine effective Young's modulus of each network is obtained from assuming the deformation of each crosslink follows the applied macroscopic displacement. Thus, the amount of stretch in each filament is known and their energy can be found in order to determine the affine Young's modulus [7].

DISCUSSION

Figure 2 shows that there exists a significant difference in the effective elasticity of the networks generated by different algorithms. The effective Young's modulus of Mikado networks reaches the affine estimate with increasing the fiber density. Nevertheless, the effective Young's modulus of the other network type does not reach the affine estimate. This difference might be because the coordination number of these network is three and much lower than what required per by the Maxwell central-force isostatic threshold. Thus, the bending energy of filaments will be higher than their stretching energy.

Despite the above difference, Figure 2 shows that the effective Young's modulus of both networks shows a similar scaling behavior, i.e. their Young's modulus scales as a power law when the fiber density is smaller than a critical value. This observation is possibly because with decreasing the fiber density, the bending mode of deformation becomes prominent in both network types. Nevertheless, with increasing the fiber density, which accompanies a significant reduction of fiber segment

length, the stretching mode of deformation starts to become more prominent and the power-law dependence of the effective Young's modulus on fiber density disappears.

Figure 2: The normalized effective Young's moduli of different types of random fiber networks as a function of their fiber density. It is seen that increasing the line density causes the mechanical response of both fiber networks to become more affine. A similar power law dependence on the fiber density is also observed. The Mikado fiber networks shows a significantly higher effective Young's modulus compared to the other type of fiber networks when the fiber density is kept constant.

INTRODUCTION

Increased central artery stiffness is an initiator and indicator of cardiovascular disease and a strong predictor of all-cause mortality, particularly deaths due to myocardial infarction, stroke, and heart failure [1]. Such stiffening is frequently associated with hypertension and aging. Hutchinson-Gilford progeria syndrome (HGPS) is an ultra-rare genetic disorder characterized by accelerated aging and premature death due to cardiovascular disease. Essential features of cardio-vascular conditions in HGPS include arterial stiffening and remodeling. Nevertheless, the development of microstructural changes in HGPS arteries involved in this process are not well characterized. Our objective was to evaluate cardiac function and biomechanically phenotype the aorta in a murine model of HGPS.

METHODS

We used the *Lmna*^{G609G/G609G} knock-in mouse model which mimics the genetics and pathophysiology of HGPS [2]. Female and male wild-type control (*Lmna*^{+/+}) and HGPS (*Lmna*^{G609G/G609G}) mice were studied at 14 weeks (100 days) and 20 weeks (140 days) of age. Noninvasive echocardiographic and vascular ultrasonic data were collected from which systolic and diastolic function as well as wall thickness of the left ventricle were quantified. The pulse wave velocity was calculated from estimates of the aortic path length traveled by the pulse wave obtained from micro-CT scans, and pulse wave transit times were assessed from pulse wave Doppler measurements near the aortic root and iliac bifurcation [3].

We used a custom experimental testing system and theoretical framework to biomechanically phenotype central arteries from HGPS mice [4]. In particular, we assessed *in vivo* extensibility and distensibility, multiaxial wall stiffness, elastic stored energy capacity, and smooth muscle capacity among other metrics, and we correlated our

findings with quantitative histology and *in vivo* measurements using ultrasound.

These findings were compared with similar data from mouse models of normal aging (up to 2 years) as well as from mice with severe elastopathy, noting that loss of elastic fiber integrity is a hallmark of normal aging in human central arteries.

RESULTS

HGPS (*Lmna*^{G609G/G609G}) mice survived to the intended 140 days of age but with significantly lower body mass than the age-matched wild-type controls (*Lmna*^{+/+}). Cardiac function was intact with trends of diastolic dysfunction and left ventricular wall thickening. Pulse wave velocity increased significantly due to marked shortening of pulse transit time, with no significant differences in aortic length.

In contrast to otherwise notable changes due to normal vascular aging or severe elastopathy, the biomechanical phenotype of the HGPS mice at 140 days was extreme and independent of sex: there was a dramatic loss of distensibility and extensibility, a striking reduction in wall stress and material stiffness, an unprecedented loss of elastic energy storage capacity, and a near total loss of vasoactive capacity in all central vessels from the *Lmna*^{G609G/G609G} progeria mice when assessed at 140 days of age. Of particular note, there was also excessive thickening of the arterial wall due to significant increases in medial and adventitial proteoglycans/glycosaminoglycans as well as reduced undulation in fibrillar collagen.

Notwithstanding similar body mass between 100- and 140-day-old HGPS mice, the vascular biomechanical phenotype at 100 days of age was significantly milder when compared with 140-day-old HGPS mice. Importantly, little proteoglycan/glycosaminoglycan was observed in the aorta at 100 days of age, and only a slight loss in smooth muscle contractile function was observed in response to either high potassium

chloride or phenylephrine. Given these observations, we then built a particle-based computational model of the arterial wall that enabled us to simulate changes in the overall biomechanical phenotype as a function of stochastically distributed local changes in cell contraction or matrix composition.

DISCUSSION

A primary function of central arteries is to store elastic energy during systole and to use this energy during diastole to augment blood flow, including both retrograde flow to perfuse the heart and antegrade flow to reduce the pulsatility to end organs. The loss of energy storage capacity we observed in HGPS mice is unprecedented even when compared to the marked losses seen in normal aging and severe elastopathy, which is expected to compromise its Windkessel effect.

Moreover, there was a significant accumulation of proteoglycans / glycosaminoglycans in the aortic wall, resulting in increased wall thickness and structural stiffness. Consistent with this, our results revealed marked increases in pulse wave velocity, a clinical indicator of central artery stiffness and all-cause morbidity and mortality. Our study suggests that accumulation of proteoglycans / glycosaminoglycans plays a critical role in vascular remodeling in the aorta and the cardiovascular disease in HGPS.

INTRODUCTION

Collagen fibers play a central role in the biomechanical behavior of connective tissues, and is therefore important in physiology and pathophysiology. [1, 2] Studies using scanning electron, polarized-light or multi-photon microscopy have shown that the collagen fibers of many connective tissues, such as sclera, skin and articular cartilage, are interwoven. [3, 4] However, the effects of this interweaving on the mechanical behavior of the tissues remain unknown. We hypothesized that tissue formed by interweaving fibers will have a stiffer behavior than if the fibers are not interwoven.

Our primary goal was to quantify the effects of the interweaving architecture of collagen fibers on the structural stiffness of connective tissues. A secondary goal was to determine how the effects of interweaving change with collagen volume fraction, fiber cross-section, and fiber bending stiffness.

Modeling. We reconstructed a model representing a region of interest $100 \mu\text{m} \times 100 \mu\text{m} \times 12 \mu\text{m}$. All fibers in a given model were identical. The model has fibers in two directions: warp and weft. The number of fibers (N) was the same in both directions. As a first approximation the fibers were modeled as linear isotropic and homogeneous, with Young's modulus of 3 MPa, and incompressible (Poisson's ratio = 0.49). We assigned an equi-biaxial stretch of 20% as displacement boundary conditions to the ends of each fiber.

Virtual experiments: To test the effects of collagen volume fraction, we varied the number of fibers within the same region of interest: $N = \{2, 3, 4, 5, 6, 7\}$, resulting in models with collagen volume fractions of 9%, 14%, 19%, 24%, 28% and 33%.

To test the effects of fiber bending stiffness, we solved two families of models. First models without bending stiffness by using truss elements. Second, models with bending stiffness by using solid elements.

Figure 1. Example of interwoven collagen fibers in the human posterior sclera imaged with polarized light microscopy.

METHODS

To have full control of the model geometry and boundary conditions, we decided to do the study using finite element modeling.

Figure 2. Example models of interweaving fibers (left column) and fibril bundles (middle and right columns) with collagen volume fraction of 24%. Top row: models with truss elements without bending stiffness. Bottom row: models with solid elements with bending stiffness.

To test the effect of collagen fiber cross-section, we did the following: In models without bending stiffness (truss elements), fibers were split into two ($n_f = 2$) or three ($n_f = 3$) “fibril” bundles of smaller cross-section. In models with bending stiffness (solid elements), fiber cross section shape was varied from the original circular cross section, to elliptical cross sections with major axis W and minor axis H . The values of W and H were selected to be consistent with the width and height of the fibril groups in the models without bending stiffness. Total cross-sectional area was the same in all models, with single fibers or multiple fibrils, and independent of elliptical shape. Equivalent non-interweaving were also developed for comparison.

Outcome measures: Structural stiffness was computed as the sum of the response forces (the forces necessary to obtain the prescribed displacement). A stiffness increase ratio was computed by dividing the structural stiffness of a model with interweaving fibers by the stiffness of the corresponding model one without interweaving fibers (non-interweaving).

RESULTS

Example results obtained from the models without bending stiffness are shown in Figures 3 and 4. Results from models with bending stiffness are shown in Figures 5 and 6.

Figure 3. Contour plots of von Mises stress in models without bending stiffness. Interweaving fibers (top right) carried more load (stress) than non-interweaving ones (top left). The load-carrying capacity of the interweaving architecture was further enhanced by splitting fibers into fibrils (bottom row).

Figure 4. Structural stiffness (left) and stiffness increase ratio (right) as a function of collagen volume fraction in models without bending stiffness. Structural stiffness of interweaving fibers was higher than that of non-interweaving fibers. Stiffness increase ratio grew nonlinearly with collagen volume fraction and was higher in fibril bundles.

Figure 5. Contour plots of von Mises stress in models with bending stiffness. The interweaving effects were similar to those in models without bending stiffness (Figure 3). The major difference was that the high stress in models with bending stiffness was mainly located at the intersection of two fibers/fibril bundles, compared with between the intersections in models without bending stiffness.

Figure 6. Structural stiffness (left) and stiffness increase ratio (right) as a function of collagen volume fraction in models with bending stiffness. In general, the magnitude and trend of structural stiffness is similar to that observed in models without bending stiffness (Figure 4). The stiffness increase ratios were lower, than in the models with no bending stiffness.

DISCUSSION

Four main findings arise from this work. First, the interweaving architecture of collagen fibers can enhance the structural stiffness of connective tissues. Second, the interweaving effects are small for low collagen volume fractions, but increase rapidly suggesting that for collagen-rich tissues the effects may be much larger. Third, collagen fiber bending stiffness can affect the stress distribution of the interweaving architecture, but its influence on the structural stiffness is limited. Fourth, the interweaving effects can be further enhanced if fibers are split into fibril bundles.

The results from our simulations should be confirmed experimentally. Also, models with geometries and mechanical properties more closely resembling biological tissues should be studied.

Our results suggest that characterizing fiber interweaving may be of important to understand how collagenous soft tissues bear loads.

A CONNECTOME-BASED NETWORK MODEL TO SIMULATE PRION-LIKE PROTEIN PROPAGATION IN NEURODEGENERATIVE DISEASES

Xuesong Zhang (1), Johannes Weickenmeier (1)

Stevens Institute of Technology
Hoboken, NJ 07030

INTRODUCTION

The prion-like spreading of toxic proteins in the brain plays a crucial role in the pathogenesis of neurodegenerative diseases (ND) such as Alzheimer's disease (AD), Parkinson's disease (PD), amyotrophic lateral sclerosis or Lou Gehrig's disease (ALS), and chronic traumatic encephalopathy (CTE) [1]. Once this particular group of proteins, including amyloid-beta and tau in AD and CTE, and alpha-synuclein in PD, start misfolding, they aggregate in plaques and tangles, that cause structural and functional dysfunction of the brain [2]. Accelerated recruitment of healthy brain tissue produces common propagation patterns of principal biomarkers in ND.

Based on the development of animal models for Alzheimer's disease, it has been shown that there is a distinct chronology in the development of the disease and the spreading of toxic proteins. There is growing evidence, that these characteristic modes of progression are linked to the structural anatomy of the brain [3]. Amyloid-beta plaques in AD are sticky aggregations of misfolded amyloid beta protein that have been found to be highly neurotoxic. Neighboring neuron cells will ultimately die, leading to cerebral atrophy on the organ level [4]. As AD progresses, healthy brain tissue is progressively infested and leads to significant changes in behavior, the loss of memory and motor control, and ultimately death.

The second dominant prion associated with AD is tau [5]. Tau can turn toxic and form neurofibrillary tangles, that causes healthy axonal pathways to breakdown. The resulting disruption of regular nutrient transport along the axon network manifests in the accelerated spreading of the disease and the progressive recruitment of functional connected regions of the brain. Animal studies have shown that misfolded proteins emerge downstream of regular transport pathways associated with the axon network [6].

The spreading of toxic amyloid beta and tau are fundamental contributors to the progression of AD; yet, we know very little about

their inter- and intracellular mechanisms behind the prion-like progression in ND and our understanding of progression patterns on the organ level is primarily based on studies of diseased patients [1].

Figure 1: Segmentation and tractography of an anatomical scan (A) and of diffusion tensor imaging (B) provides a three-dimensional reconstruction of the brain (C) and allows to incorporate a physical representation of the axon network.

The lack of experimental data and quantitative tools to model and predict the progression of NDs on the organ level, motivates the development of mathematical and computational models capable of representing known progression mechanisms. Thus far, most models use a graph-theory based representation of the structural and functional connectivity of the axon network [3]. While many of these models are able to capture hallmark features of cerebral atrophy, most remain limited in studying the relation between inter- and intracellular propagation mechanisms.

We created a high-fidelity finite element (FE) of the brain to study the propagation of misfolded tau along the axon network. Our ultimate goal is to predict the temporal and spatial distribution of toxic tau on the whole organ level. In a first step, we demonstrate that a reaction-diffusion equation-based propagation model is capable of reproducing characteristic progression patterns. Data-driven calibration and validation of the model will be part of future work.

METHODS

Our patient-specific high-fidelity model is based on medical images of a 32-year male volunteer. We obtained a T2-weighted magnetic resonance imaging scan with 160 transverse slices at a 1mm slice distance and an in-plane resolution of 256x256 voxels of edge size 0.938mm. We segmented gray matter, white matter, ventricles, and the cerebellum using Simpleware and generated a triangulated mesh of the patient's brain with a total of 395,409 elements [7]. The volunteer's connectome was reconstructed from accompanying diffusion tensor images (DTI) on a 7T Siemens scanner. We used the open source image processing library FSL to obtain the tractogram.

By co-registering the T2-weighted and DTI scan, we were able to merge the tractogram and the volumetric brain model, see Fig. 1. We convert each fiber track into a string of trusses and physically connect the brain and axon network models by merging nodes in both meshes that are closer together than a physically meaningful distance ϵ . In this way, we establish connectivity between the axon network and gray matter tissue, see Fig 1C.

We postulate that prions diffuse along the inter- and intra-cellular space of the brain. This mimics the aggregation and spreading of prions in the extracellular space of gray and white matter as well as the diffusion of toxic tau along the functionally and structurally connected axon network.

The toxic concentration c of both misfolded proteins is governed by the reaction diffusion equation [4]

$$\frac{dc}{dt} = \text{Div}(\mathbf{D} \cdot \nabla c) + \alpha c (1 - c), \quad (1)$$

where \mathbf{D} denotes the anisotropic spreading of misfolded protein. Our source term follows the classical Fisher-Kolmogorov equation and is a popular nonlinear reaction-diffusion equation that was initially proposed to model the spreading of a favored gene in population dynamics. Parameter α determines the growth rate, i.e. the speed at which healthy tissue is recruited by the propagating toxic proteins. The simulation is driven by initially seeding a minimal concentration of toxic protein in a disease specific region known from literature and will progress until the entire brain is affected, see Fig. 2A. We investigate the impact of seeding in regions associated with AD, PD, and ALS for which we have qualitative data from literature [1,2].

RESULTS AND DISCUSSION

We present our first results for the example of tau inclusions and their progression pattern in AD. Fig 2A shows the clinically observed spreading found in AD patients [1]. We note, that our three-dimensional brain model- in combination with the simple physics-based prion diffusion model- properly reproduces the clinically observed response [7]. Although we were not able to fully quantify the influence of the axon network model on the organ-level progression pattern, our initial analysis suggests that the integration of the high-fidelity brain mesh

together with the axon network model, will allow us to predict tau progression on a local scale, see Fig. 2D. As a next step, we will calibrate our model parameters using toxic tau progression data obtained from animal models [5]. Our ultimate goal is to investigate the role of intercellular amyloid beta progression and intracellular tau propagation in order to understand the dominating disease mechanisms in AD.

Figure 2: (A) Propagation pattern of tau inclusions observed in AD. The characteristic temporal progression of brain infestation was identified on the basis of AD patient brains [1]. (B) Prediction obtained using our three-dimensional ND model. Seeding of toxic tau in the entorhinal cortex (EC) accurately reproduces the clinically observed progression. (C) The progression of tau inclusion along the axon network based on initial seeding in the EC. (D) Progression along the axon network in the EC during the initial stages of AD.

DETERMINATION OF THE LINEAR VISCOELASTIC BEHAVIOR OF APONEUROSIS

INTRODUCTION

Aponeuroses are strong elastic components that transmit force efficiently from muscle to bone to assist with locomotion. The aponeurosis acts as a transition site from muscle to tendon, which then attaches to bone [1]. The mechanical behavior of the aponeurosis is thus of great interest, as its role in the body is force transmission. There have been relatively few studies of aponeurosis material properties to date [2]. Ongoing debate exists regarding the similarities and differences of the aponeurosis and tendon, which are clouded by a lack of data on aponeurosis material properties. The specific contributions that each fibrous tissue has on muscle-tendon unit mechanics is not fully understood [3]. Determining the material properties of the aponeurosis will provide evidence of its structure and function to identify how it contributes to the movement of the musculoskeletal system.

To further complicate the role of the aponeurosis in the body, many soft tissues exhibit time dependent behavior. To the best of the authors' knowledge, there have been no previous studies investigating the stress relaxation of aponeurosis. The goal of this work is to determine how the rate of relaxation of a sample undergoing stress is affected at different strain levels. This experiment will show if the level of strain affects the relaxation behavior of the aponeurosis.

METHODS

Porcine shoulders were obtained from a local abattoir to extract the triceps brachii muscle for testing. The triceps brachii aponeurosis was dissected from the muscle and the tissue was cut into dog bone samples approximately 20 mm in height by 5 mm in width. All samples were cut parallel to the muscle fiber direction (n=10). Each sample's thickness was measured using a light microscope by taking images across the entire length of the aponeurosis and averaging all of the measurements.

Tensile stress relaxation was performed on each sample with a 5965 Instron uniaxial testing system. Images were taken throughout each trial to determine the precise strain of each sample using a digital image and correlation software. Each sample was coated with graphite powder to enhance strain tracking. The test procedure was as follows: 20 cycles of preconditioning (between 0.5 N and 1 N), then two consecutive stress relaxation steps of approximately 1-2% engineering strain at a rate of 1-2%/sec and 300 seconds of relaxation.

The data was analyzed by first determining stress (equation 1) and the strain values through a digital image and correlation software.

$$\begin{aligned}\sigma &= \text{stress} & \sigma &= \frac{F}{A} \\ F &= \text{force} \\ A &= \text{area}\end{aligned}\tag{1}$$

Then the data was examined through the power series equation of stress (equation 2):

$$\sigma = at^b + C\tag{2}$$

The goal was to determine if the power coefficient (b) in equation 2 was strain dependent or independent at varying strain levels. Also, the power law coefficient (b) that resulted from the first and second strains of each test were compared through a paired two sample t-test for means (p<0.05) using equation 3.

$$t_{n-1} = \frac{\bar{y} - \mu_0}{SE(\bar{y})}\tag{3}$$

The paired two sample t-test would determine whether the relaxation after the first and second strains of each sample were

comparable. Lastly, the strain and power law coefficient were examined to determine if there was a trend or relationship between the two values. This presents a repeated approach to evaluating if relaxation behavior is dependent on strain level.

RESULTS

The output data from the 5965 Instron uniaxial testing system shows consistent, smooth stress relaxation behavior (Figure 1). The average power law constant of the 10 samples during the first relaxation phase was -0.0952 ± 0.0246 (SD) with an average R^2 value of 0.957 and during the second relaxation phase the average power law constant was -0.0869 ± 0.0077 (SD) with an average R^2 value of 0.977 (Figure 2).

Figure 1: Instron's stress vs. time output data for each sample

Figure 2: Comparison between Ramp 1 and Ramp 2 power law constants with standard deviation error bars

The paired t-test comparing the first and second relaxation phases were not significantly different ($p=0.22$). Comparison between strain and the power law coefficient of the samples yielded an R^2 value of 0.0016 with a linear slope of 0.0005 (Figure 3).

DISCUSSION

While previous studies have investigated the elastic material properties of the aponeurosis [2], we have investigated for the first time the viscoelastic relaxation behavior of the tissue. Our findings show that the rate of relaxation of the aponeurosis between strain levels of 1-4% engineering strain is independent of strain level and does not affect the

relaxation behavior of the aponeurosis (Figures 2 and 3). This is supported through two statistical analyses, one comparing the two separate stress relaxation steps and one investigating the relationship between digital image correlation strain and relaxation rate.

Figure 3: Strain vs. power law coefficient for each relaxation phase (blue circles – Ramp 1, orange squares – Ramp 2)

Future steps include investigation of directional viscoelasticity and fitting of hyperelastic and viscoelastic constitutive models. A more comprehensive material model for aponeurosis could then be applied to a more advanced computational model with attached aponeuroses to a full muscle-tendon unit. Implementations of these models, such as finite element analyses, could investigate how weak or diseased muscle versus healthy muscle interact with the aponeurosis, and potentially use these for post-surgery prediction of muscle function. For example, Rehorn and Blemker concluded that computational models of muscles tested with different dimensions of the aponeurosis impacted the overall location and magnitude of the peak stretches that were conducted within the muscle [4]. Thus, it is clear that the aponeurosis properties play a significant role in *in vivo* muscle function.

It is imperative to determine the material properties of the aponeurosis to ensure similar computational modeling of muscles with attached aponeurosis to *in vivo*. Once the material properties of the aponeurosis are known and studied more thoroughly, it will help improve the overall knowledge of how the aponeurosis contributes to the movement of the musculoskeletal system.

INTRODUCTION

Prostate cancer, one of the most common forms of cancer in America, affects nearly 165,000 men and leads to about 29,000 deaths annually.(1) Magnetic resonance imaging (MRI) has been successful at detecting prostate cancer and locating cancer lesions. However, the spatial accuracy of MR prostate images must still be validated, and appropriate correlation between MRI and histopathology should be made to display the clinical utility of MRI in prostate cancer diagnosis and treatment. Past studies have addressed this problem through the use of MRI-based prostate cutting devices that allow correlation between MRI data and histopathology data from excised prostates.(2-7) The purpose of this study was to address some limitations presented by previous studies and develop a method for 3D comparison between pre-prostatectomy MRI data and post-prostatectomy histological slices.

METHODS

Prostate Specific Membrane Antigen (PSMA) Positron Emission Tomography (PET)/MRI was performed on 10 patients with prostate cancer, both before and after chemohormonal treatment, with an imaging slice thickness of 2.5mm. The post-treatment images were imported into MIMICS (Materialise, Leuven, Belgium), where the boundary of the prostate was contoured under the guidance of an experienced radiologist (Figure 1). The prostate dimensions were measured on each MR image slice and saved for later pathological investigation. The prostate surface was then interpolated between MR image slices and a 3D volume was generated. A 3D model of the prostate was exported into 3-matic design software (Materialise, Leuven, Belgium).

To create a device that consistently cuts the prostate at 2.5mm increments, a mold template was designed in Solidworks (Dassault Systèmes, Waltham, MA). The patient specific prostate surface was subtracted from the mold template volume (Figure 2a). The mold was labeled with the patient study number and anterior/posterior, right/left, and base/apex notations. The model was exported to a stereolithography 3D printer (Form2, Formlabs, Somerville, MA). When the print was finished, it was cleaned, sterilized, and cured in isopropyl alcohol and UV light.

Figure 1: MR images obtained after chemohormonal therapy. Prior to prostatectomy, the prostate was contoured for definition of patient-specific prostate mold boundaries.

The mold was taken to surgical pathology, where it was used to section the prostate following prostatectomy. The slices of prostate were then oriented on the MRI-derived 2D contours, and a picture was taken for later analysis. The prostate slices were then taken for histological analysis.

To analyze the 3D accuracy of the MRI-based prostate mold, the post-resection prostate volume was reconstructed based on the prostate slices from surgical pathology. To do this, contours of the prostate slices were stacked on planes 2.5mm apart (Figure 2b), and lofted to create a 3D volume in Solidworks. A part comparison analysis was then performed in 3-matic to generate quantitative and qualitative regional difference maps comparing the MRI-derived prostate geometry with the representative post-prostatectomy geometry.

Figure 2: a) Mold template to guided parallel 2.5mm cuts in the prostate. After sectioning, outlines of the prostate slices lofted to create a representative post-prostatectomy 3D geometry for surface comparison

RESULTS

The patient-specific molds were used to effectively slice the unfixed prostate at 2.5mm increments. When compared to pre-prostatectomy MRI contours, the post-prostatectomy reconstructed volumes displayed patient-specific variation, as displayed in Table 1 and Figure 3. On average, the post-prostatectomy reconstructed volume dimensions were about 2mm smaller than the predicted MRI volume dimensions. This difference lies below the imaging slice resolution of 2.5mm.

Table 1: Statistics for surface point comparison between pre-prostatectomy MRI and post-prostatectomy slice reconstruction prostate geometries

Figure 3: Comparison between pre-prostatectomy MRI and post-prostatectomy slice reconstruction prostate geometries.

DISCUSSION

Pre-prostatectomy MRI data can be compared post-prostatectomy histopathological prostate slices to determine the utility of MRI for prostate cancer detection and location. This study looked to build upon other studies focused on comparing prostate partitioning and MRI to histology. It has been noted that the fit of the mold to the resected prostate, the slicing technique, and the thickness of the image slices are major factors that affect image-based model performance.(3) Accordingly, this study employed patient-specific molds based upon individualized prostate contours, image slice thickness of 2.5mm (vs 3-6mm used in previous studies) that matched pathology slice thickness, and cutting of unfixed prostate on the day of surgery to evaluate masking of the MR image and geometric ex-vivo changes to the shape of the prostate. Through the remainder of this study, more subjects will be enrolled to analyze the effectiveness of these devices for histopathological prostate analysis with MRI and PET/MRI.

MURINE VAGINAL WALL BIAXIAL CONTRACTILE RESPONSE FOLLOWING ELASTASE DIGESTION

INTRODUCTION

In the United States 1 in 10 women undergo surgical intervention for pelvic organ prolapse (POP) [1]. POP is characterized as the descent of the pelvic organs into the vaginal canal, which decreases quality of life. Although aging, child birth, and increased abdominal load are well established risk factors, the underlying mechanisms for POP are not fully understood. Elastin content and contractile function are decreased in vaginal tissues from patients with POP [2-3]. Disruption of elastin induced dilatation of the vaginal caliber and decreased tissue compliance [4]. Furthermore, the loss of elastin diminished the contractile response of the aortic wall under biaxial mechanical loading [5]. In the vaginal wall, however, the interaction between elastin and smooth muscle is not fully elucidated. Further, the effect of biaxial mechanical loading on the contractile response has not been investigated. Therefore, the objective of this study was to investigate the role of elastin and mechanical loading on the contractile response of the murine vaginal wall. It was hypothesized that decreased elastin content and increased mechanical loading will decrease the contractile response.

METHODS

Female C57BL6 mice at 4-6 months of age (at estrus) were euthanized by guillotine without anesthesia (IACUC approved). Vaginal tissue was freshly isolated and separated from the cervicovaginal complex. **Biaxial Contractility.** Isobaric-axially isometric contraction of the vaginal tissue (n=5) under physiologically-relevant loads was performed with a pressure-myograph system (Danish MyoTechnologies, Aarhus, Denmark) [5]. The unloaded configuration was identified, followed by determination of the physiologic length where the transducer-measured force remained constant over an increasing range of pressure [4, 6, 7]. The tissue was preconditioned

with cyclic pressurization and axial extension. The smooth muscle cells were preconditioned under low loads with 40 mM of KCl inducing maximum contraction. Isobaric-axially isometric contraction was assessed at the physiologic length (l_p) under 3 constant pressures (0, 7, and 15 mmHg). Further, contraction was assessed under the *in vivo* measured pressure (7mmHg) at 2 additional fixed axial lengths (4% below and above the physiologic length). Maximum contraction was induced with 40 mM of KCl. Change in outer diameter and axial force was recorded. The tissue was incubated with 15U of porcine elastase for 45 minutes and the testing protocol was repeated [4]. **Ultrasound.** Short-axis B-mode ultrasound images were acquired during testing to measure vaginal wall thickness. Images were acquired with a 40MHz transducer at the physiologic length and pressure (7 mmHg) under basal tone and when maximally contracted. This was performed for the control and elastase treated samples. Vaginal wall thickness was measured in ImageJ. **Histology and Immunohistochemistry.** Histological and immunohistochemical analysis for the control (n=4) samples were performed on 4 μ m circumferential and axial cross-sections. Tissue sections were stained with Harts Elastin stain and for alpha-smooth muscle actin. Area fractions were quantified by ImageJ Color Deconvolution plugin and a custom GNU Image Manipulation Program protocol [4]. **Statistical Analysis.** A 2-way ANOVA evaluated the effects of treatment and load on the contractile response. When necessary, this was followed by a 1-way ANOVA with Tukey post-hoc to identify the significant effect of loading and paired t-test comparing the control and elastase treated response. Change in vaginal wall thickness with contraction between the control and elastase treatment was evaluated with paired t-test. Paired t-test were used to

compare circumferential and axial area fraction. Statistical significance was set to $p < 0.05$ and data reported as mean \pm standard error of mean.

RESULTS

The 2-way ANOVA identified significant differences in the change in axial force with respect to treatment ($p < 0.003$) and pressure ($p < 0.001$) (Figure 1A). Elastase treatment significantly decreased the changes in axial force with contraction at 0 ($p < 0.007$), 7 ($p < 0.03$), and 15 ($p < 0.005$) mmHg. Further, the axial force was significantly reduced at 7 and 15 mmHg compared to 0 mmHg for the control ($p < 0.003$) and treated ($p < 0.02$) tissue. The 2-way ANOVA identified significant differences in the change in axial force with respect to treatment ($p < 0.003$) and axial length ($p < 0.001$) (Figure 1B). Elastase treatment significantly decreased the change in axial force with contraction at the physiologic length ($p < 0.01$) and 4% below ($p < 0.03$). For the control ($p < 0.001$) and elastase ($p < 0.03$) treated tissue, axial force was significantly reduced between 4% below and above the physiologic length (l_{pl}).

Figure 1: Change in axial force with contraction at 3 (A) constant pressures and (B) fixed lengths pre- (black) and post- (white) elastase digestion. Elastase treatment and mechanical loading significantly reduced the change in axial force. Statistical significance denoted by load (* $p < 0.05$, ** $p < 0.01$) and treatment ($\forall p < 0.05$, $\forall\forall p < 0.01$).

The 2-way ANOVA identified significant differences in the change in outer diameter with respect to pressure ($p < 0.001$) (Figure 2A). The change in outer diameter was significantly ($p < 0.001$) reduced at 7 and 15 mmHg compared to 0 mmHg for the control and treated tissue.

Figure 2: Change in outer diameter with contraction at 3 (A) constant pressures and (B) fixed lengths pre- (black) and post- (white) elastase digestion. Mechanical loading by pressure significantly reduced the change in outer diameter. Statistical significance denoted by load ($p < 0.01$).**

Elastin area fraction was significantly greater for axial sections compared to circumferential sections (Figure 3). Statistical significance was not identified between the two orientations for alpha smooth-muscle actin. Significant change in vaginal wall thickness under contraction was not identified between the control and elastase treatment.

Figure 3: Histological analysis on (A) circumferential (circ) and (B) axial (ax) vaginal wall cross-sections with Hart's Elastin stain. (C) Elastin area fraction was significantly larger on axial sections compared to circumferential. Statistical significance denoted by * $p < 0.05$. Scale=100μm.

DISCUSSION

This study investigated the effect of elastase digestion on vaginal wall contractile response as a function of mechanical loading. Elastase digestion significantly reduced the change in axial force observed with contraction (Figure 1). This finding is supported by prior work in the aorta from elastopathic mice, wherein a decrease in axial force with contraction compared to control was observed [4]. Note that in contrast to the findings from the murine aorta with elastin deficiency, the change in outer diameter was not significantly affected by elastase treatment in the murine vagina. This finding, however, is similar to the behavior of the murine mesentery artery following elastase digestion [8]. The significant decrease in axial force may be described by elastin composition with respect to orientation. Elastin area fraction was greater along the axial compared to the circumferential direction (Figure 3), suggesting that vaginal smooth muscle may interact with elastin. Further, increased pressure and axial length significantly decreased the change in axial force under contraction (Figure 1). Significant decreases in outer diameter, however, were only observed under increased pressures (Figure 2). These findings demonstrate that increased mechanical loading decreases the contractile response.

The findings of this study highlight the role of elastin and mechanical loading on vaginal wall contraction. This study investigated the immediate response to the loss of elastin and increased loading, however, further investigation is needed to quantify the long-term biochemical and biomechanical mediated effects. Characterizing the interaction between smooth muscle and elastin in response to mechanical loading may provide further insight into the etiology of POP and improve treatment strategies.

INTRODUCTION

3D geometric models reconstructed from medical imaging dataset of CT or MRI play an important role in surgery previsualization and intervention procedures^{1, 2}. This technique has been widely applied in neurosurgery and oral and maxillofacial surgery^{3, 4}. It has also been applied to the pelvic floor-related field for clinical use.

3D geometric pelvic floor model reconstructions are vital for the conduct of accurate 3D finite element analysis⁵⁻⁷. However, 3D model reconstruction based on manual segmentation is often time-consuming for personalized modeling, simulation and surgical planning.

Therefore, several authors have tried to apply automated segmentation and reconstruction method to pelvic floor organs⁸⁻¹¹. Edge detection and pattern recognition methods were proposed to finish this task and have shown promising results. However, there still exist problems with generalization and efficiency. For example,

reconstruction algorithms constructed from images from a few patients may not generalize well to other patients. In addition, non-parametric methods are time consuming at the inference stage.

Recently, deep convolutional neural networks (CNN) have shown great promise in computer vision¹², so many biomedical researchers have successfully applied these techniques to their domain¹³. Thus in this paper we developed a 3D geometric model reconstruction method for pelvic floor organs and muscle based on MR images, including bladder, rectum, and levator ani muscle, using an automated segmentation model based upon deep convolutional neural networks.

METHODS

MR images of 6 women with anterior and 6 with posterior vaginal prolapse were selected from University of Michigan institutional review board-approved (IRB #HUM00056743) study. 3D models of bladder,

Figure 1: Automated MR images 3D modeling Pipeline. N means slices numbers for one series of MR images. 256*256*32 means height*width*channel. Feature map with same color has same size.

rectum, and levator ani muscle were reconstructed manually from the sagittal slices at both rest and Valsalva based on our previous work¹⁴. The MR images had the same resolution and image size (256*256 pixels).

We adopted the modeling method that segmented the structures into slices first, followed by the reconstruction. A pipeline is shown in Fig.1. The pipeline includes two parts: the 2D segmentation part and the post processing part for 3D reconstruction. The 2D segmentation model was constructed using deep convolutional neural networks. U-Net was used as the basic network architecture for segmentation feature extraction¹⁵. A transfer learning technique was then used to train the U-Net. At the end of the upsampling stage we adopted the feature pyramid network idea for the pixelwise prediction by concatenating the feature map at 4 different resolution configurations to make the final prediction¹⁶. After that the 3D models were reconstructed using the contours in all slices with interpolation and the surface smoothing.

A dice coefficient was used for segmentation performance evaluation¹⁷. However, if there are no regions of interest for segmentation some slices, the original dice coefficient would always be zero. To solve this problem, therefore, we proposed to use a loss function in Eq. (1).

$$Loss = \frac{GT \cap (1-PR) + (1-GT) \cap PR}{GT \cup PR} \quad (1)$$

where GT represents the ground truth segmentation labeling, PR represents the prediction labeling. Another cross-entropy term was added to punish the situation that predicts a segmentation map with a blank interest region and vice versa.

RESULTS

The results for 2D segmentation model on testing dataset are summarized in Table 1.

Table 1: Evaluation result on testing dataset.

Class	Dice Coefficient	Presence accuracy
Bladder	0.907	0.947
Rectum	0.849	0.917
Levator ani muscle	0.619	0.879

Segmentation of the bladder had the best performance among the three classes. With our proposed loss function, average prediction presence accuracy for the three classes were all above 0.87.

The model prediction on testing sample images is shown in Fig. 2, and the 3D geometric model reconstructed on testing sample data is shown in Fig.3.

Figure 2: Visual results of segmentation map between ground truth and CNN model prediction on bladder. First row: Ground truth, Second row: Prediction map. Dice=0.97 shown good prediction. Dice=0.77 shown weak prediction on the contour.

Figure 3: 3D geometric model reconstruction result by manual segmentation and model prediction. Left: Ground truth Right: Predicted model.

DISCUSSION

In this study we developed a technique which applied deep CNN for patient-specific pelvic floor organs 3D automated reconstruction based on MR images. Compared to the previous methods⁸⁻¹¹, it showed promising segmentation performance and faster processing speed, which could be useful for faster finite element modeling and virtual surgical planning.

The segmentation performance for the bladder was better than the rectum and levator ani muscle, this being best explained by the structure shape and volume. The bladder has the largest contour on each slice and with its large volume, we had more slices to use as the training samples.

In the future we need to add more segmentation classes, and more images into our study to improve the segmentation performance.

INTRODUCTION

The dramatic remodeling of the soft tissues in the reproductive system are critical in a healthy pregnancy. One of these tissues is the cervix, which acts as a barrier between the fetus and environment. It must remodel sufficiently by term to allow for delivery [1]. One of the major medical challenges in obstetrics is preterm birth (PTB), which is defined as birth before 37 weeks. Much of current research focuses on the premature remodeling of the cervix, which is a final common pathway for many causes of PTB [2]. In the mouse, the cervix is shown to undergo a dramatic softening from day 6 to 12 of a 19-day pregnancy and a gradual softening later in pregnancy. These changes have been attributed to collagen reorganization in the tissue [3], but the contributions of other extracellular components to remodeling is not completely understood.

Cervical tissue is comprised of many components, including cells, collagen, elastin, proteoglycans, hyaluronan, and matricellular proteins [4]. Collagen fibers are shown to be the major load-bearing component of tissue, given its higher stiffness compared to other components [5]. Decorin is a major proteoglycan in the cervix and plays a role in collagen synthesis and formation [6]. A recent paper demonstrated a decorin knockout (DcnKO) mouse cervix had a significantly lower maximum stiffness and tissue strength compared to wild-type (WT) under a load-to-failure mechanical test. Moreover, this difference was only present at the early stages of pregnancy (non-pregnant (NP) and day 6) and disappeared in late pregnancy. The behavior was supported by TEM images, which showed NP mice exhibited disrupted collagen fibers, but were recovered at day 18 (d18) of pregnancy [7].

While differences are observed between WT and DcnKO models under load-to-failure mechanical tests, this test is a first step in understanding the mechanical behavior of the cervix. Hydrated soft tissue typically presents a hyperviscoelastic behavior, hence we

designed a viscoelastic mechanical test. A viscoelastic response is more likely observed *in vivo* as the cervix experiences repeated loads from the fetus or other external forces. This research aims to implement a viscoelastic protocol and identify how decorin affects the behavior of NP and late pregnancy mouse cervical tissues.

METHODS

Mouse cervix samples were collected from two time points in pregnancy, NP and d18. At the NP time point, 3 WT and 3 DcnKO were collected. At the d18 time point, 3 WT and 2 DcnKO with biglycan heterozygous were collected. Samples were prepared for whole-specimen ring tensile loading as previously described [8].

Figure 1: Loading Protocol for NP and d18 samples. Numbers above each load, denote its loading rate in mm/s. Time not to scale.

The sample was first allowed to swell for 2 hours in phosphate buffered saline with 2 mM ethylenediaminetetraacetic acid. A preload of 0.001 N was applied to ensure the sample was in contact with threaded sutures. The loading protocol consists of 2 main sections: 1) strain rate sensitivity cyclic load-unloads and 2) stress relaxation ramp-holds (Fig.1). Different load levels were applied for NP and d18 to ensure each sample could sustain a majority of the test without breaking. Between each loading, the sample was held at zero displacement for 20 minutes to recover and equilibrate. Images were taken 1/s while loading and 1/60s while holding to record deformation of the sample.

For this initial mechanical analysis, we compared raw force-extension curves of the load-unload section and raw force-time curves of the stress relaxation section. Comparison is contained to within each gestation point as the NP and D18 samples are taken to different load levels.

RESULTS

The average loading curve of the 3rd, 4th, and 5th load cycle (corresponding to loading rates of 0.1, 0.01, and 0.5 mm/s) are shown in Fig.2. A linear fit was applied to the data after the toe region to obtain a slope. At the NP time point, the WT and DcnKO exhibit similar slopes and no strain rate sensitivity. At the d18 time point, the WT samples have a larger toe region and lower slopes compared to DcnKO at all strain rates. The slopes increase with increasing strain rate. However, this increase in slope at d18 may be the result of damage – see Discussion.

Figure 2: Average Load Response A) NP samples B) d18 samples. Shading represents standard deviation of average load curve. Numbers to the left of each line denote slope in N/mm of linear fit.

For the average stress relaxation curve, differences are more apparent between WT and DcnKO at the NP time point under the highest load level (Fig.3). Only 1 of 3 DcnKO samples made it to the highest 1.5N load level. At the 2 lower load levels, there are no differences, in part due to a large standard deviation. For d18 samples, there is no apparent difference between DcnKO and WT. All samples made it through the load cycles and the equilibrium forces are similar.

Figure 3: Average Stress Relaxation Response. A) NP samples B) d18 samples. Shading represents standard deviation.

DISCUSSION

These preliminary results are a portion of what is explored in this mechanical test. Decorin has a complex effect on viscoelastic behavior that can manifest differently at each gestation point. Overall, the NP DcnKO samples could not sustain the full loading regimen. The trend between NP samples observed in the stress relaxation section are similar to those observed in mouse patellar tendon. DcnKO tendon samples had higher percent relaxation than WT; a difference that was augmented with increasing prescribed strain [9]. In soft tissue, there are various mechanisms that can contribute to a tissue's viscoelasticity, such as unraveling and reforming of the collagen crimps. Decorin's effect on viscoelasticity and how it manifests structurally needs to be explored.

There are limitations on the experiment to be considered. For d18 samples, there is considerable softening and we are unable to separate this effect from the genotypic effects. The d18 DcnKO samples were also biglycan heterozygous. Future studies will include a d18 only DcnKO and increase sample size for all groups. This initial analysis reveals slight differences between WT and DcnKO samples. Further analysis will be conducted on the dataset, including damage parameters and model fit, to tease out differences between genotypes.

INTRODUCTION

Smooth muscle cells (SMC) work in coordination with the extracellular matrix (ECM) to carry out normal mechanical function of the reproductive system [1, 2]. The non-pregnant cervix undergoes regular phasic contractions through the estrous cycle to contribute to processes such as fertilization [1, 2]. Uniaxial strips or rings are traditionally used to independently investigate the maximum contractile response from the longitudinal and circumferential cervical SMCs [1,2,3]. While maximum contractile tone can provide insights into the function of the organ, the resting or basal tone of the organ may further inform our understanding of the mechanical properties of the cervix. Additionally, explant of strips and rings alter the native cell-matrix interactions and inhibits simultaneous assessment of axial and circumferential SMC. To overcome these limitations, an inflation-extension system can be used to assess multiaxial SMC contractility and basal tone while preserving native tissue geometry and cell-matrix interactions. Therefore, the objective of this study was to quantify differences in geometry and SMC contractile tone in the circumferential and axial orientations within the non-pregnant murine cervix.

METHODS

Reproductive systems from C57/BL/6 female mice at estrus (n=9, Tulane IACUC approved) were freshly isolated immediately post-euthanasia via guillotine in order to preserve SMC contractility closest to the physiological state. Post-explant tissue was bathed in 4°C Hanks Balanced Saline Solution (HBSS) and connective tissue was fine dissected from the organs. Cuts immediately posterior of the bifurcation of the uterine horns and superior to the vaginal introitus were made. The wall between the remainder of the uterine horns was cut to allow for

cannulation. Cervical complexes were cannulated within an inflation-extension device and bathed in aerated Krebs Ringer Buffer at 37°C. **Dose Response (n=5)** To determine the normal contractile function of the cervix, an isobaric dose response protocol was performed at an estimated physiological (EP) length and pressure [4, 5]. At the constant length and pressure, tissues were subjected to increasing concentrations of potassium chloride (KCl) while circumferential and axial contractions were measured via diameter changes tracked at the mid-cervix through a digital camera and changes of force read by the force transducer, respectively. Contractile response was normalized with respect to cross sectional area (Fig. 1A). Ultrasound images (B-mode, 40MHz transducer) were made at the unloaded state to calculate thickness and student's t-tests were used to identify changes in geometry, force, circumferential stress (σ_θ), and axial stress (σ_z). **Basal-Passive (n=4)** Post-explant and cleaning, cervical complexes were cannulated in the extension-inflation device in aerated Krebs Ringer Buffer at 37°C. Unloaded geometry was recorded via a digital camera and digital micrometer. Samples were preconditioned circumferentially (P=0-7mmHg) for five cycles. An estimated physiological length was determined based on the assumption that soft tissues seek to maintain force over a range of pressures at an approximate *in vivo* length [4, 5]. Samples were subjected to secondary preconditioning at the EP length (P=0-15mmHg). Force-extension preconditioning was excluded as pilot studies showed a notable decrease in SMC contractility after the force-extension protocol. Following preconditioning, the unloaded length was re-determined as the length in which there was minimal changes in force with decreasing axial length. Three cycles of the pressure-inflation protocol was performed from (P=0-15mmHg) at -2% EP, EP, 1% EP, and 2% EP length. Samples were treated with 20mM KCl after the basal experiment

to incite phasic contractions to confirm continued SMC activation. Samples were then treated with 2mM EGTA within the bath and intraluminally in a solution of calcium free Krebs Buffer for 30 minutes to de-activate SMC. Cervices were washed out with calcium free Krebs Buffer and the experimental protocol was repeated for the passive state. Ultrasound B-mode images of the tissue at the unloaded configuration were taken after the pressure-inflation cycles for both the basal and passive experiments. The inner canal and outer circumference excluding the vaginal fornix were traced in Image-J and lines drawn between the inner and outer perimeters were used to calculate thickness. Paired t-tests were used to compare geometry between location and active state (Fig. 1B). Bilinear curve fits were applied to the basal and passive experimental data. Two-way ANOVAs (axial extension, state) followed by student's t-tests were performed for basal and passive data [6].

RESULTS

Dose Response Maximum contraction was identified at 20mM KCl (Fig. 1A). At this concentration, phasic activity was maintained and there was a significant increase in axial stress ($p<0.001$) and an inverse effect on the circumferential stress ($p<0.05$). **Basal Passive** Unloaded geometry and volume between the basal and passive state was not found to be significantly different (Fig. 1B). However, physiologic length was found to be significantly greater ($p<0.05$) in the passive state and passive outer diameter was larger compared to the basal state at matched pressures ($p<0.05$, Fig 1B). Bilinear curve fits did not reveal any significant differences in mechanical properties

Figure 1: Dose Response (A) Maximum contraction was identified at 20mM KCl. At this concentration phasic activity was maintained resulting in a significant increase in axial stress ($p<0.001$) and decrease in circumferential stress ($p<0.05$). **Basal-Passive Geometry (B)** A significant increase in the physiologic length for the passive state was measured ($p<0.05$). However, no significant changes were identified in the thickness or volume between the basal and passive state. **Basal-Passive σ_{θ} (C)** Stress-stretch curves of the basal and passive response at the estimated physiological length. No significant differences between basal and passive properties were found. A trend towards a greater circumferential stretch in the passive state was identified. **Basal-Passive σ_z (D)** Circumferential linear modulus in the basal and passive state was larger than the axial linear modulus ($p<0.05$).

between the basal and passive state. Although no significance was found, the passive state trended to have a larger transition-stretch ($p<0.1$, Fig. 1C). Circumferential linear-modulus in the basal and passive state was significantly greater than the axial linear modulus ($p<0.05$, Fig. 1D). Spontaneous contractile response was observed and an adapted pressure-inflation protocol was designed to observe how the spontaneous contraction effected the tissue in comparison to contractile reaction incited by KCl in the dose response protocol (Fig. 2) [7].

Figure 2: Spontaneous contractile response (n=2) was analyzed with an adapted pressure-inflation protocol [7]. Similar to the dose response, an increase in axial stress and decrease circumferential stress was observed in the representative sample shown.

DISCUSSION

Comparing basal and passive states within the cervix, there was a noted increase in the physiologic length ($p<0.05$) and an increase in diameter at matched pressures in the passive state ($p<0.05$). However, no significant changes in the thickness, volume, and mechanical properties between the basal and passive state were identified. There was a trend for a larger transition-stretch ($p<0.1$) in the passive state that can be visualized as the rightward shift from the basal to passive state in Figure 1C suggesting an increase in distensibility with loss of basal tone. A minimal change in mechanical properties between the basal and passive state may be related to the phasic nature of the cervix. During dose response and spontaneous contractility protocols, the phasic nature of the cervix incited dramatic changes in force in a consistent pattern. The role of basal tone may be minimal in the non-pregnant cervix. Additionally, the non-pregnant cervix is a dense fibrous tissue that is composed of approximately 80-90% collagen and the basal tone of SMC within the tissue may contribute minimally to maintain rigidity [8, 9]. Interestingly, SMCs in the cervix are quiescent mid-pregnancy and a phenotypic change activates the SMCs during labor [1, 2]. An increase in the SMC content within the cervix during pregnancy may result in different behavior between the basal tone and passive state. Further work is needed to elucidate the role of basal and max contractile tone in comparison to the passive state to inform mathematical models of the non-pregnant cervix. Understanding the role of SMC in the non-pregnant cervix may contribute to our understanding of the role of SMC in the pregnant cervix.

INTRODUCTION

It is now widely acknowledged that the biomechanical behavior of smooth muscle cells (SMC) in the aorta plays a key role in growth, remodeling, and homeostasis [1–4]. Through mechanosensitivity and mechanotransduction, aortic SMCs remain highly sensitive to biomechanical and mechanical stimuli from their extracellular matrix (ECM) [1, 5–12]. In fact, these cells can sense the state of their environment and react to the variation of its biophysical properties in some pathologies such as aortic aneurysms, but also in genetics, hemodynamics or biomechanics [6, 13–15]. SMCs undergo therefore alterations such as apoptosis, or even phenotypic switching from a mature quiescent and contractile phenotype towards a synthetic and proliferative one [1, 5, 10, 11]. A synthetic SMC is able to proliferate and migrate more than a contractile one, but it can also degrade the current “pathological” ECM and produce new ECM components in return in order to repair the tissue [2, 11]. In fact, in adulthood, only collagen of the ECM may be synthesized efficiently [12]. The collagen has a protective role for the other ECM components because it can withstand higher stress, but the increase of collagen leads to an increased stiffness and weakening of the aortic wall [1, 13]. These changes irreversibly affect the mechanical properties of the aortic tissue that becomes more vulnerable to rupture.

Since the SMC tend to maintain the preferred tension they exert on the ECM at homeostasis [2, 8, 13, 16], any biochemical or biomechanical imbalance results in a variation of this basal tone [17]. The cell tension, behavior and response, are therefore altered by pathological conditions, which leads to a vicious circle. In this way, the contractility of SMCs appears as a determinant parameter of the aortic wall state, but quantitative values of SMC basal tone have never been characterized precisely on individual cells.

METHODS

We developed an in vitro technique based on Traction Force Microscopy (TFM). Aortic SMCs from a human lineage (AoSMC, Lonza) at low passages (4-7) were cultured 2 days in conditions promoting preservation of their contractile apparatus. We performed fluorescent microscopy (FM) on these cells, notably by staining the α -Smooth Muscle Actin (α -SMA) that constitutes the contractile thin filaments of the cytoskeleton. The cells were seeded on hydrogels of varying elastic modulus (from 0.5 to 50kPa) with embedded fluorescent microbeads. During the experiment, SMCs were detached from the gels by a trypsin treatment. Since the unbinding cell no longer exerted a force on the gel, the microbeads movement was tracked using TFM. Then, using Digital Image Correlation (DIC) with the *NCorr* algorithm [18], we obtained the corresponding displacement fields. Then we used a mechanical model based on the Boussinesq solution [19], assuming linear elasticity, isotropy and plane strain, to extract the associated traction force applied by individual SMCs on the gel.

The first series of experiments consisted in one sample of each stiffness, in order to screen the range of stiffness values appropriate for SMC adhesion. Then, we performed experiments within this stiffness range using 24-well plates and achieved an advanced statistical analysis. We examined the distribution of the traction force values according to each stiffness by plotting histograms in Matlab[®]. Then, these histograms were fitted with an exponential law such as:

$$y_{model} = \frac{1}{\lambda} e^{-\lambda x} \quad (1)$$

Where x is the center of the different classes of traction force values from the histograms and y its probability. The λ parameter was determined by a nonlinear least square method that minimizes the difference between the model and experimental data.

RESULTS

SMCs showed a clear spindle shape on the gels (Fig. 1.a), with α -SMA fibers, oriented according to the direction of the cell (Fig. 1.b).

Figure 1: (a) Observation of cell morphology in bright light and (b) internal architecture using FM, for human aortic SMCs (AoSMC, Lonza). Microscope: Carl Zeiss Axio Observer.Z1/7, Objectives : Plan-Neofluar 10x/0.30.

Two major interesting and original observations about SMC traction forces were deduced from the obtained results (Fig. 2): a. they were stochastic and showed an exponential distribution, with 40% to 80% of traction forces in the range 0-10 μ N. b. They depend on the substrate stiffness: the fraction of adhesion forces below 10 μ N tend to decrease when the substrate stiffness increases, whereas the fraction of larger adhesion forces increases.

Figure 2: Histograms representing the distribution of the measured TF (Traction Force) values for each stiffness value: A) 4kPa, B) 8kPa, C) 12kPa, D) 25 kPa. Each of these histograms is represented in probability according to the classes of forces (width: $0.1 \cdot 10^{-4}$ N). The red curve represents the exponential model (Exp fitting) applied to experimental data.

DISCUSSION

Since human SMCs are particularly sensitive, specific culture conditions are required to preserve their contractility. In this way, we used cells at low passages, cultured in a differentiation medium, and they showed both the typical elongated morphology they have in the aorta and high α -SMA expression. Moreover, their contractile behavior was confirmed during TFM experiments. In fact, the adhering cells on the gels exert naturally a force on their substrate. Once removed, SMCs induced a displacement field on the fluorescent microbeads. We developed an algorithm that allowed extracting the corresponding local traction force at each cell anchorage point.

Measured adhesion forces are in good agreement with previous data on vascular SMCs [6, 20], although previous results were not obtained on single cells. We also showed that they could be predicted well by the motor-clutch model of Chan & Odde [21], that had never been extended to SMCs. Further studies will consider stimulated contractility and primary culture of cells extracted from aneurysmal human aortic tissue.

INTRODUCTION

Musculoskeletal (MSK) fibrous tissues, such as tendons and ligaments, are formed via a hierarchical collagen fiber structure which is responsible for these tissues' anisotropy and specialized mechanical properties [1]. Current treatment methods for injuries to these tissues use auto-or allografts to replace the injured tissue. Tissue engineering has been advanced as a means to overcome the limitations of auto-and allografts [1].

Two methods for attempting to replicate the structure and function of MSK fibrous tissue are 3D printing and electrospinning. There are a variety of different forms of 3D printing which use single fibers to create complex structures like MSK fibrous tissues including fused deposition modeling (FDM) and bioprinting [2]. Each method provides high resolution modelling capabilities using software and multi-axis control to deposit individual fibers. The fibers from these systems typically have a minimum range of 100 μ m-400 μ m in diameter, which is on the scale of a fascicle [1,2]. Though 3D printing has the potential to replicate the macroscale structure of MSK fibrous tissues it lacks the ability to replicate the smaller fibers and fibrils.

Electrospinning uses an electric potential to draw out a stream of fibers from a polymer solution creating a sheet of randomly oriented fibers with diameters that range from nanometers to microns, which approaches the range of fibrils and fibers [1,3]. Orientation can be manipulated by using a rotating mandrel to align fibers along a single axis [3]. One limitation of electrospinning is that the lack of control over fiber placement can prevent the creation of complex structures.

Direct-write, near-field electrospinning (DWNFE) combines the software and multi-axis control of 3D printing with the electrohydrodynamic fiber formation of near-field electrospinning to create complex, 3D scaffolds (Fig. 1) [4]. This combines the advantages of the two previous methods allowing for the fabrication of a structure

with fibers similar in size to the fibers of collagen while also meeting the macroscopic requirements needed to replicate MSK fibrous tissue.

To date, however, DWNFE has been limited to synthetic polymers which provide a biocompatible environment but lack the bioactivity of natural polymers [1, 5]. Gelatin is an appropriate candidate for MSK tissue engineering, as it is collagen based, similar to MSK tissues, maintaining much of the enzymatic active sites while being more readily available [6]. Thus, the objective of this study was to determine the impact of acetic acid (solvent) and gelatin concentrations for the DWNFE of gelatin solutions.

Figure 1: Schematic of direct-write, near-field electrospinning.

METHODS

Type A, 300 bloom, porcine gelatin (Sigma-Aldrich Saint Louis, MO, USA) was dissolved at a constant 45(w/v)% gelatin in five different acetic acid (Fisher Scientific, Fair Lawn, NJ, USA)-diH₂O concentration groups (% acetic acid groups): 60(v/v)%, 70(v/v)%, 80(v/v)%, 90(v/v)%, and 98(v/v)%. Three gelatin concentration groups (% gel groups) were also made, 30(w/v)%, 37.5(w/v)%, and 60(w/v)%, at a constant acetic acid concentration of 70(v/v)%. A custom modified Lulzbot mini (Lulzbot Inc., Loveland, CO, USA) FDM 3D printer with applied pneumatic pressure for extrusion was used to print 10mmX10mm 2-layer grid scaffolds with 1mm intended spacing. MATLAB was used to create the G-code for the grid structure. These scaffolds were imaged using a JEOL scanning electron microscope (SEM) and fibers diameters were measured using ImageJ. Three scaffolds were printed per day for three days for a total of nine scaffolds

for each group. Six fibers from each scaffold were measured. All statistics were calculated using Prism (7.05, GraphPad, San Diego, CA, USA). Normality was determined via the D'Agostino-Pearson test. Nonparametric Kruskal-Wallis tests with Dunn's post hoc analysis ($\alpha=0.05$) were run to determine statistically significant differences between the acetic acid and gelatin groups separately.

RESULTS

In terms of varying acetic acid concentration, the 60%AA group fibers, which resembled puddles, failed to form a coherent fiber structure (Fig. 2A). The 80%AA group fibers were not consistent with discontinuities in the fibers and an irregular form (Fig. 2A). The 90%AA and 70%AA groups both created continuous fibers with no discernible irregularities (Fig. 2A). A consistently printable solution could not be made for the 98%AA group. Statistical tests revealed significance between all %AA groups except between the 70%AA and 80%AA groups ($p<0.05$). The 45%gel, 70%AA group had the smallest diameter fibers with a median of 3.97 μm followed by the 80%AA group at 5.74 μm , then 90%AA with a median of 19.34 μm and finally the 60%AA with a median of 92.43 μm .

Figure 2: Effect of acetic acid concentration on fiber formation using DWNFE. A) SEM images at lower (left) and higher (right) magnification. B) Fiber diameter as a function of acetic acid concentration. ‘*’ indicates statistically significant difference between groups connected by the black bar.

Once establishing that small fibers could be formed at 45% gelatin and 70%AA, the gelatin concentration was varied while holding the acetic acid concentration at 70%AA. The 30%gel group showed the presence of puddles instead of fibers (Fig. 3A). The 37.5%gel group also showed puddles that were smaller and inconsistent (Fig. 3A). The 60% gel group is not shown because it failed to print at the speeds used for the other groups. The median diameter for the 30%gel group was 154.50 μm which was significantly different from the 45%gel group (3.97 μm) ($p<0.05$, Fig. 3B). The 37.5%gel group is statistically significantly different from both the 30%gel and the 45%gel with a median of 72.00 μm ($p<0.05$).

DISCUSSION

From the data, we found that acetic acid and gelatin concentrations impact the ability to direct-write, near-field electrospin gelatin. The 70%AA and 90%AA groups were on par with synthetic polymers (polyvinylidene fluoride) in relation to fiber diameter [4]. The 70%AA was considered the best group as it created the most stable fibers while also remaining an appropriate size for replicating physiologic dimensions. The gelatin concentration groups showed a “goldilocks”

Figure 3: The effect of gelatin concentration, at constant 70% acetic acid, on fiber formation using DWNFE. A) SEM images at lower (left) and higher (right) magnification. B) Fiber diameter as a function of gelatin concentration. ‘*’ indicates statistically significant difference between groups connected by the black bar.

zone at the 45%gel concentration as decreasing the concentration formed puddles instead of fibers, while increasing the concentration prevented fiber formation. These findings confirmed that the 45%gel group is the best concentration of those tested. From these results, we concluded that 45%gel/70%AA provides the best parameters of those tested. Further studies will be conducted with groups between 45%gel and 60%gel to see if this trend is continuous. Future work entails optimizing crosslinking of the gelatin and building larger 3D structures to allow for testing of the scaffolds’ mechanical properties as well as their impact on cells.

INTRODUCTION

Fatty infiltration is a progressive degeneration of muscle/connective tissue, which entails conversion to an adipose-like state, that occurs as a result of muscle disuse upon injury to the adjacent tendon. This process is commonly associated with tendon lesions and repairs in the rotator cuff [1]. With existing repair strategies, this fatty infiltration is associated with muscle atrophy, decreased functional outcomes, and may predict future injuries [2]–[4]. As such, accurate quantification of fatty infiltration pre- and post-operatively may be a useful biomarker for tendon repair success. However, fatty infiltration is currently assessed by a clinician or blinded observer through visual inspection and scoring the level of fatty infiltration on single slices in the coronal, sagittal, and axial [3], [5], despite the extension of fatty infiltration into the muscle belly. Here, we present a method for volumetric quantification of fatty infiltration based on anatomical landmarks and intensity histogram analysis.

METHODS

CT Dataset - Intensity histograms were assessed for micro-computed tomography (CT) scans of the operative and contralateral intact shoulder for rabbits having undergone infraspinatus repair as previously described [6]. Briefly, a gap defect was introduced in the infraspinatus of the operative shoulder and either left unrepaired (gap), repaired via reattachment of the remnant tendon to the bone (direct), or repaired using a woven collagen biotextile (scaffold). Scapulohumeral complexes were isolated post-euthanasia after 6 months and stored hydrated at 4°C for a maximum of 14 hours prior to scanning. CT scans of specimens were obtained (75-80kV, 470-500µa, 630-670ms exposure time, 42 µm voxel edge length, Inveon PET/CT, Siemens) and reconstructed (Inveon Acquisition Workplace, Siemens).

ROI Selection

Volumetric fatty infiltration metrics were investigated using an oblique cylindrical region of interest (ROI) within the muscle belly. To select a comparable ROI in each animal and minimize the effect of differences in overall animal size, ROIs were defined based on user identification of predefined anatomical features. The mid plane of the oblique cylinder is located by identification of the CT slice wherein the bifurcation in the scapula as seen from the sagittal plane first appears. Using this slice, the user identifies and selects two points, as shown in Figure 1, thereby defining the relative anatomical length (L_A) in pixels that will subsequently be used to scale and position the ROI. The radius of the oblique cylinder is calculated as:

Figure 1. Characteristic operative shoulder central slice of the ROI. The anatomical length is defined by the user selection of the points shown. White = bone, light gray = muscle, dark gray = fat, black = air

$$r_c = 0.2L_A \quad (1)$$

Where the scaling factor of 0.2 was determined manually through a bisection search approach to identify an ROI diameter that did not result in the ROI projection intersecting with the bone on any slice in the volume. The height of the ROI is calculated as:

$$h_c = L_A \quad (2)$$

The CT slices corresponding to the bottom and top of the ROI are the used to position the ROI with their slice numbers being determined as:

$$n_{bot/top} = n_{mid-plane} \pm h_c/2 \quad (3)$$

To position the ROI, a line is defined based on consistent anatomical features in the bottom and top slices as shown in Figure 2. The positions of the center of the ROI projection are located at the midpoint of the line defined by the selected features on each slice. The points are then used to define a unit vector along the axis of the oblique cylinder ROI, allowing calculation of the center of the ROI projection on each slice.

Figure 2. Anatomical feature selection and positioning of the ROI on the bottom (left) and top (right) slices of the volume.

Image Calibration – Images were calibrated prior to intensity histogram identification to ensure all images were within comparable intensity ranges. Calibration was performed by taking the average intensity of a user selected region of air, and the average intensity of a region of the carbon fiber tube housing as control intensities and scaling the image such that the mean air and mean tube values were rescaled to -1000 and 250, respectively.

Intensity Histogram Generation – Intensity histograms were generated for both the intact and operative shoulder of each rabbit three times to assess repeatability of the proposed method. For each test, the intensities contained within the ROI projection on each slice between the identified bottom and top slice were stored and the resulting histogram was produced via the built in MATLAB “histogram()” function. For each intensity histogram the mean, skew, standard deviation, and kurtosis were calculated for assessment as potential markers of fatty infiltration.

Fatty Infiltration Quantification – The percentage of voxels within the ROI that contained fat were estimated by masking the ROI in each slice of the defined volume and thresholding for intensities between -200 and 150. These thresholds were determined experimentally based on user identification of fatty regions in Slicer3D.

Statistical Analysis – Kruskal–Wallis followed by Mann–Whitney testing was used to assess statistical differences (significance set at $p \leq 0.05$).

RESULTS

Characteristic intensity histograms of the operative should for each repair type and the intact control are shown in Figure 3. Comparison of all histogram assessment metrics (mean, skew, standard deviation, and kurtosis) between the intact and operative shoulders for each repair type was statistically significant. There was no significant difference in the kurtosis or standard deviation of the operative shoulders between repair types. However, the difference in skew between both direct vs. scaffold and gap vs. scaffold repairs

Figure 3. Characteristic intensity histograms

Figure 4. Intensity Histogram Skew. Overhead bars indicate significant differences based on Mann-Whitney analysis ($p < 0.05$)

Figure 5. The volume percentage of the ROI identified as fat based on the specified threshold.

was significant for both comparisons (Fig. 4). Finally, the percentage of the ROI which was thresholded as fat was significantly different between intact and operative shoulders (Fig. 5), though substantial standard deviations in the direct and gap repair conditions prevent statistical assessment between repair conditions given the limited sample sizes in this pilot study.

DISCUSSION

The presented volumetric intensity histogram analysis demonstrates the ability to distinguish intact and operative shoulders based on the mean, skew, standard deviation, and kurtosis of the intensity histogram. Furthermore, the significant difference in skew observed between the repair conditions may be a useful fatty infiltration marker. Further work is needed to assess the correlation between intensity histogram metrics and functional outcomes following repair.

INTRODUCTION

Musculoskeletal soft tissues within and around joints are critical for effective load transmission and movement. Their anisotropic tensile properties are determined by the organization of a fibrous matrix containing highly aligned networks of collagen fibers. For example, fibers in the meniscus run primarily in one of two orthogonal directions to withstand complex, multidirectional loads [1].

Because endogenous repair is limited when these tissues are injured, surgical removal and replacement with auto- or allografts is common, but function is not totally restored due to incomplete cellular integration and nonphysiological mechanical properties of the graft [2,3]. Thus, there is a need for alternative treatment strategies based on tissue engineering approaches that aim to better reproduce the biological and mechanical characteristics of native tissue.

Electrospinning and extrusion-based 3D printing are advantageous for musculoskeletal soft tissue scaffolds because they inherently produce fibrous structures [4,5]. Melt electrowriting (MEW, Fig. 1) in particular allows greater control over scaffold architecture than electrospinning and produces smaller fiber sizes compared to conventional 3D printing methods, which has led to interest in MEW for tissue engineering [6]. Numerous studies have evaluated MEW process parameters, though these studies tend to focus on optimizing fiber diameter [7,8]. The direct effect of varying processing conditions on the mechanical properties of MEW structures is not well understood. Furthermore, there are few investigations of MEW scaffolds with geometries relevant for musculoskeletal tissue engineering [9,10], which may require high aspect ratios on the macro-scale. Therefore, this study aimed to determine how scaffold geometry and processing conditions impact fiber morphology and whole scaffold mechanical properties.

METHODS

Scaffold fabrication: A desktop fused deposition modeling 3D printer (Aleph Objects, USA) was adapted to be capable of MEW. Three process variables – stage translation speed (1, 3, or 5 mm/s), melt extrusion temperature (70, 80, or 90°C), and working distance between the nozzle and stage (1.5, 5, or 10 mm) – were investigated by systematically varying one while holding the other two constant (Fig. 1) for a total of seven unique experimental groups. MATLAB-generated G-code was used to print 12x12 mm (square) or 35x5 mm (rectangular) scaffolds (Fig. 2) consisting of alternating layers of polycaprolactone (43 kDa, Polysciences, USA) fibers oriented in the longitudinal (0°) or transverse (90°) directions and spaced 0.2 mm apart (2 or 10 layers).

Imaging: ImageJ was used to quantify fiber diameter (10 fibers per image) and interfiber spacing (30 per image) from scanning electron microscopy (SEM, Hitachi, Japan) images of 10-layer square and rectangular scaffolds (n=3/group). 2-layer scaffolds were imaged but not quantified (n=1/group).

Mechanical testing: Uniaxial tension was applied to rectangular scaffolds (n=6/group) in a universal testing system (Instron, USA) with a clamp-to-clamp length of 20 mm and a strain rate of 0.1 mm/s until failure. To track local strains more accurately, videos of each tensile test were converted to image series and input into the MATLAB-based digital image correlation program Ncorr [11]. Using a custom script, strains were determined from the Ncorr-calculated displacements representing the middle 50% of the rectangular scaffold geometry to avoid any skewing of the data related to clamping effects. Apparent tensile modulus was calculated as the slope of the linear region of each stress-strain curve. Yield strain was estimated from each curve.

Statistical analysis: Statistical analyses were performed using Prism (GraphPad, USA). Normality of datasets was evaluated via the D'Agostino-Pearson test. For fiber diameter, interfiber spacing,

apparent tensile modulus, and yield strain, nonparametric Kruskal-Wallis tests were performed using stage speed, melt temperature, or working distance as the independent variable ($\alpha = 0.05$). Dunn's post hoc tests were then performed.

Figure 1: Melt electrowriting diagram and experimental groups

RESULTS

Fiber organization was more consistent in 2-layer structures than 10-layer scaffolds. Nevertheless, fiber stacking, which suggests stable and repeatable deposition (Fig. 2), was observed in 10-layer scaffolds of all but the 5 and 10 mm working distance groups. On the other hand, many groups of rectangular scaffolds displayed angled and less consistent transverse fibers (Fig. 2), with exceptions being the 70 and 90°C groups. In terms of accuracy of fiber spacing, most groups had no more than 14% error relative to the target value of 0.2 mm, with the 3 and 5 mm/s groups being the most accurate.

Figure 2: Representative SEM images show differences in fiber architecture between square and rectangular scaffolds, though some conditions resulted in more consistent fiber architecture between geometries (middle row).

In rectangular scaffolds, when melt temperature and working distance were held constant (Fig. 3, top row), median fiber diameter decreased 49% when stage speed increased from 1 to 3 mm/s ($p < 0.05$) and decreased 56% from 1 to 5 mm/s ($p < 0.05$). Median spacing decreased 43% between 1 and 3 mm/s ($p < 0.05$) and 48% between 1 and 5 mm/s ($p < 0.05$). Similarly, median apparent tensile modulus decreased 65% from 1 to 5 mm/s ($p < 0.05$). When stage speed and working distance were held constant (Fig. 3 middle row), diameter increased 33% when melt temperature was increased from 70 to 80°C ($p < 0.05$). Spacing increased 33% from 70 to 80°C ($p < 0.05$) and 10% from 70 to 90°C ($p < 0.05$). Altering melt temperature did not result in statistically significant differences in apparent modulus ($p > 0.05$). When stage speed and melt temperature were held constant (Fig. 3 bottom row), working distance did not affect diameter or apparent modulus ($p > 0.05$). Spacing could not be measured consistently for the 5 and 10 mm groups, preventing direct comparisons. For all groups, yield strain was independent of process parameters ($p > 0.05$), with median values ranging from 3-4.5%.

Figure 3: Fiber diameter, spacing, and apparent modulus in rectangular scaffolds are dependent on processing conditions. Data are presented as median with interquartile range (box) and outliers (whiskers). Irregular architecture in the 5 and 10 mm working distance groups prevented consistent measurement of spacing (no data, N.D.). The dashed line in the spacing plots indicates the intended spacing of 0.2 mm. “*” indicates a significant difference between groups linked by a black bar.

DISCUSSION

These data suggest that tensile modulus, along with fiber diameter and spacing, in scaffolds with geometries relevant for musculoskeletal tissue engineering is determined by multiple factors, including MEW process parameters. The largest effects were due to stage speed, though similar changes in modulus with respect to melt temperature and working distance are clear, if not statistically significant, due to limited sample size. Given the specific relevance of rectangular scaffolds to tissue engineering, tensile testing was performed only on those groups, many of which displayed angled transverse fibers, which likely arose from viscoelastic “lag” during printing that was compounded by rapid changes in nozzle direction due to scaffold geometry. It is possible that these fibers contribute to the overall tensile response. Furthermore, the apparent modulus calculations permit comparisons between groups, but assume tension is applied to a homogeneous cross-section. In reality, because the fibers are arranged in a three-dimensional “logpile” structure, cross-sections are heterogeneous and contain void space. Local fiber moduli are greater than those shown in these data. These findings highlight the potential of MEW to create anatomically relevant structures that reproduce architectural elements of native collagen networks and provide a foundation for further studies involving rectangular MEW scaffolds for musculoskeletal tissue engineering.

INTRODUCTION

Trapeziometacarpal (TMC) osteoarthritis (OA) is one of the most common conditions affecting middle and older aged adults.¹ Conservative treatments often fail in the long term, and many patients will eventually require destructive surgical intervention involving removal of all or part of the trapezium and replacement with tendon, fascia, or an artificial implant.² While effective at reducing pain, these procedures compromise grip strength and can result in subsidence and disfigurement of the hand.² Efforts to replace articular cartilage (and bone) with living, functional tissue have matured substantially over the last two decades³, as has technology for generating constructs that can match the anatomical complexity and geometry of native articulating surfaces.^{3,4} For these technologies to progress towards translation, appropriate large animal models are required. Here, we evaluate the porcine accessory carpal (AC) bone as a model for the human trapezium and develop and implement methods for its replacement with an engineered replica to advance treatment of human TMC OA.

METHODS

Assessment of the AC: Eight AC bones were isolated from the right forelimbs of adult Yucatan minipigs, and four human trapezia were isolated from cadaveric donors. A custom indentation testing setup was used to evaluate cartilage mechanics of the AC via stress relaxation tests. The saddle-shaped articular cartilage surface was indented with a 2 mm diameter spherical indenter in three locations (superior, middle, and inferior). Four compressive ramps (10% strain each) were applied, with a 600s relaxation between each step. The equilibrium modulus was calculated from the second step. Human and porcine samples were fixed and imaged via μ CT (VivaCT 75, Scanco), before immersion in Lugol's solution (5% I₂ 10% KI in water) to enhance cartilage contrast. DICOMs from the initial scan were imported into ITK-SNAP⁵ and bone was segmented. A surface mesh was exported to Meshlab (ISTI) for simplification. Post-Lugol's scans were manually registered with the bone and processed similarly, with the cartilage layer segmented in a semi-automated manner. Samples were analyzed histologically with Safranin-O/fast green to visualize cartilage, bone, and fibrous tissue.

AC Contact Mechanics: CT images of the forelimb of skeletally mature Yucatan minipigs were obtained and 3D models of the bones were generated. A musculoskeletal model was generated in OpenSim, and the relative motion of the AC and its contact forces was evaluated through a passive range of motion. In 3 additional minipig forelimbs, a TekScan iScan 6900 pressure sensor was inserted between the accessory carpal and the ulnar carpal. The carpus was moved through a range of angles from 90 degrees to full extension, while contact forces were measured.

Development of AC Replacements: In Solidworks, an implant of the articulating cartilage surface and first third of the AC bone was designed using the μ CT data. A 2mm thick by 5mm deep "keel" was added for fixation. Positive molds were 3D printed out of an ABS-like photopolymer (Figure 3B). To fabricate elastomeric negative molds,

Figure 1: (A) Diagram and gross view of the human trapezium and porcine AC. Dotted line represents sectioning plane. Scale = 3mm. (B) μ CT slices in ITK-SNAP showing cartilage segmentation in red and 3D renderings. Scale = 3mm. (C) Safranin-O/fast green staining. Scale = 3mm (1mm for insets).

Sylgard 184 (polydimethylsiloxane, PDMS) was poured over the 3D printed designs, degassed, and allowed to cure at 40°C overnight. To fabricate porous anatomical implants, poly(ϵ -caprolactone) (PCL) was dissolved in chloroform at 20% wt/vol and mixed with NaCl crystals sieved to $\sim 106 \mu\text{m}$. Zirconium nanoparticles were included for radioopacity. The slurry was poured into the mold and the solvent was evaporated. The units were demolded and the salt was leached. **Implantation of Engineered AC:** Next, a proof-of-concept implantation in an adult minipig was performed. The carpus was exposed and rotated so that the articulating surface of the AC was in view. A reciprocating saw and osteotome were used to remove the surface of the AC and a 2mm burr was used to create a slot in the remaining bone, matching the keel on the implant. The construct was fixed in place with two 1mm \varnothing by 8mm bicortical screws oriented normally to the plane of the keel. Fluoroscopy confirmed implant positioning. After 1 week, the animal was sacrificed and the implant was retrieved and evaluated by μCT .

RESULTS

The porcine AC bone shows marked anatomical similarity to the human trapezium in both its size and saddle shape of its major articulating surface (Fig 1A-B). Both showed strong staining for proteoglycans on their cartilage surfaces and fibrous tissue at their peripheries (Fig 1C). The average thickness of the AC articular cartilage ranged from 350-500 μm within the contour of the main articulating surface (Fig 2A). The equilibrium modulus in the superior, middle, and inferior regions was 0.93 ± 0.54 , 1.40 ± 0.67 , and 1.36 ± 0.60 MPa, respectively. In the OpenSim model, contact force remained $\sim 0\text{N}$ as the carpus was extended, until $\sim 20^\circ$ flexion. After this point, force increased and reached a peak of 67N at full extension (Figure 2C). In the *ex vivo* experiment (Fig 2D), contact area across the joint remained close to 0 mm^2 until 15° of flexion, and then rose rapidly as the angle approached 0° (Fig 2E). Force (Fig 2F) followed the same pattern, reaching its maximum of $29.1 \pm 10.5\text{N}$ at 0° .

Using anatomic renderings generated from μCT , an implant was designed to replace the articular surface of the porcine AC (Fig 3A).

(E-F) Plots of contact area and force with respect to flexion angle as measured using a TekScan sensor.

Using a 3D printed positive mold, a PDMS negative mold was produced (Fig 3B) which was used to create a porous PCL implant (Fig 3C). This was implanted into a living pig (Fig 4A-C), which began weight bearing soon after surgery (Fig 4D). The implant remained intact and in place after 1 week. (Fig 4E-G).

DISCUSSION

In this study, we compared the porcine AC and the human trapezium. The two showed remarkable anatomic and compositional similarities. To better understand the loading of this joint, we analyzed the tissue-level mechanics of the cartilage as well as the load transfer across this joint. Loading patterns measured *ex vivo* matched that predicted via OpenSim. These models and data show that the AC is essentially unloaded, except when the carpus is fully extended. This means that when implanted into a living animal, the construct will only experience loads when the animal is standing, or in the stance phase of the gait cycle. Next, from μCT data, we

Figure 4: (A-C) Implantation of engineered ACB in a living animal. (D) Post-Op day 1 showing weight bearing and fluoroscopy showing implant. (E) Week 1 CT. (F) Implant retrieval and (G) implant μCT at week 1.

designed an implant that recapitulates the articulating surface of the AC and a process to fabricate such an implant using a porous PCL foam. This we surgically implanted into a living animal, which recovered well from surgery and was weight bearing following recovery from general anesthesia. After one week, the implant remained in place and intact, demonstrating that this approach of implant fabrication and surgical fixation is feasible for the resurfacing of the AC. Future studies will evaluate the long-term function of a cell seeded osteochondral implant (with a stem cell-laden hydrogel cap to form a cartilage layer) in a living animal. Future studies will also use clinical CT to produce anatomic renderings of the AC, allowing us to fabricate the implant to patient-specific geometry. By using the porcine AC as a model for the human trapezium, evaluating its composition, mechanics, and function, designing and fabricating an anatomic construct, and implanting it in a living animal, this study advances our work towards total biologic resurfacing of this joint as an analog for the treatment of TMC OA in humans.

INTRODUCTION

Musculoskeletal disorders, such as muscular dystrophies and acute volumetric muscle loss, are prevalent and often debilitating. [1] The specific effects of muscular disorders are more understood in muscle tissue, however tendon tissue is also affected and contributes to the decreased function of the muscle tissue. [2] In parallel to muscular diseases, tendinopathies are more understood in tendon tissue, but there is little understanding how they affect muscle tissue. While importance of mechanical signaling has been established in skeletal tissue, the endocrine function and communication (“cross-talk”) in tissues like muscle and bone are becoming increasingly recognized. [3] Specifically, at the myotendinous junction (MTJ), muscle cells express integrin proteins like paxillin and talin that integrate with tendon matrix.[4] In addition to cell-matrix interactions, cross-talk between cells may be an important aspect in the maintenance of the MTJ cell population and matrix structure. For instance, during development, tendon cells provide signals to muscle cells that help to anchor muscle to tendon, indicating this cross-talk is extremely important to the organization of muscle tissue. [5] A multi-phasic tissue may produce a gradient of growth factors sufficient to induce higher level organization and may be a key component for the synthesis of an *in vitro* MTJ model.

The development of multi-tissue platforms can enable researchers to understand how the cross-talk of muscle and tendon affects the regeneration in healthy or diseased muscle and tendon tissue. Currently *in vitro* models are often composed of one tissue and do not re-capitulate the complexity, especially at the interface of the muscle and tendon. The overlap of the two tissues may provide cross-talk crucial to the expression of MTJ specific proteins (e.g. paxillin). [6] As a first step toward developing an *in vitro* MTJ model, this research aims to determine the effects of muscle or tendon extracellular matrix on mouse myoblast cells grown in monolayer or cultured in a 3D hydrogel. Furthermore, to develop a multi-phasic tissue, special inserts were

designed to create a tunable overlap region between extracellular matrix hydrogels seeded with tendon and muscle cells.

METHODS

Porcine muscle and tendon tissues were decellularized, lyophilized and digested according to previous methods to yield muscle derived extracellular matrix (mECM) or tendon derived extracellular matrix (tECM). [7] C2C12 mouse myoblasts were cultured on tissue culture plastic in either regular growth media (RGM) consisting of DMEM supplemented with 10% FBS and 1% Penicillin/Streptomycin or muscle differentiation media (mdiff) consisting of DMEM, 1% Horse Serum, 1% FBS and 1% Penicillin/Streptomycin.

To determine effects of ECM conditioned media, cells were cultured for 5 days in monolayer in both medias, alone and supplemented with 400ug/ml of either type I collagen, mECM or tECM (Figure 1A). To determine effects of culturing cells within tissue specific matrix, mouse myoblasts were suspended in type I collagen, mECM or tECM hydrogels before cross-linking, which resulted in a stable 3D engineered tissue with seeded cells following cross-linking (Fig. 2A). Tissue constructs were cultured in either RGM or mdiff media for 5 days. In both scenarios, RNA from cells were isolated and processed. Relative gene expression analysis for Paxillin was determined through q-PCR. Furthermore, samples were normalized to cells in RGM or Collagen tissues cultured in RGM.

To create an *in vitro* MTJ model that mimics the native interface, custom inserts with engineered tissues were utilized. Mouse myoblasts and mouse primary tendon fibroblasts were seeded in various hydrogel environments prior to cross-linking. Cell-laden hydrogels at concentrations of 4.5, 5.0, 5.5 and 6.0 mg/ml were seeded on either side of a removable barrier and allowed to partially cross-link. After 5, 10 or 15 minutes the barriers were removed allowing the gels to partially mix. This resulted in biphasic gels with an overlapping region containing

both myoblasts and tendon fibroblasts of varying widths depending on time and concentration.

Figure 1: C2C12 cells cultured on tissue culture plastic cultured in RGM or Diff medias supplemented with digested type I Collagen, m-ECM or t-ECM had increased expression of Paxillin compared to cultures with non-supplemented medias or medias supplemented with collagen. $\Delta\Delta CT$ is relative to GAPDH and normalized to C2C12s cultured in regular growth media.

RESULTS

Myoblast Monolayers Cultured with Conditioned Media: Mouse myoblasts cultured in monolayer increased varying levels of paxillin expression when media was supplemented with mECM or tECM, relative to controls (Figure 1B). Fold increases of 1-2 were observed in ECM conditioned media and this shift also occurred in both media types (RGM and mDiff).

Engineered Tissues with Myoblasts: Myoblasts encapsulated in 3D hydrogel environments had increased levels of relative paxillin expression in ECM environments compared to the collagen environment (Figure 2). Fold changes of 2-4 occurred in cells within

Figure 2: Myoblast cells cultured in type I collagen and ECM derived hydrogels for a period of 5 days have increased expression of MTJ protein Paxillin in ECM hydrogels compared to collagen. **A)** Briefly cells were encapsulated in self-assembling hydrogels and cultured in either RGM or Diff media. **B)** q-PCR results of Paxillin expression relative to housekeeping gene GAPDH and normalized to samples cultured in collagen gels with RGM.

ECM hydrogels cultured in RGM. Lower fold changes occurred in tissues cultured in mDiff, but the rank order of groups was similar.

Creating Biphasic Tissues with Tunable Interfaces: After determining the effect of tissue specific microenvironments on myoblasts, we designed a way to culture and examine cells in an interface zone with different microenvironments and different cell types. Gels were allowed to self-assemble separately before divider removal resulted in biphasic gels with varying regions of mixed hydrogels (Figure 3). In all 4 concentrations of hydrogels, time had a significant effect on the width of the overlap region, while the effect of gel concentration was not as pronounced. 15 minutes of isolated self-assembly in 5.5 and 6.0 mg/ml hydrogels yielded physiologically relevant overlaps of 200-600 μm .

Figure 3: Overlapping interface regions of tendon and myoblast cells suspended in 3D hydrogels were achieved with custom cell culture inserts. **A)** Cell culture inserts were modified to have a removable divider. Cells were seeded on either side of insert divider and incubated separately for specific times, after which the divider was removed allowing the gels to overlap. **B)** Images of gels of varying concentration and separated incubation times. Both time and concentration of gels had an effect on gel overlap.

DISCUSSION

Tissue specific derived matrix increased paxillin expression in myoblasts cultured in monolayer and 3D hydrogels, suggesting that mECM or tECM contained signals that helped promote MTJ expression in myoblast cells. Interestingly the highest levels of paxillin expression was seen in myoblast cells exposed to tECM, suggesting interaction with tendon matrix may be important in MTJ signaling *in vivo*. After establishing the effect of the microenvironment on myoblast cells the next step is to study the interface of myoblasts with tendon cells. Our tissue culture insert allows hydrogels to partially self-assemble, separately allowed for the creation of a tunable overlap region with a mix of both hydrogels. This will allow us to study interactions of cells in an overlap region, and possibly examine cross-talk effects between muscle and tendon cells.

INTRODUCTION

Branching morphogenesis begins with a simple tube or cluster of cells that grow and undergo rounds of budding and/or bifurcation, leading to the formation of a complex, arborized network. The final form and function of each branched organ varies, but the molecular programs responsible for their development are often similar. In most branched epithelial tissues, growth factors from the surrounding mesenchyme signal to the epithelium to elicit cellular behaviors required for growth and branching [1]. However, growth factor signaling alone cannot fully explain how the different architecture of each organ is achieved. To understand how branched networks are generated, we require a deeper understanding of the physical mechanisms of branching morphogenesis [2]. Equipped with such knowledge, we may be able to better diagnose and treat developmental disorders, and further, to recapitulate the mechanisms employed by the embryo to engineer branched tissues *ex vivo*.

In the mouse lung, branching is highly stereotyped and is achieved by repeated use of simple branching modes: the overall architecture is established by domain branching, in which new branches form laterally off the side of an existing branch, while bifurcations build a space-filling network [3]. The airway epithelium develops concomitantly with a layer of smooth muscle, which is derived from the embryonic mesenchyme and wraps circumferentially around the airways. We previously showed that stereotyped patterns of smooth muscle differentiation are required for terminal bifurcation [4]. Here, we

examined the role of smooth muscle differentiation in shaping emerging domain branches during early murine lung development.

METHODS

Embryonic mouse lungs were isolated at embryonic day 11.5 (*E11.5*) and cultured *ex vivo* at an air-liquid interface for 24 hours. Pharmacological inhibitors or adenoviruses were added to the culture medium to manipulate smooth muscle differentiation. Genetic ablation of smooth muscle was achieved by selectively expressing the human diphtheria toxin receptor in smooth muscle cells and then treating lung explants *ex vivo* with diphtheria toxin. Immunostaining and EdU pulses were then used to assess the effects of these treatments on airway epithelial morphology, smooth muscle coverage, and epithelial proliferation. Time-lapse imaging was used to track epithelial morphology over the course of branching, and embryos expressing fluorescent reporters were used to visualize smooth muscle differentiation. Finally, a computational model of domain branching based on continuum mechanics of growing tissues was created to explore the role of smooth muscle-mediated constraint.

RESULTS

Our studies reveal a role for airway smooth muscle in sculpting emerging domain branches in the embryonic mouse lung. We have shown that domain branching is highly

stereotyped and accompanied by evolving spatial patterns of smooth muscle. Perturbing these patterns of differentiation with pharmacological, adenoviral, or genetic approaches disrupts domain branching. Enhanced wrapping of smooth muscle around the epithelium suppresses branch initiation and extension, whereas decreased smooth muscle coverage leads to ectopic and dilated branches. Ablation of smooth muscle cells using transgenic mouse models at earlier stages of differentiation affects domain branching, but ablation of mature smooth muscle cells does not. Based on these findings, we propose that domain branching is primarily regulated by the pattern of newly forming smooth muscle and not by the existing smooth muscle sheath.

Our data suggest two possible mechanisms by which smooth muscle regulates branch formation. Firstly, we identified an evolving pattern of epithelial proliferation that is complementary to the pattern of smooth muscle differentiation and perturbed when the latter is disrupted. Secondly, we determined that the primary bronchus adjacent to an emerging branch is gradually constricted, and that this thinning depends on smooth muscle differentiation. These data suggest that smooth muscle affects local epithelial behaviors (i.e. proliferation rate) and overall epithelial morphology. We hypothesized that if smooth muscle was indeed required to physically shape the growing epithelium, then epithelial volume might be unchanged between treated lungs and controls. In line with this, we found that the volume of the epithelium is conserved even in lungs where smooth muscle differentiation is disrupted and that have wider epithelial branches and even ectopic branches.

Overall, our data suggest a model in which the airway epithelium expands uniformly into the mesenchyme and is guided into a branched morphology by spatially patterned smooth muscle differentiation (**Fig. 1**). These conclusions are supported by computational modeling: domain branches only form correctly when provided with the appropriate smooth muscle constraint. In the absence of a stiff smooth muscle layer, the simulated epithelium forms multiple ectopic branches and buckles, similar to the effects observed when smooth muscle differentiation is inhibited experimentally. These data support our assertion the local presence of smooth muscle exerts a physical force to direct the expansion of the growing epithelium.

Figure 1: Differentiation of smooth muscle around the primary bronchus leads to thinning of elongating branches by physically constricting the epithelium. When differentiation is blocked, epithelial growth is unconstrained and the epithelium becomes dilated. When differentiation is enhanced, a sheath of smooth muscle envelops the epithelium, preventing branch initiation and extension.

DISCUSSION

Our work uncovers a role for smooth muscle differentiation in sculpting domain branches, and sheds additional light on the physical mechanisms of branching morphogenesis in the mouse lung. There is still much to be uncovered if we are to truly understand the complex relationships between epithelial branching and smooth muscle differentiation, and in particular, how signaling networks and mechanical forces may cooperate to achieve patterned differentiation. We show a clear spatiotemporal correlation between emerging domain branches and localized smooth muscle differentiation, and point to possible mechanisms by which this pattern of smooth muscle might guide the epithelium into its final morphology. We establish smooth muscle as a critical regulator of early lung branching morphogenesis, and anticipate that it may play similar roles in other smooth muscle-encircled epithelial tissues.

INTRODUCTION

Inhalable drug and respiratory toxicity assays are conventionally performed on human bronchial epithelial cells (HBECs) that have been differentiated for several weeks at an air-liquid interface (ALI). Porous filters have been used as ALI culture models for decades, since they were shown to promote differentiation into ciliated cells and mucus-producing goblet cells [1]. However, ALI filter culture is expensive, labor-intensive, and difficult to scale for high-throughput applications. It also remains unclear as to which biophysical cues prompt differentiation. Understanding these signals could lead to greatly simplified designs of culture platforms optimized for airway studies compatible with high-throughput methods.

The assumption that complete ALI is a uniquely necessary condition for HBEC differentiation was recently challenged by Gerovac et al. who demonstrated that a thin layer of culture media over lung cells at ALI can further improve differentiation [2]. This suggests that differentiation in submerged culture is not only possible, but that the increased availability of soluble nutrients may enhance differentiation efficiency under appropriate culture conditions. Eliminating the need for ALI could eliminate the need for filter culture platforms, and reduce the cost of drug discovery.

Limited diffusion of oxygen through culture media causes an oxygen-depleted zone to form at the cell surface during submerged culture. In contrast, ALI provides cells with increased oxygen access. Here, we hypothesize that exposure to increased oxygen levels present on the air-side of the ALI culture triggers differentiation, and that appropriately designed hyperoxic culture conditions would allow differentiation under submerged conditions. Here, we cultured HBECs on filters at standard/hyperoxic conditions, and at ALI/submerged conditions (Fig. 1) to determine the necessity of ALI cultures for differentiated studies.

Figure 1: Comparison of the three culture conditions.

METHODS

Parametric finite element simulations were performed to determine the optimal incubator oxygen level to achieve ambient (21%) oxygen concentrations at the cell surface, when cultured with 3 mm of fluid in the apical chamber in submerged culture.

Primary bronchial cells from three otherwise-healthy trauma patients were isolated at the Cystic Fibrosis Translational Research core at McGill University, seeded onto polyester Transwell® filters at ALI, and cultured until confluent. Atmospheric oxygen levels and liquid levels were then controlled for standard O₂/ALI, standard O₂/submerged and hyperoxic O₂/submerged cultures for a subsequent 25 days.

To characterize cultures, transepithelial electrical resistance (TEER) was monitored to assure epithelial layer integrity. Epithelial morphology and function were assessed via immunofluorescent labels for nuclei, the microtubule element cilia β -tubulin III strongly expressed in cilia, the tight junction marker zonula occludens-1 (ZO-1), and nuclear levels of the oxygen-sensitive marker hypoxia-inducible factor 1- α (HIF-1 α). Differentiation was determined by measuring epithelial layer thickness, ciliated surface area, and beat speed. Functional ciliation was verified using particle movement assays.

RESULTS

Simulations demonstrated that an incubator oxygen concentration of 30% would theoretically allow for the cells to experience normoxic conditions (21%) at the cell surface when submerged in 3 mm of media (Fig. 2A). Other combinations of media layer height, cell oxygen consumption rate and incubator oxygen concentrations to achieve normoxic cell conditions were plotted (Fig. 2B).

Figure 2: Finite element simulation (A) Time-dependent oxygen concentration at the cell surface for standard and hyperoxic atmospheric oxygen levels. (B) Parametric variation of cell oxygen consumption rate, media layer thickness, and atmospheric oxygen to achieve normoxic oxygen concentrations at the cell layer.

Validation. Average cell spread area was statistically similar in all three culture conditions, and cells closest to the porous filter surface adapted a flatter morphology, that is typical of basal epithelial cells. Nuclear HIF-1 α was elevated in standard/submerged culture and reduced in standard/ALI and in hyperoxic/submerged (Fig. 3A), confirming that HBECs are sufficiently sensitive to oxygenation differences caused by submersion, and that oxygen levels at the cell surface that have been reduced by submerged culture can be rescued by hyperoxic exposure. In all three conditions, TEER measurements stabilized around day 7 (Fig. 3B), and tight junction ZO-1 expression was consistently observed (Fig. 3C), confirming that cultures do not suffer adverse effects at this level of oxygen exposure. In contrast, higher oxygen levels resulted in cell death and barrier permeabilization (data not shown).

Figure 3: Culture characteristics. (A) Nuclear HIF-1 α levels in HBECs after 25 days in culture (* $p < 0.05$). (B) TEER and (C) ZO-1 (green) / nuclei (blue) from standard/ALI, standard/submerged, and hyperoxic/submerged conditions.

Differentiation. For cells from all three patient donors, the hyperoxic/submerged condition exhibited the highest rates of ciliation; while cells under standard/ALI exhibited the lowest (Fig. 4A), which was surprising given that ALI culture is the standard for HBEC

differentiation. Beat frequency of cilia was found to be lowest in standard/ALI conditions, likely a result of the presence of more concentrated levels of mucus on the epithelial surface. Moreover, both submerged conditions produced statistically thicker epithelial cell layers than the ambient-ALI cultures (Fig. 4BC). Taken together, these metrics indicate that hyperoxic/submerged culture promotes the highest rates of HBEC differentiation on filters.

Figure 4: HBEC differentiation. (A) Ciliated area of cell surface after 18 days in culture ($n=3$, * $p < 0.05$). (B) Cell layer thickness of histology slices ($n=5$, * $p < 0.001$). (C) H&E stain of cell layer histology cross-sections for standard/ALI and hyperoxic/submerged conditions.**

DISCUSSION

The finite element simulation and nucleic HIF-1 α levels confirm that controlled hyperoxic ambient conditions can compensate for the oxygen diffusion gradient present in submerged conditions. Our results show that submerged HBEC culture triggers higher rates of ciliation and allows for thicker epithelial layer formation in all three primary donors, which contradicts the widely accepted assumption that ALI is necessary for HBEC differentiation. Both increased ciliation and thicker epithelium can be a result of increased nutrient availability in submerged culture. The lower cilia beating speed observed in the standard/ALI condition is likely due to a thick mucosal layer on top of the cells, which offers resistance to cilia movement. Throughout submerged culture, these mucins excreted by goblet cells likely dissolve into the surrounding media and thus do not form the viscous dampening layer necessary for mucociliary clearance studies. Interestingly, the ability of these cell types to differentiate at all under hypoxic and hyperoxic submerged conditions suggests that improved media formulations may have already reduced the need for ALI cultures, and that hyperoxic conditions may be sufficient to eliminate ALI entirely. Intriguingly, these conditions might reflect the rapid increase in differentiated lung cells that occurs during the first trimester of fetal development, before ALI conditions exist in the lung [3].

INTRODUCTION

Ramified networks form the basic architecture for many organs in the body including the lung, kidney, and salivary gland. In the developing lung, these structures are formed via a process known as branching morphogenesis. The embryonic lung bud arises as an out-pocketing of foregut endoderm, which undergoes a series of recursive branching events to build the bronchial tree [1]. A complex network of signaling pathways regulates this process, but fibroblast growth factor (FGF) signaling has emerged as a particularly important regulator of airway branching. Focal regions of FGF-10 expression in the pulmonary mesenchyme are thought to specify the locations of new epithelial branches and thereby control the overall branching pattern [2]. Recent experiments, however, have shown that mechanical forces can also regulate lung development [3-5], but it is unclear how growth factor signaling is integrated with these biophysical cues to direct the formation of the bronchial tree.

Here, we used growth factor-loaded beads to create ectopic sources of FGF-10 and implanted them in the mesenchyme of embryonic lung explants along regions of the airway epithelium that do not normally form branches. These focal sources of exogenous FGF-10 were sufficient to induce the formation of multiple supernumerary buds in explants cultured *ex ovo*. The supernumerary buds formed simultaneously, as revealed by time-lapse microscopy, and were found to depend crucially on cell proliferation. We did not observe changes in cellular contractility during the formation of ectopic buds, despite previous work suggesting that apical constriction, downstream of FGF-10 signaling, initiates the formation of new epithelial branches during normal lung development. Taken together, our results suggest that supernumerary buds arise via an FGF-10-induced buckling mechanism. These data will help elucidate how specific patterns of FGF-10

expression give rise to the macroscopic changes in tissue form that build the bronchial tree during embryonic development.

METHODS

Fertilized White Leghorn chicken eggs were incubated at 37 °C in a forced-draft incubator to Hamburger and Hamilton (HH) stage 26. Embryonic lungs were dissected in phosphate-buffered saline (PBS) supplemented with antibiotics using fine forceps and a dissecting stereomicroscope. Small agarose beads, soaked in either PBS or 100 µg/ml FGF-10 for 1.5 hr at room temperature, were then implanted into the pulmonary mesenchyme adjacent to unbranched regions of the airway epithelium. The explants were then cultured on porous membranes at the air-liquid interface in DMEM/F12 medium (without HEPES) supplemented with 5% fetal bovine serum (FBS) and antibiotics. In some experiments, the medium was also supplemented with either 1 µM aphidicolin or 5 µM blebbistatin, to inhibit cell proliferation or non-muscle myosin II contractility, respectively.

Bright field images of cultured explants were captured at 0 and 24 hr to quantify the number of ectopic buds, as well as changes in epithelial morphology. Relative changes in epithelial contour length, as well as an epithelial tortuosity index, defined as the ratio of the contour length relative to the length of a straight line connecting the end-points of the contour, were measured after 0 and 24 hr of culture. In other experiments, to determine the role of cell proliferation during supernumerary bud formation, we used the Click-iT EdU Imaging Kit to detect proliferating cells in explants cultured with either control or FGF-10-containing beads. These explants were fixed, stained for LCAM (E-cadherin) immunofluorescence and DAPI, dehydrated in a methanol series, optically cleared with Murray's clear, and imaged as whole-mounts using a laser scanning confocal microscope. Additional explants were stained with phalloidin to visualize F-actin.

To quantify the dynamics of supernumerary bud formation, we also conducted time-lapse experiments using a stage-top incubator. Bright field images of cultured lung explants were captured every 30 minutes for 24 hr, and epithelial morphologies were quantified as described above.

RESULTS

Agarose beads containing 100 $\mu\text{g/ml}$ FGF-10 were embedded in the pulmonary mesenchyme of embryonic chicken lungs adjacent to unbranched regions of the developing airway epithelium. These FGF-10-loaded beads induced the formation of several ectopic buds after 24 hr of culture, as compared to explants cultured with control beads (Figure 1). Quantitative morphological measurements revealed an increase in both the contour length and tortuosity index at 24 hr of the airway epithelium in explants cultured with FGF-10-loaded beads. To determine the role of cell proliferation in this process, we then cultured lung explants containing FGF-10 loaded beads in the presence and absence of the cell cycle inhibitor, aphidicolin. Explants treated with aphidicolin exhibited a decreased number of supernumerary buds and showed concomitant decreases in the contour length and tortuosity index at 24 hr of the airway epithelium, which suggested that cell proliferation is required for the formation of supernumerary buds. We also quantified rates of proliferation along the airway epithelium in explants treated with control beads, FGF-10-loaded beads, and FGF-10-loaded beads + aphidicolin. Confocal imaging of fixed explants stained for EdU incorporation and LCAM immunofluorescence revealed increased levels of epithelial proliferation in the FGF-10-induced supernumerary buds (Figure 2). Time-lapse culture of lung explants containing either control or FGF-10-loaded beads further showed that the supernumerary buds formed simultaneously, a result suggestive of an epithelial buckling event [5].

Figure 1: FGF-10-loaded beads induce the formation of supernumerary buds (white asterisks) in cultured embryonic chick lungs.

Other cultured explants were stained with phalloidin to visualize F-actin and to assess the role of apical constriction during the formation of ectopic buds, since earlier work had shown apical constriction to initiate budding events during normal lung development [6]. The FGF-10-induced supernumerary buds contained no discernible increases in F-actin staining, suggesting that apical constriction is not involved in their formation. However, explants containing FGF-10-loaded beads, which were treated with the non-muscle myosin-II inhibitor, blebbistatin, exhibited a reduction in the number of supernumerary

buds. The treatment with blebbistatin did not modulate rates of cell proliferation, as determined by EdU incorporation, suggesting a role for cell contractility in suppressing the buckling morphogenesis of the airway epithelium.

Figure 2: FGF-10-loaded beads induce elevated levels of EdU incorporation in supernumerary buds.

DISCUSSION

Previous studies have used grafts of distal pulmonary mesenchyme to stimulate the formation of supernumerary buds along the (unbranched) trachea of cultured embryonic mouse lungs [7]. The distal mesenchyme expresses a variety of growth factors that have been shown to regulate airway branching morphogenesis [8], but it is not clear how specific growth factors drive the changes in the epithelial cell behavior that result in the formation of a new branch. In these experiments, FGF-10-loaded beads were sufficient to induce the formation of numerous ectopic buds, which formed simultaneously, with branching dynamics redolent of the buckling instability previously shown to govern the branching morphogenesis of cultured mesenchyme-free explants [5]. Future work will investigate how epithelial buckling is integrated with growth factor signaling to direct the formation of these supernumerary buds. These data will help uncover the mechano-regulatory mechanisms that control airway branching morphogenesis.

INTRODUCTION

Communication between cells at the tissue scale is critical not only for development, but also for processes such as wound healing¹ and maintenance of the epithelial barrier. Disrupting the delicate balance between proliferation and cell death can lead to diseases such as cancer². It is well known that not only biochemical but also mechanical cues contribute to the establishment of growth patterns across an epithelial sheet. For example, the geometry of an epithelial tissue dictates gradients of mechanical stresses that control the location of dividing cells via forces exerted on the tissue edge³. Specifically, higher geometric forces at the edges of convex epithelial tissues lead to increased proliferation in cells within these regions.

Not only can cells communicate via biochemical and mechanical means, but it is becoming increasingly clear that bioelectric gradients also play a role in coordinating growth at the tissue scale. Bioelectricity describes the membrane voltage (V_m) of cells across a tissue. V_m is defined simply as the electric potential difference across the plasma membrane⁴. This difference arises due to the different concentrations of ions such as K^+ , Na^+ , and Cl^- that exist in the cytoplasm and extracellular medium. Cells tune V_m by regulating the concentrations of such ions via channels and transporters within the plasma membrane, which open in response to various cues such as ion concentration or changes in V_m ⁵. Some ion channels even respond to physical cues that exert forces across the plasma membrane⁶. These mechanosensitive ion channels establish a possible link between mechanical and bioelectric regulatory cues. However, it is

unclear to what extent mechanical and bioelectric forces influence each other and coordinate cellular behavior across the tissue to control growth, healing, and prevention of cancer.

Bioelectricity has been documented to control striking phenotypes at the tissue scale, including organogenesis⁷ and tumor formation⁸, as well as properties of individual cells such as proliferation and apoptosis⁴. However, it is still unclear exactly what specific manipulations of V_m will lead to a desired outcome. This is not entirely surprising given the complexity of biochemical and mechanical cues surrounding the cell. We therefore wished to more thoroughly examine how mechanical factors influence the establishment of bioelectric gradients across a tissue. Since decreased V_m (depolarization) has been correlated with increased proliferation⁴, we hypothesized that the convex edges of epithelial tissues constrained to specific geometries would be more depolarized at these highly proliferating regions³. We found that this bioelectric gradient is formed by forces exerted on the tissue, which activate the mechanosensitive ion channel Piezo1. Finally, our data suggest that decreased V_m is required for increased proliferation in these high-stress regions due to enhanced entry of Ca^{2+} ions, which affect signaling through the Yap/Taz⁹ pathway.

METHODS

Mouse mammary epithelial cells were cultured to confluence on islands of fibronectin formed by microcontact printing¹⁰. Proliferation was visualized using EdU incorporation,

and immunofluorescence analysis was used to label E-cadherin, Yap/Taz, or Piezo1. The voltage reporter dyes DiBac4(3) or DiBac4(5) were used to visualize gradients of cellular Vm throughout the tissues. These molecular dyes more easily enter the plasma membrane of depolarized cells. The percent difference in mean fluorescence intensity was calculated for the outermost 2-3 cell border and innermost 5-10 cell regions of an average intensity stack comprised of at least 15 tissues. Ionic calcium was visualized using Calcium Green 1 (Thermo Fisher). Tissues were incubated for 24 hr in 10 μ M dye concentration prior to imaging. Average intensity stacks were prepared as described above.

RESULTS

Square mammary epithelial tissues show increased proliferation at their edges as visualized with EdU incorporation (**Figure 1A, B**). This is in agreement with previously published work³. Tissues treated with DiBac4(3) to visualize Vm show increased fluorescence, indicating depolarization, along the edge and convex corners, where mechanical stress is highest (**Figure 1C, D**). These results are in agreement with our hypothesis that regions of increased mechanical stress correlate with depolarized

regions of the tissue. Notably, we did not observe increases in either proliferation or depolarization in concave tissue regions of low mechanical stress. We next examined tissues comprised of cells in which we knocked out the cell adhesion protein E-cadherin (Δ E). These tissues are unable to establish the gradient of mechanical stress present in parental tissues. Knocking down E-cadherin abolished the geometric proliferation gradient (**Figure 1E**). As expected, Δ E tissues did not show a gradient of depolarization along the tissue edge and corners (**Figure 1F**). In addition to these data, we observe increased expression of the mechanosensitive ion channel Piezo1 in cells at the tissue periphery. Also, we observe increased intracellular calcium as visualized with Calcium Green 1. Nuclear localization of Yap/Taz are also increased along the tissue periphery. The patterns of both Piezo1 and Yap/Taz nuclear localization were disrupted in tissues comprised of Δ E cells.

DISCUSSION

We observe increased depolarization in convex regions of epithelial tissues constrained to specific geometries, consistent with our hypothesis that mechanical stresses are connected to Vm. Our data implicate the mechanosensitive ion channel Piezo1, increased intracellular Ca^{2+} concentration, and nuclear localization of Yap/Taz as key nodes in the link between mechanics and Vm. In the absence of mechanical stress gradients, we no longer see increased proliferation or depolarization. Further, we no longer observe the same patterns of Piezo1 expression or Yap/Taz activation. To our knowledge, this is the first study to directly establish a role for mechanical forces in Vm alteration.

Figure 1: Epithelial tissue geometry dictates the location of proliferative cells as visualized by EdU analysis (a). This trend persists across multiple images (b). Further, depolarization occurs at convex tissue regions, where mechanical stresses are highest (c). Averaging multiple tissues reveals this pattern (d). Finally, E-cadherin is required for establishment of both the proliferation (e) and Vm (f) gradients.

CHARACTERIZATION OF COLLAGEN/KERATIN HYDROGELS AS AN EXTRACELLULAR MATRIX FOR 3D IN VITRO THERMAL STRESS STUDIES

INTRODUCTION

Biomimetic engineering has become critical for use in testing drugs and other treatments before moving forward with *in vivo* models and human clinical trials. Although *in vivo* models have normally been used, many drugs risk failure in clinical trials due to the significantly dissimilar microenvironments between humans and other animals and in addition are cost extensive. Biomimetic 3D *in vitro* models can serve as an early testing platform with carefully-designed parameters that can more closely model the human tissue microenvironment.

Collagen is commonly used to create 3D *in vitro* models to serve as the ECM. However it cannot be used to study cell behavior in response to thermal changes. Collagen has a denaturing temperature of approximately 40 °C and starts melting at even lower temperatures [1]. As a consequence, many *in vitro* hyperthermic models utilize a cell monolayer approach, which is not an accurate representation of heat transfer through an organ or tissue. Therefore, an ECM with greater thermal stability is needed.

Keratin is a more thermally stable natural biomaterial that can easily be extracted from animal wool and horn and human hair and can be used to as a biologically representative ECM component; therefore it can potentially be used for thermal stress studies without compromising the ECM with a denaturing temperature between 120 and 150 °C when wet [2]. Specific keratin extracts from the hair cortex have been shown to promote cellular attachment and proliferation in numerous studies, and have been shown to promote cell growth [3]. Keratene (KTN), a form of reduced keratin, contains cysteine residues and is capable of disulfide crosslinking and self-assembly and has been shown to be more stable than its oxidative counterpart, keratose [3].

In the present study, we hypothesized that adding keratene to collagen may increase the thermal stability of *in vitro* scaffolds and tissue platforms. This mixture will serve as a potentially-useful system

to study the effect of thermal stress various doses and exposure time on cells behavior.

METHODS

Working collagen solutions of 3 and 7 mg/ml was prepared from the collagen stock solution of 6 and 14 mg/ml, respectively, by neutralizing with 10x DMEM, 1x DMEM, and 1 N NaOH. These concentrations of collagen were used because healthy tissue is less dense (3 mg/ml), whereas tumor tissue is denser in collagen and results in a stiffer ECM (7 mg/ml). 50/50, 30/70, and 20/80 w%/w% collagen/keratene (C/KTN) hydrogels were prepared by combining both stock collagen (6 and 14 mg/ml) and KTN dissolved in neutralizing buffer of equal volume. After mixing thoroughly with a spatula, gels were added to cell culture-treated 96 well-plates and incubated at 37°C for 40 minutes to allow polymerization. For cell culture experiments, gels were seeded with 0.5 million cells/ml and supplied with 100 µl of complete media. Media was changed every 2 days.

ECM structure was observed with dehydrated acellular gels through scanning electron microscopy (SEM). In addition, the thermal denaturation temperature of wet hydrogels were evaluated using differential scanning calorimetry (DSC) from 30 to 80°C at a rate of 5°C/min. For rheology, hydrogels underwent a frequency sweep at 1% strain from 1 to 15 Hz. Results were evaluated from 1 to 1.43 Hz.

Cellular studies were conducted to quantify cell viability and observe cell growth and morphology. Cell viability was quantified though CellTiter Blue viability assay at days 1, 3, 5, and 7 post-seeding. Cell viability was measured by reading fluorescence intensity with a spectrophotometer at 560_{ex}/590_{em}. Sample readings were normalized to blank solutions (no sample). Additional samples were prepared for the same time points, fixed, and stained for actin to observe morphology.

All experiments were repeated 3 times with n=3 and quantitative data was analyzed for significance with one-way ANOVA.

RESULTS

SEM images showed that the increase in keratin content corresponded with higher level of bundling of fibers as the gel becomes more porous and the fibers become thicker as shown in Figure 1. Fibers in C/KTN hydrogels are also aligned straighter than the 100% collagen gels, altering overall fiber organization.

Figure 1. SEM images of 3 and 7 mg/ml collagen and C/KTN hydrogels from high to low magnifications (top to bottom).

Higher keratin content also increased the denaturing temperature of C/KTN hydrogels for both 3 and 7 mg/ml hydrogels demonstrated by DSC in Figure 2A. Significance was observed between 100% collagen and all C/KTN hydrogels. Although there were only slight increases, C/KTN hydrogels remained stable when incubated at 42°C for 1 hour whereas collagen melted completely.

Figure 2. Thermal denaturing temperature measured by DSC (A) and storage modulus measured by rheology of various gels (B). # = $p < 0.05$ and * = $p < 0.01$.

Rheology measurements of the different hydrogels using a frequency sweep showed that there was no significant difference when adding keratin to the hydrogel (Figure 2B). However, for 7 mg/ml hydrogels, there appears to be a trend of increasing stiffness as keratin content increases. The 3 mg/ml hydrogels may not show any trend due to the fact that there is not enough keratin in the hydrogel blends.

Cell viability of C/KTN hydrogels were comparable with 100% collagen gels as shown in Figure 3A and B. Significance was only observed at days 3 and 7 between collagen and 20/80 C/KTN 50/50 C/KTN hydrogels, respectively for breast cancer cells (Figure 3B). Although 50/50 and 30/70 C/KTN hydrogels had higher viability than collagen at day 7 for both NHDF and breast cancer cells, 20/80 hydrogels had the lowest viability. However this was not significant, and at day 7, 20/80 C/KTN viability remained higher than day 5. Stained samples were also imaged and showed that the presence of keratine caused both NHDF and breast cancer cells to appear more elongated than 100% collagen hydrogels, possibly promoting cell spreading (data not shown).

Figure 3. Cell viability measurements for 3 mg/ml NHDF (A) and 7 mg/ml breast cancer cell hydrogels (B). # = $p < 0.05$ and * = $p < 0.01$.

DISCUSSION

In this study, C/KTN hydrogels of various keratine concentrations were fabricated to determine whether keratine was able to increase the thermal stability of collagen hydrogels and whether it supported cell growth and proliferation so this blend can be used for hyperthermic or thermal stress studies without compromising the ECM. The different blends, with increasing keratine content, was able to increase the thermal denaturing temperature of the ECM as shown by DSC when compared to pure collagen hydrogels. Although one previous study did create a C/KTN blend using animal horn, DSC analysis was performed on dry hydrogels and there were no comparisons with pure collagen hydrogels [4]. Because the samples were dried, one significant peak with similar shape as this study was observed at a temperature of approximately 80°C. Keratin has been shown to have a thermal denaturing temperature of up to 150°C. Therefore blending of collagen and keratin was able to increase the thermal denaturing temperature significantly as shown in this study.

In addition, presence of keratine resulted in an ECM structure of aligned and bundled fibers whereas pure collagen hydrogels were more disorganized. This may have caused the cells to spread more throughout the C/KTN hydrogels along the aligned and thicker fibers. Previous studies have also demonstrated that cells seeded on top of KTN hydrogels displayed morphology characterized by spreading whereas cells grown on top of collagen was not as spread and linear [5]. In addition, keratin derived from human hair contain binding motifs such as leucine-aspartic acid-valine (LDV) which supports cell attachment and subsequently spreading [3]. Although cell viability of C/KTN hydrogels is similar to that of pure collagen hydrogels, slight increases in viability of 50/50 and 30/70 C/KTN may reflect the elongation and spreading of cells promoted by keratine. Without SEM analysis with cellular gels however, this cannot be confirmed until further SEM studies are conducted.

In this study we were able to demonstrate the blended hydrogels' potential utility for hyperthermic *in vitro* testing increasing thermal stability and promoting cell growth with addition of keratine. With a more thermally stable biomaterial, this hydrogel can potentially be used for developing 3D *in vitro* models for thermal stress studies or testing hyperthermic treatments without compromising the ECM.

INTRODUCTION

Adipose derived stem cells (ASCs) are multipotent that can be differentiated into adipogenic, chondrogenic, and osteogenic lineages with an appropriate stimulus [1]. miRNAs are short nucleotides which regulate various cell mechanisms such as differentiation [2]. For example, the upregulation of miRNA 148b in ASCs results in the induction of osteogenesis [3]. However, no miRNAs have been evidently shown to induce the endothelial differentiation in ASCs. In this article, we used next generation sequencing to sequence the miRNAs expressed in CD34+ ASCs treated with endothelial media during the period of endothelial differentiation. Using bioinformatics techniques, we identify several miRNAs (both upregulated and downregulated) that could potentially induce endothelial-genesis in ASCs.

METHODS

Magnetic bead sorting of CD34+ cells: ASCs from 3 different donors at P0 were counted and pooled together in equal amounts. The sorting of CD34+ cells from ASCs was done using CD34 MicroBead kit (Miltenyi Biotec) by following manufacturer's instructions. Briefly, the ASCs were treated with FcR blocking reagent and then with CD34 microbeads followed by incubation at 4°C for 30 minutes. After incubation the cells were washed and added to the magnetic separation column on the magnetic stand. The CD34 depleted ASCs and CD34+ ASCs were then collected and counted. The sorted cells were then plated in 6 well plates at a density of 8000 cells per cm² and cultured till 80-90% confluence was obtained in stromal media.

CD34 surface marker characterization: The CD34+ sorted cells and CD34 depleted ASCs were stained with CD34-PE antibody during the magnetic bead sorting process. Both the sorted cell populations were analyzed by flow cytometry for the expression CD34 antibody.

Induction of endothelial differentiation: Upon reaching confluence the CD34+ cells were treated with endothelial medium containing 50 ng/ml of VEGF, 2% FBS, and 1% antibiotic in DMEM/F12 media. For controls, CD34+ cells and CD34 depleted ASCs treated with stromal medium. The media was replaced for every 3 days till 14 days.

UEA I lectin Staining: The cells were fixed with 4% paraformaldehyde for 20 min at room temperature (RT) and later blocked with 1% BSA in PBST for 30 min at RT. UEA I lectin FITC was then added in the dilution of 1:200 and incubated for 1hr at 4°C in dark. After this step the cells were washed with PBS and imaged.

miRNA isolation and quantitation: miRNAs were isolated using Purelink miRNA isolation kit (ThermoFisher) following manufacturer's instructions. The quality and purity of miRNAs was analyzed using fragment analyzer.

miRNA library preparation and sequencing: An ion proton sequencer was used to perform the miRNA sequencing. Library preparation and multiplexing with adapters was done using the kit compatible with the Ion proton sequencer.

miRNA sequencing data analysis: The obtained sequencing data was aligned to HG38 genome using STAR program [4] and interspersed with mature human miRNA sequences from miRbase.org using bedtools [5]. The miRNAs with P values < 0.05 were considered significant for further analysis. The miRNAs with fold change above 1.2 or below 0.8 are only considered as either upregulated or downregulated. Targets can [6] and miRwalk [7] were used to identify miRNA target genes and the target genes were later used to determine pathways through Kegg analysis [8].

RESULTS

The endothelial differentiation of CD34 sorted ASCs was confirmed by UEA-I lectin staining and measuring the expression of endothelial genes (eNOS, VWF, and CD31) by qPCR

a) UEA I lectin-FITC staining: Left column: CD34 sorted ASCs treated with either endothelial or stromal media for 14 days; First row-fluorescent images (FLM), second row- bright field images (BM). Right column: CD34 sorted ASCs treated with either endothelial or stromal media for 9 days; third row-fluorescent images (FLM), last row- bright field images (BM). FLM and BM images are taken from the same cells. **b) qPCR:** The bar graphs shown indicate the expression of endothelial genes (eNOS, VWF, CD31) in CD34 sorted ASCs treated with endothelial media (Endo-CD34) in relation to control CD34 sorted ASCs (Control-CD34) on Day 3, Day 9, and Day 14.

The heat maps below indicate the expression of miRNAs on day 3, day 9, and day 14 with P values < 0.05. To track the temporal expression of those significantly up/down regulated miRNAs on a particular time point we have also shown their expression on the other time points even though some of them have higher P-values.

Upregulated miRNAs on **a) day3, b) day9 and c) day14**; the temporal expression of those miRNAs was also shown.

Downregulated miRNAs on **d) day3, e) day9 and f) day14**; the temporal expression of those miRNAs was also shown.

Kegg analysis of the up and down-regulated miRNAs on day 3 targeting most of the pathways involved with regulation of endothelial and angiogenic differentiation

- a) Upregulated miRNAs: hsa-miR-181a-5p, hsa-miR-335-5p, and hsa-miR-15b-5p
- b) Downregulated miRNAs: hsa-miR-155-5p, hsa-miR-145-5p, hsa-miR-27b-3p, and hsa-125a-5p

DISCUSSION

The Kegg analysis of the miRNA targeted genes enriched several signaling pathways such as ErbB, NF-KB, Notch, HIF-, PI3K-AKT, P53, VEGF, Hippo, Ras, Rap1, mTOR, TNF, TGF-B, Insulin, MAPK, cGMP-PKG, and cAMP signaling etc. which play regulatory role in the endothelial differentiation and angiogenic proliferation. Based on these results, we hypothesize that either upregulating hsa-miR-181a-5p, hsa-miR-335-5p, and hsa-miR-15b-5p or downregulating hsa-miR-155-5p, hsa-miR-145-5p, hsa-125a-5p and hsa-miR-27b-3p using antagomirs could result in the induction of ASCs into endothelial lineage.

INTRODUCTION

The employment of biodegradable and implantable medical materials presents numerous potential advantages. In some applications, the need for additional interventions to remove the implant can be avoided.¹ In other situations, in which permanent implants represent the state-of-the-art, biodegradable designs offer the potential to eliminate problems associated with long-term tolerance of the implant. Biodegradable materials can be used to carry biologically active agents to be delivered locally such that healing/growing is promoted or enhanced. Biodegradable materials also offer great potential as scaffolding in tissue engineering (TE), as extracellular matrix (ECM) synthesized naturally by seeded cells can gradually replace them and take over supporting roles. Biodegradable scaffolds do not only perform acutely after cell seeding providing stress-shielding and mechanical support and function, but should also follow a designed load-transfer path from the degrading scaffold to the developing dense connective tissue over time.^{2,3} This load-transfer can also provide mechanical cues that are transferred downscale to impart mechano-stimulation on the cells and to guide growth of de novo tissue with appropriate mechanical properties to remain in function once the scaffold is fully absorbed.

The employment of biodegradable materials is particularly challenging in TE because scaffolds are expected to bear and withstand mechanical loads, and in addition, are inherently evolving over time. Tissue engineers must optimize the appropriate scaffold characteristics or the material formulation (among many other design parameters) which result in scaffolds that satisfy the immediate need of stress-shielding on seeded cells, yet gradually continue to provide support for an appropriate period as de novo tissue is formed, and ultimately, fade away undergoing controllable absorption. This complex and

challenging design process is largely based on empirical guesswork and trial-and-error approaches that often fail.⁴

Designing biodegradable scaffolds that provide acute support for a sufficient time, allow for a smooth load-transfer to the developing tissue, and finally degrade away in a controllable manner, requires extensive understanding and modeling tools that account for the change of properties as the material degrades. Our objective is to develop rigorous and quantitative understanding of the morphological and functional events occurring during mechanically-stimulated tissue engineering scaffold degradation during in vitro incubation, and ultimately, post-implantation in vivo function subjected to physiologic loading. Ultimately, these tools can be employed to optimize TE scaffold design, to tailor the stress-transfer between the degrading scaffold and the growing de novo ECM, and to guide the development of in vitro training protocols to better stimulate growing cells into favorable synthetic behaviors to result in successful in vivo integration.

METHODS

Scaffold Manufacture. Scaffolds were manufactured with (Mn) 80,000 g/mol Polycaprolactone (PCL) by electrospinning. Electrospinning parameters used are: electric potential of 12 kV; collector diameter of 3mm, rotational speed of 820 rpm, axial velocity of 1 cm/s and 30 cm displacement. The process was carried for 1 hour and 21 minutes. Samples were cut into 15 x 9.3 mm and 35 x 9.3 mm rectangular samples for static and dynamic experiments respectively.

Degradation protocol. Samples were dried in a vacuum oven at 40 °C and at a 2.06 bar vacuum for 24 hours and weighted afterwards. Static degradation consisted in submerging the sample in 10mL of solution, and rest at 37 °C. The liquid media tested were distilled water and NaOH solutions with pHs of 9.15, 11.75, 12.45, 13.0 and 13.3 to accelerate the degradation rate into feasible time periods. Dynamic

degradation was carried at fixed 10% nominal strain with a sinusoidal function at 1 Hz frequency. Solutions were changed weekly. The samples were dried, weighed, and tested after degradation.

Table 1. Weight loss and thickness at different degradation conditions.

Time [days]	Degradation condition		Weight loss [%]	Thickness [μm]
	Exposure	pH		
0	--	--	0	165 \pm 11
7	Static	6.4	0.06 \pm 2.44	316 \pm 27
		11.75	1.16 \pm 1.40	263 \pm 16
		12.45	1.16 \pm 1.01	238 \pm 15
		13.0	22.0 \pm 1.6	195 \pm 16
		13.3	100 \pm 1.7	--
21	Static	6.4	-0.1 \pm 1.5	254 \pm 12
	Dynamic	6.4	1.10 \pm 1.02	164 \pm 56
	Static	11.75	1.5 \pm 1.0	209 \pm 17
		12.45	3.6 \pm 1.4	207 \pm 14
		13.0	61.5 \pm 1.4	--
42	Static	6.4	-2.58 \pm 0.08	188 \pm 9
		11.75	2.12 \pm 1.25	220 \pm 14
		12.45	17.5 \pm 1.2	230 \pm 16
		13.0	100 \pm 1.2	--

Mechanical properties. Elastic properties were measured with a custom-made uniaxial-extension mechanical tester. Mechanical testing was carried at 1mm/min under wet conditions after 10 preconditioning cycles, for all periods of degradation. The deformation gradient components were calculated from the relative distance between four markers located at the vertexes of a 2mm side square. The fixed and moving ends of the mechanical tester were attached to the samples through 3 hooks and a long single-loop suture to minimize force differentials and lateral components. Samples were stretched by imposing on the actuator a displacement equivalent to 30% of the original length. From the stress-strain graph, the linear region was identified and elastic modulus calculated as the slope of the linear region. Sample thickness was measured at multiple locations with a micrometer and employed to define stress.

Microstructure. Scanning Electron Microscopy (SEM) images were taken at 3000x magnification. Images were processed using ImageJ and DiameterJ plugging to determine fiber orientation, diameter, intersection density and superficial porosity.⁵

Figure 1. Effect of degradation on mechanical and structural properties. a) Reduction of elastic modulus over time at fixed pH of 12.45. b) Effect of exposure of scaffolds to distilled water (pH 6.4) on static and dynamic conditions after 3 weeks. c) Effect of different degradation conditions on fiber orientation.

RESULTS

Static degradation. The thickness of the scaffolds increased for all scaffolds tested. Swelling peaked at 1 week after exposition to liquid media and decreased afterwards. Swelling is reduced as the pH of the media is increased. For distilled water (pH 6.4), the increase in thickness reached 90%, whereas it was only of 18% for pH 13.0. Largely alkaline environments significantly affected scaffolds properties during early exposure. After 7 days of accelerated degradation, a pH of 13.0 was

required to produce a significant weight loss (22%) and significant elastic modulus reductions, and a pH 13.3 achieved complete dissolution. No significant changes were found with pH below 13 (Table 1). At fixed pH 12.45, a reduction of 30% on elastic modulus was observed at 14 days of exposition, due to the increase of the cross section rather than degradation of mechanical properties. After 42 days, elastic modulus dropped to 16% of its original value (Figure 1a), along with a 18% weight loss, and homogenization of fiber orientation (Figure 1c). Weight losses larger than 20% produced structural collapse of the scaffold, SEM imaging revealed that scaffold fibers were mostly broken (Figure 2c) or fused in a single mass (Figure 2d). Macroscopically, scaffolds were prone to delaminate, and did not present sufficient elastic behavior to render mechanical testing significant. Static exposition to distilled water showed no significant effect on mass, fiber orientation or mechanical properties for all tested periods.

Dynamic vs static degradation. Scaffolds exposed to distilled water under dynamic conditions showed no significant mass loss or changes in the microstructure other than fiber swelling (Figure 2b). SEM images showed no evidence of damage on fibers and pH of solution did not change supporting no evidence for chemical reactions. Nevertheless, a decrease in elastic modulus of 45% was observed (Figure 1b).

Figure 2. Representative SEM images at: a) original conditions. b) dynamically degraded in distilled water. c) statically degraded at pH 13.0 after one week. d) statically degraded at pH 13.0 after 3 weeks.

DISCUSSION

PCL electrospun scaffolds will not significantly degrade during a first week of exposition to liquid media, unless highly aggressive alkaline environments are used. This means that PCL scaffolds are not likely to change properties during cell seeding process for TE applications. Significant loss of properties were achieved within 3 weeks for pHs larger than 11.75 due to damage in the microstructure and changes in chemical composition. On the other hand, dynamic loading produced a reduction in mechanical properties not related to observable structural damage or chemical reactions.

The complex environment-dependent behavior, time-evolving properties, and multi-faceted performance requirements of biodegradable scaffolds for tissue engineering demand sophisticated theoretical, experimental and computational methods to their design. Yet, tissue engineers have been limited by sub-optimal analyses based on empiricism and costly trial- and-error, mainly due to the inexistence of proper frameworks to describe polymer degradation under physiological conditions.

INTRODUCTION

Glaucoma is among the group of neurodegenerative diseases that lead to irreversible blindness in approximately 39 million people worldwide [1]. Current therapies target the rejuvenation of the trabecular meshwork that is damaged due to increased intraocular eye pressure (IOP) [3]. Other therapies target the revival of ocular cells, such as retinal ganglion cells (RGC). However, none of the proposed therapies have proven to restore visual capacity to the pre-disease state. The irreversible nature of these cases is due to damage to critical tissues including the optic nerve (ON) and retina. During normal disease progression axonal death is followed by the retraction and death of RGCs [2], loss of oligodendrocytes [3], and activation of astrocytes [3]; all of which are accompanied by mitochondrial dysfunction, inflammation, and oxidative stress [6].

Recently, transcorneal electrical stimulation (TES) has been shown to have positive effects in an *in vivo* model as well as several clinical trials as a non-invasive therapy to revitalize cells in other neurodegenerative diseases [1]. Therefore, we hypothesized that TES would slow glaucoma progression in the model. In this study, we used a DBA/2J (D2) mouse model to examine the effect of minimally invasive TES on the revitalization of diseased tissues by examining the health of the ON, retina, and changes in visual acuity (VA).

METHODS

The study is approved by the Animal Care and Use Committee at NEOMED. The model of study, the D2, is an inbred mouse that is genetically predisposed to develop glaucoma, which mirrors the disease progression that is seen in humans [7]. At approximately 8-11 months of age, animals were randomly divided into two groups: experimental and an age match control. A third group was added as a younger control at 5 months of age, as the disease likely has not had any effects by 5

months in most animals [7]. Visual acuities were established in all three groups of mice using a forced-choice swim behavioral task consisting of 2 sessions of 10 trials per day over a period of approximately 5 weeks. The visual discrimination task used was developed and characterized by Prusky [8]. Mouse VA thresholds were determined by systematically increasing the cycles/degree until animals chose lower than 7/10 trials correct. IOP was measured for both groups prior to stimulation. TES was applied to mice eyes for 10 minutes every three days for 8 weeks. Each eye was stimulated separately with a ground wire placed in the back of the neck. A symmetric biphasic square wave was applied at a current of 100 μ A, 1 ms pulse duration, at a frequency of 20 Hz. After 8 weeks, VA tests and IOP measurements were repeated after stimulation. Post transcardially perfused superior colliculus (SC) was harvested for analysis. Cholera toxin β -subunit (CTB) was used as an anterograde tracer to examine retinal uptake and transmission to the SC [9,10]. C-fos, which is an intermediate early gene upregulated in response to stimulation, is used to show activation in the SC due to the stimulation paradigm [11]. RGC soma and axon number were determined using unbiased stereological analysis. Whole mount retinas were labeled with RBPMS (RNA-binding protein with multiple splicing) to visualize RGCs [12]. ON were embedded in polybed resin and sectioned for quantification. Synapse revitalization in the retina was evaluated by co-localization of PSD95 and VGLUT1, which label pre- and post-synaptic markers in the inner plexiform layer of the retina [13]. Inflammation was measured in the ON and retina by labeling for NF κ B p65, a master regulator of cytokine production [14]. ATP availability was quantified by the ratio of AMPK to pAMPK levels in the retina and ON [15]. Growth factor receptors, such as p75, were measured at the protein level to determine efficacy and cell death markers were evaluated via protein analysis. Data were analyzed using immunohistochemistry, stereological analysis, capillary

electrophoresis, and ImageJ quantification tools. Data is represented as mean \pm stdev and evaluated for normalcy. One-way ANOVA and student's *t*-test were used to compare differences between groups, with $p < 0.05$ considered significant.

RESULTS

After 8 weeks, the VA of TES-stimulated mice increased, decreased or maintained, while the control group mice only decreased or maintained (Figure 1A). RGC numbers were significantly higher in the young control, but no statistical differences in RGC number were found between the TES-stimulated and control age-matched groups (Figure 1B). However, CTB labeling in the SC of TES-stimulated mice was increased over age-matched controls (Figure 1C). Increased levels of ATP, noted by a reduction in the ratio of pAMPK/AMPK, were found in both the retina and ON via protein analysis (Figure 1 D and E) in the TES-stimulated mice. As we continue to gather more information, we will learn more about the axon count, synapse revitalization, inflammatory markers and growth factor receptors.

Figure 1: Change in VA (A) from baseline to 8-week time points shows no significant difference between control (12m D2) and Stimulated group; however, stimulated group shows slightly more individuals with positive

change in VA (n=17 and n=17 respectively). RGC number (B) from whole mount retinas stained with RBPMS. 5m D2 had significantly more RGCs than 12m D2 and stimulated 12m D2. CTB transport to SC (C) Found to be significantly more for Stimulated group. 5m D2 transported significantly more CTB compared to 12m D2 and stimulated 12m D2. Stimulated 12m D2 showed significant increase in CTB transport compared to control 12m D2. Significantly more ATP available in the stimulated retina (D) and ON (E) compared to the age matched tissue. The ratio of pAMPK/AMPK was significantly reduced with stimulation in the retina and ON.

DISCUSSION

These findings exemplify a positive regenerative response in D2 mice to TES over an 8-week period that could reduce the signs of glaucoma progression. While the approach did not rescue RGCs, we nevertheless have shown mice that have demonstrated an increase in

VA. The increase in VA, while not significant, demonstrated a limitation in determining VA through behavior tasks and can be improved upon in further trials. Furthermore, our previous studies indicated that metabolic vulnerability play a critical role in glaucoma progression [15]. TES was able to restore ATP level in both the retina and ON. Providing more ATP to the energy-demanding RGCs is expected to improve their function [15]. It was also shown to increase transmission of CTB to the SC, which indicated a revitalized ON giving it the ability to respond to signals from the retina and transmit them to the SC [6]. Collectively, these results reflect improvement in RGC function and therefore glaucoma pathology. Our current work is focused on gathering further results regarding synaptic revitalization, changes to inflammation, and examining cell death in the ON and retina in the D2 model. Our current results combined with future work aims to show the regenerative effects of minimally invasive TES in the D2 model, thus validating it as a possible treatment strategy for future investigation.

INTRODUCTION

When significant tissue damage to the spinal cord occurs and neuronal connectivity does not ever fully recover, this can lead to severe pain, partial, or full paralysis. To combat the effects of spinal cord injury, we propose promoting neuroregeneration using a seeded biomimetic polyethylene glycol diacrylate (PEGDA) hydrogel scaffold to deliver neural progenitor cells (NPC) to the injured spinal tissue. It has been shown that axonal outgrowth, neural cell growth, and NPC differentiation, which are components of broader neuroregeneration, occur on materials with an average pore area ranging from 0.07 to 7854 μm^2 [1, 2]. Instead of considering the broad range of ideal pore areas, we focused on developing scaffolds with a mean pore area between 100 and 200 μm^2 , and an elastic modulus in the range of 40-60 kPa [3, 4]. We further enhanced the neuronal growth environment by incorporating iron oxide nanoparticles into the hydrogel matrix to provide physiological electromagnetic stimulation. To promote neuroregeneration in spinal tissue, we optimized the mechanical, chemical, and topographical characteristics of a biomimetic PEGDA scaffold. We hypothesize that by increasing cross-linking time, we can improve the PEGDA scaffold's biomechanical and cellular properties, and ultimately assist in improving neuronal growth in the spinal cord.

METHODS

The base components of the hydrogel consist of PEGDA, triethanolamine (TEA), vinylpyrrolidone (VP), eosin isothiocyanate, and iron oxide nanoparticles (IONPs). Hydrogels were photopolymerized using a 20 mW LED Lamp, with polymerization time itself tested as a variable. The ratio of PEGDA, TEA, and VP was optimized to generate gels with desired pore areas. Two molecular weights of PEGDA (575 and 700 kDa) were compared to study the effect of molecular weight on pore area and degradation. As control

sample for comparison, a 575 kDa PEGDA hydrogel fabricated following commercially available protocols was used. The hydrogel degradation rate was measured in different environments over a period of 60 days at a temperature of 37°C, on a shaking platform. These environments include a culture media (pH 7.4), millipore water (pH 7.12), and culture media adjusted to a pH of 5 and 2.

Hydrogel topography and pore area were characterized via scanning electron microscopy and images were analyzed in ImageJ with a sample size of 8 for all groups tested. Thresholding was used to identify pore area in the hydrogel and the size of these pores was measured using the particle analysis tool.

The swelling ratio of the hydrogels was found using Eq. (1) [5],

$$Q_v = 1 + \frac{\rho_p}{\rho_s} \left(\frac{M_w}{M_d} - 1 \right) \quad (1)$$

where M_w is the wet weight and M_d is the dry weight. The mass swelling ratio is equal to M_w/M_d . The volumetric swelling ratio (Q_v) is, therefore, calculated from the mass swelling ratio and the densities of the hydrogel polymer (ρ_p) and solvent (ρ_s).

Mechanical characterization of hydrogel specimens was performed via unconfined compression testing (Electro Force 3200, TA Instruments, New Castle, DE). The mechanical properties of the hydrogels were tested as function of polymerization time (crosslinking rate of either 8 or 10 minutes) and hydrogels loaded with different concentrations (0, 0.029, 0.058, and 0.116 mg/mL) of iron oxide nanoparticles (IONPs). Hydrogel samples were hydrated in milipore water to for 24 hours before testing to emulate swelling *in vitro*.

Data was reported as mean \pm standard deviation for porosity, degradability, mechanics, and physical parameters. One-way ANOVA was performed to test the differences in data across the groups and Tukey's test was performed to evaluate pairwise differences in the data. Significance level was set to $\alpha = 0.05$.

RESULTS

Topographical analysis of the hydrogel matrix shows that there is no difference between the 575 and 700 Mw PEGDA hydrogels ($p = 0.97$); however, there was a significant difference between the unoptimized control and the two optimized formulations ($p = 0.007$) (Fig. 1a). Of the two molecular weights of PEGDA tested (575 and 700 Mw) containing IONPs, the 575 PEGDA hydrogels displayed a mean pore area of $163 \pm 42 \mu\text{m}^2$, the 700 PEDGA had $164 \pm 41 \mu\text{m}^2$, and the control showed a pore area of $90 \pm 58 \mu\text{m}^2$. Degradation studies showed that PEGDA based hydrogels deteriorate faster in cell culture media with pH 5 than at pH 7.4 (Fig. 1b). The average degradation kinetics of PEGDA-based hydrogels are shown to have a negative trend in all test environments, excluding media. The average swelling ratio of the hydrogel scaffold in Millipore® water was found to be 4:1.

Compression testing of the cross-linked hydrogel specimens showed that the Young's modulus of the 58 μL group was higher than the 29 μL and 10 minute groups ($55.7 \pm 37.5 \text{ kPa}$ vs. $52 \pm 13.7 \text{ kPa}$ vs. $23.91 \pm 8.45 \text{ kPa}$; $p = 0.0039$, as shown in Fig. 2a). Conversely, maximum compressive stress was higher for the 29 μL hydrogel group followed by 116 μL and 8 minute groups, respectively ($28.4 \pm 15.8 \text{ kPa}$ vs. $10.5 \pm 6.37 \text{ kPa}$ vs. $6.36 \pm 0.95 \text{ kPa}$; $p = 0.0085$, as seen in Fig. 2b). The thickness of the 10 minute hydrogel specimens was found to be lower than specimens of 8 minutes, 116 μL , 58 μL , and 29 μL groups, respectively ($6.38 \pm 0.21 \text{ mm} < 6.48 \pm 0.58 \text{ mm} < 7.08 \pm 0.20 \text{ mm} < 7.14 \pm 0.23 \text{ mm} < 7.23 \pm 0.16 \text{ mm}$; $p = 0.0008$, as seen in Fig. 2c). Further, the diameter of the 29 μL hydrogel specimens was found to be the highest across the groups, whereas 10 minute specimens had the lowest diameter ($4.89 \pm 0.35 \text{ mm}$ vs. $3.83 \pm 0.18 \text{ mm}$; $p = 0.001$, as seen in Fig. 2d).

Figure 1: (a) Porosity - Average pore area of optimized 575 Mw and 700 Mw PEG-DA was found to be 81.7% and 82.5% higher than control specimens ($p = 0.007$). (b) Degradation - 575 and 700 Mw PEG-DA degradation study results; error bars indicate standard error and the sample size is ($n = 6$). * denotes significant level of $p < 0.05$.

DISCUSSION

While optimizing the hydrogels, it was found that the nanoparticles and the initial amount of water present in the gels did not play a large role in the overall structural properties of the gel. The ratio between PEGDA, TEA and VP, determined the rigidity and structure of the gels. These factors were further optimized to form hydrogels with proper structural properties and a mean pore area in the range of $100\text{--}200 \mu\text{m}^2$. Environments with a pH of 2 mimic the biological environment of infected and inflamed tissues, and it is shown that the degradation of the 575 Mw hydrogel in this environment has a negative trend. After saturation, a downtrend was observed in all samples except the hydrogels kept in media during the degradation study. We will improve the degradation study in the future by incorporating enzymes into the different environments. Photopolymerization time and IONP concentration was optimized to synthesize 575 kDa PEGDA hydrogels with a Young's modulus like that of native spinal tissue. Mechanical testing of the hydrogel scaffolds has shown that polymerization time and IONP concentration play a significant role in determining the material's compressive behavior. Hydrogels allowed to polymerize for 7 minutes that contain a concentration of 0.029 or 0.058 mg/mL of IONPs fall within the desired range of 40–60 kPa. In conclusion, we have created a biomimetic hydrogel scaffold that displays similar mechanical characteristics to native spinal tissue and has optimal pore areas for neural growth. Future work includes gauging the biocompatibility of these hydrogels and evaluate the effects of electromechanical stimulation on neuroblast cells seeded in the scaffolds.

Figure 2: Compression testing of hydrogel specimens. (a) Compressive modulus was higher in hydrogel specimens from the 58 μL group compared to the 29 μL and 10 min groups. (b) Maximum compressive stress is highest in the 29 μL group in comparison to the 116 μL and 8 min groups. (c-d) Thickness and diameter were found to be lower for regular hydrogels vs. IONP hydrogels, respectively. * denotes significant level of $p < 0.05$.

Maintaining Multipotency of Neural Stem Cells Using Synthetic FGF Peptide Microenvironments

INTRODUCTION

Stem cell niches play a crucial role in regulating cellular response, including both maintenance and differentiation. By mimicking stem cell niches in a defined manner, better *in vitro* models can be developed to understand various diseased conditions. In addition, these *in vitro* niche models can be used to investigate drugs and can be utilized to investigate other therapies. Our group is interested in using synthetic materials to develop consistent culture environments to specifically control stem cell culture and differentiation. Using nanofibers and peptide mimics of whole proteins, these culture substrates have been shown to mimic laminin [1] and alter neural precursor protein presentation [2] during differentiation. To further develop these substrates for stem cell investigations, we are interested in investigating their ability to maintain potency.

Neural stem cells require a number of soluble proteins to maintain potency and proliferate in culture. A critical protein to maintain potency of neural stem cells is fibroblast growth factor 2 (FGF2) [3]. The FGF2 utilized for maintaining potency for human stem cells is typically a recombinant or purified human protein. These human proteins are expensive and difficult to isolate, increasing the cost and variability of stem cell culture components [4]. However, by utilizing synthetic peptides that mimic the functions of whole proteins, we can control the presentation of the signaling motif, fabricate consistent *in vitro* culture conditions, and reduce the cost of stem cell culture conditions.

The aim of this study is to utilize synthetic alternatives to current growth components in order to maintain multipotency of human induced pluripotent neural stem cells (hNSCs). Current hNSC growth conditions require the use of FGF2 for potency and Matrigel® for cellular adhesion. Matrigel® is derived from mouse tumors and consists of primarily laminin, in addition to variable amounts of other proteins and growth factors [5]. However, by utilizing synthetic alternatives such

as YIGSR for laminin and FGF peptide (FGFp) for FGF2, we seek to fabricate a controlled and consistent stem cell culture condition that mimics whole protein conditions.

METHODS

Substrates were pretreated with UVO for 2 hr and placed in a solution of 4-chlorobutyldimethylchlorosilane (5% v/v) and 5-hexenyldimethylchlorosilane (5% v/v) in toluene for 5 hr. To immobilize alkyne functionality on the surface, glass slides were then placed in a methylene chloride solution with propargyl alcohol and pyridine for 2 hr. For YIGSR immobilization *via* copper-mediated azide-alkyne cycloaddition (CuAAC), glass slides were placed into a solution of N₃-GYIGSR peptide, sodium ascorbate and CuSO₄ for 2 hr. For surface functionalization with FGFp, cysteine-FGFp and Irgacure 2959 were dissolved in H₂O/DMF (10:1 v/v) solution. The substrates were immersed in the peptide solution and exposed to UV (254 nm) for 1 hr at room temperature. The substrates were washed with methanol, toluene and then methanol and blown dry under N₂ after each reaction. XPS was utilized to determine the concentration of the peptides. All the reactions were carried out at room temperature.

Human induced pluripotent NSCs (GlobalStem) were maintained multipotent under growth conditions as previously published [6]. The manufacturer recommended growth conditions required the use of FGF2 at 1.16 nM. Doubling time was determined after replacement of FGF2 with synthetic FGFp at 1.16 nM, 2.32 nM, and 11.6 nM. hNSC multipotency was measured by %NES⁺ cells *via* flow cytometry. Cultures were maintained until ready for passage and proliferation rate was measured by doubling time (hr). One-way ANOVA, with Tukey's correction was utilized to determine significance between culture groups, with $p \leq 0.05$ considered significant. Our current work is focused on substituting Matrigel® with YIGSR-functionalized

substrates, and investigating the use of YIGSR and FGFp dual-functionalized substrates as a culture substitute.

RESULTS

GYIGSR and FGFp dual-functionalized glass slides were fabricated *via* sequential “click” CuAAC and thiol-ene reaction. The difference between C_{1s} peak areas before (Figure 1A) and after CuAAC reaction (Figure 1B) results from the covalent bonding of the GYIGSR peptide on the surface, and C_{1s} peak area after the thiol-ene reaction results from the covalent bonding of FGF peptide (Figure 1C). The concentration of GYIGSR on the glass surface was measured to be ~52.3 pmol/cm² for single-functionalized glasses and ~48.5 pmol/cm² for dual-functionalized glasses. The concentration of FGF peptide was measured to be ~62.6 pmol/cm². The nitrogen peak increased significantly on peptide-functionalized substrates.

Figure 1: High resolution C_{1s} signals of (A) before any peptide immobilization, (B) after the GYIGSR covalent bonding and (C) after GYIGSR and FGF peptide surface modification. The area under the peak increased due to peptide attachment.

hNSCs were cultured under normal growth conditions that included Matrigel® and FGF2 as the control. Our findings suggested that FGFp at 2.32 nM best mimicked normal FGF2 culture conditions, where similar %NES positive cells, $90.8 \pm 13.7\%$ and $92.65 \pm 8.4\%$, were found for FGF2 and FGFp at 2.32 nM, respectively (Figure 2A). In addition, a similar doubling time was also found between FGF2 and FGFp at 2.32 nM, 42.9 ± 10.9 hr and 58.69 ± 6.4 hr, respectively (Figure 2B). No significant differences were found between these proliferation rates.

Figure 2: Multipotency (A) and proliferation rate (B) comparison between different concentrations of synthetic FGF peptide (1.16 nM, 2.32 nM, and 11.6 nM) and normal FGF2 concentration.

DISCUSSION

Current culture conditions for hNSCs require the use of Matrigel® for cell adhesion. However, approximately 60% of Matrigel® is composed of laminin [5], and laminin has been shown to be more favorable than Matrigel® for maintaining stemness of human induced pluripotent stem cells [7]. In addition, expansion conditions for hNSCs require whole protein FGF2, to keep hNSCs multipotent. Our findings suggest that soluble FGFp can be used as a culture substitute for FGF2, as similar hNSC potency and proliferation rates were found for the two

culture conditions. Our next step is to culture hNSCs on FGFp-tethered substrates, to ensure cells are presented with the required signaling motif in bound form compared to soluble form. In addition, these substrates will be functionalized with GYIGSR to mimic laminin [1] to assure the cells are adherent to the culture substrates. Future work will determine if utilizing this dual-functionalized substrate could eliminate the use of both bound, Matrigel®, and soluble, FGF2, factors in hNSC culture conditions.

INTRODUCTION

While possessing many desired properties for a biomaterial capable of cell encapsulation, alginate lacks the ability to interact with mammalian cells; however, alginate can be chemically modified with RGD- peptides, which promote cell adhesion, proliferation and ingrowth. Heparin, a glycosaminoglycan naturally found in the body, plays a role in preventing the formation of a thrombosis due to its anticoagulant activity and is a component of the extracellular matrix of blood vessels that has been shown to promote the growth of endothelial cells *in vitro*.¹

The aim of this study was to determine the feasibility heparin and arginyl-glycyl-aspartic acid (RGD) conjugated alginate hydrogels encapsulated with vascular endothelial growth factor (VEGF) as a wound dressing to promote vascularization. VEGF is an important component in angiogenesis that binds to heparin, and RGD promotes cell adhesion. Alginate hydrogels consisted of methacrylic anhydride (MA), RGD, and heparin, and were crosslinked with visible light. The material properties and burst pressure mechanics were evaluated to determine the structural integrity and adhesiveness of the hydrogels.

METHODS

Methacrylated Alginate (Alg-MA) Synthesis: Methacrylated alginate (Alg-MA) was synthesized as previously described.^{2,3} Briefly, sodium alginate was dissolved in PBS [1% (w/v)] solution at room temperature. A 10-fold molar excess of methacrylic anhydride was added to the alginate solution, pH 8.5, and the reaction was carried out for eight hours. The Alg-MA solution was purified via dialysis against deionized water for five days and lyophilized to yield a dry product.

Alg-MA-RGD Synthesis: Alg-MA was placed in DI water and conjugated with cysteine-L-arginyl-glycyl-L-aspartic acid (CRGD) using carbodiimide chemistry.

Methacrylated Heparin (Hep-GM) Synthesis: Sodium heparin was dissolved in deionized water [1.5g, (1% w/v)] at 60°C. Glycidyl methacrylate (GM) (1.5g) was added to the solution and stirred overnight. Hep-GM was purified via dialysis against deionized water for five days and lyophilized to obtain a dry polymer.

Hydrogel Preparation and VEGF Encapsulation: Polymer solutions were prepared in deionized water to form 3% (w/v) polymer precursor solutions. Human VEGFA was added to the copolymer solution at a ratio of 10⁶:1 (polymer:VEGF). Hydrogels without VEGF were formed as controls. Control and modified solutions were blended with photo-activators to the following concentrations: 1 mM eosin Y, 125 mM triethanolamine, and 20 mM 1-vinyl-2-pyrrolidinone.²⁻⁶ Crosslinking was achieved using LED arrays (525 nm).²

Mechanical Analysis: Rheometry was performed with a Peltier plate maintained at 37°C Hydrogel precursor solution was loaded onto the plate and crosslinked utilizing an LED ring for 5 minutes prior to collection of shear storage (G') and loss (G'') moduli. Oscillatory time sweeps were performed at 10% radial strain and 1 Hz. Burst pressure values were collected using a custom burst pressure device and collagen-based materials; the hydrogels were tested as sealants on compromised collagen substrates.

Cell Culture: Human umbilical vein endothelial cells (HUVECs, Angio Proteomie) were suspended in complete medium (0.2% Bovine brain extract, 5 ng/mL recombinant human endothelial growth factor, 10 nM L-glutamine, 0.75 units/mL heparin sulfate, 1 µg/mL hydrocortisone, 50 µg/mL ascorbic acid, 2% fetal bovine serum). HUVECs were seeded in complete media directly onto the green light polymerized hydrogels in a 96-well tissue culture polystyrene (TCPS) plate.

Cytotoxicity Assay: The cytotoxicity of VEGF-loaded RGD-modified alginate-heparin hydrogels were evaluated to observe the

effects of VEGF, RGD and heparin on cell mitochondrial activity. After 24 hours, HUVECs were analyzed using a WST-8 Cell Proliferation Assay. The optical density was measured at 450 nm; absorbance values for the samples (alginate-heparin hydrogels with and without VEGF loading) were normalized to the non-modified controls.

Tubular Assay: The angiogenic properties of alginate-heparin hydrogels modified with RGD and loaded with VEGF were evaluated qualitatively by observing the effects on microtubule network formation. Analysis was conducted following a modified Angiogenesis Tube Formation Assay protocol. Hydrogel solutions were injected into and spread to evenly coat the bottom of each well of the 96-well TCPs (0.05 mL/well) and polymerized with visible green light for 5 minutes at room temperature (23°C). HUVECs were seeded directly onto hydrogels both modified and unmodified with heparin and loaded and unloaded with VEGF in 96-well TPCs and allowed to incubate to form microtubule networks. Tissue culture plates were prepared for each of the subsequent time points (6, 12, 24, and 72 hours). At each time point, the respective 96-well plate was removed from the incubator (37°C and 5% CO₂) and qualitatively analyzed with phase contrast microscopy to observe and capture the effects on HUVEC tube formation.

RESULTS

The shear moduli (Figure 1) and burst pressure values (Figure 2) indicate appropriate structural integrity and adhesion of the alginate-heparin hydrogels. Compared to the base Alg-MA, modifications with RGD, heparin, and RGD and heparin all showed increased mitochondrial activity. Those with the RGD modification demonstrated a greater degree of activity compared to non-modified alginate. In addition, there was no observable difference in activity between VEGF-loaded hydrogels and their corresponding controls. Despite some groups demonstrating increased amounts of mitochondrial activity over other groups, all hydrogels resulted in lower activity levels compared to the non-modified controls (Figure 3).

After 6 hours, unmodified Alg-MA showed little to no signs of tube formation or cell adhesion, demonstrated by the round morphology of the HUVECs. In comparison, Alg-MA modified with RGD and heparin and loaded with VEGF promoted cell adhesion and angiogenesis via the formation of a microtubule network between adjacent cells (Figure 4).

Table 1. List of material groups and their corresponding abbreviations for labeling.

Material Group	Abbreviation
Cell Control	Cells
Alg-MA	AM
Alg-MA-RGD	AMR
Alg-MA/Hep-GM	AMH
Alg-MA-RGD/Hep-GM	AMRH
Alg-MA/VEGF	AMV
Alg-MA-RGD/VEGF	AMRV
Alg-MA/Hep-GM/VEGF	AMHV
Alg-MA-RGD/Hep-GM/VEGF	AMRHV

DISCUSSION

The rheological properties and burst pressures for the modified alginate-heparin hydrogels indicate advantageous properties for use as wound dressing materials. HUVECs seeded gels were imaged at 6, 12, 24 and 72 hours, with 24 hours showing the greatest increase in tube formation. The effects of the released VEGF on angiogenesis remain qualitative as additional drug release studies and quantitative analysis of the phase contrast images is necessary. The expected drug release profile of VEGF from the RGD modified methacrylated alginate-heparin hydrogel would be that of zero-order profile as previously

reported; release studies are planned for the future. Also, tissue adhesion with excised skin and confocal imaging are ongoing studies to further analyze the effectiveness of the novel materials as wound dressings.

COUPLED THERMAL AND ISCHEMIC STRESS INJURY TO SOFT TISSUE

Kenneth R. Diller, Gary L. McGregor

Biomedical Engineering Department
University of Texas
Austin, Texas, USA

INTRODUCTION

This paper is presented in support of the symposium/workshop at 2019 SB³C to celebrate the 70th birthday of Professor John Pearce who has been a prominent researcher in the field of thermal damage processes in tissues for many decades. He has been a faculty colleague of the senior author at the University of Texas Cockrell School of Engineering since 1982 and was an integral member of a large cohort of researchers who studied many aspects of thermal injury to living tissues. He has made many novel and ground breaking contributions to this field including developing a microscopic scale imaging technology to quantify the spatial distribution of protein denaturation (as a marker for injury) as a heat wave penetrates through tissue¹ and extensive theoretical and computational modeling analyses of thermal injury kinetics²⁻⁴. In particular, he has performed a series of in-depth evaluations of the relative efficacy and drawbacks of different mechanistic models for simulating the development of burns under defined conditions of thermal stress, including both accidental and surgical processes².

The Arrhenius formulation for modeling the kinetics of thermal injury in living tissues has been applied with success for well over a half century⁵. The rate of injury accrual, Ω , is modeled as a simple Arrhenius function of exposure time and temperature (eq. 1), and total injury is determined by integrating the rate function over the total insult time.

$$\Omega(\tau) = \int_0^\tau A e^{\left[\frac{-E_a}{RT}\right]} dt \quad (1)$$

where A is a frequency factor (s^{-1}), τ the total heating time (s), E_a an activation energy barrier (J/ mole), R the universal gas constant (8.314 J/mole/K), and T the absolute temperature (K). Subsequently, many engineers have contributed to the measurement and modeling of the kinetics of thermal injury, including Stoll⁶ and Bischof⁷, and Pearce has demonstrated that more sophisticated models are often required².

Background

In addition to pure thermal injury that occurs via molecular denaturation processes that occur above a threshold of about 43°C, lower temperatures may also have an effect on tissue injury that derives from a different mechanism caused by applied mechanical stress.

Physical deformation can result in strains that directly cause cellular injury, plus compressive stress can oppose the hydraulic pressure of blood perfusion, occluding vessels and resulting in ischemia⁸. Models for this injury process tend to involve complex constitutive equations⁹. Iaiizzo and colleagues conducted very insightful experiments to identify and quantify injury that results when thermal and mechanical stresses are applied to soft tissues simultaneously¹⁰. As the temperature of tissue increases, the rate of metabolism increases proportionally, exacerbating the requirement for supply of nutrients and oxygen and for removal of toxic metabolic byproducts. Thus, Iaiizzo showed that at elevated temperatures pressure sores develop more rapidly, and at depressed temperatures they are delayed. This type of injury, which may be termed a thermally enhanced pressure sore, is associated with only a mild increase in temperature and has a different mechanism than does a true thermal injury. The former is via ischemia; the latter via molecular denaturation. However, they may have a similar clinical presentation. Thus, thermal boundary conditions (even below the nominal 43°C threshold for thermal injury risk) for which it would be impossible to produce a full thickness burn, are fully consistent with causing a thermally enhanced pressure sore that may be misinterpreted as being a pure thermal injury. The relatively recent advent of heated vehicle seats has given rise to one such class of misclassified incidents¹¹, leading to confusion and misdirected interpretations¹², but there are many other scenarios in which the combination of applied pressure in combination with mild heating may produce similar results. This paper addresses developing a transient nonlinear fully coupled ischemic injury model of tissue under combined thermal and mechanical loading.

METHODS

The system consists of a person seated on a rigid heated surface that causes compression of superficial soft tissue against an internal skeletal structure. Heat transfer within the soft tissue is influenced by blood perfusion as described by the Pennes¹³ equation. As a mechanical stress field develops in the soft tissue, a localized spatial distribution of ischemia is produced that effect convection between flow blood and tissue, giving rise to a nonlinear coupling between the thermal and

mechanical domains. Also, the total contact area between the tissue and the heated surface will expand as the interface flattens under load, altering the heat transfer boundary conditions.

This nonlinear, coupled process was modeled with finite elements using the ANSYS software platform. Fig. 1 shows a tissue grid deformed from an initial circular geometry.

Figure 1: Finite element grid of soft tissue deformed under mechanical loading from a planar surface.

$$W = \frac{G}{2} [\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3 - 2 \ln(\lambda_1 \lambda_2 \lambda_3)] + \frac{K}{2} \ln(\lambda_1 \lambda_2 \lambda_3)^2 \quad (2)$$

$$\sigma_i = G(\lambda_1 \lambda_2 \lambda_3)^{-5/2} \left[\lambda_i^2 - \frac{\lambda_1^2 + \lambda_2^2 + \lambda_3^2}{3} \right] + K(\lambda_1 \lambda_2 \lambda_3 - 1); i = 1, 2, 3 \quad (3)$$

Eqs. (2) and (3) present a neoHookean model applied to describe the stress strain relationship in the deformed tissue¹⁴. W is internal strain energy, G is shear modulus, K is bulk modulus, λ is principle strain and σ is principle stress. Internal stress causes a pattern of ischemia that may persist over time to cause ischemic injury. The kinetics depend on the local tissue temperature that varies with distance from the heated external surface. Thus, there is a nonlinear coupling between the stress and temperature fields that directs the rate at which ischemic injury occurs. A constitutive function for the coupling of temperature and stress describes the progressive occurrence of ischemic injury over time.

RESULTS

Internal stress causes a pattern of ischemia that may persist over time to govern the kinetics of ischemic injury formation. The kinetics are a direct function of the local tissue temperature field that varies as a function of distance from the heated external surface. Thus, there is a nonlinear coupling between the stress and temperature fields that directs the rate at which ischemic injury occurs. We have developed an initial constitutive relationship for the coupling of temperature and stress leading to the progressive occurrence of ischemic injury over time.

Figure 2: Mechanical deformation of elastic tissue effects the heat transfer boundary conditions and temperature field.

DISCUSSION

Pressure ulcers most commonly develop outward from the interface of soft tissue with a rigid skeletal structure where the stress/strain values are highest under an external load. When the load embodies a heating element, the temperature gradient will be inward from the surface in the opposite direction of the stress gradient. Under these conditions, the ischemic injury may be accelerated closer to the skin surface at higher temperature even though the stress loading is lower there. Depending on the relative characteristics of the mechanical and thermal loadings, a full thickness ischemic injury may occur from the outside to inward rather than the normal inside to outward direction. The clinical presentation of such an injury may be diagnosed as a burn even though it occurred by an ischemic rather denaturation process. Our model provides a predictive tool that may be applied to interpret injury causation as well as to design human interfaces for reduced injury risk.

University of Minnesota
Minneapolis, MN, USA

Department of Biomedical Engineering
University of Minnesota
Minneapolis, MN, USA

ABSTRACT: Classical work in bioheat transfer focused on heat transfer in blood perfused tissues at physiological temperatures¹⁻³ and the ability of blood perfusion to regulate temperature for comfort within humans and animals⁴⁻⁵. While thermal physiology remains important especially in understanding how species can adapt to climate change⁶, there are now myriad applications of non-physiological temperatures that can be used to either destroy or protect biological systems at supra-physiological or subzero temperatures respectively⁷⁻⁹.

This talk is inspired by the work of John Pearce who has pioneered different experimental and analytical techniques to understand supra-physiological kinetic processes that drive irreversible changes in molecules, cells and tissues¹⁰⁻¹¹. To complement this work, we focus on kinetic processes at both high and low temperatures¹²⁻¹³. More specifically, I will review models and properties (thermal and kinetic) that determine whether the biological system will remain viable or be destroyed at both high and low non-physiological temperatures¹³. This information can prove critical to our ability to control numerous important biomedical applications ranging from burn injury and thermal therapy to cryo and biopreservation. A brief discussion of the importance of pressure on changing these kinetic processes will also be explored¹⁴⁻¹⁵. Finally, several new applications of bioheat transfer in both thermo-regulation and nanoparticle heating for diagnostics, therapy and cryopreservation will be reviewed¹⁶.
