This presentation is dedicated to Professor Y.C. Fung in celebration of his 100th year and his countless contributions to our field; it is an honor to be one of his many academic grandsons. This work was made possible by the many talented students and post-docs over the years with whom I have been fortunate to work, including those who established the early methods upon which our murine work rests: R. Gleason, S. Baek, J. Eberth, J. Ferruzzi, M. Bersi, and C. Bellini. Our mouse work has been supported over the past 15 years by grants from the NSF (BES-0084644) and NIH (R01 HL105297, R21 HL107768, U01 HL116323, R03 EB016810, R21 EB020968, R01 HL134712, P01 HL134605, U01 HL142518). I regret that the limited space here does not allow reference to the many, many works by colleagues that have contributed to our field in general and to my learning in particular – see, therefore, citations within the following.

INTRODUCTION

Arterial compliance passively regulates pulsatile blood flow during ventricular systole [1]. In the pulmonary vasculature, the main pulmonary artery (MPA) is primarily responsible for this action. It absorbs much of the stroke volume and recoil during diastole to deliver a steady flow downstream. The remainder of the pulmonary arterial tree experiences contained multi-axial stresses on account of the local hemodynamics. Moreover, the wall thickness decreases downstream with each branching generation [2]. Consequently, pulmonary arterial wall mechanics are significantly location dependent. Therefore, modeling a precise constitutive behavior demands localized material characterization of the tissue. The long-term objective of this work is to model the mechanical behavior of pulmonary arteries and study the changes brought about by the onset of pulmonary hypertension (PH). As part of this investigation, we report on region-wise characterization of material properties in porcine pulmonary artery specimens.

METHODS

Main, left, and right pulmonary arteries from six swine of mixed Yorkshire breed were procured from Animal Technologies Inc., Tyler, TX. At the time of harvest, the animals were 6-9 months old and weighed 125-250 lb. Each of the arterial branches were divided into (i) BR – Branch, (ii) MD – Middle, and (iii) ED – End segments, as shown in Fig. 1(a). The MPA bifurcation (BF) was tested separately. Square-shaped specimens (side length 5 ± 1 mm) were mounted on a CellScale Biotester (Waterloo Instruments Inc., Ontario, Canada) with orientation as shown in Fig. 1(b). Four to six specimens were tested for each region of each porcine artery. Four markers, forming a 2.5×2.5 mm square, were placed in the center of each specimen and a CCD camera was utilized to track the local tissue deformation.

Figure 1: (a) Arterial tree excised from porcine heart-lung section, and (b) specimen attached to the biaxial test bench.

All tests were performed in 1% PBS solution at 37°C following the protocol described by Rogers et al [3]. An initial 5 mN tare load, followed by ten cycles of preconditioning up to 5% strain, and final tensile stretch cycle up to 45% strain was applied to each specimen. Force and stretch responses in the longitudinal and circumferential directions were recorded. Cauchy stress versus Green-Lagrange strain were used to describe the material behavior in the circumferential (x_1) and longitudinal (x_2) directions, defined by Eqs. (1) and (2),

$$\sigma_1 = \frac{F_1 \lambda_1}{h L_{01}}, \quad \sigma_2 = \frac{F_2 \lambda_2}{h L_{02}} \quad (1)$$

$$\epsilon_1 = \frac{1}{2}(\lambda_1^2 - 1), \quad \epsilon_2 = \frac{1}{2}(\lambda_2^2 - 1) \quad (2)$$

where σ_i ($i = 1, 2$) are the Cauchy stresses, ϵ_i ($i = 1, 2$) are the Green-Lagrange strains, F_i and λ_i ($i = 1, 2$) are the load and stretch in the x_i ($i = 1, 2$) directions; h and L_{0i} ($i = 1, 2$) represent the thickness and

length of each sample, respectively, before it is stretched. From the stress-strain curves, six indices were evaluated, namely: Anisotropy index, stiffness, and strain energy, each in the circumferential and longitudinal directions. Tissue thickness was measured with Vernier calipers. Anisotropy index was calculated per the definition proposed in Langdon et al [4]. Stiffness was evaluated by means of tensile modulus and strain energy calculated as the area under the stress-strain curve. For statistical analysis, one-way ANOVA tests followed by Tukey's multiple comparison tests were used to compare the region-wise indices at the 33rd, 66th and 95th percentile stresses. A probability value less than 0.05 was considered statistically significant. A Holzapfel-Gasser-Ogden (HGO) multilayer material model [5] was fitted to the experimental stress-strain curves. An optimization strategy that utilizes both genetic and Levenberg-Marquardt algorithms was used to identify the best set of HGO constants that minimizes the sum of squares of the differences between experimental and model-predicted Cauchy stresses.

RESULTS

For brevity, only the left pulmonary artery (LPA) characterization is presented in this abstract. Table 1 lists the mean constants obtained for the BR, MD and ED regions of the LPA. In the BR and MD regions, the tissue showed a near isotropic response (Figs. 2a, b). However, the ED region (Fig. 2c) presented significant anisotropy with the circumferential direction exhibiting visibly lower stresses, relative to the longitudinal direction, for identical strain values. The anisotropy index in the ED region was higher by approximately 40% and 35% relative to the BR and MD regions (Fig. 3a). The strain energy was 15% higher in the longitudinal direction (Fig. 3b). No statistically significant differences were obtained when comparing the tensile modulus in the longitudinal ($0.105 \leq p \leq 0.98$) and circumferential ($0.131 \leq p \leq 0.98$) directions at the 66th and 95th percentiles. However, remarkable differences were encountered when specimen thickness was compared amongst the BR, MD and ED regions (Fig. 4a, $p < 0.001$). Furthermore, major differences were found between the BR and ED regions, for the longitudinal tensile modulus at the 33rd percentile stress (Fig. 4b, $p < 0.05$).

Table 1: HGO constants for BE, MD and ED regions of the LPA. The definitions of c , k_1 , k_2 , β_m , and β_A are described in [5].

Region	c (MPa)	k_1 (MPa)	k_2	β_m (Deg.)	β_A (Deg.)
BR	0.0079	0.1097	0.466	14.89	17.2
MD	0.0025	0.0012	1.097	45.84	60.89
ED	0.0038	0.0076	1.136	73.34	72.22

Figure 2: Stress (σ) – strain (ϵ) plots of porcine pulmonary arteries at 40% biaxial stretching; (a) Branch (BR), (b) Middle (MD), and (c) End (ED) regions.

DISCUSSION

In the present work we presented region-wise biaxial tensile testing results conducted on porcine LPA specimens. We found that the LPA is stiffer in the circumferentially compared to the longitudinal direction.

Significant increase in longitudinal compliance was observed in the proximal to distal direction. As it relates to the anisotropic characteristics of large animal pulmonary arteries, our results are in close agreement with those of Cabrera and colleagues [6]. A major limitation of this work is the limited range of strain values exercised on a small sample data set, due to the available load cell capacity. Future work involves excising arterial trees up to two generations (assuming the MPA to be generation 0) and region-wise tensile testing at augmented values of strain. The subsequent implementation of the HGO model for finite element analysis simulations is expected to identify regional distributions of wall stress and displacement, which may be important, within the context of our long-term objective, to differentiate normal and PH pulmonary wall mechanics.

INVESTIGATING THE EFFECTS OF EXTRACELLULAR STIFFNESS ON VASCULAR SMOOTH MUSCLE CELL STRESS AND MECHANICAL PROPERTIES

INTRODUCTION

Under pathological conditions, artery material properties are altered, influencing functions such as vessel contractility and blood flow. In some cases, like cerebral aneurysms, spatial heterogeneity in vessel properties could relate to cell mechanoadaptation, affecting tissue remodeling and determining tissue stability or failure. In vascular tissues, vascular smooth muscle cells (VSMCs) are key components in regulating the tissue's structural integrity by contracting or relaxing to adjust the vessel radius and influence blood flow, maintaining cardiovascular homeostasis. VSMC contractility and gene expression are highly sensitive to changes in extracellular mechanical properties and work in conjunction during mechanotransduction to adapt to the cell microenvironment¹. Here, we characterize how external material properties affect cell contractility and anisotropy using traction force microscopy (TFM) and cellular micro-biaxial stretching (CμBS).

METHODS

Substrate Fabrication. Polyacrylamide (PA) gels doped with fluorescent microspheres were synthesized onto glass coverslips or PDMS membranes using previously described methods². PA gel stiffness was varied by altering ratios of 40% acrylamide and 2% bis-acrylamide³. A layer of patterned 32 x 128 μm² fibronectin islands was stamped onto the top of the PA gel to facilitate cell adhesion onto the substrates. Human umbilical artery VSMCs from Lonza in between passages 5-7 were seeded onto the gel constructs, in which they adhered to the patterned fibronectin. The VSMCs were cultured overnight in supplemented Medium 199 from Gibco, incubated at 37 °C and 5% CO₂. 24 hours before imaging, a contractile state was induced in the cells by exchanging the media with supplemented serum-free Medium 199.

Imaging and Biaxial Stretching. The constructs were imaged at 40X using a confocal microscope to obtain traction images. Brightfield images were taken of VSMCs and fluorescent images were taken of the respective underlying bead layer in the PA gel. For biaxial stretching, the constructs were mounted in a custom-designed CμBS apparatus and the elastomer membranes were stretched in increments of 5% from 0% to 20%, with brightfield and fluorescent images taken at each stretch increment. The cells were then lysed with SDS and the bead layer of the gel was imaged again at the same location and at each stretch increment. The fluorescent images of the gel layers with the adhered cells were paired with respective images of the gels without the cells to perform traction calculations.

Traction Calculation. Displacement of the beads due to cellular contraction was tracked and measured using a particle image velocimetry (PIV) ImageJ plugin between the paired images with and without the adhered VSMCs⁴. Using the displacement data with the material properties of the substrate, an unconstrained Fourier transform traction cytometry (FTTC) ImageJ plugin with a filtering regularization factor of 1E-9 calculated traction stress vectors throughout the area occupied by the cell⁵. Each vector in a specified region of the image was represented by

$$\mathbf{T}^n = T_x^n \mathbf{e}_x + T_y^n \mathbf{e}_y \quad (1)$$

in which \mathbf{e}_x and \mathbf{e}_y are the unit vectors along the x and y directions, respectively. From the traction vector field, total force vectors \mathbf{f}^n were calculated by

$$\mathbf{f}^n = -T_x^n a^n \mathbf{e}_x - T_y^n a^n \mathbf{e}_y \quad (2)$$

in which n is the discrete surface and a is the area of the surface. Total force across the cell was calculated by

$$2f_i = \sum_n \frac{\mathbf{f}_i^n r_i^n}{|r_i^n|} \quad (3)$$

where r_i is the x or y component of the position vector r^n that maps the surface to the center of the cell such that

$$r^n = r_x^n \mathbf{e}_x + r_y^n \mathbf{e}_y \quad (4)$$

From the total force components f_i , x and y components of the First Piola-Kirchoff (PK1) stress P_i of the cell was calculated by

$$P_i = \frac{f_i}{A_i} \quad (5)$$

in which A_i is the axial or transverse undeformed cross-sectional area of the patterned VSMC (Fig. 1A). For biaxial stretching, P_i was calculated for each stretch increment from 0% to 20% to determine stress-strain data for further strain energy density function curve fitting.

Figure 1. A. Calculation of axial and transverse PK1 stresses in a single cell⁶. **B.** Brightfield images with corresponding displacement and traction maps on two different PA substrate stiffnesses, 5.5 kPa and 40 kPa. **C.** Axial PK1 stresses of VSMCs on all substrate stiffnesses (n≈20 per group).

RESULTS

TFM studies were conducted to investigate the effect of extracellular material properties on cell stress of micropatterned VSMCs. We measured displacements of embedded microspheres in a PA gel and subsequent tractions by the contraction of VSMCs onto their substrates (Fig. 1B). In the lower range of substrate stiffnesses (2.5 – 5.5 kPa), the internal cell stress increased along with its external stiffness. However, as substrate stiffnesses increased (13.5 – 70 kPa), the internal cell stress followed a decreasing trend. Overall, the cell stress appeared to follow a biphasic curve as a function of substrate stiffness with stress increasing with increasing substrate modulus at low moduli and decreasing with increasing substrate modulus at higher moduli, exhibiting the highest level of contractility on a ~5.5 kPa substrate (Fig. 1C).

Biaxial stretching experiments were performed to study how single-cell stress-strain behavior is influenced by extracellular properties (Fig. 2A). Tractions were calculated for single cells at each strain to determine cell stress as a function of strain (Fig. 2B). For cells on the 2.5 and 5.5 kPa PA gels, the stress-strain curves appeared similar; however, the curve dropped considerably for cells on a 40 kPa substrate, complementing results from static TFM studies (Fig. 2C). To evaluate cell stiffness, the stress-strain curves were preliminarily fitted with a linear model to estimate an axial Young's moduli from the slope (Fig. 2D). Similar to results in the TFM studies, a biphasic curve was also observed in cell stiffnesses as a function of substrate stiffness. More

Figure 2. A. Schematic of CμBS apparatus.² **B.** Brightfield images of undeformed and stretched cell with corresponding traction maps. **C.** Stress-strain curves of VSMCs on different substrate stiffnesses. (n≈5 per group). **D.** Average slopes of axial stress-strain curves across different substrate stiffnesses.

data is required to significantly draw conclusions from the biaxial stretching studies and relate results to the static studies.

DISCUSSION

Our results indicate that VSMC mechanical function is mediated by extracellular mechanical properties. We found a biphasic trend in internal stress in the static studies, different stress-strain behaviors, and a corresponding biphasic curve in cell stiffness in the biaxial studies. In upcoming experiments, we will explore and model the effect of extracellular mechanics on single-cell strain energy density.

INTRODUCTION

Traditionally, cardiovascular disease has been perceived as a greater threat to male health, and literature suggests that men are at greater risk for development of cardiovascular disease than age-matched pre-menopausal women.(2) However, the prevalence of ischemic heart disease (IHD) in women is high, as it causes approximately one third of all female deaths.(3,4) Furthermore, IHD is known to be more fatal in women and the incidence of general cardiovascular disease increases distinctly in women after menopause.(2,5) Nevertheless, the true causes and detailed mechanisms driving these differences are not fully understood.

A method that has recently gained traction in the evaluation of cardiac function is flow analysis with Four-dimensional (4D) flow magnetic resonance imaging (MRI). Of particular interest in recent studies is the amount of kinetic energy (KE) dissipation and flow vortex formation in healthy and diseased ventricles.(6-14) However, the differences between sexes in kinetic energy and vorticity metrics have not yet been thoroughly examined and related to cardiac function. Therefore, the purpose of this study was to analyze the ventricular flow dynamics and cardiac function of healthy volunteers and make comparisons based on sex.

METHODS

In this IRB-approved and HIPAA-compliant study, forty healthy volunteers (twenty-one men, nineteen women) were recruited. The subjects were scanned on a 3.0T clinical system (MR750, GE Healthcare) using a 4D Flow MRI sequence known as PC-VIPR.(15) Time-resolved flow data were reconstructed into 14 time frames per cardiac cycle. Data were imported to Enight (CEI, Apex, NC), where flow metric measurements were made at the great vessels and ventricles for each time frame of the cardiac cycle. The KE within

each ventricle was then quantified through analysis of the MR image data files and ventricular volumes using Matlab (Mathworks, Natick, MA). Efficiency indices, Reynolds number, and ventricular vorticities were also processed and computed in Enight. Two-dimensional cardiac cine images were also obtained from each patient during the 4D flow MRI session. These images were used to calculate cardiac function and cardiac strain metrics using Segment (Medviso, Lund, Sweden) (<http://segment.heiberg.se>). Data were compared using a Student's t-test and linear regression was used to determine the strength of correlations between measured parameters.

Figure 1. 4D Flow MRI was used to calculate (A) kinetic energy in the right (RV) and left (LV) ventricles. Time-averaged 4D Flow MRI magnitude data were used to segment the RV and LV (inset) and (B) flow through the main pulmonary artery (MPA) and ascending aorta (Aao)

RESULTS

Peak systolic kinetic energy was significantly higher in the left ventricle of men than it was in women (Figure 1). Additionally, peak

Figure 1: Left ventricle kinetic energy (KE) plotted over the cardiac cycle for male and female volunteers, along with a statistical summary on differences in peak systolic KE

LV efficiency index was higher in women than it was in men, although this result was not significant. Peak systolic and diastolic left ventricular vorticity Index was higher in women than in men (Figure 2). On average, ventricular vorticity was higher in women than in men ($p < 0.001$). Preliminary Reynolds number results were significantly correlated to vorticity in both men and women (Men: $r = 0.75$, $p = 0.002$; Women: $r = 0.59$, $p = 0.026$). Global circumferential LV strain ($p < 0.001$), LV long-axis strain ($p < 0.001$), and both base- ($p < 0.001$) and mid- ($p < 0.001$) and apical ($p = 0.001$) left ventricle circumferential strain were significantly higher in women than in men. Furthermore, circumferential systolic ($p = 0.001$) and diastolic ($p < 0.001$) strain rates and long axis systolic ($p = 0.02$) and diastolic ($p = 0.008$) strain rates were significantly higher in women than in men. Differences in circumferential strain measurements are shown in figure 3.

Figure 2: Left ventricle vorticity index (vorticity/stroke volume) plotted over the cardiac cycle for male and female volunteers, along with a statistical summary on differences in peak systolic vorticity index

DISCUSSION

The causes and effects of heart disease can be sex-dependent. It has been hypothesized that hormonal differences between sexes are the main drivers for the sex differences in cardiac function and disease progression. Literature suggests that estrogen can have a protective effect on the pre-menopausal female heart and leads to higher ischemia and reperfusion injury tolerance.⁽²⁾ It has also been proposed that sex steroids have a significant influence on the contraction of cardiac myocytes and the regulation of autophagy during myocardial infarction.^(2,5) However, the implications of these differences on the hemodynamic output of the heart are not yet understood. Through this study, it was observed that the male ventricle may be less efficient at producing flow than the female ventricle, due to higher kinetic energy dissipation, decreased myocardial strain, and less vorticity per amount

Figure 3: Summary of regional sex-dependent differences in left ventricle circumferential strain.

of generated flow. Taken together, these augmentations in cardiac function in the female sex may in part explain the beneficial effects of estrogen. However, further studies will need to confirm the relationship between sex hormones and cardiac function.

INTRODUCTION

The observed co-localization of “disturbed” hemodynamics and atherosclerotic lesion prevalence has led to the identification of low and oscillatory Wall Shear Stress (WSS) as a biomechanical localizing factor for vascular dysfunction [1]. However, recent evidences have underlined how consideration of only “low and oscillatory” WSS may oversimplify the complex hemodynamic milieu to which the endothelium is exposed.

In this context, recent studies have highlighted the relevance of WSS fixed points, and the stable and unstable manifolds that connect them [2][3]. These WSS topological features have a strong link with flow features like flow stagnation, separation, and recirculation, which are usually classified as “disturbed” flow. Technically, a fixed point of a vector field is a point where the vector field vanishes, while unstable/stable vector field manifolds identify contraction/expansion regions linking the fixed points. The set of fixed points and their connections form the topological skeleton of a vector field. The presence of WSS fixed points and of WSS contraction/expansion regions, highlighted by WSS manifolds, might induce focal vascular responses relevant for, e.g., early atherosclerosis, or, aneurysm rupture [3]. For these reasons, the topological skeleton analysis of the WSS vector field is of great interest and motivates the study present herein.

Lagrangian techniques have been recently proposed to identify WSS manifolds but have certain practical limitations [2]. An Eulerian approach has also been suggested, but only for 2D analytical fields [4]. Here we propose and demonstrate the use of a simple Eulerian approach for identifying WSS topological skeleton on 3D surfaces.

METHODS

Ten carotid bifurcation computational hemodynamics models from the Vascular Aging-The Link That Bridges Age to Atherosclerosis

(VALIDATE) study were considered. Details on geometry reconstruction, personalized conditions at boundaries and CFD simulations are reported elsewhere [5].

Based on Volume Contraction theory, it can be demonstrated that the computation of the divergence of a vector field gives practical information about the associated dynamical system, avoiding numerical integration for manifolds identification, as required for Lagrangian technique, thus significantly reducing the computational effort. In particular, the divergence is able to (1) encase the connections between attractors and (2) identify the basins of attractions of each attractor. For this reason, here we used a divergence-based approach for WSS manifolds identification at the luminal surface of carotid bifurcations.

As WSS divergence depends by construction upon the algebraic summation of the *magnitude* of the single gradients of WSS vector components, in some cases it might fail in properly identify WSS expansion/contraction regions. In fact, these regions describe specific directional arrangements of the vectors, but both variations in magnitude and in directions are taken into account in the divergence. Consequently, here the divergence of the normalized WSS vector field was proposed:

$$\text{DIV}(\mathbf{\tau}_u) = \nabla \cdot \left(\frac{\mathbf{\tau}}{\|\mathbf{\tau}\|_2} \right), \quad (1)$$

where $\mathbf{\tau}_u$ is the WSS unit vector. Eq. (1), neglecting the vector field magnitude variation but taking into account variation of directions of the vector field, correctly identifies WSS manifolds and is suitable for practical WSS topological analysis at the luminal surface of an arterial segment.

To complete the analysis, we propose a robust method to WSS fixed points identification at the luminal surface. The Poincarè index is considered here for WSS fixed points identification because of its mesh-independent and topologically invariant proprieties. Once identified, a

Jacobian analysis of WSS fixed points allows then to classify the fixed point attractive or repelling nature. The proposed practical approach for the WSS topological skeleton identification is applied to both cycle-average and instantaneous WSS vector fields.

The cycle-average WSS vector field at the luminal surface $\bar{\mathbf{\tau}}(\mathbf{x})$ is

$$\bar{\mathbf{\tau}}(\mathbf{x}) = \frac{1}{T} \int_0^T \mathbf{\tau}(t, \mathbf{x}) dt \quad (2)$$

where T is the cardiac cycle duration. It was previously suggested that cycle-average WSS vector field $\bar{\mathbf{\tau}}$ fixed points and their associated manifolds influence the near-wall intravascular transport [2]. However, the paradoxical observation that a $\bar{\mathbf{\tau}}$ fixed point would have never been a real instantaneous fixed point (i.e., a null vector) along the cardiac cycle, calls into question the real physical meaning of fixed points of the cycle-average WSS vector field. In fact, from the definition of the Time-Average Wall Shear Stress (TAWSS) and from the Integral Inequality Absolute Value it follows that:

$$|\bar{\mathbf{\tau}}(\mathbf{x})| = \left| \frac{1}{T} \int_0^T \mathbf{\tau}(t, \mathbf{x}) dt \right| \leq \frac{1}{T} \int_0^T |\mathbf{\tau}(t, \mathbf{x})| dt = \text{TAWSS}(\mathbf{x}) \quad (3)$$

suggesting that a null value for $|\bar{\mathbf{\tau}}|$ does not necessarily imply the same for TAWSS. Moreover, it can be easily demonstrated that a null value for TAWSS at a specific location implies the existence there of a fixed point along all cardiac cycle. Eq. (3) highlights the need for a practical method for an in-depth analysis of the kinematics of instantaneous WSS fixed points along the cardiac cycle. Hence, WSS fixed points analysis is applied here to instantaneous WSS vector field and a measure to quantify the fraction of cardiac cycle spent by instantaneous WSS fixed points at a specific location at the luminal surface is proposed:

$$RT_{x_{fp}}(e) = \frac{\bar{A}}{A_e} \frac{1}{T} \int_0^T \mathbb{I}_e(\mathbf{x}_{fp}, t) dt \quad (4)$$

where $\mathbf{x}_{fp}(t)$ is the WSS fixed point position at time $t \in [0, T]$, e is the generic triangular element of the superficial mesh of area A_e , \bar{A} the average surface area of all triangular elements of the superficial mesh and \mathbb{I} is the indicator function.

RESULTS

An analytical vector field was used for benchmarking purposes. The proposed method was compared to the classical vector field integration approach [6] and to the recent trajectory-free method [4], providing excellent results. Then, the cycle-average WSS vector field at the luminal surface of the 10 carotid bifurcation models was analyzed. The topological skeleton of the cycle-average WSS vector field of one explanatory carotid bifurcation model, including fixed points and stable/unstable manifolds is presented in Figure 1.

Figure 1: Topological skeleton of cycle-average WSS vector field.

The contraction and expansion patterns, identifying unstable and stable manifolds, represent the basins of attraction for the stable fixed points associated with the manifolds. Notably, all cycle-average WSS fixed points identified using the Poincaré index at the luminal surface of the 10 carotid bifurcation models were located within contraction regions, thus confirming the appropriateness of the proposed method. For an in-depth characterization of the WSS fixed points, the quantity $RT_{x_{fp}}(e)$, as defined in Eq. (4), was computed on the surface of all the carotid bifurcation models and an explanatory example is presented in Figure 2. For visualization purposes, regions of interest R_{fp} were identified at the luminal surface around high $RT_{x_{fp}}(e)$ areas and including the

identified cycle-average WSS fixed points locations (labeled from A_C to G_C). For the explanatory model presented in Figure 2, the results of the WSS fixed points residence times analysis are summarized in Table 1 and clearly show that: (1) in regions R_{E_C} and R_{G_C} fixed points residence times were up to 30% of the cardiac cycle; (2) instantaneous WSS fixed points resided for small fractions of the cardiac cycle (range 0.0-14.5%) in cycle-average WSS fixed points identified locations; (3) interestingly, in the cycle-average WSS stable focus B_C location, the instantaneous WSS vector presented both saddle point (2%) and stable focus (2.9%) configurations along the cardiac cycle; (4) in regions R_{D_C} , R_{E_C} , R_{F_C} instantaneous WSS fixed points were always of the same type as cycle-average WSS fixed points; (5) paradoxically, it emerged that at position C_C where a cycle-average WSS saddle point was identified, the instantaneous WSS vector never presented a fixed point along the cardiac cycle (we remind here that a WSS fixed point represents a focal point at the luminal surface subject to an atheroprone hemodynamic environment).

DISCUSSION

A practical approach to fixed points and manifolds identification was presented and applied to cardiovascular flows. The proposed approach requires the vector field and its divergence only and it can be easily implemented for 3D vector field defined on complex geometries. This practical way to analyze instantaneous WSS fixed points along the cardiac cycle allows to evaluate their residence time and how strong is local contraction/expansion using WSS divergence (data not shown). Our findings on carotid bifurcation models question the physical significance of WSS fixed points on cycle-average WSS fields, and suggest instead a focus on their dynamics. In conclusion, the practical approach proposed here could contribute to speed up studies on the physiological significance of fixed points in cardiovascular flows, in the context of the increasing interest as expressed by recent literature on this still-poorly-explored argument.

INTRODUCTION

Bicuspid aortic valve (BAV) is the most common congenital cardiac disease with an estimated incidence from 0.9% up to 2% among the world population [1]. At least one third of BAV patients develops secondary pathologies, e.g., aortic dilation or dissection as well as calcific aortic valve disease (CAVD), including aortic valve stenosis or regurgitation [2]. Altered aortic hemodynamics, characterized by abnormal flow and wall shear stresses (τ_{wall}) overloads both on aortic wall and cusps, has emerged to play a role in the pathogenesis of BAV related complications along with genetic factors [3]. According to the theory of CAVD hemodynamic etiology, an accurate quantification of stress distribution on leaflets is required to predict calcific patterns [4].

To this purpose a patient-specific fluid-structure interaction (FSI) model is herein implemented in order to accurately capture the valve dynamics and reliably compute mechanical stimuli transferred by momentum between deforming leaflets and blood flow. The most common FSI methods that were previously used to study BAV disease can be categorized as Arbitrary Lagrangian-Eulerian [4], Cut-Cell [5], and Immersed Boundary [6] method. In this study, we employed a variation of the Cut-Cell method called sub-grid geometry resolution (SGGR) which automatically adapts the Cartesian grid to the moving boundaries by implementing a curvilinear mesh. This meshing method allows to accurately capture the τ_{wall} distribution on the leaflets. Our main goal is the characterization of BAV-related flow patterns and τ_{wall} in a single patient-specific anatomy, thus overcoming previous FSI works [4, 5] adopting a parametric or paradigmatic anatomical modeling. In addition, we aim at comparing and validating the results of our FSI model against in vivo 4D flow ground-truth data. This analysis extended in time for the same patient can be helpful to guide clinical treatments and can be applied to a cohort of patients to compare

relevant hemodynamics parameters and better understand the hemodynamic etiology of BAV-related complications.

METHODS

A 26-year-old female BAV patient (right-left cusps fusion) with no calcifications was enrolled for the study. MRI images were acquired at the Multimodality Imaging Section of IRCCS Policlinico San Donato on a 1.5 T scanner (Magnetom Aera, Siemens Healthcare, Erlangen, Germany). Informed consent was obtained for the patient. The geometry of the patient's aortic root (AR) was reconstructed starting from long axis cine cardiac MRI sequences acquired on 18 planes evenly rotated around the axis passing through the center of the annulus and the STJ. First, the principal AR substructures were manually traced on each plane; second, the selected points were processed, filtered and their coordinates were used to define vertexes in Gambit (Ansys, Fluent Inc., Canonsburg, Pennsylvania). These vertexes were interpolated with non-uniform rational cubic splines (NURBS) in axial and circumferential direction, that were interpolated by bicubic surfaces to obtain the 3 sinuses. The reconstruction method implemented in MATLAB (Mathworks, Inc, Natick, MA) is described in detail in [7]. To comprehensively capture the aortic helical flow patterns, LVOT and ascending aorta were included in the model using Mimics Research (Materialise NV, Leuven, Belgium).

A laminar blood flow was assumed. The blood was modeled as a Newtonian fluid with a viscosity of 0.0035 Pa·s and a density of 1060 kg/m³. The aortic wall was preliminary modeled as a rigid body and the leaflets were modeled as hyperelastic isotropic material, using the 3rd degree Ogden model fitted on experimental data available in literature [8]. For the fused cusp, properties were averaged between the right and left coronary leaflets of a tricuspid AV, while the mechanical properties

of the non-coronary cusp were employed for the non-fused cusp. Pressure boundary conditions adjusted to the patient's heart rate were imposed at the inlet and outlet boundaries of the fluid domain. A body-fitted SGGR based FSI model was utilized because of its accurate data transfer between fluid and structural domain and incorporation of valves' leaflet thickness, hence ensuring accurate calculation of flowrates, orifice areas, mechanical stress (σ_{Mises}), and τ_{wall} . The structural part was solved by Abaqus 6.14 (SIMULIA, Dassault Systèmes, Providence, RI) and FlowVision 3.10 (Capvidia NV, Leuven, Belgium) was employed as the flow solver. FlowVision Multi-Physics Manager (Capvidia NV, Leuven, Belgium) was used to couple the two solvers during the 2-way FSI simulation.

Figure 1: Patient-specific anatomy reconstruction steps. The AR anatomy is traced from cMRI images and processed in MATLAB, Gambit and ANSYS SpaceClaim to obtain the FSI model.

RESULTS

The BAV patient hemodynamics during the cardiac cycle is illustrated in Figure 2, specifically Figure 2B and 2C present the blood flow during systolic phase and Figure 2F and 2G present the diastolic flow. The systolic open configuration and the diastolic closure are shown in Figure 2A and 2E, respectively. The typical BAV asymmetric elliptical opening generated the eccentric systolic flow jet that impinged on the ascending aorta wall, potentially explaining the common BAV-induced dilation. Recirculation zones were observed in the sinuses throughout systole and a helical flow pattern was formed in the aortic arch region during peak systolic phase. The valve calculated effective orifice area (EOA) was 1.34 cm² and geometric orifice area (GOA) at peak systole was 1.4 cm².

Figure 2: The BAV patient leaflets opening (A) and closing (E) and flow velocity streamlines during systole (B, C) and diastole (F, G).

The leaflets mechanical and fluid stress levels were evaluated on the ventricular side of the leaflets throughout the cardiac cycle (Figure

3). During systole, the non-fused leaflet attachment region exhibited higher level of stress if compared to the fused one (Figure 3A, B). On the contrary, the fused leaflets experienced higher stress (Figure 3E, F) during diastole. In addition, the overall σ_{Mises} magnitudes were higher in diastolic phase. The τ_{wall} magnitudes were higher on the free edge for both leaflets during systole (Figure 3C, D). During diastole, the highest τ_{wall} magnitudes were observed in the belly region, right below the coaptation region (Figure 3G, H).

Figure 3: Mechanical and fluid stress magnitudes comparison between the fused (A, C, E, G) and non-fused (B, D, F, H) leaflets.

DISCUSSION

The distribution of leaflets WSS is similar to the one reported in previous FSI studies [4, 5] as well as the asymmetric vortices dynamics that is characterized by a larger vortex in proximity of the fused leaflet with respect to the non-fused one. This fully-coupled FSI model is able to capture regional fluid and mechanical stresses that can help localizing regions more vulnerable to damage and calcification development.

A validation of this FSI model with 4D flow data extracted from patient's phase contrast MRI, in terms of flow patterns description and estimation of main hemodynamic parameters, is in progress. Good agreement has been found between the GOA calculated from MRI and FSI analysis ($GOA_{MRI}=1.5\pm0.2$ cm² vs $GOA_{FSI}=1.4$ cm²) at peak systole. A future development involves the full exploitation of patient-specific boundary conditions directly extracted from 4D flow data to improve the comparison between the two methods (FSI and 4D flow analysis) and to verify their reliability and accuracy. The accuracy of the FSI model will be further improved by conducting a grid independence study and modelling a compliant aortic wall.

Given the emerging off-label use of TAVR valves in BAV patients who develop CAVD at an earlier age, the feasibility of TAVR deployment will be also investigated by simulating the expansion of a commercially available self-expandable prosthesis in a calcified patient-specific BAV anatomy. This would help to inform the clinical staff whether TAVR can be considered as a safe and effective solution for BAV symptomatic patients.

ACKNOWLEDGEMENTS

Simulia and Capvidia are in an academic partnership with Dr. Bluestein. This project was supported by NIH-NIBIB-BRP U01EB026414 (DB). All the simulations were computed on Stony Brook University SeaWulf cluster. IRCCS Policlinico San Donato is a clinical research hospital partially funded by the Italian Ministry of Health.

INTRODUCTION OF A SIMPLE 2D COMPUTATIONAL MODEL TO PREDICT RISK OF CORONARY OBSTRUCTION DURING TRANSCATHETER AORTIC VALVE REPLACEMENT

INTRODUCTION

Despite the overall effectiveness of transcatheter aortic valve replacement (TAVR), complications can limit the realization of mortality and quality of life benefits for patients with severe aortic stenosis, whom conventional open-heart surgery has been deemed high risk [1-2]. Coronary obstruction is one such complication which can occur upon transcatheter valve deployment, and while a serious and potentially preventable complication, there is no consensus to which features reliably predispose risk of coronary obstruction during TAVR. Most of the guidelines developed so far have originated from clinical trials designed to exclude as many adverse outcomes as possible, which can potentially exclude a large number of potential TAVR patients, often those who have no other treatment options available. In contrast, complex computational simulations have shown potential for greater accuracy, though computational time and complexity have limited practical use. A simple, yet accurate model that is based on mechanistic insight to the precise mechanisms of coronary obstruction is essential to be able to reliably predict which patients could safely be treated with TAVR. Herein, we introduce a simple mechanistic index that can predict which high risk patients (i.e. patients with coronary artery height (h) < 14 mm and/or Sinus of Valsalva diameter (SOVd) < 30mm) are not actually at risk and are indeed candidates for TAVR pre-operatively, allowing for the most patients possible to safely undergo TAVR without coronary obstruction. An overarching objective of this study is to better understand the physical mechanism of coronary obstruction beyond the conventional parameters of h and SOVd alone.

METHODS

A patient specific 2D model was developed to assess risk of coronary obstruction during TAVR for 28 patients out of 600 aortic stenosis patients flagged as high risk for coronary obstruction (defined

as meeting $h < 14$ mm and/or $SOVd < 30$ mm) during TAVR at The Ohio State University Wexner Medical Center between January 2014 and September 2018. Informed consent was obtained from all patients and the study complied with the Institutional Review Board of The Ohio State University. With respect to the outcomes for these 28 patients, 23 received TAVR successfully while 5 patients did not receive a successful TAVR. These five include 1 male who suffered coronary obstruction, 2 females who underwent surgical aortic valve replacement with visual confirmation of coronary obstruction by the operating surgeon, and 1 male and 1 female who each had extremely low lying coronaries and were deemed surgically inoperable due to age and received medical management. The 2D model that was developed accounts for patient specific parameters beyond h and SOVd, including cusp length (L) (Figure 1A), coronary ostium size (d) (Figure 1B), the distances between the coronary ostium and the respective annulus to STJ line (W) (Figure 1B) and calcification size (t) (Figure 1C), measured from pre-TAVR CT images. From these measurements, the closest distance between native aortic valve cusp and the corresponding coronary artery ostium, DLC_{2D} , was calculated using the Pythagorean theorem Equation (1):

$$DLC_{2D} = \sqrt{(\Delta x)^2 + (\Delta y)^2} \quad (1)$$

Where Δx and Δy are the horizontal (x-direction) and vertical distances (y-direction) between a point on the cusp (P_c) and a point on the upper coronary ostium (P_o) respectively. Δx and Δy are each related to the measured parameters using Equation (2) and (3), respectively:

$$\Delta x = w - t \quad (2)$$

$$\Delta y = h + d - L \quad (3)$$

An idealized aortic root, measured parameters, and the calculated index are shown in Figure 1D,E. DLC_{2d} was then indexed with the coronary artery diameter, d , to yield a representative measure of the fractional

obstruction of the native cusp “eclipsing” the ostium (DLC_{2D}/d). A fractional value greater than unity indicates that the gap available for blood flow is greater than the coronary artery diameter. The 2D model was validated using a more complex 3D computational model that was previously developed and validated in-vitro performed using 3D printed flexible patient-specific aortic root geometries. Briefly, the pre-procedural patient specific aortic root, calcium nodules and cusps were segmented from pre-TAVR CT images using Mimics Research 18.0 (Materialise, Belgium). The segmented aortic wall, cusps and calcium nodules were then discretized in 3-Matic Research 13.0 (Materialise, Belgium). An example of the segmented aortic root (red) and cusp with calcification (yellow) anatomy before TAV implantation is depicted in Figure 1F. Finite element analysis (FEA) was performed on each patient-specific 3D anatomical model using Abaqus/Explicit 6.9 software (Simulia, Providence, RI, USA) to simulate the opening of a TAV device stent that pushes the native cusps open towards the coronary ostium. The distance from cusp to coronary ostium (DLC_{3D}) was measured post simulation, and indexed with the coronary artery diameter, d , to yield DLC_{3D}/d (Figure 1 G-H). A Mann Whitney comparison of means test was performed for the patient groups under the indices h and $SOVd$ as well as the DLC_{2D}/d and DLC_{3D}/d . Sensitivity and specificity analyses were also performed for these four indices.

Figure 1: (A-D) Aortic root measurements; **(E)** Idealized schematic representing the calculated minimum distance following a TAVR (DLC_{2D}); **(F)** Example of patient specific aortic root with left and right coronary artery; The measured distance from the closest point on the leaflet to the upper ostium of the coronary artery (DLC) from **(G)** example finite element simulated post-TAVR aortic root with DLC from top view **(H)** and side view

RESULTS

Sensitivity and specificity analyses revealed that a cut off of $DLC_{2D}/d < 0.65$ was predictive with 100% sensitivity and 78.3% specificity, while a cut off of $DLC_{3D}/d < 0.7$ was predictive with 100% sensitivity

and 95.7% specificity (Figure 2). The optimal sensitivity and specificity of h and $SOVd$ in this high-risk group was only 60% and 40% respectively for a cut off $h = 10$ mm and $SOVd$ of 30.5 mm. DLC_{2D}/d and DLC_{3D}/d between the two groups of patients were significantly different ($p < 0.00078$ and $p < 0.0018$ respectively) while neither h nor $SOVd$ were significantly different ($p > 0.32$) (Figure 3).

Figure 2: Sensitivity and Specificity of LCAh, SOVd, DLC_{3D}/d , and DLC_{2D}/d to predict coronary obstruction for high risk patients with $h < 14$ mm and/or $SOVd < 30$ mm.

Figure 3: Comparison of means for those who successfully received TAVR and those who did not for (A) DLC_{3D}/d (B) DLC_{2D}/d (C) LCAh and (D) SOVd

DISCUSSION

We have successfully developed a simple, yet highly accurate 2D model to screen patients for possible coronary obstruction during TAVR based on criteria that can be readily calculated from current pre-TAVR CT angiographic imaging. Through comparison with the more complex and computationally expensive model yielding DLC_{3D}/d , we have validated the 2D model and DLC_{2D}/d as a conservative yet more precise predictor of coronary obstruction than h and $SOVd$. Results indicate that a significantly high fraction of patients who have $h < 14$ mm and/or $SOVd < 30$ mm can be safely treated with TAVR if assessed with DLC_{2D}/d as compared to the current guidelines using $SOVd$ and h alone. These findings shed light on a rare but significant potential complication during TAVR, and can assist cardiologists in decision-making process prior to the TAVR procedure.

INTRODUCTION

Aneurysms of the posterior communicating artery (PCOM) account for approximately 25% of all cerebral aneurysms [1]. Their rupture leads to hemorrhagic stroke, which is associated with high mortality and morbidity [2]. Nowadays, an increasing number of unruptured aneurysms is diagnosed as incidental findings. Since the risk associated with treatment to prevent an aneurysm from a future rupture outweighs the natural risk of the rare event of aneurysm rupture [3], deciding whether or not to treat an aneurysm can be particularly challenging. Such treatment decisions could hence be supported by a prediction model for aneurysm rupture. PCOM aneurysms have a higher rupture risk compared to aneurysms at other locations like the middle cerebral artery or other parts of the internal carotid artery [4], however, not all PCOM aneurysms rupture.

To assess which PCOM aneurysms are more likely ruptured, we recently developed and internally validated a logistic regression model discriminating between ruptured and unruptured PCOM aneurysms based on aneurysm morphology, hemodynamics, patient characteristics and PCOM aneurysm angioarchitecture [5]. The aim of this study was to evaluate the model in an external dataset and compare its predictive performance to different machine learning (ML) classifiers.

METHODS

For comparison of the previously developed logistic regression model [5] to the ML classifiers, the same training data

of 245 aneurysms (125 ruptured, 120 unruptured, cross-sectional data) characterized by 22 hemodynamic parameters through computational fluid dynamics simulations, 25 shape parameters describing aneurysm size, elongation, and irregularity in shape, patient age and gender, and the PCOM angioarchitectures [6] were used for model training. A detailed description of the training data as well as the parameters can be found in [5] and the references therein.

The logistic regression model had previously been developed using logistic group lasso regression [7]. In the current study, five ML-classifiers that are shown in Table 1 were trained on the data of the 245 aneurysms. For performance evaluation, 33 PCOM aneurysms from two external datasets [8] were used to calculate the accuracy, sensitivity, and specificity for each of the classifiers. Furthermore, for the linear support vector machine (SVM) as well as the SVM with RBF-kernel (RBF-SVM), the area under the receiver operating (ROC) curve (AUC) was computed by using the distances to the separating hyperplane as the varying threshold. To calculate the accuracy metrics for the logistic regression model, a threshold based on the ROC curve was used [5].

RESULTS

Table 1 shows the results of the model evaluation. The largest accuracy in the test data was achieved by the decision tree that had a maximum depth of two determined by 5-fold cross-validation and used the variables size ratio (SizeR), convexity

ratio (CR), and ellipticity index (EI) to classify an aneurysm as ruptured or unruptured.

Table 1: Comparison of performance of different classifiers in test data (n=33). For the decision tree and random forest, the shown values are the mean \pm standard deviation obtained from 100 repetitions of training the classifier (kNN=k nearest neighbors).

Classifier	AUC	Accuracy	Sensitivity	Specificity
Lasso	0.59	0.61	0.50	0.68
SVM (linear)	0.63	0.64	0.50	0.74
SVM (RBF)	0.55	0.52	0.43	0.58
kNN	/	0.64	0.50	0.74
Decision Tree	/	0.76 \pm 0.000	0.79 \pm 0.000	0.74 \pm 0.000
Random Forest	/	0.61 \pm 0.044	0.52 \pm 0.074	0.67 \pm 0.053

DISCUSSION

The accuracy of the group lasso model developed based on the 245 PCOM aneurysms decreased from 0.79 in the training to 0.61 in the test data of 33 PCOM aneurysms. Similarly, the AUC decreased from 0.84 to 0.59. These results indicate that the model could have been overfitted resulting from the relatively small sample size. In contrast, the trained decision tree with a maximum depth of two yielded an accuracy of 0.76 in the test data. The sensitivity and specificity of this classifier were 0.79 and 0.74, respectively.

These results indicate that the discrimination of unruptured and ruptured PCOM aneurysms can be increased by using a decision tree as a classifier rather than the group lasso model. This finding could be explained by the fact that the trained decision tree with a maximum depth of two has a comparatively low complexity and consequently a good generalizability with respect to the underlying data, resulting in a good performance in the test data.

Figure 1 illustrates the trained decision tree with eight aneurysms belonging to the two “purest” leaves of the tree. The aneurysms illustrated in group *a* are all unruptured cases with a $CR \leq 0.877$ and $SizeR \leq 1.429$. In contrast, all four aneurysms of the second leaf from the left ($CR > 0.877$) were ruptured. The illustrated geometries show that small aneurysms ($SizeR \leq 1.429$) with a more “conical shape” (group *a*) have a lower chance of being ruptured than small aneurysms with a small neck compared the aneurysm dome (group *b*).

Interestingly, hemodynamic variables were not included in the decision tree. This finding could be explained by the fact that aneurysm shape is related to hemodynamics since the flow is influenced by geometry.

When evaluating an aneurysm rupture probability model trained on aneurysms at different locations [9] with the 33 PCOM test cases, the AUC was reduced even further to 0.54, showing that having a model particularly trained for aneurysms at the PCOM and including additional information about the aneurysm angio-architectures could improve the predictive performance compared to a general model.

At the same time, the number of cases used for model evaluation was comparably low with 33 cases and hence might

Figure 1: Illustration of trained decision tree. For group *a*, the aneurysms shown in the first row are unruptured cases from the test data, the other two aneurysms unruptured and from the training data. For group *b*, all aneurysms are ruptured aneurysms from the training data

need to be increased for a more accurate estimation of the model’s performance in an external dataset.

Furthermore, the trained classifiers could vary largely for small changes of the defined tuning parameters (e.g. number of neighbors for the kNN) due to the small training sample size.

All the ML-classifiers were trained and tested using cross-sectional data. Hence, rather than predicting a future rupture, they discriminate between ruptured and unruptured aneurysms at the time when the patient reaches the hospital. To evaluate whether the decision tree or any other classifier could also be used to assess the aneurysm rupture risk, an evaluation in longitudinal data is planned for future work.

In conclusion, the trained decision tree was able to correctly classify 76% of the PCOM aneurysms from the external datasets. Small ruptured aneurysms had a small neck relative to the aneurysm dome, whereas large aneurysms classified as ruptured were less elliptical compared to the unruptured ones.

ACKNOWLEDGEMENTS

The external data were part of the publicly available AneuRisk data and the AneuX data collected and processed in the context of the @neurIST project funded by the EU commission (IST-2004-027703) and AneuX project evaluated by the Swiss National Science Foundation and funded by the SystemsX.ch initiative (MRD 2014/261).

INTRODUCTION

Image-based computational fluid dynamics (CFD) is widely used to simulate blood flow and pressure in arterial networks. These simulations have become increasingly powerful to understand normal and pathological physiology, and improve clinical decisions. However, CFD simulations are computationally expensive and prone to numerical instabilities. These factors have limited the broader adoption of image-based CFD and its use in parametric analyses.

Reduced-order modeling (ROM) of blood flow provides the ability to study global hemodynamics of large cardiovascular networks at a fraction of the computational effort of CFD. This is valuable when multiple simulations are required, such as for data assimilation, optimization, parameter tuning, and uncertainty analysis, or for timely decision support in clinical deployment. We have developed a novel *distributed lumped parameter* (DLP) framework to compute temporal flow and pressure waveforms in cardiovascular applications. To evaluate the accuracy of the proposed DLP methodology, we have applied this framework to diverse range of healthy and diseased patient-specific cardiovascular anatomies including aortic, aorto-femoral, cerebrovascular, coronary, pulmonary and congenital heart disease models (a total of 24, 4 of each type), and have compared the DLP results to those from 3D time-dependent (3Dt) CFD simulations.

METHODS

Here we describe how to construct a DLP model from an image-based 3D geometry by assigning a resistance to each vascular segment considering various sources of energy dissipation.

Viscous and curvature effects: The energy dissipation due to blood viscosity is taken into account by modifying the well-known Poiseuille resistance ($R_v = 8\mu/\pi r^4$). First, an integral form of this equation is used to consider the spatial variation of vessel radius along

the vessel length. Next, because secondary flows in a curved vessel cause extra viscous dissipation than for the same flow in a straight vessel, the energy dissipation due to vessel curvature is considered by using an analytical model relating the viscous friction factor of a curved vessel to that of a straight vessel [1]. These two considerations lead to the following formula:

$$R_v = \frac{8\mu}{\pi} \int_0^L 0.1033K^{\frac{1}{2}} \left[\left(1 + \frac{1.729}{K}\right)^{\frac{1}{2}} - \frac{1.315}{K^{\frac{1}{2}}} \right]^{-3} \frac{1}{r^4} dx \quad (1)$$

where K is the Dean number.

Sudden expansion effect: The energy loss at sudden expansions is modeled by using a semi-empirical model as [2]:

$$R_s = \sum_{i=1}^n \frac{\rho K_t}{2A_{0,i}^2} \left(\frac{A_{0,i}^2}{A_{s,i}^2} - 1 \right)^2 |Q| \quad , \quad K_t = 1.52 \quad (2)$$

where A_s and A_0 are minimum and nominal cross-sectional areas of the artery, respectively. n is the number of expansions in each artery.

Bifurcation effect: A nonlinear resistance (R_b) is added in series to the resistances due to viscous and sudden expansion effects of a child branch, based on a semi-empirical model [3]:

$$R_b = \frac{\rho}{2Q_j A_{dat}^2} (1 + \lambda_j^2 \psi_j^2 - 2\lambda_j \psi_j \cos(\theta_j)), \quad \lambda_j = \frac{Q_j}{Q_{dat}}, \quad \psi_j = \frac{A_{dat}}{A_j} \quad (3)$$

where Q_{dat} and A_{dat} are the flow rate and the cross-sectional area of the datum supplier at the bifurcation junction, respectively, and θ_j is the angle between a datum supplier and its child branch.

Pulsatility effect: The effect of changes in velocity profile is considered by changing the viscous resistance based on the Womersley number. This is done by *numerically* calculating velocity profiles from the Womersley solution, and computing the radial

derivative at the vessel wall to obtain a modified viscous friction factor and a modified R_v accordingly.

We developed an *automated* framework (described in **Fig. 1**) to compute flow rate and pressure using the DLP model.

Fig 1. The modeling steps of the automated framework to compute blood flow and pressure in a representative patient-specific coronary model using the DLP method.

RESULTS

To evaluate the proposed DLP framework, we present three comparisons. First, we calculated relative errors between the mean values of the temporal flow rate and pressure from the DLP model against 3Dt CFD simulations at the inlet and outlets of each model. Second, for perspective, we compared the results from the 3Dt CFD with an LP model where a Poiseuille resistance is assigned to each vascular segment by considering the averaged vessel radius and neglecting other sources of dissipation. Finally, the temporal flow and pressure waveforms from the DLP model are compared with their CFD counterparts in several locations. We note that the DLP model is in no way tuned to the CFD results—it is based only on the image segmentation geometry and is fully automated. To ensure a consistent comparison between the DLP and 3Dt CFD modeling, consistent boundary conditions are employed at inlets and outlets. Due to limited space, we only present the results for 4 coronary models, although more models and other vascular domains have been considered.

Fig 1. Four coronary models and illustration of errors of mean flow rate (left panel) and pressure (middle panel) between the DLP model (\bar{Q}_{DLP} , \bar{P}_{DLP}) and the 3Dt CFD simulation (\bar{Q}_{3D} , \bar{P}_{3D}). Right panel depicts mean pressure errors between the 3Dt CFD and an LP model assigning a Poiseuille resistance to each vascular segment (\bar{P}_{Poiss}).

Four patient-specific anatomical models of the aorta and major coronary arteries are shown in **Fig. 2**. This set is relatively broad; **Model C** is “healthy” with no stenosis, **Models B** and **D** have mild stenoses in the left and right coronary arteries, respectively, and **Model A** has a severe (~80%) and a mild (~50%) stenosis in a left coronary artery. In all cases, aortic flow was prescribed at the inlet, an RCR Windkessel of the systemic circulation was coupled at the aortic

outlet, and coronary-specific LPNs that consider the time-dependent intramyocardial pressure were coupled at the coronary outlets.

As shown in **Fig. 2**, the mean values of the pressure error are 4.9%, 2.6%, 0.7% and 1.0% for **Models A, B, C**, and **D**, respectively. The maximum error of ~10% is observed for one of the coronary branches of **Model A**. For perspective, the right panel in **Fig. 2** plots error from assigning simple Poiseuille resistances to each vascular segment, which demonstrates significantly higher errors, and hence, the significant improvement of the DLP framework in predicting hydrodynamic effects. **Fig. 3** presents more detailed comparison of the DLP results against those from 3Dt CFD, demonstrating that the DLP model can accurately predict pressure waveforms at different locations of the coronary artery tree of **Model A**, including at **f** and **g** that are downstream branches of the complex stenotic region.

Fig 3. Color contours of early diastolic pressure and velocity of the coronary **Model A** and examples of comparison of temporal flow rate and pressure waveforms from the DLP model (“0D”) and the 3Dt CFD simulations (“3D”) at the boundaries

DISCUSSION

We have presented a DLP framework to predict temporal flow and pressure waveforms in 3D vasculature models. This framework is fully automated based on image geometry, and generally requires ~1/1000 of the computational cost compared to 3Dt CFD simulations. Although not shown here due to space, this framework has been applied to a range of vascular models, demonstrating, to the best of the authors' knowledge, one of the most comprehensive comparisons of a ROM to a 3Dt CFD standard. The proposed DLP framework provided consistent prediction with 3Dt CFD simulations with mean errors <7% for all models (including aforementioned non-coronary domains) spanning a reasonably broad range of geometrical and physical characteristics; for example, key parameters such as area reduction ratio ($1 - A_s/A_0$), mean curvature ratio (a/R), Reynolds (Re) and Womersley (α) spanned on the order of ~50-90%, ~0-0.5, ~100-3000 and ~1-20, respectively, in models considered.

To provide more general insight into the contribution of each sources of energy dissipation, we note that the modification due to flow separation at sudden expansions has the highest contribution to accurately predict flow and pressure distributions. Viscous resistance modified by curvature/pulsatility effect has the second highest contribution in energy losses. Finally, the modification introduced by bifurcation effects appears to improve the accuracy of the ROM for cases with more than ~20 junctions such as pulmonary models.

INTRODUCTION

In recent years, nanotechnology has been implemented in cancer treatment. Nanoparticles can be used as imaging contrast agents, or as absorptive heating generators to confine energy in tumors, or as carriers of therapeutic drugs. For most tumors, drug delivery is often done via intravenous injection. Once the drug reaches the capillaries in the tumor, it has to first pass through pores on the capillary membrane due to pressure difference, then diffuse through the interstitial space, and finally enter into the tumor cells. One challenge is the high tumor interstitial fluid pressure (IFP) that is a major barrier for drug delivery.

In this study, we tested the hypothesis that whole body hyperthermia may lower the tumor IFP to allow more nanoparticles into PC3 tumors after a systemic injection.¹ In vivo experiments were performed to evaluate the effects of whole body hyperthermia on the deposition of nanocarriers in PC3 tumors implanted on mice. Gold nanoparticles coated with ligands that specifically target PC3 tumor cells were developed first, then the nanofluid was injected through the mouse tail vein with or without 1-hour whole body hyperthermia. During the experiments, mouse body temperature and tumor IFP were also measured. MicroCT was used to analyze the total amount of nanoparticle deposition in the resected tumors.

METHODS

Gold nanoparticles were synthesized with citrate stabilization. Through ligand exchange reaction, prepared PPI-CO₂H dendrons were coated on the surface of the particles. Finally, DBCO-functionalized Fabs were attached to the dendrons, for enabling targeting of PC3 cells. The finalized nanoparticles were 50 nm in hydrodynamic diameter.² The concentration of the nanofluid was 10 mg-Au/mL.

PC3 xenograft tumors were implanted in 8 Balb/c Nu/Nu male mice (~25 g, The Jackson Lab, Bar Harbor, ME), similar to our

previous experiments.³ The tumors are randomized into two groups: the control group without whole body heating and the experimental group with one-hour whole body heating.

Mouse body temperature was monitored by a temperature reader (Bio Medic Data Systems, Seaford, DE) implanted into the mouse peritoneum 48 hours before the experiment. Mouse temperatures were measured using a scanner to activate the temperature sensor and then transfer the reading to a computer. All the mice in the heating group were given an intraperitoneal injection (i.p.) of 1 mL of saline 30 min before heating to prevent dehydration. The mouse was placed in a preheated cage within an incubator set at 39°C, for one hour.

After the one-hour heating, 200 μ L of the prepared nanofluid was injected into the mouse circulatory system via the tail vein. The mouse was later sent back to the animal facility. Twenty-four hours following the nanofluid injection, the mouse was brought back to the lab and euthanized using Na Pentobarbital overdose (160 mg/kg, i.p.). The tumor was resected and immediately scanned by a micro-CT imaging system (Skyscan 1172, Micro Photonics, PA).³

During the experiments, tumor IFP was measured by a micro-pressure transducer (Model SPR 524, Millar Instruments, Houston, TX) with a catheter tip size of 0.33 mm. The IFPs were measured at the tumor center and tumor periphery. For each tumor, IFP was recorded four times: before the heating, right after the 1-hour heating, 2 hours after the heating, and 24 hours after the heating. All the measurements were also performed on a tumor in the control group, side by side with the tumor in the experimental group.

RESULTS

The sizes of the tumors in both groups were similar (with heating 667 ± 229 mm³ vs. without heating 618 ± 122 mm³). The mice acted normally in the heating chamber and tolerated the one-hour heating well with no observed adverse effects. It was found that the mouse

body temperature increased quickly to 40°C within 15 minutes and was maintained for the rest of the heating duration.

In the tumor group with the 1-hour whole body heating the average IFP decreased approximately 40% from its baseline value right after the 1-hour heating, as shown in Figure 1. Two hours after the heating, the average tumor pressure decreased 52%, and the decrease was more evident at the tumor periphery. 24 hours after the systematic heating, the tumor interstitial pressure rebounded slightly at the periphery location, while decreased further at the center location.

Figure 1. Pressure changes from its baseline value in the experimental group.

IFP was also measured in the tumors of the control group to evaluate whether insertion of the pressure probe alone affects the IFP results. As shown in Figure 2, the average pressure of the two tumor locations does not change significantly in the control group. In the experimental group, the tumor interstitial pressure 24 hours after the whole body heating was 42% of its baseline value. Statistical analyses were performed to evaluate whether the difference between the tumor groups with or without heating is statistically significant. Statistically significance indicated by the p -value less than 0.05 is confirmed either 2 hours or 24 hours after the whole body heating.

Figure 2. Comparison of pressure changes from its baseline between the two tumor groups, * refers to $p < 0.05$.

Imaging analyses were performed to understand the number of microCT voxels in particular grayscale (GS) ranges, i.e., 0-9, 10-19, 20-29 ... 250-255. It is shown that for a tumor without any nanofluid injection, the average grayscale value is approximately 60, which will be used later as a threshold grayscale value ($GS_{threshold}$) to indicate nanoparticle presence in tumors. As shown in Figure 3, the maximal voxel number in specific grayscale range occurs at the grayscale range of 100-109, shifting it from the scope of 50-60 in tumors without nanoparticle deposition. It is evident that there are more nanoparticles delivered to the tumors after the 1-hour whole body heating, due to the observation that more voxels are in the higher grayscale ranges (grayscale value > 90) than that in the tumors of the control group.

The amount of gold nanoparticles is estimated based on the grayscale values in individual voxels. The threshold grayscale value is selected as 60, thus, in each voxel, the amount of the gold nanoparticles is calculated as $GS - GS_{threshold}$, one then can add the amounts in all the voxels. The summation is in theory proportional to the gold nanoparticle deposition in tumors, assuming that the gold nanoparticle concentration is directly proportional to the grayscale value exceeding the $GS_{threshold}$ of 60. Figure 4 illustrated that the total amount of the nanoparticles delivered into the tumors in the heating group is 36% larger than that in the tumor group without the whole-body heating. The p value equal to 0.044 suggests the positive outcome of 1-hour whole-body hyperthermia on enhancing nanoparticle delivery to PC3 tumors.

Figure 3. Total number of voxels in specific grayscale value range in both tumor groups

Figure 4. Total amount of gold nanoparticles deposited in tumors

SUMMARY

In this study, we performed *in vivo* experiments on mice to evaluate whether whole body hyperthermia enhances nanoparticle delivery to PC3 tumors. The results illustrate a decrease in IFP after 1-hour whole body hyperthermia treatment, with a statistically significant reduction evident 2 hours after the treatment and the reduction is maintained for 24 hours. The 1-hour whole body hyperthermia leads to 36% more nanoparticle delivery in the experimental group than that in the control group.

QUANTIFICATION OF TISSUE ELECTRICAL AND THERMAL RESPONSE DUE TO HIGH FREQUENCY IRREVERSIBLE ELECTROPORATION: A PILOT STUDY IN EX VIVO PERFUSED LIVERS

INTRODUCTION

High Frequency Irreversible Electroporation (H-FIRE) is a minimally invasive ablation modality that utilizes ultrashort duration bursts of bipolar pulsed electric fields to destabilize cell membranes and promote cell death via apoptotic-like cell death pathways [1]. Unlike other ablation modalities, cell death is not dependent on prolonged exposure to increased temperatures. This allows for the application of H-FIRE to tumors near and encasing critical vasculature and other thermally sensitive structures. Preclinical studies with H-FIRE have demonstrated successful ablations for intracranial meningiomas with no adverse effects attributed to the therapy [2]. Additionally, recent studies have demonstrated H-FIRE with no signs of cardiac distress or gross muscle contractions, obviating the need for cardiac synchronization and neuromuscular blockade during surgery [3, 4].

While successful ablation is achievable without generating high thermal energies, clinical application of excessive pulsing and extremely high voltages can lead to unwanted thermal effects. Determining optimal H-FIRE protocols that minimize Joule heating is key to the advancement of this therapy. In this pilot study, we sought to quantify the H-FIRE thermal damage threshold using an Arrhenius damage model and a cumulative equivalent minutes at 43 °C (CEM43) model in an *ex vivo* liver perfused organ model. Additionally, we aimed to quantify the dynamic changes in tissue conductivity due to electroporation.

METHODS

An *ex vivo* perfused organ model was used as a testbed for various H-FIRE protocols [5, 6]. Shortly, 3 porcine livers were acquired from a local abattoir within 10 minutes of sacrifice. After cannulating the hepatic artery, portal vein, and hepatic vein with Luer fittings, the liver was gravity perfused with a sucrose-supplemented PBS solution ($\sigma \approx$

$0.8 \frac{S}{m}$) to prevent coagulation. The liver was placed on a bed of ice and transported to our facilities within a 2 hour span. Upon arrival, the liver was re-perfused at 30 °C on a perfusion system according to specifications in [5, 6].

Two 18 gauge monopolar electrodes (AngioDynamics Inc., Latham, NY) were used in the delivery of H-FIRE. These electrodes were set 1 cm apart with a 1.5 cm exposure. H-FIRE was delivered using a custom-built high frequency bipolar pulse generator (Energy Pulse Systems, Lisbon, Portugal) to deliver a 100 μs energized 10-1-10 μs burst scheme as seen in Figure 1. Experimental voltage and current measurements were captured with a 1000 \times high voltage probe (P5210A; Tektronix) and a 50 MHz current probe (TCP305; Tektronix), respectively, and stored on an oscilloscope (DPO2002B; Tektronix Inc., Beaverton, OR). Three experimental conditions were tested for ablation dimensions. The applied voltage was varied between 1,500 V, 2,250 V, and 3,000 V, and 300 bursts were applied.

Figure 1. H-FIRE 10-1-10 μs voltage waveform energized for 100 μs and delivered at a frequency of 1 Hz.

Numerical simulations were developed in COMSOL Multiphysics v5.4 (COMSOL Inc., Stockholm, Sweden) to capture the electric field distribution and changes in temperature due to Joule heating. First, the electric field distribution was captured by solving the Laplace equation (1) and taking the gradient of the electric potential:

$$0 = -\nabla \cdot (\sigma \nabla \Phi) \quad (1)$$

$$\vec{E} = -\nabla \Phi \quad (2)$$

The changes in conductivity due to electroporation and temperature effects were captured with equation 3:

$$\sigma(|\vec{E}|, T) = \sigma_0 \left(1 + A \cdot \text{flc2hs}(|\vec{E}| - E_{del}, E_{range}) \right) \cdot [1 + \alpha(T - T_0)] \quad (3)$$

where σ_0 is the baseline conductivity, $|\vec{E}|$ is the magnitude of the electric field, E_{del} marks the sigmoid inflection point, E_{range} marks the span of the transition, A determines the final electroporated conductivity, and α is the temperature coefficient of resistance. The parameters σ_0 , E_{del} , E_{range} , and A were determined by matching the numerical and experimental voltage and current in a method similar to [7], taking on values of 0.194 S/m, 650 V/cm, 450 V/cm, and 1.78, respectively (Figure 2). Finally, effects of tissue perfusion were modeled using the Pennes' bioheat equation with a Joule heating term as explained in [6]. All other parameters are listed in Table 1 or are pulled directly from [6].

Two thermal dose models were implemented, an Arrhenius damage model and CEM43 [8]. CEM43 computes equivalent time of exposure to a reference temperature, typically 43 °C, calculated by:

$$CEM43 = \sum_{i=1}^N R_{CEM}^{43-T_i} t_i \quad (4)$$

where R_{CEM} takes on a value of 0.25 when below the break temperature of 43 °C and 0.5 when above the break temperature. The Arrhenius damage model is solved from the following equation:

$$\Omega(\tau) = \int_0^\tau \xi \cdot e^{-\frac{E_a}{RT(t)}} dt \quad (5)$$

where ξ is the pre-exponential factor, E_a is the activation energy, R is the universal gas constant, and T is the temperature.

Finally, thermal thresholds were determined by matching the dimensions of tissue whitening in the ablation region with those predicted from the model. The numerical values that best captured the long and short axis of the experimental regions of tissue whitening are reported as the thermal threshold values.

Table 1. Numerical modeling parameters

Parameter	Symbol/units	Value	Ref.
Temperature coefficient	$\alpha, \frac{\%}{^\circ\text{C}}$	2	[6]
Tissue perfusion	$\omega_b, \frac{1}{s}$	3.575e-3	[6]
Activation energy	$E_a, \frac{1}{s}$	5.51e41	[8]
Pre-exponential factor	$\xi, \frac{J}{mol}$	2.769e5	[8]

RESULTS and DISCUSSION

The experimental voltage/current data were collected at ~250 V (n = 9), ~2,250 V (n = 7), and ~2700 V (n = 11). Figure 2a shows the numerical voltage and current-fitting functions demonstrated for the conductivity curve in Figure 2b. Determination of the relationship between the change in conductivity and the applied electric field is

important in modeling the electric field redistribution due to electroporation effects.

Figure 2. a) Comparison between the experimental and numerically predicted current ($R^2 = 0.94$) and b) resulting conductivity curve fit from the COMSOL simulation.

Figure 3. Ablation dimensions 2 hours after treatment.

Our data indicate a slight increase in the ablation as a function of applied voltage. Additionally, measurements (n=2) of the tissue whitening regions from the 1500V data group indicates a CEM43 value of 720 ± 613 and an Ω value of 0.207 ± 0.11 . These values best fit our experimental measurements of thermal damage, but future work will be done to (1) increase sample size and (2) definitively verify the presence of thermal damage through histological and pathological analyses. It is important to note that perfusion across the *ex vivo* tissue varied significantly and a higher sample number should provide less variations in the measurement.

INTRODUCTION

Pancreatic cancer is one of the most lethal forms of malignancy with minimal survival and a mortality rate comparable to its incidence. Due to the lack of specific symptoms and the aggressive nature of this disease, patients present with inoperable locally advanced tumors or metastatic disease at the time of diagnosis. Locally advanced pancreatic cancer (LAPC) patients have a five-year survival rate of < 12% [1]. Concurrent chemo-radiation therapy (CRT) is a standard option for LAPC but has significant toxicity. CRT typically stabilizes tumor progression for a time, and only a small subset of patients (10% to 15%) exhibit an objective response.

Hyperthermia is a well know radiation and chemotherapy sensitizer, that has pleiotropic biologic and physiologic effects to enhance effectiveness of other therapies [2]. Magnetic nanoparticle hyperthermia delivers localized heating by exposing magnetic nanoparticles (MNPs) deposited in the tumor to an alternating magnetic field (AMF). Recent advances in endoscopic ultrasound (EUS) guiding procedures for pancreas facilitate minimally invasive EUS guided delivery of MNPs. Repeated magnetic nanoparticle hyperthermia (MNPH) treatments can be performed by remotely activating MNPs after a single EUS guided delivery of MNPs into pancreatic tumors. Non-overlapping toxicities of MNPH and CRT offer significant potential to enhance therapeutic ratio [2] and may enable reduced dosing of CRT to achieve similar or improved outcomes with reduced toxicity. Local control of large tumors with radiation and chemo-therapies presents challenges, whereas physics of heat deposition and control provides advantages for MNPH.

Both MNPs and human tissue generate heat when exposed to AMF. MNPS generate heat through magnetic hysteresis loss power [3], whereas AMF-coupled tissue heating is a consequence of induced Foucault (eddy) currents [4].

Objective of this computational modelling study was to elucidate the role of tumor volume in treating LAPC with MNPH using finite element bio-heat transfer methods. Preliminary results indicate the need to reduce the non-specific eddy current heating of human tissue when exposed to AMF and large tumors are inherently easy to treat with MNPH.

METHODS

Bio-heat transfer: Pennes's bioheat equation was used to model the heat transfer in human tissue.

$$\rho_n c_n \frac{\partial T_n}{\partial t} = k_n \nabla^2 T_n + \rho_b c_b \omega_{b,n} (T_b - T_n) + Q_{m,n} + Q_p \quad [1]$$

where, n and b represent tissue (tumor, $n=1$; healthy $n=2$) and blood parameters, respectively. For either tumor or healthy tissue, ρ_n , c_n , k_n , T_n , $Q_{m,n}$ denote the density, specific heat, thermal conductivity, local temperature, and metabolic heat generation rates. Correspondingly, for the blood ρ_b , c_b , ω_b , T_b denote density, specific heat, perfusion rate, and temperature, respectively.

Eddy current heating: Non-specific tissue heating depends on AMF amplitude (H), frequency (f), and varies along the radial distance (r) of the tissue volume:

$$P_{eddy\ current} \propto \sigma_t (\pi \mu_0 r f H)^2 \quad [2]$$

where, σ_t electrical conductivity of the cylinder (idealised tissue) and μ_0 is the permeability of vacuum.

MNPs and heating rate: For modelling, the heating properties of MNPs from a previous experimental study were used [3]. The MNP heating rate is reported as specific loss power (SLP), and for the present effort was fixed at $5 \cdot 10^5 \frac{W}{m^3}$ for AMF having amplitude 10 kA/m at frequency 150 kHz [3]. A uniform distribution of MNPs in half the tumor volume was assumed, representing a volumetric heat

source which presents a realistic simulation of MNPs delivered via a single injection site into a tumor. The total tumor volume determines the maximum injection volume of MNP formulation into the tumor, as previously described [5]. Tumor volume-normalized MNP dose and fixed AMF conditions were used to study the role tumor size on the achievable temperatures in the tumor.

The Pennes bioheat equation was used to model MNP heat transfer in tumor and surrounding tissues. COMSOL Multiphysics® finite element software was used to solve the bioheat equation. The model was verified and validated comparing to the analytical solutions and experimental data available in the literature. The tumor and normal tissue model geometry used for this study is described in the Figure 1. Optimized mesh had 103466 tetrahedral and triangular mesh elements.

Figure 1: Geometry and the mesh used in the study.

A constant blood perfusion of $6.4 \cdot 10^{-3} \frac{1}{s}$ was used for all the tissue types. A treatment duration of 20 min with a time step of 30 s was modeled. Thermophysical properties used in this study were obtained from literature and are reported in Table 1.

Table 1: Thermophysical properties

Property	Torso	Pancreas
Heat capacity [$J/kg \cdot K$]	3640	4750
Density [kg/m^3]	1079	1800
Thermal Conductivity [$W/m \cdot K$]	0.52	0.59
Metabolic Heating Rate [W/m^3]	1578	1657

Convective heat flux boundary condition with a convective heat transfer coefficient of $10 \left[\frac{W}{m^2 \cdot K} \right]$ and an ambient temperature of $20 [^{\circ}C]$ was enforced on the cylindrical surfaces of the torso. The circular surfaces for the torso were fixed at a temperature of $37 [^{\circ}C]$ to represent nominal body temperature far away from the heating source.

RESULTS

Non-specific eddy current heating is significant at the outer surface of the torso (Figure 2). Temperatures above $40^{\circ}C$ in 5 – 8 mm thick outer layer of the torso is a potential safety concern. Large tumors realized a higher tumor thermal dose compared to small tumors when treated with tumor volume-normalized MION dose and fixed AMF amplitude and frequency (Figure 3).

Figure 2: Temperature distribution after exposing tumor volume-normalized MNP dose to AMF for 20 min, for small tumor with a radius of 2 cm shown. Color legend reports temperature in $^{\circ}C$. Non-specific eddy current heating on the superficial tissue due to AMF exposure is within the clinically acceptable limits.

Figure 3: Tumor temperatures as a function of tumor radius, r_t .

DISCUSSION

Simulation results are consistent with previously reported *in vivo* results [6]. Briefly, tumor volume-normalized MNP dose of $5 \frac{mg Fe}{cm^3 \text{ of tumor}}$ in MiaPaCa-02 subcutaneous human xenograft mouse models exposed to AMF amplitude of 6.5 kA/m (rms) at 160 kHz for 20 min resulted in superficial temperature due non-specific heating $38^{\circ}C$ and tumor temperatures of $44^{\circ}C$ for large tumors ($0.30 cm^3$) and $42^{\circ}C$ for small tumors ($0.15 cm^3$). Simulation results follow a similar trend of higher tumor temperatures in large tumors compared to the small tumors. Strategies for reducing the superficial non-specific eddy-current heating will be presented. Future studies will include thermal dose dependent blood perfusion and human voxel models to facilitate development of clinical AMF devices and related technologies to translate MNPH therapy for LAPC to the clinic.

INTRODUCTION

Selective and remote manipulation of proteins in living systems with high spatial and temporal resolutions is important to elucidate the post-genome *in situ* protein function and develop precise therapeutics for disease treatment. Though current approaches, including chromophore-assisted light inactivation (CALI)^[1], optogenetics^[2], and photoswitches^[3], made significant developments in optical control of protein function, there are many drawbacks to overcome. Optogenetics requires genetic modification and is limited to light sensitive proteins. CALI utilizes chromophores as photosensitizers to inactivate protein by generation of reactive oxygen species (ROS). However, outcomes of CALI highly rely on ROS generation efficiency, which is dependent on both chromophore selection and cell microenvironment. Photoswitch uses molecules (*i.e.* azobenzene) that switch their conformation during light exposure. However, the working wavelength for photoswitch is narrow in ultraviolet and visible range which limits its further applications *in vivo*. Therefore, it remains challenging to optically control protein activity in live cells without genetic modification and independent of the cellular microenvironment (*i.e.* ROS).

Nanoparticles provide an interface to manipulate protein and cellular activity with high spatial and temporal precision. Physically, it is possible to apply short laser pulses to excite plasmonic nanoparticles and create a nanoscale hotspot, or “thermal confinement” when the pulse duration is less than the heat diffusion^[4]. We have recently introduced the possibility of “molecular hyperthermia” (MH), defined as using ultrashort nanosecond laser pulses to excite plasmonic gold nanoparticle (AuNP) to unfold and inactivate targeted proteins with a very well-defined impact zone (in nm size) (Fig. 1). In this report, we demonstrate for the first time that MH can photo-inactivate protease activated receptor 2 (PAR2) in live cells without compromising cell viability. Since MH thermally inactivates protein of interest, it doesn't

depend on cellular microenvironment and doesn't require genetic modification. Our results indicate that MH is a promising new approach to manipulate protein activity in live cells.

Figure 1. Schematic to illustrate the time and length scales of molecular hyperthermia (MH) compared with hyperthermia.

METHODS

We firstly synthesized AuNP (45 nm) following modified Frens' method^[5]. To functionalize AuNPs, we conjugated antibodies (anti-PAR2 antibody MAB3949) onto AuNP by heterobifunctional polyethylene glycol (OPSS-PEG-SVA, 3.4 kDa). Then polyethylene glycol 2-mercaptoethyl ether acetic acid (Thiol-PEG-Carboxyl, 600 Da) was used to backfill and stabilize AuNP. AuNP-PEG was synthesized by stabilizing bare AuNP with Thiol-PEG-Carboxyl and used as the negative control.

Secondly, to monitor PAR2 activity, we cultured HEK293 cells with fluorescence resonance energy transfer (FRET) calcium (Ca²⁺)

indicator TN-XXL transferred^[6] in 96 well plate. PAR2 activation was triggered by a PAR2 agonist (2-aminothiazol-4-yl-LIGRL-NH₂, 2AT) that leads to Ca²⁺ release and was monitored by plate reader. 2-photon microscope was used to monitor the spatial resolution of PAR2 photo-inactivation by MH. We set excitation wavelength at 436 nm (810 for 2-photon microscope) and collected emission at 485 nm and 527 nm. The FRET ratio ($\Delta R/R$) was calculated with following equation:

$$\frac{\Delta R}{R} = \frac{\text{Fluorescence 527}}{\text{Baseline 527}} / \frac{\text{Fluorescence 485}}{\text{Baseline 485}} - 1 \quad (1)$$

Thirdly, a pulsed nanosecond laser (532 nm, Full width half maximum = 6 ns) was used to create MH *in situ*. Cells were incubated with functionalized AuNP solution to target PAR2. The extra particles were washed away and cells were irradiated with nanosecond laser pulses. PAR2 activity was checked after MH experiments. To investigate the spatial resolution of MH, a multichannel perfusion system was used to load artificial cerebrospinal fluid (ACSF) and 2AT. The 2-photon imaging system was used to monitor the PAR2 inactivation *in situ*. ACSF was perfused to cells for the first 52 seconds to obtain the base line followed by perfusing 2AT for 16 seconds. ImageJ was used to analyze images.

Lastly, WST-1 assay was used to investigate cell proliferation after MH. WST-1 stock solution was diluted 10 times with cell medium. After MH, the medium was replaced with 100 μ L WST-1 working solution for each well. Cells were then incubated at 37 °C and 5% CO₂ for 3.5 hours and absorbance was read by plate reader at 450 nm.

RESULTS

Firstly, we tested and confirmed that the engineered HEK293 cells with Ca²⁺ indicator is a robust model to study PAR2 activity. PAR2 is a G-protein coupled receptor (GPCR) that leads to Ca²⁺ signaling upon activation. Incubation of HEK293 cells with 2AT leads to a robust response of $\Delta R/R$ increase due to Ca²⁺ release (Fig. 2A). To target PAR2 receptor, antibody modified AuNP was used (AuNP-MAB3949), and AuNP conjugated with polyethylene glycol (AuNP-PEG) was used as the negative control (Fig. 2B).

Next, we tested the effect of MH on PAR2 activity. Comparing PAR2 activity treated by AuNP-MAB3949 and AuNP-PEG under the same laser exposure (532 nm, 100 mJ/cm², 10 pulses), significant drop (>80 %) in PAR2 activity was observed for AuNP-MAB3949 group at concentrations above 0.32 nM (Fig. 2C), while only 20% for AuNP-PEG group. At the same conditions, there is no significant difference in the cell proliferation between groups using AuNP-PEG and AuNP-MAB3949, suggesting a specific molecular level photo-inactivation by MH (Fig. 2D).

Finally, to demonstrate the precise spatial control of PAR2 by MH, we compared the cellular PAR2 response with and without laser irradiation in the same petri-dish by partially blocking the laser (Fig. 2E). The results suggest that the region without laser irradiation had an obvious Ca²⁺ release after 2AT loading while the region with laser irradiation has a much attenuated Ca²⁺ release (Fig. 2F). This suggests a high spatial control of PAR2 activity with optical manipulation using MH.

DISCUSSION

In this study, we demonstrate a novel method molecular hyperthermia (MH) to optically control protein activity in live cells by showing a GPCR (PAR2) can be photo-inactivated by MH without compromising cell proliferation. PAR2 is implicated in disease

conditions including allergic asthma, cancer, arthritis, and chronic pain. Photo-inactivation of PAR2 will help us understand and treat diseases such as chronic pain. Furthermore, to apply MH *in vivo*, gold nanorod could be used with near-infrared laser to manipulate proteins of interest. This promising method overcomes the drawback of current approaches to manipulate protein activity and brings new promises for precise therapeutics of diseases.

In conclusion, we have demonstrated the ability of a newly developed MH technique to manipulate protein activity in live cells. Future works to further understand the underlying mechanism and *in vivo* testing are planned.

INTRODUCTION

Recently, we showed that radiofrequency heating of metal forms (i.e. aluminum foil) can improve the warming rate of cryopreserved carotid artery (1 mm thick) tissue systems at rates ≥ 1000 °C/min thereby outrunning damaging ice crystals during warming. This is a significant (i.e. order of magnitude) improvement over rates available from conventional convective approaches. This increased warming rate can in turn be used to either reduce the need for CPA thereby reducing toxicity[1], or increase the thickness of the tissue that can be rewarmed from the cryopreserved state. However, as the thickness of the tissue increases, there will be a diffusive limit for boundary loading where the cryoprotectant (CPA) concentration in the center is insufficient to protect from ice formation even during warming with metal forms. This CPA concentration in the center sets the minimum threshold on the warming rate, which is called critical warming rate (CWR). This work probes that diffusive limit.

METHODS

In this study, we present both modeling and experimental data in arterial tissue (porcine carotid – 1mm to aorta – 2 mm) loaded with a variety of available CPAs (i.e. DP6 - 6M, VS55 - 8.4M, and M22 - 9.3M) and rewarmed with metal forms. In general, using high concentration M22 increases the chance of success and the least concentrated DP6 will be the least promising in terms of viability under the same loading conditions. We use

a combination of diffusive CPA loading and estimation of critical cooling and warming rates needed within the tissue to avoid ice crystallization (i.e. failure). We compare these critical warming rates estimated by modelling with rates measured by thermometry, during metal forms rewarming. In general, the CWR to avoid ice crystallization increase dramatically as the CPA concentration is reduced within the tissue. In short, we predicted the CWR needed in the center of the tissue compared to those available from metal forms.

Fig. 1. Theoretical warming rate required at the center of tissue loaded by DP6, VS55 or M22, and the warming rate that can be achieved at the center region if nanowarming (300 °C/min) or Al foil warming (1300 °C/min) technique is applied

RESULTS and DISCUSSION

As we have published [1], the metal forms (i.e. aluminum foils) are placed next to the tissue under an alternating magnetic field (20 kA/m, 360 kHz) to obtain warming rates in excess of 1300 °C/min. Using previously published CPA diffusivity, loading steps and times without toxicity at low temperature [2] we estimate CPA concentrations within the tissue slices and predict CWRs required to successfully rewarm 1.3 mm thick tissue. For instance, DP6 should be successful with 1.3 mm, but fail at 1.5 mm while M22 should be successful at 1.5 mm, but fail at 2 mm as shown in **Error! Reference source not found.**. In short, 1.5 mm-thick iliac arteries are predicted to be the thickest tissues that can be cryopreserved and rewarmed with this approach.

Experiments were then carried out under the same CPA loading conditions as modelled ($n \geq 6$ for each CPA and artery case) to verify the viability predictions. The experimental results in Fig.2 show nearly 100% viability for both the thin carotid arteries (~1 mm) and thick carotid arteries (~1.3 mm) diffused by DP6, over 90% for 1.5 mm-thick iliac diffused by M22, and less than 40% for 2 mm-thick aorta with M22. These experiments are in agreement with the model predictions in Fig. 1, showing 1.5 mm thick tissues as a maximum with this approach.

In general, diffusion of heat (i.e. higher warming rates) and mass of CPA (i.e. higher CPA concentrations in deep tissue without toxicity) are the two keys to successful rewarming cryopreserved tissues at rates above CWR, therefore, avoiding damaging ice. However, this needs to be balanced with the toxicity due to exposure to CPAs. A solution to rewarming thicker arteries (i.e. 2 mm-thick aorta) or organ slices in the future is increased CPA-loading and/or increasing the warming rates. For

Fig. 3. Experimental results of metal forms heated arterial tissues from 0.8 to 2 mm thickness

Fig. 2. CPA distribution for different thickness tissues after 6 steps of 15 min step-loading

instance, we can increase the exposure times of tissues to CPA as shown in Fig.3. However, increased exposure times often result in higher toxicity. On the other hand, the predicted warming rate needed at the center of a 2 mm tissue loaded with M22 is approximately 5000°C/min. Perhaps, these rates and even higher can be achieved through optimal design and material composition of metal forms in the future.

In summary, diffusive modeling of CPA delivery and heating provided a relatively accurate prediction of the success of metal forms cryopreservation as a function of tissue thickness and CPA type. A key to increasing the thickness of the tissue was either increased CPA loading or increased heating rates from metal forms.

COUNTERINTUITIVE SCALING EFFECTS IN THE DEVELOPING THERMOMECHANICAL STRESS DURING CRYOGENIC COOLING OF THE KIDNEY WITH IMPLICATIONS TO ELECTROMAGNETIC REWARMING FOR ORGAN RECOVERY

Prem K. Solanki and Yoed Rabin

INTRODUCTION

The need for long-term preservation of organs and large-size tissue specimens is unquestionable, with vitrification (*vitreous* means *glassy* in Latin) as the most promising method for suspending the biological clock while preserving cell viability and tissue functionality. Vitrification necessitates rapid cooling of the specimen, which is permeated with cryoprotective agents (CPAs), down to the glass transition temperature (T_g) in order to trap it in an amorphous, solid-like state. Unfortunately, the rapid cooling and rewarming rates required for vitrification, coupled with the low thermal diffusivity of the biological material, may yield hazardous effects of thermomechanical stress. Thermomechanical stress might be one of the primary causes of cryopreservation failure, driven by differential thermal expansion (or contraction) and resulting in structural damage, such as plastic deformations and fractures.

The current study investigates thermomechanical effects in rabbit and human kidney models, contained in cylindrical containers and exposed to realistic cryopreservation protocols. The thermomechanical stress is simulated using previously established numerical framework [1], based on finite elements analysis (FEA). Analytical results of simplified cases are also presented to explain counterintuitive observations during stress development.

The onset of rewarming from cryogenic storage has been identified to be the most dangerous to structural failure [2]. Volumetric heating techniques, such as electromagnetic heating in the radiofrequency (RF) range, have been proposed previously to alleviate structural damage during the rewarming phase of the cryogenic protocol. The current study presents a computational framework to simulate the corresponding thermomechanical effects. Furthermore, the computational framework presented in this study can serve as the foundation for optimization of RF heating parameters, including the design of the cooling chamber, the

container, and the cryoprotocol.

METHODS

Commercial FEA software packages are employed to solve the coupled electromagnetic, thermal, and solid mechanics fields. The proposed framework starts with a bidirectional-coupled problem of the electromagnetic and thermal fields, to solve for the transient temperature distribution within the specimen. This bidirectional coupling enables the incorporation of temperature-dependent material properties in the electromagnetic model and a heat-generation term dependent on the spatial electric field in the heat transfer model. Next, a unidirectional-coupled problem of the thermal field and mechanical stress distribution is solved, where the specimen is modelled as a Maxwell fluid with temperature-dependent viscosity.

Figure 1: Schematic illustration of the problem geometry (not drawn to scale), where the size of the resonance chamber depends on the specimen and electromagnetic frequency.

The geometric model consists of a cylindrical resonance chamber with a coaxial antenna as the power source (Fig. 1). The kidney models are imported from a previous study [3], where the human kidney model is 21-fold larger than the rabbit kidney. Appropriate curvature is added to the edges of the cylindrical CPA container to avoid thermal runaway.

The dimensions of cylindrical resonance chamber are different for the rabbit kidney and human kidney models, yielding resonance frequencies of 434 MHz and 108 MHz in the TE₁₁₁ resonance mode, respectively. The TE₁₁₁ resonance mode is selected to achieve high heating power at the center of the resonance chamber [4].

Electromagnetic model: The spatial distribution of the electric field for a nonmagnetic dielectric material in a resonance chamber is determined by the Maxwell equations in the frequency domain:

$$\nabla \times (\nabla \times \mathbf{E}) - \omega^2 \mu_0 \epsilon_0 \epsilon_{rc} \mathbf{E} = 0 \quad (1)$$

where \mathbf{E} is the electric field, f is the frequency, $\omega = 2\pi f$ is the angular frequency of the electromagnetic field, ϵ_0 and μ_0 are the electric and magnetic permeability of free space, respectively, and ϵ_{rc} is a complex relative permittivity given by $\epsilon_{rc} = \epsilon' - j\epsilon''$, where ϵ' is the dielectric constant and ϵ'' is the dielectric loss factor.

The walls of the resonance chamber are assumed to be perfect electric conductors:

$$\hat{n} \times \mathbf{E} = 0 \quad (2)$$

where \hat{n} is a unit vector perpendicular to the resonance chamber wall.

Heat Transfer model: Heat transfer within the CPA domain is assumed solely by conduction:

$$\rho C_p \dot{T} = \nabla \cdot (k \nabla T) + \pi f \epsilon'' |\mathbf{E}_{RMS}|^2 \quad (3)$$

where ρ is the density, C_p is the specific heat, T is the temperature, k is the thermal conductivity, and E_{RMS} is the root-mean-square value of the electric field.

A thermal protocol for specimen vitrification consisting of four phases is considered here: convective cooling, storage, RF rewarming, and convective rewarming, Fig. 2.

Solid Mechanics model: The total strain rate in the Maxwell fluid model is calculated as [2]:

$$\dot{\epsilon}_{total} = \dot{\epsilon}_{creep} + \dot{\epsilon}_{elastic} + \dot{\epsilon}_{thermal} \quad (4)$$

$$\dot{\epsilon}_{creep} = \frac{\mathbf{S}}{2\eta} \quad (5)$$

$$\dot{\epsilon}_{elastic} = \frac{1}{E_e} [(1 + \nu)\dot{\sigma} - \nu \mathbf{I} \cdot \text{tr}(\dot{\sigma})] \quad (6)$$

$$\dot{\epsilon}_{thermal} = \beta \dot{T} \mathbf{I} \quad (7)$$

where \mathbf{S} is the deviatoric stress tensor, η is the viscosity, E_e is the elastic modulus, ν is the Poisson ratio, \mathbf{I} is the identity matrix, tr is the trace matrix, and β is the linear thermal expansion coefficient.

Note that although developed by the same famous physicist and mathematician, the Maxwell electromagnetic model and the Maxwell fluid model are completely unrelated.

RESULTS AND DISCUSSION

Figure 2 displays the temperature and stress histories at the center and edge of the specimen, at the locations displayed in Fig. 1. The cooling phase of the protocol for rabbit and human kidney models is consistent with [3]. As the specimen begins to cool below room temperature, the CPA becomes increasingly viscous, and thermomechanical stress development follows. The stress in the specimen reaches a local maximum value as the temperature approaches storage temperature, followed by stress relaxation to insignificantly low level. This is due to the selected storage temperature, which is very close to T_g in order to facilitate stress relaxation [5].

Figure 2: Maximum principal stress and temperature history at points displayed in Fig. 1 for (A) Rabbit kidney and (B) Human kidney. The microwave rewarming section of the thermal protocol is highlighted in red.

The maximum stress at the center of a specimen has been shown directly proportional to the cooling rate at the geometric center of the specimen and to the characteristic dimension of the specimen to second power in simplified cases [5]. In the current study however, the peak stress developed in the rabbit kidney model is found higher than the peak stress developed in the human kidney model despite the former being smaller in dimension.

The above counterintuitive observation is associated with the time variation of the temperature distribution across the specimen while it gains solid-like properties during cooling. It is associated with a 12 orders of magnitude exponential increase in viscosity with the decreasing temperature during vitrification. Due to the underlying principles of heat transfer, the outer region of the larger specimen gains solid-like properties much earlier than the inner region. In general, the corresponding thermal history results in compressive circumferential stress on the outer surface and tensile stress at the center, where tensile stress is the primary cause of fractures in brittle materials. The smaller specimen however becomes a solid-like material subject to a much more uniform temperature, which give rise to a lower compressive stress at the outer surface but to a higher tensile stress at the center. Note that the radial decay in tensile stress and buildup of compressive stress is nonlinear, while other specimen sizes and cryoprotocols may result in different stress distributions. As a result of the parameters tested in this study, the smaller specimen experiences an overall higher tensile stress, which makes it more prone to structural damage.

PATIENT-SPECIFIC ESTIMATION OF ASCENDING THORACIC AORTIC ANEURYSM GROWTH AND REMODELING: FEM BASED CONSTRAINED MIXTURE MODEL

S. Jamaledin Mousavi, Stéphane Avril

Mines Saint-Etienne, Univ Lyon, Univ Jean Monnet, INSERM, U 1059
Sainbiose, Centre CIS, F - 42023 Saint-Etienne France

INTRODUCTION

Growth and remodeling (G&R) are fundamental mechanobiological processes in normal tissue development and in various pathological conditions. It is suggested that G&R in tissues may be mediated by mechanical stresses. For example, cardiac hypertrophy and normal cardiac growth develop in response to increased hemodynamic loading and altered systolic and diastolic wall stresses [1]. Sustained hypertension is also associated with changes such as increased wall thickness in large arteries [2]. This adaptation ability of soft tissues is related to the existence of a mechanical homeostasis across multiple length and time scales in the vasculature. At the tissue scale, this manifests through continuous mass changes of the components of the extracellular matrix (ECM) such as collagen, elastin and proteoglycans [3].

In the current paper, we are interested in continuum finite-element formulations to simulate G&R in arteries. The first model of mechano-regulated soft tissue growth was presented by Rodriguez et al in the mid-1990s, incorporating the associated growth by multiplicative decomposition of the total deformation gradient into an elastic and inelastic part. Thereafter, this conceptual simplicity has been widely used by others [4]. Although many theories of G&R have modelled the tissue as a homogenized (single-constituent) solid continuum, the constrained mixture model (CMM) has been increasingly employed by a number of authors [3-5], to simulate G&R in arteries, including non-homogenized [3] and homogenized [5] approaches.

Although computational modeling of vasculature G&R has significantly improved our insights of the G&R processes, developing patient-specific models are still a challenging problem (layer specificity, irregular boundary conditions and complex deformations) and an open question. These problems can become extremely challenging in the case of ascending thoracic aortic aneurysms

(ATAA) evolution due to the simultaneous and region specific evolution of geometry, material properties, and hemodynamic loads. Therefore, it is interesting to develop a continuum finite-element model (FEM) to simulate G&R of ATAA evolution.

METHODS

According to the CMT, we assume that all constituents (elastin, e, collagen fiber families, c_j , and SMCs, m) in the mixture deform together under the total deformation gradient \mathbf{F} in the stressed field while each constituent has a different “total” deformation gradient resulting from its own deposition stretch of \mathbf{G}_h^i with $\{i \in \{e, c_j, m\}\}$ respect to the reference homeostatic configuration. Thus, for each differential mass increment of the i th constituent deposited at time, the total deformation gradient of each constituent ($\mathbf{F}_{\text{tot}}^i = \mathbf{F} \mathbf{G}_h^i$) may be rewritten by a multiplicative decomposition into an elastic, \mathbf{F}_{el}^i , and inelastic (named G&R) parts, \mathbf{F}_{gr}^i , as $\mathbf{F}_{\text{tot}}^i = \mathbf{F}_{\text{el}}^i \mathbf{F}_{\text{gr}}^i$ [5].

A strain energy density function is defined for the different components of the arterial wall based on the CMT. The intima layer is disregarded here as it is very thin. Based on the mass fractions of each individual component, ρ_t^i , in media and adventitia, the specific strain energy density function may be written as [6]:

$$W = \rho_t^e \left[\frac{\mu_e}{2} (\bar{I}_1^e - 1) + \kappa (J_{\text{el}}^e - 1) \right] + \rho_t^{c_j} \frac{k_1^{c_j}}{k_2^{c_j}} (e^{k_2^{c_j} (I_4^{c_j} - 1)^2} - 1) + \rho_t^m \frac{k_1^m}{k_2^m} (e^{k_2^m (I_4^m - 1)^2} - 1) \quad (1)$$

with $\bar{I}_1^i = \text{tr}(\bar{\mathbf{F}}_{\text{el}}^{(T)} \bar{\mathbf{F}}_{\text{el}}^i)$, $\bar{I}_4^i = \mathbf{F}_{\text{el}}^{(T)} \mathbf{F}_{\text{el}}^i : \mathbf{a}_0^i \otimes \mathbf{a}_0^i$, $\bar{\mathbf{F}}_{\text{el}}^i = J_{\text{el}}^{i-1/3} \mathbf{F}_{\text{el}}^i$ and $J_{\text{el}}^i = \det(\mathbf{F}_{\text{el}}^i)$, where μ_e , $k_1^{c_j}$ and k_1^m are stress-like material parameters, κ is bulk modulus, $k_2^{c_j}$ and k_2^m are dimensionless material parameters and \mathbf{a}_0^i denotes the corresponding fiber direction in

reference configuration. In the Eq. 1 the two first terms correspond to the behavior of elastin enforcing incompressibility while third and fourth terms model the behavior of the collagen fiber families and SMCs, respectively.

In CMT-based models, G&R is a conceptual phenomenon during which simultaneous degradation and deposition of different constituents continuously occur. This mass turnover is a stress mediated process during which extant mass is continuously degraded and new mass is deposited into the extant matrix by a stress mediated rate [5, 8, 14]. In this work, in two-layer arterial models, mass turnover of collagen families is mediated by SMC stresses in the media and by collagen stresses in the adventitia (for the latter, it is assumed that fibroblasts of the adventitia would be sensitive to the stresses of collagen, both in intensity and directionality).

The multiplicative decomposition of the inelastic G&R deformation gradient of the i th constituent deposited at different times can be written as $\mathbf{F}_{gr}^i = \mathbf{F}_g^i \mathbf{F}_r^i$, where \mathbf{F}_g^i and \mathbf{F}_r^i are inelastic deformation gradients due to growth and remodeling, respectively. The former is related to any change in the mass per unit reference volume and the latter captures changes in the microstructure due to mass turnover. Therefore, having the net mass production rate, the evolution of the inelastic G&R deformation gradient of the i th constituent at time t can be calculated by solving a system of non-linear equations [5]. The proposed model was implemented within the commercial FE software Abaqus through a coupled user material subroutine (UMAT). It is assumed that each element is a mixture of elastin, collagen and SMCs with mass density varying regionally. The deformation of the artery is computed for every time step corresponding to one month of real time.

To demonstrate the applicability of the model to predict patient-specific wall G&R, the model was employed onto the geometry of a real human ATAA. An ATAA specimen and the preoperative CT scan of the patient were obtained after informed consent from a donor undergoing elective surgery for ATAA repair at CHU-SE (Saint-Etienne, France). A 3D structural mesh (the edge of each element was locally aligned with the material directions of the artery) made of hexahedral elements was reconstructed across ATA. 97% of total elastin, 100% of total SMC, and 15% of total axial and diagonal collagen fibers were assigned to the media. Conversely, the rest for each constituent were assigned to the adventitia. Both ends of the ATAA model were fixed in axial and circumferential directions, allowing only radial displacements. For the same patient, 4D flow MRI datasets were also acquired, revealing a jet flow impingement against the aortic wall around the bulge region (downstream the area of maximum dilatation). Guzzardi et al. [7] found that regions with largest WSS underwent greater elastin degradation associated with vessel wall remodeling. Consequently, based on these findings we considered a localized elastin degradation with an exponential on the ATAA G&R.

RESULTS

The G&R response of a patient-specific ATAA to localized elastin degradation is shown in Fig. 1-a, c and e. Due to change of shape, the stress distribution is in continuous adaptation. For all cases, elastin loss induces a transfer of stress to the adventitia in the damaged region. Moreover, an increase of t_{dam} results in an increase of maximum principal stresses in the arterial wall. It is induced by the related increase of elastin degradation rate. In Fig. 1-b, d and f, the distribution of collagen mass density for different t_{dam} shows that most of the collagen is deposited in the media where elastin has been lost (recall that $\sim 97\%$ of the elastin is in media), causing finally a

thickening of the arterial wall. It is noteworthy that increase of t_{dam} accelerates collagen deposition and consequently wall thickening.

Figure 1: Distribution of the maximum principal stress (first column) and normalized collagen mass density (second column) in a two-layer patient-specific human ATAA responding to localized elastin loss, $t_{dam} = 20$ (a and b), $t_{dam} = 40$ (c and d) and $t_{dam} = 80$ (e and f) days. In all cases it is assumed that $k_{\sigma}^c = \frac{0.05}{t^c}$

DISCUSSION

We considered multiple elastin degradation rate leading to different aneurysm growth rate. Although the global shape of the aneurysm remains similar, the thickening and collagen production rates are different for different cases. Different temporal damage constants showed significant effects on the expansion rate where the higher damage rate delivers the higher G&R rate. In the patient-specific study it also appears that collagen deposition tends to compensate the elastin loss. It is worth noting that as aneurysm grows, principal stress may not necessarily increase in the damaged location. This is observed in AAA growth as well. Moreover, although elastin was degraded locally, dilatation of the ATAA was spread across a larger area due to stress redistribution.

This altogether indicates that the present model has the potential for clinical applications to predict G&R of patient-specific geometries if a realistic rate of elastin loss and collagen growth parameter are available.

INTRODUCTION

Ascending thoracic aortic aneurysm (ATAA), a local dilatation in the aorta, tends to expand gradually and sometimes result in a sudden rupture. When an aortic aneurysm ruptures, the mortality rate is very high [1,2]. From a biomechanical viewpoint, aneurysms rupture when the stress in the wall exceeds its strength. Nowadays finite element method can be used to predict the wall stress on a patient-specific basis, but there is no practical way to obtain the tissue's strength noninvasively. Early studies have shown that there exist relationships between aneurysms strength and prerule response features. Sugita et al. found that the ATAA strength correlates significantly with a particular stress at a "yield point" before rupture [3]. A recent study found that the ATAA strength has correlation with the tension at the point where the curvature of the total tension strain curve attains maximum [4]. Besides, it was also found that some clinical factors could significantly affect the mechanical properties of the ATAA tissue [5]. Motivated by these findings, a statistical model which could relate ATAA strength to these features is expected to be developed and thus predict the rupture strength. Nowadays, machine learning regression algorithms have earned much importance for the prediction in aneurysm biomechanics [6]. In our work, machine learning regression models are tested to evaluate the feasibility of predicting ATAA strength. The input to the machine learning is certain prerule response features derived from stress strain curves and some clinical parameters.

METHODS

Dataset used in this study is obtained from Prof. Auricchio's lab as described in [5]. Briefly, 187 specimens of ATAA were excised from 68 patients who underwent elective surgical repair. Stress-strain curves were obtained from uniaxial tensile tests. Through pre-screening of ATAA ruptures, 30 curves with too much noise are excluded. Principal

component analysis (PCA) is applied to the remaining curves to reduce data noise.

Two groups of features are used as the basis for regression. The first is the global parameters (GP) comprised of continuous and categorical clinical parameters. Continuous parameters include age, body mass index (BMI), maximum ATAA diameter (Dmax) and aortic size index (ASI). Values of categorical parameters are obtained through one-hot encoding method: HP: hypertension (1 = hypertensive subject; 0 = no-hypertensive subject), Gender (1=Female; 0=Male), BAV: bicuspid aortic valve (1 = presence of BAV; 0 = no presence of BAV) Zone: (1= Anterior, 0 =Posterior) and Direction (1 = Circumferential, 0 = Longitudinal). The second set of features consists of 8 curve geometric parameters (CG): the curvature, the stress, the strain and the slope of both maximum curvature point and transition point, which are two particular points of stress-stretch curves as shown in figure 1.

Figure 1: Representative ATAA stress-stretch curve

A typical ATAA stress-stretch curve as shown in figure 1 has a J-shape with a compliant elastin-dominated region at the low stress range turning into a transition phase in the middle and a stiff collagen-dominated region at the high stress range. The maximum curvature of the curve (MC) may reflect how fast the collagen recruitment is, and the stress and strain at this point (MC_stra, MC_stre) may suggest how early the transition occurs and the slope (MC_slope) could be a measurement of the early stiffness. In our work, a transition point is identified based on slope change of the curves. As shown in Figure 1, the slope of a typical stress-strain curve changes significantly in the transition period while becoming stable when it comes to exponential phase. We define the transition point as the point where the rate of change of the curve slope begins to decrease, i.e., the onset of the decreasing of second derivative. The stress and strain (TP_stra and TP_stre) may reflect the end of the transitional phase. The slope (TP_slope) may represent the stiffness of the specimen when collagen fibers fully come into load bearing. The curvature at the transition point (TP_curv) may indicate the change of collagen stiffness when it comes to exponential range.

To facilitate the computation of derivatives, we fit the stress and strain curves to a third-order NURBS function with 3 knot intervals. At the same time, knot positions for each curve are optimized to maintain a smooth change of slope.

Regressions are performed separately over 2 groups of features using a 10-fold cross-validation. A machine learning library, Scikit-learn, is used in the study [7]. The first group is the curve geometric parameters (CG). The second group is the union of curve features (CG) and global features (GP). Ensemble techniques, including ensemble.randomforest regressor (ERF) and ensemble.gradientboosting regressor (EGB) are selected because they can handle mixed input data (continuous data and categorical data). Average mean-square error (AMSE) and average cross-validation score (ACVS) are used to measure the performance.

RESULTS

Table 1 illustrates the regression results on the two groups of features, CG and GP&CG. Note that EGB model shows better performance than ERF model. It can be also seen that global features slightly help to improve the prediction score and reduce AMSE. A good performance of training dataset is observed, as shown the Figure 2.

EGB	0.0529	0.840	0.0444	0.858

Figure 2: Performance of training dataset

DISCUSSION

In this study, we use machine learning to predict the rupture stress of ATAA. We obtain 0.044 average mean-square error using the union of prerupture geometric features and clinical parameters as input. In

overall, the regression results are decent. Figure 3 shows the relative feature importance of each individual feature in the regression model. Note that the stress at the transition point is the most important factor among the curve geometric parameters and age is the most important parameter among clinical parameters. It should be noted that clinical parameters in our work show substantially less contribution when considering two sets of features together.

To evaluate the reliability of the models, we develop a test dataset which consisted of truncated ATAA curves where a tailing segment of arbitrary length is removed. It is worth mentioning that the transition phase of the curves is retained. The truncated curves are subjected to feature harvesting and new curve parameters are generated. We then apply the machine learning models to predict the rupture stress of truncated curves. The R^2 (coefficient of correlation) score and the mean-square error (MSE) are used to evaluate the test dataset performance. Table 2 illustrates the test results, which are very similar to train scores as shown in Table 1. Figure 4 shows the predicted rupture stress vs the rupture stress. The rupture stresses are predicted to within the same level of accuracy as in training. At the same time, we also found that predicted rupture stresses are greater than truncated curve end stress mostly, with only 3 samples slightly lower. This test confirms that the regression result is reasonably trustworthy.

INTRODUCTION

Abdominal aortic aneurysm (AAA) is a vascular disease characterized by the enlargement of the infrarenal aorta by more than 50% and typically a diameter of 5.5 cm is considered aneurysmal. However, smaller AAA are also prone to rupture and severe cases can lead to fatality. Recently, biomechanics-based rupture risk assessment strategies have been postulated as a better measure of the disease severity compared to maximum diameter [1-3]. As computational approaches involve complex finite element models, we aim to utilize geometric predictors of wall stress as part of a rupture risk assessment strategy. In this work, we identify geometric attributes that correlate strongly with wall stress using a cohort of 100 patient-specific AAA models derived from asymptomatic, unruptured, electively repaired AAA.

METHODS

The abdominal computed tomography angiography (CTA) scans of 100 patients who were diagnosed with AAA were obtained from an existing database in the Department of Radiology at Allegheny General Hospital (Pittsburgh, PA). The standard of care images in Digital Imaging and Communications in Medicine (DICOM) format are the input for the in-house segmentation code AAASeg. A point cloud is generated with the three segmented boundaries along with volumetric binary masks representing the three regions of interest in the aneurysm (lumen, wall, and thrombus) [1]. Surface and volumetric meshes were generated from the masks using the in-house meshing code AAAMesh. Two different volume meshes were generated for each AAA; one with a uniform wall thickness of 1.5 mm and the other with a patient-specific wall thickness distribution (measured from the segmented images).

Using the aforementioned volume meshes, finite element analysis (FEA) was performed with ADINA (Adina R&D Inc., Watertown,

MA). A Mooney-Rivlin constitutive model [2] was used to represent the AAA wall material properties while the AAA sac was subject to an intraluminal pressure of 120 mmHg in at least 24 time steps. The results of the simulations were post-processed and visualized using Ansys EnSight (Ansys Inc., Canonsburg, PA) to generate the first principal stress distributions, from which the three biomechanical parameters (peak wall stress: PWS, 99th percentile wall stress: 99thWS, and spatially averaged wall stress: SAWS) were computed.

Using the algorithms described by Shum *et al.*, [3] patient-specific geometric indices were calculated that best assess the shape, size, curvature, and wall thickness of each AAA. Forty-five indices were calculated for the non-uniform wall thickness models and 32 for the uniform wall thickness models. The Biquintic Hermite Finite Element (BQFE) method was employed to compute the curvature based indices, as described in Lee *et al* [4]. Point clouds generated from the segmentation were used to calculate the 1D and 2D indices, while the 3D indices were calculated using the volume and surface meshes.

To identify the geometric indices that most correlate with wall stress, a series of tests of hypothesis was carried out. When the p-value was lower than a chosen level of significance, the corresponding geometric index is said to have substantially high correlation with the biomechanical parameter. To account for multiple testing, the Bonferroni correction [5] was applied and the corrected significant level was established at 0.00111 for the non-uniform wall thickness models and 0.00156 for the uniform wall thickness models.

RESULTS

The first principal stress distributions for three exemplary AAA models with non-uniform wall thickness are shown in Fig. 1. The mean and maximum PWS for the non-uniform wall thickness models were 76.9 ± 27.7 N/cm² and 183.0 N/cm², respectively, while the AAA

models with uniform wall thickness exhibited a mean PWS of 54.5 ± 19.6 N/cm² and a maximum of 143.0 N/cm². The mean and maximum 99thWS for the non-uniform wall thickness AAA were 49.0 ± 16.6 N/cm² and 112.0 N/cm², respectively, while for the uniform wall thickness AAA the mean 99thWS was 39.5 ± 9.7 N/cm² and the maximum 99thWS was 69.4 N/cm². The mean and maximum SAWS were 23.2 ± 8.2 N/cm² and 46.3 N/cm², respectively, for the non-uniform wall thickness AAA, and 23.0 ± 5.8 N/cm² and 46.1 N/cm², respectively, for the uniform wall thickness AAA.

Figure 1: First principal stress map for three exemplary AAA models (non-uniform wall thickness) with (a) small, (b) average, and (c) large maximum diameter. The PWS, 99thWS and SAWS of each model are also indicated.

For all AAA models, the geometric indices significantly correlated with PWS, 99thWS, and SAWS (obtained from the tests of hypothesis) were subject to stepwise regression analysis to identify the most accurate predictors of each of the biomechanical parameters. The outcome of this analysis is shown in Table 1, along with the corresponding regression coefficients and standard errors of the regression residuals. For the non-uniform wall thickness models, minimum wall thickness (TH_{min}), AAA sac volume (V), distal neck diameter ($D_{neck,d}$), and proximal neck diameter ($D_{neck,p}$) were the most significant predictors of PWS. Similarly, TH_{min} , V , and $D_{neck,d}$ were the predictors of 99thWS, while the mean wall thickness at the maximum diameter cross-section (TH_{Dmax}), isoperimetric ratio (IPR), AAA sac length (L), and TH_{min} were the predictors of SAWS. The stepwise regression for SAWS had the highest coefficient of determination (0.67) with a standard deviation of 4.8 N/cm². For the uniform wall thickness models, five indices predicted PWS accurately: average diameter (D_{ave}), L2-norm of the mean curvature (MLN), minimum diameter (D_{min}), area averaged Mean curvature (MAA), and maximum compactness (C_{max}). Three indices were predictors of 99thWS: D_{ave} , MAA, and IPR, while five indices were found to be good predictors of SAWS: D_{ave} , MAA, V , $D_{neck,p}$, and IPR. SAWS also had the highest coefficient of determination (0.94) with a standard deviation of 1.4 N/cm².

DISCUSSION

The variation of PWS amongst the individual AAA (23.1 - 183.0 N/cm² for non-uniform wall thickness and 18.1 - 143.0 N/cm² for uniform wall thickness), was greater than the variation of 99thWS (15.9 - 112.0 N/cm² for non-uniform wall thickness and 16.3 - 69.4 N/cm² for uniform wall thickness) and SAWS' variation (8.1 - 46.3 N/cm² for non-uniform wall thickness and 10.8 - 46.1 N/cm² for uniform wall thickness).

The outcome of the stepwise regression analyses for the non-uniform wall thickness models revealed that TH_{min} was a strong predictor of all three biomechanical parameters. PWS, 99thWS, and SAWS were negatively correlated with TH_{min} , which can be explained by the fact that rupture (likely where the highest wall stress to strength ratio exists) occurs where the wall is thinnest, as Raghavan and co-workers confirmed in an autopsy study [6]. AAA size also plays a role in predicting wall stress; 1D and 3D size indices $D_{neck,p}$, $D_{neck,d}$, and V were positively correlated with PWS and 99thWS. In the present work, the significant predictors of wall stress did not include D_{max} for any of the biomechanical parameters. We infer from this that, after the effect of the geometric indices listed in Table 1 are accounted for, D_{max} appears to have a lesser influence on wall stress for asymptomatic, unruptured AAA compared to symptomatic, ruptured AAA [5].

For the uniform wall thickness models, D_{ave} and MAA were strong predictors of all three biomechanical parameters. PWS, 99thWS, and SAWS were negatively correlated with MAA, which was also the strongest predictor in the regression models. This is evident by the larger regression coefficients obtained for MAA, MLN, IPR, and C_{max} , in contrast to D_{ave} , D_{min} , V , and $D_{neck,p}$. Such finding is in agreement with the observations by Giannoglou *et al.*, [7] who reported on shape and curvature based indices as metrics for rupture risk assessment.

We infer from this study that wall thickness, size and curvature based indices may act as reliable surrogates of wall stress for asymptomatic and unruptured AAA, and can be used as part of an improved rupture risk assessment strategy compared to D_{max} alone.

Table 1: The significantly correlated geometric indices along with the regression coefficients and standard errors of the regression residual with PWS, 99thWS, and SAWS for the non-uniform and uniform wall thickness AAA models.

Biomechanical parameter	Non-uniform wall thickness		Uniform wall thickness	
	Geometric index and regression coefficient	Standard error [N/cm ²]	Geometric index and regression coefficient	Standard error [N/cm ²]
PWS	TH_{min} (-37.23) V (0.0752) $D_{neck,d}$ (0.264) $D_{neck,p}$ (0.46)	17.6	D_{ave} (0.62) MLN (133.94) D_{min} (0.57) MAA (-640.32) C_{max} (29.44)	11.5
99 th WS	TH_{min} (-20.19) V (0.064) $D_{neck,d}$ (0.15)	10.8	D_{ave} (0.62) MAA (-452.30) IPR (2.865)	4.5

A PARTICLE-BASED MODEL REVEALS AN INSIDIOUS FEED-BACK LOOP BETWEEN AORTIC LAMELLAR DISRUPTION AND CELL APOPTOSIS

Hossein Ahmadzadeh (1), Jay D. Humphrey (1)

(1) Department of Biomedical Engineering,
Yale University,

INTRODUCTION

Thoracic aortic aneurysms are often associated with intramural dissection and delamination that start from either an intimal tear or a localized defect within the media. These dissections can propagate and eventually merge with the lumen of the vessel, creating the so-called “false-lumen” which may be filled with blood and develop thrombus over time. Understanding the mechanism by which an aortic dissection grows has remained mostly elusive. Nonetheless, aorta undergoing dissection often exhibit medial degeneration, as characterized by fragmentation of elastic fibers, dysfunction or apoptosis of smooth muscle cells (SMCs), and localized pooling of glycosaminoglycans (GAGs).

To study the biomechanics of aortic dissection, we previously developed a data-driven approach based on a smoothed particle hydrodynamics (SPH) framework (1). Here, we extend our model to include the potential mechanical roles of SMCs dysfunction and apoptosis, degradation of or damage to elastic fibers, and pooling of GAGs on the delamination of the media that may precede dissection. Being a particle-based method, our method allows us to model rupture or and damage to the elastic fibers and to capture the interplay between cellular dysfunction and microstructural defects, as implicated in medial degeneration.

METHODS

We model the aortic wall using our previous formulation for SPH (1). Briefly, we represent the computational domain of the aortic wall with an arrangement of particles that carry information on their surrounding volume and mechanical quantities such as displacement and stress. The domain of the problem is assumed to be a circular cross-section of the descending thoracic aorta of mouse in a passive homeostatic reference configuration with inner and outer radii $R_{in} = 646.8 \mu\text{m}$ and

$R_{out} = 687.0 \mu\text{m}$, for which the luminal pressure is 102 mmHg and the axial stretch is 1.62. The wall is divided into a media that occupies two-thirds and an adventitia that occupies one-third of the wall. The media is further decomposed into repeating layers of elastic fibers (or lamellae) that separate layers of smooth muscle cells (SMCs) and diffuse aggregating GAGs. The adventitia consists primarily of a dense network of fibrillar collagen with some elastin but no SMCs.

Consistently, SPH particles are categorized into three main groups: particles M_{el} (shown red in Fig. 1) primarily model the elastic lamellae of the media, particles M_{int} (blue) represent intra-lamellar SMCs, and fibrillar collagen, and particles A (green) represent the extracellular matrix of the adventitia, which consists primarily of collagen.

Figure 1: Particle arrangement in the SPH model.

The general form of strain energy function at each particle is

$$W(\mathbf{C}_i, \mathbf{M}_i^k) = \phi_r^e \left(\frac{\mu}{2} (I_{ii}^e - 3) - \mu \ln J_i + \frac{\hat{\lambda}}{2} (\ln J_i)^2 \right) + \sum_{k=1}^4 \phi_r^{c_k} \left(\frac{c_1^k}{4c_2^k} \left(\exp \left[c_2^k (I_{ii}^k - 1)^2 \right] - 1 \right) \right), \quad (1)$$

where the first term accounts for the neo-Hookean behavior of elastin dominated regions (with μ and $\hat{\lambda}$ as the Lamé constants) and the second term represents the collective behavior of circumferentially-oriented SMCs and collagen fibers which are divided into four families representing locally oriented fiber bundles, namely axial ($k = 1$), circumferential ($k = 2$), and symmetric diagonal ($k = 3, 4$) families. The active stress generated by SMC contraction is assumed to act primarily in the circumferential direction. Following (2):

$$\sigma_{\theta,i}^{\text{act}} = \phi_{M_{int}}^{c_2} T_{\max} \lambda_{\theta,i} \left[1 - \left(\frac{\lambda_{\max} - \lambda_{\theta,i}}{\lambda_{\max} - \lambda_{\min}} \right)^2 \right]. \quad (2)$$

To model the process of cell apoptosis and replacement with GAGs, a pool of intra-lamellar particles is assumed to undergo the following three steps:

1. *Loss of contractility*: First, the active stress of the designated particles is reduced to zero.
2. *Reduction in stiffness*: Next, the material behavior of the designated medial particles transforms to that of a pure GAG particle (orange in Fig. 1), written as:

$$\sigma_i^{\text{GAG}} = \frac{1}{J_i} \mu^{\text{GAG}} (\mathbf{B}_i - \mathbf{I}), \quad (3)$$

where the shear modulus (μ^{GAG}) is assumed to be considerably smaller than the shear modulus of the original particles.

3. *GAG swelling*: Finally, the hydrostatic pressure generated by swelling of the negatively charged GAGs is added:

$$\sigma_i^{\text{GAG}} = \frac{1}{J_i} \mu^{\text{GAG}} (\mathbf{B}_i - \mathbf{I}) - RT \left(\sqrt{(c^{\text{FC}})^2 + (c^*)^2} - c^* \right) \mathbf{I}, \quad (4)$$

where c^{FC} is the concentration of GAGs (chosen to be $c^* = 200$ mEq/l, equivalent to ~ 155 kPa Gibbs-Donnan swelling pressure).

RESULTS

We first examined the bulk response of the aorta, such as the relation between the intraluminal pressure and outer diameter as well as the mean circumferential stress-stretch behaviors. Such comparisons show that the SPH method captures bulk behaviors well while including separate lamellar units that are ignored in the analytical solution. The results also show that SMC contraction constricts the vessel by $\sim 23\%$ in agreement with experimental findings for the murine descending thoracic aorta (3).

We next examined the effect of cell apoptosis and replacement by GAGs on the distribution of the mechanical stresses in the wall. A pool of intra-lamellar particles experienced the three steps of SMC apoptosis and replacement with GAGs. Of particular interest, the change in circumferential stress in the vicinity of a pool, particularly within the nearest and second nearest lamellar and intra-lamellar regions (shown in Fig. 1) is studied. During the first step, loss of contractility within the pool increased the circumferential stress in the nearby regions (Table 1, step I). As SMCs apoptosed and were replaced by GAGs, the reduced tensile stiffness led to an increased circumferential stress experienced by the particles (Table 1, step II).

	Elastic lamella	Nearest intra-lamellar space	Second elastic lamella
Baseline stress	162 kPa	180 kPa	123 kPa
Step I: Loss of contractility	280 kPa	225 kPa	145 kPa

Step II: Stiffness reduction	282 kPa	228 kPa	148 kPa
Step III: GAG swelling	400 kPa	245 kPa	162 kPa
Step IV: Lamellar disruption	0 kPa	400 kPa	380 kPa

Table 1: Hoop stress concentration near a pool of cells undergoing apoptosis and replacement with GAGs.

Swelling the GAGs within a pool resulted in a much higher circumferential stress on the elastic lamellae surrounding the pool (GAG swelling), but, interestingly, with only a slight effect on stress in the nearest intra-lamellar space, indicating the protective role of elastic lamellae against alterations within their intra-lamellar regions. We then added one additional step (step IV: lamellar disruption) and assumed that the increase in stress in the nearest elastic lamellae causes lamellar rupture. The stress in the disrupted elastic lamellae dropped to zero and the excessive stress transferred to the adjacent intra-lamellar space, substantially increasing circumferential stress in the nearest intra-lamellar region. This result demonstrates how SMC apoptosis and replacement with GAGs in one layer can cause damage in SMCs of the close-by intra-lamellar space through rupture of the shared elastic lamella. Interestingly, following rupture of the elastic lamellae, there was a marked increase in stress in the second nearest elastic lamellae (Table 1, step IV, second elastic lamella), a process that could repeat. This finding suggests that swelling within an intra-lamellar space with subsequent lamellar disruption increases the vulnerability of distant elastic lamellae to rupture and reveals a mechanical mechanism that can explain the transmural propagation of damage. Moreover, this SPH model reveals a two-way feedback loop between cell apoptosis and GAG accumulation with disruption of elastic lamellae. Independent of the triggering event within such a feedback loop, cell apoptosis can induce lamellar disruption, which in return can increase the stress experienced by other SMCs and lead to further cell apoptosis (Fig. 2).

Figure 2: Model predicted two-way feedback loop.

DISCUSSION

In conclusion, our findings reveal key insights into the propagation of damage within the aortic media due to diverse defects, including dysfunction of SMCs and accumulation of GAGs within the intra-lamellar regions and elastic fiber fragmentation across the wall. It appears that there is a strong interplay between cellular dysfunction (cell apoptosis and replacement with GAGs) and microstructural failures (elastic lamellae disruption) that manifests as a feedback loop, thus suggesting that independent of the initiating event, diverse defects can trigger a progressive deterioration of structural integrity (4).

INTRODUCTION

Thoracic aortic aneurysm (TAA) is a chronic vascular disease and the 13th leading cause of death in the US¹. TAA can result from a genetic disorder such as Marfan syndrome (MFS)². Mutations of the FBN-1 gene encoding for fibrillin-1 protein are known to give rise to defective elastic fibers and initiation of MFS³. Fibrillin-1 is the most abundant component making complex extracellular structures called microfibrils, which are important components in forming the scaffold for elastin fibers. However, the complete sequence of cellular events that links weakening of the elastin fibers to dilation and rupture of the vessel wall remains unclear. It is well accepted that aortic dilation occurs due to the compromised structural integrity, which is caused by unbalanced matrix remodeling, eventually altering passive biomechanical properties of the wall and making it more susceptible to rupture⁴. On the other hand, loss of contractility due to apoptosis and phenotypic switching of the contractile smooth muscle cells is thought to alter the active biomechanics of the wall⁵.

Recently, more studies have shown the involvement of SMC progenitor cells in vascular diseases⁶. However, the role of progenitor cells in progression of TAA has not been studied before.

In this work, we studied the cell and extracellular matrix (ECM) alterations as a function of age and related these changes to biomechanical properties of the wall.

METHODS

Animal model: A mouse model of MFS (Fbn1 C1041G/+, Het) was used to study progression of TAA and cellular events over a 3-12 month time course. Wild type (WT) C57Bl/6 mice were used as control groups, with n=5 for each genotype at each time point.

Ultrasound: Vevo 3100 small animal ultrasound was used to image and measure aortic diameters at the proximal and distal ascending aorta and

three main points of the aortic root (aortic annulus, Sinus of Valsalva and sinotubular junction).

Immunohistochemistry (IHC): Sections of proximal ascending aorta were stained for specific markers to localize and quantify cellular alterations in aortic adventitia and media. A complete list of primary antibodies used for IHC, their targets, and the relevant aortic layer is presented in Table 1. All images were then used for quantification of the intended marker normalized to the area of the relevant aortic layer using ImagePro Plus software.

Table 1: List of Primary Antibodies Used for IHC.

Target	Aortic layer	Primary antibody
Smooth Muscle Cells (SMCs)	Media	α -smooth muscle actin (α -SMA) smooth muscle myosin heavy chain (SM-MHC)
SMC Progenitor Cells	Adventitia	stem cell antigen-1 (Sca-1)
Proliferating Cells	Media	phospho-histone H3 (PH3)
Apoptotic Cells	Media	Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL)

Second harmonic generation (SHG): SHG microscopy was used to quantitate aortic medial collagen. Quantification was performed similarly to IHC quantification of medial markers.

Wire myography: Active and passive biomechanical responses of the aortic wall under circumferential uniaxial stretch were studied using a wire myograph. Ascending aorta was divided into two sections, proximal and distal, to acknowledge the potential difference in response due to different embryonic origin of the SMCs in each segment.

RESULTS

Ultrasound Data show that aortic diameter significantly increases with time in Het mice. There is a statistically significant difference between genotypes independent of time.

IHC Images demonstrate that while SM-MHC expression in WT mice remains nearly constant, the expression in Het mice at 3 months is comparable to that of WT mice, but it decreases at 6 months and starts to recover to the WT level by 12 months. Expression of α -SMA in both WT and Het mice was nearly constant throughout the time course. Sca-1 expression is significantly higher in het mice vs. WT. Medial cell density showed the same trends for WT and Het over time, where it was significantly higher at 6 months compared to 3 and 12 months. Proliferation and apoptosis were both negligible for all time points. Quantification data for SM-MHC and Sca-1 is presented in Figure 1.

Figure 1: Quantification of fractional area of (a) media and (b) adventitia showing (a) SM-MHC and (b) Sca-1 positive staining from the IHC images over a time course of 3-12 months.

SHG Images show a time-dependent increase in medial collagen expression in Het mice vs. WT indicating the remodeling of ECM.

Myography Biomechanical data show the maximum active force in Het mice is lower than in WT mice at the same age for both proximal and distal ascending aorta. Slope of the toe region of the stress-strain curve, corresponding to elastic behavior of the artery, decreases with time and in aneurysm. There is a similar trend of biomechanical properties for proximal and distal ascending aorta. Figure 2 shows the stress-strain curves demonstrating biomechanical properties of the ascending aorta.

Figure 2: Stress-Strain curves showing the biomechanical properties of the proximal and distal ascending aorta of WT and Het mice at 6, 9 and 12 months.

DISCUSSION

Our results demonstrate that aortic diameter increases most rapidly after 6 months in Het mice in both proximal and distal ascending aorta. At the same age, Het mice show a minimum in SM-MHC expression, suggesting the loss of contractile SMCs. These findings are consistent with the decrease in active force measurements, corresponding to decreased contractility of the wall. The increased Sca-1 expression in Het mice together with the absence of proliferation and apoptosis suggests a role of migration of differentiated SMC progenitor cells in maintaining the medial cell density. Continuous increase in medial collagen deposition from 6 to 12 months reflects the changes in ECM which lead to stiffer walls. These changes are also demonstrated in passive biomechanical measurements, together with the higher distensibility of the arteries as indicated by decreased slope of the stress-strain curves.

INTRODUCTION

Cerebral aneurysm (CA) rupture can lead to subarachnoid hemorrhage which is associated with high rates of morbidity and mortality (40-65%) [1]. As risks associated with current treatments of CAs are significant, there is a need for improved treatment and risk assessment. Increased understanding of the temporal development of the disease is essential to meet both these needs. It is commonly accepted that mechanical factors such as abnormal hemodynamics can lead to wall degradation that can in turn alter aneurysm morphology altering the biaxial load state [2]. Ideally, these changes in intramural stress would lead to adaptive collagen remodeling to maintain homeostatic stress. Given the range of CA wall pathology, one would expect a range in capacity for effective remodeling [3].

Although collagen fiber remodeling in CAs is a critical factor in progression, it has received little attention [3]. Unfortunately, in vivo imaging of collagen fibers is not possible and hence such studies must necessarily be done in vitro. While CA tissue can be obtained during surgical clipping, these specimens are typically small and only represent one time point.

Animal models for cerebral aneurysms can address some of these challenges. They provide entire aneurysm domes and can be obtained at selected time points during disease progression. In the present study, an elastase induced rabbit model was used to create saccular aneurysms. The clinical relevance, including geometry, hemodynamics and histology wall types has been previously demonstrated [4, 5]. The objective of the present study is to explore the value of rabbit models in studying wall remodeling in saccular aneurysms.

METHODS

Samples: Twenty-two saccular aneurysms were created in rabbit carotid arteries using vessel ligation and elastase incubation [6].

Aneurysm samples along with control vessels were harvested at four time points (2 weeks, 4 weeks, 8 weeks and 12 weeks) after creation.

Solid Mechanics Simulation: Animal specific 3D models were reconstructed for the aneurysm dome from 3DRA images and the equations of equilibrium were approximated using the finite element method via FEBio Software Suite [7].

Uniaxial Testing and MPM: A custom-built mechanical testing system enabled concurrent imaging under MPM and uniaxial testing [8]. Samples were cut into dogbone shape with long axis aligned in the longitudinal direction [9] such that the specimen length 6 mm and the width at the mid-region was 1.2 mm. Specimens were preconditioned to 20% extension with three cycles and tested quasi-statically to failure.

Constitutive Modeling: The strain energy for each wall layer was modeled as the sum of isotropic and anisotropic contributions

$$W = \frac{\alpha_0}{2}(I_1 - 3) + W_{aniso}$$

Fiber orientation in the medial layer was analyzed in MPM stacks using open source software (CT-Fire) [10]. Adventitial contributions to the anisotropic response were assumed to be negligible as the stretch range was below levels needed for fiber recruitment in that layer. The distribution of collagen fibers was modeled as a planar distribution

$$W = \frac{1}{\pi} \int_0^\pi \rho w_f d\theta$$

where w_f is the normalized fiber train energy function

$$w_f = \frac{\alpha_1}{2}(\lambda_f^2 - 1)^2 \cdot H(\lambda_f - 1)$$

λ_f is the fiber stretch which can be obtained from the right Cauchy Green strain tensor for arbitrary fiber direction $\mathbf{m}_0 = \cos\theta\mathbf{e}_1 + \sin\theta\mathbf{e}_2$

$$\lambda_f^2 = \mathbf{C} : \mathbf{m}_0 \otimes \mathbf{m}_0 = \lambda_1^2 \cos^2\theta + \lambda_2^2 \sin^2\theta$$

the Heaviside function H is introduced so fibers do not resist loading in compression and ρ is the probability density function (PDF)

$$\rho = \frac{1}{2I_0(\beta_1)} e^{\beta_1 \cos 2(\theta - \alpha_1)} + \frac{1}{2I_0(\beta_2)} e^{\beta_2 \cos 2(\theta - \alpha_2)}$$

The parameters in the PDF were obtaining as best fits to fiber angle data obtained from MPM images. It then follows that the diagonal components of the Cauchy stress tensor are,

$$\sigma_{11} = \alpha_0 \left(\lambda_1^2 - \frac{1}{\lambda_1^2 \lambda_2^2} \right) + \frac{2}{\pi} \lambda_1^2 \int_0^\pi \rho \frac{\partial w_f}{\partial \lambda_f^2} \cos^2 \theta d\theta$$

$$\sigma_{22} = \alpha_0 \left(\lambda_2^2 - \frac{1}{\lambda_1^2 \lambda_2^2} \right) + \frac{2}{\pi} \lambda_2^2 \int_0^\pi \rho \frac{\partial w_f}{\partial \lambda_f^2} \sin^2 \theta d\theta.$$

For uniaxial testing, $\sigma_{22} = 0$, providing an implicit relation between λ_1 and λ_2 . Stress stretch data was used to obtain the material constants from σ_{11} .

RESULTS

Does the collagen structure remodel in response to altered load? Whereas the wall of the control artery is predominantly loaded in the circumferential direction, after the formation of an aneurysm the longitudinal stress increases to approximately half the circumferential stress, Figure 1. Hence, to recover homeostasis the vessel must remodel.

Figure 1. Increased loading in axial direction after IA formation

In the control artery, the media and adventitia contain the majority of the collagen fibers, Figure 2. Collagen is not recruited under axial load in either layer until relatively high stretch ($\lambda=2$).

Figure 2. Collagen structure of control artery at different stretch levels

Figure 3. Collagen structure of aneurysm at unloaded state

In the remodeled elastase induced aneurysm, an additional layer developed between the media and adventitia that displayed a stronger SHG signal and a multi-directional distribution of fibers. This new layer was found in 3 out of 5 cases at 2-weeks and all other cases at later time points (n=17). Collagen fibers in this layer reoriented when recruited to load bearing, providing a stiffer response at low stretch, Figure 4. By $\lambda=1.4$, all fibers in new layer were aligned in the loading direction.

Figure 4. Collagen fibers in new layer reoriented and were recruited to load bearing even at low axial stretch

Does the rabbit model display heterogeneity in strength? As shown in Figure 5, human aneurysms vary in strength: some are weak and others are more robust [3]. Our data for the elastase induced aneurysms also showed two groups: high strength (blue) and low strength (red), Figure 5 suggesting the rabbit model might be useful for evaluating treatment methods that enhance remodeling.

Figure 5. Failure stress of rabbit vs. human cerebral aneurysms [3]

DISCUSSION

This study demonstrated the rabbit model has the capacity to remodel in response to altered load. A new collagen layer with multi-directional fibers was created between the media and adventitia during remodeling in response to altered mechanical loads. This layer was found as early as 2 weeks. The rabbit model can also capture the heterogeneity in strength found in human aneurysms. Growth and remodeling theories can be used to interpret this data and provide a tool for better understanding aneurysm evolution. Data for mechanical properties and collagen architecture can be used to inform such models. In ongoing work, we considered two time points-initiation at time zero, corresponding to the control artery and 8 weeks after creation, Figure 6. Mechanical, cellular and fiber data are being used to inform these models, Figure 6.

INTRODUCTION

Glioblastoma multiforme (GBM) is the most common primary malignant brain tumor, representing 16% of all brain tumors [1]. The prognosis of GBM patients remains poor (median survival of 15 months), and 70% of patients experience recurrence within one year. The lead source of recurrence is the invasive nature of GBM, for which cell migration plays a decisive role [2].

Chan and Odde [3] proposed the motor-clutch model to describe the dynamics of retrograde flow and adhesion force in an F-actin protrusion of a cell. The model assumes that the pulling of myosin motors generates F-actin flow and stretches the adhesion proteins as clutches, which bind and apply force to deform a compliant substrate. The motor-clutch model successfully explains the substrate stiffness sensitivity of F-actin flow and the traction force exerted by the single F-actin bundle of neuron cells. Bangasser et al. [4] extended this approach to a cell migration simulator (CMS) that links together multiple motor-clutch systems as modules, and simulates cell migration by calculating the force balance among all modules. The CMS successfully predicts the stiffness sensitivity of migration, traction force, and F-actin flow of U251 glioma cells.

One of the major limitations of the CMS is the treatment of substrate stiffness via a spring constant for all modules, which assumes implicitly that the effect of the deformation from other modules is negligible, and the link between the spring constant and the Young's modulus of the substrate is unclear. In this study, an elastic isotropic continuous substrate is used to investigate the effect of interactions between modules, and a distributed loading mechanism of modules on the substrate is proposed to describe the link between the spring constant and the stiffness of the substrate.

Figure 1: Each module (motor-clutch model [3]) of CMS [4] has a circular adhesion with distributed force ($\mathbf{f}_m(\mathbf{r})$) on the continuous substrate.

METHODS

The CMS adopts the direct Gillespie Stochastic Simulation Algorithm by assuming that all chemical events (e.g. clutch bindings) occur as Markov processes, and each time step can be calculated accordingly [4,5]. The substrate spring constant κ_s is required in the force balance calculation, and the substrate displacement for module m , $\mathbf{x}_{s,m}$, is updated by $\mathbf{x}_{s,m} = \mathbf{f}_m / \kappa_s$, where \mathbf{f}_m is the module force.

In order to link the Young's modulus (E_Y) of the substrate to the spring constant κ_s , we assume that each module applies a distributed force ($\mathbf{f}_m(\mathbf{r})$) on the substrate based on the observation of focal adhesions within a finite area [6] (Fig. 1). According to the Boussinesq solution for a tangential point load on an elastic isotropic half-space [7], the displacement field ($\mathbf{u}(\mathbf{x})$) on the surface of the half-space deformed by $\mathbf{f}_m(\mathbf{r})$ distributed over an area A is

$$\mathbf{u}(\mathbf{x}) = \int_A d\mathbf{r} \mathbf{G}(\mathbf{x} - \mathbf{r}) \mathbf{f}_m(\mathbf{r}), \quad (1)$$

where $\mathbf{G}(\mathbf{x} - \mathbf{r})$ is the Green's function for the Boussinesq solution. Assuming that the force, $\mathbf{f}_m(\mathbf{r})$, is linearly decreasing with radial position \mathbf{r} within a circle of radius a , with the total module force F_m , and $\mathbf{f}_m(\mathbf{r})$ can be written by

$$\mathbf{f}_m(\mathbf{r}) = \frac{3}{\pi a^2} \left(1 - \frac{|\mathbf{r}|}{a}\right) F_m. \quad (3)$$

Using Eq. 1-3, the spring constant κ_s can be derived by the total force (F_m) divided by central displacement in the area, and is given by

$$\kappa_{\text{sub}} \sim E_Y \cdot a. \quad (4)$$

Now we consider four models to describe the module adhesion:

- **a1**: $a = 1\mu\text{m}$, and $\kappa_{\text{sub}} = E_Y$, which is equivalent to the original CMS.
- **a1(int)**: $a = 1\mu\text{m}$, with the interactive contribution from other modules by updating the module reference position and substrate position with the correction displacement $\mathbf{u}_{\text{other}}$,
$$\mathbf{u}_{\text{other}} = \sum_m^{\text{other}} \int d\mathbf{x}' \mathbf{G}(\mathbf{x} - \mathbf{x}') \mathbf{f}_m(\mathbf{x}'). \quad (5)$$
- **a0.5**: $a = 0.5\mu\text{m}$, and $\kappa_{\text{sub}} = 0.5E_Y$.
- **a(force)**: The radius is proportional to module force ($|\mathbf{f}_m|$),
$$a = 0.5 + 1.5 \frac{|\mathbf{f}_m| - 50}{150}, 50\text{pN} < |\mathbf{f}_m| < 200\text{pN}. \quad (6)$$

RESULTS

Simulated cells for model a1 (original CMS) have maximum migration with random motility coefficient ($\text{rmc} \sim 5\mu\text{m}^2/\text{min}$), at the optimal stiffness of 1kPa (Fig. 2, a1), which is consistent with Bangasser et al. [4] (the base parameters with low motor and clutch number in [4] are used). When we account for the contribution from other modules (Model a(int)), the rmc magnitude decreases (Fig. 2, a1(int)). With smaller adhesion radius (Model a0.5), the substrate spring constant becomes half of the Young's modulus, $\kappa_{\text{sub}} = 0.5E_Y$, and hence the optimal stiffness shifts to the right ($\sim 10\text{kPa}$) (Fig. 2, a0.5).

When the clutch binding rate, $k_{\text{on}}(1/\text{s})$ increases, the optimal stiffness shifts to softer stiffness for Model a1, and the relation is close to linear in the log-log scale with the slope -2 ($\log(\text{kPa})/\log(1/\text{s})$) (Fig. 3, a1). Model a(int) has similar k_{on} sensitivity of the optimal stiffness (Fig. 3, a1(int)). For the smaller adhesion radius (Model a0.5), the k_{on} sensitivity remains similar, but the optimal stiffness shifts to higher values (Fig. 3, a0.5). With the radius proportional to the module force (Model a(force)), the k_{on} sensitivity slope becomes higher, ~ -3 (Fig. 3, a(force)), showing that the optimal stiffness for migration is more sensitive to the parameter k_{on} than in original CMS.

There are ten major parameters having significant effect on the migration results, including the number (n_c), binding force (F_b), binding rate (k_{on}), unbinding rate (k_{off}), stiffness (κ_c) of clutches, the number (n_m) and pulling force (F_{motor}) of motors, polymerization rate (v_{poly}), birth rate (k_{birth}), and capping rate (k_{cap}) of modules. In a complete parameter analysis, it was shown that there are 4 types of parameter groups, and each group shows specific behavior of CMS. For example, the clutch-binding group (n_c , F_b , k_{on} , k_{off}) has a negative effect on the optimal stiffness of migration and F-actin retrograde flow, and a positive effect on the traction force. The effects of different adhesion models are similar for all four groups, and are more significant in migration, and hence the migration of CMS in k_{on} parameter space is shown in this study.

DISCUSSION

This study has investigated the migration response of CMS with various continuum-substrate adhesion models. Model a1 is the original CMS with the radius of adhesion area, $a = 1\mu\text{m}$, and results in the same value of the spring constant and the Young's modulus of the

substrate, $\kappa_{\text{sub}} = E_Y$. Model a1 shows a similar optimal stiffness of migration as in Bangasser et al. [4], and a shift in optimal stiffness with different values of k_{on} , which has not been reported before.

Model a1(int) considers the displacement by other modules, resulting in reduced migration coefficient. The correction for displacement is usually along the opposite direction of the module polymerization, and hence reduces the polymerization and the migration (polymerization rate has been shown to promote the migration [8]). Model a0.5 shifts the optimal stiffness of migration to higher stiffness, since the spring constant becomes half of the substrate Young's modulus, $\kappa_{\text{sub}} = 0.5E_Y$. Model a(force) increases the k_{on} sensitivity of the optimal stiffness, which may arise from the change of module force with different k_{on} (data not shown).

In summary, different cell adhesion models show different migration patterns of CMS, but the overall trend of optimal stiffness and parameter k_{on} sensitivity remains similar.

Figure 2: The substrate stiffness sensitivity of random motility coefficient (rmc) of 10 simulated cells by CMS with a1, a1(int), a0.5 adhesion model (Methods). All error bars are s.e.m.

Figure 3: The optimal stiffness of cell migration shifts with various clutch binding rate $k_{\text{on}}(1/\text{s})$ for a1, a1(int), a0.5, a(force) adhesion model (Methods) with linear regression fits.

RED BLOOD CELL BIOMECHANICS IN CHRONIC FATIGUE SYNDROME

INTRODUCTION

Chronic Fatigue Syndrome (CFS) is a multi-systemic illness of unknown etiology, affecting millions worldwide [1], with the capacity to persist for several years. It is characterized by persistent or relapsing unexplained fatigue of at least 6 months' duration that is not alleviated by rest. CFS can be debilitating, and its clinical definition includes a broad cluster of symptoms and signs that give it its distinct character, and its diagnosis is based on these characteristic symptom patterns including cognitive impairment, post-exertional malaise, unrefreshing sleep, headache, hypersensitivity to noise, light or certain food items. Although an abnormal profile of circulating proinflammatory cytokines, and the presence of chronic oxidative and nitrosative stresses have been identified and correlated with severity in CFS [2], there are no reliable molecular or cellular biomarkers of the disease.

In the present work, we focus on the pathophysiological changes in red blood cells (RBCs) since CFS is a systemic disease rather than of a particular organ or tissue, and RBCs, comprising ~45% of blood volume, are responsible for microvascular perfusion and tissue oxygenation. RBCs deform and travel through microvessels smaller than their diameter to facilitate the optimal transfer of gases between blood and tissue. The usual shape of a RBC is a biconcave discoid, which is changed to an ellipsoid due to shear flow. This shape gives them a specific surface area-to-volume ratio which facilitates large reversible deformations and elastic transformation [3]. We used a high throughput microfluidic platform to assess the changes in RBC deformability between CFS patients and matching healthy controls. We also performed computational studies to have a better understanding of the cell deformation. In order to explore the mechanisms for observed changes in cell deformability, we explored the membrane fluidity, reactive oxygen species, and surface charge, of RBCs.

METHODS

CFS patients previously diagnosed by physicians using the Canadian Consensus Criteria [4] were selected for the study. Written consent was obtained following Stanford IRB-40146. RBCs were isolated by centrifugation of blood obtained from patients and age-

Figure 1. RBC perfusion through microfluidic platform.

gender matched healthy controls collected in lithium heparin tubes and centrifuged at 250x g for 10 minutes in order to separate blood into the different fractions. All experiments were performed within 3-6 h of blood draw at room temperature.

To assess deformability of the RBCs, we used a high throughput microfluidic device [5]. 10^7 RBCs/ml were delivered through the microfluidic channels using a custom vacuum-based delivery system at a pressure of -2 psi. The flow of RBCs through the smallest of channels, 5 μ m x 5 μ m, was visualized at 40X magnification (Leica) and 4000 fps

using a high speed CMOS camera (Phantom VEO 410L), followed by automated image processing using ImagePRO (Media Cybernetics Inc.). For each experiment, at least two microfluidic devices were used

Figure 2. Membrane fluidity of RBCs.

the cells through these channels.

Plasma membrane fluidity was measured using pyrenedecanoic acid (PDA), according to previously established methodologies [5]. The PDA monomers interact with each other and get converted to excimers. This in turn changes the emission spectrum. A ratio of the excimers to monomers gives an estimate of the membrane fluidity.

Figure 3. ROS measurement.

The reactive oxygen species (ROS) contents were estimated using Di(Acetoxyethyl Ester) (6-Carboxy-2',7'-Dichlorodihydrofluorescein Diacetate) (Thermofisher Scientific). This non-fluorescent molecule is converted to a fluorescent form due to the removal of acetate groups by ROS activity.

Figure 5. Cell Deformation as a function of Ca.

Our computational approach for solving the motion of deformable, suspended bodies in viscous flows is a modified immersed-finite-element method (IFEM) [6]. The problem is broken into two computational domains: The fluid domain which is Eulerian and the series of particles which are Lagrangian. The fluid solver is a massively parallel, finite volume code which is coupled to the Lagrangian meshes of the particles via an immersed boundary force. A series of interpolation and spreading steps are conducted between the mesh via parallelized stencils so that the forces and velocities of the particle can be communicated between the two domains.

Figure 4. Surface charge of RBCs.

For this purpose, about 5 μL of whole blood was diluted in 20 mL of 0.9% wt/vol NaCl and the zeta potential of the RBC's in the resulting suspension was measured using Phase Analysis Light Scattering

per condition, and at least 100 cells were tested per device. Statistical analysis was done using Students' t-test or 2-way ANOVA with Tukey's post hoc test. Since the 5 μm width is smaller than the major diameter of the RBCs, we recorded and analyzed the entry, movement and exit of

species (ROS) contents were estimated using Di(Acetoxyethyl Ester) (6-Carboxy-2',7'-Dichlorodihydrofluorescein Diacetate) (Thermofisher Scientific). This non-fluorescent molecule is converted to a fluorescent form due to the removal of acetate groups by ROS activity.

Our computational approach for solving the motion of deformable, suspended bodies in viscous flows is a modified immersed-finite-element method (IFEM) [6]. The problem is broken into two computational domains: The fluid domain which is Eulerian and the series of particles which are Lagrangian. The fluid solver is a massively parallel, finite volume code which is coupled to the Lagrangian meshes of the particles via an immersed boundary force. A series of interpolation and spreading steps are conducted between the mesh via parallelized stencils so that the forces and velocities of the particle can be communicated between the two domains.

Surface charge was assessed by measuring zeta potential, which is the potential difference between a medium and stationary layer of fluid (interfacial double layer) attached to a particle dispersed in the medium. We tested the zeta potentials of RBC's with the NanoBrook

Omni (Brookhaven Instruments Corporation).

(PALS). The negative charges (mainly sialic acid groups) in the glycocalyx of RBCs and vascular endothelial cells facilitate frictionless blood flow through blood vessels. Loss of charge would correspond to a reduction in zeta potential. In addition to influencing blood flow, charge affects RBC mechanical properties and curvature, and loss of charge would correspond to lower deformability.

RESULTS

RBC deformability. We observed that RBCs from CFS patients had higher entry time, lower average transit velocity and lower elongation index as compared to those from healthy controls (Fig. 1). This collectively implies lower deformability in CFS patients. We also observed significantly different changes in size and fatigue properties of RBCs between healthy controls and CFS patients.

Membrane fluidity. We observed lower membrane fluidity in RBCs from CFS patients as compared to healthy controls (Fig. 2).

Reactive oxygen species (ROS). Higher levels of ROS were detected in RBCs from CFS patients as compared to healthy controls (Fig. 3).

Simulations. We used numerical simulations to determine the quantitative relationship between the cell elasticity, i.e., shear modulus, and the deformation, relaxation, and transient velocity in the microchannels of our microfluidic device. The differences were expressed in terms of the capillary number $Ca = \eta u / \mu_s$, where η is the viscosity of the media, u is the bulk velocity of the fluid inside the channel and μ_s is the shear modulus of the membrane. We use simulation to find the optimal operating conditions for the experiment, such as flow strength and channel dimensions. In addition, a universal curve was constructed based on the simulation results, which relates the deformation to the capillary number. This curve was directly utilized to translate the experimentally measured deformation to the cell elasticity. Fig. 4 shows the different RBC shapes for 2 capillary numbers.

RBC surface charge. We observed a decrease in zeta potential for CFS patients, compared to healthy controls (Fig. 5).

DISCUSSION

Together, the various estimates show that the RBCs in CFS patients are significantly less deformable than those of healthy controls. We speculate that the larger and less deformable RBCs in CFS patients may partly explain the musculoskeletal pain and fatigue in the pathophysiology of CFS due to impaired microvascular perfusion and tissue oxygenation. It has been shown that the quality of life of ME/CFS patients was significantly worse as compared to patients with diseases like sclerosis, cancer (multiple types, such as colon, breast and prostate), type II diabetes, rheumatoid arthritis and chronic renal failure, among others. This work introduces a new paradigm in our understanding of the mechanistic aspects of ME/CFS. It also opens the possibility of a diagnostic platform for ME/CFS using RBC deformability as the biomarker.

INTRODUCTION

High sensitivity of mammalian hearing is achieved by cochlear amplification. The basis of this amplification is the motility of outer hair cells (OHCs) [1]. This motility is possibly based on the voltage-dependent conformational changes of the motor protein prestin densely embedded in the lateral membrane of OHCs [2-6]. However, the membrane structure of prestin has not yet been clarified. In the present study, to analyze the membrane structure of prestin, the genes of prestin equipped with different affinity tags were transfected into Chinese hamster ovary (CHO) cells and the plasma membrane isolated from this cell was investigated by force spectroscopy using an atomic force microscope (AFM).

MATERIALS AND METHODS

The C-terminal part of gerbil prestin cDNA (*gPres*) was labeled with 3×FLAG tag (3×DYKDDDDK), Avi tag (GLNDIFEAQKIEWHE) or 6×His tag (6×H), and was inserted into a mammalian expression vector. This vector was transfected into CHO cells by lipofection and the cells were subjected to drug selection to generate stable expression cell lines. The prestin RNA expression was confirmed by reverse transcription polymerase chain reaction (RT-PCR) and the protein expression was checked by immunofluorescence staining and by Western blotting.

To confirm the activity of prestin expressed in the generated cell line, the electrophysiological properties of the cell line were measured. Measurements of cell capacitance were performed using the “membrane test” feature of pCLAMP 8.0 acquisition software. To determine the voltage dependence of

membrane capacitance, cell potential was swung from -140 mV to +70 mV. After the measurements, the membrane capacitance was plotted versus the membrane potential. The membrane capacitance was fitted to the derivative of a Boltzmann function,

$$C_m(V) = C_{lin} + \frac{Q_{max}}{\alpha e^{\frac{V-V_{1/2}}{\alpha}} \left(1 + e^{-\frac{V-V_{1/2}}{\alpha}}\right)^2}, \quad (1)$$

where C_{lin} is the linear capacitance, Q_{max} is the maximum charge transfer, α is the slope factor of the voltage dependence of the charge transfer, V is the membrane potential and $V_{1/2}$ is the voltage at half-maximal charge transfer.

Gold-coated atomic force microscopic (AFM) cantilevers were incubated with a drop of mixture of two alkane thiols, i.e., protein resistant oligoethylene glycol (OEG) thiols and biotinylated alkane thiols. After incubation with the mixture, the surfaces were incubated with streptavidin. The cells were then grown on a dish and the inside-out plasma membranes were isolated. Such membranes were incubated with the biotin ligase and prestin was biotinylated so that prestin connects with the streptavidin-coated AFM cantilever via biotin-streptavidin binding. Finally, Avi-tagged prestin was pulled out from the plasma membrane of CHO cell and force curves were obtained. In this study, force peaks detected in the obtained force curves were fitted by the worm-like chain (WLC) model [7, 8]. The WLC model is represented by the following formula:

$$F(z) = \frac{kT}{b} \left(\frac{1}{4(1-z/L)^2} - \frac{1}{4} + \frac{z}{L} \right), \quad (2)$$

where F is the tensile force, z is the extension length, k is Boltzmann's constant, T is the temperature (in Kelvin) and b is the persistence length, which reflects the polymer stiffness. In this study, the persistence length of 0.4 nm was employed [8]. By using this formula, the contour length L of each force peak, which describes the length of stretched portion of the molecule, was calculated.

RESULTS AND DISCUSSION

To confirm the expression of prestin mRNA, it was extracted from the cell line and the cDNA synthesis was performed. After RT-PCR, the PCR products were subjected to agarose gel electrophoresis. As shown in Fig. 1, bands were observed at around 2200 bp from 6 clones out of 8 clones (FE1:1-3, 1-9, 1-14, 2-2, 2-3, 2-6, 2-9 and 2-14). Since the size of prestin cDNA should be 2235 bp, these bands possibly represent the prestin.

The activity of prestin expressed in the generated cell lines was examined by patch-clamp measurements. The membrane capacitance versus membrane potential measured in a prestin-expressing CHO cell is shown in Fig. 2. As shown in this figure, prestin-expressing cells exhibited bell-shaped nonlinear membrane capacitance (NLC) fitted to Eq. (2), similar to that in OHCs, suggesting that the functional prestin was expressed in the generated cell line.

The relationship between the force applied to the protein and extension distance, i.e., force-extension (FE) curve, was obtained and saw-toothed patterns were observed. The worm-like chain (WLC) model was applied to the FE curve and the force due to the extraction of N domain at 265 amino acid (aa) and that due to the extraction of the loop between N and M domains at 285 aa were detected (Fig. 3).

Inhibition of GSK-3 β by LiCl Does Not Affect MSC Differentiation *In Vitro* or Bone Formation *In Situ*

INTRODUCTION

Osteoporosis is a disease that occurs due to an imbalance in the normal bone remodeling process, resulting in an overall reduction of bone mineral density (BMD) and architectural degradation in trabecular bone. This decrease in BMD ultimately increases fracture risk and poses the potential for more serious repercussions as the disease progresses [1]. Thus it is important to identify potential targets for drug development or other interventions. Current treatment of osteoporosis is limited to the administration of bisphosphonates - drugs that target osteoclasts to prevent bone resorption but do not directly effect bone formation. New drugs or potential targeting pathways that act to stimulate osteogenesis through paracrine signaling to mitigate the effects of aging on osteoblast activity could provide a means to restore BMD, rather than simply mitigating further declines.

Upregulation of factors that initiate osteogenesis can push cells towards an osteogenic fate. The canonical WNT pathway is involved in the control of bone formation by activating transcription factors that control ECM production, and has been identified as a potential target for the treatment of osteoporosis. Recently, drugs that block sclerostin (SOST), a well-known inhibitor of the pathway, have undergone clinical trials. While SOST antibody reduced fracture risk and promoted bone formation [2], the FDA has blocked its release due to adverse cardiovascular events [3]. Other targets in the WNT pathway might have similar efficacy without these effects. One potential target is GSK-3 β , which is normally inhibited by WNT signaling to allow β -catenin accumulation.

We attempted to affect GSK-3 β activity using lithium chloride (LiCl) which directly affects GSK-3 β to inhibit degradation of β -catenin [4] and may be a valuable tool for osteogenesis experiments. An *in vivo* study showed a two-fold increase in bone volume change in an osteoporotic mouse model when the mouse was treated with LiCl [4]. However, *in vitro* studies evaluating the effect of LiCl usage on osteoblast progenitors, mesenchymal stem cells (MSCs), have been inconclusive regarding osteogenic potential.

Because it is still unclear whether LiCl acting on the WNT pathway is sufficient to induce osteogenesis in MSCs, we investigated its effects in two *in vitro* models. First, we applied an *in situ* bone marrow model to evaluate the effects of LiCl on the bone marrow niche, eliminating any potential systemic effects that may present in *in vivo* studies. Secondly, we

evaluated the effects of LiCl treatment on MSCs in 2-D culture with and without osteogenic supplements.

METHODS

For the *in situ* experiments, bone explants were harvested from the cervical vertebrae of pigs within 2-3 hours of slaughter. The explants were cultured in a bioreactor for 28 days during which time explants were exposed to normal or drug-treated (5 mM or 12 mM LiCl) media, and static or mechanically stimulated conditions. Mechanical stimulation consisted of sinusoidal vibration with a peak acceleration of ± 0.3 g at 50 Hz which affects the mechanobiological signaling in bone marrow [5]. To investigate the role of cell-secreted factors, we used two media exchange protocols, with the entire volume of media changed once a week or half of the volume changed twice a week. Bone explants were imaged with a μ CT scanner before and after culture to measure changes in bone volume (Fig. 1a) [6]. Additionally, media was supplemented with 0.5 mM Alizarin Red and Xylenol Orange for 24 hours on day 6 and day 27, respectively, for dynamic histomorphometry (Fig. 1b).

Fig. 1. Changes due to bone remodeling were measured using two techniques. (a) Registered μ CT images were compared to identify bone formation (blue) and resorption (yellow) by directly comparing image volumes. (b) Standard dynamic histomorphometry was used to measure bone formation to account for the limited resolution of the μ CT scans. Scale bar represents 50 μ m.

A 2-D culture study was performed to test the effects of LiCl on differentiation potential of porcine MSCs. Media was supplemented with 5 mM or 12 mM LiCl with or without ascorbic acid 2-phosphate (AA2P) and β -glycerol phosphate (BGP). Standard osteogenic media was used as a positive control and growth media as a negative control [7]. A calcium assay was used to compare calcium deposition as a result of treatment (Stanbio Laboratory, USA).

RESULTS

Neither LiCl treatment nor mechanical stimulation had an affect on bone formation or resorption rates in the *in situ*

culture (Fig. 2a). When media was changed once a week, no changes in bone formation across any groups were seen regardless of drug treatment or loading conditions and bone formation and resorption occurred at the same rate (Fig. 2a). Similarly, bone formation rates measured using dynamic histomorphometry showed no differences between groups (Fig. 2b). However, the rate shifted in favor of bone formation when media changes were modified to reduce the total volume changed at each time point.

Fig. 2. (a) Bone formation and resorption rates measured via μ CT histomorphometry were compared between groups with complete media changes ($n = 5$, LiCl; $n = 10$, CNT and LMMS) and partial media changes ($n = 4$, LiCl; $n = 3$, CNT and LMMS). Bone formation was higher and resorption rate was lower when half the volume of media was changed. LiCl treatment had no effect (* $p < 0.05$, two-factor ANOVA). (b) Bone formation rates measured via μ CT were higher than those measured via dynamic histomorphometry ($n = 4$) (* $p < 0.01$, Student's t -test).

Two-dimensional cultures showed no change in calcium deposition and MSC differentiation when using LiCl. Addition of AA2P and BGP increased calcium deposition, but were still less than half of that for osteogenic media (Fig. 3).

Fig. 3. The effect of LiCl treatment on MSCs was tested in 2-D culture. There were no differences between LiCl treated and negative control groups. Addition of osteogenic supplements increased calcium deposition, which was still lower than standard osteogenic differentiation media (* $p < 0.01$, two-factor ANOVA).

DISCUSSION

LiCl acts as an inhibitor of GSK-3 β , which allows β -

catenin to accumulate and translocate to the nucleus where a cascade of events increase osteogenesis. However, there have been contradictory results on the behavior of MSCs treated with LiCl. Our data showed that LiCl did not affect calcium deposition in MSC cultures, contrary to previous results where an increase in osteogenic behavior was found [9, 10]. The main difference between our experiment and others is that our treatment groups were not supplemented with dexamethasone, which acts on the glucocorticoid receptor to drive osteogenesis [9-11]. This suggests that GSK-3 β inhibition by LiCl alone is not sufficient for MSC differentiation, that it acts on pre-osteoblasts or osteoblasts, or requires systemic hormones.

The combination of *in situ* and 2-D cell culture in this study provided a unique method to assess the effects of GSK-3 β on osteogenesis. An important limitation is the small number of samples studied.

The effect of the media changes on bone formation demonstrates that paracrine signaling was essential to bone formation in the bioreactor. Neither LiCl treatment nor mechanical stimulation was able to compensate for the depletion of secreted signaling factors in the media. As a result, bone formation and bone resorption occurred at almost identical rates, which were so low that they may reflect image registration errors. However, when paracrine signaling was maintained, the rates of bone formation increased while resorption decreased.

LiCl had no effect on bone formation *in situ*, even with paracrine signaling, suggesting that bone formation in this system is not rate limited by WNT signaling. This is consistent with our recent findings that bone formation can occur *in situ* without altered SOST expression [5]. Other systemic factors, such as circulating hormones, may have affected bone formation in previous *in vivo* studies [4]. While cell secreted paracrine factors were able to affect bone formation in our bioreactor, systemic hormones such as glucocorticoids that might interact with GSK-3 β are likely not present.

INTRODUCTION

Bronchoconstriction, a narrowing of the airways characteristic of asthma, is regulated by two key processes: the generation of contractile force (via actomyosin crossbridges within airway smooth muscle (ASM) cells) and the transmission of this contractile force to the surrounding extracellular matrix (via integrin-mediated adhesions). In several experimental studies, deep inspirations (DIs) have been observed to reverse bronchoconstriction in healthy subjects, but this reversal was transient or not seen in asthmatics [1–3]. The mechanisms underlying this result are currently unknown. Motivated by these observations, previous research has focussed on understanding how contractile force generation is modulated by oscillatory loading. However, integrins are well-known to respond to environmental fluctuations, and are therefore also an important factor to consider. In this study, we develop a theoretical model to study how both crossbridges and integrins respond to oscillatory loading of the ECM. Using the model, we investigate the mechanical coupling between the two processes and suggest bistability (which arises due to mechanical cooperativity) as a possible mechanism behind differing responses to DIs.

METHODS

The mathematical model (sketched in Fig. 1) consists of three elements in series representing the ECM, integrins and the ASM cell. Within the cell, we consider a passive stiffness as well as parallel contractile units that are governed by the well-established Huxley–Hai–Murphy (HHM) model [4]. The HHM model is an advection–reaction system where myosin crossbridges undergo transitions between four states, accounting for phosphorylation and dephosphorylation of the crossbridges and their attachment and

detachment to actin filaments. Transition rate functions are governed by local kinetics, and contractile force is generated by crossbridges in the attached states. Similarly, we consider local binding and rupture kinetics of integrins, adapting a formulation from our previous model of cell–matrix adhesion dynamics [5]. These elements are coupled to, and respond to, mechanical loading, which is applied via an oscillatory displacement condition to the ECM (L_T , Fig. 1b).

Figure 1: Schematic diagram of the components considered in our model of ASM cell–matrix interactions. Three elements in series represent the ECM, integrins and the cell (consisting of a passive stiffness and parallel contractile units modelled by a 4-state Huxley–Hai–Murphy model [4]). The integrin and crossbridge binding and rupture rates depend on local kinetics and the effective stiffness of the cell and integrin elements evolve in time as binding and deformation-induced rupture occur. The collective integrin spring constant, $k_I(t)$, is determined by an underlying distribution of bound integrins, $b(x,t)$, where x is a coordinate local to each integrin [5].

RESULTS

Due to load-dependent unbinding of integrins and crossbridges, we find that both force transmission and force generation are affected by increasing amplitudes of oscillatory loading (Fig. 2). Moreover, there is a close mechanical coupling between the two processes from which a regulatory mechanism appears to emerge due to negative feedback: integrins and crossbridges have a competing effect on cell deformation, and a decrease in integrin density promotes crossbridge attachment. For intermediate amplitudes of loading we observe a region of bistability where shared loading and cooperativity between integrins can allow an initially high adhesion state to persist. This is analogous to a result reported in our earlier study [5], in which only integrin dynamics were modelled. However, in this fully-coupled model, we observe an additional region (Fig. 3) due to a similar cooperativity between crossbridges. The different regions are attainable as a dimensionless parameter β , which describes the relative strengths of the crossbridges and integrins, varies; for low β , integrin cooperativity is dominant; for high β , crossbridge cooperativity dominates. In both cases, the existence of bistability has interesting consequences. We find that large perturbations in oscillation amplitude (representing DIs) can result in a dramatic reduction in the total contractile force transmitted to the ECM. When bistability is present, this reduction can either persist or recover depending on where the unperturbed oscillation amplitude lies relative to the bistable region. Specifically, if this unperturbed amplitude is bistable, a permanent switch in behaviour is possible. It has been observed that DIs can reverse bronchoconstriction in non-asthmatics but not in asthmatics, and we propose that an underlying bistability could explain this.

Figure 2: Stable steady states for the densities of (a) bound integrins, (b) attached crossbridges, and (c) total contractile force when oscillations of amplitude A were applied to the ECM. Shading highlights bistability and arrows indicate hysteresis loops.

Figure 3: The regions of bistability (white) are from integrin cooperativity (1) and crossbridge cooperativity (2) respectively. Bistable regions shift as the dimensionless parameter β varies, which is a ratio involving the total number and stiffnesses of crossbridges and integrins, describing their relative strength.

DISCUSSION

Motivated by understanding the role of both actomyosin crossbridges and integrins in regulating bronchoconstriction, we developed a mathematical model of their combined responses to oscillatory loading. By coupling local binding kinetics to higher scale relative motion, we demonstrate the existence of mechanical feedback and mechanical cooperativity. To our knowledge, interacting crossbridge and integrin dynamics have not been considered at this level of detail before. A consequence of the mechanical cooperativity is the existence of bistability under certain parameter regimes. In these cases, it is possible to see a permanent switch in qualitative behaviour where large amplitude perturbations lead to reduced levels of total contractile force. Our mathematical model therefore predicts results of clinical significance: we propose that bistability could be a mechanism underlying experimental observations on the bronchodilatory effect of deep inspirations in non-asthmatics. Moreover, the model provides insight into parameters that influence the bistability; for example, we have observed that an increase in passive cell stiffness results in a narrower bistable region, which could be relevant to understanding the ineffectiveness of DIs at reversing bronchoconstriction in asthmatics. In summary, our work highlights the importance of considering both contractile force generation and contractile force transmission, generates hypotheses for the differing responses to DIs in asthmatics and non-asthmatics, and suggests bistability and mechanical cooperativity as important directions for future experimental study.

EXTRACELLULAR MATRIX STIFFNESS REGULATES CALCIUM OSCILLATIONS IN MULTICELLULAR ENSEMBLES, BUT NOT IN ISOLATED CELLS

INTRODUCTION

Cellular constriction must be coordinated across multiple length scales for organs to perform vital life processes such as breathing, beating of the heart, maintenance of blood pressure and the peristaltic contractions of the gut. For instance, in order to regulate the flow of air through the airway tree, it is not sufficient that airway smooth muscle (ASM) cells constrict in response to inhaled agonist. These cells need to connect with each other and constrict in a coordinated fashion so as to generate enough force to constrict an entire airway. In the airway, such coordination is achieved by intercellular communication using Ca^{2+} waves. When an airway is exposed to inhaled agonists such as histamine, cytosolic Ca^{2+} oscillations are initialized in the ASM cells. The Ca^{2+} oscillations in adjacent ASM cells are offset in phase such that Ca^{2+} waves appear to move around the circumference of the airway. When the agonist dose increases, the amplitude of the Ca^{2+} oscillations stay the same, but the frequency of Ca^{2+} oscillations increases monotonically with agonist dose. Higher frequency of Ca^{2+} oscillations is accompanied by greater constriction of the airway lumen¹. While intracellular biochemical pathways that regulate this phenomenon have been subject to numerous studies in the past two decades, the role of extracellular mechanical factors in coordinating cellular contractions is not well understood.

Here, we use a protein-coated silicone substrate of tunable-stiffness to simulate the ECM of soft, healthy airways (Young's modulus $E=300$ Pa), and stiff, remodeled airways ($E=13$ kPa). Human ASM cells are cultured either isolated from each other or in patterns that promote cell-cell connections. ASM are subjected to a low dose of agonist (10^{-5} M histamine), and the cell reactivity is measured. Cell reactivity is quantified by imaging the variation in intensity of cytosolic Ca^{2+} with a fluorescent marker over time, and then data processing to obtain a mean oscillation period. We find that ECM stiffness regulates

the Ca^{2+} oscillation frequency of ASM in multicellular groups, yet it has no impact on the frequency of individual, isolated cells. Those ASM that are connected to other have an increased oscillation frequency on stiffer substrates, suggesting that they are at a higher tone and more primed to constrict, simply due to the mechanical environment. This has implications for understanding the role of matrix remodeling in the etiology of widespread diseases such as asthma and hypertension.

METHODS

NuSil Gel Fabrication and Photopatterning. Microtissue mimics and isolated cell cultures were developed in order to test the relationship between ECM stiffness and calcium frequency on ASM in different configurations. NuSil (NuSil Silicone Technologies, Carpinteria, CA), a silicone substrate of tunable stiffness², was used to mimic the stiffness of healthy and diseased airways. Required volumes of crosslinker were added to the silicone base component in order to create substrates of 0.3 kPa and 13 kPa. Incubating these substrate with 0.1% gelatin allowed protein to coat the surface. In order to create the geometry of the microtissue, only patterned islands on the gel were coated with protein. In order to pattern desired shapes, such as small airway rings, the gel was coated with surface blockers Poly-L-Lysine (PLL; Sigma-Aldrich, St. Louise, MO) and mPEG-SVA (Laysan Bio, Arab, AL), which were then removed by a UV-activatable reagent in specific areas. Protein adhered to the gel in these exposed areas, and the rest of the surface remained blocked from cell adhesion by the PLL-mPEG compound.

Human Airway Smooth Muscle Culture. Human airway smooth muscle cells were obtained through the Gift of Hope Foundation, and used before passage number 7. Cells were seeded onto patterned and unpatterned gels, and allowed to adhere in 10% bovine serum media for

at least 4 hours. The media was then replaced by serum-free media, and incubated for at least 24 hours.

Fluorescent Dye Loading. ASM were incubated with 0.5 μ M Fluo4-AM for 30 minutes at room temperature, then incubated in dye-free media for an additional 30 minutes to allow the cell esterases to cleave the AM ester. This allows Fluo4 to fluoresce with increasing Ca^{2+} concentration. Cells were imaged immediately after loading the fluorescent dye. A representative image of an ASM microtissue loaded with Fluo4 is shown in Fig 1A, false-colored.

Calcium Imaging. A low dose of histamine (10^{-5} M) was added to the cell media at the start of imaging. ASM were imaged using a Leica DMi8 microscope with a 20x objective. Images were taken at 1 frame per second with a 50ms exposure time, for a total of 5 minutes per sample.

Data Analysis. Each image sequence was opened in Fiji/ImageJ³. Regions of interest (ROIs) of 5x5 pixels were hand-selected in the cytoplasm of each cell (Fig 1B). The mean greyscale intensity over the area of the ROI was recorded for each time frame. A custom MATLAB (Mathworks, Natick, MA) code read the intensity values over time and corrected the data for photobleaching. A representative Ca^{2+} oscillation experiencing photobleaching is shown in Fig 1C, with the exponential fit correction dashed line. The bleach-corrected data is shown in Fig 1D. From this data, the peaks of the oscillations were identified, and the average of the time between the peaks was recorded as the mean period for the cell. SigmaPlot (Systat Software, San Jose, CA) was used to run Mann-Whitney Rank Sum tests for statistical analysis of the data.

Figure 1: (A) Human airway smooth muscle microtissue on gelatin-coated NuSil (13kPa) with fluorescently labeled Ca^{2+} . Bar = 200 μ m. (B) Zoomed-in region of the ring to highlight the 5x5 pixel ROI for intensity recordings, shown as a white box. The colorbar represents increasing Ca^{2+} concentration as increasing brightness. (C) Representative raw data calcium signal from an ROI, which must be corrected for photobleaching. Subtracting an exponential fit will accomplish this. (D) Calcium oscillation post bleach correction, with peaks identified and periods measured as the time between peaks.

RESULTS

Our results show that matrix stiffness effects frequency of Ca^{2+} oscillations in multicellular ensembles of HASM cells, like the image of the ASM ring shown in Fig 2A. The mean Ca^{2+} oscillation frequency per cell is significantly lower on the stiffer ECM than on the soft ECM ($P < 0.001$) (Fig 2B). ASM on stiff matrix oscillated with a mean period

Figure 2: (A) Phase image of multicellular ASM ring. (B) Box plot of mean Ca^{2+} oscillation periods of individual cells within the ASM rings. (C) Phase image of isolated ASM cells. (D) Box plot of mean Ca^{2+} oscillation periods of individual, isolated cells. Bar = 200 μ m.

of 21.8 seconds ($N=172$), whereas the ASM on soft matrix had Ca^{2+} oscillation periods averaging at 44.1 seconds ($N=195$).

Single, isolated cells (Fig 2C) do not show any relationship between Ca^{2+} frequency and ECM stiffness. The mean period data between cells on soft ($N=29$) and stiff ($N=24$) ECM is not statistically significant ($P=0.668$) (Fig 2D).

DISCUSSION

Our study explores the relationship between extracellular matrix stiffening and smooth muscle cell reactivity. With our method of producing these microtissue, we were able to precisely control the mechanical properties to mimic the in vivo environment, while imaging and collecting data. Although photobleaching of the fluorescent dye limited the time series length, we were still able to record enough variations in intensity to measure oscillation periods. We have found that increasing ECM stiffness will increase the frequency of intracellular Ca^{2+} oscillations in the ASM ensembles, but not in isolated ASM cells. The significance of this result is twofold. 1) It provides another example of contrasting behavior between isolated cells and interacting cells to the growing body of research on collective cell dynamics^{4,5}. 2) Our data demonstrates that any ECM remodeling that increases the stiffness of the ECM will induce higher frequency Ca^{2+} oscillations in smooth muscle cell ensembles. Since the frequency of Ca^{2+} oscillations is highly correlated with the amount of force generated by the smooth muscle, this suggests that changes in ECM mechanics can be the primary pathway for the development of diseases such as asthma and hypertension.

INTRODUCTION

The anterior band of the ulnar collateral ligament (UCL) is commonly subjected to repetitive stress in overhead-throwing athletes, causing high sub-failure strain and change in mechanical properties of the ligament [1]. Understanding the effect of repetitive loading in the UCL mechanical properties is essential for diagnosing pathological conditions in the UCL. Additionally, monitoring changes in UCL mechanical properties could potentially quantify the risk of injury and prevent injuries by modifying cycles of throwing and resting and number of throws. Ultrasound shear wave elastography (SWE) is an imaging technique designed to non-invasively measure the shear modulus of soft tissues [2]. The objective of this study was to evaluate the repeatability and to quantify changes in the UCL shear modulus of overhead-throwing athletes over the course of a competitive season. Additionally, a follow-up case study of an injured player is presented. The results of this study show that SWE could be a useful clinical tool for evaluating the health of the elbow UCL.

METHODS

Sixteen healthy non-throwing participants (age = 27.1 ± 4.9 ; BMI = 22.1 ± 3.2 kg/m²) were recruited to determine of intra- and day-to-day reliabilities of UCL shear modulus. Five healthy football quarterbacks (age = 19.80 ± 1.30 ; BMI = 26.60 ± 0.54 kg/m²) and seventeen healthy baseball players (age = 20.29 ± 1.99 ; BMI = 26.71 ± 1.46 kg/m²) including six position players and eleven pitchers were recruited. The protocol quantified changes in shear modulus of the UCL at pre-season and season-end time points for the baseball players and pre-season, mid-season and season-end time points for the football quarterbacks. Additionally, in a case study, one injured baseball pitcher (age=24 and BMI=24.3 kg/m²) with partial UCL tear was recruited. During the SWE measurement, the participants laid supine with the shoulder at 30° of abduction and 90° of external rotation and the elbow at 30° of flexion [3] (Figure 1(a)). For the statistical analysis, intra-class correlation

coefficient (ICC) and Cronbach's alpha reliability coefficient were used to calculate the measurement reliability of the shear modulus in healthy non-throwing participants. A one-way repeated measures ANOVA, followed by post hoc Bonferroni correction, was also employed to evaluate the effect of time on the UCL shear modulus values in overhead throwing athletes.

RESULTS

The B-mode image and shear modulus map of the UCL within the rectangular ROI are shown in Figure 1(b) and 1(c). The ICC and Cronbach's alpha for the intra-day reliability were 0.72 (95% CI = 0.59 - 0.83) and 0.93 respectively, indicating the good reliability. The day-to-day reliability was excellent based on the associated ICC (0.95 with 95% CI = 0.88 - 0.98) and Cronbach's alpha (0.96). There was no significant difference between the dominant and non-dominant arms in the UCL shear modulus (average \pm standard deviation) in healthy non-throwing individuals (109.82 ± 43.45 kPa vs. $103.90 \pm$

Figure 1: a) Set-up, b) UCL shown with triangles (ME: medial epicondyle, C: coronoid) and c) elastography map

35.61 kPa). The UCL shear modulus values for the dominant arm in baseball players at pre-season and season-end were 347.64 ± 420.05 kPa and 210.83 ± 209.44 kPa respectively; for the non-dominant arm were 503.95 ± 590.59 kPa and 312.67 ± 240.66 kPa, respectively (Figure 2). Additionally, the average UCL shear modulus in both arms of baseball position players was found to be higher than pitchers at the pre-season (i.e. 729.10 ± 596.26 kPa versus 260.36 ± 377.62 kPa) and season-end time points (i.e. 248.16 ± 66.32 kPa versus 205.15 ± 64.87 kPa) (Figure 2a). The shear modulus values for the football quarterbacks for the dominant arm at pre-season, mid-season and season-end were 447.56 ± 339.13 , 113.62 ± 52.19 and 207.02 ± 277.88 respectively; for the non-dominant arm were 808.15 ± 578.34 , 463.75 ± 190.49 and 491.42 ± 420.03 , respectively. Time had a significant effect on UCL shear modulus on the dominant arm in football quarterbacks ($p=0.04$). Additionally, a meaningful difference in shear modulus between the pre-season and season-end time points was obtained ($p = 0.05$). In the case study, the UCL shear modulus of the injured elbow was lower than that of the uninjured elbow, especially within a week after injury (186.45 kPa vs. 879.59 kPa). After 8 weeks of recovery, the shear modulus returned to levels similar to those of the contralateral arm. After 8 weeks, the player progressively resumed throwing activity and he was clear to play at week 25 (Figure 3).

Figure 2: UCL shear modulus of dominant arm is lower in baseball pitchers compared to the fielders (a) the shear modulus changes over the course of a competitive season for fielders (b), pitchers (c), and football quarterbacks (d).

Figure 3: Longitudinal evaluation of torn UCL in the injured baseball pitcher.

DISCUSSION

This study showed that SWE is a reliable tool for the assessment of the shear modulus of the UCL. The shear modulus of the UCL in the dominant arm was pronounced compared to the non-dominant arm in

baseball players and football quarterbacks, possibly due to the repetitive loading applied during throwing exercise. The UCL shear modulus in healthy non-throwing individuals was lower than those in both baseball players and football quarterbacks in both arms at all-time points. This might be explained by adaptation and remodeling responses of the ligament to strength training. It was found that the shear modulus of the injured UCL of the baseball pitcher was around 79% lower than that of the healthy one within a week after injury.

The UCL shear modulus in the non-dominant arm of football players was higher than those of the baseball players. This may have been caused by the difference in strength training. The decrease in UCL shear modulus of the dominant arm over the course of the season was higher in the football players compared to the baseball players. This may be explained by differences in the UCL loading because of weight of the balls, kinematics of the arm during throwing, and quantity of throws during training sessions and games. Repetitive loading applied to the dominant arm of throwing athletes may cause a decrease in the shear modulus of that arm. This can be clearly observed in the similarity of the shear modulus of both arms in fielders (Figure 2b) compared to the dissimilar values in the arms of pitchers and quarterbacks (Figure 2c and 2d). These results suggest that the UCL's mechanical properties may uniquely change after repetitive loading in different overhead-throwing sports.

Several studies have investigated the ex-vivo mechanical response of connective tissues to repetitive loading. Rigby et al. [4] reported that if the strain applied to rat tail tendons does not exceed approximately 4%, the specimen can be cycled for a long period of time without damage. Weisman et al. [5] reported a clear relationship between softening (ratio of last cycle peak load to first cycle peak load) and reduction in strength of the ligament as a function of cyclic stress of the medial collateral ligament in rats. Mechanical response of connective tissues to repetitive loading has also been studied in human cadaveric connective tissues. Pollock et al. [6] studied the mechanical response of the inferior glenohumeral ligament to varying sub-failure cyclic strains in 33 fresh frozen human cadaver shoulders. They found that the group of ligaments subjected to higher cycling sub-failure strains demonstrated a significantly greater decrease in load compared to the lower cycling level. To our knowledge, this is the first study to provide information about the UCL shear modulus in overhead-throwing athletes over the course of a competitive season.

Our proposed protocol for evaluating the UCL shear modulus using SWE offers several potential applications for trainers, coaches and practitioners. First, it can be used as a potential tool for evaluating the health status of the UCL and early detection of injury for future sports medicine applications. It could also be applied to evaluate the degree of injury for providing a more accurate diagnosis, and helping medical doctors identify the optimal intervention strategy. The limitation of this study is that our sample for overhead throwing athletes consisted only of college baseball players and football quarterbacks from a single college. In conclusion, SWE could be a reliable tool for quantifying the changes in UCL shear modulus in overhead-throwing athletes over time.

INTRODUCTION

Tendon's viscoelastic behavior can be attributed to two mechanisms: fluid flow and intrinsic viscoelasticity [1]. These two mechanisms are difficult to distinguish under tensile loading, and thus their relative contribution is not known. Knowing this is important for evaluation of tendon's inelastic behaviors including viscoelasticity, damage, and plastic deformation. While it is commonly assumed that fluid flow has a small contribution due to tendon's parallel fibril structure, tendon has a large Poisson's ratio ($\nu > 2$) that exceeds the limit of incompressibility ($\nu = 0.5$) [2]. This indicates that tendon experiences volume loss during tensile loading, causing fluid flow which can contribute to the overall viscoelastic behavior of the tissue. Tendon's biphasic parameters, in particular, the permeability, are required to evaluate the fluid flow contribution to tendon viscoelasticity, but these are not well studied and the reported values vary by several orders of magnitude 10^{-16} to $10^{-13} \text{ m}^4(\text{N} \cdot \text{sec})^{-1}$ [3], [4].

The objective of this study was to quantify the permeability of tendon using a combination of osmotic loading and finite element (FE) modeling. Changes to tendon's geometry during osmotic loading isolates the effect of fluid flow, which was done using SPEG, a combination of physiological saline and polyethylene glycol (PEG). SPEG controls hydration without diffusion of solutes or changing mechanical properties [5]. The lateral strain over time was fit to a FE model to determine the permeability and other biphasic properties.

METHODS

Tail tendon fascicles were harvested from mature Long-Evans female rats and 60 mm long fascicles were cut in half to obtain paired samples between fresh frozen control and three osmotic loading groups

of 1%, 8% and 15% SPEG ($n=5$ per group), where SPEG solutions were made from polyethylene glycol (PEG 20 kDa) and 0.9% saline. Water content (ϕ_w) was measured immediately after dissection for the fresh frozen group (as explained previously [5]). The osmotic loading groups were first placed in 8% SPEG for 16 min (which maintains ϕ_w at the fresh frozen level [5]), then the solution was changed to either 1%, 8% or 15% SPEG, held for 16 min, and ϕ_w measured (Fig 1A). We performed paired t-tests between fresh frozen and SPEG groups ($p = 0.05$), and Pearson's correlation between ϕ_w and SPEG concentration ($p = 0.05$). Additionally, the lateral width (a) of the

Figure 1: (A) Paired halves of bisected tendons were used as fresh frozen control or equilibrated in 8% SPEG followed by the osmotic loading buffer solution (1%, 8%, or 15% SPEG). (B) Lateral width (a) was measured over time in solution (scale = 1 mm). (C) FE analysis included a quarter ellipse with a pressure boundary condition.

Figure 2: Water content of tissue at the end of osmotic loading. Error bars = 95% CI, * different from fresh frozen ($p < 0.05$)

fascicle was measured throughout the test using a CCD camera (Figure 1B). The lateral strain calculated as $\epsilon_l = a/a_0 - 1$, and the volumetric strain was calculated as $\epsilon_{vol} = 2\epsilon_l$. We compared the magnitude of ϵ_l between 1% and 15% SPEG (t-test $p = 0.05$).

A FE model was developed using FEBio (v2.8 febio.org) to calculate the biphasic properties assuming a plane-strain, symmetric elliptical cylinder cross section (semi major axes 0.14 mm, eccentricity 0.8) (Figure 1C). The pressure boundary condition, calculated relative to 8% SPEG using a phenomenological relation [6], was -63 kPa for 1% SPEG and 146 kPa for 15% SPEG. The solid matrix was modeled using a Holmes-Mow material (modulus E , Poisson's ratio ν , nonlinearity factor β) [7]. Isotropic permeability was modeled with deformation dependency as [7]:

$$k(J) = k_0 \left(\frac{J - \phi_0}{1 - \phi_0} \right)^\alpha e^{\frac{1}{2} M (J^2 - 1)}. \quad (1)$$

Where, J is the Jacobian of deformation, ϕ_0 is the reference solid volume fraction ($\phi_0 = 1 - (\phi_w)_0$ set to $\phi_0 = 0.6$); k_0 is the reference permeability, and $[\alpha, M]$ are positive parameters. In summary, the fitted model parameters were: $E, \nu, \beta, k_0, M, \alpha$. For curve-fitting, we used a constrained multivariable nonlinear optimization method with twenty random initial points. The solution with the minimum residual RMSE was taken as the optimal answer.

RESULTS

The water content of fresh frozen samples was $\phi_w = 42\% \pm 9\%$, and correlated with the osmolality of SPEG ($r = -0.66, p < 0.05$) (Fig. 2). The 1% SPEG samples had $\phi_w = 53\% \pm 6\%$, which was 11% higher than the fresh frozen. The ϕ_w for the 8% SPEG group was not different compared to the fresh frozen group and the ϕ_w for 15% SPEG was less than 1% SPEG ($\phi_w = 38\% \pm 7\%$) but not different from fresh frozen.

The 1% SPEG caused swelling, which resulted in 0.065 ± 0.025 lateral strain (Fig. 3). Conversely, the 15% SPEG caused a compressive lateral strain of -0.026 ± 0.016 , which was 60% smaller in magnitude compared to that of 1% SPEG ($p < 0.05$). By assuming transverse isotropy, these result in 0.132 and -0.056 volumetric strain for 1% SPEG and 15% SPEG, respectively.

Figure 3: Transverse strain and the model fits. Experiment line is mean \pm standard deviation

Table 1: Results of optimization

	E (MPa)	ν	β	$k_0 \left(\frac{m^4}{N \cdot sec} \right)$	M	α
1% SPEG	0.14	0.05	2.88	1.70×10^{-16}	2.01	1.92
15% SPEG	0.44	0.28	4.88	1.08×10^{-16}	3.18	2.71

Figure 4: Predicted deformation-dependent permeability.

The FE model fit the experiments extremely well (Fig. 3), where the RMSE was less than 0.0015 for both concentrations, less than 5% of the maximum corresponding lateral strain. Notably, the modulus was 0.14 MPa for 1% SPEG, which was less than a third of 15% SPEG, and the reference hydraulic permeability (k_0) for 1% SPEG was $1.70 \times 10^{-16} m^4(N \cdot sec)^{-1}$, and similarly $1.08 \times 10^{-16} m^4(N \cdot sec)^{-1}$ for 15% SPEG (Table 1). By using the fitted permeability parameters (Eq. 1) the permeability was plotted as a function of volumetric strain ($\epsilon_{vol} = J - 1$) (Fig. 4), which indicates permeability is sensitive to deformation and decreases at lower ϵ_{vol} .

DISCUSSION

Using a combination of osmotic loading and biphasic FE modeling, we calculated the reference permeability (k_0) of tendon of $\sim 10^{-16} m^4(N \cdot sec)^{-1}$, and showed that it decreases with a decrease to volume, which occurs during tensile loading [2]. These findings agree with the ranges of permeability of similar tissues, such as ligament, and annulus fibrosus [8-9].

An increase of buffer concentration decreased ϕ_w , as previously reported [5], and the observed changes to ϕ_w were similar to the estimated ϵ_{vol} in both solutions. This indicates that osmotic loading caused influx and exudation of water. The changes to width (a) were larger with 1% SPEG, despite the smaller relative pressure in the 1% solution, due to the weaker modulus in lateral tension. This indicates that tendon has lateral tension-compression nonlinearity (Table 1).

This study only evaluated transverse permeability and the axial tendon permeability was not studied. In tendon's tensile loading and uniform osmotic loading, axial flow does not occur, because of high aspect ratio and symmetry of sample.

In conclusion, we calculated tendon's deformation-dependent permeability and other biphasic parameters by osmotic loading, which eliminates the effect of axial fibers. Future studies will include these biphasic parameters combined with axial loading to understand the share of different viscoelastic mechanisms and other inelastic behaviors such as damage and plastic deformation in tendon.

THREE DIMENSIONAL MORPHOLOGICAL CHANGES IN CARPAL TUNNEL LIGAMENT ARCH IN RESPONSE TO WRIST COMPRESSIVE FORCES

Rakshit Shah (1,2), Zong-Ming Li (1,2)

INTRODUCTION

The carpal tunnel is formed by the transverse carpal ligament (TCL) at the volar boundary and the carpal bones at the medial, lateral, and dorsal boundaries. The tunnel serves as a passageway for the median nerve and digit flexor tendons. Prolonged median nerve compression could lead to carpal tunnel syndrome (CTS). The positioning of the median nerve directly beneath the TCL makes it susceptible to compression neuropathy.

Increasing the carpal arch area may potentially provide relief for median nerve compression as a possible treatment for CTS. Carpal arch area has been shown to increase during compressive force application to the carpal bones in modeling and in vitro studies [1, 2]. In vivo compressive force applied in the radioulnar direction across the wrist have been demonstrated as a non-invasive method to increase carpal arch cross-sectional area [3]. With the increase in radio-ulnar wrist compressive force a decrease in TCL-formed ligament arch width and an increase in ligament arch height and area were observed. To date, the change in carpal tunnel morphology with radioulnar compression has only been evaluated in the distal cross-section of the ligament arch. A comprehensive understanding of the volumetric change in ligament arch at the inlet (proximal) and outlet (distal) during application of wrist compressive forces in radio-ulnar direction is still unavailable.

Therefore, the purpose of the current study was to investigate the relative changes in the ligament arch volumes in response to radio-ulnar wrist compression (RWC) forces, at the distal and proximal carpal tunnel regions. For this purpose, a three-dimensional reconstruction of the ligament arch was accomplished. It was hypothesized that an increase in RWC force will lead to an increase in the ligament arch volumes at both regions of the tunnel. The increase in ligament arch volume will be more pronounced at the proximal tunnel region compared to distal tunnel region.

METHODS

Six male cadaveric left hands were used for this study. Change in segmental volume was calculated for the ligament arch at the two tunnel regions (distal and proximal) for three compressive force levels (0N, 10N, and 20N). The contents of the carpal tunnel were excavated from each specimen and a medical balloon along with a catheter ultrasound probe (AcuNav 8F, ACUSON, Siemens Medical Solutions USA Inc.) was inserted inside the tunnel. The balloon was inflated to maintain an elevated pathophysiological intra-tunnel pressure of 60 mmHg. Each specimen was secured on a thermoplastic splint with the hand in a supine and anatomically neutral position (Fig. 1). The four TCL-bone attachment sites were marked and digitized using a 3D MicroScribe digitizer. We used a compressive force application system as described in our previous study [3]. The system was positioned and adjusted to either apply no compressive force (0 N) or a transverse compressive

Fig. 1 Experimental Setup

force (10 or 20N). Each trial of compression lasted for 4 minutes with a 4 minutes break between each trial. During each trial, the catheter ultrasound probe driven by a robot arm (Denso Corp.) was rotated circumferentially in increments of 1 degree inside the carpal tunnel to collect ultrasound (US) images in the radial planes. The testing order of the compressive forces (0, 10, and 20 N) were randomized for each specimen.

From each US image, the two-dimensional (2D) image coordinates of the tunnel's internal surface points were extracted using a custom algorithm. The 2D surface points were then transformed into the robot's coordinate system using encoded kinematic transformation to generate three-dimensional (3D) point clouds of each tunnel's inner surface. The proximal and distal boundaries of the carpal tunnel were then determined from the digitized TCL-bone attachment sites. The 3D surface points were trimmed at the boundaries to extract a 3D model of the carpal tunnel (Fig. 2). The generated 3D model was then segmented into the ligament arch based on ligament insertion to the carpal bones, and the arch was further divided into the distal and proximal regions of tunnel. From the segmented regions of the tunnel for each trial, the ligament arch volume (LAV) at each region was calculated.

Fig. 2 Reconstructed carpal tunnels during 0N, 10N, and 20N force application

Two-way repeated measures ANOVA was performed to determine whether the LAV varied significantly with the factors of Forces (0, 10, and 20 N) and Regions (distal and proximal). Holm-Sidak's post hoc analysis was performed for pairwise comparisons. Statistical analyses were performed using SigmaStat 4.0 (Systat Software Inc). An α level of 0.05 was considered for statistical significance.

RESULTS

The effects of the RWC on the ligament arch was investigated using a robot-assisted ultrasonography. In general, as the magnitude of compressive force increased, the LAV increased. This was true for both the distal and proximal tunnel regions. At the distal region, LAV during forces of 0, 10, and 20N were $254.1 \pm 67.8 \text{ mm}^3$, $308.2 \pm 77.3 \text{ mm}^3$, and $322.3 \pm 80.8 \text{ mm}^3$ respectively. The proximal region LAV during compressive forces of 0, 10, and 20 N were $737.2 \pm 140.4 \text{ mm}^3$, $1052.0 \pm 176.6 \text{ mm}^3$, and $1126.3 \pm 191.1 \text{ mm}^3$ respectively.

Ligament arch volume (LAV) was significantly affected by the factors of Forces ($P < 0.001$) and Regions ($P < 0.001$). The interaction of the two factors were also significant ($P < 0.001$). Pairwise comparisons showed that LAV significantly increased when the force increased from 0N to 10N and from 0N to 20N at both regions ($P < 0.05$, Fig. 3). LAV did not significantly increase when force increased from 10N to 20N at the distal region ($P = 0.235$) but significantly increased at the proximal region ($P < 0.05$). LAV was significantly smaller in distal region compared to proximal region at all force levels ($P < 0.05$).

Fig. 3 Ligament Arch Volume at distal and proximal regions at different force levels (0, 10, 20 N)

DISCUSSION

The current study evaluated, using robot-assisted ultrasonography, the effect of radioulnar compressive forces applied across the wrist on the ligament arch volume at the distal and proximal tunnel regions. We found that with the application of compressive forces, the carpal tunnel ligament arch changed in volume at both the inlet and outlet of the carpal tunnel.

The ligament arch increased in volume when a force of 10 N or 20 N was applied compared to no force application. These findings support the findings of a previous study where an increase in distal ligament arch cross-sectional area was observed with the application of wrist compressive forces [3]. LAV showed a more pronounced increase in the proximal region compared to the distal region. The difference in ligament arch volume change between the regions may have been contributed by the distal tunnel being narrower [4], and the TCL being thicker [4] and less elastic distally [5] than the proximal tunnel region.

The study provided a better understanding of the effects of radio-ulnar wrist compressive forces on the TCL-formed ligament arch. The current study observed that the increase in the ligament arch area with compression seen by other studies at the distal region [3], extended to the proximal region of the tunnel. Our previous study showed that the median nerve being housed near the ligament arch showed an increase in circularity distally with RWC [3]. The current findings corroborate a similar beneficial effects of median nerve circularity with an increase in ligament arch volume at both the inlet and outlet of the tunnels. Therefore, the application of external wrist compressive forces could potentially lead to the decompression of the median nerve in patients suffering from carpal tunnel syndrome, relieving their symptoms.

INTRODUCTION

Abnormal loading of ligamentous joint capsules induces pain cascades by activating the innervating nociceptive fibers [1]. An in vitro neuron-seeded collagen gel system that replicates the capsular ligament's sensory innervation and collagenous microstructure has been used to define relationships between collagen organization and neuronal nociceptive signaling due to macroscale loading [2,3]. But, that model does not include fibroblast-like synoviocytes (FLS), which are abundantly interspersed in the extracellular matrix (ECM) [4,5]. FLS respond to their local environment, but they can also remodel the ECM [4,6]. Although capsule nerves and FLS are mechanosensitive [2-4,6], their interactions with each other and the surrounding network has not been studied in the context of pain due to a lack of in vitro models.

Non-physiologic loading initiates pathological ECM remodeling by fibroblasts, including their secretion of the interstitial collagenase MMP-1 [4,7]. MMP-1 is elevated in joint tissues after trauma and with degeneration [8]. Although MMP-1 has recently been shown to have a role in nociception and ECM degradation in painful joint diseases [8,9], its role in joint pain is unknown. This study tested effects of FLS on collagen gel mechanics and neuronal MMP-1 after stretch. Primary FLS cells were integrated in an in vitro dorsal root ganglia (DRG)-seeded collagen gel system [2,3]. Since capsular ligaments have variable FLS densities regionally [5], and mechanical properties of fibroblast-embedded collagen gels depend on their initial concentration [10], FLS were seeded here at two concentrations. Gel failure properties and stiffness were quantified. Regional strains and collagen organization were measured during loading curve since neurons respond to their local network [2,3]. Collagen fiber alignment maps were captured and fiber orientation angles were quantified by circular variance (CV), with lower CV indicating tighter clustering and more fiber alignment [2]. Because FLS concentration was found to modulate biomechanics, MMP-1 was

assessed after gel failure for the low FLS concentration.

METHODS

Cells were harvested from Sprague-Dawley rats, with IACUC-approval. DRGs were harvested from embryonic day 18 rats [3,11] and FLS from adult hind knees [12], cultured, and passaged at 90% confluence. On passage 4, cultures were suspended in Type I collagen solution (2mg/mL; Corning) at concentrations simulating those in the outer (5×10^4 cells/mL; low FLS; n=8) or inner (1×10^5 cells/mL; high FLS; n=3) layer of the capsular ligament [5]. Gels were cast (1mL/well) and set at 37°C. Because FLS alter gel mechanics that may influence neuron signaling, gels without FLS were included as a control (no FLS; n=8). On DIV1, DRGs (6-10/gel) were seeded on the gel [3,11]. On DIV8, additional collagen (150 μ L) was added to encapsulate the DRGs.

On DIV9, gels were cut (21mmX8mm) and a grid was drawn on the surface to track elemental strains [2]. Using a planar test machine (574LE2; TestResources; 500g load cells), gels were immersed in a 37°C PBS bath. Testing was integrated with a polarized light imaging system [2] and high-speed cameras (Vision Research) that acquired collagen alignment maps and tracked markers. Force and displacement data (200Hz) were synchronized with images (500Hz). Slack was removed (loading <2mN) and gels were displaced to failure at 0.5mm/s.

Peak force defined failure; stiffness was taken as the slope of the force-displacement curve between 20-80% of maximum force [13]. Marker positions were digitized (Fiji software; NIH) from images before loading (ref), and at 20% of maximum force, 80% of maximum force, and failure. LS-DYNA (LSTC) calculated maximum principal strain (MPS) from marker positions for each grid element and averaged for each gel [2]. CV was quantified from collagen alignment maps taken before loading (ref) and at failure [2] and normalized to reference. Differences in failure force and displacement, stiffness, and reference CV were tested by an ANOVA and Tukey HSD tests. MPS at 20%, 80%

and 100% of failure was compared between groups by a repeated-measures ANOVA. Paired t-tests compared CV changes for each group.

Because low FLS concentration altered strains, a subset of gels (no FLS $n=5$; low FLS $n=4$) were immunolabeled after failure for MMP-1 and β III tubulin. Gels were blocked, incubated overnight with primary antibodies to MMP-1 (1:100) and β III tubulin (1:200), washed, and incubated with secondary antibodies (1:1000). Gels were imaged (Leica TCS SP8 Confocal) with stacks (3-5/gel) of 6 40X images taken at 1 μ m steps up to 5 μ m. Equal numbers of images were taken with DRG axons and soma. The maximum intensity projection of each stack was generated using Fiji; the number of positive pixels above that in controls and naïve FLS cultures was quantified. MMP-1 labeling and its co-localization with β III tubulin (neuronal) were computed, with co-localization normalized to total β III tubulin. Total and neuronal MMP-1 were separately compared between groups by t-tests.

RESULTS

Although neither the force nor displacement at failure are different ($p>0.4$) between any group, high FLS concentration has lower force and higher displacement at failure (Fig. 1). The stiffness of the high FLS group is significantly lower ($p=0.03$) than gels without FLS (Fig. 1). MPS exhibits different increases depending on FLS concentration, with significant differences ($p<0.01$) between groups at both 80% of failure and failure, and highest strains experienced by high FLS gels (Fig. 2A).

Fig. 1: Failure force and displacement are not significantly different between groups ($p>0.4$). Stiffness is lower for high FLS ($*p=0.03$).

Fig. 2: (A) MPS is different at 80% and 100% (fail) of failure, with high over low ($\#p<0.01$) and both over no ($*p<0.01$) FLS. (B) Reference CV of high gels is greater ($p<0.01$) than low ($\#$) and no ($*$) FLS, (C) but not at failure, unlike no and low FLS ($*p<0.01$).

Prior to any loading, high FLS gels exhibit significantly higher ($p<0.01$) CV than the low FLS and no FLS gels (Fig. 2B). Yet, for no and low FLS gels, collagen reorganizes significantly ($p<0.01$) at failure from its reference state (Fig. 2C). Although the CV of two high FLS gels decreases (Fig. 2C), this change is not significant ($p=0.68$).

Following strains (Fig. 2A), there is significantly more ($p<0.01$) MMP-1 in low FLS gels than in gels without FLS (Fig. 3). Positive MMP-1 labeling is observed in both the soma and axons of DRGs in low FLS gels; very little MMP-1 labeling is evident in gels with no FLS (Fig. 3). The co-localization of MMP-1 with β III tubulin further reveals that neuronal MMP-1 is also increased ($p<0.01$) in the presence of FLS.

Fig. 3: Images of DRG soma and axons showing MMP-1 labeling for low FLS gel, but scarce labeling in no FLS gel. MMP-1 labeling is greater in the low FLS group ($*p<0.01$).

DISCUSSION

This is the first demonstration of concentration-dependent effects of primary FLS on collagen gel mechanics and neuronal MMP-1. Although failure properties trend differently, significance was not reached (Fig. 1), likely due to the small size of the high FLS group. The decreased stiffness in that group (Fig. 1) is opposite what is found with dermal fibroblasts at the same concentration [10]. This difference may be due to phenotypic differences or FLS remodeling collagen fibers more since they were cultured longer here [4,6,7]. Since strains directly modulate neuronal neurotransmitters and injury markers [2,3], and FLS increase strains (Fig. 2A), they may lower the threshold for neuronal signaling. Yet, at low loads, MPS was below the pain threshold [1,2], suggesting that may be minor. The higher reference CV of high FLS gels indicates more collagen fiber spread (Fig. 2B), which may also be due to FLS remodeling and can mediate neuronal responses. Low FLS produce similar reorganization of collagen as no FLS (Fig. 2C), which may mean that the difference in MMP-1 labeling (Fig. 3) may not be due to differences in matrix reorganization, suggesting that FLS, either directly or through mechanical effects (Fig. 2A), may regulate neuronal MMP-1 expression (Fig. 3). Studies with these FLS concentrations find they regulate inflammation [12], supporting that notion.

The presence of FLS increases both total and neuronal MMP-1 (Fig. 3). Yet, it is unclear if this is due to FLS or DRGs or both. Both cell types express MMP-1 after a mechanical injury, during pathological remodeling, or in “activated” states like rheumatoid arthritis or spinal cord injury [4,7,14]. Since MMP-1 interacts with neuronal cell surface receptors [9], it is possible that increased neuronal MMP-1 (Fig. 3) is due to neuronal receptor binding of the enzyme. Regardless of source, its elevation after loading is made more relevant by the fact that neurons increase their calcium signaling in the presence of exogenous MMP-1 [9]. Investigating relationships to nociceptive signaling and matrix composition with FLS would clarify FLS-DRG interactions contributing to joint pain.

AGING ADVERSELY AFFECTS DIFFERENT RAT ROTATOR CUFF TENDONS SIMILARLY

Joseph B. Newton, George W. Fryhofer, Snehal S. Shetye, Ashley B. Rodriguez,

INTRODUCTION

Rotator cuff tendon tears are a common injury affecting a large portion of the population. Of these rotator cuff tears, 90% involve injury to the supraspinatus tendon, 35% to the infraspinatus, and 25% to the subscapularis [1-6]. Further, advancing age is directly correlated with increased incidence of such tears. However, the age related changes in tendon mechanical properties that may predispose the supraspinatus to injury relative to the other rotator cuff tendons is unclear [7]. Therefore, the objective of this study was to define the age-related alterations in rotator cuff tendon fatigue mechanics to determine whether the supraspinatus is more susceptible to injury due to aging than the infraspinatus and subscapularis. We hypothesized that aging would adversely and preferentially affect supraspinatus tendon fatigue mechanics when compared to the subscapularis and infraspinatus tendons.

METHODS

Experimental design and sample preparation: 7-month juvenile (n=10), 18-month adult (n=10), 27-month old (n=10), and 36-month old (n=10) male F344XBN rats were obtained from the National Institute of Aging (IACUC approved), approximating respective human ages of 18, 43, 63, and 90 years old. After 3 weeks of facility acclimation, all animals were sacrificed. Lower and upper subscapularis (LS & US, respectively [7]), supraspinatus (SS), and infraspinatus (IS), muscle-tendon complexes were then each carefully dissected from the scapula of the right shoulder and removed with the proximal humerus for mechanical testing. Muscle, along with extraneous tissue was removed from each tendon and cross-sectional area of each tendon was measured using a custom laser device [8]. Each humerus was potted in a custom acrylic cylinder secured with polymethyl-methacrylate, leaving the proximal humerus exposed. The

head of the humerus was secured using a self-tapping screw to prevent failure at the growth plate. Mechanical testing: The LS, US, SS, and IS from each animal were mechanically tested independently on an Instron ElectroPuls E3000. Maximum stresses were calculated from previous ramp to failure testing on contralateral shoulders for each tendon for each group. Mechanical testing consisted of a 0.1N preload, a ramp to 40% maximum load at 1% strain per minute, and cycles to failure (7-40% maximum load at 2Hz). During loading, force and displacement data were acquired and analyzed using MATLAB (Mathworks; Natick, MA). A line was fit to the triphasic peak strain vs. cycles curve, and all fatigue parameters were calculated at breakpoints 1 (BP1) and 2 (BP2) (Figure 1). Cycles to failure, secant modulus and stiffness, peak strain, laxity (resistance of material to elastic deformation), and hysteresis (measure of energy dissipation) were evaluated. A 2-way ANOVA with Bonferroni post-hoc tests was used to compare the different ages for each tendon with significance set to $p < 0.05$.

Figure 1: Example peak strain vs. cycles (% of failure) curve. Fatigue parameters were calculated at breakpoints 1 (BP1) and 2 (BP2).

RESULTS

Significant changes in hysteresis at BP2 were seen with aging in all rat rotator cuff tendons tested in fatigue. Secant modulus at BP2 significantly decreased in the LS, SS, and IS in the geriatric group compared to juvenile animals, and in the LS and IS between geriatric and adult rats (Fig. 2). The SS and IS were similar with significant increases in hysteresis in adult, aged, and geriatric animals compared to juvenile (Fig. 3). Peak strain at BP2 was significantly increased in the LS geriatric tendons compared to juvenile and adult, increased in the SS aged tendons compared to juvenile and adult, and in the IS adult tendons from juvenile (Fig. 4). Surprisingly, there were no significant changes in cycles to failure in the LS or SS. The US had increased cycles to failure between juvenile and aged, and the IS had the highest number of cycles to failure in the geriatric group (Fig. 5).

Figure 2: Significant changes in the LS, SS, and IS secant modulus were seen with aging at BP2 between juvenile and geriatric animals.

Figure 3: Hysteresis at BP2 increased with aging in SS and IS, and decreased with LS and US.

Figure 4: The LS had the highest peak strain in the geriatric group, the SS in the aged group, and IS in the adult group at BP 2.

Figure 5: No changes in cycles to failure were detected in the LS and SS. The US had the highest number of cycles to failure in the aged group. The IS had a significant increase in cycles to failure in the geriatric group.

DISCUSSION

Advancing age correlated with significant detrimental changes in the fatigue properties of all rat rotator cuff tendons, supporting that aging, in general, is a factor in the increase of rotator cuff tears seen in humans. Interestingly, supraspinatus fatigue response was not preferentially affected by aging when compared to the other rotator cuff tendons, which is not consistent with tear frequency observed clinically. Significant decreases in secant modulus in the LS, SS, and IS, and changes in hysteresis in all rotator cuff tendons indicate altered load transmission and energy dissipation capacity with aging. Previous literature has shown significant accumulation with aging of advanced glycation end products, cross-linking, and fatty infiltration within the supraspinatus [10]. It has also been shown that the supraspinatus has a decreased fiber alignment response to loading as a result of aging [11]. This altered biochemical and structural environment within the rat rotator cuff tendons may explain the significant changes shown in fatigue mechanical properties in this study. Surprisingly, cycles to failure was highest in the IS in the geriatric group; however, this may be explained by an increase in IS cross sectional area in the geriatric group (not shown). A limitation of this study is that it only analyzes fatigue mechanical properties. It has been shown that significant biochemical compositional, cellular, and structural changes exist with aging in the supraspinatus; however, none of the current studies analyze these changes in reference to the other rotator cuff tendons [10-12]. In summary, this study demonstrates that aging has a significant effect on fatigue properties of the rat rotator cuff, though the supraspinatus was not preferentially affected. Thus, other factors may explain the predominance of supraspinatus tears with age. Future studies will investigate the histological, morphological, and biochemical changes in all rotator cuff tendons in response to aging.

COMPARISON OF THE DEFORMATION BEHAVIOR OF THE ANTERIOR CRUCIATE LIGAMENT IN RESPONSE TO VARIOUS EXTERNAL KNEE LOADINGS

Satoshi Yamakawa (1, 2), Richard E. Debski (1), Hiromichi Fujie (2)

(1) University of Pittsburgh, Pittsburgh, PA,
USA

(2) Tokyo Metropolitan University, Tokyo
Japan

INTRODUCTION

The primary function of the anterior cruciate ligament (ACL) is transmitting tensile forces between the femur and tibia for stabilizing the knee joint. There generally exists a one-to-one relation between stress and strain. Thus, quantitative biomechanical data on the strain behavior of the ACL during physiological knee motions are necessary for a better understanding of the mechanical function of the ACL. Although previous studies determined the strain distribution in the ACL in response to an axial load applied to the ACL, they did not determine the strain distribution in response to external knee loadings [1, 2]. Therefore, the objective of the present study was to determine the strain distribution in the ACL in response to various knee loads.

METHODS

A 6-DOF robotic testing system (FR-2010, Technology Service, Japan) was used to apply loads to knee joints with respect to the knee joint coordinate system [3]. Human cadaveric knees (n=10) were dissected down to the joint capsule and fixed to the robotic testing system. 100 N of anterior tibial load, 5 Nm of internal torque, 5 Nm/10 Nm of internal/valgus torque (simulated pivot shift), and 10 Nm of valgus torque were applied to the intact knee at full extension and 30 degrees of flexion. Afterwards, the medial condyle was removed, and the medial view of the ACL was recorded during the reproduction of the intact knee motion with an HD video camera (HDR-XR500V, SONY). In the recorded image, the medial surface of the ACL was transversely divided into 4 regions from the anterior to posterior fibers and was longitudinally divided into 5 regions: 0-10%, 10-20%, 20-80%, 80-90%, and 90-100% of the length from the femoral attachment (Figure 1). By applying the rotational stereoscopic image method [4] the length changes between each marker were calculated to analyze fiber strains.

The reference configuration (zero strain) was defined for the knee at full extension, when 0.5 Nm of extension torque was applied.

Willcoxon signed-rank test was performed to compare the strain values in each region between each external load. P values < 0.05 were considered statistically significant.

**Figure 1 Twenty portions on the ACL surface layer
for the strain distribution**

RESULTS

Tensile strain occurred in all regions at full extension for all loading conditions. In response to an anterior tibial load, the maximum strain of 6.8% occurred in the femoral insertion site of the most posterior (75-100% of width direction) fibers (Figure 2). In response to an internal torque, the maximum strain of 4.7% occurred at the femoral insertion site of the most posterior fiber (Figure 3). During the simulated pivot shift, the maximum strain of 6.1% occurred at the tibial insertion site in the most anterior (0-25% of width direction) fibers (Figure 4). In response to the valgus torque, the maximum strain of 4.3% occurred at the tibial site in the posterior (50-75% of width direction) fibers. At 30

degrees of flexion, tensile strain did not occur in several regions in the posterior fibers. However, in anterior fibers, tensile strain occurred in almost of all regions.

DISCUSSION

At full extension, the entire ACL was strained in all loading conditions. This result indicated that all medial fibers of the ACL are functional in response to any external knee load at full extension.

At 30 degrees of flexion, unstrained regions occurred in the posterior fibers while the anterior fibers were strained. Unstrained fibers suggests that tensile force was not transmitted to the posterior side of the medial fibers. However, previous studies reported that the posterior fibers (posteromedial bundle) of the ACL were functional in the flexed knee. These results indicate that in the posterior fibers, medial fibers become non-functional in the flexed knee while lateral fibers become more functional. The present results suggested that the load distribution is changing not only width direction but also medial and lateral direction.

The trend that strain was large in the posterior side occurred in response to the anterior tibial load as well as internal and valgus torques at full extension. But, in the simulated pivot shift application, that trend did not occur. This result suggested that in the extended knee, the posterior fibers act mainly against the simple external load such as that applied to along a single axis, but the ACL mobilizes all fibers in response to complex external loads such as the pivot shift.

The present results indicated a complex site- and load-dependent strain distribution of the ACL. The deformation behavior (strain distribution) has a strong relationship to the force transmission of the tissue. Our results suggest that the deformation behavior is important for the improvement and the development of ACL reconstruction procedure. In addition, the deformation behavior of the lateral side of the ACL is important for normal function. In the future, the deformation behavior of the lateral fibers and the entire ACL will be determined.

INTRODUCTION

The National Highway Transportation Safety Administration (NHTSA) uses the Head Injury Criterion (HIC) as a federal rule for frontal and side impact head protection requirements. The advanced finite element (FE) human head model and the simulation of animal brain injury data scaled to the human head model, a new Brain Injury Criterion (BrIC) [1], based on head rotational velocity measure was proposed by the NHTSA to complement the HIC. However, the accuracy of the methods for describing brain injury location, severity and pathology was very limited and the scaling of the animal head rotation motion to the human brain model based on mass information alone is questionable considering the geometrical and neuraxis differences between the animal brain and the human brain. To better correlate model-predicted biomechanical responses with the severity and location of injuries observed in animal experimental models the use of the FE animal brain model is essential. The objectives of the study is 1) to develop an anatomically realistic monkey head model with anatomical structures modeled similar to the latest human head model developed previously [2] to facilitate the translation of the tissue level response parameters; 2) to investigate the effect of angular accelerations of different planes on the severity and pathology of the Diffuse Axonal Injury (DAI) assessed by various biomechanical response parameters in the FE monkey model simulating experimental brain injury. Collectively, the tissue-level injury threshold was established; and 3) by translating the tissue-level injury threshold to the human head model, the real-world injury data was assessed and evaluated. The monkey head model developed can be used directly to simulate a wide range of brain injury types and severities.

METHODS

Development of FE Rhesus monkey head: Reported experimental studies of diffuse axonal injury, subdural hematoma and concussion on the subhuman primates often use Rhesus monkey (*Macaca Mulata*). The FE model of the Rhesus monkey brain was developed using MRI images [3]. Figure 1 illustrates the process involved in developing the monkey brain model. The MRI images were processed using 3D slicer to generate STL surface and imported to the Hypermesh v13.0 for meshing. The segregation of the various brain structures was performed so that the anatomical boundary can be properly represented. The brain contents were meshed with hexahedral elements using ANSYS ICEM CFD 13.0. The mesh of the white matter was differentiated from the grey matter based on the brain atlas [3]. The FE brain model consisted of grey and white matters, cerebellum, corpus callosum, brainstem, thalamus, pia matter, arachnoid mater, dural mater and dual partition and CSF. In addition, detailed skull, facial bone and flesh mesh were also developed based on data [4] (Figure 2).

Figure 1: Development of rhesus monkey FE model

Figure 2: Developed monkey FE head model

The monkey head model has over 500,000 hexahedral and 206,000 quadrilateral shell elements with an average element size at 0.8 mm.

The material models and associated properties defined for the monkey brain, meninges, CSF, skull, facial bones and flesh were the same as the GHBMC 50th percentile male head model (Global Human Body Models Consortium) [2] and updated recently (M50 v5.0).

Simulate head rotational injury experiments and determine the tissue level injury thresholds: The head acceleration time-history measured from the monkey experimental study [5,6] were applied to the FE model. The center of rotation was in the neck at 7.345cm distance from the center of the gravity of the head. The head rotated 60 degrees in the coronal, oblique and sagittal planes of which the overall magnitude were nearly identical. The brain mass of the monkey model (109g) was scaled to the mass of the brain for each test subject. Maximum principal strain (MPS) and Cumulative Strain Damage Measure (CSDM) at 0.5 MPS level were examined in the whole brain, brainstem, white matter and corpus callosum. The localized responses were correlated to the DAI grade sustained in the experimental animals.

Assess the real-world brain injury risk: The two volunteer impact cases [7,8] and three US NCAP cases were simulated by the GHBMC M50 human head model to evaluate predictability of the tissue level thresholds developed from monkey model analysis. BrIC was also used to assess the brain injury risk. All simulations were performed by LS-DYNA MPP R8.1 on a Linux based cluster.

RESULTS AND DISCUSSION

Brain responses correlated to DAI severity: Figure 3 shows a comparison of MPS in the subcortical white matter, corpus callosum and brainstem between the head rotation in the coronal, oblique and sagittal planes. The coronal rotation produced MPS of 45% and 54% higher for brainstem, 8% and 48% higher for corpus callosum, 13% and 22% higher for white matter as compared to those from oblique and sagittal rotations, respectively. Notice that MPS peaked at 13-15 ms, about 5 ms after the angular deceleration peaked, 9 ms after angular velocity peaked and 5 ms after head was stopped at 10-11 ms.

Figure 3: Comparison of MPS in various brain structures due to coronal, sagittal and oblique head rotation

The model predicted high MPS in the brainstem and corpus callosum structure, which suggested that more severe DAI was expected from coronal and oblique rotations as compared to that from sagittal rotation of similar magnitude. This localized tissue response pattern correlated well with the DAI pathological findings that damage to the brainstem and corpus callosum is responsible for the longer duration of coma experienced by the experimental animals than those with damage to the cerebral white matter. Figure 4 shows strain contours in the brainstem, corpus callosum and white matter from sagittal, coronal, and oblique head rotations.

The CSDM volume percentage at >0.5 MPS produced by a coronal rotation was 57% and 53% higher in the brainstem and 5% and 49% higher in the corpus callosum as compared to those by the oblique and sagittal rotations, respectively. Again, coronal and oblique loadings resulted in more strained brain tissues in the regions leading to more severe DAI pathology.

Figure 4: Comparison of MPS contours in various structures due to (a) sagittal, (c) coronal and (3) oblique head rotations

Tissue level thresholds for DAI: The MPS and CSDM analyzed not only clearly differentiated the three DAI grades associated with respective head rotation but also accurately identified the structures associated with each DAI grade level. The MPS and CSDM threshold for predicting DAI 0-1 injury was determined to be 1.3 and 50% (>MPS 0.5) in the brainstem, corpus callosum and cerebral white matter.

Assess the of human brain injury by tissue level thresholds vs. BrIC: The threshold level developed from above study was translated to the GHBMC human head model. Model predicted no injury for the volunteer cases and predict no DAI grade 0-1 for the NCAP cases.

On the other hand, the BrIC predicted 14% and 4% of AIS 4 brain injury, and 67% and 25% of AIS 2 brain injury for frontal and lateral volunteer tests, respectively. The BrIC predicted 8-12% of AIS 4 brain injury, and 46-60% of AIS 2 brain injury for all three NCAP cases.

CONCLUSIONS

The new FE primate head model developed in this study predicted the severity of axonal damages resulted from head rotations in different planes. The specific injury localization pattern was presumably dictated by the anatomy and material properties of the brain and is loading direction sensitive. The tissue-level thresholds established by the direct correlation of the monkey model prediction with the brain pathology found in the experimental animals can be used to assess the injury risk for humans. The human head model accurately predicted real world brain injury risk by using the tissue level thresholds. The BrIC significantly over predicted risk of brain injury and should be refined to improve its predictive capabilities. The rotational brain injury criterion is needed but BrIC needs to be further evaluated.

INTRODUCTION

This study develops a computational biomechanics model of the mouse brain that can be used to understand mechanisms of Traumatic Axonal Injuries (TAI). Mouse models are commonly used together with blunt impact experiments to understand the pathologies and neurophysiological deficits related to TAI [1,2]. However, the relationship between the motion of the mouse head and the biomechanics of the mouse brain is not well established. Here we develop a Finite Element Model (FEM) of the mouse brain with inclusion of axonal fiber tracts, and use this to compute the strain in the brain tissue in response to a range of head rotational impulse profiles. We then compare the predicted strains in the tissue to the strains observed in specific experiments on mouse brain sections during controlled rotations. This model of the mouse brain will be used in future multiscale efforts examining the relationship between brain biomechanics and TAI.

METHODS

The experimental brain tissue strain responses were obtained using biomechanical experiments on mouse head specimens (n=5) subjected to sagittal rotations. Prior to testing, mice were sacrificed in accordance with a Johns Hopkins University IACUC approved protocol, and their isolated heads were transected in the mid-sagittal plane to expose the intracranial contents. The transected mouse heads were potted in a custom 3D printed mold to control the skull rotation and attached to a drop tower base fixture for experimental testing (Figure 1). A drop mass was released from a predefined height and subsequently impacted a rotary fixture at the tower base. Upon impact, the potted specimen in the rotary fixture achieved a peak angular velocity of 100, 150 or 200 rad/s over a 90-degree rotation. The exposed mid-sagittal surface of the mouse brain was divided into 6 different regions and analyzed to

determine the regional tissue response. Digital Image Correlation (DIC) was used to obtain brain surface strains during accelerated and decelerated rotations of the transected mouse heads.

The mouse brain FEM was derived from an average Diffusion Tensor Imaging Atlas [3]. The anatomy of the model was generated by converting fractional anisotropy voxel data to hexahedral elements and white matter tractography to embedded truss elements, which is similar to the modeling approach by Garimella and Kraft [4]. Brain elements were modeled as an Ogden hyperelastic material with shear moduli described through a Prony series to incorporate viscoelasticity. The instantaneous shear moduli and the viscoelastic material properties of the brain tissue were calibrated to align the FEM strains to their experimental match pairs for 150 rad/s tests. Next, using these calibrated properties, simulations were performed at 100 rad/s and 200 rad/s to determine if the model accurately portrayed the experimental strains for separate loading conditions. The percent error between the FEM and experimental peak region-averaged maximum principal strains during the acceleration phase was used for analysis.

RESULTS

The transected mouse brain experiments showed that peripheral tissue regions sustained larger strains than the central regions for all three loading conditions. The left column of figure 2 shows the DIC-based strain profile for a 150 rad/s test in which the peak strains occur from 2.7 ms after rotation was initiated. The higher peripheral strains can also be seen at the same time period. For 150 rad/s tests, the average peak maximum principal strains were 5.7 ± 2.3 %, 7.6 ± 2.4 %, 7.9 ± 3.5 % and 8.6 ± 3.7 % for the Rostral Ventral (RV), Caudal Ventral (CV), Rostral Dorsal (RD) and Caudal Dorsal (CD) peripheral regions, while the Rostral Middle (RM) and Caudal Middle (CM) central regions were 4.4 ± 1.7 % and 3.9 ± 1.3 %, respectively (mean \pm 1 standard deviation).

Average experimental strain corridors for the three different rostral-based regions are shown in figure 3. Distinct acceleration-based and deceleration-based strains can be seen at $t = 2.7\text{ms}$ and $t = 13.3\text{ms}$, respectively.

For the mouse FEM calibration simulations at 150 rad/s, the instantaneous shear moduli of the cerebellum, cerebral cortex, and subcortical model regions were 3.10, 4.65 and 9.30 kPa, respectively. These brain tissue property values are within the published experimental ranges in the biomechanics literature. At 150 rad/s the best and worst fits occurred in the RD and CM regions, with peak strain percent errors of 6.1% and 106.8% during the acceleration phase, respectively. The same regional trends were observed when the calibrated material parameters were used to simulate 100 rad/s and 200 rad/s loading conditions.

DISCUSSION

This research developed a computational biomechanics model of a mouse brain for TAI mechanisms analysis by incorporating white matter fiber tracts and tissue strain validation. This study lays the groundwork for examining the *in-vivo* mechanical response of white matter fiber tracts and their corresponding pathological outcome, which is critical for understanding the link between primary insult and resulting neurophysiological deficits following injury. Future research would include examining various statistical measures for computational and experimental comparisons, FEM prediction of brain deformation under *in-vivo* experimental conditions, and correlation of brain strain responses to axonal injury outcomes [2].

INTRODUCTION

Traumatic brain injury (TBI) remains a leading cause of mortality and morbidity in the United States [1]. Experimental studies of the human head using cadavers [2] or live humans [3] have provided valuable insight into the injury etiology. However, ethical, technical and financial constraints limit the extent to which humans are tested to deduce the underlying injury mechanisms. In addition, individual differences in injury tolerance and concussion history and the relatively unreliable diagnosis could confound the interpretation of findings.

Controlled animal injury models such as rodent avoid these inherent challenges in humans, and they have been extensively used to study injury [4]. Similar to human head models, finite element (FE) models of the rat head also serve as an important bridge to relate impact kinematics, brain responses, and clinical indicators of injury. To date, a number of FE models of the rat head have been developed [5]–[8]. However, they have significant disparities in modeling. In particular, brain-skull interface condition has been defined variously as either sliding contact with [5], [8] or without separation [7], or via a layer of linear elastic material to simulate the cerebrospinal fluid [6]. The diverse brain-skull interface conditions could result in inconsistent brain mechanical responses under the same impact conditions.

In this study, we developed a Worcester Rat Head Injury Model (WRHIM) with high mesh quality to parametrically investigate the significance of brain-skull interface conditions using an *in vivo* rat head rotation impact profile. The results will provide important insights into further model improvement in the future.

METHODS

The Worcester Rat Head Injury Model (WRHIM) was created based on a brain mask segmented from the Waxholm Space Atlas of the Sprague Dawley Rat Brain [9]. The brain mask was imported into Geomagic (Geomagic, Inc., Research Triangle Park, NC) for surface

smoothing and further into TrueGrid (version 3.1.3; XYZ Scientific Application, Inc., Livermore, CA) for meshing. Multi-blocks for the cerebrum, cerebellum, brainstem, and spinal cord were created that conformed to the brain geometry (Fig. 1). The brain had a mass of 2.5g. Its mesh consisted of 202.6 k high-quality hexahedral elements and 210.6 k nodes with an average element size of 0.22 mm (± 0.05 mm). The mesh successfully passed a variety of quality criteria [10]. The brain was modeled by a first-order isotropic Ogden hyper-viscoelastic material derived from porcine brain tension test (strain rate of 30/s [11]).

Fig. 1 The Worcester Rat Head Injury Model (WRHIM) with high-quality hexahedral elements of the brain (element and node numbers of 202.6 k and 210.6 k, respectively, with an average element size of 0.22 mm).

Three brain-skull interface conditions were investigated. 1) A layer of cerebrospinal fluid (CSF; thickness of 0.1 mm) was created between the brain and skull by sharing nodes with its surrounding anatomical structures. A linear viscoelastic material identical to that in SIMon [12] was used to allow relative brain-skull tangential motion. 2) The CSF layer was modeled by a softer linear viscoelastic material identical to that of the GHBM [10], where the initial shear modulus was 0.005 times that of the SIMon counterpart. 3) A sliding contact allowing interface separation with a low friction coefficient of 0.05 was defined between the brain and skull, without CSF.

We simulated a rearward sagittal head rotation by prescribing the angular acceleration profile averaged from three tests on Sprague-Dawley male rats [7]. These experiments measured relative brain-skull displacements at different depths beneath the brain surface, which provided valuable data to validate rat head injury models. Reduced element integration scheme (C3D8R) along with relax stiffness hourglass control (a high scaling factor of 100) [13] was used to preserve simulation accuracy with improved efficiency. For each brain-skull interface definition, relative brain-skull displacements at the reported locations were extracted and compared with the experiment. Element-wise cumulative maximum principal strains over the entire simulation, regardless of time of occurrence, were also compared.

RESULTS

For all interface conditions, relative brain-skull displacements increased with the increase in the depth towards deeper brain (Fig. 2). The sliding interface condition and the stiffer CSF led to similar displacements. GHBMC soft CSF matched well with the experiments for locations at 0.5 and 1 mm below the brain surface. In the deeper brain (2 mm below surface), all displacements were overestimated relative to the experiments.

Fig. 2 (a) Rotational acceleration profile used in simulations; (b) Peak magnitudes of simulated relative brain-skull displacement for the three brain-skull interface conditions as compared to the experiments.

When rotational velocity reached its peak (0.5 ms), the patterns of relative brain-skull displacement were largely similar for the three brain-skull interface conditions (Fig. 3). However, they differed significantly when the rotational velocity crossed zero (1.8 ms). A soft CSF produced the largest x-directional displacement near the neocortex (circles). A soft CSF and the sliding interface produced similar z-directional displacement in the central brain larger than that from a stiff CSF (arrows). A stiff CSF also led to larger strains in the cerebrum than a soft CSF or the sliding interface especially near the surface (Fig. 4).

DISCUSSION AND CONCLUSION

In this study, we developed the Worcester Rat Head Injury Model (WRHIM) with high mesh quality for the brain. We investigated the significance of brain-skull interface conditions on the relative brain-skull displacement and brain strain using data from an *in vivo* rat head rotation experiment. Our results confirmed that the brain-skull interface conditions played an important role in model behavior.

A softer CSF layer appeared to allow a more reasonable relative displacement near the surface (Fig. 2), which may be preferred in subsequent model development. The overestimated large displacement towards the deeper brain regions may be mitigated by further considering material property heterogeneity and the inclusion of white matter anisotropy to provide reinforcement from the white matter fibers. The isotropic material properties used from porcine brain samples may be a limitation in this study, as new data on rat brain material properties [14] are emerging that account for regional brain property heterogeneity. Regardless, this study enhanced our understanding how to further improve the WRHIM in the future.

Finally, the *in vivo* impact accelerations simulated here were much higher than those in a recent rodent injury model simulating human concussion (magnitude of 1640–1730 krad/s^2 vs. 214–364 krad/s^2 ; impulse duration of 0.5 ms vs. 1.6–3.4 ms for the major acceleration peak [4]). It merits further investigation how the different choices of brain-skull interface conditions and brain material properties affect rat brain strains under these loading conditions that are more relevant to sports-related concussion.

Fig. 3 Patterns of relative brain-skull displacement on a representative sagittal plane for the three brain-skull interface conditions when the rotational velocity reached its peak magnitude (0.5 ms) and crossed zero (1.8 ms).

Fig. 4 Patterns of element-wise cumulative maximum principal strain over the entire simulation, regardless of the time of occurrence, on a representative sagittal plane for the three brain-skull interface conditions.

INTRODUCTION

Computational modeling is an incredibly powerful and widely implemented tool for the analysis of biomechanical systems. Advancements in computational power and software capabilities have allowed researchers to create high fidelity models of the human body capable of modeling the body's response to complex dynamic boundary conditions. These models provide advantages when compared to more traditional experimental methodologies, as it is often difficult and costly to perform cadaver experiments for all potential boundary conditions of interest. With all of their advantages however, computational models still have their caveats. One of these is the fact that a deterministic model only represents a single individual and cannot accurately predict risk of injury across a specific population group.

Across the human population, there exists a great deal of natural variation both in mechanical properties as well as musculoskeletal geometry. Material properties for example can have coefficients of variation (COV) of 80% or higher and these material properties play a critical role in determining if a response was injurious or not. Additionally, overall size of the subject as well as less obvious geometrical differences can have significant effects on the response and corresponding injury prediction. Exercising a computational model within a probabilistic framework helps to overcome these deficits and allows the model to account for these inherent variabilities. Rather than reporting an injury vs. no injury response as with a deterministic model, the probabilistic model will return a probability of injury relevant to the population of study.

METHODS

In this study we utilized a provided human torso model (Advanced Total Body Model, ATBM) (figure 1) within a probabilistic framework as a proof of concept for quantifying risk of injury due to behind armor blunt trauma. Boundary conditions consisted of 100 gram impactor with an initial velocity of 65.2 m/s centered over the heart. Boundary conditions directly replicated the experimental setup of a whole body PMHS experimental setup. Rib cortical bone strains were output and compared to a threshold [1] for definition of fracture.

Probabilistic analyses were set up for three versions of the model representing a 5th percentile female, 50th percentile male, and 95th percentile male. Material properties of the major structures in the models as well as the boundary conditions were all included in the probabilistic analysis. Distributions were defined for each model parameter to replace the individual values typically defined for a deterministic model. A Latin Hypercube sampling technique was then used to generate 300 random samples of each model size, each with a unique set of material properties and boundary conditions sampled from their respective distributions. Each sample was then run and post processed to export the element by element strains of the rib cortical bone. Combining these responses allows the calculation of the response distribution at each individual element, capturing the response variability that would be expected across a population.

Custom code was then written to take these response distributions and calculate the probability of injury on an element by element basis and produce a probability of injury contour plot (Figure 2). In order to accomplish this strain results for each element of interest in the model were output for every timestep, for every model sample resulting in nearly 1 billion data points. At each element and timestep

a deterministic injury prediction was made for a sample. Then the positive injury predictions were summed across the 300 samples. The percentage of models that predicted an injury for that element at that timestep defines the probability of injury. Rib fracture analysis was completed for all three subject sizes and compared quantitatively as well as qualitatively with the probability of failure contours.

Figure 1: 95th Male ATBM with skin, muscle, and adipose tissue hidden to expose ribs and organ detail

RESULTS

Figure 2 shows a comparison of the predicted rib fracture probabilities for the 5th percentile female and 95th percentile male. The female model had a 34% probability of at least one rib fracture, 1 17% chance of between 2 and 5 fractures, and an 8% chance of 6 or greater fractures. Conversely the 95th percentile male had a 10% chance of at least 1 fracture, a 5% chance of between 2 and 5 fractures, and a 0% chance of 6 or more fractures.

Figure 2: Example probability of injury contour for rib fracture. Contour colors represent the probability of fracture at each element. 95th percentile male results are on the left with 5th percentile female results on the right.

DISCUSSION

While time consuming and technically challenging, we believe that this probabilistic approach to injury prediction gives significant advantages to the traditional deterministic approach. Typically, a deterministic model is used along with a safety factor to determine if a piece of equipment or loading environment is safe. This approach while useful is a blunt tool that ignores the complex interaction human variability has on responses. In order to be sure something is safe large safety factors must be used which result in non-optimal designs which could be improved with a more complete understanding of their interaction with the human system. Additionally, probability of injury prediction results can be directly correlated to military incapacitation scales to convert the probability of injury into an incapacitation level probability. For example, the 5th percentile female results shown in figure 2 correspond to a 34% chance of a MCIS 1 injury, 17% chance of a MCIS 2 injury, and an 8% chance of a MCIS 3 injury. These injury codes offer an actionable interpretation of model results for military decision makers to use. A MCIS score of 1 corresponds to a minor injury with no loss to the mission, MCIS 2 is a moderate injury which leads to slight functional incapacitation but is not life threatening, and MCIS 3 is a serious injury that takes a soldier out of a mission but is recoverable [2].

By moving away from the blunt application of safety factors and deterministic models, a more refined understanding of how the human body interacts with the environment can be achieved. This will lead to optimized equipment designs that work across the variability of the human population, that are safer, lighter, and more comfortable. While the work done in this study is a proof of concept, when applied along with rigorous model development, verification, and validation methodologies the probabilistic approach to injury prediction will help better explain the “so what” of modeling results and help users make actionable decisions from those results.

INTRODUCTION

Traumatic brain injury (TBI) is one of the leading causes of death and disability of young people in the world [1]. The biomechanical properties of the brain tissue are of great importance to understand the injury mechanism and to improve prognosis of TBI [2]. While most of the brain tissue characterization studies focused on normal tissues [3,4], few studies investigated the injured brain [5].

Many different methods have been used to introduce injury in the animal model, such as lateral fluid percussion (LFP), weight drop closed head model, and controlled cortical impact (CCI) [6]. CCI can control the velocity, depth, duration, and site of impact accurately [7]. Therefore, CCI is one of the mostly used methods in animal models.

Many researchers have investigated the influences of the impact depth, velocity, or the geometry of impactor head [8,9]. They demonstrated that modifying these components influences the location and severity of injury. However, most studies adopted a certain impact angle when inducing the injury to brain and little is known about the viscoelastic properties of the brain tissue after the impact. Understanding the viscoelastic properties of the injured tissue under different impact angles can provide vital information for in-depth knowledge of the injury mechanism.

In this study, we induced brain injury using CCI and characterized the viscoelastic properties of injured tissue. The impact was introduced with 3 different impact velocities and 3 different angles. Viscoelastic properties of the injured region and its contralateral region were characterized and compared. Results could help guide further animal experiments and verify corresponding computer simulation models.

METHODS

A total of 54 adult mice of SPF grade were used in this study. A custom-built CCI device (Figure 1) with a cylindrical impactor head of

3 mm diameter was used to implement injury on the left hemisphere of each mouse. Craniotomy was carried out before introducing injury to the brain. The impact velocities (v) and impact angles (θ) were 0.6 m/s, 0.8 m/s, 1.0 m/s, and 0°, 30°, 50°, respectively.

Figure 1. Schematic drawings of the custom-built CCI device.

The mouse brain was taken out immediately for the indentation test after the impact. Coronal slices with a thickness of 3 mm were prepared for testing. With a custom-built indentation device, we conducted indentation test on the impact region and the corresponding contralateral regions on the other uninjured hemisphere. Up to 8% strain of the sample thickness was indented for the ramp-hold test.

We recorded the indentation force and computed viscoelastic properties by fitting the force with 2-term Prony series. A custom-written MATLAB (Mathworks, Natick, MA, USA) code was used for fitting and optimization to estimate the instantaneous shear modulus G_0 and long-time shear modulus G_∞ .

One-way and two-way ANOVA tests followed by a Bonferroni test (significance level of 0.05) for the G_0 and G_∞ values were used to evaluate the significances of the impact velocity and angle.

RESULTS

A typical force-time curve is shown in Figure 2(a). G_0 and G_∞ values were estimated by fitting 2-term Prony series. Variations of the experiment data were shown by plotting the 95% confidence interval region (Figure 2(b)).

Figure 2: (a) A typical experimental and fitted force-time curve. (b) A typical averaged relaxation curve. The red-shaded area indicates the 95% confidence interval.

Results showed that the average values for both G_0 and G_∞ are lower at impact regions for all impact velocities and angles (Figure 3). For G_0 , its average values will increase with the rise of impact angles on the uninjured hemisphere when velocity is low. But for G_∞ , we did not observe similar patterns.

Figure 3: Comparisons of the influence created by different impact angles and velocities in terms of (a, b) instantaneous shear modulus G_0 , and (c, d) long-term shear modulus G_∞ with 95% confidence interval. The test areas were (a, c) healthy contralateral regions, (b, d) injured regions.

The one-way ANOVA tests showed that G_0 at the impact region and the contralateral side was influenced significantly with the impact angle changing when velocity was 0.6 m/s. However, no significant differences were observed for G_∞ . The two-way ANOVA tests indicated

that the impact angle played a vital role in the changing viscoelastic properties of the injured tissue.

DISCUSSION

Many indentation tests have been used to investigate the viscoelastic properties of the mouse brain. Elkin et al. (2011) showed that the average instantaneous shear modulus was ~1 kPa, which is slightly lower than our results [10,11]. Lee et al. (2014) showed that the instantaneous shear modulus for the cerebral cortex and hippocampus region of healthy mouse brain was 3.8 kPa and 1.0 kPa, respectively [12]. Our results for instantaneous shear modulus are around 2.3 kPa for the cerebral cortex and 2.2 kPa for hippocampus regions, respectively. The differences are probably due to the rat model used and a higher strain rate. As for the injured brain tissue region, studies have shown an increased degree of damage with the increase of impact velocities [13]. In this study, we did not observe a significant influence of the impact velocity based on the measured shear modulus. This may be due to the comparatively lower maximum speed we chose.

It is important to highlight that no single animal model of TBI can mimic the entire spectrum of observations of human TBI. Our CCI model was carried out based on the exposed dura that required trephination of the skull. However, latest epidemiological researches have indicated that 85-89% of TBI patients were caused by blunt, closed head trauma [14]. Thus, a future study of the effect of an external impact on the closed animal skull, rather than the exposed dura will be meaningful. In addition, more CCI model configurations, e.g. a larger impact angle and a higher speed of impactor, may provide more information about the biomedical properties of brain tissues.

In this study, we characterized the viscoelastic properties of the injured brain tissue using a mouse CCI model. We observed that the impact angles had a more significant role than the impact velocities. These results showed that the proposed protocol of studying CCI injury using a mouse model is useful in probing the mechanism of brain injury and also provide insights into the influence of impact angle during CCI.

INTRODUCTION

During fetal development, the human brain forms complex cortical folds and axonal connections (Fig. 1). Abnormalities in cortical folding, as well as disorders including epilepsy and autism, have been linked to abnormal connectivity [3]. However, the physical and biological mechanisms underlying this linkage remain unclear.

Physical and biological evidence suggests that brain folding, or wrinkling, occurs as the outer cortical surface (prospective gray matter) grows faster than the underlying subcortex (prospective white matter) [4], and most computational models of folding approximate subcortical tissue as a passive, nongrowing substrate [5]. However, since axons can elongate in response to tension, several models have hypothesized that the prospective white matter may also grow in response to mechanical feedback [6-7]. These studies elucidated effects of certain subcortical properties (eg. stress-dependent growth rate, anisotropic axon orientations) on folding, but – to date – none have considered the effect of folding on subcortical axon organization.

In this study, we focus on evolution of subcortical axon fibers, which develop during and after the period of brain folding in human. We find that only a model incorporating mechanical feedback, anisotropy, *and* evolving axon density (a novel aspect of our model) accurately predicts axonal organization during early brain development.

METHODS

We developed an axisymmetric model in COMSOL Multiphysics 5.3a, starting from a hollow spherical geometry to approximate the initial curvature and internal lumen of the early brain. We represent brain tissue as a nearly incompressible, modified neo Hookean material with uniform, isotropic stiffness.

As described in [6], we defined the total deformation tensor such that $\mathbf{F} = \mathbf{F}^* \cdot \mathbf{G}$, where \mathbf{F}^* represents elastic deformation and \mathbf{G} represents growth. To account for anisotropic (orthotropic) and stress-dependent growth effects, we defined $\mathbf{G} = G_1 \mathbf{e}_1 \mathbf{e}_1 + G_2 \mathbf{e}_2 \mathbf{e}_2 + G_3 \mathbf{e}_3 \mathbf{e}_3$ where the growth rate in each direction ($i = 1, 2$ or 3) at time t is:

$$\dot{G}_i = [af_i(\sigma_i - \sigma_0) + g_{c,i}]G_i \quad (1)$$

For each direction, $\sigma_i = \sigma_i(\mathbf{F}^*)$ is the nondimensionalized Cauchy stress. In this study, we assumed a target stress of $\sigma_0 = 0$ for all cases.

At early stages of development, axons constitute a relatively small proportion of the subcortical tissue. Therefore, we assume stress-dependent growth (axonal elongation) is proportional to both the stress-dependent growth rate (a , units 1/T) and volume fraction of axonal fibers in the i -direction (f_i), which accounts for both orientation and density. Constant growth rate $g_{c,i}$ (units 1/T) is set to zero in subcortical layers and the radial direction ($i = 1$), while a is set to zero in the cortex.

Figure 1: Brain folding and connectivity over development. A. Cortical surfaces from [1]. B. Subcortical tractography from [2].

If stress-dependent growth is primarily growth of axons, but axons only represent a fraction of the total tissue, axon volume fractions must evolve over time as shown for f_1 :

$$f_1(t) = \frac{f_{1,0}V + \Delta G_1(t)V}{G_1(t)G_2(t)G_3(t)V} = \frac{f_{1,0} + (G_1 - 1)}{G_1G_2G_3} \quad (2)$$

where V is the initial unit volume and $f_{1,0}$ is the initial volume fraction of axons in the radial direction. A similar equation can be written for axon fractions in tangential direction, f_2 . For simplicity, here we do not consider the axisymmetric direction ($f_{3,0} = 0$).

RESULTS

Since the brain exhibits a generally radial orientation prior to folding (Fig. 1B), we first considered the case where $f_{1,0} = 2f_{2,0} = 0.2$. As shown in Fig. 2A, we let a small region of cortex grow slightly faster (green) to break symmetry and initiate folding. Folding triggers stress-dependent radial growth beneath gyri and tangential growth beneath sulci, consistent with past models [6]. However, by specifying axon volume fractions, we note that this results in accumulation of radially-oriented axons beneath gyri (projection fibers) and tangentially-oriented axons beneath sulci (short association fibers).

In our hollow model, we also notice accumulation of tangential fibers along the ventricular (inner) surface, similar to long association fibers found deep in the white matter.

Figure 2: Axisymmetric model of cortical folding and evolving axonal organization. A. Initial and final geometries. B. Evolution of radial axon (projection fiber) density with folding. C. Evolution of tangential axon (association fiber) density with folding.

Subcortical anisotropy can, in turn, influence subcortical growth and patterns of folding [7]. Therefore, we also considered the geometric consequences of an initially isotropic subcortex ($f_{1,0} = f_{2,0} = 0.15$) or constant axon volume fractions ($f_1 = 2f_2 = 0.5$ or $f_1 = f_2 = 0.4$, similar to previous models). Notably, models with constant volume fractions showed less elaborate folding, and models with isotropic subcortical growth showed increased expansion of the ventricle (Fig. 3).

DISCUSSION

In this study, we build upon previous models of cortical folding to understand development of the underlying substrate, the prospective white matter. Consistent patterns in axon organization have been reported for many years [8-9] and represent neural circuits integral to brain functions such as perception, movement, and cognition. Here, we propose a simplified model that generates structures resembling short-

range (U-shaped) association fibers, long-range (deep tangential) association fibers, and projection (radial) fibers. Future work will test these concepts on a realistic, 3D geometry for comparison to observed tractography in human, as well as other species (including lissencephalic species, for which U-shaped fibers would not be predicted).

Despite a clear correlation between brain folding and subcortical organization, past theories have failed to resolve the question: Does axon connectivity cause folding, or does fold formation influence axon connectivity? Most studies have focused on the former. Van Essen [3] proposed the well-known axon tension hypothesis, in which axons pull the folds together, but this was shown to be inconsistent with measured stresses in the developing brain [10]. More recently, Holland et al. [7] proposed a mechanical feedback model in which pre-existing axon orientation (eg. U-shaped association fibers) guides folding, but this theory depends on axon orientations measured after folding. Our results do not disprove the possibility of anisotropy-induced folding, but suggest an alternative (or complementary) mechanism of folding-induced anisotropy, consistent with the general trajectory of folding and axon development in human.

INTRODUCTION

Intracranial aneurysms (ICA), or brain aneurysms, are abnormal focal dilations and weakenings of arterial blood vessels in the brain with a prevalence of 0.5-6% in adults [1]. 50-80% of subarachnoid hemorrhage (SAH) cases result from the incidental rupture of an ICA. These rupture events, accounting for 5-8% of all strokes, are most common between ages 40 and 65 and are associated with a mortality rate as high as 40% within the first week [2-4].

Aneurysm treatment therapeutics have evolved quickly with the introduction of Guglielmi detachable coils (GDC) and flow diverting stents. However, challenges still remain for the treatment of both giant and irregularly shaped aneurysms, associated primarily with aneurysmal recanalization and incomplete occlusion [5,6]. One potential way to address these shortcomings is with the use of an expandable shape memory polymer (SMP) foam device. Such devices would take advantage of the shape recovery properties of the SMP and undergo a large, controlled expansion from a compressed state to completely fill the patient's aneurysmal space.

The use of SMP-based devices for the treatment of neurovascular pathologies isn't a new concept. Various SMPs, each with a unique thermomechanical behavior, have been investigated for their use in clot removal, vascular stenting, and aneurysm occlusion [7]. Very few of these investigations, however, detail the process of synthesizing a polymer with desirable characteristics for use in medical device design. In this study, we demonstrated synthesis procedures for both pristine and porous aliphatic polyurethane SMP. By tailoring the ratios between monomer components, a wide range of glass transition temperatures (T_g) and mechanical properties of the SMP could be obtained. We present investigations into the thermo-mechanical properties of a novel SMP foam manufactured using aliphatic polyurethane SMP and a sugar template scarification technique. The results of the investigation are

discussed in terms of their efficacy for use in the endovascular embolization treatment of intracranial aneurysms.

METHODS

Twelve different SMP compositions were synthesized by varying the ratios of the three monomers (**Table 1**): (i) Hexamethylene Diisocyanate (HDI), (ii) Triethanolamine (TEA), and (iii) N,N,N',N'-tetrakis (hydroxypropyl) ethylenediamine (HPED), obtained from Sigma Aldrich without modification. The monomer ratios used during synthesis are summarized in Table 1.

Table 1: Monomer composition table w/ synthesis procedure details

	Monomer Content (%)			Stirring Time (sec)	Heating Rate (°C/hr)
	HDI	HPED	TEA		
SMP1	53.5	46.5	0.0	150	30.0*
SMP2	53.9	44.5	1.6	170	29.6
SMP3	54.3	42.5	3.2	200	29.2
SMP4	55.1	38.4	6.5	225	26.4
SMP5	56.0	34.1	9.9	240	25.2
SMP6	56.9	29.7	13.4	255	23.6
SMP7	57.8	25.1	17.1	270	21.1
SMP8	58.8	20.4	20.8	285	18.5
SMP9	59.7	15.6	24.7	310	15.9
SMP10	60.7	10.6	28.7	330	12.5
SMP11	61.8	5.4	32.8	350	9.6
SMP12	62.3	2.7	35.0	445	8.5

To synthesize pristine SMP, the monomers were combined in a glove box under dry nitrogen atmosphere to prevent moisture uptake. Once combined, the monomers were mixed gently with a magnetic stir bar for the times specified in **Table 1** until optically clear. The mixture was transferred to silicone molds and degassed 5 times in a vacuum oven to -0.8 torr. The molds were then heated at a low vacuum to 130 °C according to Table 1 and allowed to cure at that temperature for 1 hr.

The glass transition temperature (T_g) of each composition was determined using both differential scanning calorimetry (DSC) and dynamic mechanical analysis (DMA). A desirable T_g (39°C) was selected from the composition table, and used in the synthesis of foam samples. To create SMP foam, the liquid monomer mixture was cast over a rectangular sugar scaffold with uniform grain size and allowed to cure following procedures for pristine SMP synthesis. After curing, excess SMP was cut away, and the sugar was dissolved out of the solid using water bath sonication at 40 °C

The mechanical properties of pristine SMP samples were characterized using uniaxial tensile testing at T_g+10 °C. An Instron uniaxial testing device was used to conduct both failure and cyclic testing. Specimens were tested within a heated environmental chamber and allowed to reach equilibrium with the chamber for 10 minutes before testing. Failure testing was performed first on pristine samples at a rate of 2mm/min. Cyclic tests followed, and consisted of 3 cycles of preconditioning at 25% failure strain and 10 testing cycles at 50% failure strain. The SMP foam samples underwent uniaxial compressive testing, at room temperature, T_g , and $T_g+10^\circ\text{C}$, also using the Instron uniaxial testing device.

RESULTS

We were able to synthesize pristine SMP samples with T_g 's ranging from 87 °C to 33 °C. Failure stresses of the pristine SMP samples at T_g+10 °C ranged from 3.34 MPa to 6.88 MPa, and failure strains ranged from 16.2% to 54.4%. We also demonstrated an SMP foam with good shape recovery within a minute of heating above T_g (Fig. 2). Both the pristine and foam samples exhibited a significant reduction in elastic modulus when heated above their respective T_g , as was expected. The measured elastic modulus of the SMP foam was 2.7 MPa at room temperature and 0.23 and 0.18 at 39 °C (T_g) and 49 °C (T_g+10 °C) respectively. The elastic modulus of the pristine samples decreased initially but stabilized after 3-4 loading cycles (Fig. 1c). Both pristine and foam samples exhibited a large stress reduction during cyclic loading (Fig. 1b & Fig. 3), with the maximum stress decreasing by 7% and 17% over 10 cycles at T_g+10 °C for the pristine and foam samples respectively.

DISCUSSION

The objective of this project was to conduct a thorough characterization of an aliphatic polyurethane SMP material to evaluate its potential for applications in medical device design, specifically for the treatment of intracranial aneurysms. We showed that we can vary the T_g of the SMP material to achieve a composition which initiates shape recovery between human body temperature (37 °C) and the threshold for tissue damage (45 °C), which is ideal for applications in the human body.

For endovascular delivery methods, compressibility is an important factor as it allows large devices to travel through narrow arteries to their target, where they will be deployed. While the pristine form of this material was qualitatively observed to have limited compressibility, we demonstrated that the material can be synthesized as a foam with regular porosity that can withstand much higher compression ratios. Cyclic testing revealed a significant stress relaxation behavior, which is a concern when considering applications where an implanted device is expected to perform a permanent structural role within the body. Future investigations could investigate the relationship between pore size in the SMP foam and the material's mechanical properties with a specific focus on compression ratio. Constrained and unconstrained shape recovery characteristics will also be important topics for future study

Figure 1: Representative cyclic mechanical testing results (SMP3) when tested at 50% of the observed failure strain (T_g+10 °C) showing: (a) the relaxation trend in the peak stress with an increasing # of cycles, (b) the increase in the cumulative stress reduction and (c) the convergence of the elastic modulus with an increasing # of cycles.

Figure 2: Shape recovery of the porous SMP foam in response to direct heating above the SMP's T_g .

Figure 3: Mechanical characterization of the fabricated SMP foam under cyclic compressive load conditions: mechanical response of the SMP foam at T_g and $T_g + 10$ °C under cyclic compressive loading.

INTRODUCTION

Congestive heart failure (CHF) is a progressive disease that affects millions of people worldwide.¹ More than 5 million Americans suffer from CHF and 670,000 new cases are diagnosed each year.¹⁻³ Health care costs for these patients continues to grow every day and currently amounts to approximately \$35 billion annually.⁴ In the chronic stages of CHF, treatment consists of pharmacological therapies, intravenous support, and inevitably a heart transplantation, when a patient qualifies and a donor heart becomes available.¹⁻³ In the U.S.,

over 3,000 patients are on the waiting list at any given time, however, on average only 2200 transplants take place in a year. Greater than 20% of patients on the heart transplant waiting list die due to lack of available donor hearts. The lack of donor hearts and the increasing need for ventricular support has supported the design and development of alternative methods of support, such as mechanical circulatory devices, including total artificial hearts (TAHs) domains that are combined under one pump and ventricular assist devices (VADs) for adults and pediatric

patients.⁵ As a new invention, we are developing a novel TAH (*Dragon Heart*). This TAH (**Fig. 1**) occupies a space of 50 mm x 50 mm. This new device utilizes the inner hub space of a centrifugal VAD by placing an axial pump through the center. The more compact size of this device has less foreign surface and therefore reduces a risk of infection and an immune response. The impellers of the pumps will be levitated in a magnetic field per 3rd generation technology. Building on a prior design effort⁵, we present the computational studies, and prototype testing of the centrifugal and axial flow blood pumps that constitute the *Dragon Heart*.

METHODS

Design Approach: The axial flow blood pump was designed to support the pulmonary circulation and to generate 3 L/min of flow with a pressure rise of approximately 20 mmHg. The centrifugal flow blood pump was designed to support the systemic circulation and to produce 3 L/min of flow with a pressure rise of greater than 95 mmHg. Both pumps were designed to have an operating rotational speed less

Fig. 1: Continuous Flow Heart Pump. 1) Upper Housing, 2) Centrifugal Left Ventricular Assist Device (LVAD), 3) Axial Right Ventricular Assist Device (RVAD), and 4) Lower Housing. This configuration comprises two separate pump and ventricular assist devices (VADs) for adults and pediatric

Fig. 2: Centrifugal LVAD and Axial RVAD of the Dragon Heart. Analyzed through computational studies and prototype testing.

than 12000 RPM, a maximum shear stress less than 425 Pa, and a blood damage index less than 2 %.

We used computer aided design (CAD) software to create a 3-D model of the pumps (**Fig. 2**). The geometries were imported into ANSYS workbench, where they were meshed utilizing TurboGrid and ANSYS Mesh. The mesh was refined through grid independence studies and achievement of quality metrics. The mesh was then imported into CFX-Pre where boundary conditions were set. A viscosity of 3.5 centipoise was assigned with a design of 1050 kg/m³ to represent the fluid properties of blood. The impellers were set in rotating reference frames, while the inlet and outlet volutes, inducer, and diffuser domains were defined in the stationary reference frames. The models were then imported into CFX Solver for simulation. We analyzed the pressure generation, fluid forces on the levitated impellers, particle resonance times and scalar stresses for blood damage studies. In parallel, we used the CAD models to 3-D print prototypes of the pumps for testing. The models were then placed in our hydraulic flow loop using a shaft-driven configuration and evaluated for pressure/flow (P-Q) profiles.

RESULTS

Fig. 3A illustrates the pressure generation from the computational analyses and prototype testing for the centrifugal and axial blood pumps. The prototype of the centrifugal pump slightly outperformed the computational predictions; in contrast, the axial flow computational studies outperformed the prototype. Both design achieved their target performance goals. **Fig. 3B** displays the scalar stress approximations for the centrifugal and axial designs. Higher stress levels were found at the leading edge, blade tip clearance, and the cutwater region in the centrifugal pump. Similarly, higher fluid stress levels were simulated along the blade tip surface, leading and trailing edges of the impellers and in the diffuser region. The scalar stress levels were found to be lower than the target cutoff level. Radial and axial fluid forces were estimated to be less than 0.5 N and 10 N, respectively.

DISCUSSION

In this study, we advanced the design of the *Dragon Heart*. The computational studies revealed that these pumps were able to achieve the pressure and flow requirements to sustain patients with CHF. Both pump demonstrated the ability to impart energy to the blood in the systemic and pulmonary circulations. Computational data trends followed theoretical expectations, whereby faster rotational speeds produced higher pressures and higher flow rates yielded lower pressures. Shear stresses and blood damage estimations were below threshold levels and met requirements. Radial force estimations were low given the axi-symmetry and radially centered position. Similarly, axial force estimations for the axial blood pump remained less than 10 N and followed theoretical trends whereby higher axial forces occurred with higher pressure rises and faster speeds.

When comparing the computational and experimental data, we observed that the centrifugal prototype slightly outperformed the computational data (less than 5% difference). In contrast, the computational predictions for the axial pump significantly outperformed the experimental data for the prototype. Experimental data was both repeatable and reproducible for both prototypes. There are several factors that contribute to the deviation between experimental data and computational modeling. First, there is a geometric mismatch between model and physical prototype. During testing of the axial and centrifugal prototypes, shafts were used to drive rotation, but shafts were not included in the computational study since the device will incorporate a magnetic suspension. Parts of the shafts were always exposed to the analog fluid during experiments and likely contributed to disturbed flow conditions. In particular, a shaft sleeve was employed

at the outlet of the axial prototype, which reduces the effective fluid domain and compresses the flow at the outlet, as compared to the

Fig. 3: Centrifugal LVAD and Axial RVAD of the Dragon Heart. Analyzed through computational studies and prototype testing.

computational predictions. Thus, this would have contributed to the lower experimental pressures that were measured. During the manufacturing of the prototypes, rotor clearances were made 15% larger to ensure no impeller touchdown. In addition, the 3-D printing methods have an accuracy of 0.001" per linear inch. All of these factors together contributed to the deviation in computational and experimental findings.

CONCLUSIONS

This study describes the next phase of the pump designs in the development of the *Dragon Heart*. Computational studies and prototype testing revealed that the pump geometries achieved targeted design requirements. Future work will include the design of the motor and magnetic suspension, MRI studies to map the flow of the pumps, hemolytic experiments, and acute animal studies.

INTRODUCTION

Blood pumps expose blood to high stresses, causing blood damage (hemolysis and platelet activation), which causes in thrombosis and leads to thrombo-embolic complications and device failure. Blood damage is a serious problem in both centrifugal and roller blood pumps [1,2]. For example, 18% of LVAD patients suffer from hemolysis, which markedly decreased survivability from 89% to 39% at 1 year [2]. In order to reduce the blood damage, the friction force experienced by blood should be reduced. Superhydrophobic (SHP) surfaces have a demonstrated capability of reducing the flow drag [3]. Micro-/nano-scale structures on SHP surface would reduce the liquid-solid contact by trapping a thin layer of air on the surface, and blood flow over a SHP surface would experience a smaller friction force, thus reducing mechanical stress-induced hemolysis and platelet activation. We have recently provided a demonstration that a superhydrophobic coating can reduce damage to porcine blood in an in vitro flow loop [4].

Here, we report a novel sand-casting technique to prepare SHP surfaces using biocompatible components such as PDMS and silica nanoparticles. The resulted surface is SHP, has enhanced blood repellency, can reduce the water drag forces by up to 72% compared to plain PDMS, has exceptional durability, is flexible and shape-customizable, and can be used on blood pump housing or roller pump tube. Our SHP surface improves on existing SHP surfaces reported in the literature, as they either have durability problem or could not be conveniently shape-customized.

METHODS

The SHP item is prepared in four steps (Figure 1). First, SiO₂ nano particles were functionalized to be SHP. Second, a composite of the SHP SiO₂ & PDMS was prepared. Third, a SHP SiO₂ “nano-sand”

mold for casting the final SHP item was fabricated by pressing the prepared composite into a confined cavity under pressure. The mold can have a 3D complex shape. Finally, a SHP item was casted using the prepared mold. Liquid repellence was tested using water and everyday fluids. Porcine blood was used to test the blood repellence property. As blood damage is related with the shear/friction force, friction forces induced by water jetting on our casted sample have been measured. Mechanical durability of the prepared sample was evaluated. Flexibility and 3D shape-customizability have also been demonstrated.

Figure 1 The processes of sand-casting SHP items. (a) Synthesize HP-SiO₂ nano-particles, (b) prepare HP-SiO₂ & PDMS composite powder, (c) prepare the SHP SiO₂ mold, (d) cast SHP items using the prepared SHP mold.

RESULTS

As shown in Figure 2 the casted sample is super-hydrophobic (water contact angle = 158°, sliding angle < 10°), and is blood repellent (blood contact angle = 150.6° ± 1.44°). When a porcine blood droplet was dispensed onto the surface, it rolled off without

leaving any blood stains (Figure 2b). In comparison, on PDMS or PC surfaces, which are common materials in blood pumps, blood would adhere and stain the surfaces (Figure 2c, d). Durability performance of the casted sample are shown in Figure 3a and b, demonstrating superior durability compared to alternative SHP coatings. After 5 hours of high-speed (9.7 m/s) water jetting (Figure 3a), or after 40m worth of abrasion with the #800 grit sandpaper under 10kPa of pressure (Figure 3b), the contact angle maintained above 150°. In contrast, spray-coated and dip-coated SHP samples lost their high contact angle quickly in the same tests. The superior durability was due to the thicker SHP functional layer during the sand-casting, and this thickness could be controlled by varying the sandcasting seepage time. Figure 3c demonstrates that the casted sample is flexible and deformable, and that repeated deformation doesn't compromise its SHP properties. These findings reveal that the casted sample can be durable enough for use as tubings or blood pumps for procedures such as cardiac surgery, which lasts for a few hours.

Figure 2 (a) Water contact angle and quick roll-off of a water droplet on the casted SHP sample; (b) blood contact angle of the casted SHP sample, and blood rolling off the casted sample without leaving stains; (c) blood contact angle of PDMS, and blood flowing off PDMS while leaving stains; (d) blood contact angle of polycarbonate, and blood adhered on the surface.

Figure 3 (a-b) High speed water jetting test, and sandpaper abrasion test; (c) demonstration of flexibility and durable SHP

after repeated bending; (d) drag reduction test showed that the SHP surface experienced much lower drag forces compared with non-SHP PDMS at water jetting velocities smaller than 4.2 m/s. (e) Casting 3D SHP components of complex geometries.

Moreover, the casted sample can evidently reduce the flow drag by up to 72%, when exposed to water jets of less than 4.2 m/s velocities (Figure 3d). This drag reduction ratio was similar to that for SHP aluminum surfaces [3], but higher than the salinized copper surface [5]. Drag reduction was due to two factors. First, SiO₂ particles functionalized with -CH₃ groups had reduced surface energy and repelled water [6,7]. Second, multi-scale micro-structure formed on the casted surface would help generate micro air-pockets on the surface, reducing liquid-solid contact and thus fluid friction. As blood damage is related with the friction induced shear force, the demonstrated SHP and drag reduction capability of the casted surface will be promising in reducing the blood damage for blood pump applications. Also, the developed sand-casting method is versatile and can be customized into 3D SHP items of complex geometries (Figure 3e), which has been demonstrated by prototyping pyramid, dome-shaped, and rectangular SHP items. With these demonstrated advantages, the sand-casting technique developed in this study can be readily scaled up to fabricate a flexible roller pump tube for the heart lung machine or a pumping housing for the centrifugal blood pump applications.

DISCUSSION

The method developed in this study has evident comparative advantages over the reported methods for preparing SHP surfaces. As for the surface modification techniques, such as lithography, nano-/micro-imprinting, etching, spray or dip coating, particle deposition, atomic layer deposition, liquid flame spray et al., they generally prepare coating with a thin SHP layer which would be vulnerable to mechanical damage and thus is not durable. In contrast, the sand-casting method developed in this study can prepare a very durable SHP surface, owing to the high bonding strength of HP-SiO₂ particles on the casted surface and the existence of a sub-surface SiO₂ layer with a controllable thickness. Also, the casted SHP items reported in this study are SHP as prepared, requiring no surface abrasion, and can thus be conveniently customized into complex 3D geometries. Therefore, in this study, a general sand-casting method has been developed to prepare durable, flexible, 3D-geometry customizable, fluorine-free, superhydrophobic and blood-repellent components using bio-compatible materials. With all these features, the developed methods can be readily used to reduce the blood damage in biomedical devices such as the roller blood pump and the centrifugal blood pump.

INTRODUCTION

Arterial stiffening occurs naturally with age as elastin degrades and collagen content increases [1]. Increased stiffness, synonymous with decreased capacitance, can lead to hypertension as well as an overall higher risk of cardiovascular disease (CVD). Over one third of the U.S. population has hypertension, with less than half of patients effectively treated by medical therapy [2]. It is estimated [3] that 25% of all cardiovascular events are attributable to hypertension. Despite the severity of hypertension, treatment options are limited to medication and lifestyle changes.

In this work, we investigate the potential use of a compliant aortic implant, inspired by existing stent-grafts, to therapeutically reduce blood pressure in patients with uncontrolled hypertension. Aortic stent-grafts (SG) offer a minimally invasive, endovascular alternative to open surgery for patients with aortic conditions such as aneurysm or dissection. Although current SGs offer good short-term outcomes, there is growing evidence that the compliance mismatch between SG and native vessel may contribute to complications including new aortic tears, persistent hypertension, and pseudoaneurysm [4-7]. A stent-graft that mitigates these problems by maintaining or increasing aortic capacitance would also have the potential to reduce the risk of hypertension-related conditions.

We have developed a double-walled stent-graft (DWSG) design, which incorporates capacitance through a compressible gas layer within a stiff outer wall. To simulate the effect of the DWSG on blood pressure, a prototype was placed in an experimental flow model of the arterial system. Next, the prototype was isolated and inflated, to quantify the capacitance C (Eq. 1) over a range of pressures.

$$C = \frac{d(\text{lumen volume})}{d(\text{lumen pressure})} \quad (1)$$

An axisymmetric finite element (FE) model of the DWSG was developed for comparison to the inflation results. From the FE model, both the capacitance and Poiseuille flow resistance of the DWSG were

obtained; these values were put into a lumped parameter model of the flow setup for direct comparison of the pressure profiles.

METHODS

Flow Loop Experiment (FLE): A model of the aorta was built using latex and PVC tubing (Fig. 1a). The DWSG was constructed using thin latex tubing for the inner membrane and a stiff 1" PVC tube for the outer wall. The prototype was placed in the descending aorta section and filled with a known quantity of gas through a valve in the outer wall. A pump provided a pulsatile flow profile at 60 beats per minute, and a needle valve supplied peripheral resistance downstream of the aorta. Pressure was recorded upstream of the stent-graft for cases with different quantities of gas in the DWSG. The pulse pressure was defined as the difference between the peak and minimum pressures in each cycle.

Figure 1: (a) Flow loop diagram; (b) Lumped parameter model: variables correspond to elements labeled in (a). R_c , L_c are from four-element Windkessel model [8].

Inflation Experiment: The DWSG prototype was placed into a rigid, closed test system. After a known charge of gas was added to the membrane layer, the lumen was filled with water through valve-controlled ports. Additional water was added to the lumen in 1mL increments while the pressure was recorded. Six different gas charges from 10 to 70mL were tested, with the specified volumes referring to

the gas volume at atmospheric pressure. Although CO₂ gas would be used in the final device, tests were conducted with ambient air, due to its abundance and the similar behavior of both gases at low pressures. After each test, the lumen was emptied of water, then the gas was removed and measured to confirm that none had escaped during the test.

FE & Ideal Gas Law Model: An axisymmetric model of the DWSG membrane was created (Fig. 2a), to evaluate how it deforms in response to pressure, in the absence of a confined gas. This result was combined with calculations from the ideal gas law to understand how the gas-filled membrane layer should respond to changes in lumen pressure.

Figure 2: (a) Prestretch and inflation steps of DWSG inflation FE model; (b) Deformed FE mesh at different pressures. Rigid outer wall is not modeled in the simulation but is shown for clarity.

In Abaqus (Dassault Systemes), the elastic membrane was modeled using membrane-type shell elements. An axial prestretch was applied to the membrane, simulating the stretch that is imposed during prototype construction. A series of static pressures was applied to the stretched membrane, with the ends held fixed at their prestretched positions. The resulting volume in the gas layer was calculated in MATLAB (Mathworks) using the deformed membrane coordinates and the fixed position of the outer wall. To account for the effect of the enclosed gas, the intersection points were found between pressure-volume curves for the deformed membrane and for a fixed charge of an ideal gas. The output of this calculation was the relationship between the luminal pressure and the volume of liquid in the DWSG lumen. The derivative of this relationship (dV/dP) was defined as the capacitance of the DWSG. Additionally, the Poiseuille resistance of the DWSG was found by integrating Poiseuille's law over the axial length.

Lumped Parameter Model: A model of the experimental flow loop setup was created (Fig. 1b) to compare pressure profiles from the FLE to those predicted by capacitance and resistance values obtained from the inflation and FE models. The lumped parameter model was based on the four-element Windkessel model [8], but instead of a single capacitor, capacitor-resistor pairs were used to represent three distinct segments of the aorta. A flow rate was prescribed to match pump output from experiments, and peripheral resistance was tuned to match mean pressure from the flow loop with a rigid stent-graft segment. All parameters were held constant across runs, aside from R_2 and C_2 , which were specified based on the FE or inflation results. Changes in pulse pressure from the rigid stent-graft case were compared among the models and experiment.

RESULTS

The slope of a linear fit was used to estimate the capacitance in both the FE and inflation data. The fit only considered pressures over 40mmHg, since lower pressures are not physiologically relevant in the aorta. Resistance from the DWSG inflation could not be calculated because membrane buckling inhibited measurement of the lumen radius from photos. Radius of the lumen in the FE model was taken as the x-position of the membrane at each axial position.

Capacitance increased with gas charge in both the inflation and FE model for smaller gas charges (Fig. 3a). The FE model always under-predicted capacitance, and at higher charge it showed a decrease in capacitance, likely as the hyperelastic membrane entered its higher stiffness regime. Resistance increased sharply with charge, due to a decreased lumen radius with higher gas charge (Fig. 2b) and the fact that resistance is proportional to $1/r^4$.

Figure 3: (a) Capacitance and resistance measurements compared for FE and inflation; (b) Reduction in pulse pressure for flow loop measurements and lumped parameter predictions.

Capacitance estimates from the inflation and FE model, and resistance from only the FE model, were put into the lumped parameter model, and the resulting pulse pressures are shown in Figure 3b. Predicted PP followed the same trend as measurements from the flow loop, but the predictions showed a much greater reduction in PP than the flow loop for all gas charges.

DISCUSSION

This work demonstrates the DWSG's potential to reduce lumen pressure when compared to a rigid stent-graft. Static measurements of DWSG capacitance and resistance, when used to predict pressures seen in the flow loop, overestimated the pressure reduction at different gas charges. This result suggests that inertia of the blood and viscosity of the gas, which were neglected by the FE model and inflation, may have significant effect on stent-graft performance.

One parameter that may be important to investigate in future work is the ratio of pressure change across the membrane to pressure in the gas (Fig. 4). As the ratio decreases toward zero, a change in lumen pressure will cause a larger change in gas volume. Larger gas charge, though exhibiting large capacitance, led to a higher ratio over the relevant range of lumen pressures. A very small gas charge actually led to negative ratio values; at sufficiently small charge, the volume of gas was always below that of the unpressurized, prestretched membrane, so the gas was always experiencing a negative pressure.

Figure 4: Ratio of pressure across DWSG membrane to gas pressure, for FE model.

INTRODUCTION

The respiratory system's structural complexity makes it difficult to deliver medication to specific locations. Engineers, computational scientists, experimental biologists, and clinicians have been working together to produce devices for precise drug delivery. One such scenario where medication must be delivered to a complex respiratory tract is for the treatment of aspergillosis in avian patients. When brought into captivity or where environmental conditions are suitable, birds are susceptible to fungal infections, specifically with *Aspergillus* spp. This disease can be fatal for the host, as it manifests and grows in several parts of the respiratory system, including the sinus cavities, trachea, and pulmonary parenchyma and air sac membranes [1]. Direct inhalation of the anti-fungal medication amphotericin B has been used as a treatment protocol with limited success [2]. A precise delivery of medication to the lung and air sac membranes of birds is still an open research area.

Additionally, several key device development considerations pose challenges to drug delivery devices. Whole body exposure to aerosolized medication can be toxic, expensive and inefficiency uses of large quantities of drug. In the case of avian patients, patient training to use drug delivery devices is challenging and repeatable treatments in the wild pose greater challenges for dosing accurately. For intratracheal devices, smaller lung geometries also complicate the aerosol flow physics as trachea diameters decrease in size with smaller birds. Liquid versus dry aerosol delivery devices contribute to device complexity and effect aerosol efficacy. Therefore, development of a device for repeatable and efficient drug delivery must make suitable design decisions to address challenges relevant to the species under consideration.

This study presents a new dry aerosol (DA) device to deliver dry amphotericin B in powder form to the lung of an experimental avian species (mallard duck) in order to develop a method for prophylactically treating birds while they are in captivity during oiled-

wildlife rehabilitation efforts. The goal was to reduce the asymmetric delivery of medication to the lung, as the liquid spray (LS) device (Penn Century MicroSprayer® Aerosolizer) was found deliver medication unevenly, with medication only reaching one lung lobe [3]. The advantage of using the DA device stems from the ability to prolong the shelf life of the amphotericin B, since it never goes into solution. The new DA device is compared to the previously used LS device. The DA device is evaluated for its left/right (L/R) distribution, drug delivery efficiency, and overall device efficiency.

Figure 1: Dry Aerosol Device: (A) Whole device view; (B) Flow control valve; (C) Amphotericin B powder storage capsules; (D) Pressure regulator

METHODS

The DA device was manufactured using traditional subtractive machining, and it is composed the following components: a) interchangeable needle shaft, b) storage capsules for dry powder formulation of amphotericin B, c) device body, d) pressure regulator, e) flow control valve, and f) external air source. Both the device body and the storage capsules are made from Polytetrafluoroethylene (PTFE), and

the device shaft is made of stainless steel. The device body served as the housing for all components and allows for regulated pressure control, with manual valve control for drug insufflation (Figure 1). Each storage capsule is loaded before use allowing for storage ahead of experimental use.

In order to assess device performance metrics, several experimental procedures were conducted to evaluate the differences between the LS device with the DA device. First, a manufactured 3D printed trachea model was tested. Second, explanted chicken tracheas from above the glottis to below the first bifurcation were tested with attached collection reservoirs mimicking the downstream lung physiology. In both cases the shaft of the dry aerosol device was introduced into the tracheal lumen until resistance was met at the bifurcation, then retracted between 2cm-10cm distance. The DA device was loaded with 120 mg dry weight of surrogate powder (sucrose) to emulate the clinically used amphotericin B. The drug delivered efficiency is defined as the percent of total drug found in collection reservoirs from the total drug loaded into the device. The overall device efficiency is defined as percent of total drug minus drug lost to the environment from the total drug loaded into the device.

RESULTS

There was appreciable differences when using the 3D printed model of the trachea compared to the explanted trachea (Figure 2). When using the 3D printed model, the drug delivery efficiency was comparable for both LS and DA devices ($73.4\% \pm 8.9\%$ and $73.9 \pm 2.8\%$ respectively). However, when using the explanted trachea, the DA device had a lower drug delivery efficiency ($46.4\% \pm 5.4\%$) since the tracheal wall is real tissue, and not idealized plastic material. It is important to note that the overall efficiency of the device was not possible to quantify using gross tissue weight due to evaporation of wet tracheal tissue.

Figure 2: Efficiency (left) and distribution (right) comparisons between LS and DA devices.

Figure 3: Effect of retraction distance on L/R distribution

The main goal of this study was to regain symmetric distribution by using the DA device in comparison to the LS device. Results show that when using either the DA or LS device with the 3D printed trachea, the L/R distribution remained asymmetric. For the LS device, left bronchi drug delivered was $15.8\% \pm 2.1\%$ compared to $61.3 \pm 2.1\%$. For the DA device, left bronchi drug delivered was $16.3\% \pm 5.1\%$ compared to $83.6 \pm 5.1\%$. Inspection of LS device aerosol generation through high-speed imaging showed two interesting findings: 1) the aerosol spray was initially a jet until breakup occurs, dictating the direction of the majority of the stream and, 2) once the aerosol was created, a large droplet aggregate was formed at the tracheal wall leading to dripping of the liquid instead of passive aerosol distribution. The DA device had a similar phenomena occur, but instead, due to the lack of aggregation at the wall, the asymmetry was reduced, but the drug delivery efficiency was also reduced (Figure 2). By increasing the retraction distance, the increase in L/R distribution went from 20.1% to 86.3%, where 100% is perfectly symmetric (Figure 3). In order to mitigate this phenomena for the DA device, the jet momentum must be reduced, and passively carried down the trachea towards the bifurcation.

DISCUSSION

Development of devices for precision delivery of medication for respiratory diseases requires expertise that spans multiple disciplines. In this study, development of a specific device for prophylactic treatment of oiled wildlife birds has shown the complexity of the underlying assumptions when developing and testing devices. By controlling only one specific parameter with a model of the 3D printed trachea proved to be not representative of the *in-vitro* or *in-vivo* usage. Moreover, the flow physics of aerosol generation, driving fluid, and ultimate deposition is an area where much work has left to be done and is currently being pursued by the authors.

Specific to free-ranging birds, current methodologies to treat birds infected with aspergillosis requires intravenous delivery of anti-fungal agents, some of which prove to have systemic toxicity risks. Our proposed method of utilizing dry powder to administer anti-fungal agents directly to the bird trachea lumen have several benefits including reducing systemic toxicity, longer shelf-life and stability of anti-fungal agents, and using water-insoluble drugs. Our focus was to recover symmetric delivery and by understanding the configuration of the device parameters, L/R lung distribution was increased.

INTRODUCTION

While mechanical valve designs evolved to improve hemodynamic performance specifically bileaflet ones, blood damage remains a seemingly non-avoidable risk¹. Blood damage includes platelet activation, thrombosis and hemolysis. Thromboembolism is considered the most common complication affecting 0.1-5.7% of patients after mechanical valve implantation². Due to this, mechanical heart valves require lifelong antithrombotic therapies that may lead to hemorrhage³. Turbulent stresses are well established factors contributing to valve related hemolysis and platelet activation⁴. Therefore, minimizing turbulent stresses may help in minimizing the risk of blood damage. Aerospace applications utilize vortex generators (VGs) as a passive flow control technique that delays boundary layer separation⁵. Application of vortex generators on valve leaflets to minimize transvalvular pressure and turbulent stresses may seem effective in-vitro¹, however may also provide optimal geometry for clot formation in between the different slots.

Since the mid-1990s, the so-called “Lotus effect” has been adopted to develop a multitude of surfaces for superhydrophobicity, self-cleaning, low adhesion, and drag reduction in fluid flow, as well as antifouling⁶. Superhydrophobic surfaces are water repellent surfaces. They are characterized by low contact angle hysteresis (less than 10 degrees) along with a self-cleaning effect⁶. In other words, liquid droplets roll off the surface transporting impurities or waste products with them. The objective of this study is to test in-vitro the effect of superhydrophobic valve leaflets with vortex generators on hemodynamics and on the risk of thrombus formation and blood damage.

METHODS

Five different 23 mm bileaflet mechanical heart valves (BMHV) were 3D printed and designed as follows (Figure 1a-1d): one

BMHV was designed without VGs and considered the control case while the four others had different VG configurations mounted on the downstream side of the BMHV: (1) with 4 co-rotating equally distant VGs, (2) with counter-rotating 8 closely spaced VGs, (3) with counter-rotating 4 far spaced VGs, and (4) with counter-rotating 4 closely spaced VGs. VG heights were chosen to be 1 mm, length 2.8 mm, the spacing 5 mm and set at an angle of incidence of 23° based on Bradbury et al.³ Leaflets length is 20 mm. A commercially available superhydrophobic coating - the Ultra-Ever Dry (UltraTech International, Inc., Jacksonville, FL) - was used in this study. The coating is formed of two layers a bottom coat and a top coat. Both layers were applied as spray to the flat (without vortex generators) 3D printed aortic valve leaflets. After drying the coating, droplets of blood were tested on the surface to check for beading (Figure 1e). Once the coating is proven effective, the valve was hemodynamically tested in a pulse duplicator left heart simulator flow loop under a cardiac output of 5 L/min, a heart rate of 1 beat per second and systolic to diastolic pressures of 120/80 mmHg. In addition, the 4 different configurations of vortex generators along with the one without leaflet generators prior to applying the superhydrophobic coating were hemodynamically tested as well. A 100 different consecutive cycles of pressure and flow data were recorded at a sampling frequency of 100 Hz. Particle image velocimetry was performed to visualize the flow field. Time-resolved PIV images were acquired with a resulting spatial and temporal resolutions of 0.035 mm/pixel and 1000 Hz respectively. Phase locked measurements were recorded for 4 phases of the cardiac cycle (acceleration, peak, deceleration and diastole) repetitively with 250 ensembles each with a spatial resolution of 0.0325 mm/pixel. Refraction was corrected using a calibration in DaVis particle image velocimetry software (DaVis 7.2, LaVision Germany). Principal Reynolds Shear Stresses (RSS) were evaluated.

Figure 1: Schematic of the four types of vortex generators used in this study: (a) co-rotating, (b) 8 equally spaced counter-rotating VGs, (c) 4 far spaced counter-rotating VGs and (d) 4 closely spaced counter-rotating VGs; (e) whole blood on a bileaflet mechanical heart valve with a hierarchical coating

RESULTS

Figure 2 displays the Reynolds shear stress contours of the different valve cases at different time points throughout the cardiac cycle. Qualitatively during acceleration, when VGs are far spaced, the distribution of RSS looks different compared to all the other cases irrespective of the magnitude. During mid-systole, more dispersion due to turbulent advection is noted with the 4 far and closely spaced counter-rotating VGs along with the control case without any VG. Decay in RSS is observed in all the cases with increasing distance from the valve. Quantitatively, RSS magnitudes decreased significantly with VGs compared to the control case. At peak systole, RSS magnitudes calculated for the VG cases were also lower than those calculated without VGs. RSS was found to be 38.13 ± 0.89 , 12.95 ± 0.32 , 15.75 ± 0.71 , 24.54 ± 0.84 and 16.33 ± 0.58 Pa for control, co-rotating VGs, 8 counter-rotating VGs, 4 far-spaced VGs and 4 closely-spaced VGs respectively. The co-rotating VGs yielded the lowest RSS magnitudes with statistically significant differences compared with all the other cases ($p < 0.001$).

Figure 3 displays the principal RSS for the control valve and the superhydrophobically coated valve. RSS were higher with the superhydrophobic leaflet valve reaching a maximum of 160 ± 3.5 Pa at peak systole compared with 65 ± 4.2 Pa without the coating.

Figure 2: Principal Reynolds shear stresses at different phases in the cardiac cycle. Flow from left to right.

Figure 3: Principal Reynolds shear stresses at different phases in the cardiac cycle for the control valve and the superhydrophobic coated valve. Flow from right to left.

DISCUSSION

RSS is commonly used to predict blood damage, despite the fact it is a statistical measure and not an actual stress experienced by blood cells⁷. Counter-rotating VGs (owing to the geometry) may have enhanced turbulence compared to the co-rotating ones. This may be due to interaction of opposite signed axial vortices. While co-rotating VGs generated same sign axial vortices that helped streamline the flow and maintain a high velocity and a more gradual decay. Without any VGs, the early separation not only leads to stronger turbulence, but also to more energy dissipation.

Superhydrophobic coating leads to skin friction reduction in fluid flow⁶. The addition of the superhydrophobic coating leads to the introduction of “free slip” boundary condition instead of the “no slip” boundary condition. Therefore, for valve case, the tangential component of the velocity is unrestricted instead of being equal to zero. Surface slip is unlikely to improve energy loss performance as shown in the results with the increase of turbulence.

The results of this study indicate that applying the superhydrophobic coating alone on the valve surface may be enough from the low-adhesion standpoint however not sufficient to reduce turbulence. Ongoing studies combining vortex generators and superhydrophobic coatings are currently performed to maximize optimal hemodynamics occurrence.

INTRODUCTION

The coagulation cascade of blood may be initiated by flow-induced platelet activation and aggregation, which prompts clot formation in prosthetic cardiovascular devices and vascular disease processes. Upon activation, platelets undergo complex morphological changes. Activated platelets polymerize fibrinogen into a fibrin network that enmeshes red blood cells. Continuum methods fail to capture subcellular mechanisms such as filopodia formation during platelet activation, while utilizing molecular dynamics is computationally prohibitive. A multiscale approach offers a means to bridge the gap between macroscopic flow and the cellular scales.

We developed a multiscale model for simulating platelet activation and aggregation in viscous blood flows¹. This model incorporates a Dissipative Particle Dynamics (DPD) model of viscous flow that interfaces with Coarse Grained Molecular Dynamics (CGMD) model of mechanobiology-based platelets², to simulate their activation via mechanotransduction pathways³ and their aggregation by recruitment of flowing platelets by activated platelets deposited onto a blood vessel wall⁴. This model bridges the gap between macroscopic transport flow-induced platelet activation and aggregation scales and the ensuing molecular events, and is further validated through the use of several shear-based techniques that allow observation of platelet shape change and motion over a wide range of shear stresses and exposure durations³.

METHODS

Our multiple spatiotemporal model employs a modified DPD to describe viscous blood flow in stenoses and microchannels⁵, and CGMD to describe the intra-platelet constituents to study the mechanotransduction process². Spatially, the DPD-CGMD is interfaced by imposing a hybrid force field¹. In this spatial interface, the Lennard-Jones term helps maintain the cytoskeleton-confined shape and the

incompressibility of platelets against the applied shear stress of circumfluent flow. The dissipative and random terms maintain the local flow thermodynamic and mechanical properties, and exchange momentum to express interactions between the platelet and the flow. Temporally, an event-driven multiple time-stepping (MTS) scheme⁶ is developed as an efficient numeric solver on top supercomputers⁷.

The platelet membrane in our model includes 67,004 integrin $\alpha\text{IIb}\beta 3$ receptors represented by particles and distributed uniformly on the membrane (Fig. 1). The aggregation force field between the receptor particles of different platelets is modeled as:

$$F_{ij} = D_0 \left(e^{-2\alpha(r_{ij}-r_0)} - 2e^{-\alpha(r_{ij}-r_0)} \right) \mathbf{e}_{ij} + f^A(t_{ij}) \left(1 - \frac{r_{ij}}{d_c} \right) \mathbf{e}_{ij} \quad (1)$$

Figure 1: Aggregation of adjacent platelets in shear flows

This molecular-level hybrid force field combines the Morse potential and Hooke force to mimic the binding of $\alpha\text{IIb}\beta 3$ and fibrinogen (Fg) during platelet aggregation. The simulation setup is in Fig. 1.

We validated our numerical method by correlating numerical simulations and model predictions with in vitro results. For aggregation experiments, purified platelets were prepared as previously described³, diluted to 100,000/ μ l, mixed with isolated red blood cells at a hematocrit of 40%, and perfused through 100 μ m \times 1 mm microchannels (μ -Slide VI^{0.1} Luer, ibidi USA, Inc., Madison, WI) pre-coated with 100 μ g/ml von Willebrand factor using a syringe pump (Fig. 2a). This ensured that margined platelets adhered to the walls of the channel. Then, isolated platelets were diluted to 150,000/ μ l, treated with 1.5 mg/ml Fg (Enzyme Research Laboratories, South Bend, IN), and perfused over the adhered platelets at shear stresses up to 10 dyne/cm² to initiate aggregation. Aggregation events were observed at 100 \times magnification under a DIC microscope (Ti-E, Nikon, Melville, NY) at 100-420 fps (Neo 5.5 sCMOS, Andor Technology Ltd., Belfast, UK). We measured the length of the bond and contact time between aggregating platelets. (Fig. 2b)

Figure 2: (a) Set-up for aggregation experiments. b) Sequential imaging of platelet aggregation/disaggregation under flow.

RESULTS

Our multiscale model describes the biophysical properties for platelets down to the *nm*-length and *ps*-time scale². Membrane Young's modulus is 31.2 μ N/m and shear modulus is 33 \pm 9 μ N/m. The cytoplasm is modeled by modified Morse potential⁸ and its viscosity is 4.1 mPa·s. Actin filament stiffness is 56.3 \pm 1.0 pN/nm.

Using this model, we simulated the dynamics of platelet aggregation by recruitment of unactivated platelets flowing in viscous shear flow by an activated platelet deposited onto a blood vessel wall⁴, shown in Fig. 1. This simulated the platelet aggregation that is mediated by fibrinogen (Fg) via α IIb β 3 receptors. The binding of α IIb β 3 and Fg is accurately modeled at the molecular scale. This simulation studies a shear stress of 6.7 dyne/cm² and a shear rate of 619 s⁻¹ with a flow viscosity of 1.07 mPa·s. During the simulation, our multiscale platelet model continuously changes its morphology in response to the dynamic flow stress while flowing and flipping. As platelets are approaching, the receptor α IIb β 3 and the Fg form a bridge (α IIb β 3-Fg- α IIb β 3) which initiates platelet aggregation. With the progress of platelet aggregation, contact area first increases rapidly then stabilizes with time, wherein bond formation becomes more prominent and few bonds are broken. Fig. 3 shows the consistent growth of aggregation contact area, which possesses significant increments as the platelet receptors engage in aggressive bond formation with fibrinogen. Finally, this process leads to an equilibrium phase and forms a stable aggregate. The evolution of contact area through this process demonstrates that aggregation begins with transient bond formation, but as adjustment of contact position concludes, bond formation stabilizes with time, and more permanent bonds are formed, finally leading to a stable aggregate.

In addition, we compared our aggregation model with deformable and rigid platelet models (Fig. 3). We found that a rigid platelet in

aggregation led to a very significant underestimation of contact area by 89%, and detaching force by 91~93%. In the final equilibrium state, the deformable model is more stable than the rigid model under shear stress. Hence, rigid platelet aggregates are unstable and more likely to detach.

DISCUSSION

Our approach is the first multiscale numeric method for simulating the platelet activation and aggregation under flow that includes bonding and receptors on the platelet's membrane. Biophysical properties of a platelet are accurately described down to a *nm*-length and *ps*-time scale, and the viscous flow is described at a μ m-length and *ns*-time scale. Platelets are allowed to continuously deform in response to flow stress. In platelet recruitment aggregation, the microscale properties of the receptor-ligand interactions were precisely modeled at molecular scales and correlated well with in vitro results, including contact area and detaching force. With this improvement, the aggregation model is able to illustrate the microphenomena that have otherwise been missing.

Ongoing experiments have employed this model to study aggregation of multiple platelets in shear flow. Fig. 1 shows a schema for depicting three platelets flowing, deforming and aggregating in free flow. Using numeric simulations, we can then quantify the effect of platelet deformability and flow conditions on platelet aggregation characteristics.

In ongoing studies, a platelet-mediated thrombus growth model under shear was developed. This thrombus model adapts the molecular-scale properties of our current recruitment aggregation model, thus predicting macro-scale properties using micro-scale principles. Such a model has the advantage of reflecting molecular level changes in receptor-ligand bond formation. We expect our model to be adopted by other fields, such as drug delivery, by considering the impact of mechanical events triggering biochemical responses.

INTRODUCTION

Thrombosis is a process whereby a blood clot forms *in situ* within a vessel and impedes blood flow. The main three factors contributing to thrombosis can be summarized by Virchow's Triad (Fig. 1). Alone or in combination, hemodynamics, endothelial damage, and blood hypercoagulability all contribute to thrombus formation.

While blood viscosity is known to exhibit a nonlinear behavior, a Newtonian assumption is often employed in computational analyses. This assumption is valid in healthy arteries where shear rates are high and blood recirculation is low. However, in pathological geometries, such as aneurysms, the Newtonian assumption fails, and thus nonlinear viscous effects become exceedingly important. Previous computational models of thrombosis have investigated coagulation through chemistry based formulations focusing on protein dynamics [1-2] but have generally excluded complex 3D hemodynamics. In this work, we developed a computational framework to investigate the interplay between 3D hemodynamics and thrombosis initiation. The salient features of our computational framework are: i) the ability to solve hemodynamics in 3D image based patient-specific vascular models; ii) nonlinear viscous models of blood flow; and iii) a flexible computational framework for non-linear scalar models of protein dynamics that can be easily customized to include an arbitrary number of species and protein interactions. Here, we apply this framework to a human aortic aneurysm model to illustrate non-Newtonian viscous effects and scalar modeling for thrombosis simulation.

Figure 1: Virchow's Triad

METHODS

A patient-specific thoracic aortic aneurysm geometric model was built from computed tomography angiography image data using the validated software package CRIMSON (www.crimson.software). Blood was modeled as both Newtonian and non-Newtonian fluids with a density of 1060 kg/m³. Vessel walls were modeled as rigid. A volumetric flow waveform derived from echocardiography data was imposed at the inflow face of the model. Three-element Windkessel models were used to represent the behavior of the distal vascular beds for each outflow face. Numerical values of the Windkessel parameters were tuned to match clinical measurements from duplex Doppler ultrasonography and cardiac catheterization. Mesh independence analysis was completed and a final mesh of ~23 million elements was used for the non-Newtonian analysis (Fig. 2).

Two non-Newtonian constitutive models, Power Law and Carreau-Yasuda (CY), were implemented within CRIMSON and validated against analytical solutions. The CY model, described in Eq. 1, was chosen for all patient-specific studies due to its ability to approximate viscous behavior of blood at low shear rates.

$$\mu(\gamma) = \mu_{\infty} + (\mu_0 - \mu_{\infty}) \left(1 + (\lambda\gamma)^a\right)^{\frac{n-1}{a}} \quad (1)$$

where μ is blood viscosity, γ is the shear rate and μ_{∞} , μ_0 , λ , n , and a are material parameters. Here, we used $\mu_{\infty} = 0.0035$ Pa, $\mu_0 = 0.16$ Pa s, $\lambda = 8.2$ s, $n = 0.2128$, and $a = 0.64$ kg/m³ [3].

To model thrombus formation, a staggered finite element approach for solving the reaction-advection-diffusion (RAD) equations was implemented, see Eq. 2. Here, c refers to scalar concentrations, D to diffusivity, R to reaction terms, and \mathbf{u} to blood velocity. The reaction terms used can be found in Eqs. 3-6 where k values represent different reaction rates.

$$\frac{\partial c_i}{\partial t} + \nabla \cdot (-D_i \nabla c_i) = R_i - \mathbf{u} \cdot \nabla c_i \quad (2)$$

$$\frac{d[IIa]}{dt} = -k_{in}[IIa] + (k_{surf} + k_{II}^{AP} \cdot [AP]) \cdot [II] \quad (3)$$

$$\frac{d[II]}{dt} = -(k_{surf} + k_{II}^{AP} \cdot [AP]) \cdot [II] \quad (4)$$

$$\frac{d[AP]}{dt} = k_{AP}^{AP} \cdot [AP] \cdot [RP] + k_{AP}^{IIa} \cdot [RP] \quad (5)$$

$$\frac{d[RP]}{dt} = -k_{AP}^{AP} \cdot [AP] \cdot [RP] - k_{AP}^{IIa} \cdot [RP] \quad (6)$$

These reaction terms represent a previously described 4 scalar reaction model for thrombus formation that has been shown to match patient-specific data [4] and describes thrombin generation via four key players: thrombin (IIa), prothrombin (II), activated platelets (AP), and resting platelets (RP). This RAD was implemented within our non-Newtonian fluid description to develop a framework for investigating thrombus formation in pathological scenarios. RAD simulations were run using the same fluid boundary and initial conditions and the CY model of non-Newtonian viscosity, as described above. A zero Dirichlet boundary condition was applied on the walls for all four scalars, different Dirichlet inflow boundary conditions were applied for each scalar, along with zero Neumann outflow boundary conditions. Initial conditions were chosen to be the same value as the inflow conditions for each scalar.

RESULTS

Fig. 2 shows the impact of viscosity in an aortic aneurysm model. Simulations were run until pressure periodicity was reached, using a Newtonian (left) and CY non-Newtonian assumption (right) (Fig. 2D). Newtonian viscosity was chosen to match the μ_∞ value so that at high shear rates both models produce the same value of viscosity. To investigate the transient effects of non-Newtonian viscosity, three time points in the cardiac cycle are shown: diastole, systole, and transitional (Fig. 2E). The models produced different in-plane flow patterns (Fig. 2B), the Newtonian model showing higher near-wall velocities and gradients compared to the CY model. Lastly, wall shear stress (WSS) was observed to differ both qualitatively and quantitatively between the models (Fig. 2C).

Figure 2: Newtonian and CY results in an aortic aneurysm. A) 2D cross section for velocity contours; B) In-plane velocity for Newtonian and CY viscosity; C) WSS magnitude for Newtonian and CY viscosity; D) Constitutive models for viscosity; E) Definitions of diastole, transitional, and systole.

Fig. 3 shows results from our RAD finite element system. Fig. 3A, D shows a representative 2D cross section of the aortic aneurysm for two given time points along with the velocity profiles. Prothrombin degradation (Fig. 3 B, E) and thrombin generation (Fig. 3C, F) are shown. Thrombin is formed through interaction with prothrombin and activated platelets and propagated through the domain.

Figure 3: Scalar model of thrombin formation in a patient-specific aortic aneurysm. Velocity field, prothrombin concentration, and thrombin concentration at time t=0s A-C), and t=0.5s D-F), respectively.

DISCUSSION

We have successfully developed a computational framework for investigating nonlinear RAD phenomena involving non-Newtonian hemodynamics in imaged-based cardiovascular models. The combination of these two will for the first time enable the study of thrombus initiation using both a complex description of hemodynamics and biochemistry. We have applied this framework to investigate a patient-specific model of an aortic aneurysm. Results show the successful implementation of the RAD equations with nonlinear reaction terms involving 4 scalars. We were able to solve these equations in conjunction with the Navier-Stokes using one-way coupling between the fluid and scalar problems.

Future investigations will expand the staggered finite element strategy for RAD to include an arbitrary number of scalars using a python interface. This will allow for increased flexibility and user-friendliness enabling users to implement reaction networks on the fly. Our framework will allow for the modeling of thrombosis initiation in complex image-based geometries, using a variety of non-Newtonian descriptions of the fluid. Ultimately, this approach will provide insight into the complex interplay of various blood constituents and potentially reveal new physics of thrombus initiation. Future work will also employ animal models to capture parameters of *in vivo* venous thrombosis to better inform our computational model.

INTRODUCTION

Thrombosis is a common complication resulting from implantation of cardiovascular devices. Computational simulation is a powerful tool to provide predictions on thrombus growth in a given geometry and can be used to evaluate the risk of medical devices after implantation. To accurately predict thrombus growth, simulation in a three-dimensional (3D) geometry is necessary.

Taylor *et al.* developed a thrombosis model that simulates thrombus deposition and growth in a two-dimensional domain, with spatial and time scales relevant to medical devices [1,2]. The model assumes that platelet activation, which depends on wall shear stress, availability of adenosine diphosphate (ADP) and concentration of surface adherent platelets, predominantly contributes to thrombus growth, while the fluid velocity field is affected by the thrombus and coupled to the simulation [1,2]. However, the rate of chemical platelet activation by ADP was assumed to increase linearly with the ADP concentrations once enough ADP accumulated [1,2], which does not match the experimental observations, where the activation is temporary [3,4]. In addition, the thrombus breakdown mechanism, though included in the model, was not activated [1,2]. To describe the device-induced thrombosis procedure more accurately, the current study proposes to modify the existing computational thrombosis model.

Applying the modified thrombosis model, a 3D simulation of thrombus growth was performed to provide a prediction in a time scale relevant to medical devices. The goal is to develop a macroscopic computational thrombosis model that can accurately predict thrombus deposition and growth in a 3D geometry.

METHODS

The velocity (\mathbf{u}) and pressure (p) fields of laminar fluid flow were solved via the continuity (Eq. 1) and Navier-Stokes equations.

$$\nabla \cdot \mathbf{u} = 0 \quad (1)$$

To simulate thrombosis, the Navier-Stokes equation was modified into Eq. 2:

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} = -\frac{1}{\rho} \nabla p + \nu \nabla^2 \mathbf{u} - \nu F(\varepsilon) \mathbf{u} \quad (2)$$

where a Brinkman term ($\nu F(\varepsilon) \mathbf{u}$) was used to couple the velocity field with thrombus growth and F was a function of the platelet aggregation intensity (ε), whose concentration depends on the following species: activated platelets, non-activated platelets, surface adherent platelets, and ADP. These species were calculated in bulk concentrations to match the scale of the system geometry, through a set of convection-diffusion-reaction equations (Eq. 3):

$$\frac{\partial Q}{\partial t} + (\mathbf{u} \cdot \nabla) Q = D \nabla^2 Q + R \quad (3)$$

where Q is a scalar, D is the diffusion coefficient, and R is a source or sink.

The modified computational model was applied to simulate thrombosis in a backward facing step (BFS), an asymmetric expansion. Prior to simulations, a 3D mesh of the geometry was constructed by SolidWorks (Waltham, MA, USA), with dimensions shown in Figure 1. At the inlet, blood flow was set to be Newtonian, fully developed, steady, and laminar, with a Reynolds number of 490.

Figure 1: Dimensions of the backward facing step model used for computational studies. Heights of the channel and size of the step match those of the device used in Taylor *et al.* (2014) [5].

The computational thrombosis model was applied using OpenFoam (OpenCFD, Ltd, 543 Bracknell, UK) and thrombus growth was simulated for 30 min. To validate the results, the simulated thrombus growth was compared with *in vitro* measurements obtained from magnetic resonance imaging (MRI). In those experiments, bovine blood was circulated through the BFS model, a thrombus grew within the separation region, and the thrombus size was measured at different time points based on analysis of the MRI scans [5].

RESULTS

The simulation results show that the thrombus is grown right at the step over time, which matches the MRI experimental observations [5]. The volume of the simulated thrombus over time is compared to the *in vitro* MRI data in Figure 2.

Figure 2: Volume of the simulated thrombus at an asymmetric expansion in comparison to *in vitro* MRI data [5].

The MRI data show that the thrombus volume increases quickly during the first 20 minutes and reaches a constant value after 25

minutes. On the other hand, the simulations predict that the thrombus volume will increase in a similar way and the resultant volumes match the MRI data well during the first 20 minutes of thrombus growth but are lower than the MRI data after that time point.

DISCUSSION

As shown in Figure 2, the rapid increase in thrombus volume at early time points implies rapid thrombus growth. Though the simulation results match the MRI data well during the first 20 minutes, the clot volume is under-predicted at later time points. A possible reason is that the current model only involves ADP as the major platelet activator and effects of the coagulation cascade are not considered. To improve the predictions on thrombus growth, future studies should involve clotting factors that are main contributors to platelet activation and the coagulation cascade, such as thrombin. As thrombin is converted from pro-thrombin and inhibited by anti-thrombin III, both the conversion and inhibition mechanisms should be included as well.

Comparing to the two-dimensional simulations, the three-dimensional simulations are more beneficial as they provide more useful information that is not available in two dimensions (e.g. increase in thrombus volume over time). The current thrombosis model provides prediction on thrombus deposition and growth that match the MRI experimental observations at early time points. However, since the model describes the thrombosis procedure using only four species to reduce the computational cost, the simulation results do not match the MRI data at later time points. The current computational model is limited to predictions for short-term thrombus deposition and growth (i.e. within 20 min). To provide accurate predictions for long-term device-induced thrombosis (i.e. from 20 min to hours), the current model requires modifications so that the thrombosis procedure can be described more accurately, such as including the effects of the coagulation cascade.

INTRODUCTION

Thrombosis is a life-threatening condition, where a blood clot forms within the vasculature and impedes the blood flow to a vital organ. Thrombi can also break apart or become dislodged, leading to life threatening conditions such as myocardial infarction and pulmonary embolism. Moreover, thrombi or blood clot can form in blood-contacting medical devices and thwart device functionality. Thus, it's a critical need to understand the mechanical properties of thrombi under blood flow to both enhance clinical diagnoses and develop therapeutic treatments. Previous research has mainly focused on two-dimensional models (2D) of thrombi-blood interaction¹, and clot growth².

Fluid-solid interactions (FSI) can play a dramatic effect on the mechanical response of blood clots. The goal of our research was, therefore, to develop a 3D non-linear FSI model that couples clot mechanics with the blood flow to better understand the role of clot and blood mechanical properties on this complex interaction.

METHODS

A 3D model of the blood clot was generated using SolidWorks 2017 (Dassault Systems) and was meshed using Ansys 18.1. Geometric parameters of the murine blood vessel were based on a recent study¹. We created a FSI model consisting of blood and thrombus using FEBio 2.8³. We utilized a Neo-Hookean constitutive model for the thrombus and assigned a range of stiffness values to the clot. The non-linear stress-strain behavior of the compressible neo-Hookean model is derived from the following hyperelastic strain-energy density function:

$$W = \frac{\mu}{2}(I_1 - 3) - \mu \ln J + \frac{\lambda}{2}(\ln J)^2 \quad (1)$$

Where I_1 is the first invariant of the right Cauchy-Green strain tensor, J is the determinant of the deformation gradient tensor, μ and λ are Lamé parameters. In our study, μ was assigned different values of 180 Pa, 108 Pa and 36 Pa. We used Preview 2.1 for pre-processing the model. Cyclic pressure boundary conditions were applied representing blood flow at the inlet. It is known that blood behaves like a Newtonian fluid under the high shear rate, while under the low shear rate, it behaves like non-Newtonian fluids⁴. We have considered both Newtonian and non-Newtonian flows for a range of blood clot properties in this study.

We used the Carreau-Yasuda model to represent the non-Newtonian behavior of blood. The dependency of the dynamic viscosity on the shear rate was modeled by the following equation:

$$\mu = \mu_{\infty} + (\mu_0 - \mu_{\infty})((1 + (\dot{\gamma})^2)^{\frac{n-1}{a}}) \quad (2)$$

where $\dot{\gamma}$, μ , n are the engineering shear rate, viscosity, slope of the power law respectively, and a defines the shape of the transition region. The rheological properties of blood were taken from the literature⁴. We used the post-processor software, PostView 2.3.2 to visualize our results.

RESULTS

Figure 1 depicts the total displacement state of the clot when inlet pressure is at maximum value for Newtonian versus non-Newtonian flow. The dome of the thrombus encounters the maximum displacement in both cases. Clot under Newtonian blood flow experience 38% higher displacement than the clot under non-Newtonian flow for the same clot stiffness. Figure 2 portrays the shear stress distribution inside the clot, and it can be noticed that shear stress value is higher in the region proximal to the inlet and in immediate vicinity of the vein wall. The clot

under Newtonian flow experienced noticeably higher shear stresses throughout its thickness. Figure 3 shows the maximum shear rate of the fluid at the timepoint corresponding to maximum pressure at the inlet. Newtonian blood model predicts a shear rate that is nearly twice as high as the outcome of the non-Newtonian model near the clot. Figure 4 represents total displacement distribution of the clots having different stiffness values under non-Newtonian flow. Decreasing the shear modulus from 180 Pa to 36 Pa in the Neo-Hookean model results in a 235% increase in maximum total displacement of the clot.

Figure 1: Total displacement distribution of the clot. Left: Newtonian, right: non-Newtonian (unit is in meter and shear modulus of the clot is 180 Pa).

Figure 2: Shear Stress distribution inside the clot. Left: Newtonian, right: non-Newtonian (Fluid flows from negative X to positive X direction. Units are in Pa and shear modulus of the clot is 180 Pa).

Figure 3: Illustration of maximum fluid shear rate over the clot. Left: Newtonian, right: non-Newtonian (Direction of fluid flow is perpendicular to the view. Units are in $1/s$).

Figure 4: Total displacement distribution of the clot with different stiffness under non-Newtonian flow: (A) 180 Pa, (B) 108 Pa and (C) 36 Pa shear modulus. Units are in meters)

DISCUSSION

The goal of our study was to develop a 3D FSI model of blood-thrombus interaction to study the effect of Newtonian versus non-Newtonian fluid assumption combined with variations in thrombus stiffness. Since red blood cell density and deformability may change with age and different pathological states, including the non-Newtonian behavior of blood in the simulations can lead to more accurate predictions of shear rate particularly near the clot. On the other hand, our results showed that modeling blood as Newtonian can overpredict the shear rate and clot deformation (figures 1, 3). Additionally, blood clots can have different stiffness at different stages of development and different sites in the body. Our results show that the deformation state of the clot can change dramatically because of changes in its mechanical properties (figure 4). Including a deformable blood vessel in the model could further improve the predictive value of our modeling approach.

Furthermore, our study may have important implications for design of mechanical thrombectomy devices⁵. Since these devices directly interact with the clot, the stiffness of the clot and its deformation, strain and stress states could directly impact the removal of the clot by the device. Understanding the complex interaction of the clot with blood for different blood and clot properties can provide more insight into risk predictors for clot dislodgement and embolism. Our results also show that different regions of the clot experience very different states and magnitudes of stress (figure 2). This implies that as blood clots develop over time, different regions of the clot can exhibit region-specific mechanical properties to resist these very different states of stress. Thus, our results lay the groundwork for further computational and experimental investigations into the complex mechanical behavior and properties of developing blood clots.

INTRODUCTION

Valve-in-valve (ViV) placement is an emergent treatment option for degenerated bioprosthetic surgical aortic valves where a transcatheter aortic valve replacement (TAVR) is done inside a failed surgical valve [1]. Reduced leaflet motion as a result of hypoattenuated leaflet thickening (HALT) was recently diagnosed by high-resolution CT scans in bioprosthetic aortic valves in general [2], with highest occurrence after ViV placement [3, 4]. Subclinical leaflet thrombosis was suggested as the reason for the reduced leaflet motion because the phenomenon was resolved in patients receiving anticoagulants [5], medications that are not routinely given to bioprosthetic heart valve patients. Various causes for thrombosis formation have been suggested. One is the hemodynamic factors involved with low blood flow rate and regions of flow stagnation near the leaflets, due to valve confinement [6]. To date, several studies examined the hemodynamic cause of HALT post-ViV by experimental and numerical models. Experimental studies were limited to idealized geometry [7], or could not capture the region of interest in post-ViV procedure [8]. In numerical study, only complete or no confinements, where the TAVR valve is surrounded by surgical leaflets, were accounted for [9]. Our research aims to explore and compare deployments of the latest version of TAVR devices (Medtronic Evolut PRO, Edwards Sapien 3) inside a surgical bioprosthetic valve (Sorin Mitroflow) and to assess the partial confinement influence on the hemodynamics near the ViV's region.

METHODS

The dry modeling of the surgical and TAVR procedures were simulated by finite element analysis in Abaqus Explicit (Simulia, Dassault Systèmes). Three dimensional models of Mitroflow, Sapien 3, and Evolut PRO valves were generated (Figure 1). To model the

surgical procedure, an available aortic root anatomy was deformed to the round shape of the surgical valve's suture ring. The Mitroflow valve was investigated because it is more susceptible to early degeneration than other surgical valves [10], while both Sapien 3 and Evolut PRO are the latest FDA-approved TAVR devices and are clinically being used for ViV placement in Mitroflow valves [11,12]. To simulate ViV procedure, TAVR valve deployments inside the surgical valve model were modeled as superelastic expansion and deployment by balloon inflation, for the Evolut and Sapien devices, respectively. The cuff and leaflets were displaced to the deployed stent configuration and the percentage of leaflets confinement was calculated. Post-procedural hemodynamics models were created from the finite elements models results. Computational fluid dynamics (CFD) simulations of the flow through the prosthetic valve with stationary leaflets in the systolic configuration were solved by ANSYS Fluent (ANSYS, Inc.). To validate each valve model, an in-vitro experimental setup was built. Hydrostatic pressure was applied on each valve experimentally and numerically, and their diastolic configurations were compared.

Figure 1: Geometries and dimensions of the bioprosthetic valve models

RESULTS

The mechanical stresses distribution in the surgical valve leaflets and the contact between the leaflets and the deployed stents in ViV configuration were examined. The Evolut stent positioning was not uniform in all direction and the stresses and contact distribution varied among the three leaflets of the surgical valve (Figure 2A). In the Sapien case, the stresses and the contact between the stent and the leaflets were similarly distributed in all the surgical valve leaflets (Figure 2B). The highest stress magnitudes were mainly located at the middle of the surgical leaflets and were higher with the Sapien compared to the Evolut.

Figure 2: Mechanical stress distribution in the Mitroflow valve's leaflets for (A) Evolut PRO and (B) Sapien 3 deployments

Sapien leaflets were completely confined by the surgical valve leaflets (Figure 3) while the Evolut leaflets were partially confined, creating pockets (neo-sinuses) that cover only 60.3% of the leaflet height (Figure 3). The neo-sinuses in the Sapien case were deeper and narrower than in the Evolut. Preliminary CFD simulation of the systolic flow through the valves has shown a more stagnant flow near the TAVR leaflets in the Sapien valve compared to the Evolut (Figure 3).

Figure 3: Deployed configurations of Sapien 3 and Evolut PRO inside a Mitroflow valve and the CFD results of the systolic hemodynamics

DISCUSSION

This study evaluated the post-procedural configuration of the latest TAVR devices inside a Sorin Mitroflow valve. Better anchoring of the deployed stent by the surgical valve leaflets was achieved in the Sapien stent compared to the Evolut stent. These differences between the stents can be explained by the balloon inflation deployment of the Sapien and the fact that its deployment is independent of the root anatomy, whereas the Evolut self-expandable stent positioning was influenced by the aortic root geometry. Complete confinement was found after intra-annular deployment (Sapien 3), while partial confinement was found after supra-annular deployment (Evolut PRO). The neo-sinuses, that created in the confined region between the leaflets of the TAVR and the surgical valve, are especially important because they are suspected as regions of flow stagnation that can lead to thrombus formation. Preliminary CFD result has shown stagnating local flow in the neo-sinuses, while the stagnant flow was more dominant in the Sapien ViV configuration compared to the Evolut. These findings can be explained by the ViV configuration for each valve as with the Sapien valve, deeper and narrower neo-sinuses were formed.

Since the lower part of the Evolut stent is wider compared to the middle, a more aortic deployment of the Evolut stent may results in better anchoring of the stent, as well as smaller neo-sinuses, and therefore can help reducing the risks for leaflets thrombosis. These results, of the first numerical simulation of ViV with Evolut or CoreValve, demonstrates the partial confinement that was ignored in previous HALT studies. In the next phase, these hemodynamic models will be solved by fluid structure interaction (FSI) analysis while the TAVR leaflets will be used as the compliant parts in the FSI simulations.

INTRODUCTION

Measurements of free energy landscapes are critical for understanding the basis of many physical, chemical and biological interactions. Boltzmann distribution based energy reconstruction methods, which are used to calculate free energies, are based on the assumption that all possible configurations of the system are sampled [1]. In practice, the limiting factor in accurate free energy reconstructions is the imperfect sampling of a potential field, particularly in the case of interactions with steep gradients and short reaction coordinates [2]. One of the approaches to overcome this limit is to differentially sample the potential landscape to increase sampling times at sharp sections of the landscape. This is possible if we can classify the landscape into regions of differential interaction strengths. The classification can then be used to dynamically vary the probe speed to match the interaction strength and thereby sufficiently sample the entire landscape. The probe would then spend greater time at regions of steep gradients as compared to shallow gradients thereby capturing all possible configurations for the entire system irrespective of potential gradients or length of reaction coordinates. In this paper, we show through cantilever dynamics simulations and application of machine learning algorithms that it is possible to classify an atomic force microscope (AFM) cantilever probe's Brownian excitations within an external force field into regions of differential strength and detect the transitions between these regions.

METHODS

Simulated deflection data was generated using numerical integration of the cantilever dynamics equation used to model the behavior of a fluctuating AFM cantilever probe ($k=1000$ pN/nm, $f_0=25$

kHz, $Q = 3$) under the influence of an external energy field (6-3 chemical force field) as per equation (1) [3].

$$m \cdot \ddot{z}(t + \Delta t) = F_n + F(z(t)) + k \cdot z(t) - b \cdot \dot{z}(t) \quad (1)$$

Where $z(t)$ is the cantilever trajectory in Å, m , k and b are cantilever's mass, spring constant and quality respectively. $F_n = \sqrt{4k_B T b B}$ is thermal force with T and B as temperature and bandwidth respectively. The external force field $F(z(t))$ is modeled as per equation (2)

$$F(z(t)) = 100 \left(\frac{0.1}{z} \right)^6 - 0.0006 \left(\frac{0.1}{z} \right)^3 \quad (2)$$

The deflections were parsed into multiple small segments and 17 aggregate statistics were computed for each segment, representing features or characteristics of the segments. The computed deflection based features are maximum, minimum, mean, median, mode, skew, kurtosis, variance, standard deviation, fitted gradient, fitted intercept, absolute energy, entropy, number of peaks/valleys, distance between peaks/valleys, percent of observations above mean deflection and percent of observations below mean deflection. The features are then used to group the segments into n distinct clusters or classes using an unsupervised machine learning algorithm (KMEANS) [4]. The clusters can be of different sizes. Each segment's features are iteratively allotted to each cluster until a final configuration is reached in which the centroid of each resulting cluster is maximally distant from the other clusters in terms of Euclidian distances. Since the ideal number of clusters is not pre-determined, hence the above approach is repeated for a range of cluster counts ranging from 1 to 9.

The simulation generated 1 million deflection points which was divided into 1000-point equal size segments. Analysis was performed using Numpy, Pandas and Scikit-learn libraries with custom routines written in Python 3.

RESULTS

An optimal cluster count is determined by minimizing total sum of squared errors (SSE) or distortion for the data points against the cluster centroids. This is also called elbow analysis. The formula for distortion is shown in equation (3) below

$$distortion = \sum_{i=1}^m \sum_{j=1}^n \left(x_j^{(i)} - \mu_{c(i),j} \right)^2 \quad (3)$$

where x is feature vector of a given segment and μ is the centroid of a cluster. A sharp decrease in distortion across consecutive cluster counts indicates a sharp decrease in SSE which indicates that an optimum is reached. Figure 1 shows two optimal cluster counts corresponding to two (2) clusters and five (5) clusters respectively. Two clusters are not relevant for the analysis since they indicate only general trends, such as probe interaction can be broadly classified as far away from surface and in contact with surface. On the other hand, five clusters captures the complete probe behavior as it samples over the entire energy landscape including short reaction coordinates experienced when the probe instantaneously jumps to the surface. Hence, five clusters are chosen as the optimal configuration for the given interaction.

Figure 1: Choosing the optimal number of clusters based on minimization of distortion

The KMEANS model was trained by fitting the segment-based features dataset into five clusters. The fitted model was then used to classify each segment into one of the five clusters/classes. Figure 2 shows the raw deflection data (black) generated using the Brownian simulation with superimposed classes for each of the 1000 segments.

Figure 2: AFM force curve (black) overlaid with machine learning based predictions showing regions of varying interaction strengths

Each class is distinguished by a distinct color and represents a probe location and a corresponding interaction strength. The color coding is

described in Table 1 below. As can be seen, interaction strength is strongly coupled to the class predicted by the algorithm. Regions far from the surface and contact have low interactions and are shown in red and purple color respectively. The approach and contact regions have medium interaction strengths and are depicted by yellow and blue regions respectively. Finally, the near contact (or snap in) region has the highest adhesive force and is shown in green color.

Table 1: Probe locations their corresponding interaction strengths as predicted by the machine learning algorithm

Probe Location	Interaction Strength	Color
Far from surface	Weak/None	Red
Approaching surface	Medium	Yellow
Near contact	Strong	Green
Contact	Medium	Blue
After contact	Weak/None	Purple

DISCUSSION

It has been shown that the predicted classes strongly correlate with the strength of interaction and can be used an excellent proxy for the interaction strength. A direct inference of this result is that the segment based features contain sufficient and significant information about the interaction and thus machine learning algorithms can successfully learn and predict differential strengths of the interaction including regions of transition across classes. This method, when integrated into the AFM deflection data collection process, can detect regions in potential landscapes with sharp gradients in real-time and therefore adjust probe speed to increase sampling counts in those regions. This leads to accurate Boltzmann distribution-based energy reconstructions for all subsequently collected datasets, limited only by the hardware of the AFM system in terms of implementing a feedback loop to control the probe speed and direction.

A great advantage of this approach is that we can use the flexibility of the machine learning approach to rapidly experiment with a variety of tunable parameters such as number of classes, segment sizes, types of features, bin widths, classification algorithm choice etc. to identify the best solution spaces to measure any given interaction, before setting up the experiment. This allows to get good reproducible experimental results with lesser expenditure of precious experimental resources, thereby increasing the generalizability of this machine learning based approach.

ACKNOWLEDGEMENTS

The author would like to acknowledge the contribution of PACE, a high performance computing environment at Georgia Institute of Technology, Atlanta for simulation of AFM cantilever probe fluctuations.

INTRODUCTION

Respiratory distress syndrome is a condition that affects all age groups including infants. Premature infants are more prone to this disorder, and in this case it is called neonate respiratory distress syndrome NRDS. To remedy NRDS, patients have to be sedated, intubated and mechanically ventilated while they receive instillation of liquid surfactant replacement therapy [1]. There are multiple surfactant replacement therapy drugs available, including Alveofact®, Curosurf® and Survanta® with Curosurf and Survanta proven to be the best treatments [2]. The most common method of delivery for these surfactant replacement drugs is via instillation of a liquid formulation [3]. However, delivery of surfactant as a dry powder aerosol has not been well explored, and its efficacy is poorly understood.

Using a micrometer-sized excipient enhanced growth (EEG) spray dried powder produced from the Survanta commercial product which is aerosolized using a novel dry powder inhaler (DPI), we can mitigate some of the problems that may arise when using the liquid form of Survanta. The liquid delivery of Survanta does not penetrate all the regions of the lungs and therefore some of the alveolar regions of the lung will not receive any surfactant and may collapse. By changing to an aerosol delivery method, the treatment may penetrate with high efficiency into the distal region of the lung. *We hypothesized that rats that receive EEG Survanta aerosol powder will have improved lung mechanics compared to the ones that received liquid Survanta.* We also did not anticipate any inflammation reaction due to the delivery of surfactant in a powder form.

METHODS

Dispersions containing Survanta, mannitol and leucine in a ratio of 45:33:22 % w/w in a 5%v/v ethanol in water mixture with a solids concentration of 0.125% w/v were spray dried using the Büchi Nano

Spray Dryer B-90 HP (Büchi Labortechnik AG, Flawil, Switzerland). Spray drying parameters included an inlet temperature of 70 °C and a gas inlet flow of 120 L/min. Micrometer-sized EEG powders were collected into vials and stored at 2 to 4 °C. Sprague Dawley rats were purchased from Hilltop lab animal, Inc and were housed at Virginia Commonwealth University (VCU) vivarium. The studies performed were approved by VCU Institutional Animal Care and Use Committee and all procedures were performed according to their guidelines.

Rats were surfactant depleted with two warm phosphate buffer saline (PBS) lavages (10 ml/kg). We administered either liquid Survanta at 50 mg/kg using the standard of care instillation method via a 3ml syringe and or EEG Survanta surfactant powder (10 mg) aerosolized and delivered via a novel low actuation air volume dry powder inhaler (Figure 1). After the treatments, the rats were ventilated at 8 ml/kg for a total duration of 10 minutes on a Scireq rodent mechanical ventilator. Ventilation mechanics were measured before the surfactant depletion, after surfactant depletion, and 10 min following treatment. Bronchoalveolar lavage fluid was collected and centrifuged. Supernatant was saved for further analysis, and cytospin was obtained by resuspending and centrifuging the remaining cells onto microscope slides. The slides were then stained. To assess inflammatory response, differential blood cell counts were performed on the lavage.

The statistical analysis was performed via GraphPad Prism using an ANOVA test followed by pairwise comparisons as appropriate.

Fig. 1: Novel low actuation air volume dry powder inhaler used to aerosolize the EEG Survanta powder.

RESULTS

Airway compliance measured after 10 minutes of mechanical ventilation was normalized to the compliance before surfactant depletion and showed that there was a significant improvement with aerosol EEG Surfactant compared to instilled liquid Surfactant. We also saw a significant increase in normalized compliance of the aerosolized EEG Surfactant compared to the normalized compliance after the depletion but before the treatment, however the normalized compliance of the instilled liquid Surfactant was not significant from measurements taken after depletion (Figure 2.A). Though there was no significant difference between the normalized resistance of the liquid Surfactant treatment compared to the EEG Surfactant, the aerosolized powder treatment was closer to the healthy state and significantly different to the normalized resistance taken after the depletion than the liquid Surfactant group (Figure 2.B). The normalized elastance also showed a significant decrease in aerosolized EEG Surfactant compared to the liquid Surfactant (Figure 2.C).

Fig. 2: Ventilation mechanics of healthy rats, after surfactant depletion (SD) and following Surfactant instillation and aerosol delivery. * p-value < 0.05, **p-value<0.01, *p-value<0.001, **** p-value<0.000, ns: non-significant. n=5 for treatments.**

Since neutrophils are the first white blood cells to enter a given tissue during inflammation, and accumulation of neutrophils signifies an inflammatory reaction [4], we quantified the number of neutrophils relative to the total of white blood cells present in a 300 cells count. There was no statistical difference between percent neutrophils present

following liquid instillation of Surfactant compared to following aerosolization of the EEG Surfactant powder (Figure 3). Further, the overall low percentage indicated that there was no acute inflammatory response to the Surfactant in either form.

Fig. 3: % neutrophil obtained by number of neutrophils per 300 count of white blood cell count. n=5 per group No statistical differences were observed

DISCUSSION

Lung surfactant is critical to lung function and without it the alveoli will collapse resulting in respiratory distress. For a neonate, it is important to use a surfactant replacement therapy to remedy to NRDS. Current therapy utilizes the invasive instillation of liquid surfactants which although effective is distressing to both the patient and the physician. Alternative methods which are less invasive, such as aerosolized surfactant delivered to lungs should be considered. The results obtained in this study show significant compliance and elastance improvement following aerosol delivery of EEG Surfactant compared to liquid instillation of Surfactant, and the resistance shows the same trend though not significant. The results suggested that aerosolized spray dried powder Surfactant may be more effective than the clinically used liquid Surfactant administration for short-term lung mechanics improvements. It is likely that the aerosolized EEG Surfactant penetrates and distributes more efficiently inside the lungs, however further studies are ongoing to confirm this. The cytospin data showed no statistical significance between the liquid Surfactant and the powder form and a low neutrophil count, indicating that there were no signs of inflammation with either treatment.

In summary, an EEG Surfactant powder delivered using a novel DPI is promising method of surfactant replacement therapy. Future studies need to be performed to optimize the delivery system of the EEG Surfactant powder and to determine if the efficacy is dose dependent.

INTRODUCTION

The blood viscosity is a basic biological parameter affecting the blood flow both in large arteries and in microcirculations, and hence it can be used for potential diagnoses of blood-related diseases. Since it is known that elevated blood viscosity is found in blood from patients with diabetes mellitus [1] and other hematologic disorders, a rheological description of the relative viscosity will allow us to precise diagnosis of patients with hematologic disorders. The relative viscosity of a suspension of particles has been modeled as a polynomial function of the volume fraction for suspension of rigid spherical particles [2, 3]. However, a polynomial law in dense suspensions of non-spherical deformable particles such as red blood cells (RBCs) is still missing due to complexity of the phenomenon. We thus numerically investigate the behavior of RBCs in shear flow, and quantify the bulk suspension rheology by the stresslet tensor [3]. Our numerical model has been successfully applied to the analysis of hydrodynamic interactions of blood cells in micro vessels [4-6] and cell adhesion [7]. By using the model, we investigate the effect of the shear rate, volume fraction of RBCs and viscosity ratio between the cytoplasm and plasma on the relative viscosity.

METHODS

We consider a cellular flow consisting of plasma and RBCs with radius a in a rectangular box of size $16a \times 10a \times 16a$ along the stream-wise x , wall-normal y , and span-wise z directions, with a resolution of 8 fluid lattices per radius of RBC. An RBC is modeled as a biconcave capsule, or a Newtonian fluid enclosed by a thin elastic membrane, with a major diameter $8 \mu\text{m}$ ($= 2a$), and maximum thickness $2 \mu\text{m}$ ($= a/2$). The membrane follows the Skalak constitutive law [8]. The internal and external fluid is solved by the lattice-Boltzmann method (LBM). The load acting on the membrane is solved by the finite

element method (FEM). The LBM and FEM are coupled by the immersed boundary method. The precise description of the numerical model and methods are referred to our recent work [9]. The shear flow is generated by moving top and bottom walls, and the problem is characterized by the Capillary number,

$$Ca = \mu_0 \dot{\gamma} a / G_s, \quad (1)$$

where G_s is the membrane surface shear elastic modulus, μ_0 is the plasma viscosity ($= 1.2 \text{ mPa}\cdot\text{s}$). For the analysis of the suspension rheology, we consider the contribution of the suspended particles to the bulk viscosity in terms of the particle stress tensor $\Sigma^{(p)}$ [6]:

$$\Sigma^{(p)} = \sum_i^N \mathbf{S}_i / V, \quad (2)$$

and

$$\mathbf{S}_i = \int [(\mathbf{x}\mathbf{q} + \mathbf{q}\mathbf{x})/2 - \mu_0(1 - \lambda)(\mathbf{v}\mathbf{n} + \mathbf{n}\mathbf{v})] dA_i, \quad (3)$$

where V is the volume of the domain and \mathbf{S}_i is the stresslet of the i -th particle, \mathbf{x} is the membrane position relative to the center of the RBC, \mathbf{q} the load acting on the membrane, \mathbf{n} the surface normal vector, λ ($= \mu_1/\mu_0$) the viscosity ratio between the cytoplasmic viscosity μ_1 and plasma viscosity μ_0 , \mathbf{v} the interfacial velocity of the membrane, and A_i the membrane surface area of the i -th RBC. Finally, the relative viscosity can be expressed by

$$\mu_{re} = 1 + \Sigma_{12}^{(p)} / (\mu_0 \dot{\gamma}). \quad (4)$$

RESULTS

Figure 1 shows the example of the numerical results of dense suspension ($\phi = 0.41$) for $Ca = 0.1$ and $\lambda = 5$, which can be assumed as the physiological relevant viscosity ratio. We calculated the relative viscosity μ_{re} in such dense suspension and compare with those reported in previous experimental works [10, 11], where μ_{re} of normal human RBC suspensions for $\lambda = 5$ and $\phi \geq 0.4$ was measured. Out

numerical results of μ_{re} obtained well agree with the experimental results (shear-thinning character) as shown in Fig.2(a). Therefore, our numerical model is able to capture the rheological character of the blood based on the cellular-scale dynamics.

Next, individual RBCs in semi-dilute ($\phi = 0.05$) and dense suspensions are investigated, and examples of snapshots of the numerical results are shown in Fig.2(b), where, RBCs subjected to low Ca ($= 0.05$) in dilute suspension show tumbling or rolling motion, while most of them sifted to swinging motion in dense suspension ϕ ($= 0.4$). Figure 2(c) shows the numerical results of μ_{re} as a function of ϕ for $\lambda = 5$. μ_{re} for each Ca exponentially increases with ϕ , and tends to decrease as Ca increases. In recent our work [9], we showed that a simple polynomial approach cannot be applied to RBC suspensions; this issue cannot be solved by any higher-order expansions, since they necessarily involve particle-particle interactions and thus any higher-order coefficients would depend on the local flow and/or on the local microstructure. Rosti & Brandt (2018) have proposed that the effective volume fraction ϕ_e , which is a collective volume fraction for deformed particles, is able to describe μ_{re} of suspensions of deformable particles [12]. Here, we define ϕ_e with the semi-middle axis of the deformed RBC. The numerical results of μ_{re} successfully collapses on a single non-linear curve at least for $Ca \leq 0.2$. The single non-linear curves are fitted by a general exponential expression based on the Krieger-Dougherty formula [2]:

$$\mu_{re} = (1 - \alpha\phi_e)^{-\beta}, \quad (6)$$

where, $\alpha = 0.5$ and $\beta = 2.2$ for $\lambda = 5$. The single non-linear master curves for other different λ ($= 0.1, 1$ and 10) are also displayed in Fig.2(d).

Figure 1: Snapshots of one of the numerical result for dense suspensions ($\phi = 0.41$) at $Ca = 0.1$ and $\lambda = 5$.

DISCUSSION

Deformability of RBCs is dependent not only on cytoplasmic viscosity but also on the membrane shear elasticity, plasma protein and membrane viscosity. Although we ignore the membrane viscosity, the previous *in vitro* experiment showed that old RBCs have a higher viscosity without significant difference in membrane shear modulus [13]. Hence it would be interesting to study how the membrane viscosity changes the relative viscosity. In more recent numerical studies modeled sickle RBCs [14] or RBCs in diabetes mellitus [15], and estimated the patient-specific abnormal hemorheology. Those hematologic disorders impair the cell deformability resulting in high blood viscosity. If our proposed master curves especially at high λ ($= 10$) will be validated with future experimental studies, our numerical results may be able to provide precise diagnosis or drug efficacy for patients with those hematologic disorders.

In summary, the relative viscosity μ_{re} can be well described as a function of an effective volume fraction ϕ_e , defined by the volume of

spheres of radius equal to the semi-middle axis of the deformed RBC. μ_{re} successfully collapses on a single non-linear curve as a function of ϕ_e at least for $Ca \leq 0.2$.

Figure 2: (a) Relative viscosity μ_{re} for $\phi = 0.41$ as a function of the shear rate (or Ca). The experimental results of normal human RBC suspension [10, 11] are also displayed. (b) Snapshots of individual RBCs subjected to low $Ca = 0.05$ in dilute or dense suspension. (c) μ_{re} as a function of ϕ for different Ca . Those results (a-c) are obtained with $\lambda = 5$. (d) μ_{re} as a function of the effective volume fraction ϕ_e . The master curves in each λ are also displayed.

INTRODUCTION

Microencapsulation of single cells has emerged as a powerful tool for accurate diagnosis and more effective disease treatment strategies, such as in single cell diagnostic assays^{1,2}. Single cell encapsulation is usually accomplished with the assistance of microfluidic devices, in which cell-laden droplets are generated by shear force between two immiscible fluids. One drawback for this method is that the cell-laden droplets are usually dispersed in oil phase after generation, which is not favorable for cell viability^{3,4}. Also, the number of cell-laden droplets is usually small among the generated droplets due to the low cell density essential for one single cell encapsulation (~30 K/mL), which brings a lot of inconvenience to the following applications^{5,6}.

To sort between cell laden and empty microcapsules, cells can be optically detected after generation, and the cell-laden droplets can therefore be selectively extracted by external forces such as dielectrophoresis (DEP)⁷. However, these methods require labeling of the cells which can be detrimental to future applications, especially in tissue engineering and regenerative medicine due to toxicity⁸.

Deep learning has been very efficient in detecting subtle features in images or even surpassing human performance⁹. In this study, we proposed a deep learning-based method for single-cell-laden droplet detection. The detection model takes bright field microscopy graphs as input and does not rely on any extra labeling of the cells. This detection method was further combined with an external DEP force for on-chip real-time extraction of single-cell-laden droplets from oil into aqueous phase. The results indicate this system can achieve considerable high efficiency and purity in extraction of single-cell-laden droplets. Moreover, the cell viability is not compromised after extraction.

METHODS

Experimental Setup. The general system design and experiment setup are shown in Figure 1A and Figure 1B, respectively. Briefly, a microfluidic device is placed on stage of the microscope for

observation. The microfluidic device design is shown in Figure 1C. In the extraction region, two needles were used as the electrodes (E1 and E2). These two electrodes are loop connected to a switch which is controlled by a micro-controller. A voltage was applied on the circuit of the electrodes and switch, as illustrated in Figure 1D. The extraction region of the device is monitored using a cell phone which is wirelessly connected to a computer for real-time image capturing and transferring. The deep learning detection model running on the computer then determines whether the droplet in the detection region is empty or cell-laden. If a cell-laden droplet appears in the detection region, the computer program will send a corresponding signal to a micro-controller which activates DEP to extract the cell-laden droplets into the aqueous phase. The wire connection of the microchip is shown in Figure 1E.

Figure 1. Schematic illustration of the system design. (A) Structure showing the experimental workflow. (B) 3D sketch of the whole experimental setup. (C) Sketch showing the microfluidic device (top view) (D) Circuit connection of the electrodes, switch, and controller. (E) A real picture showing circuit connection of the switch and controller.

Deep Learning Models. The detection model is based on a current state-of-the-art model for object detection, i.e., single shot multiplexer detector (SSD)¹⁰. Three different backend structures were used in this study for comparison, i.e., MobileNet¹¹, GoogLeNet (Inception)¹², and Residual-Net (ResNet)¹³. The backend models were first pre-trained on the open source COCO dataset¹⁴. Then it is further trained with our self-collected droplet images, including both cell-laden and empty (no cell-laden) ones. The fine-tuning was performed using tensorflow¹⁰. The trained models are evaluated using precision (P) and recall (R) which are defined as following:

$$P = TP / (TP + FP) \quad (1)$$

$$R = TP / (TP + FN) \quad (2)$$

where TP, FP, and FN denotes number of true positives, false positives, and false negatives, respectively.

Statistical Analysis. Statistical analysis is performed in excel using Student's two-tailed t-test assuming equal variance. At least three independent runs were conducted for all experiments.

RESULTS

Generation and Characterization of Droplets. The aqueous solution of 2% (w/v) alginate in saline with MDA-MB-231 cells (30 K/mL) was introduced into I1, oil emulsion was introduced into I2, and the aqueous solution of 1.3 % (w/v) carboxymethyl cellulose in saline with 10 mM calcium chloride was introduced into I3 as the extraction phase (figure 1). Droplets are generated at the flow focusing and gelled into calcium hydrogel by Ca^{2+} . After generation, micrographs of the droplets were captured at the downstream camera region and decided by the detection model whether there are cells in the droplets or not. If the droplets are cell-laden ones, the detection model will send an activation signal to the microcontroller, which controls the switch. DEP force will be applied to the cell-laden droplets consequently, and the droplets will be selectively extracted into the aqueous phase.

Detection Model Training and Characterization. The trained models took images as input and outputted a numerical value (between 0 and 1) indicating the probability that a cell-laden droplet is in the image. This value was then compared with a custom-defined threshold. If the value is greater than the threshold, the detection model takes the image as a positive (with cell-laden droplets). The relation between the model performance and threshold was examined. It was determined that at threshold of 0.9, all three models can achieve precision and recall which are higher than 0.9. Therefore, 0.9 was used as the threshold value in the rest of the study. The model with MobileNet backend achieves the fastest inference time of ~16 ms.

Characterization of Cell Phone Camera. In this study, acquisition speed of 30 fps is used, which means the time interval between two adjacent image frames is about 33 ms. We found that there was some noise in the actual acquisition speed. The actual time interval between two adjacent image frames is about 18-50 ms. For actual real time application at 30 fps, we need the deep learning model to perform single frame inference within 18 ms so we adopted the MobileNet as our backend model for detection for the remainder of the study.

Model Performance on real-time detection. One concern about the detection is that cells might be out of focus when the droplets pass the detection region. The model performs pretty well even for cells which are out of focus. However, due to the small size of single cells (~10 μ m), some cells might be inevitably out of focus too much and are not captured in the images. Therefore, we conducted quantitative study by comparing the number of cells flowed into the flow focusing region and the number of cell-laden droplets detected at the downstream (Figure 2). As shown in Figure 2A (top right), the cells before the flow focusing

region were observed under phase field. Because the contrast between the cell (shining dot, indicated by the red arrow) and the background is quite obvious, we can get the exact number of cells flowing into the extraction channel. Meanwhile, real-time detection was performed at the downstream under bright field. The quantitative data was shown in Figure 2B. About 80% of the cells can be detected using the detection model under bright field.

Figure 2. Real-time detection and extraction of cell-laden droplets.

(A) Representative images showing the cell appearance before flow focusing junction under phase and detection at the downstream under bright field. (B) Quantitative data showing the detection efficiency of the model. (C) Typical image sequence showing the extraction of the cell-laden droplets from oil into aqueous phase.

Real-time Selective Extraction of Cell-laden Droplets. Then we conducted real-time extraction of cell-laden droplets. Typical graphs showing selective extraction of the droplets from oil into aqueous phase are shown in Figure 2C. When the model decides that a cell-laden droplet is in the detection region, the green box turns to red (which is just for visual effect and not necessary for extraction). The switch is activated, and the cell-laden droplet is extracted from oil into aqueous phase by the DEP force. When an empty droplet passes, the switch stays off and the droplet passes the electrode region without being extracted.

DISCUSSION

Capsules were able to be extracted from an oil to aqueous phase using deep learning-based detection with a high detection rate. More research needs to be conducted to address single cells that may be out of the plane of focus that cannot be detected. We have demonstrated that high accuracy single cell extraction without harmful labeling is possible. Using a cell phone for detection can allow for a wide range of researchers to utilize this technology in various applications.

INTRODUCTION

The recently-discovered glymphatic system¹ circulates cerebrospinal fluid (CSF) through the brain, sweeping away proteins and metabolic waste and playing a role similar to the lymphatic system in the rest of the body. Primarily active during sleep², the glymphatic system drives CSF through annular perivascular spaces (PVSs) surrounding arteries and veins, from which it accesses deeper brain tissue. The glymphatic system may play a key role in preventing neurological disorders, such as Alzheimer's and Parkinson's diseases, that are associated with accumulation of waste proteins (in these two examples, amyloid- β and tau). The glymphatic system also has potential for drug delivery³.

However, both the characteristics of biotransport via the glymphatic system and the mechanisms driving that biotransport have been topics of open debate in recent publications. In mice, PVS widths have been estimated from \sim nm to \sim μ m. CSF in PVSs has been said to flow either parallel² or anti-parallel^{4,5} to the blood in the adjacent vasculature. CSF flow has been suggested to pulse in synchrony with either the respiratory or cardiac cycle.

In results just published,⁶ we use *in vivo* particle tracking to measure CSF flow in PVSs surrounding pial arteries in mice, with high resolution in space and time. We show that PVSs surrounding the middle cerebral arteries of mice have characteristic cross-sectional size similar to the artery, 44 μ m on average, and smaller size estimates were probably made because PVSs collapse during tissue fixation. We measure typical flow speeds around 20 μ m/s, implying laminar flow in which protein transport is dominated by advection (not diffusion). We find that CSF is nearly stagnant near artery bifurcations, possibly explaining why amyloid- β accumulates there in Alzheimer's patients. In results currently under review⁷, we show that the elongated, eccentric PVS shapes we observe *in vivo* have lower hydraulic resistance than

circular, concentric annuli with the same cross-sectional area. Moreover, we show that hydraulic resistance is minimized when elongation is moderate, and that the elongation we observe *in vivo* nearly minimizes resistance. Thus, PVSs may have evolved their elongated shapes to optimize CSF pumping efficiency.

METHODS

All experiments were approved by the University Committee on Animal Resources of the University of Rochester Medical Center (Protocol No. 2011-023), and an effort was made to minimize the number of animals used. We injected 1- μ m tracer particles into the cisterna magna of male mice, age 8-12 weeks, anaesthetized with ketamine-xylazine to approximate sleep. We also injected intravascular fluorescein isothiocyanate-dextran to make arteries visible. We performed two-photon imaging through a cranial window using a resonant scanner B scope (Thorlabs) with a Mai Tai DeepSee HP Ti:Sapphire laser and a water immersion lens. Typically, we observed flow near the bifurcation of the middle cerebral artery, though we have seen the same phenomena in other pial PVSs as well. Images were recorded at 30 Hz. We used artery images to register the resulting movies during post-processing, removing translations caused by large-scale motions of the mouse with respect to the scope, which would distort flow velocity measurements. We tracked particles using an in-house algorithm written in Matlab, excluding stagnant particles that had apparently adhered to the vessel wall. We calculated hydraulic resistance by solving the Stokes equation numerically, with no-slip boundary conditions, using the Matlab Partial Differential Equation Toolbox. In cases where analytic solutions are known, our results agreed within 1%. Fits to experimental observations were determined by finding the circles and ellipses that have the same normalized second central moments as the corresponding dyed regions.

RESULTS

First, we examined characteristics of CSF flow in PVSs by averaging over time. Figure 1 shows the mean flow measured in one experiment (about 10 minutes long, using about 3×10^5 measurements). The mean velocity points in the same direction as blood flow, which proceeds from top-right to bottom-left along the artery shown here. CSF is nearly stagnant in the interior of the arterial bifurcation. The flow is fastest where other arteries and veins come close, narrowing the PVS. A narrower PVS dictates faster flow according to the continuity equation (conservation of mass).

Using the overall root-mean-square particle velocity U , characteristic size $L = 44 \mu\text{m}$, and viscosity $\nu = 0.697 \times 10^{-6} \text{ m}^2/\text{s}$, we calculate the Reynolds number $\text{Re} = UL/\nu \sim 10^{-3}$. Its small value suggests laminar flow, consistent with the smooth particle motions we observe. (However, the CSF flows we observe in PVSs do oscillate visibly as the artery walls pulse, as will be discussed in a separate presentation.) Finding $\text{Re} \ll 1$ also implies that the nonlinear term of the Navier-Stokes equation can accurately be neglected in future analyses. We also calculate the Péclet number $\text{Pe} = UL/D \sim 10^2$, where $D \sim 10^{-10} \text{ m}^2/\text{s}$ is the material diffusivity of proteins like amyloid- β . Finding $\text{Pe} \gg 1$ implies that flow dominates diffusion in transporting proteins through this part of the glymphatic system.

The regions where we observe tracer particles have widths similar to the artery, and much larger than the $\sim\text{nm}$ widths measured in fixed tissue. We confirmed the larger widths by making *in vivo* three-dimensional images (not plotted) with dye in the arteries and dye of another color in the PVSs. By continuing that imaging through fixation, we found that during that process, PVSs collapse and dye infiltrates artery walls, implying that *in vivo* studies are essential.

Figure 1: The mean flow of CSF in PVSs, obtained by tracking the motion of $1\text{-}\mu\text{m}$ spheres flowing through the brain of a live mouse. Left: velocity; right: speed. CSF flows in the same direction as the blood and is nearly stagnant in the interior regions of arterial bifurcations. CSF speed varies among animals but is about $20 \mu\text{m/s}$ on average. Adapted from [6].

We observe particles crossing from one side of an artery to the other only rarely, suggesting that the PVSs is narrow or closed above and below the artery—not a circular annulus. That observation is consistent with cross-sections measured *in vivo*, which show elongated PVSs, as in Figure 2a. We wondered if the elongated shapes might have lower hydraulic resistance (volume flowrate per unit pressure, per unit length) than circular annuli. To test that hypothesis, we considered Stokes flow in straight annuli, assuming the streamlines to be oriented along the annulus. In that case, the momentum equation (Stokes equation) simplifies to a Poisson equation, which together with no-slip conditions at the boundaries of the annulus, fully specifies the flow and the hydraulic

resistance. Modeling the PVS as the space between a circular artery and an elliptical outer boundary, we varied the ellipse elongation and PVS area. Figure 2b shows the velocity profile in one of the resulting shapes. Figure 2c shows the hydraulic resistance of many such shapes. Increasing the area reduces the hydraulic resistance, as expected. For a given area, we always find a moderate elongation for which the shape is optimal, in that it minimizes resistance. By fitting circles and ellipses to three published *in vivo* images of PVSs, we calculated the area, elongation, and resistance of each; all are nearly optimal. Thus, PVSs may have evolved their elongated shapes to optimize CSF pumping efficiency.

Figure 2: (a) PVSs surrounding pial arteries are elongated, not circular. (b) Velocity profile in a PVS-like shape. (c) Hydraulic resistance of PVS-like shapes. Each curve has a minimum, where pumping efficiency is optimal. Three curves correspond to areas matching real PVSs; their minima are marked in red. The actual shapes, marked in purple, are nearly optimal. Adapted from [7].

DISCUSSION

Our high-resolution measurements of the flow of CSF in PVSs show low- Re , high- Pe flow, parallel to blood flow, that is faster where PVSs narrow and nearly stagnant behind arterial bifurcations. By calculating the hydraulic resistance of a family of PVS-like shapes, we found that over a wide range of parameters, there is always a moderate elongation for which the shape is optimal and maximizes pumping efficiency. The three images of pial PVSs that we found in the literature all have near-optimal shapes. In future work, we hope to perform similar studies on smaller, more distal PVSs. We would also like to consider how artery wall pulsation, which seems to be the primary driver of CSF flow, affects which PVS shapes are optimal for efficient pumping.

PREDICTION OF CAROTID RESTENOSIS RISK AFTER ENDARTERECTOMY BY HEMODYNAMIC AND GEOMETRIC ANALYSIS: A 5-YEARS FOLLOW-UP

INTRODUCTION

Restenosis is the main complication affecting patients outcome after carotid endarterectomy (CEA) [1]. The evidence that late (>5 years) restenosis is similar to primary atherosclerotic lesions [1], for which a key role of low and oscillatory wall shear stress (WSS) is established [2], has led to identify in local hemodynamic disturbances a possible contributor to the development of late restenosis after CEA. Additionally, the clinical translation of the role of hemodynamic disturbances in vascular pathology have motivated the identification of specific geometric attributes of the carotid bifurcation as surrogate markers of the burden of low and oscillatory WSS [3].

The elucidation of the mechanistic processes underlying restenosis development would greatly help clinical decision making about the appropriate CEA closure technique. Clinical debate currently exists concerning closure based on a direct suture (primary closure, PC), or on the interposition of a synthetic graft (patch graft, PG) [4]. To minimize the risk of narrowing of the arterial lumen, the use of PG is recommended for routine use by current guidelines [5]. However, PG involves longer cross-clamping time, higher risk of neurocognitive deficits, infection, pseudoaneurysm development. A selective use for PG based on carotid diameters has also been suggested [4, 5].

Here we aim to establish whether hemodynamics and geometry post-CEA can predict the risk of late restenosis at 5 years in a cohort of 12 real world patients submitted to 13 CEA with two different closure techniques (9 PG, 4 PC). In detail, personalized computational fluid dynamics (CFD) simulations and a geometric analysis were performed and compared with clinical follow up data of intima-media thickness (IMT) at 5 years, to investigate the hemodynamics-driven processes underlying restenosis development and potentially guiding the PG vs. PC clinical decision.

METHODS

The study was approved by the I.R.C.C.S. Fondazione Policlinico Ethics Committee and patients provided informed consent.

Patient population data. 13 carotid endarterectomy procedures were performed in 12 asymptomatic patients with diameter stenosis >70%, as defined by a peak systolic velocity (PSV) >200 cm/s measured by Doppler Ultrasound (DUS). According to European guidelines [5], PG angioplasty was performed in 9 cases (PG1-9), PC in 4 cases (PC1-4). All patients were submitted to DUS follow-up at 3 months, 2 and 5 years. Cases with PSV >130 cm/s (indicating a diameter stenosis >50%) were defined as cases of restenosis. No patients presented restenosis at 3 months and 2 years follow ups. Two patients died for myocardial infarction (PG4), and pancreatic carcinoma (PG8) at 3 years. After 5 years, eligible patients were submitted to DUS follow-up for IMT measurements with linear 8 MHz probe and iU22 ultrasound scanner (Philips Ultrasound, USA). IMT values were automatically extracted with Qlab (Philips Ultrasound, USA) at these locations: internal carotid artery (ICA) distal to the carotid bulb (CB); CB; distal end of the common carotid artery (CCA), i.e., the flow divider (FD); CCA at 1 and 2 cm below the flow divider (FD-1cm and FD-2cm, respectively).

Computational hemodynamics. MRI acquisitions (Siemens 1.5T Avanto) were performed within 1 month after surgery and used for 3D geometry reconstruction [6]. The governing equations of fluid motion were solved using P1 bubble-P1 tetrahedral finite elements in the library LifeV (<http://www.lifev.org>). Patient-specific flow rate waveforms were extracted from echo-color DUS at the CCA and ICA and imposed as boundary conditions [6]. At the external carotid artery (ECA) outlet section, a traction-free condition was imposed [6]. The distributions at the luminal surface of time-averaged WSS (TAWSS), and oscillatory shear index (OSI) were calculated. The bifurcation

region was delimited by sections CCA3, ICA5 and ECA2 (Fig. 1A). Data from all 13 models were pooled to identify the 20th percentile value of TAWSS, and 80th percentile values of OSI. The burden of disturbed WSS was quantified by the surface area exposed to TAWSS, below (OSI above) the corresponding threshold value, and divided by the model surface area [2]. These hemodynamic descriptors are denoted Low Shear Area (LSA) and Oscillatory Shear Area (OSA).

Geometric analysis. Descriptors quantifying the expansion at the bulb (i.e., flare), and the tortuosity of the CCA were considered [3]. Flare was calculated as the ratio between the maximum CCA cross-sectional area (CCA_{max}) and the CCA3 area (Fig. 1A). Tortuosity was calculated between the “inflection point”, i.e. the point where the CCA-ICA centerline changes concavity, and the CCA3 centerline point (Fig. 1B) as $Tort=L/D-1$, where L and D are the curvilinear and Euclidean distance between the two points, respectively.

Statistical analysis. The relationship between the hemodynamic descriptors and the combination of geometric descriptors was quantified by multiple linear regression analysis. The quality of the regression was evaluated with the adjusted coefficient of determination R^2 , and the relative contribution of each predictor was determined from the standardized regression coefficients β . Then, linear regression analysis was used to identify relationships between hemodynamic or geometric descriptors with maximum IMT values.

Figure 1: A) CCA_{max} and CCA3 sections, whose ratio defines the flare, are shown in blue. CCA_{max} is normal to the average of the ICA and ECA centerlines. B) The centerline segment between the CCA3 centerline point and the inflection point was used to calculate tortuosity as $L/D - 1$.

RESULTS

Statistically significant differences were observed between the PG and PC groups for LSA and flare ($P < 0.05$), but not OSA nor tortuosity. In detail, PG patients exhibited larger average values of LSA than PC patients ($40.85\% \pm 19.10\%$ vs. $19.42\% \pm 10.61\%$), and higher flare values (2.60 ± 1.42 vs. 1.33 ± 0.10). This is not unexpected, since the inserted PG substitutes a portion of the endarterectomized vessel wall which is removed in PC. Notwithstanding the small sample size, a direct relationship emerged between flare and LSA ($P < 0.05$), but not OSA (Table 1). Linear regressions revealed direct associations between maximum IMT at 5 years and both LSA ($R^2 = 0.58$, $P = 0.006$), and flare ($R^2 = 0.74$, $P < 0.001$) (Fig. 2A), whereas maximum IMT was not correlated with either OSA ($R^2 = 0.15$, $P = 0.241$), or tortuosity ($R^2 = 0.25$, $P = 0.116$). At 5 years, DUS highlighted the presence of a $>70\%$ restenosis in PG1, and $>50\%$ restenosis in PG2 (right and left carotid in the same patient), confirmed by magnetic resonance angiography and intra-operative arteriography (Fig. 2B,C). A clear co-localization emerged between the area exposed to low WSS and the restenosis location (Fig. 2D). This is further confirmed for all cases in Fig. 3, where morphological DUS observations, presented with TAWSS and OSI distributions, allow to appreciate by visual inspection the co-localization between disturbed hemodynamics and observations of myointimal thickening or new atheroma development.

Table 1: Multiple regression of geometry vs. hemodynamics.

	Adjusted R^2	β flare	β tortuosity
LSA	0.359*	0.743*	-0.255
OSA	0.132	0.574	-0.200

* $P < 0.05$

DISCUSSION

While the mechanisms leading to restenosis after CEA are still being defined, the establishment of flow disturbances at the bifurcation has been often interpreted by surgeons as an harbinger of complications [4,5]. Here, we successfully linked disturbed hemodynamics after CEA to verified clinical cases of late restenosis, additionally exploring the clinical translation of such a link through surrogate geometric predictors of disturbed hemodynamics. These findings imply that the arteriotomy after CEA should avoid creating a large and sudden expansion, as it is linked to restenosis via the generation of flow disturbances. This is particularly true in obliged PG arteriotomy repair strategies. Our findings suggest also that hemodynamic and geometric analyses hold potential for the stratification of patients at risk for development of late restenosis, providing useful indications about (1) the best arteriotomy repair strategy, and (2) the best follow up strategy. In particular, geometric analysis could be easily integrated in a surgical planning pipeline to virtually explore personalized post-operative scenarios.

INTRODUCTION

Pulmonary hypertension (PH) is a progressive disease characterized by increased pulmonary artery (PA) and right ventricle (RV) pressure, and elevated pulmonary vascular resistance. It can lead to narrow PA, a thicker RV wall, and eventually RV failure and death [1]. It affects 10 to 52 cases per million with a higher incidence in women [2]. Typically, PH is diagnosed at an advanced stage of development and patients survive three to five years from the time of diagnosis. Clinical diagnosis of PH involves invasive methods such as Right Heart Catheterization (RHC). Several computational studies propose to quantitatively characterize the disease and improve its diagnosis, prognosis, and treatment [3-5]. However, these studies were performed at steady state conditions. The current work aims to improve the computational predictions by performing simulating pulsatile flow conditions with geometries up to the 7th generation of the pulmonary tree and transient resistance boundary conditions. A comparison of normal and diseased (PH) states is performed to establish the differences in flow dynamics between the states.

METHODS

Scanned patient data were reconstructed to obtain 3D patient specific geometries for a healthy subject and a PH subject. Extensions at the inflow and outflow boundaries were integrated into the 3D model to exclude boundary effects from the simulations results. Transient resistances at each outlet were assigned based on the diameter of the outlets to obtain the desired inlet pressure [3-5]. A pulsatile inlet velocity boundary condition was generated using a velocity waveform of a PH patient measured with a Volcano catheter and adjusted based on the patient-specific cardiac output. The pressure waveform, also measured with this catheter, was used to generate an inlet pressure at the proximal main PA (MPA). The resistances at the outlets were

iteratively adjusted so that the inlet pressure was matched with the desired MPA pressure at each time step. The Navier-Stokes equations (Equations 1 and 2) were solved using the well validated solver Fluent 19.0 (Ansys Inc., Canonsburg, PA).

$$\nabla \cdot \mathbf{u} = 0 \quad (1)$$

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} = -\nabla p + \nabla \cdot [(\nu)(\nabla \mathbf{u} + \nabla \mathbf{u}^T)] \quad (2)$$

The simulations were run for at least three cycles for periodic convergence. Figure 1 shows all the steps of the protocol from image segmentation to data post-processing.

Figure 2 illustrates the inlet velocity boundary condition and the matched pressure waveform at the proximal MPA.

Figure 2: Centerline velocity (a) and pressure (b) recorded at the main pulmonary artery.

The CFD results were post-processed and visualized using Ansys CFD Post (Ansys Inc, Canonsburg, PA) and Paraview (Sandia National Laboratory, Kitware Inc, Los Alamos National Laboratory). Oscillatory shear index (OSI) distributions were obtained using the formulation given in Equation (3). This index shows the variation of WSS in time at each point of the endoluminal wall.

$$OSI = 0.5 \left(1 - \frac{\left| \int_0^T \vec{\tau}_w dt \right|}{\int_0^T |\vec{\tau}_w| dt} \right) \quad (3)$$

RESULTS

The systolic pressure distribution, illustrated in Figure 3 for the healthy model, shows a high pressure at the proximal MPA and low pressure at the distal PAs. This is expected due to the acceleration phase of the cycle. Figure 3 also shows the WSS distribution for this model with relatively high values of WSS at the bifurcations of the distal PAs.

Figure 4 shows the OSI distributions on the pulmonary artery walls of the healthy and PH subjects for one cardiac cycle. The inlet extensions of the geometry were excluded from the results for the sake of clarity. Both models show relatively high OSI at proximal MPA, left PA, and right PA. However, the PH model has a lower OSI compared to the healthy model throughout most of the PA branches.

DISCUSSION

The blood flow in the pulmonary arteries of a healthy and a PH subject have been simulated using an advanced computational model. In addition, a comparative analysis was performed based on CFD simulations of healthy and PH pulmonary artery models. The preliminary results show clear differences between the two models in terms of their OSI distributions. Prior work from others on PH suggest similar differences in the wall shear stress WSS distributions [6]. The hemodynamic differences between healthy and PH patient models could help diagnose the disease or classify PH severity (e.g. World Health Organization classification). Tang et al. [6] provided evidence for a correlation between PH and WSS and differences in mean WSS between healthy and PH CFD models. We have simulated two patient-specific geometries, which limits the applicability of this study to general clinical outcomes. In addition, other hemodynamic indices could be correlated to clinical variables measured during diagnosis and follow-up of PH patients to obtain meaningful relationships between non-invasive CFD-derived metrics and invasively measured or calculated metrics indicative of PH severity.

INTRODUCTION

Approximately one in seven Americans have chronic kidney disease (CKD), of which 1.5% have end stage renal disease and must either begin hemodialysis or receive a kidney transplant. The creation and maintenance of hemodialysis vascular access provides a lifeline to patients reliant on dialysis. Due to its longevity, access-related costs and mortality, arteriovenous fistulae (AVF) is the preferred method of vascular access [1]. Despite its many advantages, AVF can be undermined by early primary failure rates and unsuccessful maturation [2]. These failures are attributed to peri-anastomotic venous segment stenosis [3] which can be quantified by generating three-dimensional (3D) models of the fistula and measuring cross-sectional area (CSA) through the venous segment. To develop patient-specific 3D AVF models we want an operator-independent imaging modality that yields high resolution images without the use of harmful ionizing radiation or contrast agents that may prove toxic to patients with advanced renal failure [4]. For these reasons, we use contrast-free magnetic resonance imaging (MRI) imaging modality. The aim of this study is to generate a set of AVF-specific tools to measure cross-sectional areas in AVF models using MRIs. Analysis was performed in swine, but techniques can be applied into clinical settings.

METHODS

Six male Yorkshire Cross domestic swine were purchased from a USDA-approved vendor and kept at the University of Arizona Animal Care Center. After 7 days of acclimation to the experimental facilities, AVFs were created by joining the external femoral artery and femoral vein (Figure 1(a)). The AVFs are allowed to mature for 28 days [5] and black blood (BB) contrast-free MRIs (parameters shown in Table 1) are performed. To generate the model from BB MRIs, control points should be selected in both the vein and artery are selected (Figure 1(b)). The

artery control points should be selected approximately 3 cm proximal and 1 cm distal. One of the vein control points should include the anastomosis plane and the proximal part of the vein, approximately 3cm from the anastomosis plane [6]. Additional control points may be selected in case of complex/non-cylindrical shapes.

Figure 1: (a) Surgical configuration of AVF, (b) Selection of control points

The control points are then interpolated throughout the vein and artery using a 3D version of dynamic programming (DP) [7]. Given the centerlines, the segmentation is performed using polar DP (Figure 2B) [8]. Given the segmentation, a 3D model is generated (Figure 2C) [9]. The 3D model centerline is refined using a 3D fast marching algorithm [10]. Using the centerline we can acquire CSA at different distances from the anastomosis plane, shown in Figure 2D. The concatenation of all venous CSAs is shown in Figure 2E.

Table 1: Contrast-free MRI parameters.

MR Imaging Parameters	SWINE 1	SWINE 2	SWINE 3	SWINE 4	SWINE 5	SWINE 6
Slice Thickness (mm)	0.75	0.8	0.8	0.8	0.8	0.8
In plane resolution (mm) x (mm)	0.7813 x 0.7813	0.7813 x 0.7813	0.7813 x 0.7813	0.7813 x 0.7813	0.7813 x 0.7813	0.7813 x 0.7813
Matrix Size (pixels)	320 x 320	320 x 266	320 x 266	320 x 266	320 x 266	320 x 266

Repetition time (ms)	1400	1700	1790	1690	1710	1690

Figure 2: Steps to generate cross-sectional area.

RESULTS

Dividing the artery into three parts allows us to compartmentalize the effects of the fistula on the artery. Table 2 shows that the proximal region of the artery is dilated when compared to its distal counterpart; yet both regions are dilated (more than doubled) when compared to their non-AVF arterial CSAs counterparts (Table 3). Figure 3 shows the heterogeneity of each fistula. Even with standardized surgery procedures, which can be quantified by the small variation in the maximum and mean curvature (Table 4), there is a big variation in not only the functional parameter of each AVF (i.e., minimum CSA) but also the profile of each AVF. Even in cases where the minimum CSA is similar (e.g., Swine 1 and 4), analyzing the CSA profile allows us to get a better understanding of where the stenosis is occurring. This can help physicians localize regions of intervention thus reducing the stress to the AVF.

Table 2: Arterial CSA Analysis.

Mean CSA Region (mm ²):	SWINE 1	SWINE 2	SWINE 3	SWINE 4	SWINE 5	SWINE 6
Proximal	85.1	85.4	74.3	44.7	28.2	86.3

Maximum Curvature	0.29	0.25	0.23	0.25	0.26	0.26

Figure 3: Representation of venous cross-sectional area plotted with respect to the distance from anastomosis.

DISCUSSION

Our findings suggest that differences hemodynamics plays a role in the maturation of the fistula. Future studies will aim to assess the causal relationship between hemodynamic profiles at baseline (3 days after the surgery) and which genomic pathways get activated in order to develop the functional changes seen 28 days after surgery. The ability to find relationship between non-invasive tools and genomics will allow us to intervene before occlusion of AVFs occurs.

INTRODUCTION

Cancer metastasis has been identified as one of the major causes of cancer-related deaths [1, 2]. During metastasis, small amounts of primary tumor cells migrate from the parent tumor to other tissues, where they form secondary tumors [3]. The mechanism for secondary tumor homing to new tissues locations remains under investigation, but it is well established that cancer cell migration is enabled largely by circulating cancer cells crossing the vascular endothelial barrier and traveling via the blood vessels [3, 4]. It has been suggested that the migration of cancer cells across the endothelium, in search of locations to colonize for secondary tumor formation, could be due to glycocalyx (GCX) dysfunction, which allows for cancer cell attachment to endothelial cells [4].

Endothelial glycocalyx dysfunction could be a result of multiple factors, and the most common way of GCX dysfunction is through inflammatory stress and enzyme activities which is mostly characterized by the specific loss of GCX components [5]. Currently, evidence is also emerging to suggest that disturbed flow patterns within the vascular system could also result in GCX dysfunction. Harding *et al* recently showed that disturbed flow patterns resulted in the decrease in the expression of GCX in rat cells [6].

We hypothesize that disturbed flow patterns in the vascular system will enhance the attachment of cancer cells to the endothelium due to disturbed flow induced dysfunctions in the glycocalyx. Our results provide evidence to support the fact that hemodynamics and the endothelial glycocalyx, together, play an important role in mediating cancer-endothelial cell interactions relevant to secondary tumor formation.

METHODS

A parallel plate flow chamber [6], was used to create disturbed flow patterns similar to what is observed *in vivo*. After introducing disturbed and laminar flow patterns to human umbilical vein endothelial cells (HUVEC) for 4 hours at 15 dynes/cm², we co-incubated HUVEC monolayers with Red Cell Tracker labeled stage IV breast cancer cell (4T1) or human breast adenocarcinoma cell (MCF7) in circulation, for an hour at 1 dynes/cm².

We investigated endothelial cell expression of GCX and the adhesion molecule E-selectin and made correlations to the level of attachment of 4T1 or MCF7 breast cancer cells.

In addition, we confirmed our results *in vivo*, 14 hours after no treatment or intravital treatment of Balb/c mice with 5 units (U) of neuraminidase (an enzyme that

degrades one component of the GCX: sialic acid). Red Cell Tracker labeled 4T1 breast cancer cells were injected into these mice intravitally and allowed to circulate for an hour. Mice were then sacrificed. Endothelial integrity was confirmed. GCX integrity or degradation was confirmed. 4T1 attachment to the blood vessel wall endothelial cells was quantified in the Balb/c mice lungs.

RESULTS

Disturbed flow enhances the attachment of 4T1 and MCF7 breast cancer cells to cultured HUVEC. Labeled 4T1 and MCF7 breast cancer cells were co-incubated, separately, with flow conditioned HUVEC. Compared to laminar flow conditions, 4T1 breast cancer cell attachment to the endothelium in disturbed flow conditions was increased by 2.35 ± 0.29 fold. For MCF7, exposure to disturbed flow resulted in a 2.34 ± 0.42 fold increase in attachment to HUVEC.

Differences in breast cancer cell attachment to HUVEC do not correlate to expression of E-selectin adhesion molecules. In fact, there is non-differential expression of E-selectin adhesion molecules between disturbed and laminar flow regions. We found that no statistically significant difference between the HUVEC expression of E-selectin adhesion molecules in disturbed versus laminar flow regions.

Elevated breast cancer cell attachment to HUVEC coincides with HUVEC glycocalyx degradation in disturbed flow regions, and is a result of glycocalyx degradation. Expression of GCX was assessed by wheat germ agglutinin (WGA) staining and showed an intact GCX on the surface of HUVEC monolayers in laminar flow conditions. After introducing HUVEC monolayers to disturbed flow patterns, the GCX coverage of and thickness on HUVEC were both reduced by about 60%. We attributed the increased breast cancer cell attachment to this reduction in GCX coverage. To confirm the role of the GCX in cancer-endothelial cell adhesion, we degraded the GCX in laminar flow conditions and successfully induced cancer cell attachment in the same region.

In vivo, neuraminidase-induced GCX degradation leads to increased attachment of 4T1 breast cancer cells in the pulmonary blood vessel wall endothelium. When *in vivo* experiments were performed to confirm *in vitro* findings, first we investigated the expression of GCX before and after treating Balb/c mice with 5 U of neuraminidase. We found that there was a statistically significant 20% decrease in the thickness of GCX in neuraminidase treated mice, in comparison with non-treated mice. After treating Balb/c mice with 5 U of Neur,

there was also a statistically significant increase in the attachment of 4T1 breast cancer cells to the blood vessel walls in the lungs of neuraminidase treated Balb/c mice, in comparison with non-treated mice. Specifically, we observed a 2.2 ± 0.11 fold increase in the attachment of 4T1 breast cancer cells to the lung blood vessel walls of neuraminidase treated mice, compared to untreated mice.

DISCUSSION

In this study, we showed evidence to support the importance of endothelial cell GCX in regulation of cancer cell attachment to the endothelium. In summary, we found that conditioning endothelial cells in disturbed flow conditions results in an increase in cancer cell attachment to the endothelium, which is independent of E-selectin expression and in correlation with GCX expression. We also confirmed that the increase in cancer attachment occurs as a direct result of decreased GCX expression *in vitro* and *in vivo*. Our results provide new insight into the possible pathway leading to secondary tumor formation during the progression of cancer.

INTRODUCTION

Ventricular septal defects (VSDs), the most common type of congenital heart defect (CHD), are characterized by a hole between the two ventricles, resulting in left-to-right shunting and increased flow in the right ventricle and pulmonary artery (PA).¹ The severity of the VSD is often diagnosed by the shunt size, which is measured by the ratio between the pulmonary and systemic flow (Qp:Qs ratio), with small, moderate, and large VSDs having <1.5:1, 2:1, and a 3:1 Qp:Qs ratio, respectively. If the VSD is left untreated or repaired late, it can lead to pulmonary arterial hypertension (PAH) in ~28% of VSD patients.² PAH is characterized by elevated PA pressure >25 mmHg and distal PA remodeling. Although previous studies have investigated the hemodynamics and its effect on cellular function in PAH, most have only focused on the disease progression and on the larger PAs.^{3,4} Few have investigated the initiation of PAH in the context of small, distal PA hemodynamics, which are most severely affected by the remodeling process in PAH. Difficulties in assessing the hemodynamics in the small, distal PAs include the lack of *in vivo* flow and morphometry measurements, specifically in pediatric patients. We hypothesize that VSDs alter PA hemodynamics and mechanical stimuli on vessel walls, which may initiate cellular dysfunctional pathways in the small PAs and thereby contribute to the initiation of vascular remodeling and PAH.

In this study, we perform computational fluid dynamics (CFD) simulations to study the hemodynamics of the entire PA tree in different sized VSDs to understand the mechanical conditions present at initiation of PAH. We use a patient-specific geometry of the pediatric PA geometry to simulate large PA hemodynamics (>1mm diameter vessels). To model small PAs (<1mm diameter), we develop a preliminary scaling law of the PA morphometry tree based on regression analysis of healthy PA models. With a scaled pediatric PA morphometry tree, we estimate hypothetical hemodynamics in the distal PAs. To our knowledge, this is the first study investigating the hemodynamics at the initiation of VSD-induced PAH that quantifies hemodynamics in the entire PA tree.

METHODS

To model the proximal PAs (>1mm diameter) in a VSD patient, we created a 3D geometric model of the healthy PAs of a 1-year-old male patient (body surface area BSA 0.49m², Ht=75.6cm, Wt=11.3kg) from a CT scan using the open-source software package, SimVascular (simvascular.org). For CFD simulations, we used a backflow stabilized

3D Navier-Stokes fluid solver with fluid-structure interaction and variable deformable walls using the coupled momentum method and an elastic modulus of 311kPa.^{5,6} At the inlet, we prescribed a generalized normal PA inflow waveform at the main PA, scaled to mean flows of 2.5, 3.75, 5, and 7.5 L/min for control (no VSD), small, moderate, and large VSD conditions. Assuming a cardiac index of 5 L/min/m² for our 1-year-old patient, the mean flow rates for the three VSD conditions corresponded to Qp:Qs of 1.5:1, 2:1, and 3:1, respectively.⁷ At every outlet, we prescribed a 3-element Windkessel model tuned to match a normal target PA pressure. Outlet boundary conditions were chosen to be consistent for all VSD conditions under the assumption of healthy distal PA vascular resistance and capacitance at the initiation of PAH prior to any remodeling. The 3D PA simulation setup is shown in Figure 1a. From the proximal PA simulation, we extracted pressure, velocity, wall shear stress (WSS), oscillatory shear index (OSI), and strain measurements at 50 random arterial segments throughout the PA model.

Due to the lack of pediatric PA morphometry data, we performed a morphometric analysis of the proximal PAs in different sized patients to extrapolate the distal PA morphometry, which cannot be easily imaged *in vivo*, for any patient size. We used CT/MRA images from a cohort of 12 healthy patients ranging in BSA 0.49-2.01 m² to build patient-specific models of the large, proximal PAs (>1 mm diameter, limited by image resolution) in SimVascular. We performed a morphometric analysis of the proximal PAs in the model using the diameter-defined Strahler method to categorize vessels into orders by diameter.⁸ Regression analyses of the vessel orders and diameters were performed for each patient. Trends in vessel orders and diameters for a BSA similar to our proximal PA model patient were extrapolated to the small PAs by scaling Huang et al.'s PA morphometry findings.⁸ A mathematical distal PA model (<1mm diameter vessels) for a 1-year-old with a BSA of 0.49 m² was created according to Spilker et al.'s methods and assuming: (1) the branching pattern of the distal PAs is uniform across all patients, and (2) extrapolation of the proximal PA scaling roughly estimates the distal PA sizes.⁹

We modeled the distal PA hemodynamics by extrapolating the outlet flows from the proximal PA model to the generalized distal PA morphometric model (Fig 1b). To extrapolate flows down to 50μm diameter vessels and calculate wall shear stress (WSS), we apply Poiseuille assumptions with a viscosity power law to account for non-Newtonian effects in the small PAs according to Pries and Secomb's *in vivo* findings.¹⁰

Figure 1: (a) Proximal PA model simulation setup with a prescribed inlet flow waveform and Windkessel outlet boundary conditions. (b) Distal PA mathematical model setup with extrapolated outlet flows from the 3D PA simulation to a BSA-scaled PA morphometry tree

RESULTS

In our proximal 3D model, we found that the average 1st invariant of Green's strain decreased down the PA tree and increased with VSD size (Fig 2a). Local OSI remained the same across different VSD sizes. Pressure waveforms were dampened in the distal PAs and increased in magnitude with larger VSDs. Proximal PA WSS increased with larger VSDs and down the tree with smaller vessels.

Preliminary multi-variable regression analysis of proximal PA morphometry data from pediatric and adult PAs showed logarithmic increases in vessel diameter with BSA. We used regression analyses relating BSA, vessel order, and vessel diameter to predict vessel diameters of the distal PAs for a 1-year-old.

With the 1-year-old scaled distal PA morphometric model, we found that the WSS increased with the smaller, distal PA tree and exceeded 200 dyn/cm² in the large VSD conditions. Figure 2b shows increasing WSS from the proximal and distal PA hemodynamics which also increase with VSD size.

Figure 2: (a) The 1st invariant of Green's strain decreased down the tree and increased with VSD size. (b) WSS increased from the proximal PAs (~1cm-1mm) to the distal PAs (1mm-10µm) and increased with VSD size.

DISCUSSION

Knowledge of the hemodynamics in the small, distal PAs is significant for our understanding of the remodeling process that occurs in PAH. Our study estimates WSS values to be a magnitude higher in the small PAs compared to the large PAs, indicating that remodeling of small PAs may be subject to large hemodynamic differences even before the initiation of PAH. This is significant in informing mechanotransduction studies investigating the initiation of PAH, specifically as a result of the mechanical stimuli involved in untreated CHD patients who later develop PAH. Previous shear stress related gene expression studies on PAH have used much lower WSS values, which correspond mostly to the largest PAs where dilation and remodeling usually occur in late stages of PAH, not initiation or early stages.^{3,11}

Furthermore, our preliminary results on the scaling of PA morphometry with patient size provides an initial understanding of how the PAs develop with age. Although morphometric studies have been extensively explored more than two decades ago, questions into how the entire PA tree grows in number and dimensions with age have yet to be answered thoroughly in humans.^{12,13} We hope that our preliminary study of *in vivo* PA diameters at different vessel orders will elucidate unknowns into pre-acinar PA morphometry growth. Even with the knowledge of pre-acinar PA growth, which is useful for studying pediatric PAs, assumptions of the intra-acinar vessels must still be made for hemodynamic studies of the small vessels.

This is the first study to estimate the hemodynamics of the entire pediatric PA tree with VSD conditions, showing much higher WSS estimates in the small PAs than previously believed. These results have implications for the design of future biological studies assessing the effects of mechanical stimuli on endothelial cells as well as vascular wall mechanics that may occur during the initiation of PAH.

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a complex vascular disease associated with a chronically elevated pulmonary arterial pressure. The onset and early progression of PAH can be traced to changes in the morphometry and structure of the distal vasculature tree. The overall goal of this work is to develop a computational model of PAH that couples hemodynamics with a vascular growth model. However, since the present medical imaging modalities are unable to provide accurate information on the downstream blood vessels, we need to establish the geometry of the distal arterial tree, consistent with pulmonary arterial literature. Moreover, modeling the growth and remodeling of the PAH through a fluid-solid growth formulation mandates the definition of the homeostatic baseline state in the distal vessels. The primary objective of the present work is to determine the homeostatic state in the distal arterial tree based on an extension of Murray's law and steady state hemodynamics.

METHODS

The composition and geometry of blood vessels strive to minimize the power consumption and dissipation which includes the metabolic cost of blood supply, power needed to overcome the viscous drag, and cost of maintaining the vessel wall materials. In this study, we assume that the target homeostatic state is governed by such an optimization rule [1]. To this end, the metabolic cost of the arterial wall constituents, C_{wall} , is assumed to be proportional to the mass of each constituent M_R^i with the constants α^i , which are the metabolic cost of each constituent per volume. Here, superscript i indicates each constituent. Similarly, the metabolic power needed for the supply of blood, C_{blood} , is proportional to the volume of blood that needs to be sustained with the constant α^b , which is the metabolic cost of blood per unit volume. Finally, the power

per unit length needed to overcome the resistance (viscous drag forces) is computed using Poiseuille equation (C_{drag}).

The vascular wall is assumed to be composed of elastin, collagen fibers, and smooth muscle cell. In addition, a thin-walled model is used for simulating the mechanics of the wall. The total energy cost per unit length in each individual blood vessel can be written as:

$$C(M_R^i, R) = C_{wall} + C_{blood} + C_{drag} \quad (1)$$

$$= \frac{2\pi R}{\rho_w} \sum \alpha^i M_R^i + \alpha^b \pi R^2 + \frac{8\mu q^s{}^2}{\rho_b R^4}$$

where q^s is the steady state flow rate in the vessel and R is the radius of each vessel. The mechanical equilibrium dictates that the vessel wall must bear the load applied by the intraluminal pressure. Therefore, the mechanical equilibrium as a constraint is applied through

$$p^s R = T_{\theta\theta} \quad (2)$$

where p^s is the intraluminal pressure, and $T_{\theta\theta}$ is the tension in circumferential direction. Finally, a generalization of this minimization to a bifurcating tree involves consideration of the steady state hemodynamics at each bifurcation. This will be achieved by applying the conservation laws for the flow, $q_{d1}^s + q_{d2}^s = q_p^s$, and pressure, $p_{d1}^s = p_{d2}^s = p_p^s$, at the bifurcations. In addition, consistent with the assumption for the cost function, the flow in each vessel is assumed to follow a Poiseuille's solution. The boundary conditions for this problem are either pressure or flow, imposed at the root inlet and terminal vessels outlets (uniformly). Once the geometry and mechanical structure of the arterial tree is defined, an analytical solution based on Womersley's deformable wall theory [2] is applied to simulate the pulsatile hemodynamics in the arterial tree defined as a fractal tree [3].

Figure 1 Symmetric tree – homeostatic optimization results: (a) diameter distribution compared to reported data of larger vessels; (b) thickness to diameter ratio distribution versus diameter; (c) ratio of structural stiffness to the unstressed radius versus generation number; (d) pulse wave velocity versus generation number.

RESULTS

Diameters of vessels as a result of optimization are shown in **Fig. 1a**. Our analysis demonstrates that for the linear Womersley theory to be valid, the tree optimization must start from the third bifurcation downstream of the main pulmonary artery. A morphometry study, by Huang and colleagues [4], on the branching pattern and vascular geometry of the human pulmonary arterial trees found 15 orders in the pulmonary arteries using Strahler ordering model. In their study, 1st and 15th orders correspond to precapillary vessels and right/left pulmonary arteries, respectively. A comparison of results obtained in the current study to the results from Huang et al. [4] indicates an agreement between the diameter of our 1st generation and their 14th order pulmonary vessel. **Figure 1b** shows the thickness to diameter ratio of the arteries varying from 7.5% in larger vessels to ~9% in smaller vessels. Using a linearization of the optimization results at the corresponding p^3 , structural stiffness ratio to unstressed radius is computed and compared with other studies (**Fig. 1c**). Finally, the results of pulsatile hemodynamics are represented by the pulse wave velocity across different generations of the arterial tree (**Fig. 1d**).

DISCUSSION

We have described a model for identifying homeostatic state coupled with hemodynamics in a network of blood vessels with deformable wall. This model combines a constrained mixture model, which is widely used for modeling growth and remodeling, and a principle of minimum work to identify the otherwise unmeasurable quantities in downstream blood vessels. Applying the framework on a simple fractal tree with 14-19 generations produced physiologically reasonable results. The results compared against experimental data are shown in **Fig. 1**. A comparison with the data from [4] showed a great agreement of the first vessel diameter with what was observed in human pulmonary arterial tree. The wall thickness is obtained from the wall

constituents mass resulting from the optimization. The results for thickness show excellent compatibility with limited experimental data in pressurized pulmonary vasculature [5,6]. Experimental studies on the structure of pulmonary vasculature showed a uniform stiffness across the entire pulmonary arteries [7,8]. However, a 15% decrease in the stiffness is observed in the model. It is worth noting that predicted stiffnesses in **Fig. 1c** are linearized at each vessel's estimated *in-vivo* pressure. Another distally unmeasurable but valuable characteristic of pulmonary vasculature is the pulse wave velocity distribution along the tree. The pulse wave velocity depends on a variety of factors including wall stiffness and vessel size. As shown for two harmonics where the 1st is the leading and the 9th is of least contribution **Fig. 1d**, a decrease of the pulse wave velocity across the generations is the result of decrease in the structural stiffness as well as vessel size variability. The pulse wave velocity in larger vessels, however, shows a great agreement with pulse wave velocity measured in large pulmonary arteries in [9,10].

INTRODUCTION

Cells are known to adapt their cytoskeletal structure in response to intracellular signals and changes in the extracellular microenvironment. When cultured on 2D substrates, the cells adopt a more spread and spindle-like morphology with an increase in the stiffness of the substrate [1]. In 3D, cancer cells are known to adapt to the microenvironment by switching between different migration strategies while invading into the surrounding matrix. Each of these migration modes is characterized by unique cell morphologies. Emerging evidence shows that geometric constraints on the cell shape can have an impact on cell stiffness, contractility, cell fate and the ability of the cells to proliferate and differentiate. Therefore, studying the mechanism of cell morphological changes can help understand the fundamental mechanisms of mechanotransduction.

While cell shapes in both 2D and 3D have been considered in many studies, the mechanisms that regulate cell morphological changes remain poorly understood both qualitatively and quantitatively. In this article, we present a chemo-mechanical approach that integrates signaling with free energy associated with mechanical deformation and active contraction to reveal the mechanism of cell morphological adaptation to the microenvironment. Specifically, we modeled the signaling pathways that regulate active recruitment of contractile elements in response to the changes in the prop, the non-linear strain stiffening of the matrix and the engagement of adhesions to obtain the total active potential or free energy of the cell matrix system. We find that different cell shapes are associated with different mechanical stresses and thus have different total energies. We then study how the stress-dependent contributions to the cell active potential due to the cortical actin network and the action fibers that run along the cell body can induce changes in shapes of cells. The role of adhesions which

mechanically link the cytoskeleton with the extracellular matrix and regulate mechanotransduction is also studied.

METHODS

To elucidate mechanisms that determine the cell body shape, a chemo-mechanical energy-based model has been developed. The cell-ECM system energy associated with each cell shape is calculated and compared. The energy difference drives the cell shape to evolve from one to another, and the minimum energy determines the equilibrium cell shape. To calculate the system energy, the cell contracted state is considered to be derived from an imaginary quiescent reference state. Myosin motors are not engaged on the actin fibers, and no force or deformation is induced in this state. From the reference state to the contracted state, the energy change is divided into three categories: the cell energy, cell-matrix interface energy, and the matrix energy.

The cell is an active contractile material [2]. It extracts chemical potential energy from myosin motors to actively perform mechanical work. The cell energy thus contains mainly the chemical energy and the motor work. The chemical energy decreases with the increasing amount of myosin motors that are recruited to the cytoskeleton. This energy then converts to the mechanical work done by the myosin motors. The summation of chemical energy and motor work is defined as the cell active potential.

The cell-matrix interface energy characterizes the cell surface tension with originates from the cell membrane tension and cortical tension. This energy increases with the cell surface area.

The matrix energy is the strain energy stored in the matrix as the cell pulls the surrounding collagen fibers. It is calculated using a new constitutive model for collagen networks we have recently developed that accounts for the stiffening of the network along the direction of tensile principal strain directions [3].

RESULTS

When the cell properties are kept the same, and only the aspect ratio increases, the displacement field induced by cell contraction becomes larger and more anisotropic (Fig. 1a). As the cell adopts an elongated shape, the volumetric stress in the cell cytoskeleton increases (Fig. 1a & b). This is because, in the elongated configuration, the cell is less relaxed due to the geometrical constraint. It is as if the elongated cell is in a stiff matrix. The elevated volumetric stress stimulates the mechanosensitive feedback pathways (Rho-ROCK, Ca^{2+}), upregulating the myosin motors recruitment. More myosin motors are recruited with the increased cell aspect ratio (Fig. 1b). This leads to a decreased cell chemical energy, which scales with the motor density (Fig. 1c). Largely determined by the chemical energy, the cell active potential and matrix energy ($U - \Gamma$) decrease as the cell elongates (Fig. 3d). This suggests that the cell actomyosin activity naturally favors an elongated shape. On the other hand, as the cell evolves into an elongated shape with the same volume, the cell surface area increases. This causes the interface energy (Γ) to increase (Fig. 1d). Overall, the competition between the cell energy and the interfacial energy determines a non-monotonic total free energy curve, with the points of local minimum energy indicating the optimal cell shape (Fig. 1d). In some parameter ranges, two minima can be found. In the bistable region, the cell shape can adopt either shape. The cell shape of a cell population exhibits a bimodal distribution.

Figure 1: (a) The displacement field induced by cell contraction, and the cytoskeleton volumetric stress field. (b) The average cytoskeleton volumetric stress and myosin motor density with different cell shapes. (c) The relation between the chemical energy and the myosin density in (c). (d) The changes in energy as the cell elongates. The local minima of the total energy indicate the preferred cell shapes.

We then predicted that the cell aspect ratio depends on multiple intracellular signaling and extracellular properties (Fig. 2). For example, our model shows that the myosin motor recruitment regulated by feedback is the driving force for cell elongation. If the feedback strength α/β increases, the myosin recruitment from cell elongation further increases. The chemical energy reduction makes the elongated shape more energetically favorable. The model predicts that the cell aspect ratio will increase with the feedback strength α/β as plotted in Fig. 2. Similarly, the impact of the matrix stiffness and the adhesion density are also predicted. The cell aspect ratio increases with increasing matrix stiffness and adhesion density. Here the impact of ROCK inhibitor and integrin inhibitor are qualitatively marked on the phase diagram (Fig. 2). This prediction is consistent with the experimental results. The cells

under the treatment of Y-27632 or 4B4 mAb both show rounder morphology compared with the control [4].

Figure 2: The phase diagram of the cell aspect ratio and stability regions. The adhesion density, feedback strength, interface energy, and matrix stiffness are varied. Here, ξ denotes the scale factor of the ECM stiffness, η denotes the scale factor of adhesion density.

DISCUSSION

Cell morphology evolution is a complicated process that involves crosstalk between intracellular activity and extracellular matrix deformation. Using an energetic approach, our computational model reveals the driving forces underlying the cell shape change and has successfully predicted its dependence on the matrix and the cell biomechanical properties. Specifically, our model identifies that the myosin motor recruitment can lower the system energy as the cell aspect ratio increases, driving the elongation. On the other hand, we found that the cortical tension and the membrane tension increase the system energy when the cell elongates, favoring a round shape which has a minimal surface area. This competition determines a non-monotonic correlation between the cell shape and system energy. The cell shape with the lowest system energy is predicted to be the optimum that the cells should evolve into eventually. The model is applied to predict the shape of cells cultured in collagen with different concentrations under the treatment of Y-27632 and 4B4 mAb. The predictions agree well with experimental results from the literature, validating the model's ability to explain and predict cell shape changes.

INTRODUCTION

Collagen bundles exist in dense connective tissues, such as tendons and elastic arteries, as parallel wavy fibers [1]. The structure, known as crimp, contribute to the mechanical functionality of the tissue [2]. Cells embedded in this tissue follow the crimp structure and have wavy cytoskeleton and nuclei. We previously demonstrated that fibroblasts in engineered wavy fibrous structures have increased collagen synthesis and altered mechanotransduction compared with aligned straight fibers [3, 4]. Geometric constraints of cell morphology have been shown to control nuclear shape and chromatin dynamics through myosin-mediated cytoskeletal structures [5-7]. To understand how the wavy morphology regulates cell behavior and expression, we hypothesize that actomyosin structures control nuclear shape, which lead to changed chromatin organization.

METHODS

Microfabrication Fibronectin patterns were printed with the “stamp-off” method [8]. Briefly, PDMS membranes were coated with 50 µg/ml fibronectin and negative regions were removed with PDMS stamps treated with UV/Ozone or air plasma. Positive line patterns were 15 µm in width and the wavy pattern had an inner curvature of 100-133/mm. Pluronic-F127 (0.2 mM) incubation passivated the negative regions before cell culture.

Cell Culture Human bone marrow-derived mesenchymal stem cells or mouse embryonic fibroblasts were seeded on the patterned PDMS membrane for one hour or on the polyacrylamide gel overnight. Myosin activity was inhibited with 50 µM blebbistatin (Bleb) for 30 minutes.

Imaging and Analysis Cytoskeleton organization was examined by fluorescently labeling f-actin with AlexaFluor phalloidin (Invitrogen) and cell nuclei were labeled by DAPI. A custom Matlab program

confirmed cell conformity to the patterns and segmented the nucleus to calculate the elliptical Fourier analysis (EFA, [9]) of nuclear perimeter as well as the chromatin condensation index (CCI, [10]).

Traction Force Microscopy (TFM) For TFM, fibronectin patterns were printed on glass and transferred onto polyacrylamide gels (9 kPa) with embedded fluorescent beads (0.2 µm). Cells were seeded on the gel overnight and imaged on a spinning disk confocal microscope (Nikon/Yokogawa) at 20x magnification. Displacement and traction maps were calculated with the ImageJ plugins PIV and FTTC [11].

Statistical Analysis R was used to generate plots and perform one-way ANOVA analysis with post-hoc test ($\alpha=0.05$). All experiments were repeated at least once, with more than 33 cells per group.

RESULTS

Cells conformed to the fibronectin patterns and had actin structures that followed the long axis of the cell. In the wavy pattern, strong actin arcs could be seen in the concave edges, sometimes spanning the pattern (Figure 1A). Fewer, often wavy, actin fibers were found on top of the nucleus in the wavy cells. Nuclear shapes also followed the patterns, with increased deviation from the ellipse in the wavy cells, as seen in the EFA results (Figure 1B). A concomitant increase in chromatin condensation (CCI), as analyzed from the bright DAPI clusters, was seen in the wavy patterns. Since morphology-associated nuclear changes have been attributed to actomyosin tension, we measured cell contractility with TFM. Significant increases (231%) in contractility was found in the wavy cells. Surprisingly, while myosin inhibition with blebbistatin (Bleb) reduced contractility in both groups ($p<10^{-10}$), it did not abolish the differences in contractility or change nuclear shape in the straight and wavy cells (Figure 2, 3A). However, myosin inhibition attenuated the difference in nuclear organization between the straight and wavy shape cells (Figure 3B).

Figure 1: (A) Confocal images of representative cells in the line and wavy patterns. Scale bars = 10 μ m. (B) Wavy patterns increase nuclear shape (EFA) and chromatin condensation index (CCI, ** $p<0.01$, *** $p<0.001$)

Figure 2: (A) Representative patterned cells on polyacrylamide gels and TFM maps (Scale bar = 10 μ m or 1.2 kPa) (B) Wavy cells have higher average cell stress, even with blebbistatin treatment (*** $p<0.001$).

Figure 3: Myosin inhibition had no effects on nuclear shape (A) but reduced changes in chromatin condensation (B) in the wavy cells (* $p<0.05$, ** $p<0.01$).

DISCUSSION

ECM crimp contributes to the structure-function relationships in elastic dense connective tissues and is disrupted with aging and injury [12-14]. While the mechanical role of the crimp structure is widely reported, few studies have investigated its role in the embedded cells. Using microcontact-printed straight and wavy fibronectin patterns, we demonstrated that cells conform to the line patterns with changed actin cytoskeleton and nuclear structures (Figure 1). Wavy cell morphology enhanced cell contractility, nuclear deformation, and chromatin condensation (Figure 2). Interestingly, the increased nuclear deformation and cell tension did not correspond with increases in projected nuclear area ($p=0.31$), suggesting curvature-induced nuclear morphological differences are different from cell aspect ratio-related regulations reported previously [15]. Most studies have found the actomyosin cytoskeleton responsible for the cell shape-induced nuclear changes [5, 15] and we confirmed its role in chromatin condensation (Figure 3B, [16]). However, contrary to our hypothesis, myosin-inhibition did not alter nuclear shape or eliminate the differences in curvature-induced cell traction force in our study (Figure 2,3). We have previously demonstrated that curvature-induced nuclear deformation is actin-dependent [17]. Current findings therefore indicate that wavy structures induced myosin-independent mechanisms to regulate traction forces and nuclear organization.

INTRODUCTION

In developing tissue, mechanical forces are integral to a range of processes including cell differentiation, tissue morphogenesis, electrophysiology and contractility, but exact roles remain unknown. When mechanical forces are perturbed by experimental intervention or developmental abnormalities, their disruption can lead to congenital defects and disease. To date, tissue-level mechanical strains have been estimated by computational modeling, or by utilizing oil microdroplets as coarse-grained force sensors (1-2). Both methods lack ideal capabilities, which are (i) direct measurement of strain, (ii) at high spatial resolution over time, and (iii) with minimal perturbation of the system. We hypothesized that an extracellular matrix protein-based mechanical biosensor could measure the magnitude, direction and developmental timing of cell-generated strains within developing tissues and organs. Here we fabricated, calibrated and tested a fluorescently labeled fibronectin (FN)-based nano-mechanical biosensor (NMBS), which when applied to a tissue can deform in 3-D to provide a fluorescence-based strain readout during morphogenesis.

METHODS

To construct the NMBS we engineered a 2-D square-lattice mesh of fluorescent FN using a surface-initiated assembly based approach (Figure 1) (3). Briefly, a micropattern of interest is generated in a computer-aided design program and then transferred to a transparency photomask. The photomask is used in photolithography to expose a photoresist coated glass wafer, and then developed. A polydimethylsiloxane (PDMS) elastomer patterned stamp for microcontact printing is made by casting over the topographically-patterned photoresist-coated glass wafer. PDMS stamps are coated with the desired ECM protein, i.e. fluorescently labeled Alexa Fluor-633 human FN solution. The FN-coated PDMS stamps are stamped onto

poly(N-isopropyl acrylamide) (PIPAAm) coated glass coverslips leaving a microcontact-printed fluorescently-labeled FN-based square-lattice mesh, or NMBS, onto the sacrificial PIPAAm surface. PIPAAm is thermoresponsive in water and enables transfer of the FN-mesh to other surfaces. We have NMBS with dimensions of 10 μm lines by 100 μm spacing, 10 μm lines by 20 μm spacing, and 2 μm lines by 2 μm spacing, all 2-5 nm in thickness.

To track tissue strain, the NMBS is transferred to a sacrificial carrier substrate that in turn is used to transfer the NMBS onto a tissue. The NMBS-patterned PIPAAm-coated glass coverslip is placed with NMBS face down onto a Type A gelatin carrier surface. Room temperature ddH₂O is added to the glass coverslip causing dissolution of the PIPAAm and subsequent release and integration of the NMBS into the top surface of the gelatin. The NMBS-patterned gelatin gel is then lifted and placed with NMBS face down onto the desired tissue surface. This provides a general approach for transferring the NMBS to a range of tissues and surfaces. Finally, incubation at 37°C for 5 min melts the gelatin, integrating the NMBS onto the tissue surface.

Figure 1: Fabrication of the NMBS via Surface-initiated Assembly

For *ex vivo* experiments, chick skin feather bud explants and *Drosophila* ovarioles genetically engineered to express Moesin-GFP and Histone-2B-RFP were utilized to create developmental strain maps through live spinning disk confocal microscopy of the NMBS. Stem cell-derived cardiomyocytes were maintained following standardized protocols and were utilized for analysis of cardiac beat frequency and contractile strain via NMBS tracking on a widefield fluorescence microscope in combination with Fluo-4 calcium imaging studies. Quantification and analysis of the NMBS over time was performed through computational image analysis using custom Matlab, Imaris, and ImageJ code following *in vivo* fluorescence imaging studies.

RESULTS

To validate the NMBS as a strain biosensor, FN-NMBS were mechanically calibrated by application onto polydimethylsiloxane (PDMS) “dog-bones” and placed under uniaxial mechanical strain testing. Images of fiduciary marks were utilized to correlate the tensile and compressive macroscopic strain with the FN-NMBS quantified microscopic strain. Following external mechanical deformation, the FN-NMBS exhibited high correlation between microscopic and macroscopic strain verifying its accuracy as a strain sensor (Figure 2).

Figure 2: Uniaxial mechanical testing reveals correlation between NMBS microscopic strain and fiduciary macro strain tracking.

Finite element modeling simulations of uniaxial strain testing compared to the fluorescence data obtained via the FN-NMBS, confirmed the accuracy of the NMBS to track tissue level tensile and compressive strain. High-resolution fluorescence imaging of the NMBS applied to developing *Drosophila* ovarioles (Moesin-GFP, Green, Histone-2B-RFP, Blue, Alexa-633 NMBS, Red) revealed muscular contractions achieving 45% tensile and -46% compression strains every 10 seconds in a biphasic pulsatile fashion (Figure 3a, b).

Figure 3: Live imaging and analysis of NMBS demonstrates tracking of *ex vivo* strain in 3D during *Drosophila* ovariole development.

Additionally, the NMBS was applied to *Drosophila* ovarioles for 3-D strain mapping during ovariole growth and morphogenesis. Following 3 hours of time-lapse imaging, strain maps were constructed revealing 80% tensile and -60% compression strains throughout the tissue accompanying an ~18% increase in ovariole volume.

Finally, the NMBS was applied to stem-cell derived cardiomyocyte (CM) monolayers to determine CM beat frequency variation and characterize contractile strain. Fluo-4 calcium indicator dyes was used to confirm CM beat frequency and correlate the NMBS data to electrical activity (Figure 4a; NMBS, Red, Fluo-4, Green). By using a Fast Fourier Transform (FFT) of the NMBS signal during CM contraction, we were able to construct a beat frequency map within the field of CMs to uncover 2 primary beat frequencies of 1.18 Hz (Pink) and 0.64 Hz (Grey) (Figure 4b). In addition to the beat frequency quantification, we were able to construct displacement and strain maps for CM contractile cycles showing a maximum displacement of 9 μ m per contraction (Figure 4c). Following quantification and imaging of spontaneous CM activity, we electrical stimulated cells at 1, 2, and 3 Hz to validate the accuracy of the NMBS. In all cases, the NMBS beat frequency was an exact match to the stimulation rate.

Figure 4: Live imaging of NMBS applied to cardiomyocytes reveals location specific beat frequencies and maps displacement.

DISCUSSION

By using our custom open-source Matlab, Imaris, and ImageJ software, we are able to track a wide range of microscopic tensile strain above 100% and compressive strain below -80% in various biological applications to quantify a variety of dynamic biomechanical properties. In the future, we plan to measure and map cardiac tissue strain in developing *Xenopus* embryos during heart tube formation and looping. Obtaining a map of the biomechanical strain during cardiac tissue development and utilizing this to improve current engineered cardiac tissues is one of our long-term goals that will bring us one-step closer to realizing the potential of human iPSC-derived cardiac cells for heart regeneration. Importantly, the impact will be even broader, as the tools developed, and knowledge gained are transferable to other cellular, tissue, and organ systems where developmental forces can guide physiology and engineering strategies.

INTRODUCTION

Mechanical forces and hedgehog (Hh) signaling are necessary for the development and maintenance of the tendon enthesis [1]. Loading deprivation of mouse shoulders during postnatal development causes structural, compositional, and functional defects in the tendon enthesis, including reduced collagen fiber alignment, decreased mineral content, and impaired mechanical function [1, 2]. Loss of Hh signaling or Hh-responsive cells leads to significant defects in enthesis formation [1, 3]. Studies in other tissues have shown that both mechano-responsiveness and Hh signaling are regulated by the primary cilium, an antenna-like nonmotile organelle that projects from the cell's surface [4]. However, there is a lack of understanding about the crosstalk between cilium-mediated mechanotransduction and Hh signaling, and whether the cilium controls these processes during tendon enthesis development. Therefore, the current study evaluated the effects of *in vivo* loading on tendon enthesis cilium assembly and related Hh signaling.

METHODS

All animal procedures were approved by the Columbia University Institutional Animal Care and Use Committee. For overloading, 11-week old C57BL/6 male mice were allocated into three groups: treadmill running for 2 weeks, treadmill running for 4 weeks, or cage activity control (N=5 per group). The treadmill protocol consisted of downhill running at 10.2 m/min for 10 min followed by 13.2 m/min for another 40 min each day, 5 days a week, at a decline of 15 degrees. The unloading model followed the protocol from our previous study, which showed that neonatal botulinum toxin (BtxA)-induced paralysis leads to major defects in enthesis formation, and that decreased loading causes an increase in the number of Hh-responsive (i.e., Gli1+) cells [1-3]. To examine the crosstalk among primary cilium, mechanical loading, and Hh signaling, reporter mice were created by

crossing Gli1 Cre^{ERT2} mice with Rosa26-mT/mG mice [1, 3]. 0.2 U BtxA in saline was delivered to mouse shoulder muscles twice per week from birth through sacrifice at day 56 (P56). The contralateral limbs were injected with saline and served as controls. To label Gli1+ cells, tamoxifen was dissolved in corn oil and injected subcutaneously at P14 or P28. Conditional knockdown of Ihh signaling. To evaluate whether Ihh hedgehog signaling contributes to primary cilium assembly/disassembly, ScxCre mice were crossed with Smo^{f/f} mice. Humerus-supraspinatus tendon complexes from these mice were used for immunohistochemistry to examine cilia [1, 5, 6]. Immunohistochemistry and gene expression. Humerus-supraspinatus tendon complexes were prepared for frozen sections. Immunohistochemistry was used to label primary cilium (acetylated tubulin), Collagen type X, and Gli1 [4]; DAPI was used to visualize nuclei. The percentage of ciliated cells and the percentage of Gli1+ cells (normalized by the total cell number) were determined from histologic sections. Percent ciliation of Gli1+ cells was calculated as the number of cells positive for both primary cilium and Gli1 signaling, normalized by cells only expressing Gli1. For mice from treadmill running and cage activity groups, mRNA was isolated from tendon entheses using TRIzol reagent and Invitrogen PureLink RNA Mini kit [7]. The relative abundance of cilium- and Hh signaling-related genes were evaluated by SYBR-based quantitative RT-PCR. Data are presented as mean ± SD. Paired *t*-tests or unpaired *t*-tests, where appropriate, were used to compare cell percentages and gene expression of control and running groups.

RESULTS

There were more Gli1+/ciliated cells at the tendon enthesis of P7 mice than P28 mice, demonstrating coincident decreases in both Hh signaling and cilium assembly with maturity (Fig. 1). Muscle loading

regulated cilium assembly and Hh signaling. After 2 or 4 weeks of running, fewer cells at tendon enthesis possessed cilia compared to cage activity. However, the percentages of Gli1+ cells and Gli1+ cells with cilia were not affected by treadmill running (Fig. 2A-E). All genes related to cilium and Hh signaling were down-regulated in tendon entheses of treadmill running mice, with statistically significant differences for *Ift88*, *Kif3a*, *DYNC2H1*, and *Gli2* (Fig. 2F). Compared to contralateral loaded controls, BtxA-induced unloading led to a significant increase in the number of ciliated cells, but a decrease of Gli+ cells with primary cilia (Fig. 3). *ScxCre*; *Smo^{fl/fl}* mice showed significantly increased cilium presence in tendon cells, compared to control (Fig. 4).

Fig. 1: There were more ciliated (red, arrowheads) and Gli1+ (green) cells in immature (P7; A, B) than mature (P28: C, D) entheses (blue: nuclei). Middle panels are magnified images of the cells highlighted by dotted lines (N=3). Most of cells with cilia (E) were at the fibrocartilage region (green, Collagen X).

Fig. 2: Overloading via treadmill running led to loss of cilia in tendon enthesis cells. Entheses from cage activity and treadmill running for 4 weeks are shown (A-B, D-E). (C) There was a decrease in cells with primary cilia (red, arrowheads) after treadmill running, but the number of Gli1+ (green) cells was unchanged. (F) Expression of primary cilium and Hh-related genes was similarly downregulated after treadmill running (N=5 **P*<0.05).

DISCUSSION

Hh signaling was highly co-localized with primary cilium in the postnatal developing enthesis. The presence of cilia and Hh signaling showed reduced trends with tendon maturity, consistent with our previous study [1, 3]. Manipulation of *in vivo* physiological loading of tendon enthesis regulated primary cilium assembly, with unloading causing cilia formation and overloading inducing cilia loss [8]. But the disagreement between an increase of cilium-positive cells caused by unloading and a decrease of the percentage of Gli1+ cells with primary

cilium showed that cilium assembly is not fully synchronized with Hh signaling. This difference may also arise due to Gli1- cells forming primary cilia, due to unloading. Conditional knockdown of *Smo* promoted cilium assembly in tendon cells, indicating crosstalk between Hh signaling and cilium. These results indirectly support the idea that the primary cilium acts as both a mechanosensor and a Hh signaling hub at the developing tendon enthesis [7, 8]. To further examine the role of the primary cilium in tendon enthesis function and the influence of Hh signaling on cilium assembly, future work will use transgenic mice to examine structure and function of tendons with inhibited cilium assembly and address whether tendons with dysfunctional primary cilia can respond to mechanical loading and hedgehog signaling.

Fig. 3: BtxA unloading caused cilium assembly in the entheses. The entheses of BtxA and saline administration with tamoxifen injected at P14 (TA_P14), or P28 (TA_P28) were examined (A-H). Compared to the saline group, the percentage of ciliated cells (I) in the BtxA group was increased, but the percentage of Gli1+ cells with cilia (J) was reduced (N=4-5 **P*<0.05).

Fig. 4: Conditional knockdown of *Smo* in *Scx*-positive cells caused cilium assembly in tendon entheses. Representative images of control and knockdown mice are shown (A-B). The percentage of cells with primary cilia (C) was increased in knockdown mice.

SENSING THE CURVATURE: PROTRUSIVE SENSITIVITY OF INVASIVE BREAST CANCER CELLS

Apratim Mukherjee (1), Bahareh Behkam (1), Amrinder S. Nain (1)

INTRODUCTION

Cancer metastasis requires cells at the tumor boundary to biophysically probe the surrounding extracellular matrix (ECM) fibers through the formation of protrusions prior to detachment and subsequent migration through the ECM [1]. The fibers that the cell protrusions interact with span a wide range of diameters (from tens of nanometers to micrometers) [2], and *in vitro* assays have previously demonstrated that the fiber diameter can strongly influence both cell morphology and focal adhesion arrangements [3,4]. Using non-electrospinning Spinneret based Tunable Engineered Parameters (STEP) platform, we have previously shown that highly metastatic MDA-MB-231 cells form longer protrusions compared to their non-cancerous MCF-10A counterparts [5,6]. We found that the protrusions elongated in a diameter dependent manner by *coiling* (wrapping-around) the fibers. However, our understanding of how fiber curvature regulates *coiling* (protrusion sensitivity) remains limited.

Here, using quantitative high spatiotemporal video microscopy, we interrogate the sensitivity (*coiling*) of individual protrusions to fiber curvature. Specifically, we employ a suspended network of fibers with contrasting curvatures that decouples protrusive dynamics from bulk cell body migration [6]. Our method constrains cell body migration to large diameter ($\geq 2 \mu\text{m}$) *base fibers* while allowing studying single protrusions on smaller diameter *protrusive fibers* of different diameters (135, 270, 450, 600 and 1000 nm) (**Fig. 1A**). Interestingly, we find that protrusion tip *coiling* coincides with highly persistent translocation of endogenous granules into the protrusions.

METHODS

The previously reported non-electrospinning Spinneret based Tunable Engineered Parameters (STEP) method [6] was used to spin the protrusive fiber network described above. Polystyrene (PS, Scientific

Products, Ontario, NY, MW = $2 \times 10^6 \text{ g mol}^{-1}$) was dissolved in p-xylene (Fisher Scientific, Pittsburgh, PA) at (w/w) concentrations of 7, 8, 10, 12 and 14% to prepare solutions to spin the $\sim 135 \text{ nm}$, $\sim 270 \text{ nm}$, $\sim 450 \text{ nm}$, $\sim 600 \text{ nm}$, and $\sim 1000 \text{ nm}$ diameter *protrusive fibers* respectively. The spacing between consecutive *base* and *protrusive fibers* was fixed at $\sim 200 \mu\text{m}$ and $\sim 75 \mu\text{m}$ respectively.

MDA-MB-231 mammary ductal adenocarcinoma cells were cultured in Leibovitz's L-15 media (Thermo Fisher Scientific, Waltham, MA) supplemented with 10% Fetal Bovine Serum and 1% penicillin/streptomycin. Prior to seeding the cells, the protrusion scaffolds were incubated with $4 \mu\text{g/ml}$ Fibronectin (Invitrogen, Carlsbad, CA) for 3 hours, followed by cell seeding at a density of $\sim 300,000 \text{ cells/ml}$. Cells were imaged using an AxioObserver Z.1 (with mRm camera) microscope (Carl Zeiss, Germany) at $63\times$ (water immersion objective) magnification with 1 second imaging interval. ImageJ (National Institutes of Health, Bethesda, MD) was used to analyze the images.

At least three independent experiments were conducted for each defined metric and statistical analysis of the data was performed using RStudio (RStudio, Boston, MA). One-way analysis of variance (ANOVA) with the Tukey test was used to test for statistical significance between the different data sets.

RESULTS

Using the STEP platform we investigated MDA-MB-231 protrusive behavior at high spatiotemporal resolution ($63\times$ magnification/1 second imaging interval) and found that protrusions extended on suspended fibers by *coiling* around the fiber axis. We defined morphodynamic metrics of protrusion length (L) and eccentricity (E: broadening of protrusion base) to characterize the *protrusive cycle* (growth, maturation and retraction) of a single

protrusion (**Fig. 1A,B**) and the maximum *coil* width (**Fig. 1C,D**) to quantify *coiling* dynamics. We found that the *coiling* occurred in “spurts” synchronously with the growth phase of the *protrusive cycle*. Furthermore, while the fiber diameters at either extreme of the tested range (~135 nm and ~1000 nm) resulted in *coiling* initiation independent of an increase in E, on the intermediate diameters (~270 nm - ~600 nm) a significant increase in E was necessary prior to *coiling* initiation (**Fig. 1E**). Thus, we found that both the average E at *coiling* initiation and the time it takes for *coiling* to be initiated exhibit biphasic relationships with increasing fiber diameter (**Fig. 1F,G**).

Figure 1: Morphodynamic metrics used to quantitate *coiling* dynamics. (A) Schematic of the protrusion fiber network along with definition of the metrics used to quantitate the protrusive cycle and *coiling* dynamics. Inset shows SEM image of a 2 μm base fiber and a 450 nm diameter protrusive fiber. (B) Representative protrusive cycle. (C, D) Phase images and schematic showing the temporal evolution of *coiling* on a 600 nm diameter protrusive fiber. (E) Increase in E is typically required prior to *coiling* initiation (representative profile for a 600 nm fiber diameter case) (F, G) Average eccentricity at *coil* initiation and time taken for *coiling* to be initiated as a function of fiber diameter. n values: 21, 21, 23, 20, 20 for the diameters 135, 270, 450, 600, 1000 nm, respectively. All scale bars are 5 μm .

To investigate the dynamics of individual *coiling* events we defined additional metrics of *coil* growth rate (rate at which the *coil* width increases) and the time taken to reach maximum *coil* width. We found that both the maximum *coil* width and *coil* growth rate exhibited an increase with increasing fiber diameter (**Fig. 2A,B**) whereas the time taken to reach the maximum width showed a biphasic response with increasing fiber diameter (**Fig. 2C**).

Figure 2: Individual *coiling* dynamics are regulated by fiber diameter. (A) Maximum *coil* width (B) *Coil* growth rate and (C) Time to reach maximum *coil* width as a function of the protrusive fiber diameter. n values: 117, 75, 113, 111, 77 for the diameters 135, 270, 450, 600, 1000 nm, respectively.

We also observed endogenous granules translocating into the protrusions (**Fig. 3A**) during the growth phase of the *protrusive cycle* which coincides with the *coiling* spurts (**Fig. 3B**). Given that fiber diameter regulated *coiling* kinetics, we thus inquired whether the granule dynamics were also influenced by the fiber diameter. We found

that similar to the trends shown by the individual *coiling* dynamics, the speed and persistence (ratio of displacement to the total distance) of the granules increased with increasing fiber diameter (**Fig. 3C,D**). Furthermore, mean square displacement (MSD) analysis of the granules trajectory revealed that the granules exhibited superdiffusive motion with the MSD exponent also increasing as a function of fiber diameter (MSD exponent of 1.37 ± 0.07 , 1.57 ± 0.05 , and 1.77 ± 0.04 on ~135, ~450, and ~1000 nm diameter fibers respectively).

Figure 3: Dynamics of granule translocation into protrusions. (A) Representative time lapse images showing a granule entering into a protrusion (yellow arrows mark granule location; scale bar is 5 μm). (B) Percentage of total granule translocation cases during each stage of the *protrusive cycle* (n = 89 granules). (C, D) Granule speed and persistence as a function of fiber diameter. n values: 19, 17, 12, 21, 20 for the diameters 135, 270, 450, 600, 1000 nm, respectively.

DISCUSSION

In this study, we quantitatively investigated the dynamics of single protrusion-fiber interactions and found that the fiber diameter plays a significant role in regulating protrusion tip *coiling* dynamics. While both the average E at *coiling* initiation and the time taken to initiate *coiling* exhibit a biphasic response with increasing fiber diameter, the individual *coiling* kinetics (maximum width and growth rate) increases as a function of fiber diameter. The observed differences and similarities in *coiling* dynamics between fibers on either extreme of the investigated range can be potentially explained based on available surface area for the protrusions. The smallest tested diameter fibers (~135 nm) do not provide enough surface area for the maturation of focal adhesions whereas in contrast, the largest examined diameter fibers (~1000 nm) provide sufficient area for cells to attach faster.

In summary, our platform of suspended ECM mimicking fibers allows systematic investigation of how cancer cells biophysically sense fibers of varying diameters, thus allowing us in the future to characterize conditions which either promote or hinder metastatic invasion.

INTRODUCTION

Cell-generated forces drive cell migration and rearrange the surrounding extracellular matrix (ECM). These forces are fundamental to physiological processes such as morphogenesis and wound healing and are altered in disease states such as cancer [1-3]. Quantifying cell-generated forces in 3D, then, is pertinent to better understanding cell migration and matrix remodeling in these contexts. Yet much remains unknown about cell forces in these processes, in part due to the limitations of current methods of measuring cell forces [4].

Traction force microscopy, or TFM, is the most commonly used approach for cell force measurement [1]. Traditional methods of TFM rely on measuring the deformation of 2D substrates to calculate cell forces [2]. However, cells exhibit different migratory modes and focal adhesion dynamics in 3D compared to 2D [5, 6], and these modes are highly dependent on ECM properties; as a result, cell forces measured in 2D may not be representative of the cell forces that would be exerted in a 3D environment [6]. Moreover, the substrates used in classical TFM are linear elastic, while ECM and engineered equivalents have been shown to have nonlinear elastic and viscoelastic properties [7].

In order to improve upon these limitations, 3D approaches have been developed to incorporate more native ECM-like environments such as collagen gels [8]. While these methods address the limitations of traditional 2D techniques, they utilize constitutive models of the ECM to solve for traction forces. In doing so, these methods fail to capture the specific local fiber architecture or account for the fact that as cells migrate and generate forces, they in turn reorganize the surrounding ECM, causing local anisotropy in both fiber alignment and stiffness due to strain stiffening [9].

This work aims to address an unfulfilled need in the field for a method of accurately measuring traction forces in 3D at the fiber level [1, 10].

METHODS

Toward this end, we are developing a method of measuring forces on the fiber level with the following steps: 1) image acquisition of cells deforming 3D matrices using SHG imaging, 2) image analysis of the fiber network architecture from SHG images using a fiber extraction algorithm [11], 3) network deformation tracking using a shape context method [12], and 4) inputting deformations into a discrete network model [13], from which cell forces can be calculated. In order to develop this TFM approach, we must first validate each of these steps. With this in mind, we focus here on the various methods we are using to validate this approach.

Image Analysis: The FiBeR Extraction (FIRE) algorithm [11] has been used in the literature to quantify collagen fiber architecture from SHG image z-stacks. FIRE finds fiber architectures by taking an image stack, flattening it, applying a Gaussian filter, and then binarizing the image using a pixel value threshold. It then utilizes a minimum distance from pixels to the background and traces along the maximal ridges of the distance function. Using an input threshold, the algorithm identifies nucleation points, and then connects these points to local maxima of the distance function, thereby creating a network of nucleation points and branches representing the network architecture.

To test the FIRE algorithm's validity for network architecture extraction, 3 mg/mL collagen gels were created as described in [14] and were imaged at 880 nm using a MaiTai Ti:Sapphire laser to obtain SHG signal for collagen fiber visualization. SHG z-stack images were collapsed using a maximum image projection and qualitatively compared to a z-projection of the extracted network.

Network Deformation Tracking: Once network architectures are extracted from SHG images, deformations of network fibers and nodes (crosslinks within the network) are tracked by registering nodes at each time point based on their so-called shape context, an idea first presented

by Belongie et al. [12]. A shape context, or polar histogram, is constructed for each node in the undeformed and deformed configurations based on the spatial distribution of the other nodes around it. A cost function is constructed based on the match of the shape contexts for each node between images. This cost function is a Chi squared statistic, calculated as follows:

$$C_{ij} = C(p_i, p_j) = \frac{1}{2} \sum_{k=1}^K \frac{[h_i(k) - h_j(k)]^2}{h_i(k) + h_j(k)} \quad (1)$$

Where C_{ij} is the cost matrix, a function of points p_i in the initial image and p_j in the deformed image; K is the number of histogram bins; and $h_i(k)$ and $h_j(k)$ are the K -bin normalized histograms at p_i and p_j . Once the cost matrix is created, nodes are matched by minimizing the cost associated with registering nodes using the LAPJV Jonker-Volgenant algorithm for the linear assignment problem in MATLAB [15].

To assess the tracking accuracy, we created networks computationally in MATLAB, deformed them by uniaxially stretching the networks, and then added varying amounts of noise to assess the limits of this method of network deformation tracking.

Force Calculation: Finally, using the tracked network deformations, forces exerted on the network are calculated using a discrete network code [13] where network nodes are modeled as pin joints and fibers are modeled by a nonlinear force-strain equation:

$$f = \frac{AE}{B} [\exp(B\varepsilon) - 1] \quad (2)$$

Where f is the fiber force, A is the fiber cross-sectional area, E and B are material parameters relating to the elastic modulus and nonlinearity, respectively, and ε is the Green strain.

After applying the deformations found by the tracking algorithm to this network model, traction forces may then be found by calculating forces on the interior nodes of the network. Nodes with a resulting nonzero force correspond to those that have an external force applied upon them, and the resulting traction forces can be found accordingly.

To test this portion of the method, simulated cell contractions were applied to networks at a patch of nodes, and the resulting deformation was tracked. Forces calculated from tracking were then compared to the applied forces.

RESULTS

Image Analysis Assessment of the network architecture extraction was performed by visual inspection, and the resulting fiber organization (Fig. 1B) was in good agreement with what was considered the ground truth, the SHG image (Fig. 1A). A 3D view of the resulting reconstructed fiber network is shown in Figure 1C.

Figure 1: A. Collapsed SHG z-stack of a 3D collagen gel. B. Z-projection of the extracted network architecture from the FIRE algorithm. C. The discrete network model reconstruction.

Network Deformation Tracking Networks were subjected to levels of noise ranging from 0.1% to 5%, and the resulting fiber forces from the tracked deformation were plotted against the fiber forces from the actual deformation (Fig. 2). It can be noted that tracked fiber force measurements start to deviate from exact fiber force values at roughly 4-5% added noise.

Figure 2: Sensitivity of the tracking algorithm to noise (n= 883).

Force Calculation Results of the validation of the force calculation are shown in Fig. 3. This work demonstrated that the methods do well with low (~100 nN) and medium (~1000 nN) forces, but have a harder time calculating traction force when high forces (~2000 nN) are applied, due to the fact the tracking algorithm is imperfect at larger deformations.

Figure 3: Forces applied to a network versus the measured forces from tracking (error bars= 95% confidence intervals; $p < 0.001$).

DISCUSSION

We present here the first work towards fiber-level traction force microscopy in collagen gels, which, once complete, can provide better insight into fundamental biological and pathological processes such as development and cancer. The results in our preliminary validation studies hold promise that our approach can accurately calculate traction forces with moderate noise and deformation present, and we are continuing to work on improving our deformation tracking methods for higher noise and deformation levels as we expand into experimental validation techniques.

INTRODUCTION

Injurious-stretch of the spinal facet capsular ligament is a cause of neck pain and supraphysiologic stretch of the innervated capsule induces axonal injury, neuronal hyperexcitability, and upregulation of pain neuromodulators [1-5]. The capsule's extracellular matrix (ECM) is composed of type-I collagen with varying fiber orientations [6,7]. The structural heterogeneity of the capsule leads to complex loading of the innervating afferents, depending on its deformations and matrix organization. Although painful tissue loading, neuronal activation, and collagen reorganization thresholds exist [5,8-12], mechanical thresholds for neuronal dysfunction and/or injury are lacking.

The neuronal cytoskeleton is coupled to the surrounding collagen matrix by the $\alpha_2\beta_1$ integrin subunit and the NR2B subunit of the NMDA receptor, enabling ligament primary afferents to sense microstructural mechanical cues [13-15]. Inhibiting the $\alpha_2\beta_1$ integrin prevents loading-induced substance P increases that are typical with painful loading [16], suggesting that integrin subunit may mediate pain, neuronal dysfunction and/or neuronal injury. Yet, that has not been investigated, partly due to a lack of mechanical thresholds for neuronal dysfunction. This study tested the hypothesis that integrin-mediated ECM-neuron interaction has a role in the strain thresholds for afferent NMDA regulation (a proxy of dysfunction) and/or injury. A previously characterized in vitro neuron-collagen gel model of the capsular ligament [3,5,16] was used to test effects of β_1 integrin inhibition on neuronal responses to macroscopic failure loading. Because extrasynaptic NMDA is increased after neuronal injury and the NR2B subunit is highly expressed in extrasynaptic NMDA receptors that are activated by stretch [15,17], NR2B expression was used as a measure of neuronal dysfunction. ATF3, which is upregulated in neurons within hours after spinal cord and peripheral nerve injuries [18,19], was used as a marker of injury.

METHODS

Gels were made of collagen solution (2mg/mL) derived from rat tails in 12-well plates and incubated at physiological conditions. Dorsal root ganglia were harvested from day 18 rat embryos, dissociated, and plated on gels at 3×10^5 cells/mL. Gels were cultured for 7 days with Neurobasal Media supplemented with 1% FBS, 2% B-27, 0.2% GlutaMAX, 0.25% D-Glucose, 10mM FdU, 10mM uridine, and 2.5S NGF, which was changed every 2-3 days. On day 4, collagen solution (100 μ L) encapsulated the neurons; on day 7, gels (n=12) underwent biaxial loading in a planar tester (574LE2; TestResources). In a subset of gels (n=4), the integrin β_1 subunit inhibitor TC-I15 (100 μ M; Tocris) [16], was added 36hrs before testing.

Gels were stamped into a cruciform (21mmX8mm) and a grid was drawn on the surface to define elements and calculate strains (Fig. 1). In a 37°C PBS bath, each arm of the gel was secured to microclamps equipped with load cells (500g; ± 2 mN sensitivity). A camera (Phantom-v9.1; Vision Research) tracked marker positions (500fps; 14.5pixels/mm) while arms were displaced at 3.8mm/s simulating injury rates [20,21]. Force and displacement data (200Hz) were synchronized with imaging, and filtered [3]. A subset of gels (n=8) was put in the bath as unloaded controls for neuronal assays.

Fig 1: Image of gel in reference unloaded configuration shows its elemental marker grid in the test device with loading axes. Strain map image shows elemental MPS at failure with matching plot.

Failure was defined at the peak force detected on any arm and confirmed visually (Fig. 1). Markers at failure were digitized and their positions relative to unloaded reference were tracked with ProAnalyst (Xcitex). Maximum principal strain (MPS) was calculated with LS-DYNA software (LSTC) [22]. Force, displacement, and MPS were compared between groups by separate t-tests.

After loading, gels were transferred to fresh media supplemented with 1% penicillin-streptomycin for 24hrs and fixed in 4% paraformaldehyde for immunolabeling. Half of each gel was labeled for β_1 integrin and half for NR2B and ATF3; β III-tubulin labeling was included for all assays. Gels were incubated overnight at 4°C with anti- β III-tubulin (1:200), either anti- β_1 integrin (1:200) or anti-ATF3 (1:400), and anti-NR2B (1:500), followed by secondary antibodies. Gels were slide-mounted and each element (2100X1800pixels²) was imaged by a Zeiss 710 confocal microscope. Densitometry quantified each label [23]. The amount of β_1 integrin in loaded gels was normalized to unloaded untreated gels. For each element, neuronal NR2B and neuronal ATF3 was calculated and β III-tubulin, respectively, and normalized to unloaded control gels. Differences in normalized β_1 integrin for each treatment group were compared by t-tests separately for control or loaded gels. Effects of inhibition on neuronal NR2B and ATF3 were evaluated by two-way ANOVAs.

Strain thresholds for upregulation of NR2B and ATF3 were calculated by logistic regressions of elemental normalized expression of each and MPS [5]. Each element was assigned a value of 1 if the normalized expression was more than in unloaded controls and 0 if it was below control. Elements from unloaded gels were included in the regressions with MPS of 0 since they were not loaded. The 50th-percentile threshold (p50) was defined for each regression and compared by ANCOVA chi-squared goodness-of-fit tests.

RESULTS

Force (29.9 ± 10.5 mN), displacement (4.1 ± 1.8 mm), and MPS ($31.2 \pm 19.1\%$) at failure with inhibition are not different ($p > 0.12$) from untreated values (24.9 ± 9.5 mN; 4.5 ± 1.1 mm; $25.1 \pm 13.3\%$). Integrin inhibition significantly decreases β_1 integrin expression in both unloaded gels ($41 \pm 14\%$; $p < 0.001$) and failed gels ($39 \pm 8\%$; $p < 0.001$) (Fig. 2). Both neuronal NR2B ($p < 0.049$) and ATF3 ($p < 0.008$) increase significantly after loading with and without inhibition (Fig. 2). Yet, the increases in NR2B (2.0 ± 0.8 over control) and ATF3 (1.7 ± 0.7 over control) in inhibitor-treated gels after failure are less robust and not different from the corresponding increases in untreated gels (NR2B 2.2 ± 0.9 over control; ATF 2.5 ± 1.1 over control).

Fig 2: NR2B and ATF3 increase after failure with and without treatment. NR2B is primarily in cell bodies in controls and axonal after failure.

The 50th percentile strain threshold for upregulation of NR2B (15.5%) is significantly ($p < 0.001$) higher than that for ATF3 (14.7%) in untreated gels (Fig. 3). Although the p50 for each of NR2B (17.7%) and ATF3 (18.3%) are higher ($p < 0.02$) with β_1 integrin inhibition than without (Fig. 3), they are not different ($p = 0.43$) from each other.

DISCUSSION

Although inhibiting the β_1 integrin subunit has been shown to regulate neuronal modulation of the neuropeptide substance P [16],

Fig 3: Fits of NR2B and ATF3 against elemental MPS show higher thresholds for NR2B ($p = 0.006$) and ATF3 ($p = 0.018$) for treated gels than untreated.

this study demonstrates its potential as possibly preventing possible neuronal dysfunction and injury (Figs. 2 & 3). Because the integrin $\alpha_2\beta_1$ mediates binding between the neuronal cytoskeleton and ECM [14], inhibition attenuates the force transfer to the cytoskeleton by collagen fiber deformation and reorientation during macroscopic stretch [3,9]. The collagen heterogeneity of the capsular ligament produces non-uniform local stresses and strains from macroscopic stretch [3]. Although this study did not evaluate local stresses or effects of regional collagen orientation on neuronal injury or dysfunction, microstructural effects likely play a role.

The dose of the integrin inhibitor used in this study matched the lowest dose found to reduce axonal substance P expression after painful stretch and to alter effects between substance P and regional strain [16]. The finding that strain thresholds for NR2B and ATF3 increases change with treatment (Fig. 3) may mean neuronal injury, dysfunction, and nociceptive modulation are mediated in some part by integrin signaling. Substance P expression is mediated by the MAPK and ERK pathways [24], both of which are secondary messengers in integrin-mediated pathways [25], as well as signaling effectors in the cellular stress response that corresponds to ATF3 expression [26]. Although this study suggests stretch-induced integrin activation may be drive the transcriptional changes associated with nociception and neuronal dysfunction, additional studies identifying the specific signaling mechanisms between nociception, neuronal activation and ATF3 expression would provide insight into these pathways and their relationship to mechanical responses at the macro- and micro-scales. Nevertheless, this study demonstrates a possible role of the integrin signaling pathway in mediating stretch-induced neuronal dysfunction and injury.

VERTEBRAL ENDPLATE REMODELING REDUCES SMALL MOLECULE DIFFUSION INTO DEGENERATIVE INTERVERTEBRAL DISCS

INTRODUCTION

Intervertebral disc degeneration is associated with a cascade of cellular, compositional and structural changes to the nucleus pulposus (NP), annulus fibrosus (AF) and bony and cartilage vertebral endplates (EP), and is frequently associated with back pain. Low back pain is the most common cause of disability in the United States, and has a prevalence greater than heart conditions, stroke and cancer combined [1]. Despite this clinical burden, the etiology of disc degeneration remains poorly understood. The disc is the largest avascular structure in the body; cells within the disc therefore rely on diffusive and convective transport via the vasculature in the EP to receive nutrients and eliminate waste products [2]. For this reason, it has long been hypothesized that compromised trans-endplate transport plays a critical role in disc homeostasis, and the initiation and progression of disc degeneration. Despite this critical role, the relationships between endplate structure, function and disc nutrition remain poorly understood. Here, we utilize an *in vivo* rabbit puncture degeneration model to study these interactions, and hypothesize that increasing remodeling of the bony and cartilaginous EP, characterized by increased stiffness and bone density, and reduced vascularity, will reduce small molecule transport into the degenerating disc.

METHODS

Following IACUC approval, 11 male New Zealand white rabbits underwent a surgical procedure to puncture 4 lumbar spine levels per animal. The adjacent, non-punctured levels were utilized as healthy controls. Three animals were euthanized 4 and 8 weeks post puncture, and five animals were euthanized at 12 weeks post puncture. A subset of the punctured discs were utilized in this study. Three animals designated for the 12 week time point received subcutaneous injections

of calcein (25 mg/kg) at 6 weeks post-puncture and alizarin (25 mg/kg) at 10 weeks post-puncture to label newly deposited mineral. At the 12 week time point, 3 animals were administered the small molecule, non-ionic MRI contrast agent gadodiamide intravenously, 30 minutes prior to euthanasia [2]. Quantitative MRI T1 mapping of the lumbar spinal levels was performed immediately after euthanasia using an inversion-recovery sequence at 4.7T using a custom solenoid coil. Gadodiamide is a T1 shortening agent, and thus the percent reduction in T1 (discs without gadodiamide versus those with gadodiamide at each time point) provides a measure of small molecule diffusion into the disc. Significant differences ($p < 0.05$) in outcomes were assessed via Kruskal-Wallis with Dunn's multiple comparison testing.

Motion segments ($n=4-6$ per group) were subjected to μ CT scanning at 10 μ m isotropic resolution to quantify bone volume fraction and trabecular morphometry parameters in the vertebral endplate between the growth plate and disc. Following μ CT, motion segments were cryosectioned in the sagittal plane using Kawamoto's tape method to 20 μ m thickness [3]. AFM-nanoindentation (≥ 12 indents per region, $n=3-5$ per group) was performed on sections at the AF-EP and NP-EP interfaces using microspherical tips ($R \approx 12.5 \mu\text{m}$, 10 $\mu\text{m/s}$ rate). The effective indentation modulus, E_{ind} (in MPa), was calculated via the finite thickness-corrected Hertz model [4]. Motion segments from animals receiving the calcein and alizarin labels were fixed in formalin, prior to cryosectioning at 20 μ m using Kawamoto's tape method, and imaged using fluorescent microscopy. Additional motion segments ($n=3$ per group) were processed for paraffin histology, sectioned to 10 μ m thickness, and stained with Mallory-Heidenhain trichrome stain to visualize the vasculature in the vertebral endplate, or with alcian blue and picrosirius red to visualize overall degenerative changes to the disc. Second harmonic generation imaging (SHG) was also performed on

paraffin sections to visualize collagen organization at the AF-EP and NP-EP interfaces. Significant differences ($p<0.05$) in quantitative outcomes were assessed via Kruskal-Wallis with Dunn's multiple comparison testing.

RESULTS

In the rabbit puncture model, degeneration progressed with time post-injury, and was characterized by loss of disc height, disorganization of the annulus fibrosus, anterior osteophyte formation, and increases in NP collagen content. SHG showed progressive disorganization of lamellae at the AF-EP interface as well as increases in organized collagen deposition within the cartilage endplate at 4 and 8 weeks, compared to controls. Mallory-Heidenhain staining, which stains erythrocytes in the vasculature orange, revealed a marked reduction in vessel density and size in the vertebral endplate adjacent to the NP at 8 and 12 weeks (Figure 1).

Figure 1: Stain for endplate vasculature (arrows) and SHG of the AF-EP and NP-EP (arrows indicate cartilage EP) interfaces in each group. Scale = 500µm.

Figure 2: (A) Calcein (green) and alizarin (red) labeling in the vertebral endplate adjacent to the disc 12 weeks post-puncture. Scale = 100 µm. (B) Bone volume fraction of the vertebral endplate for each experimental group. Bars denote $p<0.05$.

Calcein and alizarin labelling demonstrated increased mineral deposition in the vertebral endplate adjacent to punctured discs, localized to the margins of the marrow and vascular channels (Figure 2A). Bone volume fraction, measured via μ CT, was significantly

increased in the vertebral endplate adjacent to punctured discs compared to intact controls at 8 and 12 weeks post-puncture (Figure 2B). Trabecular thickness was also significantly increased at 4, 8 and 12 weeks in the vertebral endplate of punctured discs compared to controls.

AFM analysis demonstrated progressive increases in indentation modulus of the AF-EP interface, as well as the cartilaginous endplate adjacent to the NP, with increasing time post-puncture. Finally, gadodiamide diffusion into the NP was reduced in the 12 week puncture-degenerated group compared to healthy controls, while transport into the AF of degenerative discs increased compared to controls.

Figure 3: (A) AFM indentation modulus of disc interfaces. Bars denote $p<0.05$, * = $p<0.05$ compared with all other time points. (B) Diffusion into the disc measured by post-contrast enhanced T1 mapping. Bars denote $p<0.05$.

DISCUSSION

The role of small molecule trans-endplate transport in the initiation and progression of disc degeneration is a debated topic in the field. Furthermore, the structure-function relationships governing disc nutrition remain poorly understood. Degeneration of the disc in the rabbit annular puncture model resulted in significant alterations to the adjacent vertebral bony endplate and disc interfaces. *In vivo* calcein and alizarin labelling revealed new mineralization occurring in the vertebral endplate at both 6 and 10 weeks post-puncture, particularly at the borders of the marrow and vascular channels. This bone remodeling led to significant increases in bone volume fraction and reductions in vessel size and density. Disorganization of the AF-EP interface was evident on SHG imaging, as well as increased organized collagen within the cartilage endplate between the NP and bony EP. Furthermore, the interfaces between the bone and disc progressively stiffened with increasing severity of degeneration. These structural and functional changes were concomitant with reductions in small molecule diffusion into the NP. As NP cells rely entirely on diffusive transport for nutrient and waste product exchange, the reduction in disc nutrition may promulgate the progression of degeneration in the NP. Interestingly, diffusion into the AF region increased compared to controls, which may be due to neovascularization in the anterior osteophytes and peripheral annulus fibrosus local to the puncture. This work furthers our knowledge of the role of diffusive transport in disc degeneration, and may be leveraged towards the improved diagnosis and treatment of patients with disc degeneration and back pain.

INTRODUCTION

The facet capsular ligament (FCL) is a spinal ligament that spans the synovial joint formed by the articular facets [1] on the posterior aspect of the spine (Figures 1A&B). The FCL is composed primarily of collagen fibers and elastin fibers. The FCLs span most of the length of the spine, but the lumbar region is of particular interest to us due to its possible role in low back pain (LBP). LBP is a major public health problem, affecting 80% of adults in the United States and creating a significant burden on society and the health care system [1]. The presence of nociceptive nerves in the lumbar FCL [2,3] suggest that it may be involved in LBP.

Because of the irregular geometry of the FCL, even the simplest body motions can cause complex tissue deformations. We have shown previously [2] that the lumbar FCL undergoes a significant amount of in-plane shear during spinal flexion and extension. The mechanical properties of the lumbar FCL during these types of motion, however, have yet to be characterized in detail. Ianuzzi *et al.* [3], determined the principal strains of the lumbar FCL *in situ* during flexion and extension, but they didn't estimate the tissue stress. The objective of this work was to quantify the mechanical behavior of the lumbar FCL during planar shear testing.

METHODS

Cadaveric lumbar spines, ages 20 – 67 (mean: 53.2 ± 21.7) years obtained through the Minnesota Anatomy Bequest program, and were scanned in a 3T MRI system at the University's Center for Magnetic Resonance Research to grade the health of the facet joints and the intervertebral discs. Discs were graded on the Pfirrmann scale [4], and facet joints were graded on the Fujiwara scale [5]. Spine grading was performed separately by an orthopedic surgeon and a spine research

specialist. The facet joints ($n = 10$, L4-L5 level), were then resected from motion segments (Figure 1A).

To prepare the ligaments for mechanical testing, all posterior musculature was cleared, and the FCL was stripped of its surface membranes (Figure 1B). The curved ligament surface was flattened, and the trabecular bone was removed to facilitate loading of the sample into the testing machine, while still maintaining physiological attachments to the bone.

Figure 1: A.) L4-L5 Motion segment B.) Right facet with FCL C.) Shear testing setup of right FCL. During extension testing the actuator on the right (lateral) moved to stretch the sample. Next, for shear testing, the actuator on the left (medial) moved up or down while the lateral actuator remained fixed.

Mechanical characterization of the FCL was completed on a planar biaxial tester. Two, six-degree-of-freedom load cells were used, with each measuring one normal and two shear forces. Testing (Figure 1C) was completed in two stages. First, a series of uniaxial extension tests were performed to precondition the sample, with the final extension cycle being analyzed. Second, a shear strain was imposed on the ligament as might occur in spinal flexion and extension (10 cycles each

at 0.1 Hz). The ligaments were displaced to 20% strain based on previous research that showed that a 20% strain was a large enough strain to stretch the FCL out of the toe region, but not damage the tissue [6].

The force and displacement data from the load cells and actuators were used to calculate the first Piola-Kirchhoff stress and the engineering strain in the ligament. Surface displacement tracking was performed, following a previously described protocol [6]. Briefly, video data from the cycles of interest were converted in to image stacks, and the undeformed image was imported into Abaqus CAE to generate a planer mesh of the ligament surface, bordered by the bone on the medial and lateral sides. The images were then processed by an image correlation code, and the surface strains were calculated.

A 3D finite element model was developed for each sample geometry using FEBio (2.5.2). The FCL was defined as a Neo-Hookean matrix with a 2D exponential fiber family (Eq. 1)

$$W = C_1(I_1 - 3) + \frac{\xi}{\alpha\beta} \left(\exp[\alpha(I_n - 1)^\beta] - 1 \right) \quad (1)$$

where C_1 is the neo-Hookean constant, I_1 is the first strain invariant, ξ is the fiber modulus, and I_n is the square of the stretch in the fiber direction. The fiber distribution is defined with a von Mises fiber distribution (Eq. 2).

$$R(\mathbf{n}) = \frac{\exp[b(2n_1^2 - 1)]}{2\pi I_0(b)} \quad (2)$$

where I_0 is the modified Bessel function of the zeroth order, \mathbf{n} is the vector defining the fiber direction, and b is the fiber concentration parameter. The experimental data was fit to the models using a modified *fminsearch* in Matlab (2018b). To visualize the fiber distribution from the FE model fits, a random point cloud was generated from the von Mises distribution using Matlab (2018b) [7].

RESULTS

Figure 2: There were three different types of data seen from the mechanical tests (top row) the images shown are from representative samples A.) Asymmetric force during negative shear, B.) Symmetric in-plane shear force, and C.) Asymmetric force during positive shear. The second row is the FE model fit (black and green line) to the data (blue and red dots). The third row is a represented 2D fiber alignment generated from the von Mises distribution fit from the FE model.

Mechanical results for in-plane shear data are shown in Figure 2A-C. All samples ($n=10$) show one of the three different types, an asymmetric force in either the negative shear direction (Figure 2A, D), the positive shear direction (Figure 2C, E), or a symmetric shear force (Figure 2B, F). The matrix parameter C_1 from Eq. 1, had an average and 95% confidence interval of 0.018 ± 0.020 MPa, similar to that reported previously [6]. For the fibers, β was 5.71 ± 2.17 , ξ was 4.27 ± 2.93 MPa, and α was 1.94 ± 1.02 . The fiber parameters were higher in magnitude than those previously reported [6].

The fiber alignment and distribution are represented by Figure 2G-I, which the three different types of data. Figure 2G represents fibers that are aligned ($b=3.58$) in the direction $\theta = -31.35^\circ$ from the horizontal. Figure 2H represents fibers that are not aligned ($b < 1$). Figure 2I represents fibers are highly aligned ($b > 4.5$, $\theta = +16.86^\circ$). The fiber angle was negative for the 3 samples that showed the high negative shear type response. Similarly, the fiber angle was positive for the samples ($n=3$) that had high positive shear. The fiber angle and level of alignment had a wide range for the samples ($n=4$) of the symmetric shear forces. There was not a relationship between the fiber orientation and alignment of FCLs that were taken from the same donor.

DISCUSSION

The ranges of fiber orientation and alignment shown here have a dramatic effect on the shear mechanical response of the tissue. The strain ranges shown in Figure 2A, B, and C for both the positive and negative shear are comparable to what has been reported by Ianuzzi *et al.* [3] for physiological spinal flexion and extension. However, the range of forces and amount of strain at which tissue forces rose sharply varied from sample to sample.

These data indicate that there is more complexity in the fiber orientation and alignment than has been previously suggested and future imaging in combination with mechanical studies could elucidate these complex fiber structures of the lumbar FCLs. Patient-specific FCL models may be necessary to capture individual variation in structure and the resulting effects on spinal kinematics and kinetics.

INTRODUCTION

The intervertebral disc is comprised of the nucleus pulposus (NP) surrounded by the annulus fibrosus (AF). In the healthy disc, both tissues are comprised primarily of water (~85% in the NP, decreasing to ~65% in the outer AF) [1]. Aging and degeneration have been noted by a continuous decrease in NP water content, resulting in altered disc joint mechanics [1]. Previous studies have shown that noninvasive measurements of disc water content, such as T2 mapping, can be used to detect early changes in degeneration [2]. Such detection is important for identifying discs for preventative treatment strategies. However, those techniques largely rely on correlations to biochemical composition and do not directly measure water content. Moreover, water content is an important parameter for computational models that include tissue-swelling behavior [3].

Currently, measuring tissue water content is dependent on destructive techniques (e.g., lyophilization), therefore, is limited to *ex situ* tissues [1]. Alternatively, magnetic resonance imaging (MRI) has been used to estimate disc water content, as signal intensity depends on the proton density within the tissue [4]. However, MRI signal intensity is dependent on scan-parameters and the concentration of free water molecules in the tissue. Even further complications may occur when water molecules that rigidly bound to collagen macromolecules (e.g., ~3% of water in the NP and ~10% of water in the AF) do not appear on MRI due to a short T2 time [5, 6]. The objective of this study was to directly measure tissue water content using MRI. NP and AF water contents were measured noninvasively using T2 imaging and compared with traditional techniques. To generate a range of water content for comparison, healthy discs were mechanically dehydrated.

METHODS

Gravimetric water content (GWC), defined as the fraction of water mass divided by tissue mass, is related to volumetric water

content (volume fraction, VWC) through tissue and water mass density (ρ , $\rho_{\text{water}} = 1 \text{ g/cm}^3$, Eq. 1). Although GWC is widely used to report water content, MRI signal intensity (SI) correlates with VWC ($\text{SI}(\text{echo time} = 0) \propto \text{VWC}$) or spin density. Specifically, T2 relaxation times are calculated by curve-fitting MR SI versus echo time to an exponential function ($\text{SI} = \text{SI}_0 \exp(-\text{TE}/T_2)$, TE: echo time; relaxation rate, $R_2 = 1/T_2$). A known tissue mass density is need to directly compare water content calculated by MRI and traditional techniques.

$$\text{GWC} = \frac{V_{\text{water}} \rho_{\text{water}}}{V_{\text{tissue}} \rho_{\text{tissue}}} = \text{VWC} \frac{\rho_{\text{water}}}{\rho_{\text{tissue}}} = \frac{\text{VWC}}{\rho_{\text{tissue}}} \quad (1)$$

Bovine caudal spine sections were obtained from a local abattoir to prepare bone-disc-bone motion segments ($n = 20$). Before testing, samples were thawed and hydrated in 0.15 M phosphate-buffered saline (150 mmol/L 1x PBS) for 24 hours at 4°C and equilibrated to room temperature for one hour prior to imaging.

Before scanning, samples were put into a custom-built plastic compression device (Fig. 1a). Images were first acquired with no load applied. To calculate tissue spin density, T2 relaxation was determined for 2.5 mmol/L gadolinium water, which was placed next to the specimen and served as a phantom reference (Fig. 1a). Each sample was imaged using a 3D Fast Low Angle Shot (FLASH) sequence to record 3D geometric information (7T Bruker MRI machine; FOV = 3.2 X 3.2 X 2.8 cm). Then, samples underwent a 2D scan at the mid-disc height using a T2 Rapid Imaging with Refocused Echoes (RARE) sequence to calculate T2 relaxation times (TEs = 7ms, 21ms, 35ms, 49ms, 63ms, FOV = 5 X 5 X 0.12 cm, slice thickness = 1.2 mm, in-plane resolution = 0.39 mm/pixel). TR was set to 8 sec to enable full relaxation from both the gadolinium water and disc [7]. Then, samples were compressed in 1x PBS for 24 hours at 4°C before re-equilibrating to room temperature to force fluid out of the disc. After dehydration

through mechanical loading, MR imaging was repeated, as described above.

After imaging, samples were quickly unloaded and removed from the device. Explants from the NP center and AF were prepared (6mm in diameter) from a 1-2mm thick transverse slice cut from the mid-disc height. The mass of the hydrated tissue ('wet-mass') was measured on an analytical balance (0.1 mg accuracy). Then, tissue volume was calculated by measuring fluid volume displacement after placing the tissue explant in a bath, according to the Archimedes principle (Fig. 1b) [8] Tissue mass density was calculated by dividing wet-mass over volume. Then, explants were lyophilized for 48 hours to obtain dry mass. GWC was calculated, as defined above.

Fig 1: (a) Schematic of plastic compression device with gadolinium water (2.5 mmol/L). HDPE: high-density polyethylene, PMMA: poly (methyl methacrylate). (b) Schematic of tissue volume measurements [12]. Inset: example of T2 scan with circles representing regions of interest for NP and AF.

Exponential models were fit to MR SI versus TE times to calculate T2 and SI₀ on each pixel (*fit* function in Matlab 2018a). Spin density (SD) was calculated by normalizing the tissue SI₀ by SI₀ of gadolinium water. NP and AF region of interest (6 mm in diameter) were selected to calculate averaged SD, T2, and R2 values (Fig. 1 inset). SD and SD normalized by mass density were correlated with GWC. Mass density and R2 were correlated with GWC and SD. Significance was assumed at $p \leq 0.05$.

RESULTS

Three samples were excluded due to damage in the NP (e.g., blood from a fractured endplate). Mechanical compression successfully dehydrated disc samples and generated a wide range of NP GWC (from 0.69 to 0.84). MR spin density was greater than GWC (0.81-0.92) but was positively correlated with GWC ($p < 0.001$; Fig. 2a-open circles). Spin density normalized by mass density (ρ_{tissue}) resulted in a near perfect match with GWC (slope = 1.02, $R^2 = 0.91$, $p < 0.001$; Fig. 2a-black dots). NP mass density (range: 1.07 - 1.17 g/cm³) and NP relaxation rate (R2) were negatively correlated with both GWC and spin density ($p < 0.001$; Fig. 2b & 2c). NP T2 values (44 - 105 ms) increased with GWC and SD, as expected.

Similar to the NP, AF spin density was positively correlated with GWC ($p < 0.001$; Fig. 2d-circles). Normalizing spin density by mass density resulted in a stronger correlation with GWC ($p < 0.001$), but values were lower than GWC values (Fig. 2d-black dots versus cyan line). Unlike the NP, AF mass density (1.08 - 1.23 g/cm³) was not correlated with either GWC or spin density ($p > 0.2$, Fig. 2e). AF R2 values were approximately 2X greater than NP R2 values (Fig. 2c & 2f). Correlations between R2 and water content were stronger than correlations with GWC (Fig. 2d vs. 2f).

DISCUSSION

Fig. 2: Results for NP (1st row) and AF (2nd row): (a & d) Spin density (SD) and SD/mass density (ρ_{tissue}) vs. gravimetric water content (GWC). (b & e) Mass density vs. GWC and SD. (c & f) R2 vs. GWC and SD. $p < 0.005$ for (a)-(d) and (f).

Direct measurements of tissue water content are largely limited to destructive methods that require drying out tissue explants. Fast measurements of water content, on the order of minutes (vs. days), using noninvasive techniques is valuable for tracking tissue hydration with loading, disease progression, or biological repair, as tissue hydration affects joint-level mechanics. Quantitative MR parameters, such as T2 or T1ρ relaxation times, are strongly correlated with water or glycosaminoglycan content [2]. However, the relaxation times represent the behavior during the exponential decay in signal intensity, while the y-intercept should be proportional to the direct water content in the tissue ($\text{SD} \propto \text{SI at } t = 0 \text{ ms}$). In this study, we demonstrated that normalizing spin density by mass density provided excellent agreement between MR measured water content and water content measured through lyophilization.

However, these findings may be limited to homogenous structures, such as the nucleus pulposus and, potentially, articular cartilage. Agreement between MR measures and lyophilization measurements were not as strong for the AF, a fiber-reinforced tissue. This discrepancy is likely due to a higher concentration of bound water molecules in the AF, compared to the NP (~3% in NP and ~10% in AF) [5], where water molecules bound to collagen fibers have T2 values that are too short to be detected in MR imaging [6]. The greater concentration of bound water molecules partially explains the underestimation in MR-related water measurements (Fig. 2d).

To the best of our knowledge, this is the first study to report disc tissue mass density. NP mass density decreased with an increase in water content, but was always greater than 1.0, resulting in spin density values that were consistently larger than GWC. In conclusion, normalizing quantitative MR parameters with mass density or using the empirical formula (GWC vs SD in Fig. 1a) allow for noninvasive measurements of NP water content.

INTRODUCTION

A significant portion of the military population develops severe neck pain in the course of their duties [1, 2]. It has been hypothesized that neck pain is a consequence of accelerated degeneration of the intervertebral discs of the cervical spine due to the loading from heavy head-supported mass including helmets and accessories worn by military personnel who also experience complex cyclic loading profiles during military missions [3]. In addition, some military operational transportation which includes riding on high speed special operations boats has also been reported to result in high magnitude cyclic loading on cervical spine discs [4].

We present a methodology to computationally predict fatigue damage to intervertebral discs over extended periods of time, by integrating kinematics-based biomechanical models with a continuum damage mechanics-based theory of disc degeneration. In our previous work [5], we made a preliminary assumption of a uniform stress distribution in the disc annulus. In reality this is an over simplification of the complex stress state present. To overcome this approximation, we have developed a validated finite element model of the human cervical spine the offers the complex stress state to be fully modeled. In this study, we explore how the integration of this advanced model improves our insight into the location of damage initiation and pattern of damage progression in the intervertebral disc annulus.

METHODS

In this study, a non-linear, multiaxial fatigue damage model was developed to predict fatigue damage in the intervertebral disc annulus over decade long periods of time. The modeling framework includes four primary components: 1) a non-linear fatigue damage evolution law; 2) ability to capture the effects of aging and damage recovery, accurately mimicking biological phenomena; 3) a fatigue damage model

that takes into account the multiaxial stress state in the disc; and 4) correlation with an established clinical grading system for disc degeneration. Figure 1 depicts an overview of the overarching process used to construct the computational framework including model development, model calibration and application.

Figure 1: Overview of the computational framework of the damage model.

Nash [6] proposed that the total damage to a biological structure can be segregated based on the cause of damage, according to Equation (1) given below:

$$D_{tot} = D_m + D_a + D_d - H \quad (1)$$

where D_m is the damage due to mechanical loading, D_a is the damage due to aging, D_d is the damage due to disease and H is the recovery of mechanical damage that occurs during rest. Chaboche and Lemaître [7] proposed a non-linear continuous fatigue damage model for the evolution of mechanical damage, which is described by Equation (2) below:

$$\frac{\delta D_m}{\delta N} = D_m^\alpha \left[\frac{\sigma_a}{M_0(1-b\sigma_{mean})} \right]^\beta \quad (2)$$

where D_m is the mechanical damage ($0 \leq D_m \leq 1$), N is the number of loading cycles, σ_a is the alternating stress and σ_{mean} is the mean stress of the load cycle. M_0 , a , b and β are material parameters which can be determined from non-linear curve fitting processes using stress-life data from fatigue testing experiments on the disc annulus. Integrating the right-hand side of Equation (2) over the number of cycles, we can estimate the total mechanical damage.

The damage model takes into account the multiaxial stress state in the disc. Ion et al. [8] elucidates the use of the signed Von-Mises equivalent stress for multiaxial fatigue calculation in a material, which is the approach we have adopted for our model.

In order to overcome the approximation of uniform stress in the disc annulus, we have developed a validated three-dimensional finite element model of the human cervical spine. This model includes separate mesh regions for cortical bone, trabecular bone, disc nucleus, disc annulus and the major spinal ligaments. By applying the gait cycle loading histories for walking with an Advanced Combat Helmet at the cervical joints of this model (obtained from a rigid full body model [5]), we can obtain the signed Von-Mises stress histories for each element in the disc annuli of the cervical spine. These element-wise stress histories can then be used as input to the fatigue damage model, enabling us to estimate the location-wise damage evolution in the disc annuli. This overcomes the approximation of a uniform stress distribution and enables us to predict the location of damage initiation and pattern of damage progression in the disc annuli. This process of integrating the finite element model and the fatigue damage model has been shown schematically in Figure 2.

Figure 2: Schematic representation of the integration of the validated finite element model of the human cervical spine with the fatigue damage model.

RESULTS

The various damage model parameters that were obtained from curve fitting processes have been shown in Table 1.

Table 1: Model parameters obtained from curve fitting processes.

Parameter	a	β	M_0 (MPa)	C_a (year ⁻¹)
Value	9.8865	2.9737	17.8154	0.0030

The gait cycle loading history for walking with an Advanced Combat Helmet was applied to the validated finite element model of the C4-C5 cervical spine segment. Signed Von-Mises stress histories were recorded for each element of the disc annulus and fed as input to the fatigue damage model. Figure 3 shows the Von-Mises stress contours on the disc annulus at simulation times of 0.4 s, 0.8 s and 1.2 s.

Figure 3: Von-Mises stress contours on the disc annulus at simulation times of 0.4 s, 0.8 s and 1.2 s.

The fatigue damage model was then run for each element in the disc annulus, for a period of 30 years. Figure 4 shows the fatigue damage contours on the disc annulus at times of 10, 20 and 30 years. We continue this process for the entire cervical spine and are currently working to extend to the full spine.

Figure 4: Fatigue damage contours on the disc annulus at times of 10, 20 and 30 years.

DISCUSSION

The location-specific damage evolution predicted by our model conforms to the results obtained by Qasim et al. [9]. Our model has significant real-life implications, including the ability to predict the effect of different spinal postures, loading profiles, etc. on the location-specific fatigue damage evolution in the intervertebral disc annulus.

INTRODUCTION

Mechanical properties, and morphological features of the vertebral cancellous bone play a fundamental role in terms of resistance to fracture and capability of withstanding a specific surgical treatment (e.g., internal fixation vs. bone cement augmentation) [1]. The cancellous bone is a porous solid structure saturated with interstitial fluid, thus its mechanical behavior can be regarded as poroelastic [2]. Previous studies have shown that the elastic modulus (E) of the cancellous bone is associated to its mechanical strength [3]. In addition, the morphology of the solid skeleton (density of pores) relates to how quickly fluids move into the bone, and the physical macroscopic parameter quantifying the ease of fluid motion is the hydraulic permeability (K). Hence, for instance, K may quantify the ease of penetration of bone cement within the vertebral body [4]. Therefore, knowledge of the mechanical properties of the vertebral cancellous bone is highly relevant for both management and prevention of vertebral fractures. However, for practical purposes, such properties should be determined in a minimally invasive fashion.

Bone densitometry (DEXA) and quantitative CT-scan are two mildly invasive diagnostic tools providing information on bone density. Specifically, DEXA provides the bone mass density (BMD), and previous studies attempted to correlate such a measurement with E [3, 4] and K [4] of cancellous bones. Similarly, radiographic density of the CT images have been related to the elastic properties (i.e. E) of bones [5]. Micro-CT technique provides high-resolution images that allow

determining bone morphological parameters, such as porosity or bone volume fraction.

The objectives of this study were: (1) to verify whether the vertebral bone volume fraction measured via micro-CT is a good predictor for vertebral mechanical properties; and (2) to compare the predictive capabilities of the vertebral bone volume fraction to those of BMD measured via DEXA.

METHODS

Vertebrae L1, L2 and L3 of were obtained from a 54 y.o. white Caucasian male donor. A schematic of the specimen preparation and the experimental workflow is reported in Figure 1. The vertebral bodies were sliced along the plane orthogonal to the rostral-caudal axis. Each vertebral body yielded 3 slices of ~5mm thickness, for a total of nine vertebral body slices (3 vertebrae x 3 slices => n=9). The BMD of each slice was measured by means of a Hologic QDR 4500 X-ray densitometer (Hologic, Waltam, MA, USA). Subsequently, the slices were tested for indentation to simultaneously yield E and K. Finally, the slices were imaged via micro-CT to determine the volumetric bone fraction.

During the indentation test, the slices were embedded in a phosphate buffer solution, and compressed by a cylindrical indenter (5mm diameter) at the left posterolateral region. The indenter was connected to a servoelectric testing system (Instron E3000, Norwood, MA) with a 5kN load cell. A stress-relaxation test was performed by compressing of 5% (with respect to the initial height of the sample) the vertebral slice at 0.25mm/s rate.

The final displacement was held for 800 seconds, and the time dependent reaction of the sample was measured at a sampling rate of 10Hz. The relaxation of the reaction force of the sample over time was curve-fitted with the solution of a finite element model (FEBio 2.6.2, University of Utah, UT) simulating the indentation test on a vertebral slice. Specifically, the vertebral slice was modeled as a biphasic material; its solid phase was isotropic elastic non-compressible with Young's modulus E ; fluid percolation through the vertebral slice was assumed to be governed by Darcy's law with constant hydraulic permeability K . The computational domain changed from slice to slice in order to reflect the geometrical characteristics (shape and size) of the sample tested. A total of ~27,000 tetrahedral elements were used to discretize the vertebral slice and the indenter. The optimization parameters of the curve-fitting were K and E . After indentation, a micro-CT (SkyScan1176, Bruker BioSpin Corp., Manning Park, MA) imaged the slices at 50kV with 18 μ m resolution. The produced images were analyzed via an open source image-processing software (ImageJ, NIH) to yield the bone volume fraction (BV/TV), defined as the ratio of the volume occupied by the bone to the total volume in the indented region. A simple linear regression analysis investigated the correlation between BV/TV and K or E ; another regression analysis verified correlations between BMD and BV/TV, K or E .

Figure 1 – Specimen preparation and testing workflow

RESULTS

The vertebral slices had BMD ranging from 0.491 to 0.084 g/cm². Their K , E and BV/TV ranged from $4.3 \cdot 10^{-3}$ to $3.3 \cdot 10^{-1}$ mm⁴·N⁻¹·s⁻¹, 3.18 to 18.95MPa, and 0.11 to 0.36, respectively. We found a strong relationships between BV/TV and K ($p < 0.05$; $R^2 = 87.1\%$), and E ($p < 0.05$; $R^2 = 71.9\%$), see Figure 2a-b. When trying to relate BMD to mechanical properties and morphology of the vertebrae, no correlation was found between BMD and either BV/TV or E ($p > 0.05$). However, we found a linear correlation between BMD and K ($p < 0.05$; $R^2 = 73.4\%$), see Figure 2c.

DISCUSSION

The objectives of this study were: (1) verifying whether the bone volume fraction measured via micro-CT image analysis could be a good predictor of fundamental vertebral mechanical properties such as hydraulic permeability and elastic modulus; and (2) compare the prediction capabilities of the bone volume

fraction to those of bone mineral density determined via bone densitometry.

The mechanical properties of the vertebrae were measured from analysis of stress-relaxation tests performed via indentation. The magnitude of the measured hydraulic permeability was similar to that previously reported for [6], while the values of the elastic modulus were smaller than those observed in vertebrae [7]. Regression analyses suggest that BV/TV is a strong predictor for K and E . In addition, as previously reported [4], the relationship between BV/TV and K is non-linear.

We found that BMD may represent a good predictor for K ($p < 0.05$; $R^2 = 73.4\%$), in contrast with previous studies showing weak correlation between bone density and hydraulic permeability [4]. However, differently from previous observations [3, 4], BMD was not correlated to either elasticity (E) or morphologic (BV/TV) properties of the vertebrae ($p \sim 0.1$).

In summary, we identified the bone volume fraction, measured via micro-CT, as a strong predictor of the mechanical properties of the vertebral cancellous bone.

Figure 2 – Morphology (BV/TV) correlates with: (a) hydraulic permeability (K) and (b) elastic modulus (E); (c) bone density (BMD) correlates with permeability (K).

INTRODUCTION

Over 4.5 million individuals in the US suffer from rotator cuff tendinopathy, leading to lost days from work, occupational challenges, and recreational limitations (1). The pathogenesis of tendinopathy, leading to tendon rupture, is associated with intrinsic (e.g. age, joint laxity, muscle weakness) and extrinsic (e.g. mechanical load, fatigue) factors (2). It is hypothesized that these factors compromise tissue function through the accumulation of micro-damage and/or alterations in cellular metabolism driving poor quality matrix turnover. However, mechanistic studies of tendon lesion etiology are difficult in patients, which typically represent late-stages of disease progression. Therefore, our objective was to establish murine models of rotator cuff tendinopathy based on clinically observed correlates with disease prevalence. Specifically, we examined beneficial through pathologic levels of rotator cuff loading. We hypothesized that muscle overloading or underloading can each drive structural and functional degeneration, increasing the risk of rupture.

METHODS

All procedures were approved by the Columbia University Institutional Animal Care and Use Committee. 12-week old C57BL6/J male mice (n=95) were subjected to one of three rotator cuff tendinopathy models modulating supraspinatus muscle activity. Muscle paralysis was induced by injecting botulinum toxin-A (BtxA) into the supraspinatus muscle. Overuse was achieved using two downhill treadmill running protocols with an initial rate of 17 cm/s for 10 minutes followed by up to 22 cm/s for 40 min each day at a decline of 15 degrees (Overuse +) or 25 cm/s for 30 min each day at a decline of 10 degrees (Overuse ++). Both protocols were performed 5 days a week. Supraspinatus tendon/muscle imbalance was created by surgical excision of the infraspinatus tendon (Tenectomy). All procedures were performed bilaterally, and results were compared to age-matched cage

activity control animals. Animals were euthanized at 3 d, 1 wk, 2 wk, and 4 wk time points. Gait function was assessed at 4-week time points for BtxA and treadmill groups (Noldus, CatWalk XT). Mice were placed in a walkway and allowed to freely explore without incentives, footprints of three compliant runs per animals were recorded, and spatiotemporal data was processed for forelimbs. Bone morphometry of the humeral head and tendon cross-sectional area were determined using micro-computed tomography (μ CT, Bruker, Skyscan 1272). Supraspinatus tendon-to-bone mechanical properties were assessed using quasi-static uniaxial tension tests to failure (TA Instruments, Electroforce 3230). For histological sections, mouse shoulders were dissected, fixed in 4% paraformaldehyde, decalcified in formic acid (Immunocal, StatLab), and embedded in paraffin using standard techniques. 5 μ m sections were obtained and stained with hematoxylin and eosin. Treatment groups were compared using ANOVA and specific differences from control animals were determined using Dunnett's multiple comparisons test; $P < 0.05$ was considered significant. All statistical analyses were performed using GraphPad Prism 7. All data shown as mean \pm standard deviation.

RESULTS

At 4 weeks, gait analysis demonstrated changes in walking pattern due to overuse, including significant decreases in cadence (Overuse + & Overuse ++, $P < 0.0001$, Fig 1) and stride length (Overuse +, $P = 0.0097$; Overuse ++, $P = 0.0192$), while paralysis resulted in changes in weight bearing, with a lower ratio of forelimb/hindlimb intensity (BtxA, $P = 0.013$; n=10/group, Fig. 1). Bone morphometric analysis revealed thickening of the cortical bone due to high-intensity overuse (Overuse ++, $P = 0.0005$) and thinning due to muscle paralysis (BtxA, $P = 0.0005$, Fig 2). Furthermore, there were significant losses in trabecular bone volume/total volume in the BtxA ($P < 0.001$) and tenectomy groups ($P = 0.008$), and an increase in the Overuse + group ($P = 0.043$,

n=10/group, Fig. 2). These results were driven by local changes in trabecular structure, with BtxA and tenectomy resulting in increased trabecular spacing ($P=0.002$, $P=0.012$, respectively), BtxA resulting in decreased trabecular thickness ($P=0.010$), and treadmill running resulting in increased trabecular thickness (Overuse +, $P=0.023$; Overuse ++, $P=0.0008$). Additionally, cortical and trabecular mineral densities were decreased in the BtxA ($P<0.001$, $P<0.001$, respectively) and tenectomy ($P=0.001$, $P=0.005$, respectively) groups. High-intensity overuse increased cortical mineral density (Overuse ++, $P<0.0001$). The subchondral bone appeared thinner in BtxA and tenectomy groups and thicker with overuse (Fig. 3). The cross-sectional area of the supraspinatus tendon was significantly decreased due to treadmill running (Overuse +, $P=0.007$; Overuse ++, $P<0.0001$; n=10/group, Fig. 4). Tendon-to-bone stiffness was significantly higher in the moderate overuse group (Overuse +, $P=0.0016$, Fig. 4). Young's modulus and ultimate stress were significantly higher in both overuse groups (Overuse +, $P=0.0002$, $P<0.001$; Overuse ++, $P<0.0001$, $P=0.016$; n=9-10/group, Fig. 4). Maximum force was significantly decreased in the BtxA group ($P=0.004$, Fig. 4).

DISCUSSION

Modulating supraspinatus muscle activity had significant impacts on mouse gait as well as the structure and function of the supraspinatus tendon and humeral head. Overuse activity caused changes in walking pattern, driving increased bone mass and tendon stiffness and potentially reducing tissue extensibility and increasing the risk of rupture. Conversely, reduced activity due to BtxA altered animal weight bearing, resulting in decreased bone mass and tendon strength. Surprisingly, surgical destabilization of the rotator cuff with tenectomy primarily affected the bone structure within the humeral head. Similarly, before surgical repair, patients exhibit bone loss at the supraspinatus tendon attachment site of the greater tuberosity (3). However, tendon mechanical properties have been observed to decrease with injury (4) or increase due to ageing (5), suggesting both conditions can increase the risk of rupture. In summary, our results recapitulate clinically observable alterations in rotator cuff structure and function by modulating muscle activity using murine models. Future work will include transcriptomic analyses and immunohistochemistry from each timepoint to determine the biological mechanisms driving functional loss, and how these models overlap with pre-existing clinical evidence at the molecular-scale.

THE EFFECT OF FATIGUE ON THE IMPACT RESPONSE OF RAT ULNA

INTRODUCTION

Bones are under constant load and impact, so understanding fatigue properties of bones is important in characterizing mechanical properties of bone. Combining fatigue loading and impact, we may understand the effect of fatigue loading on the impact response given different recovery times. Using rats as an animal model, we evaluated the effect of fatigue loading to investigate (1) whether the non-destructive cyclic loading can induce woven bone formation, which is a repairing response to damage, and (2) how would the impact response change given different rest time after cyclic loading.

METHODS

Cyclic fatigue loading was performed on 16 healthy male Sprague-Dawley rats, at 18 weeks of age followed with micro-computed tomography (micro-CT) scan and impact loading test (Fig.1). All protocols were approved by the IACUC at UIUC.

Fatigue loading: Under continuous anesthesia, the rats were placed on a bed between the actuator and the load cell. The right forelimb was positioned with the elbow and volar flexed carpus placed in epoxy-potted aluminum cups [1, 2, 3]. The ulna was loaded axially in compression with a haversine waveform of 0.055N/g at 2Hz across the carpus and the olecranon. Due to the natural shape of the bone, a bending moment was induced along the diaphysis. Loading was stopped when the peak displacement reached $0.75\text{mm} \pm 0.20\text{mm}$ [1]. Pain relief (Meloxicam, 2mg/kg) was given through subcutaneous injection immediately after loading. The left forelimb served as control.

Fixation and CT imaging: Eight rats were euthanized and dissected within 24 hours after loading. The rest were euthanized and dissected 7 days later. All (left and right) ulnae were harvested and potted in customized fixture with epoxy (Fig. 2 A&B). Prior to impact testing, micro-CT scans were acquired for each specimen. Every scan acquired

996 slices of the diaphysis with each containing 996×1016 voxels. Images were binarized and filtered for further analysis.

Impact testing: A drop-tower system (Fig. 2C) was designed for the impact test. The specimen was secured in place during the test and total potential energy from the impact was equal to 17.5% of potential energy of the rat landing from a height of 0.2m. the peak forces of each specimen were recorded.

Figure 1: Experimental design for evaluating the effect of cyclic loading on the impact response of the rat ulna.

Figure 2: Specimen fixation and impact test apparatus.

RESULTS

There was no relationship found between the body weight and the cycle number needed to reach fatigue. Four rats did not produce useful information and thus were excluded. Ulnae exposed to fatigue loading and rested for 1-day were mechanically more damaged than those had 7-day rest. Of the 6 ulnae that had 1-day rest: 2 were severely damaged before impact loading, 3 of the remaining resulted in full fracture after impact, and 1 stayed intact. However, among the specimens had 7-day rest, only 1 of 6 loaded ulnae fractured after impact, and none of the control ulnae fractured. The fracture rate of the loaded ulnae was five times greater in the 1-day rest group than 7-day (Fig. 3). The peak impact forces were 38.73% higher in the control ulnae than the loaded ($P = 0.0055$) in 7-day rest group and in 1-day rest group. The loaded ulnae with 7-day rest had noticeable woven bone formation, shown as a ring of disorganized bone on the periosteal surface (Fig. 1). Normalized volume with respect to weight (Fig. 4) indicated that the difference between the control and loaded ulnae in 1-day rest group was not significant ($P = 0.27$), but it was in the 7-day rest group ($P = 0.0092$). The controls from both groups were not significantly different.

Figure 3: fracture rate of the specimens.

Figure 4: normalized bone volumes with respect to body weight.

DISCUSSION

A single bout of cyclic loading with peak force of 0.055N/g body weight on a rat ulna was enough to induce fatigue damage and cause woven bone formation as a repairing process [4, 5], if rest was given. However, even with 7-day rest, the peak impact forces among loaded ulnae were still significantly lower than the control ($P = 0.0055$), which means the bones recovered partially. Woven bone formation on the periosteal side might have resulted from the higher strain on the periosteal side during cyclic loading. The partial recovery was attributed to the rapid formation of woven bone [6]. The fracture rate indicated that rest time was important in preventing fracture while the bone was fatigued. The difference between the normalized volume among loaded ulnae was attributed to the formation of woven bone as well. However, woven bone did not provide as robust support as healthy cortical bone as shown by the difference between peak impact forces in 7-day rest group loaded and control ulnae.

MICROINDENTATION MAPS TWO GRADIENTS IN MECHANICAL PROPERTIES ACROSS THE ZONES OF THE GROWTH PLATE

INTRODUCTION

The growth plate (*i.e.* physis) is a cartilage tissue that functions to lengthen growing limbs and displays remarkable mechanical characteristics. It is similar to articular cartilage in composition and features zonally varying mechanical properties. However, its structure differs significantly from articular cartilage, especially in the proliferative (PZ) and hypertrophic (HZ) zones (**Fig 1.c**). Notably, the relatively soft physal cartilage forms strong interfaces to the adjacent epiphyseal and metaphyseal bone. Despite these strong interfaces, ~18% of pediatric fractures occur in the physis.¹

In some transphyseal fractures, a bony bar forms across the physis and arrests growth or causes an angular deformity. Current methods of resecting bony bars have 18-35% success rates in restoring limb growth.² Typically, adipose tissue is implanted after bony bar resection; this tissue is chosen with little consideration to mechanical function and often becomes necrotic, breaks down or dislodges following surgery.³ In the case of articular cartilage repair, however, mechanical characterization has informed the design of implants that mimic the native tissue properties; likewise, mechanical and chemical characterization of the physis may guide the design of better implants that are mechanically robust, form strong interfaces, and mimic the native mechanical environment to facilitate chondrocyte growth.

The physis, however, is a difficult tissue to mechanically evaluate. Its small dimensions, irregular shape, and confinement between bony tissue has restricted previous work to various compression tests of excised tissues,^{4,5} one shear loading study,⁶ and one atomic force microscopy (AFM) study.⁷ Compression tests have provided valuable results for tissue stiffness, permeability, and anisotropy, but require semi-confinement of the native interfaces to measure spatial variations in properties. Due to the semi-confinement, purely intrinsic properties of the cartilage cannot be measured. Prior results from AFM are only

Figure 1: a) X-ray microscopy (XRM) of 9 week old rabbit tibia plateau visualizes mineralized tissue and the absence thereof in the growth plates (arrows). b) cartilage growth plate, *i.e.* physis (P), features strong bone-cartilage interfaces with the epiphysis (E) and metaphysis (M). c) (P) cartilage varies in structure between reserve (RZ), proliferative (PZ), and hypertrophic (HZ) zones.

reported for cranial growth plates, which differ in structural organization to limb-lengthening growth plates. The probe size of AFM ($R = 20$ nm) may also be too small compared to the feature size of physal cartilage (~ 20 μ m chondrocyte lacunae) and is incapable of capturing the aggregate tissue response. Therefore, a test method that can adequately evaluate the aggregate tissue response and map spatially varying intrinsic mechanical properties is desired.

The objective of this study was to combine microindentation and Raman spectroscopic imaging to characterize the intrinsic mechanical properties and chemistry of the 9 week old rabbit physis. The instantaneous elastic modulus was evaluated across the physis and compared to spatial variations in mineral and protein content previously mapped with Raman spectroscopy.⁸ X-ray microscopy (XRM) was also performed to visualize the stochastic interdigitation of the epiphysis-physis interface, which resembles osteochondral interface but is coarser in feature size than the opposite metaphysis-physis interface.

METHODS

A previously frozen femur of a 9-week-old New Zealand white rabbit was sectioned in the sagittal plane and polished (precision polisher; EXAKT 400CS). Microindentation (Hysitron TI 950 TriboIndenter, xZ-500 extended displacement stage) was performed at 164 points across a $1000 \times 75 \mu\text{m}$ region (**Fig 2.a**) using a $R = 50 \mu\text{m}$ spherical probe. The probe was lifted off the sample surface, indented to a depth of $\sim 15 \mu\text{m}$ at a rate of $180 \mu\text{m/s}$ (**Fig 2.b**) and then held for 45 seconds. Hertzian contact and an instantaneous Poisson's ratio $\nu = 0.5$ were assumed to calculate the instantaneous Young's modulus, E_{inst} , at each site. Each row in the map was averaged and plotted against distance across the physis (**Fig 2.c**).

Previous Raman spectroscopy imaging⁸ (Renishaw InVia, 785 nm laser, $63\times$ immersion objective, $\sim 1 \mu\text{m}$ spot size) evaluated peak areas characteristic of mineralization ($\nu_2\text{PO}_4^{3-}$, $415\text{-}465\text{cm}^{-1}$), collagen matrix (amide III, $1215\text{-}1300\text{cm}^{-1}$), and non-collagenous proteins (Phenylalanine, $995\text{-}1020\text{cm}^{-1}$) for 1600 points in a $285 \times 1185 \mu\text{m}$ area (**Fig 2.d**). Peak ratios were plotted with respect to percent distance across the physis for each column of points, then averaged over all samples to reveal trends using Matlab (**Fig 2.e**) ($n = 8$ samples, 20 columns each). Further imaging was performed using XRM (Zeiss, Xradia 520 Versa; 80kV, 7W, 401 images) to visualize mineralized tissues and their interfaces with the physis.

RESULTS

Microindentation mapping found the instantaneous modulus, E_{inst} , of physal cartilage to range $0.15 - 1.5 \text{ MPa}$, with the highest stiffness in the reserve zone (RZ) and the lowest in the PZ. Stiffness steadily increased moving from the PZ to the HZ. Across the bone-cartilage interfaces, we found a sharp increase in stiffness to values ranging $750\text{-}950 \text{ MPa}$ for epiphyseal bone (E), and $60\text{-}300 \text{ MPa}$ for the more heterogeneous metaphyseal bone (M). Significant relaxation of $\sim 70\%$ was observed in cartilage indents during the 45 second hold time.

We observed an irregular interface between epiphyseal dense bone and physal cartilage through 3D XRM imaging (**Fig 1.a**), previous 2D Raman spectral mapping (**Fig 2.d**),⁸ and microindentation mapping. Raman spectroscopy maps showed a rapid change in mineralization at the epiphysis/physis interface, but a more gradual rise at the heterogeneous metaphysis/physis interface (**Fig 2.e**).

DISCUSSION

Microindentation results revealed two different gradients in mechanical stiffness in the physal cartilage. First, a sharp gradient was found at the epiphysis-physis interface and across the RZ, where elastic modulus values decreased sharply from 1.5 MPa near the interface to 150 kPa . However, this gradient was sometimes absent in the columns of the heatmap due to the protrusion of epiphyseal bone that extended into the RZ cartilage (**Fig 2.a**). Interestingly, the RZ cartilage appears to be nestled between these bony protrusions, which could contribute to a strong cohesive interface. The RZ was observed to be thin (5-10% of total (P) thickness) compared to other reported physal zone dimensions;⁴ this is likely due to differences in animal model and that the reserve zone thickness is thought to decrease with age. Overall, the RZ was the stiffest of the physal zones, which correlates with a lack of non-collagenous proteins (NCP) typically found in cells (**Fig 2.d and 2.e**). This indicates the relative modulus of the PZ and HZ is due to their high cellular volume. The second gradient in stiffness occurs across the PZ and HZ, with stiffness steadily increasing from 150 kPa (PZ) to 350 kPa (HZ). This trend agrees with the trend reported by Radhakrishnan.⁷ While Raman imaging found that mineral:matrix ratio rises gradually at the physis-metaphysis interface (albeit with high variance), the mechanical properties were observed to rise sharply.

Figure 2: a) Overlay of microindentation map spanning epiphyseal bone (E), physal cartilage (P), and metaphyseal bone (M); b) Representative loading curve from microindentation; c) Mean stiffness \pm SD plotted across % physis (E-P interface at 0%); d) Raman mapping of mineral:matrix (Min:Mat) and non-collagenous protein:matrix (NCP:Mat) peak area ratios; e) Columns of Raman heatmaps plotted with respect to % across physis and averaged \pm SD.

The instantaneous modulus results are within range of previously reported equilibrium stiffness values ($0.3 - 1.1 \text{ MPa}$),⁵ however, the equilibrium response of our tests is significantly lower. One explanation for lower stiffness values may be due to the small-scale indentations being less prone to the stiffening effect of friction, as is present in unconfined compression. Future finite element modeling of indentation may enable us to determine anisotropic properties. Additionally, our relaxation data enables us to fit poroelastic models and characterize the equilibrium response and permeability in future analyses. Beyond this study, 3D XRM images could be used in combination with microindentation data to model the multi-scale mechanics of the physis and its interfaces.

INTRODUCTION

Cells respond to local mechanical and topographic cues to regulate their phenotype and biosynthetic activities¹⁻³, with 'stiff' environments driving a fibrotic phenotype³. In the context of intervertebral disc injury, loss of nucleus pulposus swelling and release of residual strains in the annulus fibrosus (AF) alter the mechanics and organization of the cellular microenvironment⁴. Here, we used in vivo and in vitro models to test the hypothesis that altered fiber organization in the AF regulates the emergence of fibrotic phenotypes seen in the context of intervertebral disc injury and subsequent degeneration.

METHODS

New Zealand White rabbits were subjected to annulus puncture⁵ with a 16-gauge needle to 5 mm depth, with 2-, 4-, and 8-week survival. The annulus fibrosus was assessed via second harmonic generation imaging and staining for alpha smooth muscle actin (α SMA). Fiber environment organization was quantified through an angular spread metric that was calculated as the standard deviation of the fiber angle distribution. Briefly, higher angular spread denotes a more disorganized fiber environment. For in vitro studies, bovine annulus cells were seeded onto electrospun PCL scaffolds, and a tensile stretching device was used to apply prestrain to scaffolds prior to cell seeding ($\epsilon = 9\%$ prestrain). Cell-seeded aligned and nonaligned prestrained and free swelling scaffolds (NE, NF, AE, AF) were assessed at 24 hours for fiber organization (angular spread), focal adhesions, YAP/TAZ nuclear localization, α SMA+ stress fibers, and baseline ECM synthesis. For the ECM synthesis assay, methionine was replaced in the cell culture media with L-Azidohomoalanine (AHA), which was incorporated into nascent ECM deposited by seeded cells⁶. Following 48 hour culture, AHA was visualized through

Figure 1: (a-d) Second harmonic generation (SHG) imaging with immunofluorescence revealed that injury leads to (e) progressively more disorganized fibers and (f) the emergence of a fibrotic (alpha smooth muscle actin+, SMA) phenotype (n = 3 animals per group, * p < 0.05).

Figure 2: Strain mediated changes in fiber organization modulated the mechanobiologic response of AF cells (n = 40 cells from 8 scaffolds). Local fiber organization correlated with both nuclear/cytoplasmic YAP/TAZ and focal adhesion area (n = 60 cells from 12 scaffolds).

click chemistry and the area of deposition was determined as the AHA-positive area minus cell area.

RESULTS

In the in vivo model, release of residual strains via needle puncture resulted in progressive disorganization of the AF (Fig 1a-e) and the emergence of fibrotic phenotypes (i.e., α SMA expressing cells) after 2 weeks; these fibrotic signatures remained elevated through 8 weeks (Fig 1f). In the in vitro model, both baseline fabrication parameters

(aligned vs nonaligned) and prestrain dictated fiber organization at the cellular length scale (Fig 2). This organization had a significant effect on cell spreading (aspect ratio and spread area), with aligned microenvironments promoting elongation and minimizing spread area. These organized, pre-strained fiber environments limited focal adhesion area and maintained nuclear levels of YAP/TAZ at a low level (Fig 2). Likewise, incorporation of α SMA into stress fibers depended on the organizational and prestrained state of fibrous environments, with aligned prestrained scaffolds reducing the fibrotic phenotype compared to nonaligned free swelling scaffolds (Fig 3). This phenotypic shift was observed in concert with altered cellular synthetic activity, where the deposition of nascent matrix was predicted by local fiber organization (Fig 3).

DISCUSSION

Taken together, our data suggest that strain-mediated topography mediated cellular responses, where highly aligned environments curbed cell spreading, nuclear YAP localization, focal adhesion area, α SMA+ stress fibers, and nascent matrix deposition. Our findings also suggest that fibrotic phenotypes emerge with the release of residual strains in the annulus of injured discs (Fig 1). This pathomechanobiologic event was replicated by an in vitro scaffold system, where cellular perception of the local environment was dictated by both baseline and strain-mediated fiber organization. Fiber organization provided cues (contact guidance) in aligned environments to modulate cell shape and size such that YAP/TAZ remained largely cytosolic (Fig 2), which in turn, suppressed incorporation of α SMA into stress fibers and the development of a fibrotic phenotype³ that culminated in lower matrix production (Fig 3). Continuing work is focused on using this scaffold-based system to evaluate pharmacologies that might inhibit this fibrotic remodeling response after injury.

INTRODUCTION

Tendon injuries are a major orthopaedic issue that account for significant pain and lost work [1]. Unfortunately, tendon injuries often heal poorly and are difficult to treat [1]. Treatment of tendon injury prior to rupture may reduce disability risk. Currently, injured tendons are primarily treated non-operatively by nonsteroidal anti-inflammatory drugs, physical therapy, electro- or cryo- therapy, orthoses, platelet-rich plasma injections, and photobiomodulation (PBM). Yet many non-operative interventions leave patients with persisting symptoms [2]. Thus, there is a need to improve non-operative treatments of injured tendons. To do so, a better basic science understanding of how non-operative treatments improve tendon health is needed. PBM, the application of low power near-infrared light, has shown promising results in the clinic [3] and with small animal models for adults [4,5]; however, no work has established the influence of PBM on tendon maturation. Additionally, the cellular mechanism of PBM remains elusive, and little work has investigated paired functional outcomes of normal tendon healing compared to tendon healing with PBM.

We hypothesized that the initial response of tendon to PBM results in increased mitochondria metabolism, and we expected this response to be amplified during tendon healing due to an increase in numbers of cells from remodeling. In this study, we aimed to establish the cellular response of tendon to PBM and to measure the effect of PBM on the cellular, structural, and functional properties of tendon 1) during maturation and 2) during adult healing using paired experiments.

METHODS

All experiments were approved by the University of Delaware IACUC. For all experiments, CD1 mice (Envigo) were used. To investigate the cellular mechanisms of PBM during postnatal growth, unilateral Achilles tendons of anesthetized neonatal (P14) littermates

were dosed through the skin once (30mW/cm² to 2.5J/cm²). Continuous wave and concurrent near-infrared light (980:810nm, 80:20 power ratio, 1.5cm² cross-sectional area, LightForce FXi Laser, LiteCure) was used for all experiments. Mice were euthanized at 4hrs (N=4, 2 males, 2 females) and 24hrs (N=4, 2 males, 2 females) after PBM, and RNA were isolated from control and PBM-dosed tendons using a commercially available kit (PureLink RNA Mini Kit, Invitrogen) following tissue pulverization (MM400, Retsh). Total RNA were reverse-transcribed using Superscript VILO (Invitrogen). Subsequent quantitative Real Time-PCR was performed using a LightCycler 96 System (Roche) and RT² Profiler PCR Array for Mouse Mitochondria (330231, Qiagen) with PowerUp SYBR Green (Applied Biosystems). Δ CT values were calculated for each gene using the average of *Actb*, *B2m*, *Gapdh*, *Gusb*, and *Hsp90ab1* as reference genes. To assess the effect of PBM on postnatal maturation of tendon, unilateral Achilles tendons of anesthetized P16 mice were dosed (30mW/cm² to 2.5J/cm²) daily for 4-weeks (N=12, 6 males, 6 females). To assess the effect of PBM on adult tendon healing, bilateral Achilles tenotomy was performed at 6-months (N=4 females, retired breeders) for gene expression studies or at P56 (N=13, 7 males, 6 females) for biomechanical and histological comparisons. For all outcomes, tendons were injured and then healed for 1-week following which unilateral Achilles tendons were dosed (300mW/cm² to 2.5J/cm²) daily for 3 consecutive days (gene expression) or daily for 7-weeks (biomechanics or histology). To investigate the cellular mechanism of PBM during healing, mice were euthanized 4hrs after the third dose of PBM, and the same method of RNA isolation and qRT-PCR described above was followed. For biomechanical testing, mice were euthanized after dosing periods then either frozen in PBS-soaked gauze at -20C for uniaxial tensile testing (N=7-8) or the tendons were dissected and fixed in 4% PFA for histology (N=5). Mice were thawed and tendons dissected prior to

mechanical tests. Uniaxial tensile tests were comprised of a preload of 0.01N, 10 preconditioning cycles from 0.02-0.04N at 0.02mm/s, and ramp to failure at 0.02mm/s (5848, Instron). Cross-sectional areas (CSA) of tendon were assumed as ellipsoidal and gauge lengths (L) were measured using a scaled image after preload. CSA and L were used to measure stress and strain. For histology, tendons were paraffin embedded, sectioned, and stained with picrosirius red, Toluidine Blue, and Hematoxylin & Eosin (H&E). Picrosirius red stained slides were imaged using circular polarized light microscopy (Stemi 2000, Zeiss) to assess collagen alignment and were semi-quantitatively scored by three blinded individuals. H&E sections were used to quantify the gap spacing of healing tissue. Immunolocalization of COL1A2, BCL-2, and COX-1 was performed (N=5) at 1:100 dilutions (COL1A2: sc-393573; BCL-2: sc-19998; COX-1: sc-23960) and detected using a commercially available kit (IHC Select HRP/DAB, Millipore). A repeated measure (control vs. PBM tendon) two-way ANOVA with Sidak's correction for multiple comparisons was performed for the Δ CT of each gene and for mechanical outcomes (Young's Modulus, Ultimate Stress (US), Strain at US, Area Under the Curve (AUC) at US, Stiffness, and Ultimate Load). Δ CT was converted to $2^{-\Delta\text{CT}}$, log base-2 transformed, and presented as mean \pm 95% confidence intervals. Paired t-tests were used to compare collagen alignment and gap space.

RESULTS

In the maturing tendon, *Slc25a24* and *Bcl2l1* were upregulated 4hrs after PBM compared to untreated control (Fig 1A-B), however localization of BCL2, COL1A2, and COX1 was unaffected by daily PBM during maturation (Fig 1C-D, not shown). Genes associated with apoptosis (*Trp53*, *Hsp90aa1*), small molecule transport (*Slc25a14*, *Slc25a24*), and outer membrane transport (*Tom34*) were downregulated at 24hrs compared to 4hrs after PBM (Fig 1A). Collagen alignment was semi-quantitatively decreased by PBM during maturation (Fig 1E-G). No changes in mechanics were observed for PBM during maturation (not shown).

Figure 1: During maturation, one dose of PBM acutely altered mitochondria-related gene expression. (A) Gene expression heat map for fold change of 4hr and 24hr after PBM. (B) *Bcl2l1* and (C) *Slc25a24* were significantly upregulated in PBM groups at 4hrs but not 24hrs after a single dose of PBM. (C-D) After 4wks of PBM dosing, Achilles tendons did not show a noticeable increase in BCL2 immunolocalization. (E-G) PBM treated tendons demonstrated slight decreases in alignment (from picrosirius red staining) compared to control groups. Lines: Significant differences, $p < 0.05$.

During healing, genes associated with membrane translocation of cytochrome c oxidase (*Cox18*) were down regulated after PBM compared to control (Fig 2A-B). *Slc25a13* and *Slc25a19* were down and upregulated after PBM compared to control, respectively (Fig 2C-D). No differences were observed in gap space, structure (Figure 2E-F), or protein localization (not shown) between control and PBM groups, with fatty and glycan-rich (Figure 2E'-F') regions observed in both

groups. Stiffness increased with PBM compared to controls for females (Fig 2G). Young's modulus increased for females compared to males with PBM (Fig 2H). Strain increased for males compared to females with PBM and compared to controls (Fig 2I).

Figure 2: During tendon healing, daily PBM has sex-dependent effects on tendon mechanics. (A) Gene expression heat map for fold change of 4hr after PBM. (B) *Cox18*, (C) *Slc25a13*, and (D) *Slc25a19* were differentially regulated at 4hrs after a single dose of PBM. Lines: Significant differences, $p < 0.05$. (E-F, Scale: 200 μ m) Gap space, fat infiltration, and (E'-F', Scale: 50 μ m) proteoglycan presence were not altered by PBM. Bars: Gap space, Arrows: Fat infiltration. (G) Stiffness of female tendons with PBM increased compared to controls, (H) Young's modulus of female tendons with PBM increased compared to males with PBM, and (I) strain of male tendons increased with PBM compared to controls and females with PBM. Mean \pm SD.

DISCUSSION

In this study, we found that PBM acutely changes mitochondria gene expression during maturation and healing, yet this effect was not amplified during healing, contrasting our hypothesis. The cellular changes from PBM may have a negligible effect on tendon structure and mechanics during maturation. The effect of PBM on functional outcomes of tendon healing may be sex-dependent [6]. Increased stiffness with PBM compared to controls for females suggests that PBM therapy may be beneficial during healing to improve functional outcomes. It remains unclear if the difference in power of the maturation study (30mW/cm²) compared to the healing study (300mW/cm²) may translate to changes in mechanical properties during healing and not influence tendon properties during maturation. A limitation of this study is that sex differences for gene expression were not assessed because of the small sample sizes (N=2).

This was the first study to assess the paired (control vs. therapy) effect of PBM on tendon maturation and healing, and these data warrant further investigation of the effect of power on tendon maturation and the sex-dependent mechanism of PBM during tendon healing.

INTRODUCTION

Fibroblasts are stromal cells with roles in development, repair, wound healing, and extracellular matrix (ECM) remodeling [1]. They remodel their ECM by mechanotransduction mechanisms [2-4]. Fibroblast-collagen interactions studied using 3D fibroblast-populated collagen gels report fibroblast-induced changes in mechanical properties and network microstructure [2,3]. Fibroblasts are defined broadly by their morphology, ability to adhere, and lack of lineage-specific markers, but are functionally and phenotypically diverse [1,4]. Fibroblast-like synoviocytes (FLS) are a unique class of fibroblast-like cells found in the lining and capsular ligament of synovial joints [5,6]. Although FLS have a role in inflammation and degradation, particularly in rheumatoid arthritis [5], little is known about their regulation of matrix mechanics. Defining if, and how, FLS alter matrix mechanics and/or microstructure will help define load-induced cell signaling in tissues, like the capsular ligament, in which FLS reside.

The effect of primary FLS cells on matrix mechanics and microstructure was investigated using a 3D collagen gel system under tensile failure. Since 3T3-collagen interactions in 3D gels are more extensively studied than FLS and are known to exert mechanical forces on their surrounding collagen fibers [7,8], gels with 3T3 also were included and outcomes compared between cell types. Seeding fibroblast concentrations in gels range from 5×10^4 to 2×10^6 cells/mL, with primary cell lines generally on the lower end due to their eventual senescence and less robust proliferation compared to immortalized cell lines like NIH 3T3 cells [7-11]. To test effects of concentration within the limits of primary FLS growth, two concentrations were used in the low range (5×10^4 & 1×10^5 cells/mL). But, these concentrations have differential effects on matrix failure mechanics [9]. Macroscopic gel mechanics were quantified by force-displacement curves and stiffness. Force and regional strains were compared at several displacements

during loading. Network microstructure was analyzed using collagen alignment maps at those same displacements, and collagen fiber orientation was quantified using circular variance (CV), with a lower CV indicating a tighter clustering and more fiber alignment [12].

METHODS

FLS were harvested from adult Sprague-Dawley rats by removing the capsular tissue surrounding the hind limb joint [10,11], and cultured in DMEM with 10% FBS and 1% P-S. NIH 3T3 fibroblasts were maintained in the same feeding media. Media was changed every other day and cultures were passaged at 90% confluence. In 2D, FLS are elongated, polygonal and have a branched morphology; 3T3 cells are rounder but still branched (Fig. 1A). On passage 4, cultures were resuspended in Type I collagen solution (2mg/mL; Corning) at a concentration of either 5×10^4 cells/mL (low FLS $n=5$; low 3T3 $n=4$) or 1×10^5 cells/mL (high FLS $n=3$; high 3T3 $n=4$) [7-11]. Collagen was cast in 12-well plates (1mL/well) and allowed to gel at 37°C.

On DIV9, gels were cut (21mmX8mm) and the surface marked for strain tracking [12]. Gels were loaded into a planar test machine (574LE2; TestResources; 500g load cells) and immersed in a 37°C PBS bath. The test setup was integrated with polarized light imaging [12] and high-speed cameras (Phantom-v9.1; Vision Research) to acquire alignment maps and track markers. Gels underwent uniaxial displacement to failure at 0.5mm/s, with force and displacement data (200Hz) synchronized with imaging (500Hz) (Fig. 1B).

Force data were filtered by a 10-point moving average filter [12]. Failure was defined as maximum (peak) force and stiffness was calculated as the slope of the loading curve over 20-80% of peak force [13]. Marker positions in images were digitized at reference, and at 20%, 80% and 100% (failure) of peak force. LS-DYNA (LSTC) calculated maximum principal strains (MPS) for elements defined by the markers (Fig. 1) and elements averaged for each gel [12]. Collagen

alignment maps were generated at the same points during loading as MPS and used to calculate the CV [12]; CV at failure was normalized to reference for each gel. Differences in stiffness and reference CV were tested between cell type and concentration by two-way ANOVA. Force, MPS, and normalized CV were compared between FLS and 3T3 for each concentration using repeated-measures ANOVAs.

RESULTS

Gel contraction is observed with the high FLS concentration causing it to pull away from the well wall during culture, producing shrunken gels with a curled circular edge (Fig. 1C). No contraction was observed for the high 3T3 group or either low concentration group (Fig. 1C). Before loading, collagen organization in the high FLS gels is different from all other groups, with significantly higher CV ($p < 0.05$), indicating a larger spread of collagen fibers (Fig. 2).

Figure 1: (A) Labeling of the intermediate filament vimentin shows elongated FLS morphology and rounded 3T3s. (B) A low FLS gel before loading (reference) and at failure (peak force). (C) Images with high concentration of FLS or 3T3 show FLS gel contraction.

Figure 2: Histograms show the spread of fiber angles for high FLS and low 3T3 gels. High FLS gels exhibit greater CV than low FLS (& $p = 0.04$), low 3T3 (# $p < 0.05$), and high 3T3 (* $p < 0.05$).

Although loading curves are similar for both cell types at low concentration, failure force is consistently higher for 3T3 than FLS gels with the high concentration (Fig. 3A). Forces at both 80% ($p = 0.03$) and 100% ($p < 0.01$) of peak are significantly higher for gels with 3T3s than FLS at a high concentration (Fig. 3A). Yet, it is not different between cell types at 20% of peak at either concentration (Fig. 3A). Stiffness differences are not significant ($p > 0.08$), despite a 10-fold lower value in gels with high FLS than those with low FLS and nearly 20-fold lower value than high 3T3 gels (Fig 3B).

As with force, MPS is different between cell types at the high concentration (Fig. 3C). Although peak force is lower in the high FLS group, MPS in high FLS gels is greater ($p < 0.01$) than 3T3 at the same concentration (Fig. 3C). MPS at 80% of peak force is different ($p = 0.03$) between cell types at the high concentration. Across all displacements tested, FLS and 3T3 gels are only different at failure for low concentration, with FLS gels having a higher CV (greater disorganization relative to reference) than 3T3 gels ($p < 0.01$) (Fig. 3C).

DISCUSSION

At the high concentration, FLS-embedded gels exhibit different macroscopic mechanics, stiffness, and microstructure than gels with embedded 3T3s (Figs. 2 & 3). Although the mechanism by which FLS gels contract was not further investigated here, fibroblast-mediated contraction may occur by cell contraction, traction forces, initial

Figure 3: (A) Forces are not different at low concentration, but high FLS gels have lower (*) peak force than high 3T3. (B) Although stiffness of high FLS gels is lower than other groups, it is not significant. (C) MPS is not different at 20% of peak; but at peak, high FLS gels undergo larger MPS than high 3T3 gels (*), and low FLS have higher normalized CV than low 3T3 (*).

elongation and spreading, or by ECM remodeling [2-4], which is supported by the decreased stiffness and initial disorganized matrix (Figs. 1-3). Dermal fibroblasts cultured at the same concentrations used here alter gel modulus by 1.12 (low) and 3 (high) times, respectively, after only DIV1, but increase modulus [9], which is the opposite from the effect of FLS on stiffness (Fig. 3B). Although strain increases with CV in gels without fibroblasts [12], the MPS of high FLS is greater than high 3T3, but the normalized CV is not different (Fig. 3C), possibly due to FLS exerting traction forces [2]. Visualizing cells is needed to define their interactions with the gel matrix.

The concentration-dependent effect of FLS on collagen gel mechanics and microstructure, that differs from 3T3s, is particularly relevant since different regions of synovial joints have different FLS densities [6]. It implies variable mechanosensitive properties may be conferred based on the regional anatomical FLS cell density. In this same collagen gel system absent fibroblasts, pain-related signaling in embedded nerve fibers and collagen network reorganization are induced at strains of similar magnitudes [12]. Given the current findings that both local strains and collagen organization are altered by the presence of FLS (Figs. 2 & 3), it is likely that nerve fibers in FLS-dense regions may be even *more* susceptible to such changes than those in FLS-sparse regions. Including FLS and neurons together will better simulate biologic conditions relevant to trauma and pain. Nonetheless, these findings demonstrate FLS cells exhibit a unique phenotype and action on matrix mechanics and support that primary FLS have distinct behavior at relevant biologic concentrations for systems mimicking the capsular ligaments of synovial joints.

CONTACT EXPERIMENTS REVEAL PRESSURE EVOLUTION IN SOFT HYDRATED INTERFACES

Christopher L. Johnson (1), Jiho Kim (1), Alison C. Dunn (1)

INTRODUCTION

Sliding tissues in the human body such as the blink of the eye or the articulation of the knee joint are critical for sensing and mobility. The slip surfaces are often hydrated, surface-bound extracellular matrix or large hydrophilic molecules, like the mucins and glycoproteins in the tear film, or lubricin in large articulating joints (Figure 1). Their function as low-friction, efficient sliding bearings depends upon how they respond to the pressures in the interface. The mechanics of soft, hydrated tissues are very complex, so we use high-water-content crosslinked hydrogels as a controlled proxy to study the contact mechanics of soft, hydrated surfaces.

Figure 1: The human tear film is comprised of hydrophilic mucins and glycoproteins which mediate the eyelid/cornea interface.

The standard for indentation and contact measurements is to perform them at moderate indentation rates to both avoid long-term creep but account for quick relaxations that occur due to fluid effects. In addition, recent work has established novel probes both as solid

hydrogels [1] and as thin hydrogel membranes which impart a constant-pressure experiment [2]. Those studies have advanced not only contact mechanics but understanding of soft-soft hydrated lubrication, in that the composition of the crosslinked hydrogel inherently controls the interface pressure. While that is true, interfaces in the body are not contacted at moderate timescales, but rather held in contact, such as in the knee joint or the eyelid resting on the cornea when the eye is not blinking. Thus the question we seek to answer is this: Do contact models like the Hertz model [3] or Winkler model [4] describe the behavior of long-duration soft, hydrated contacts? In this study we perform creep relaxation experiments in three contacting configurations such as hard probe-soft substrate, the inverse, and both soft components.

METHODS

Materials

Soft probes and flat substrates were molded either in combination delrin/polyolefin molds or between polystyrene plates, and allowed to equilibrate in water for > 2 hours before testing. The composition was a polyacrylamide of 7.5% acrylamide, 0.3% bisacrylamide, 0.15 % radical donator (APS), and 0.15% initiator (TEMED), all on a weight per total weight basis. This hydrogel was optically transparent and fell in the “ideal” range defined by Pruitt et al [5]. The hard probe was a steel sphere of 1.5 mm diameter (McMaster-Carr) spray-painted black to reduce reflections.

Instrument

A custom, instrumented microindenter was used in force-control mode to apply and hold a light load in the interface (0.50, 0.75, and 1.00 mN). Simultaneously, either particle-exclusion or particle-inclusion microscopy was used to view the contact and record its changes in time up to 10 minutes (Figure 2). Images were recorded with Nikon software on an inverted spinning-disk confocal microscope, using LED

illumination at 470 nm (Ti-E, Nikon Instruments). Particles are 468/508 green fluorescent polystyrene spheres of 1.0 μm diameter (Fisher Scientific). All experiments are submerged in water at 25°C.

Figure 2: Particle exclusion or inclusion microscopy is used to reveal contact made by an optically-transparent hydrogel.

The viewing area was always constant at 2.3mm x 2.3mm, and the size of the contact area was measured using the known scale in ImageJ software [6]. Finally, the force data and contact areas were anchored together by matching the time at which the force reached its steady-state value. The force was divided by contact area to calculate the average pressure at all time points.

RESULTS

The self-mated, or Gemini contact between the hydrogel probe and hydrogel slab was revealed using particle exclusion microscopy. Contact area increased $\sim 20\%$ over 10 minutes (Figure 3, top). This method was also used for a hard probe-on-soft substrate. Particle exclusion had limited success with only a soft probe, so the probe was impregnated with the same particles during polymerization, and the contact area was revealed to increase by only 10% over the same duration (Figure 3, bottom). Each experiment was repeated at least 3X, so these images are representative.

Figure 3: Contact areas increase in time.

All configurations exhibited creep relaxation, manifested as increasing contact area under a constant-load contact experiment. The soft substrate configuration had the greatest extent of contact area growth, the Gemini contact a moderate extent, and the soft-probe the least extent (Figure 4).

Figure 4: The normalized pressure over time decreases as a function of contact configuration and applied load.

DISCUSSION

These results add a new dimension to contact mechanics of soft materials, moving from quasi-static results that may fit neatly to a Hertz contact or other model to time-dependent responses that evolve if the load is allowed to persist. Preliminary calculations of contact pressure evolution indicate that the Hertz model is only valid over short durations of contact. Our data suggest that for long times, Gemini contact approaches a constant-pressure contact model, which depends upon the equilibrium osmotic pressure of the 7.5 % polyacrylamide material rather than the applied loads. This conclusion supports recent findings on hydrogel lubrication which connect the resistance to slip with the material composition [7,8]. This study is limited in that the same microscopy technique was not used in all measurements, though care was taken to ensure repeatability.

This study provides further understanding of what controls the contact between surfaces of high-water-content hydrogels, with the analogy to compliant and hydrated biological tissue contact, such as the eyelid against the cornea or cartilage against cartilage. Further, it adds to the background knowledge required for materials selection when designing a prosthetic device or coating to contact biological tissues such that it best mimics the natural interaction.

INTRODUCTION

Ultrasound shear wave elastography (SWE) can be classified as transient or harmonic based on its temporal characteristics. Most transient ultrasound elastography methods use high-intensity ultrasound ‘push’ pulses that generate a shear wave with a wide frequency spectrum [1]. Several studies have shown biases in the shear wave group velocity measurements of transient methods. These biases can be mitigated by calculating the phase velocity as a function of frequency. However, the energy distribution within the frequency spectrum of transient waves cannot be easily controlled. Therefore, the amplitude of the shear wave may not be optimal at the desired frequency. Conversely, harmonic methods have a narrow frequency bandwidth, which means that the wave energy can be concentrated at the desired frequency. These differences make it difficult to compare measurements obtained with transient and harmonic methods. Several narrowband harmonic imaging techniques have been developed to estimate mechanical properties of tissues. However, all these techniques employ more than one transducer, which may not be optimal for clinical use due to the added complexity to the measurement. The objective of this study was to introduce a narrowband shear wave generation method produced by ‘push’ pulses with sinusoidally-modulated intensity using a single clinical transducer. In the method, named harmonic shear wave imaging (HSWI), it may be possible to directly compare measurements of wave speed to those obtained using magnetic resonance elastography (MRE). This is desirable for the diagnosis of diseases affecting the stiffness of soft tissues.

METHODS

In HSWI method, the duration of each push pulse was varied sinusoidally with a preset main frequency to modulate the acoustic radiation force for exciting the shear waves (Figure 1). The duration of the push pulse was set to vary between $D_{min} = 9.6 \mu s$ (50 cycles at 5.208 MHz) and $D_{max} = 105.6 \mu s$ (550 cycles at 5.208 MHz). The duration of the n th push pulse was determined by equation (1):

$$D_n = D_{min} + \frac{(D_{max} - D_{min})}{2} [\sin(2\pi(n-1)/N_{pp}) + 1] \quad (1)$$

where $n = \{1, 2, \dots, N_{pp}\}$. One complete excitation cycle was constructed by a preset number of push pulses (N_{pp}). The N_{pp} at each frequency was chosen to produce smooth sinusoidal waves. Plane wave acquisition pulses were transmitted between push pulses to measure shear wave propagation.

Figure 1: The sequentially excited shear waves with a sinusoidal variation of intensity

The filtered data was processed by using local frequency estimation (LFE) to obtain the 2D quantitative map of shear wave speed. HSWI was validated on a CIRS homogeneous elasticity phantom and agarose gels with different concentrations. HSWI was also performed in the rectus femoris muscle of a healthy male individual to evaluate the HSWI performance in vivo.

RESULTS

Table 1 shows the shear wave speeds measured by HSWI, MRE and SSI from the rectus femoris muscle in vivo, CIRS phantom and agarose gels. In general, the shear wave speeds obtained by the three elastography methods were similar. Figure 2 shows a 2D shear wave

speed map reconstructed by HSWI with a frequency of 500 Hz on the CIRS phantom as an example. Additionally, the comparison between the dispersion curve obtained in CIRS phantom using SSI and shear wave speed obtained using HSWI are shown in Figure 3.

Table 1: Comparison between the shear wave phase velocities of the CIRS phantom obtained by the SSI and HSWI methods.

	Rectus femoris muscle	CIRS	0.4 % agarose	0.5 % agarose	0.6 % agarose	
HSWI	100 Hz	2.11±0.04	N/P	1.52±0.09	1.85±0.03	N/P
	200 Hz	2.53±0.09	2.63±0.03	1.51±0.07	1.99±0.04	N/P
	250 Hz	2.71±0.08	2.72±0.06	1.55±0.03	1.97±0.03	2.91±0.05
	450 Hz	3.00±0.19	2.74±0.02	1.55±0.07	1.94±0.04	2.91±0.02
	500 Hz	3.02±0.17	2.79±0.02	1.53±0.06	1.93±0.02	3.00±0.04
	550 Hz	3.06±0.08	2.87±0.01	1.57±0.04	2.00±0.06	2.93±0.05
MRE	N/P	N/P	1.57	1.96	2.94	
SSI	2.56±0.07	2.98±0.01	1.72±0.08	2.20±0.02	2.98±0.01	

Figure 2: 2D shear wave speed map reconstructed by HSWI.

Figure 3: Comparison between the shear wave phase velocities of the CIRS phantom obtained by the SSI and HSWI methods.

Fourier analysis of the sequence of push pulses used in HSWI indicate that the majority of the excitation energy concentrates at the main frequency. The HSWI frequency spectrum is shown in Figure 4. The normalized intensity represents the intensity at the fundamental frequency in HSWI divided by the intensity in shear wave dispersion ultrasound vibrometry (SDUV) method developed by Chen et al. [5] at the same frequency, while the same amplitude was selected for both methods. It can be observed that the intensity of the spectrum at the fundamental frequency is higher in HSWI compared to SDUV. The reason for this difference is that HSWI transmits several push pulses during one push cycle of the excitation while SDUV transmits only one.

Figure 4: The frequency spectrum in HSWI and SDUV

DISCUSSION

Phantom experiments showed that the shear wave speeds obtained using HSWI and MRE were comparable. The results from HSWI in the rectus femoris muscle of a healthy male individual showed an increase of speed with frequency, as expected, due to the viscoelasticity of the tissue. It can be seen that for lower frequencies, similar to those commonly used in MRE, the wave speed measured by HSWI is lower. Therefore, this represents an example of the difference between HSWI and SSI in vivo. The novelty of our paper is that we introduced a narrowband shear wave generation and shear wave detection technique using a single clinical transducer.

Unlike transient methods, the energy in HSWI is concentrated around a narrow frequency range. Nenadic et al. [2, 3] employed 2D FFT to obtain frequency-dependent shear wave speed for shear wave propagations in bladder wall with viscoelastic properties. However, the application of 2D FFT for obtaining the dispersion curve is limited in the case of in vivo measurements with noisy 2D FFT data [2]. Brum et al. [4] measured the shear wave speed dispersion in the Achilles tendon of ten healthy individuals based on 2D FFT, reporting the maximum shear wave amplitude around 400 Hz. HSWI concentrate most of the energy at the main frequency (Figure 4) that is comparable to MRE, which typically operates at a single frequency between 50-100 Hz. Hence, although no direct comparison between HSWI and SDUV or the mentioned transient methods was made in this study experimentally, it is reasonable to expect that shear waves with higher intensity are generated in HSWI, specially at lower frequencies.

Measurements of shear wave speed by HSWI are, in principle, comparable to MRE because of the use of a single-frequency mechanical excitation. The results in this study showed that the shear wave speeds of the agarose gels measured by HSWI and MRE were comparable. Hence, HSWI might be a useful clinical tool for staging the level of liver fibrosis. In addition, HSWI could also be applied to the differential diagnosis of benign and malignant thyroid nodules, and the evaluation of the stiffness of muscles. The limitation of this study is that, in the LFE algorithm, a higher number of wavelengths of the harmonic shear wave should be present inside the ROI to obtain accurate estimation.

INTRODUCTION

While cells within tissues generate and sense three-dimensional (3D) states of strain, the current understanding of the mechanics of fibrous extracellular matrices (ECMs) stems mainly from uniaxial, biaxial, and shear tests. Here, we demonstrate that the multiaxial deformations of fiber networks in 3D cannot be inferred solely based on these tests. The interdependence of the three principal strains gives rise to anomalous ratios of biaxial to uniaxial stiffness between 8 and 9 and apparent Poisson's ratios larger than 1. The reconstituted networks [1]–[3] and collagen-rich tissues such as tendons [4] and cartilage [5] exhibit large Poisson effects in stretch tests. These observations are explained using a microstructural network model and a coarse-grained constitutive framework that predicts the network Poisson effect and stress-strain responses in uniaxial, biaxial, and triaxial modes of deformation as a function of the microstructural properties of the network, including fiber mechanics and pore size of the network. We explore the consequences of the multiaxial effects for cell-ECM interactions and rheometry and test our findings using axial-shear rheometry experiments and cancerous mammary acini seeded atop fibrous matrices. We use reconstituted collagen type I networks as a model system for fibrous ECMs.

METHODS

Fiber networks were generated using three-dimensional diluted lattices and Voronoi tessellations. The initial network geometry was created by placing fibers over the edges connecting the first and second nearest neighbors in a body-centered cubic lattice or a three-dimensional Voronoi diagram with random seed points. The pore size of the three-dimensional networks was tuned by changing the number of the seed

points. The average nodal coordination number of the network was tuned by randomly detaching fibers from junctions shared by multiple fibers. Fiber waviness was then induced by shaping individual filaments into half-sine waves. Individual fibers were modeled as elastic Timoshenko beams that are flexible in stretching, bending, twisting, and transverse shear. Finite element modeling was performed using the finite element package Abaqus (Simulia, Providence, RI). Mechanical loading was performed by prescribing the displacements of the nodes located on the sample boundaries.

In the rheometry experiments, Collagen type I gels were prepared using collagen isolated from calf skin (MP Biomedicals, Santa Ana, CA, USA), with pH between 7 and 7.5. The gels were polymerized at 37°C. The gels were tested using a Kinexus rheometer (Malvern, Malvern, UK). The shear moduli of the samples were measured by applying a small oscillatory shear strain of 2% at a frequency of 10 rad/sec. Axial strain was applied by changing the gap between the plates.

In the cell-ECM experiments, Rat tail collagen (Corning, Corning, NY) was gelled at concentrations of 1, 2, and 3 mg/mL on pre-chilled glass-bottom imaging dishes (MatTek, Ashland, MA) according to the manufacturer's protocol. MCF10AT acini were cultured and extracted as previously described [6]. Gel deformation was evaluated through measuring displacement field generated by particle image velocimetry using 1- μ m Nile-red (535/575) fluorescent beads (Life Technologies, Carlsbad, CA).

RESULTS

The fiber network model showed that in uniaxial tension, the fibers oriented transverse to the direction of loading buckle, leading to a

large Poisson effect, with apparent Poisson's ratios >1 . To test the effect of pore size on the Poisson effect, we tuned the density of fibers in the networks by changing the number of the random seeds used to generate the network geometry. The tests indicated increases of apparent Poisson's ratio with increases of pore size (Fig. 1). We then performed biaxial loading of the networks and found anomalous stiffening of the networks in biaxial loading with ratios of biaxial over uniaxial stiffness above 8 (Fig. 1c).

Figure 1: Variation of anomalous apparent Poisson's ratio and biaxial stiffening with polymer concentration and pore size.

Next, we studied the coupling of axial and shear modes of loading. Rheometry experiments combining axial and shear loading (Fig. 2) demonstrated that network shear stiffness changes in proportion to the applied axial stress. Computational results from clamped fiber network models also followed a linear trend (Fig. 2). The fiber network model also showed a quadratic increase of shear stiffness with volumetric strain. (Fig. 2).

Figure 2: Variation of network shear stiffness against (a) axial stress and (b) volumetric strain.

Using insights from our network model we developed a constitutive model for the multiaxial behavior of the tested networks. This model has the same spirit as our previous models of the long-range force transmission in fibrous networks. The model is governed by the strain energy density function

$$W = W_b + \sum_{i=1}^3 f(\lambda_i) + g\left(\sum_{i=1}^3 \sum_{j \neq i} \lambda_i^2 \lambda_j^{2+\alpha}\right). \quad (1)$$

Here, W_b is a neo-Hookean energy describing the strain energy of the isotropic, background fibers. f and g are exponential functions that resemble the strain-stiffening of collagen networks in terms of the principal stretches λ . Finally, α is the parameter coupling the principal stretches. Changing α tunes the apparent Poisson's ratio of the model. Using 6 parameters, this model reproduces the stress-strain curves in uniaxial, biaxial, and triaxial loading, as well as the Poisson effect in uniaxial and biaxial loading. We used the constitutive law to model Poisson effect in the formation of fibrous tracts by a pair of contractile cells.

Our cell-ECM experiments demonstrated a drastic Poisson effect in collagen networks induced by cellular forces (Fig. 3). Densified tracts of aligned fibers formed between a pair of contracting cell clusters, an effect related to the invasion of cancer cells.

Measurements of deformation demonstrated that a large Poisson effect is involved in the formation of the fibrous tracts (Fig. 3). The experimentally observed Poisson effect was reproduced by our constitutive model (Fig. 3).

Figure 3: Deformation of collagen networks by a pair of cell clusters

Our models indicate that the anomalous Poisson effect leads to a 100-fold increase of the apparent stiffness of thin samples of collagen in extensional rheometry, and the stiffening effect increases with decreasing gel thickness (Fig. 4).

Figure 4: Influence of the Poisson effect on the apparent stiffness of thin collagen networks in extensional rheology.

DISCUSSION

The results of our models also agree with the results of stretch tests [7] and extensional rheology [8], [9] of samples with various aspect ratios gathered from the literature (Fig. 4).

The results of our cell-ECM experiments indicate that in less dense collagen networks, Poisson effect facilitates the densification of fibers and the formation of fibrous tracts, an effect associated with the invasion of acinar cancer cells. We expect that the results of our experiments and the introduced constitutive model aid in the design of new models for cancer invasion and fibrosis.

INTRODUCTION

The mechanical function of the uterus is crucial for protection of the fetus in a healthy pregnancy. Throughout gestation, the uterine wall remains in a passive state and accommodates the expanding amniotic sac by growing, unfolding, and stretching. Then—ideally at term (defined as 37 weeks)—the onset of labor triggers a functional change in the uterus: the tissue becomes highly contractile to safely deliver the baby. Early contractile activation of uterine tissue can lead to preterm labor and birth (PTB). In 2014, 9.56 percent of pregnancies ended in PTB; it is also the leading cause of death in children under five years of age [1]. Characterizing uterine muscle, collagen fiber orientation, and dispersion is important for understanding the anisotropic material properties that could lead to mechanical failure of the uterus and cause PTB.

Previous studies using magnetic resonance imaging (MRI) have shown that collagen structure exhibits significant anisotropy across different regions of the uterus and cervix [2]; the fiber architecture was also found to be anisotropic through different layers of the uterine wall, which consists of the perimetrium, myometrium and endometrium [3]; previous optical coherence tomography (OCT) [4] studies determined the alignment and local distribution of collagen fibers within the cervix [5]. Therefore, similar to what has been done for the cervix, the goal of this research is to use OCT to characterize maps of fiber orientation and dispersion within different regions of the uterine wall.

METHODS

Tissue Collection: Three nonpregnant (NP) and two pregnant (PG) term uterine tissue samples were collected from consenting hysterectomy patients. Pregnant patients underwent cesarean hysterectomy due to accreta, a medical condition in which the placenta grows too deeply into the uterine wall. Patient age ranged from 36 to 47 with various recorded obstetric histories. Immediately after hysterectomy, a specimen was collected from each of three uterine locations: the anterior, the posterior, and the fundus, which is the superior-most end of the uterine corpus. All specimens spanned the depth of the uterine wall, which ranged from 15 to 25 mm, and covered a square cross-sectional area with an edge length between 10 and 15 mm. All specimens were flash frozen using dry ice immediately after collection and stored in a -80°C freezer prior to OCT. Fiber directionality data from one nulliparous NP uterus are presented in this abstract. Two more NP uterus samples with parity of one and two and two more PG uterus samples with parity of two and four have been collected and are under analysis to investigate the relationship between parity and uterine fiber structure.

Optical Coherence Tomography (OCT): Three-dimensional volumetric image-sets were obtained from human uterus samples using a commercial spectral domain OCT system, TELESTO (Thorlabs GmbH, Germany), with $6.5\text{ }\mu\text{m}$ axial resolution, $15\text{ }\mu\text{m}$ lateral resolution, and 2.51 mm imaging depth, in air. Each specimen was sliced into five or six slices parallel to the uterine wall. The thickness of each slice ranged from 2 to 4

mm. The slices were numbered from external layer to internal layer with increasing numbers starting from 1. In our experiments, each slice was laid on top of a coarse cork taped to a weighing boat. The bottom of the specimen slice was submerged into phosphate-buffered saline (PBS) to keep the tissue hydrated while the top was dried to avoid reflection. Samples were placed on a linear translation stage underneath the objective. For each slice, both sides were imaged with multiple volumes obtained by moving along the x- or y-axis. Each volume consists of $1375 \times 1375 \times 512$ voxels, corresponding to a tissue volume of $5.5 \text{ mm} \times 5.5 \text{ mm} \times 2.51 \text{ mm}$. Since the surface of the slice was not flat, the axial position of the slice was also adjusted to obtain well-focused images. An overlap of 10% was applied between adjacent volumes for image stitching. A white-light camera image was obtained simultaneously with an OCT image to delineate the field of view of the tissue.

Fiber Direction Characterization: Three-dimensional data was generated by stitching volumes based on OCT data and shift-invariant features within the *en face* plane of the camera image [6]. All volumes were stitched together to form a new complete volume for each specimen slice. Fiber directionality and dispersion analysis was performed by using pixel-wise weighted summation [7]. The fiber direction, α , of a pixel of interest, is determined as:

$$\alpha = \arg(\sum_{j=1}^N w_j \times \exp(i\alpha_j)) \quad (1)$$

For a target pixel, there were multiple fiber direction candidates α_j pointing toward its neighboring pixels. A weight w_j was assigned to each candidate, whose total count was N .

A fiber orientation map was generated on one 2D plane parallel to the top surface of the total volume by combining the fiber direction information of each pixel (Fig. 1). A fiber concentration was generated by quantifying the distribution of continuous angles of fiber orientation. Each concentration was then divided by the maximum concentration value to create a normalized histogram (Fig. 2).

Figure 1. (A) fiber orientation map of anterior specimen slice 5 (innermost layer) with a vertical depth of 560 μm . Black holes are empty regions of no tissue. (B) fiber orientation map of anterior specimen slice 1 (outermost layer) with a vertical depth of 250 μm .

RESULTS

At the inner portion of uterine wall, two major near-orthogonal overlapping fiber groups are characterized with two dominant peaks corresponding to angles of 45° and 150° (Fig 2A), indicating a primarily interweaving bundle structure. Conversely, the outer layer fiber dispersion concentrations are scattered without dominant peaks throughout the entire degree

range (Fig 2B), meaning it is comprised of a cluster-like high dispersion arrangement. In the middle layer, the fiber bundles exhibit a structure intermediate to the inner and outer layers, with evident but less pronounced peaks.

Figure 2. (A) normalized histogram of fiber orientation concentration of anterior specimen slice 5 (innermost layer). (B) normalized histogram of fiber orientation concentration of anterior specimen slice 1 (outermost layer).

Similar characteristics are observed in the posterior specimen; the fundus specimen does not exhibit identifiable local structure.

DISCUSSION

In this study, a workflow of experiments and data processing techniques were used to characterize the architecture of human uterine tissue. The preliminary results show that the internal portion of the uterine wall has a primarily interweaving fiber structure while the external portion consists of more randomly distributed fibers. The same protocol will be applied to four more patient samples with parity varying from zero (nulliparous) to four to investigate the effect of repeated pregnancy on uterine architecture. In addition to *en face* imagery, transverse plane data will be exploited to help us understand the fiber orientation in the direction orthogonal to the uterine wall.

The research and conclusions described in this abstract have the following limitations: due to IRB tissue collection protocol, full uterus sample could not be collected for imaging to perform characterization of global fiber structure; due to time constraints, the data were not analyzed in the transverse plane, though such an analysis could yield valuable information about fiber orientation across layers of the uterine wall.

CADHERIN-11 REGULATES AORTIC VALVE INTERSTITIAL CELL FORCE GENERATION AND MECHANICAL PROPERTIES

Matthew R. Bersi (1), Meghan A. Bowler (1), W. David Merryman (1)

(1) Department of Biomedical Engineering
Vanderbilt University
Nashville, Tennessee, USA

INTRODUCTION

Calcific aortic valve disease (CAVD) is a degenerative condition that affects 25% of people over 65 and often necessitates total valve replacement in severe cases [1]. With increasing numbers of CAVD patients, there is a need to better understand the biological mechanisms underlying CAVD initiation and progression in order to develop non-invasive pharmacologic therapies for valvular calcification.

Aortic valve interstitial cells (AVICs) are a heterogeneous population of fibroblast-like cells that regulate the structural integrity of the valve. When activated by transforming growth factor beta 1 (TGF- β 1), AVICs transition to a myofibroblast phenotype characterized by increased contractility, collagen deposition and expression of smooth muscle alpha-actin (α SMA) and cadherin-11 (CDH11). The resulting increases in intra- and intercellular tensions can cause tearing of the cell membrane leading to cellular apoptosis and calcific nodule formation.

CDH11 was first identified as a potential therapeutic target for CAVD when it was found to be enriched in calcified human aortic valves and required for calcific nodule formation *in vitro* [2]. CDH11 is a mechanosensitive transmembrane protein involved in cell-cell adhesion; homotypic bonds formed by CDH11 are stronger than those of other mesenchymal cadherins – such as cadherin-2 (CDH2) [3]. CDH11 is also the only cadherin known to participate in focal adhesions [4] and has been shown to increase secretion of the proinflammatory cytokine IL-6 by AVICs. Together, these characteristics make CDH11 a unique protein with the potential to sense interactions with the local mechanical environment in order to influence valvular inflammation and matrix synthesis. To better understand CDH11's role in CAVD and AVIC phenotype, we examined how CDH11 influences AVIC force generation and bulk mechanical properties as measured by traction force microscopy and micropipette aspiration, respectively.

METHODS

Isolation of AVICs – Murine aortic valves were excised from *Cdh11*^{+/+}, *Cdh11*^{+/-}, and *Cdh11*^{-/-} immortalized mice and digested in 2 mg/mL collagenase for 30 minutes at room temperature. Following digestion, valves were seeded on 0.1% gelatin-coated tissue culture treated plates and expanded in DMEM supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin antibiotic to yield AVICs.

Traction force microscopy (TFM) – AVIC traction force generation was quantified for each cell line ($n > 72$ for single cells and $n > 25$ for cell pairs) using standard methods [5]. Briefly, AVICs were seeded on soft (1 kPa), fibronectin-coated polyacrylamide gels with embedded fluorescent microspheres/beads overnight prior to imaging. Comparisons of the bead distributions below each cell before and after detachment from the gel were used to compute gel displacement fields via a subpixel image correlation approach. Combined with polyacrylamide gel material properties, displacements were used to reconstruct traction forces on the surface of the gel using a regularized Fourier transform traction cytometry (reg-FTTC) framework.

Given the reconstructed traction fields, total force generated by each cell $|F|$ was calculated as

$$|F| = \int_{\Omega} |\mathbf{T}(\mathbf{x})| d\mathbf{x} \equiv \iint_{\Omega} \sqrt{T_x(x, y)^2 + T_y(x, y)^2} dx dy \quad (1)$$

where $T_x(x, y)$ and $T_y(x, y)$ denote components of the reconstructed traction vector $\mathbf{T}(\mathbf{x})$ within the cell boundary Ω . Cell-cell interaction forces \mathbf{F}_{cc} were estimated from the traction imbalance that arises when the reconstructed traction field is partitioned at the cell contact border. Values were computed as $\mathbf{F}_{cc} = (\mathbf{F}_1 - \mathbf{F}_2)/2$, where \mathbf{F}_1 and \mathbf{F}_2 denote the resultant traction force vectors in each cell of the doublet [6].

Figure 1: (A) Reconstructed traction force maps from AVIC TFM reveal that (B) CDH11 depletion reduces AVIC force generation.

Figure 2: (A) TFM of AVIC doublets reveal that (B) CDH11 depletion reduces AVIC cell-cell interaction forces.

Micropipette Aspiration (MA) – AVICs were gently lifted from tissue culture plates using 0.05% trypsin for no more than 5 minutes and resuspended in DMEM. 100 uL of resuspended cells were then placed in a 35mm dish under a microscope contained within a custom built MA system made up of a precision microfluidic controller, a secondary reservoir, and hand-pulled glass micropipettes fractured to a diameter ~8μm. Upon equilibration of pressures in the MA system, single cells were aspirated at a constant rate of 4 Pa/s for 150 s (maximum aspiration pressure of 600 Pa). Tracking of the cell's leading edge upon aspiration generated characteristic L/a vs. ΔP curves, where L denotes the aspiration distance and a denotes the micropipette radius. From this linear aspiration behavior, the AVIC stiffness E was computed as

$$E = \frac{3\Delta P}{2\phi(\eta)} \frac{a}{L} \quad (2)$$

where $\phi(\eta) = 2.1$ denotes a wall function accounting for the micropipette wall thickness [7].

Statistical analysis – AVIC traction force and stiffness was compared by one-way ANOVA with post-hoc Tukey HSD tests. Non-parametric statistics were performed when tests for normality and/or equal variance failed. Values of $p < 0.05$ were considered significant.

RESULTS

Cdh11 transgenic AVICs showed a CDH11-dependent reduction in traction force generation (Fig. 1). In particular, reconstructed traction maps revealed an ~40% reduction in average traction force magnitude in *Cdh11*^{+/+} and *Cdh11*^{-/-} AVICs, relative to *Cdh11*^{+/+}. Similarly, loss of CDH11 in AVIC cell doublets altered the magnitude of measured cell-cell interaction forces F_{cc} . Accounting for cell size, normalization of F_{cc} by the border length (blue curve; Fig. 2A) revealed a similar CDH11-dependent reduction, as expected due to impaired adhesion (Fig. 2B).

Single-cell AVIC stiffness measurements also exhibited a CDH11-

Figure 3: CDH11 depletion (A) increases αSMA expression which correlates with (B) increased AVIC stiffness, as measured by MA.

dependent response. In particular, MA stiffness was increased following loss of CDH11 (Fig. 3B). Western blotting for αSMA (Fig. 3A) revealed a significant increase after CDH11 depletion, suggesting that AVIC contractility is positively correlated with AVIC stiffness.

DISCUSSION

While CDH11 expression regulates AVIC contraction and contributes to disease progression, it is clear that this effect is potentiated by more than cell-cell interactions alone. In particular, AVICs are involved in complex interactions with resident and recruited (immune) cells as well as the local mechanical environment of the valve.

TFM revealed a CDH11-dependent reduction in AVIC force generation that was normalized across genotypes when divided by cell area. This suggests CDH11 alters cell spreading, likely through its interaction with focal adhesion complexes. Indeed, immunostaining for the focal adhesion protein vinculin has shown that *Cdh11*^{-/-} AVICs have fewer, but longer, focal adhesions relative to *Cdh11*^{+/+} [8].

AVIC stiffness, as measured by MA, was found to be increased in CDH11-depleted cells consistent with an increase in αSMA protein expression. That AVIC stiffness positively correlates with AVIC contractility suggests a potential functional adaptation of *Cdh11* transgenic AVICs in response to altered mechanical loading [9].

While targeting CDH11 has shown beneficial effects for CAVD, mechanical analysis of *Cdh11* transgenic AVICs suggests that there is a CDH11-dependent relationship between AVIC mechanobiology, disease progression, and the aortic valve mechanical environment. Further insight into the impact of pharmacologic treatments on the biophysical properties of AVICs is warranted in order to better design therapeutic treatment strategies for CAVD.

INTRODUCTION

Following myocardial infarction (MI), the long-term remodeling of the damaged infarct region is a crucial determinant of patient outcome and risk of progression to heart failure [1]. The complex remodeling process involves changes in both the shape and structure of the infarct region, also referred to as infarct scar, that may negatively affect ventricular performance [2]. During the first few weeks after MI, myocytes necrose and their components are resorbed, while myofibroblasts infiltrate the tissue and deposit collagen [3]. The replacement of the necrotic myocytes with collagen results in both an increase in stiffness and a net decrease in tissue volume. By measuring the thickness of the scar along with one or more in-plane scar dimensions, a number of studies have reported changes in scar shape. However, these measurements are typically performed in intact, mechanically loaded hearts, where changes in stiffness could also cause changes in dimensions in the absence of volumetric remodeling.

To better understand the geometric changes that occur during infarct healing, we recently performed an exhaustive review of quantitative studies of infarct remodeling and found that some studies reported in-plane expansion of the healing infarct while others reported in-plane compaction (shrinkage) when dimensions were measured at end diastole in intact hearts [4]. All studies that measured wall thickness reported gradual thinning of the scar, which can aggravate adverse remodeling of the left ventricle (LV) by increasing wall stresses. In order to better interpret these reports and separate the contributions of volumetric growth and remodeling (changes in volume and stress-free shape), infarct stiffening, and elevated LV diastolic pressures typical after infarction, in this study we employed a finite-element model that incorporated prescribed volumetric shrinkage in the infarct scar. We tested whether changes in scar stiffness and loading observed following

MI can reproduce observed changes in *in vivo* infarct dimensions if volume loss in the scar occurs isotropically in the unloaded state.

METHODS

A finite-element (FE) model of the diastolic rat left ventricle (LV) was constructed. A rat LV geometry was derived by fitting manually segmented contours from cine-MRI scans, and a representative infarct geometry was derived from late-gadolinium enhancement (LGE) MRI images. A physiologic myofiber structure was assigned, and a transversely isotropic Mooney-Rivlin (TIMR) material was used to model material properties of the normal myocardium. Realistic diastolic pressures were applied to the endocardium to inflate the LV while the displacement of basal surface nodes was fixed longitudinally. In simulations in which the scar was stiffened, the isotropic term of the TIMR material equation was increased to mimic the reported properties of rat infarct scar 6 weeks post-MI [2]. Inflation simulations were run with the FEBio finite element solver [5].

A kinematic growth framework [6] was implemented in a custom FEBio plug-in to simulate isotropic scar volume loss in the initial unloaded state, resulting in 100%, 90%, 80%, 70%, or 60% of the original scar volume remaining prior to the onset of inflation. Then, in-plane scar area on the epicardial surface and average scar thickness were calculated over a range of end-diastolic pressures (EDPs) from 0.75 to 1.5 kPa. Finally, these metrics were normalized to their respective values in the non-remodeled scar at an EDP of 0.75 kPa.

RESULTS

In the absence of scar stiffening, isotropic volume loss (Figure 1A, Left) produced apparent scar compaction or expansion depending on the simulated EDP and the amount of remaining scar volume. With a

doubling of EDP as reported by Fomovsky at some time points following infarction in the rat [2], only the simulations with very limited volume loss (90% or 100% of original volume remaining) fell within the experimentally reported range of in-plane dimensions. All of the simulated cases predicted thinning of the scar at a post-MI EDP of 1.5 kPa (Figure 1A, Right), although the simulations with more volume loss fell closer to the experimental mean.

Simulations of isotropic volume loss accompanied by a physiologic degree of scar stiffening (Figure 1B, Left) predicted in-plane compaction at all diastolic pressures, regardless of the extent of volume loss; these predictions were clearly inconsistent with the experimental data. Moreover, nearly all simulations predicted an increase in scar thickness at end-diastole, due to reduced in-plane stretch (and associated thinning of the incompressible scar) during inflation from the remodeled, unloaded state (Figure 1B, Right). This prediction was also inconsistent with experimental measurements. Overall, these simulations revealed that when previously reported data on post-infarction stiffening and diastolic pressures are incorporated into a finite-element model of the infarcted rat left ventricle, no amount of isotropic volume loss produces dimensional changes consistent with *in vivo* scar dimensions documented in the infarct healing literature.

Figure 1. Scar area and scar thickness ratios for (A) non-stiffened infarct and (B) stiffened infarct of varying volumes. Gray boxes indicate the range between the 25th and 75th percentiles of observed *in vivo* dimensions at various times during remodeling [4].

DISCUSSION

The goal of this study was to determine whether a volumetric growth model that assumes isotropic volume loss in the unloaded state could reproduce observed changes in *in vivo* infarct dimensions when appropriately constrained by known changes in scar material properties and loading. The simulations provide strong evidence that the assumption of isotropic volume loss is inconsistent with available data. We believe this finding raises interesting questions about how to model – or even conceptualize – the replacement of muscle by scar in three dimensions. It is not immediately apparent why degrading myocytes and replacing them with collagen and other extracellular matrix should be associated with a change in shape of a region of tissue in its stress-free state. Modeling at the level of the individual proteins and components may be necessary to understand the packing of these elements in the remodeling tissue. These questions have potentially important therapeutic implications, since increasing wall thickness is thought by some to be the primary mechanism by which biomaterial injections limit adverse remodeling of the LV following infarction [7].

The current model still contains several limitations. First, increasing only the isotropic term within the scar material does not allow us to precisely match previously published biaxial testing data on infarct scar; a better match could be achieved by employing a custom strain-energy function as proposed by Fomovsky et al. [2]. Second, only one representative infarct geometry was used in the simulations. Infarcts of different size, location, and transmuralty may exhibit different loaded dimension changes. Third, in-plane area ratio is calculated in this study but is compared to normalized in-plane dimension changes from studies that reported a variety of infarct measurements (i.e. absolute circumferential segment length, infarct-containing segment), some of which may contain contributions from the infarct borderzone and remote remodeling. Overall, we consider it very unlikely that any of these factors would alter predicted or measured dimensions enough to invalidate our conclusions.

In conclusion, the present study demonstrates that a volumetric growth model that assumes isotropic volume loss within the scar region in the unloaded LV and accounts for known changes in scar material properties and LV pressures cannot reproduce reported changes in *in vivo* infarct dimensions. The assumption of isotropic volume loss is thus inconsistent with available data, which raises interesting questions about how to envision and appropriately model the replacement of muscle by scar in three dimensions.

INTRODUCTION

Platelet adhesion to blood vessel walls in shear flows is essential in initiating coagulation cascade of blood and prompting clot formation in prosthetic cardiovascular devices and vascular disease processes. In the adhesion process, platelets undergo complex and rapid receptor-ligand binding such as bond association and breakage. Experimental methods have been improved through enhancing the μm -length and ms-time scale results. However, numerical approaches are still very limited. Continuum methods cannot capture the molecular mechanism of vWF-mediated platelet GPIb α binding. Utilizing molecular dynamics (MD), although allowing atomic details, is too computationally prohibitive for large-scale simulations. To bridge this gap, a multiscale model can be developed to depict the platelet's biophysical properties at the cellular scales coupled with macroscopic flows, thus predicting platelet motion under flow conditions.

In this study, we present a novel multiscale flow-mediated platelet adhesion model under viscous blood flow conditions. Following our previous effort^{1,2}, we adopt a multiscale DPD-CGMD model that combines a Dissipative Particle Dynamics (DPD) for viscous blood flows that interfaces with Coarse Grained Molecular Dynamics (CGMD) for mechanobiology-based platelets². We extended this model by simulating the mechanism of the platelet GPIb α receptor and von Willebrand factor (vWF) binding near a blood vessel wall under shear stress. The platelet GPIb α receptor and the vWF ligand are modeled at a 10-nm length scale. The formation and breakage of the GPIb α -vWF bonds are simulated at a ns-time scale. We validate this numerical model through the use of shear-based experimental techniques that allow observation and measurement of platelet morphological changes and motions over a wide range of shear stresses (0~30 dyne/cm²) with a ms-time scale image resolution.

METHODS

Employing a modified DPD to describe viscous blood flow in microchannels and stenoses³, our multiple spatiotemporal scales model employs a unique CGMD approach to describe the intra-platelet constituents in order to model the mechanotransduction processes². Spatially, the DPD-CGMD is interfaced by imposing a hybrid force field¹. In this spatial interface, the Lennard-Jones term describes the cytoskeleton-confined shape and the incompressibility of platelets against the applied shear stress of circumfluent flow; and the dissipative and random terms maintain the local flow thermodynamic and mechanical properties, and exchange momentum to express interactions between the platelet and the flow.

In the nanoscale, we developed a mechanobiology-based platelet model to describe key constituents and biophysical properties². We modeled a bilayer membrane, an ellipsoid-based discoid shape, rigid filamentous core, gel-like cytoplasm using the Morse potential⁴, and actin filaments. An α -helix structure was used to mimic a protrusible actin filament.

The platelet's bilayer membrane has a total of 67,004 particles and its surface area is about 28.6 μm^2 . We define the platelet GPIb α with 16,751 copies per platelet, wherein the reported range of GPIb α is between 12,000 to 25,000 per human platelet⁵. Thus, the density of platelet GPIb α in our model is 585 / μm^2 . The vWF is fixed on the blood vessel and functions to bind to a platelet GPIb α receptor and initiate platelet adhesion. We define a uniform distribution of vWF at a density of 600/ μm^2 on top of blood vessel walls. The force field between the platelet GPIb α receptor and the vWF ligand is described by a hybrid force field combining Morse and Hooke potentials:

$$E_{\text{Adhesion}} = E_{\text{Morse}} + E_{\text{Hooke}} \quad (1)$$

where

$$E_{Morse} = D_0 \left(e^{-2\alpha(r_{ij}-r_0)} - 2e^{-\alpha(r_{ij}-r_0)} \right) e_{ij} \quad (r < r_c) \quad (2)$$

$$E_{Hooke} = k_1(r - r_b)^2 + k_2(r - r_b)^4 \quad (r < r_c) \quad (3)$$

In Eq (2), D_0 is the well depth of repulsive force, α is the scaling factor, r_0 is the zero-force length. This term is used to keep a certain distance between the receptor and the ligand in adhesion. In Eq (3), k_1 and k_2 are the adhesive coefficients and depends on time duration of adhesion. r_c is the force relaxation distance and is equal to the dissociation and mechanical distance of the GPIIb α -vWF bond. Fig. 1 shows the simulation scheme of platelet adhesion to the blood vessel wall under a shear stress of 30 dyne/cm². The simulation is conducted in a box of size 18 \times 8 \times 8 μ m. No-slip boundary condition is applied on y-axis and periodic boundary condition is used on both x- and z-axis.

Figure 1: Adhesion of platelet to blood vessel wall in shear flow

We validated our numerical method by correlating simulations and model predictions with in vitro results. In our modeling, we split a whole rotation of an adhered platelet into two periods: period 1 and 2, i.e., ω_1 and ω_2 as indicated in Fig. 1. The period ω_1 is the lift-off period of an adhered platelet from a horizontal position to vertical position wherein the disassociation of the GPIIb α -vWF bonds are mimicked. Period ω_2 is the falling period of the platelet from its upright position back to a horizontal position, wherein the GPIIb α -vWF bonds form as the platelet re-attaches to the vWF-coated vessel wall. In period ω_1 , we adjust the adhesive coefficients of the model to correlate with in vitro measurements. In period ω_2 , we tune the force relaxation distance.

For adhesion experiments, purified platelets were prepared as previously described³, diluted to 150,000/ μ l and perfused through 100 μ m \times 1 mm microchannels (μ -Slide VI^{0.1} Luer, ibidi USA, Inc., Madison, WI) pre-coated with 100 μ g/ml vWF using a syringe pump (Fig. 2a). Perfused platelets were exposed to wall shear stresses of 5-30 dyne/cm². Adhesion events, defined as platelets flipping or sliding on the vWF-coated surface, were observed at 100 \times magnification on a DIC microscope (Ti-E, Nikon, Melville, NY) at up to 1000 fps (Neo 5.5 sCMOS, Andor Technology Ltd., Belfast, UK). We measured platelet major and minor diameters, cross-sectional area, thickness, translational velocity, and angular flipping velocity for each adhesion event (Fig. 2b).

Figure 2: (a) Set-up for adhesion experiments. b) Sequential imaging of platelet adhesion and flipping under flow.

RESULTS

Our multiscale model describes the biophysical properties for platelets down to the *nm*-length and *ps*-time scale². Membrane Young's modulus is 31.2 μ N/m and shear modulus is 33 \pm 9 μ N/m. The cytoplasm is modeled by modified Morse potential⁵ and its viscosity is 4.1 mPa \cdot s. Actin filament stiffness is 56.3 \pm 1.0 pN/nm.

The experiments indicate two periods, ω_1 and ω_2 , during flipping on the vWF surface. The first period describes rotation of the platelet from a horizontal to vertical position, whereby the force exerted by the flow on the platelet lifts it off the vWF substrate and breaks existing GPIIb α -vWF bonds. In the second period, the fluid force exerted on the platelet pushes it towards the vWF substrate, thereby allowing GPIIb α -vWF bonds to re-form. We observed a difference in the two periods, where $t(\omega_1)$ = 16.35 \pm 5.14 ms and $t(\omega_2)$ = 13.62 \pm 4.16 ms (n =30, p >0.05) at 6.7 dyne/cm² and 91.5 fps (Fig. 3). Ongoing experiments extend this analysis to shear stresses up to 30 dyne/cm², with significant increase in translational and flipping velocities, and reduced discrepancy between the two flipping periods, anticipated with an increase in shear stress. In ongoing experiments, the camera frame rate has been adjusted to 1000 fps to increase temporal resolution to 1 μ s/frame, allowing capture of the platelet rotation trajectory in a μ s-time scale. Wall shear stress has been increased to 30 dyne/cm² to capture a complete rotation of an adhered platelet in approximately 10 ms. We have correlated the rotation angles with the projected platelet areas on the vWF-coated channel surface, thus calculating the angular speed of platelet rotation as a function of adhesion contact area. This relationship will be used to validate the parameters in our model (Eqs. 1-3) and adjust the adhesive coefficients.

DISCUSSION

We developed the first multiscale flow-mediated platelet adhesion model under viscous blood flow conditions. This model can describe the molecular mechanism for the platelet GPIIb α and vWF binding. In our model, the receptor-ligand coefficients are determined through correlation with platelet rotation angular speeds measured in vitro. Phenomena of platelet rotating, sliding, and adhering to vWF-coated vessel walls closely follow behavior observed in our experiments. Using this model, we can precisely simulate the formation and breakage of GPIIb α -vWF bonds, measure platelet adhesion area, and predict the platelet adhesion force strength that are otherwise difficult to quantify under in vitro flow conditions. In future studies, this model can be extended to study a platelet-mediated thrombus growth model under shear flow. This thrombus model will incorporate our previous platelet flipping, activation and aggregation models¹⁻³, and coupled with this adhesion model reflecting molecular level changes in receptor-ligand bond formation. We expect our model to be adopted by other fields, such as drug delivery, by considering the impact of mechanical events triggering biochemical responses.

INTRODUCTION

Region-of-interest (ROI) selection has been used for localization of diagnostically relevant regions in medical images [1]. For localized cerebrovascular diseases like intracranial aneurysms (IAs), automated and accurate ROI selection can help enable objective quantitative analyses of the medical images [2]. For example, accurate ROI selection enables accurate image-based 3D morphologic and computational fluid dynamics (CFD) analyses of localized vasculature to study progression, rupture and treatment of IAs [3, 4]. Objective localization of the computational domain helps reduce the inconsistencies in hemodynamics [5]. Furthermore, for efficient transfer and storage of medical images, image compression is required [2]. Automated ROI selection methods can enable use of hybrid techniques for lossless compression of ROI and lossy compression of the remaining regions [2].

For ROI selection in medical images, automated methods have been proposed for purposes such as pancreatic segmentation [6], left ventricular segmentation [7], etc. But these ROI selection methods have not been adopted in cerebrovascular disease localization. Currently, for the ROI selection in cerebrovascular disease, localization relies on manual operation of the image around the site of the vascular disease like IA [3, 5], arteriovenous malformations [8], etc. This manual operation of ROI selection is user-dependent, thereby subjective, inconsistent and inefficient. Furthermore, ROI-based compression techniques require the localization method to be automated [2].

To make ROI selection objective and automated, we developed a deep-learning based technique for ROI selection of major arteries susceptible to cerebrovascular diseases from 3D medical images. As an example, we applied our technique to automatically calculate ROI from 3D digital subtraction angiography (DSA, gold standard for cerebrovascular images [9]) images of intracranial aneurysm patients.

METHODS

Convolutional Neural Networks (CNN) have been used extensively for object detection in computer vision field [10]. Borrowing its concept, we present a novel, computationally efficient 2D parallel CNN for the automated detection and localization of major arteries susceptible to IAs. Our 2D parallel CNN was compared with the

Figure 1: Manual bounding box on representative case.

traditional 3D serial CNN to compare their performances in terms of accuracy and computational cost. Our methodology uses patient specific 3D DSA images as the inputs, to automatically predict the geometrical features of the cuboidal bounding-box encompassing the major arteries susceptible to IAs to obtain the ROI objectively. This cuboidal bounding-box is defined by 6 scalar geometrical features namely, the coordinates of its center (X_c, Y_c, Z_c) and its dimensions (l_x, l_y, l_z), as shown in Fig. 1. The 6 output parameters are normalized by the length, height and width (512 voxels each) to yield values between 0 and 1.

Figure 2: 2D parallel CNN architecture trained to predict geometrical features of the cuboidal bounding box for ROI.

2D Serial and 3D Parallel CNNs

A novel computationally efficient 2D parallel CNN (shown in Fig. 2) and a traditionally used 3D serial CNN (shown in Fig. 3) for object detection in 3D images [10] were built.

As shown in Fig. 2, the 2D parallel CNN takes 3 standard 2D average intensity projections (AIP) of size 512^2 as inputs in 3 parallel encoding paths respectively. The dimensionality of the complete network decreases from 3D to 2D with 2D projections as inputs. This dimensionality reduction saves computational costs and reduces memory requirements.

Contrarily, a 3D serial CNN shown in Fig. 3 uses the complete 3D DSA as an input and the subsequent computations are done in 3D. The internal architecture of the 3D CNN (For eg. Number of convolutional layers, filters, strides, etc.) were kept the same for both the architectures for an objective comparison with the 2D parallel CNN.

Figure 3: 3D serial CNN architecture trained to predict geometrical features of the cuboidal bounding box.

The networks' parameters were initialized using the Xavier uniform initializer [11] and trained using the Adam's optimizer [12] with a batch size of 16. The Learning Rate (LR) was initially set to $10E-4$ with decay coefficients β_1 and β_2 set to 0.99 and 0.9 respectively. Drop-out of 0.4 and a L2 regularization with regularization rate of 0.075 was added at fully-connected layers to ensure models don't over-fit to training data. Mean squared error loss function was used for model training. Mean absolute error was also monitored for evaluating relative performance of the model on the training and validation cohorts for ensuring convergence and avoiding over-fitting.

Patient Database

For model training and evaluation, 225 patient-specific 3D DSA images of the anterior and posterior cerebral arteries with IAs were retrospectively collected from Gates Vascular Institute, Buffalo, NY between 2009 and 2018. The database was randomly divided into training (n=180), validation (n=30) and testing (n=15) cohorts.

Rules for Manual ROI Computation

The bounding box were set up manually for training to encompass the major arteries such that, for images coming from: a) anterior cerebral circulation, the complete internal carotid artery (ICA), posterior communicating artery (PCOM), anterior communicating artery (ACOM) (complete A1, A2 up till 20D) and mid cerebral artery (MCA) (complete M1, M2 up till 20D) were included, and b) posterior cerebral circulation, the ROI was set up such that the basilar artery (BA) and 40D of posterior cerebral Artery (PCA) were included.

Metrics for Evaluation

To evaluate the trade-off between accuracy and computational cost, both the architectures were compared using the object detection metrics, Intersection Over Union (IoU) and Intersection Over True (IoT), along with the time taken for prediction. With A and B as the region encompassed by the true and predicted labels respectively, IoU and IOT were defined as

$$IoU = \frac{A \cap B}{A \cup B}, IOT = \frac{A \cap B}{A} \quad (1)$$

Under-prediction might leave out the important vasculature required for further analyses. For the same reason, IoT was also monitored along with IoU as a higher IoT would indicate that the prediction is accurately encompassing the necessary vessels of interest. The acceptable cutoff of IoU for the object detection problem is 0.6 [13].

RESULTS

The performance of the 2D parallel CNN and 3D serial CNN architectures on the training and validation cohorts with progressing epochs while learning the model are shown in Fig. 4. The mean squared loss and the mean absolute error plateau after about ~500 epochs ensuring the convergence of the model trainings. Performance on validation cohorts ensures model was not over-fit to training cohort.

The performance of the 2D parallel CNN and 3D serial CNN architectures in terms of the IoU and IoT on the validation cohort (n=30)

Figure 4: 2D parallel CNN and 3D serial architectures' performance during model training.

post-training can be seen in Table 1. The models predict with an average IoU of 0.68 ± 0.11 and 0.67 ± 0.23 with the 2D parallel and 3D serial CNN models respectively. These predictions meet the cut-off criteria for object detection. Higher IoT further shows safe over-prediction.

The trade-off of both the models in terms of speed for prediction and 'accuracy' are listed in Table 1. The 2D parallel CNN performed ~5 fold faster than the 3D serial CNN, while maintaining the same level of accuracy in terms of the IoU and IoT cut-offs.

The 2D parallel CNN model yielded an IoU of 0.68 ± 0.14 on the testing cohort (n=15), indicating the feasibility of the methodology.

Table 1: Comparison of 2D parallel and 3D serial architecture based on predictions on validation cohort (n=30).

Parameter	2D Parallel	3D Serial
Time (s)/case	8.13 ± 0.52	42.44 ± 1.35
IoU	0.68 ± 0.11	0.67 ± 0.13
IoT	0.81 ± 0.15	0.82 ± 0.14

DISCUSSION

The accuracy of both the CNNs, measured in terms of IoU and IoT was within the established cut-offs. Moreover, a higher IoT indicated that the models were over-predicting the bounding-boxes. Over-predictions for the bounding-boxes are acceptable whereas severe under-predictions would lead to missing major arteries in the localization. The results on the validation cohort from the novel 2D parallel and traditional 3D serial CNNs show that the architectures are at par in terms of accuracy. But, in terms of the computational cost required for the predictions of the bounding-box parameters with each architecture, the 2D parallel architecture clearly supersedes its counterpart. The results on the independent testing cohort indicated the model was not over-fit to the training and validation cohorts.

CONCLUSIONS

In this study we presented a novel 2D parallel architecture for automated ROI selection in medical images. Comparison of the novel 2D parallel CNN with the traditional 3D serial CNN architecture showed that 2D parallel CNN was the superior choice based on an optimum trade-off between accuracy and computational cost.

INTRODUCTION

Computational techniques to simulate cardiovascular flows in three-dimensional models of arteries have attracted significant interest owing to their applications in disease research, medical device design, and surgical planning [1]. To model the fluid-structure interaction (FSI) in compliant arteries, a number of computational methods such as Arbitrary Lagrangian-Eulerian (ALE) methods, immersed methods, Coupled Momentum Method (CMM) etc. have been proposed. Among these, the CMM is particularly attractive since it employs a membrane approach to model the arterial wall, thereby resulting in no additional degrees of freedom compared to a rigid-wall problem [2]. However, the linear membrane model employed in CMM limits its applicability to cases where the arterial wall exhibits small deformations. In this work, we present a nonlinear ALE-FSI extension to CMM that can account for large deformations of arterial wall, while preserving the computational efficiency of CMM to a large degree.

Another important issue concerning the development of patient-specific FSI models is the knowledge of in-vivo state of stress in medically-imaged anatomies. In this work, we adapt a forward incremental prestress approach, proposed for 3D geometries by Gee et al. [3], to a membrane formulation. Through a combination of the membrane prestress algorithm and the nonlinear ALE-FSI formulation, we present an integrated framework to model cardiovascular flows with large wall deformations, while accounting for in-vivo state of stress in medically-imaged vessel geometries.

METHODS

To account for the nonlinear behavior of arterial wall, we employ an ALE approach wherein the fluid is described in ALE configuration, while the arterial wall is modeled as a nonlinear membrane using a Total Lagrangian formulation. The large deformations of the arterial

wall are handled via a moving mesh approach using a linear elasticity equation driven by Dirichlet boundary conditions. We utilize a stabilized finite element formulation for Navier-Stokes equation and solve the resulting system of equation in a semi-segregated manner, wherein the fluid-solid equations are solved monolithically as one system while the mesh equations are solved as a separate system.

To obtain the in-vivo state of stress of arterial wall, required for any subsequent FSI simulations, we utilize a forward incremental prestress approach for biological membranes. Referring to Fig. 1, this

Figure 1: Schematic for forward incremental prestress approach showing various configurations.

algorithm begins with the medically-imaged configuration, albeit without any external loading (corresponding to deformation gradient, $F=I$). At a given step n , we load this configuration with n^{th} increment of applied pressure and solve for equilibrium. Upon obtaining equilibrium, we update the history deformation gradient, F_R ; delete the obtained displacement, and proceed to the next iteration. This approach allows us to eventually obtain a configuration that is in

equilibrium with in-vivo pressure loading, but deviates from the medically-imaged geometry by a non-zero displacement. Therefore, we perform additional load-increment-free iterations to progressively reduce this deviation between the obtained equilibrium and the medically-imaged geometry to a prescribed tolerance.

RESULTS

Fig. 2 shows the velocity distribution and mesh motion in a cylindrical channel with prescribed inlet flow and zero pressure outlet boundary condition at two different time instants. It can be observed that the mesh displacement follows the large deformations of the vessel wall to maintain a good aspect ratio mesh throughout the simulations, thereby confirming the effectiveness of our moving mesh ALE approach.

Figure 2: Mesh profile in a cylindrical channel at different time instants.

To model the effect of prestress on arterial wall behavior, we consider a pressure-inflation test on a mouse aortic geometry. Here, the arterial wall is modeled using a Neo-Hookean constitutive model (with $c=8$ kPa), with fixed ends boundary condition. We consider two cases: (i) the prestress algorithm is used to obtain the state of stress in medically-imaged geometry at $p = 80$ mmHg; and (ii) the prestress is neglected and the medically-imaged geometry is loaded using a standard forward analysis to obtain the state of stress at $p = 80$ mmHg. The top row of Fig. 3 demonstrates that neglecting prestress results in significant over-estimation of von Mises stress. Moreover, while Fig. 3a shows the state of stress in the medically-imaged geometry; neglecting prestress results in a deformed geometry (Fig. 3b) that deviates from the medically-imaged geometry by a non-zero displacement field. Further loading of these configurations to $p = 120$ mmHg results in additional overestimation of von Mises stress when prestress is neglected. Notably, neglecting the prestress results in unrealistically large deformations of the vessel geometry (Fig. 3d).

Figure 3: Pressure-inflation test on mice aorta with (a, c) and without prestress (b, d) at $p=80$ mmHg (top row) and $p=120$ mmHg (bottom row)

Next, we consider the effect of inclusion of prestress in an FSI simulation. To this end, we again consider a mice aorta geometry with a prescribed inlet flow (with time period, $T = 0.142$ s), and RCR outflow boundary conditions [4]. Fig. 4(a) and (b) shows the spatial distribution of pressure at peak systole for cases with and without the inclusion of prestress, demonstrating significantly lower pressure for the case where prestress is ignored. In Fig. 4c, the pulse pressure is higher for the case where prestress is included. This can be attributed to the fact that the presence of prestress makes the vessel wall relatively stiff, resulting in increased pulse pressure.

Figure 4: FSI simulation - Spatial distribution of pressure for cases with (a) and without (b) prestress inclusion at peak systole. Corresponding pressure waveform showing increased pulse pressure with inclusion of prestress.

DISCUSSION

The primary contributions of this work are two-fold: (a) development of a novel nonlinear ALE-FSI framework that allows for large deformations of arterial wall, and (b) development of a forward incremental prestress approach for biological membranes. The developed formulation extends the capabilities of CMM by incorporating a moving mesh approach to allow large wall deformations, while employing a nonlinear membrane description of arterial wall for computational efficiency. Our results highlight the importance of including the prestress in cardiovascular simulations. Specifically, ignoring the presence of prestress resulted in significant over-estimation of wall stress and yielded unrealistically large deformations of the arterial wall. Correspondingly, ignoring the prestress in an FSI simulation was found to result in an underestimation of pulse pressure.

The nonlinear ALE-FSI formulation has been implemented within the CRIMSON software (www.crimson.software), which provides a well-established workflow for cardiovascular simulations. This formulation will enhance the capabilities of CRIMSON to allow investigations of cardiovascular flows in cases with large wall deformations, such as ascending thoracic aorta as well as venous hemodynamics. Future work will focus on investigating cases with more complex subject-specific geometries as well as incorporating regionally-varying mechanical properties of arterial wall.

INTRODUCTION

An estimated 700,000 acute ischemic strokes (AIS) occur annually in the United States [1] due to embolic occlusion of a cerebral artery. Despite improved recanalization rates with new stent retriever devices, over 15% of patients cannot be recanalized with the current technology, and another 17% die within 90 days despite successful recanalization [1]. To date, there is little understanding of why some thromboemboli are successfully removed and others are not. In order to better understand the underlying mechanics of a lodged embolus in a cerebral artery and determine the optimal surgical procedure for its removal, we are developing a continuum-based fluid-structure interaction (FSI) model to predict thromboemboli adhesion and dislodgement under cyclically applied aspiration. The model will allow for patient-specific cerebral artery geometries, blood and thromboemboli mechanical properties, and hemodynamic conditions to be investigated.

METHODS

The modeling framework was developed to simulate a thromboembolus lodged in a cerebral artery, exposed to blood on both proximal and distal surfaces, that is cyclically aspirated by a closely positioned cerebral catheter (**Fig 1A**). The framework combines established thromboemboli and cerebral artery mechanical models with a new model for their interface. The thromboembolus is modeled as an incompressible viscoelastic medium capable of large deformations. The artery will be assumed initially to be rigid but later improved with an anisotropic hyperelastic model for middle cerebral arteries [2]. Although no computational model exists for the thrombus-artery interface, there are models for coarsely ligated biofilms that suggest this interface can be treated using cohesive zone concepts [3] (**Fig. 1B**) where a physical surface with negligible inertia is able to provide traction (s) as a function of its opening displacement (δ) and rate ($\dot{\delta}$) (**Eq. 1**):

$$\mathbf{s} = f(\delta, \dot{\delta})\mathbf{e} \quad (1)$$

Figure 1: A) Proposed model incorporating a lodged clot in a cerebral artery exposed to cyclic aspiration [4]. **B)** Diagram of the cohesive zone model as the clot pulls away from the arterial wall.

Following the assumptions of a coarsely ligated film, we adopt an Oldroyd-B type rheological model (**Eq. 2**):

$$\delta = \delta_e + \delta_p \quad (2)$$

Where the displacement is a combination of both elastic and viscous components. We then develop the following constitutive equation for the force provided by the cohesive zone (**Eq. 3**):

$$f = k \delta_e + \eta_{c1} \dot{\delta} \quad (3)$$

For our AIS application, we assume that the constitutive parameters, which depend on the evolving biochemistry, will vary slowly relative to the external loading imposed during aspiration. Therefore, the constitutive parameters will be treated as constants and determined experimentally. We also hypothesize that a thromboemboli can be removed at lower pressure magnitudes under cyclic versus static aspiration [5] and avoid fracture and distal embolization. To investigate

this hypothesis, all three constitutive models have been implemented into OpenFOAM's finite-volume open-source software in an FSI framework. A previously validated viscoelastic solver for blood [6] is used to simulate local blood flow while a new solid mechanics solver [7] designed for non-linear viscoelastic materials will be used to simulate the thromboembolus.

In brief, the FSI algorithm works by first setting the fluid mesh interface displacement based on interpolation from the solid domain. The solid interface grid-point displacements are interpolated to grid-point displacements of the fluid interface using the AMI approach [8]. Once the displacements have been interpolated to the fluid interface grid-points, they can then be interpolated back to their cell centers before solving for the fluid mesh deformation using a Laplace motion equation. With the updated fluid domain, the fluid governing equations are solved and the resultant pressure and traction forces at the fluid FSI interface are interpolated to the solid interface. Finally, the solid governing equations are solved. Aitken relaxation is used for setting the interface displacement within this inner loop and is then iterated until the FSI residual falls below a predefined tolerance.

Figure 2: A) Experimental and B) computational models of the AIS vessel, catheter and embolus analog used for tracking.

To validate the computational solver, an experimental flow loop and chamber were developed (Fig. 2A) to track the displacement of an embolus analog under controlled cyclic aspiration. The flow loop consists of a Cliq Medical aspirator (DHCL Group, Taiwan), a 3-way ASCO solenoid valve (ASCO Valve, Inc) that is controlled by a self-programmed Arduino Uno controller (Arduino AG), an optically clear 3D-printed chamber to mimic a 5x-enlarged middle cerebral artery, and an embolus analog made of neoprene rubber.

Figure 3: Pressure waveform measured experimentally and applied in computational simulations.

Cyclic pressures were applied at a frequency of 0.5 Hz and with maximum and minimum pressures of approximately 5 And -60 mmHg, respectively (Fig. 3). The embolus analogs motion was tracked using a camera and motion analyzed in Matlab. A computational model and mesh were created in Pointwise (Pointwise, Inc) to mimic the experimental setup, imported into OpenFOAM (Fig. 2B), and the same pressure waveform applied as a boundary condition on the catheter inlet. FSI coupling boundary conditions were applied at the fluid-solid

interface and a traction free condition applied on the downstream surface of the clot.

RESULTS

To validate the full FSI model, extreme cases of both the embolus and cohesive zone properties are being studied both experimentally and computationally: a) deformable embolus with an infinitely stiff cohesive zone (Fig. 5) and b) a rigid embolus with a deformable cohesive zone. The viscoelastic properties of the embolus analog material were first determined using cyclic loading in a material testing device and fit to an Oldroyd-B viscoelastic constitutive model. The first case (infinitely stiff cohesive zone) was performed to validate the solid-mechanics model and FSI coupling in order to accurately predict thromboembolus deformation under cyclic aspiration. The predicted displacements were nearly identical with the computational model slightly under-predicting peak displacement at the center of the embolus by 2 and 7% at two time points in Fig. 4.

Figure 4: Comparison of A) experimental and B) computational embolus displacements at two time points during cyclic aspiration.

DISCUSSION

We have developed both an experimental and computational framework for studying the effects of cyclic aspiration on a lodged thromboembolus analog. We will next test our computational solver in another extreme case with a rigid solid and a viscoelastic cohesive zone. We have also collected mechanical testing data for embolus analogs made from bovine blood (Fig. 5) and fit the results to the same Oldroyd-B viscoelastic constitutive model and will be incorporating these new parameters into the solid mechanics portion of the FSI solver.

Figure 5: A) Cyclic loading and B) stress-relaxation mechanical tests of embolus analogs made from bovine blood.

INTRODUCTION

It is now well established that hemodynamics is associated with the onset and evolution of several cardiovascular disorders such as aneurysms, stenoses, or blood clot formation due to thrombosis. As it provides a comprehensive access to blood flows in-vivo, flow quantification techniques based on time-resolved 3D phase-contrast magnetic resonance imaging (3D PC-MRI) has gained an increasing interest over the last decades [1]. A method to overcome some MRI limitations consists in coupling Computational Fluids Dynamics (CFD) with planar MRI flow measurements as boundary conditions to predict the 3D velocity fields. Nevertheless, a prerequisite to couple CFD to MRI is to ensure that the two techniques converge towards compatible outcomes. Therefore, considerable emphasis has been dedicated to compare and cross-analyze MRI measurements to CFD predictions [2,3]. Despite these efforts, there is still no consensus in the literature on whether or not the two techniques lead to the same outcomes and several limitations are generally pointed out to explain the reported discrepancies. The large variety of possible input options, from the MRI setup (acquisition parameters and post-processing corrections) to the choice of the CFD strategy (numerics, boundary conditions,...) or the framework of the study (in-vivo/in-vitro/in-silico) makes it difficult to draw generalized conclusions.

In this work, we develop a fully controllable, reproducible and MRI compatible experiment designed to generate flow typical of that observed in the cardiovascular system, while removing classical in-vivo sources of discrepancies such as segmentation errors, geometry motions or blood rheology. The flow is predicted by means of high-resolution CFD and compared with velocity data measured by 4D Flow MRI. A quantitative analysis of velocity and Wall Shear Stress (WSS) differences is performed to highlight the potential

discrepancies and a generic comparison protocol is proposed to systematically correct for the sources of discrepancies.

Figure 1: Schematic representation of the flow phantom (left) and the experimental test bench (right).

METHODS

A rigid phantom was designed to mimic the flow through an aortic arch and complemented by a bifurcation in analogy with collateral arteries as well as a protuberance to replicate blood flow patterns in abdominal aortic aneurysms (see Fig. 1). To get a flow split at the bifurcation independent of the outlet boundary condition, and therefore allow a flow distribution purely driven by the fluid mechanics in the domain of interest, a unique outlet was created by merging the collateral segment with the main branch. Several MRI scans were acquired under pulsatile inflow waveform and the measurements were corrected from several types of artifacts (velocity offsets, partial volume effects, image noise). The flow was

simultaneously predicted by means of YALES2BIO, an in-house low-dissipative 4th-order accurate flow solver (<http://imag.umontpellier.fr/~yales2bio/>), already validated in multiple configurations [4,5]. A pixel-based inflow boundary condition was imposed thanks to the velocity profile measured by a time-resolved 2D PC-MRI scan acquired at the inlet of the flow phantom (see [6] for more details). Several comparisons of velocity fields were performed, varying the level of post-processing adopted for both the MRI and CFD outcomes, using the Pearson's product moment correlation as an indicator of the linearity between the two techniques. The baseline comparison case was defined according to what often appears in the literature, namely to the instantaneous CFD fields compared to the raw MRI measurements. The impact of down sampling the WSS on the correlations was also investigated at peak systole.

RESULTS

As presented in Table 1, velocity correlations may be significantly altered depending on the level of post-processing. The main correlation improvements are obtained either by down sampling the phase-averaged CFD or by correcting for the MRI phase offset artifacts.

$r_{ \mathbf{u} }^2$	\mathbf{u}_{inst}	\mathbf{u}_{HR}	\mathbf{u}_{LR}
Raw MRI	0.63	0.67	0.21
Phase offset corr.	0.81	0.85	0.85
$\mathbf{u}_{wall} = 0$	0.89	0.92	0.96
$\nabla \cdot \mathbf{u} = 0$	0.89	0.93	0.97

Table 1: Magnitude velocity correlation at peak systole, as a function of the level of post-processing. \mathbf{u}_{inst} stands for the instantaneous high resolution CFD velocity field of the 40th computed cycle. \mathbf{u}_{HR} corresponds to the phase-averaged CFD field and \mathbf{u}_{LR} to the phase-averaged velocity down sampled to the MRI spatial resolution. "Phase offset corr." corresponds to the raw MRI dataset corrected from eddy currents and noise artifacts. " $\mathbf{u}_{wall} = 0$ " refers to the corrected MRI dataset where a no-slip boundary condition is applied at walls and " $\nabla \cdot \mathbf{u} = 0$ " refers to the resulting MRI velocity field modified to meet the divergence-free condition.

Phase-averaged CFD velocity fields are qualitatively compared with MRI velocity data corrected from phase offsets (i.e eddy currents and noise masking) in Fig. 2. Removing the first 10th cycles and phase-averaging the CFD velocity over 30 cycles was found to be sufficient to get a reasonable averaged value. Results reveal excellent agreements for the velocity magnitude and highly similar patterns even in the complex flow regions. For example, MRI and CFD capture the recirculation in the aneurysm or back flow in the bifurcation at late diastole.

As presented in Fig. 3, WSS correlations are generally lower than the corresponding velocity correlations. This is mainly due to the sensitivity of the WSS computation to the spatial resolution and residual noise in the near-wall voxels. Moreover, as reflected by the discrepancies observed between WSS computed from \mathbf{u}_{HR} (WSS_{HR}) and \mathbf{u}_{LR} (WSS_{LR}), down sampling significantly degrades the accuracy of the gradient computation since the intra-voxel averaging smoothens the (strong) velocity gradients present in the wall vicinity.

Figure 2: Comparison in the coronal plane of CFD magnitude velocity fields (\mathbf{u}_{HR} in Table 1) with MRI measurements (" $\nabla \cdot \mathbf{u} = 0$ " in Table 1) at 2 mm resolution at different instants of the cycle indicated by the red lines on the flow rate waveforms below.

DISCUSSION

Since PC-MRI and CFD are drastically different modalities, a direct comparison of their outcomes leads to systematic errors. Results show that the gain obtained by degrading the CFD data is not negligible, yet smaller, compared to the improvement generated by processing, denoising and correcting the raw MRI data. While only poor correlations are obtained when straightforward treatments are applied ($r^2 = 63\%$), a very strong correlation (97% for the velocity, 84% for the WSS) could be reached by carefully post-processing the two datasets. While this methodology was developed under in-vitro conditions, the proposed corrections are also applicable in-vivo.

Figure 3: WSS maps on boundary walls at peak systole. (a) WSS calculated from \mathbf{u}_{HR} , (b) from \mathbf{u}_{LR} (with zero velocity imposed on boundary walls) and (c) from \mathbf{u}_{MRI} (third row in Table 1). Bland-Altman plots of the comparison between (d) WSS_{HR} and WSS_{MRI} (corresponding to $r^2 = 0.48$) and (e) WSS_{LR} and WSS_{MRI} corresponding to $r^2 = 0.84$.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) procedures are rapidly becoming the dominant option for aortic valve replacement and are expected to eventually become the standard-of-care for AV replacement. However, prosthetic valves used in TAVR are susceptible to several “malfunctions” such paravalvular regurgitation, leaflet tears, endocarditis and leaflet thrombosis. Since malfunctions like leaflet thrombosis can modify valve motion and downstream hemodynamics, monitoring changes in flow quantities in the valve vicinity might provide insights into potential valve dysfunction. Characterizing the kinematics of, and hemodynamics around healthy and dysfunctional valves is a key first step in such monitoring approaches. This study combines experimental and computational approaches to characterize valve kinematics and transvalvular hemodynamics for healthy and thrombosed TAV models. Imaging data from *in vitro* experiments of prosthetic valves are used to decompose leaflet motion into its principal components and these are used to synthesize dynamic leaflet models. We also present data from direct numerical simulation (DNS) for flow through a two-parameter, idealized aortic valve model under healthy and thrombosed conditions. Simulation data is used to explore the detection of leaflet thrombosis using data from embedded sensors.

METHODS

To simulate transvalvular flow, we used an extensively validated, versatile, incompressible flow solver “ViCar3D”^{2,3}. This solver has previously been used for DNS of flow through aortic stenoses⁴, mitral valves⁵ and left ventricles⁶. We performed DNS of transvalvular flow in the aorta with the objective of exploring the use of sensors embedded within the TAV to detect malfunctions such as leaflet thrombosis. We employed an idealized aorta model based on clinical data⁷ and included a simple, generic bioprosthetic aortic valve whose motion was governed

by a reduced degree-of-freedom (DOF) model. The valve displacement can in general be expressed as a convolution sum of M spatial and temporal modes, as follows:

$$\mathbf{d}_v(\mathbf{x}, t) = \sum_{i=1}^M c_i(t) \mathbf{b}_i(\mathbf{x}) \quad (1)$$

We describe later in this abstract as to how these modes may be extracted from experimental data. Once the spatial modes have been chosen, the time-coefficient may be obtained by solving a dynamical equation for the leaflets. For a 1-mode ($M=1$) leaflet model, which is the focus of the current study, an equation for the time-coefficient is obtained by integrating the Newtons second law for a leaflet as follows:

$$\frac{d^2 c_i}{dt^2} = \frac{\int \Delta p ds}{\int \alpha(\mathbf{b} \cdot \mathbf{n}) ds} - \frac{K}{\alpha} (c_i - c_0) \quad (2)$$

where Δp is the pressure difference across the leaflet surface obtained from the flow simulation, α is mass coefficient and K is a stiffness coefficient. This simple, ODE based, two-parameter model can be coupled with the full Navier-Stokes’ equations and employed in a wide range of numerical experiments.

Mode shapes can be directly extracted from experimental data and here we have extracted this modal information from high-speed imaging data of an in-vitro experiment with a TAV (Figure 1 (a)). Leaflet edges were reconstructed using MATLAB’s image processing module by placing marker points along the edge and fitting smooth splines through them (Figure 1 (a)). We use the method of snapshots¹ to extract the principal components associated with the leaflet motion. For each leaflet, the ‘ n ’ coordinates of the spline points were recorded along the rows of a matrix, $\Delta \mathbf{X}$, while the evolution of each spline point over ‘ Nt ’ time levels was ordered along its columns. To obtain the principal components of leaflet motion, singular value decomposition (SVD) of $\Delta \mathbf{X}$ was computed, which takes the form: $\Delta \mathbf{X} = \mathbf{U} \mathbf{\Sigma} \mathbf{V}^T$. \mathbf{V} and \mathbf{U} are unitary matrices representing the spatial distribution of orthonormal

basis vectors and their temporal evolution, respectively. Σ is a diagonal matrix containing $r = \min(n, Nt)$ positive entries in descending order, called the singular values of ΔX . Squares of the singular values represent the fractional contribution of individual modes to the total spatio-temporal information contained in ΔX .

RESULTS AND DISCUSSION

An example of snapshot PCA implementation is illustrated in Figure 1. For each of the 19 (Nt) snapshot of the prosthetic valve⁸ in motion, 20 marker points were manually placed on the leaflet edge and smooth splines, with 100 (n) divisions, were fit through these marker points (Figure 1 (a)). PCA of the spline coordinates was used to create a low-order reconstruction of the leaflet edge, using only the first (Figure 1 (b)) and the first 3 (Figure 1 (c)) out of the possible 19 singular values. A remarkable improvement from using one mode and an excellent edge tracking is observed with the first three modes. This data will eventually be employed in the dynamical model of the leaflets (Eqs. 1 & 2) to synthesize realistic leaflet kinematics in our transvalvular simulations. For now, we employ a simple modal shape \mathbf{b} based on visual observation of the leaflets.

Figure 1: (a) Image of prosthetic valve configuration⁸ with spline fits (solid lines) and discrete marker points (+). Reconstruction of (dotted black lines) using PCA (b) mode 1 and (c) modes 1+2+3.

We simulated three transvalvular flow cases, one in which all leaflets of the valve open fully – referred to as the “healthy” case – the next in which one valve leaflet thrombosed (modeled with a higher stiffness) and consequently exhibits reduced leaflet motion (RLM) – referred to as “RLM #1” case. Finally, the third case involved two leaflets with RLM, referred to as “RLM #2” case. The degree of RLM is illustrated in the insets of Figure 2 (b) and Figure 2 (c). A sinusoidal flow-rate was prescribed to drive flow through the aorta and valve. The pressure difference across the leaflet surface and the valve displacement/velocity provide the boundary conditions for the structure and flow solvers, respectively. The stroke volume through the aorta was 60 ml. The simulation Reynolds number with respect to aorta diameter and peak aortic velocity, based on clinical blood flow measurements in patients with prosthetic aortic valves⁹, was 4300. Virtual probes were placed at three circumferential locations on the valve skirt (S1, S2, S3) and three corresponding downstream locations on the aorta wall (A1, A2, A3) (Figure 2 (a) inset). Each probe recorded the pressure difference relative to the reference outlet pressure and this information was used to develop a correlation-like metric to distinguish the healthy valve from the dysfunctional one.

The time-varying pressure difference at the six probe locations during one systole are illustrated in Figure 2 for (a) healthy, (b) RLM #1 (Leaflet 1 has RLM) and (c) RLM #2 cases. Leaflet dysfunction may be inferred from azimuthal asymmetry in pressure signals. In the healthy case, the three pressure signals on the valve skirt (S1, S2, S3) are identical and smooth. Pressure downstream of the valve, although jagged, is symmetrical. The jaggedness is attributed to increased flow turbulence resulting from the interaction of blood with the valve leaflets. Both RLM cases, on the other hand, shows azimuthal asymmetry in

pressure signals, both upstream and downstream of the valve (Figure 2 (b)). RLM resulted in a greater pressure drop across the valve, indicated by a decrease in A1, A2 and A3 measurements and greater downstream turbulence, as inferred from increased jaggedness. We then computed the normalized pressure cross-deviation, as shown in Eq. (3), and the values for each probe in the two cases are shown in Table 1. The healthy case results in very small q for each probe, indicating high azimuthal symmetry. The RLM cases, on the other hand results in elevated q for each probe but in each case, one azimuthal location recorded significantly larger cross-deviation. For instance, in RLM #1, S1 and A1 recorded larger values than the other probes at corresponding axial locations and particularly, S1 recorded nearly two orders of magnitude larger pressure than S2 and S3. Likewise, in RLM #2 case, A2 and S2 recorded nearly 5 times larger deviations. The metric is thus able to discriminate healthy valves from with leaflet thrombosis. Further, monitoring pressure asymmetry on the valve skirt may be more reliable for detecting valve dysfunction, due to a lack of flow turbulence, as opposed to the aortic wall surface downstream of the valve.

$$q_i = \frac{\prod_{j=1, j \neq i}^3 |p_i - p_j|}{p_i^2} \quad (3)$$

Table 1: Comparison of pressure ($\times 10^{-4}$) recorded by the six probes in the healthy and RLM cases.

	q_{A1}	q_{A2}	q_{A3}	q_{S1}	q_{S2}	q_{S3}
Healthy	17	27	20	0.19	0.32	0.2
RLM #1	291	57	68	148	5	0.5
RLM #2	76	646	109	10	49	13

Figure 2: Pressure recorded by the six probes placed in the vicinity of the aortic valve in (a) healthy and (b) RLM #1 case. Probe locations are shown in the insets of (a).

The current study demonstrates the use of reduced-order leaflet models for investigating the coupled biophysics of transcatheter aortic valves. The advantages of such models are that they require limited information for parameterization and they are simpler and more efficient to implement in a computation. Here we have used these models to guide the placement of embedded sensors for detecting leaflet thrombosis. Ongoing work is using these computational models as a basis for a comprehensive study that employs machine learning tools for optimizing sensor configurations for such applications.

INTRODUCTION

The recently-discovered glymphatic system¹ circulates cerebrospinal fluid (CSF) through the brain, sweeping away proteins and metabolic waste and playing a role similar to the lymphatic system in the rest of the body. Primarily active during sleep², the glymphatic system drives CSF through annular perivascular spaces (PVSs) surrounding arteries and veins, from which it accesses deeper brain tissue. The glymphatic system may play a key role in preventing neurological disorders, such as Alzheimer's and Parkinson's diseases, that are associated with accumulation of waste proteins (in these two examples, amyloid- β and tau). The glymphatic system also has potential for drug delivery³.

However, both the characteristics of biotransport via the glymphatic system and the mechanisms driving that biotransport have been topics of open debate in recent publications. In mice, PVS widths have been estimated from \sim nm to \sim μ m. CSF in PVSs has been said to flow either parallel² or anti-parallel^{4,5} to the blood in the adjacent vasculature. CSF flow has been suggested to pulse in synchrony with either the respiratory or cardiac cycle.

In results just published,⁶ we use *in vivo* particle tracking to measure CSF flow in PVSs surrounding pial arteries in mice, with high resolution in space and time. We show that the flow pulses in synchrony with the cardiac cycle, consistent with a peristalsis-like "perivascular pumping" in which CSF is driven by the motion of the adjacent artery wall.⁷ We alter that motion by inducing high blood pressure to stiffen the wall, and we show that the mean CSF flow speed is reduced \sim 40%. Perivascular pumping appears to be the primary driver of CSF flow in healthy mice, and its disruption by high blood pressure may relate to the fact that early-onset hypertension is a known risk factor for Alzheimer's disease in humans.

METHODS

All experiments were approved by the University Committee on Animal Resources of the University of Rochester Medical Center (Protocol No. 2011-023), and an effort was made to minimize the number of animals used. We injected 1- μ m tracer particles into the cisterna magnas of male mice, age 8-12 weeks, anaesthetized with ketamine-xylazine to approximate sleep. We also injected intravascular fluorescein isothiocyanate-dextran to make arteries visible. We performed two-photon imaging through a cranial window using a resonant scanner B scope (Thorlabs) with a Mai Tai DeepSee HP Ti:Sapphire laser and a water immersion lens. Typically, we observed flow near the bifurcation of the middle cerebral artery, though we have seen the same phenomena in other pial PVSs as well. Images were recorded at 30 Hz. Simultaneously, we measured ECG (at 1 kHz) and respiration (at 250 Hz). To increase blood pressure, we infused Angiotensin-II in 0.9% NaCl into a femoral vein catheter at 5 ng g⁻¹ min⁻¹ at a volumetric rate of 1 μ l min⁻¹ using a syringe pump. Control mice received an infusion of NaCl 0.9% instead. We used artery images to register the resulting movies during post-processing, removing translations caused by large-scale motions of the mouse with respect to the scope, which would distort flow velocity measurements. We tracked particles using an in-house algorithm written in Matlab, excluding stagnant particles that had apparently adhered to the vessel wall. The results presented below come from 7 hypertension experiments and 6 control experiments, each involving 19728 ± 4358 tracked particles and 355013 ± 85957 total measurements (mean \pm standard error of the mean).

RESULTS

Our videos showed CSF flow in PVSs to be visibly pulsatile, so we set out to study the nature of that pulsation. Using the entire set of

measurements from one control experiment (normal blood pressure), we calculated the root-mean-square flow velocity v_{rms} as a function of time by averaging the squared velocity of all tracked particles in each frame of the video, then calculating the square root of that average. Then we compared v_{rms} to the simultaneous ECG signal, which measured the cardiac cycle, and respiration signal. Specifically, we divided each cardiac cycle into a fixed number of bins and also divided each respiratory cycle into a fixed number of bins. Then, we categorized every v_{rms} measurement, based on the time at which it was made, as falling into a particular cardiac cycle bin and a particular respiratory cycle bin. For example, a measurement might have been made at the moment when 25% of the cardiac cycle had elapsed since the last heartbeat and 45% of the respiratory cycle had elapsed since the last breath; it would be assigned to the (25%,45%) bins. Once all measurements were assigned, we calculated the average for each bin pair. In other words, we calculated the average of v_{rms} , conditioned both on fraction of the cardiac cycle and fraction of the respiratory cycle.

Figure 1 shows the results of conditional averaging. The average speed varies significantly with the cardiac cycle, from $\sim 15 \mu\text{m/s}$ during much of the cycle to nearly $50 \mu\text{m/s}$ soon after the heartbeat. The average speed varies much less, however, with the respiratory cycle ($\sim 20 \mu\text{m/s}$ to $\sim 25 \mu\text{m/s}$). We have also calculated statistics of the delay time between each peak in v_{rms} and the corresponding peaks in ECG and respiration. The results (not plotted) show that the delay from a heartbeat to a peak in v_{rms} is typically 35 ms and almost never more than 100 ms, whereas the delay from a breath to a peak in v_{rms} is almost equally likely to take values from 0 to 300 ms, with values as large as 500 ms also observed. Thus, our measurements show that CSF flow pulses in synchrony with the cardiac cycle.

Figure 1: CSF flow pulses in synchrony with the cardiac cycle, not the respiratory cycle. Conditionally averaging the root-mean-square velocity on both cycles shows strong dependence on cardiac activity and weak or negligible dependence on respiratory activity. Protruding plots show averages conditioned on the cardiac (left) or respiratory (right) cycle alone. Adapted from [6].

The observed synchronization between CSF flow and the cardiac cycle supports an existing hypothesis that motion of the adjacent artery walls drives CSF via perivascular pumping⁷. To test that hypothesis, we changed the wall motion by inducing high blood pressure. High pressure causes muscular artery walls to flex harder in order to maintain the same diameter, stiffening the tissue, and presumably changing wave propagation dynamics. We found that Angiotensin-II increases blood pressure in mice from about 80 mmHg to about 135 mmHg in about 2 min, allowing measurements in the same mouse with both normal and high blood pressure. The measured wall deformation and velocity (not plotted) did change significantly, as we expected. The mean flow speed also changed significantly, as Figure 2 shows, dropping on average from

$30 \mu\text{m/s}$ to $18 \mu\text{m/s}$. Our measurements further show that when blood pressure is normal, pulsations vary the flow speed between faster and slower, but when blood pressure is high, pulsations typically cause backflow during part of the cardiac cycle, reducing overall pumping efficiency.

Figure 2: High blood pressure reduces net flow of CSF. CSF flow speed, averaged over all particles observed in the small boxes shown, during ~ 10 min with normal blood pressure and ~ 10 min with high blood pressure. Solid boxes contained at least 20 measurements; hollow boxes, less than 20. Scale bars are $40 \mu\text{m}$. Insets indicate the mean flow in green and example particle paths in cyan, showing that backflow is common when blood pressure is high. Scale bars are $5 \mu\text{m}$. Adapted from [6].

DISCUSSION

Our high-resolution measurements of the flow of CSF in PVSs demonstrate that perivascular pumping is the primary driver of glymphatic flow in healthy mice. Furthermore, the finding that high blood pressure reduces CSF flow significantly may relate to the fact that early-onset hypertension is a known risk factor for Alzheimer's disease in humans. However, that idea should be addressed in future studies, since chronic hypertension in humans and acute hypertension in mice are not the same thing. Future studies could also consider drivers other than perivascular pumping, such as osmotic pressure and vessel volume changes, especially in pathological conditions like traumatic brain injury and stroke.

INTRODUCTION

Blood viscosity is a crucial biophysical parameter implicated in various physiologic and pathophysiologic conditions, including microvascular disease and some hematologic disorders. The primary determinants of blood viscosity are hematocrit, blood cell deformability, plasma viscosity, and cellular aggregation, all of which may individually contribute to an alteration of blood viscosity in response to a range of pathologic scenarios¹. Therefore, monitoring blood viscosity has a unique potential to assess and monitor circulatory health and disease.

Here, we present a simple microfluidic device for measuring whole blood viscosity (WBV) by means of micro particle image velocimetry (μ PIV). Using this micro-platform, we assess the viscosity of whole blood samples obtained from healthy donors as well as individuals with sickle cell disease (SCD). Red blood cells (RBCs) of people with SCD are intrinsically more adhesive and rigid due to a genetic mutation in hemoglobin that results in intracellular polymer, thereby affecting the WBV. Disease severity in SCD has been linked to cellular adhesion, impaired RBC deformability, and increased WBV, wherein the latter has been shown to increase, at least in part, stroke events in children². However, the precise relationship between these parameters has yet to be elucidated. Here, we describe a subject-specific WBV profile among the study group, encompassing a range both above and below a normal level. More importantly, we show an inverse correlation between WBV and RBC adhesion, which may provide a novel insight into the pathophysiologic progression of SCD.

METHODS

The microfluidic system consists of three layers: a microfluidic channel, a constant pressure pump, and an optical microscope as illustrated in Figure 1. The microfluidic channel was fabricated based

on a lamination technique as we have previously described³. The assembled microchannel was then connected to a reservoir containing 500 μ l of whole blood. The pressure pump delivered a constant pressure of 15 mmHg into the reservoir allowing the blood sample to flow across the microchannel. Image acquisition of flowing blood cells was performed at two random fields of view (FOV) at a 4X magnification and at least 500 subsequent images were recorded for each FOV.

Figure 1. Schematic view of the experimental setup. A constant pressure pump is used to deliver pressurized air into a blood-containing reservoir. The whole blood sample then flows through a microfluidic channel placed on a motorized microscope stage. The velocity vectors within the field of interest are obtained through particle image velocimetry (PIV), where the cellular components of blood are employed as tracing particles.

In this study, blood cells were utilized as tracing particles for the PIV calculations and assumed to provide the average velocity through the microchannel, instead of using additional fluorescent particles, in order to minimize sample manipulation that could alter the hemodynamic properties. Two-image cross correlation method was employed in Matlab using “PIVlab” which produced 250 pairs of velocity fields for each FOV⁴. Time-averaged flow velocities were computed for both FOVs and the mean of those values were assigned as the average velocity of the sample. A calibration curve was generated to link the average velocity to viscosity by using various glycerol/PBS mixtures (0-100%) with known viscosities⁵. A 20 μ l solution containing fluorescently labeled 2 μ m-diameter beads was added into the reservoir prior to the PIV experiments when a glycerol/PBS mixture was tested.

RBC adhesion experiments were carried out in a different microchannel that was functionalized with an endothelium-associated protein, laminin (LN) as we have previously described³. Collected blood samples were transferred into two separate tubes dedicated for either the adhesion or viscosity measurements.

Figure 2. Calibration curves for estimating viscosity based on the average velocity in the microchannel. Glycerol/PBS solutions at varying concentrations between 0% to 100% were mixed with 2 μ m-diameter fluorescent beads and flowed through the microchannel at 15 mmHg reservoir pressure. (A) For each glycerol concentration, and thus the known fluid viscosity, an average flow velocity was obtained via PIV. (B) To increase the accuracy, more data points were acquired between average velocities 0.1-0.4 mm/s, since this represented the velocity range for the tested blood samples. N=4 for velocity measurements.

RESULTS

We assessed the viscosity of whole blood samples from healthy donors with no hemoglobin disorders (HbAA) as well as from individuals with homozygous SCD (HbSS) as shown in Figure 3A. We first quantified the average axial velocities via μ PIV at a constant pressure within the physiological range (15 mmHg) and then obtained the corresponding estimated viscosity value utilizing the calibration curve (Fig. 2). The measured viscosity values were largely heterogeneous and demonstrated a subject-specific manner in the SCD study population ranging from 4.2 mPa.s to 17.7 mPa.s. We segregated these subjects into two groups: high viscosity group and low viscosity group based on the mean viscosity level (Fig. 3A). Notably, subjects with higher viscosity displayed significantly lower RBC adhesion to LN (Fig. 3B, $p=0.02$). There was an inverse correlation between RBC adhesion and WBV (Fig. 4, $PCC=0.59$, $p=0.02$).

Since both WBV and RBC adhesion are clinically important parameters, we tested whether WBV would correlate with clinical phenotype. Interestingly, subjects with lower WBV tended to have higher lactate dehydrogenase (LDH) levels (Fig. 5) indicative of an ongoing in vivo hemolysis.

DISCUSSION

We present a microfluidic approach to assess WBV via the integration of microfabrication and μ PIV. We have shown that viscosity

Figure 3. Measured whole blood viscosity and RBC adhesion profiles for healthy (HbAA) and homozygous SCD (HbSS) blood samples. (A) HbSS samples display a significant heterogeneity in WBV. High viscosity and low viscosity groups were identified based on the mean threshold viscosity level of 7.9 mPa.s. (B) Subjects in the low viscosity group (N=10) had significantly greater RBC adhesion to laminin compared to those in the high viscosity group (N=5) *in vitro* ($p=0.04$, non-parametric Mann-Whitney test).

Figure 4. WBV is subject-specific and associates with (A) RBC adhesion to LN and (B) subject LDH level.

of HbSS blood samples varies significantly in a subject dependent fashion and may provide clinically relevant information. For the first time, we have demonstrated a significant (inverse) link between WBV and RBC adhesion wherein subjects with lower WBV displayed greater RBC adhesion. Further, decreasing values of WBV corresponded to higher LDH levels in these subjects, indicating an elevated state of in vivo hemolysis. Notably, these results suggest that subjects with a more severe disease phenotype (increased RBC adhesion and LDH) have lower WBV values. WBV has been implicated in variant sickle disorders, which have a higher Hgb and, in our hands, lower RBC adhesion to LN⁶. This is consistent with the data presented here, in which hemolytic disease has an inverse association with WBV. We speculate that significantly reduced hematocrit levels in subjects with the more severe disease phenotype account for a decreased cellular viscosity. WBV may contribute to a different spectrum of disease, such as variant sickle cell disease, osteonecrosis, and retinopathy.

INTRODUCTION

Sickle cell disease (SCD) is an inherited hematological disorder resulting from a point mutation in the β -globin gene [1]. The mutated hemoglobin molecule (sickle hemoglobin or HbS) polymerizes under deoxygenated conditions and is associated with decreased red cell deformability as well as damage to the cell membrane and cytoskeleton [2-3]. The result are injured, inflexible red cells and dramatic changes in blood rheology under both normoxic and hypoxic conditions. Clinical complications include the vaso-occlusive crisis, a hallmark event of the disease, where red cells obstruct the vasculature leading to pain episodes, organ damage, and tissue necrosis. In addition to acute complications, patients suffer from chronic pain, anemia, and infections severely limiting their health and lifestyle [4].

Despite improvements in patient clinical care over the past several decades, there is still a critical gap in optimizing treatments based on unique patient phenotypes, which are highly variable. Patient phenotypic diversity is a cause of clinical concern as available treatment options respond differently among patients and few, if any, known clinical parameters predict treatment efficacy [5]. This dearth of effective biomarkers has also severely hampered development of new therapies with only two drugs approved for clinical use in the last 20 years. One promising approach is to quantify the changes in blood rheology under conditions that are relevant in vivo and under treatment. Because the blood rheology is directly linked to the pathophysiology, rheological parameters may provide a set of metrics that is patient-specific to allow for individualized treatments.

In this work, we have developed a microfluidic system to quantify oxygen-dependent rheology for SCD blood. Our microfluidic system incorporates physiologically relevant blood flow velocity, oxygen tension response, and blood pressure, all of which may contribute to pathology in vivo. We present new quantitative metrics that may serve

as biomarkers to categorize patient severity, and we demonstrate the application of our platform and metrics to evaluate transfusion therapy.

METHODS

Device Design: We developed a microfluidic platform mimicking physiological features of the vascular microenvironment to investigate SCD blood impairment process. The platform is a trilayer polydimethylsiloxane (PDMS) construct sub-sectioned into a bypass and experimental zone to prevent blood packing. The blood layer consists of an arteriole/venule sized channel with a cross-sectional area of $15\ \mu\text{m}$ by $15\ \mu\text{m}$. The hydration layer is $100\ \mu\text{m}$ tall and prevents blood dehydration at experimental temperature of 37°C . The gas layer is $150\ \mu\text{m}$ tall and each zone has independent gas control diffusively coupled to the blood layer to control oxygen concentrations (Figure 1).

Figure 1: Microfluidic system for studying sickle blood flow consisting of a blood layer (red), hydration layer (blue), and gas layer (black).

Oxygen Transport Modeling and Validation: A COMSOL model was generated to verify oxygen diffusion in the device design. The device was modeled as a PDMS construct with diffusion coefficient of $3.3 \times 10^{-5}\ \text{cm}^2/\text{s}$ and fluid layers using the diffusion coefficient of $4 \times 10^{-5}\ \text{cm}^2/\text{s}$. Device external walls were modeled as oxygen supply zones at

160 mmHg oxygen tension except the bottom wall which was modeled as a no flux region to represent the glass slide device is bonded to. Model result analysis shows that oxygen tension reached 0 mmHg in experimental zone while bypass section stayed at 160 mmHg (Figure 2A). To experimentally verify oxygen concentrations in the device, a solution with oxygen sensitive dye at 1 mM Ru(bpy)₃ phosphate-buffered saline (PBS) was perfused through the blood channel of the microfluidic device. As a 0 mmHg oxygen control, 1 mM Ru(bpy)₃ with sodium metabisulfite (SMS) oxygen scavenger at saturating concentrations was used for calibration. Experimental verification revealed similar findings as our modeling results (Figure 2B).

Figure 2: COMSOL oxygen transport modeling (A) and experimental validation (B) shows oxygen temporal response takes approximately 60 seconds to reach 0 mmHg after switching oxygen supply in experimental section while bypass section remains unaltered at 160 mmHg.

Blood Testing Setup: To measure blood rheological properties, microfluidic device was mounted on a microscope setup capable of controlling temperature, oxygen tension, and blood perfusion as previously described [6]. Video data was collected using a high-speed camera and analyzed using a custom MATLAB script.

RESULTS

Flow behavior index reveals a functional change in the blood rheology under hypoxic conditions: We quantified device impedance with whole sickle blood across 9 unique SCD patient samples, 3 oxygen tensions (92 mmHg, 46 mmHg, and 0 mmHg), and a range of pressure biases. Using a circuit model of the device, we extracted apparent viscosity from the impedance data, and we applied a power law fluid model to determine the flow behavior index, which indicates the deviation of the fluid from a Newtonian model. We found that at 92 and 46 mmHg oxygen tension, the flow behavior index is respectively 0.74 ± 0.075 and 0.76 ± 0.049 indicating a shear thinning fluid common for blood (mean \pm SD). At 0 mmHg however, a transition occurs where the value goes to 0.87 ± 0.056 indicating a loss of shear thinning behavior (Figure 3A).

Flow behavior index can be used to identify clinical transfusion targets: Transfusion therapy is among the most common treatments for SCD patients and works by diluting SCD red cells with normal, healthy donor cells. A recurring issue with this treatment is that patients can develop alloimmunity and/or iron overload and thus each patient should be transfused to the minimal target for clinical efficacy, but no patient-specific metric exists to predict an effective target. To evaluate the ability of our system to identify clinical targets, we simulated transfusion therapy by mixing type-matched genotype healthy donor blood with SCD at the following ratios (indicated as SS blood percentage/AA blood percentage): 100/0, 70/30, 30/70, 10/90, and 0/100 and evaluated the rheological response of the blood to varying oxygen and blood pressure. We found that at or below a 30/70 mix, the

flow behavior index is similar at all oxygen tensions indicating therapeutic efficacy (Figure 3B).

Figure 3: A). Flow behavior index of 9 samples shows sickle blood loses shear thinning behavior as oxygen tension decreases below 46 mmHg. B). Simulated transfusion experiment reveals the potential of using the flow behavior index to identify patient specific transfusion target values.

DISCUSSION

There is a significant need to identify markers which can help predict and understand SCD patient diversity as well as models to better test and characterize therapeutics. In this study, we introduce a new microfluidic platform capable of quantifying SCD blood rheology, and we reveal a rheological metric, the flow behavior index, that is highly sensitive to oxygen tension and putative therapy and appears to be patient specific. We discover that SCD blood undergoes a transition which occurs below 46 mmHg oxygen tension to a fluid that expresses decreased shear thinning behavior. This quantitative metric allows characterization of blood response to oxygen tension and possibly permits identification of patients who are at increased risk to develop complications. In addition to identifying potential clinical markers, our platform was used to characterize a simulated transfusion therapy. We successfully tested and were able to identify target transfusion therapy values that limit the flow behavior index dependency on oxygen tension and potentially predict clinical efficacy. Thus, we have demonstrated the potential to use this assay to predict patient-specific transfusion targets.

Overall, our work has the potential to better address the needs of SCD patients via quantification of blood flow mechanics. The microenvironment where SCD complications occur, however, is complex, and gleaning clinically relevant information from simplified systems remains a challenge. Nonetheless, the model system and metrics presented here show promise to aid in our efforts to understand patient diversity, predict clinical prognosis, and develop new therapies.

INTRODUCTION

Biological cells are known to respond to flow fields around them and change their activities in the physiological environment. In contrast, non-physiological high shear flow generated by medical or engineering devices, e.g., ventricular-assisted devices [1], jet injectors [2], and microfluidic cell sorters [3], can induce a rupture of the cell membrane and subsequent cell death. For the development of such the devices, it is essential to understand the mechanism of the membrane rupture and control it. However, as the details of the membrane rupture are elusive in experiments, its mechanism is not fully understood.

Many experiments and numerical simulations have been conducted on biological cells under shear flow [4,5]. These studies have shown that the cells, e.g., red blood cells, are elongated and the membrane tension increases under shear flow. When the tension exceeds the limit of the membrane, the membrane rupture may occur. This is the *common* mechanism of the membrane rupture under shear flow. On the other hand, the molecular dynamics (MD) simulation study [6] has shown that the Kelvin-Helmholtz-like instability of the phospholipid bilayer, which is the fundamental structure of the cell membrane, can occur under high shear flow. This hydrodynamic instability immediately leads to the membrane rupture. Compared to the tension-induced rupture, the details of the hydrodynamic-instability-induced rupture are less understood.

In this study, in order to understand the hydrodynamic-instability-induced rupture of the phospholipid bilayer under shear flow, we performed MD simulations of phospholipid bilayers under high shear flow and explained the underlying mechanism of instability at the molecular level in the frameworks of linear stability analysis.

METHODS

System We employed three dipalmitoylphosphatidylcholine (DPPC) bilayer systems in rectangular simulation box with periodic

boundary conditions. To model molecules, we used the MARTINI force field [7], which is a coarse-grained (CG) model suitable for semi-quantitative evaluation of lipid dynamics. The three systems were composed of 256 DPPC and 14,000 water, 512 DPPC and 28,000 water, and 768 DPPC and 42,000 water, respectively. The snapshots of the smallest system are shown in Fig. 1A. The systems were well-equilibrated by at least 1- μ s MD simulation at a constant temperature (323 K) and pressure (0.1 MPa). The sizes of the simulation boxes (l_x , l_y , l_z) were 12.8 \times 6.3 \times 25.3, 25.4 \times 6.3 \times 25.3, and 37.9 \times 6.3 \times 25.5 nm³, respectively.

MD Simulation under Shear Flow In the shear simulation, the systems were divided into 1-nm-bins in the z -direction (Fig. 1A). To keep the temperature of the system under shear flow, the temperature of molecules in each bin is separately kept constant (323 K). The velocities of water in the top and bottom bins (shown in red in Fig. 1A) were respectively set to $(v_x, 0, 0)$ and $(-v_x, 0, 0)$ during the shear simulation to express the shear flow. The shear rate $\dot{\gamma}$ was defined as $\dot{\gamma} = 2v_x/(l_z - 2)$. The velocity difference between the bilayer Δu was defined $\Delta u = \dot{\gamma}l_t$, where l_t was the thickness of the bilayer. The shear simulations were performed at a constant temperature and volume condition for 200 ns. Because of the statistical nature of the bilayer rupture [8], we performed three replicates of the shear simulations, starting from different initial configurations, for each system and each shear rate condition.

Linear Stability Analysis Let us consider a water bath divided by an interface consisting of a phospholipid bilayer, which is thin enough to neglect its thickness (see Fig. 1B). We assume a uniform displacement along the y -direction and the water as the incompressible inviscid fluid. The velocities and densities of water in the upper and lower regions are constant except on the interface and denoted as u_u , u_l , ρ_u , and ρ_l , respectively. For the deformation energy of the bilayer, we use the Helfrich Hamiltonian F [9],

$$F = \int \left\{ \sigma + \frac{1}{2} k_c (c_1 + c_2 - 2c_0)^2 \right\} dA, \quad (1)$$

where σ and k_c are the tension and the bending modulus of the bilayer, respectively. c_1 and c_2 are principal curvatures, and c_0 is the spontaneous curvature. dA is the surface element. As a result of a conventional linear stability analysis with equation (1) [10], we can obtain a stability criterion as

$$|\Delta u| < \sqrt{\frac{4\pi}{\rho} \left(\frac{\sigma}{\lambda} + \frac{4\pi^2 k_c}{\lambda^3} \right)}, \quad (2)$$

where λ is the wave length of bilayer undulation and $\Delta u = u_u - u_l$. Additionally, we assume $\rho = \rho_u = \rho_l$ and $c_0 = 0$. In the MD simulation here, the water density ρ is 986 kg/m³, and tension σ is 0 mN/m. Because of the considerable variation of the bending modulus k_c reported in previous simulation and experimental studies [11-13], we use various k_c in the range from 4.0×10^{-20} to 12.8×10^{-20} J.

RESULTS

Representative snapshots of the largest bilayer system under shear flow are shown in Fig. 2. When the applied shear rate is below a critical level, the bilayer maintains its continuous structure with undulation during the shear simulation. Conversely, above a critical level, the bilayer undulation suddenly starts to be larger (Fig. 2B-D) and the bilayer is torn (ruptured) (Fig. 2E). The relationship between the velocity difference calculated from the shear rate and the maximum wave length of the bilayer undulation in the system is shown in Fig. 3. The maximum wave length corresponds to the system box length in the flow direction x . The critical velocity difference $|\Delta u_c|$, where the bilayer rupture occurs, (which expected to be between green circle and red cross in Fig. 3) tends to decrease with increasing the wave length. The stability criterions calculated from equation (2) with various k_c are also plotted in Fig. 3. The tendency, $|\Delta u_c|$ decreases with λ , obtained from the MD simulations agrees with the theoretical prediction.

DISCUSSION

In our MD simulation, we observed the hydrodynamic instability of the bilayer and subsequent bilayer rupture (Fig. 2) as with the previous MD simulation study [6]. The hydrodynamic-instability-induced bilayer rupture observed here was successfully explained by the linear stability analysis for the macroscopic fluid-fluid interface divided by a thin membrane with the Helfrich Hamiltonian (Fig. 3).

The critical velocity difference $|\Delta u_c|$, where the bilayer rupture occurs, is estimated to be in the range from 10^1 to 10^2 m/s (Fig. 3), which corresponds to the shear rate in the range from 10^9 to 10^{10} s⁻¹. One may think that such the shear flow in the nanometer scale is extremely drastic and the instability might not occur except in highly specific situations. According to the equation (2), the larger λ , the smaller $|\Delta u_c|$. Thus, for example, $|\Delta u_c|$ in the micrometer scale (1-10 μ m), which corresponds to the typical length scale of a single cell, is estimated to be about 3-5 orders of magnitude smaller than that in nanometer scale here (~ 10 nm). This implies that the shear-induced instability might occur in the larger membrane, e.g., the membrane of a single cell, under much lower shear rate. However, it must be noted that great care is required to discuss the instability in the cell membrane in more detail because of some assumptions in the MD simulation and the theory and the difference between the mechanical characteristics of the phospholipid bilayer and actual cell membranes.

INTRODUCTION

Acute ischaemic stroke occurs when a blood clot blocks a cerebral artery that supplies nutrient and oxygen to the brain. Thrombolytic therapy is used to dissolve the blood clot, which involves a clot-dissolving drug, such as recombinant tissue-type plasminogen activator (tPA). Although less invasive than mechanical thrombectomy, thrombolytic therapy can be ineffective in certain clinical scenarios and is currently limited to a subset of patients due to the risk of bleeding complications. In order to evaluate the effectiveness of thrombolytic therapy in different clinical settings, we have developed a computational model for thrombolysis in acute ischaemic stroke [1]. Among many factors that influence the effectiveness of thrombolytic treatment, the size and location of the clot are associated with the likelihood of successful recanalisation and clinical outcomes. By using a recently developed computational framework for thrombolytic therapy, we have simulated a number of clinically relevant scenarios to investigate the effects of clot size and location on clot lysis dynamics and recanalization upon intravenous thrombolysis using tPA.

METHODS

Three-dimensional (3D) Patient-specific Geometry A 3D patient geometry is reconstructed from MR images using Mimics 19.0 (Materialise, Leuven). Figure 1 shows the patient-specific geometry used in this study, which includes the internal carotid bifurcation into the A1 segment of anterior cerebral arteries (ACA) and the M1 segment of middle cerebral arteries (M1), as well as the M1 bifurcation into the M2 segments (M2-1 and M2-2). Clot regions numbered 1 to 7 are artificially assigned in the M1 segment and the M2 inferior branch (M2-1). The smallest clot in M1 and M2 is represented by Clot 1 and Clot 5, respectively. By adding the subsequent regions, the clot size in each

branch can be increased. Furthermore, a very long clot extending from region 1 in M1 to region 7 in M2-1 can also be simulated by including the region of M1 bifurcation as shown in Figure 1.

Figure 1: The patient-specific geometry used in this study.

Description of Mathematical Model Our computational model incorporates multiscale physical and biochemical phenomena, including models for (i) blood flow, (ii) species transport, (iii) fibrinolytic reactions and (iv) estimation of clot properties [1]. The macroscopic transport phenomena, i.e., blood flow and species transport of key proteins (tPA, plasminogen, plasmin and anti-plasmin), are described by the modified Navier-Stokes equations with the Darcian momentum source term and the convection-diffusion-reaction equations, respectively. Reaction rates are calculated from the fibrinolytic reaction kinetics, which also affect the clot properties and consequently the Darcian momentum source term. A three-element

Windkessel model is coupled with the Navier-Stokes equations for physiological pressures at each outlet. A compartmental model for systemic concentrations of fibrinolytic proteins is solved to provide inlet boundary conditions for the convection-diffusion-reaction equations. For the estimation of clot properties and reactions kinetics of thrombolysis, the clot is assumed to be composed of a fibrin fibre network alone, ignoring the presence of any cellular components.

These model equations are implemented in an open source computational fluid dynamics (CFD) code, OpenFOAM 4.0. Computations are performed using High Performance Computing (HPC) facilities (Imperial College Research Computing Service [2]).

RESULTS

Here we present flow and clot lysis patterns of two representative scenarios with the largest clot in each occlusion site, when an initial bolus is administered at Time = 60 s. Figure 2 shows flow velocity and clot resistance for the M1 (top) and M2 (bottom) clots at two time points, which correspond to Clot 1-4 and Clot 5-7 in Figure 1, respectively. For both scenarios, there is no visible flow in the occluded branch at Time = 150 s, due to high initial clot resistance of $1.8 \times 10^{13} \text{ m}^{-2}$ (= permeability of $5.6 \times 10^{-14} \text{ m}^2$). The clot starts to degrade from its front, followed by gradual reduction in clot resistance and consequently reduced clot volume during clot dissolution. It is noticed in the M2 clot that there is a large stagnation zone between the M1 bifurcation and the clot front at Time = 150 s, unlike in the M1 clot. This is because the M2 clot is positioned distal to the M1 bifurcation, which results in a slower penetration of tPA and hence a delayed degradation of the M2 clot than the M1 clot. A breakthrough path is established at around 360 s and 470 s for the M1 and M2 clots, respectively. This results in a high-velocity jet, allowing convective transport of tPA to become dominant thereafter.

Figure 2: Flow and clot lysis patterns for the largest clots in each occlusion site: M1 clot (top) and M2 clot (bottom).

Simulation results for different clot sizes and locations are compared in Figure 3 in terms of changes in clot volume over time. While reduction in clot volume starts at around 5.5 mins for all clots, complete lysis takes between 5.5 to 9 mins depending on the clot size and location. A general trend is that smaller clots dissolve faster, as expected. When comparing different locations for clots of a similar size, clots in the M2 segment tend to take longer to dissolve than those in the M1 segment, e.g., C1-2 vs C5 and C1-3 vs C5-6. This can be explained

by the large stagnation zone initially formed between the M1 bifurcation and the clot front, as in Figure 1, which slows down the transport of tPA in that region.

Figure 3: Change in clot volume over time.

DISCUSSION

Our results for lysis patterns show that the lysis front is asymmetric due to the curvature of the blood vessel. Interestingly, faster lysis occurs always from the inner curvature of the vessel due to the presence of recirculation zone and accordingly prolonged residence time of tPA there. As a result, a breakthrough pathway is established at the fast dissolving side, allowing a high-velocity jet to pass through. As clot lysis is accelerated by the convective transport of tPA, flow in the blocked branch is reestablished rapidly before the obstructive clot is completely dissolved.

Comparisons of results for all the simulated scenarios suggest that clots in the M2 segment need a longer time for complete dissolution than those in the M1 segment, mainly due to the presence of a stagnation zone near the front of M2 clots. However, clinical studies reported that distal occlusion is more likely to achieve recanalisation success and a good clinical outcome than proximal occlusion [3]. This is because of the size of distal clots being smaller than proximal ones [3]. Based on our simulation results and clinical observations, we can conclude that recanalisation times are strongly influenced by the size of clots, which is location dependent, and the distance between the clot and its adjacent bifurcation.

In summary, our simulation platform for thrombolysis in ischaemic stroke can offer an in-depth understanding of drug transport and clot lysis under various clinical scenarios. We have validated the predicted temporal concentration profiles for fibrinolytic proteins against available in vitro experimental data, demonstrating satisfactory agreement. However, the predicted recanalization time appears to be shorter than clinical observations [4] due to the assumption of a fibrin only clot with a high initial permeability. Further improvement of the model is underway to incorporate the presence of cellular components in the clot, and to simulate a new tPA delivery system for targeted thrombolytic therapy.

INTRODUCTION

Sickle cell disease (SCD) is a genetic disorder that affects millions of people around the world. In SCD, hypoxia causes intracellular polymerization of the sickle hemoglobin, leading to increased stiffness and morphological changes in red cells. The changes in red cell biomechanics subsequently cause increased blood viscosity and can even completely obstruct blood flow in the microcirculation. Impaired and occluded flow lead to tissue ischemia and necrosis, chronic infections, severe pain, stroke, and even sudden death in rare cases [1].

Even with this conceptual understanding of the disease etiology, we are still unable to predict which patients will experience the most severe symptoms or which patients will respond best to which treatments. Previous studies have shown that patient clinical outcomes, including response to treatment, are strongly correlated with changes in the apparent viscosity of whole blood under hypoxic conditions [2,3]. Our ability to build predictive models from these data sets is limited, however, because the parameter space of clinical conditions is far too large to sample experimentally.

Mathematical modeling associated with experimental data can provide a reliable way to probe a much larger parameter space with the goal of building a predictive model that is applicable to a broader set of patient-specific variables as well as treatment conditions. Here, we modeled blood as a non-Newtonian fluid, evaluated the changes in apparent viscosity as a function of oxygen tension for a fixed drop in blood pressure, and parameterized the model based on experimental results using a microfluidic blood viscometer.

METHODS

Blood Rheology: Discarded whole blood from patients with sickle cell disease (SCD) and from normal, healthy individuals was collected at the University of Minnesota Medical Center and Massachusetts General

Hospital. To characterize the blood's rheological properties, a microfluidic blood viscometer was mounted on a temperature-regulated microscope and blood was perfused using an electronic pressure regulator. Blood oxygen tension was controlled using a previously developed solenoid valve gas mixing setup [4]. Video data were collected using a high-speed camera and analyzed using a custom MATLAB script that implements the Kanade-Lucas-Tomasi feature tracking algorithm. An example data set is shown in Fig. 1.

Figure 1: Velocity tracking data of an SCD sample shows response to oxygen tension cyclical modulation between high oxygen (21%) and low oxygen (0%).

Mathematical Flow Modeling: For the mathematical model, the flow is considered to be parallel, fully developed, isothermal, steady flow in a rectangular channel. The momentum conservation law under these assumptions is described by Eq. 1.

$$-\nabla p + \nabla \cdot (\eta \dot{\gamma}) = 0 \quad (1)$$

where p is the mechanical pressure, $\dot{\gamma}$ is the rate of strain tensor, and η is the apparent viscosity of blood.

Blood was expressed as a non-Newtonian fluid by using Carreau-Yasuda model [5]. In this model, the viscosity is a function of the rate of strain as given by Eq. 2.

$$\eta = \eta_{\infty} + (\eta_0 - \eta_{\infty}) \left[1 + \left(\frac{\dot{\gamma}}{\dot{\gamma}_0} \right)^a \right]^{\frac{1-n}{a}} \quad (2)$$

Here $\dot{\gamma}$ is the second invariant of the rate of strain tensor, and η_{∞} , η_0 , $\dot{\gamma}_0$, a , and n are material parameters that are adjusted based on the experimental data.

Equation 1 was solved using a second-order Finite Difference Method to discretize the spatial derivatives. The resulting nonlinear algebraic system of equations is solved using Newton-Raphson iteration method. Model parameters were adjusted manually to fit the data.

RESULTS

Figure 2 shows the axial (z) velocity profile within the channel for high oxygenation (right) and low oxygenation (left) blood level. As expected, the velocity field was symmetric and had a maximum along the channel centerline.

Figure 2: Velocity profile along the transverse direction of the capillary for oxygen tension equal to 21% (left) and 0% (right). Blood is considerably faster in high- O_2 case. Scales has applied to both cases.

Figure 3 compares the numerical simulation results (solid line) with experimental data (open circles) for SCD (right) and healthy (left) blood. The computed velocity $u_z(x, y)$ from Fig. 2 was averaged over y direction to simulate the experimental measurement of y -averaged velocity from the video. As the oxygen tension is reduced, the velocity decreased for SCD blood. Conversely, for the healthy cells the mean velocity shows negligible variation.

Figure 3: Mean velocity along transversal direction for healthy (left) and SCD (right) blood at 21% (red) and 0% (blue) of oxygen tension. Open circles are experimental data and solid lines are numerical simulations results.

Table 1 shows the parameters values associated with the model results in Fig. 3. Certain features are notable. First, $\dot{\gamma}_0$ was quite large ($720+ s^{-1}$) when compared with the shear rate in the channel (maximum of $610 s^{-1}$), indicating that the flow is close to Newtonian and the viscosity well approximated by η_0 . Second, consistent with the reduced flow rate of SCD blood, η_0 was larger for SCD blood than for healthy blood, and for SCD blood, η_0 increased when oxygen was removed.

Table 1: Parameter values for SCD and healthy blood.

O ₂ Tension	$\dot{\gamma}_0 (s^{-1})$	$\eta_0 (cP)$	$\eta_{\infty} (cP)$	a	n
SCA 21%	720	3.6	1.5	5	0.6
SCA 0%	1200	4.9	2.3	5	0.8
Healthy 21%	10000	2.1	1.1	5	0.5
Healthy 0%	10000	2.05	1.0	5	0.5

DISCUSSION

The dependence of SCD blood viscosity on oxygen tension was studied by correlating mathematical modelling and simulation with experimental data from human SCD blood. Viscosity was described by the Carreau-Yasuda model, where the material parameters were manually adjusted to fit with the experimental data. The velocity profile obtained by Carreau-Yasuda viscosity model shows good agreement with the experimental observation. Results show that deoxygenation increase the viscosity of the SCD blood, leading to the change in the velocity profile observed experimentally. For healthy blood, no significant alteration was observed. Under the conditions studied, it appears that a Newtonian model would have described the flow accurately, but we choose the Carreau-Yasuda model to maintain flexibility and robustness in future studies.

The major contribution of our work is in develop a method that convert experimental data from a well-controlled in-vitro study in a computational model that could be extended to relevant in vivo geometries and conditions. Specifically, the parameters of Table 1 (possibly drawing in more data to define $\dot{\gamma}_0$, etc.) as a basis for Finite-Element Simulation of non-Newtonian SCD blood flow in the microvasculature.

INTRODUCTION

Atherosclerotic plaque rupture, a major cause of stroke and myocardial infarction [1], was shown to correlate with high structural plaque stresses [2]. Hence, plaque stress analyses are of great value as they can aid plaque rupture risk assessment. Plaque stresses can be obtained with finite element (FE) modeling, where correct representation of the plaque material properties is of great importance for the accuracy of the stress results [3]. However, this essential information on plaque material properties is still majorly lacking [4].

This work aims assessing human coronary plaque material properties. In this study, ex-vivo inflation tests, which mimic the in-vivo loading conditions, were performed with excised atherosclerotic human coronaries, and test results were analyzed with inverse FE modeling (iFEM) for component-wise plaque properties.

METHODS

Ex-vivo inflation testing

Ten atherosclerotic coronary arteries were collected post-mortem at Erasmus Medical Center (MC). The intact atherosclerotic human coronary samples were mechanically tested in an ex-vivo inflation setting, which imposes mechanical loading and boundary conditions closely mimicking the physiological ones. Samples were tested in phosphate buffered saline at 37°C, after ten cycles of mechanical preconditioning of 20% axial stretch and intraluminal pressurization between 0 to 80 mmHg. During the tests intraluminal pressure was increased quasi-statically in increments of 10 mmHg up to 120 mmHg.

During the inflation, the samples were imaged with a high frequency ultrasound (US) system (Vevo 2100, VisualSonics Inc.) using a linear array probe (MS550S) with a center frequency of 40 MHz (Fig. 1). Raw radiofrequency (RF) US data were collected at preselected cross-sections (~ 3 per artery) at each pressure step.

Figure 1: The protocol for plaque mechanical characterization including MRI, inflation testing, US measurements & iFEM.

Full-field plaque deformation measurements

The acquired RF US data was analyzed to assess the full-field deformation on the plaque cross-sections during inflation testing. The in-plane displacements were obtained with a coarse-to-fine 2-D cross-correlation method in three iterations. A median filter of 5 x 5 displacement pixels was applied after each iteration to decrease the

amount of outlying displacement values. The final spatial resolution for the displacement estimates was 15 μm in axial direction (along the US probe) and 55 μm in the lateral direction (across the probe) [5]. This technique was used before for the high-frequency US scanners, for the first time, by our group for porcine iliac arteries [6].

MRI acquisitions

The essential plaque composition and morphology information for the FE models plaque geometry was acquired from high resolution magnetic resonance imaging (MRI) with a 7T, high field scanner (General Electric, Connecticut, USA). MRI scans were performed before the inflation tests and the acquired multi-sequential (T1, T2 and proton density weighted) images were segmented for the arterial wall, fibrous intima, lipid pool and calcifications (Fig. 2). The segmented MRI images were co-registered to US data by using the medical image registration software *elastix* [7] (Fig. 1).

Figure 2: T1, T2 and PD weighted images of a plaque cross-section.

Inverse finite element modeling (iFEM)

A 2-D FE model of each plaque cross-section was created to simulate the ex-vivo inflation testing. All tissue components within the FE model were assumed to be isotropic, and constructed as nearly incompressible Neo-Hookean solids, characterized with a single material parameter constant, C_1 . A highly stiff material behavior for calcification and a compliant one for lipid were selected. The iFEM aimed to assess the material properties (C_1 values) of the fibrous intima and the arterial wall, hence they were not predefined. In the FE simulations, three intraluminal pressure steps, 1) from 10-80 mmHg, 2) 80-100 mmHg and 3) 100-120 mmHg were applied to mimic the inflation testing conditions. The simulations were performed in ABAQUS (Dassault Systèmes) under plane strain assumption.

The iFEM approach employed a grid search optimization algorithm, where at each iteration fibrous intima and arterial wall C_1 values were varied, FE model was rerun and root mean square error of the experimentally-measured and model-predicted displacements was calculated (Fig. 1). The C_1 values that resulted in the minimum error were accepted as the optimal estimations of the material properties. The optimization was performed for the three pressure steps (10-80 mmHg, 80-100 mmHg and 100-120 mmHg) separately.

RESULTS

Multi-sequential, high resolution (50 μm in-plane resolution) MRI images were obtained successfully for all 10 coronaries, allowing accurate plaque composition and morphology assessment through component-wise segmentation. Artery segments were successfully prepared for the inflation tests by removing the surrounding connective tissue, cannulation and closing the side branches, even the microscopic ones. The tests and US data acquisition were successfully performed by achieving stabilized pressure for all test samples for each pressure step, by preventing any leakage during pressurization.

In total, 26 cross-sections from the 10 coronary vessels were selected for further material characterization with iFEM. Of the 26 cross-sections, the material characterization of one cross-section has been completed. For the cross-section, iFEM achieved a satisfactory error minimization, where the relative differences between the experimentally-determined and model-predicted displacements were

5.7% for the pressure step (step 1) from 10 to 80 mmHg, 3.3% from 80 to 100 mmHg (step 2) and 2.1% from 100 to 120 mmHg (step 3). Accordingly, the C_1 values derived for the three pressure steps for the fibrous intima were 23.4 kPa, 77.1 kPa and 112.9 kPa, and for the arterial wall 16.7 kPa, 18.5 kPa and 16.7 kPa (Figure 3).

Figure 3: iFEM-estimated material properties of a cross-section.

DISCUSSION

We successfully developed a pipeline to obtain component-wise material properties of atherosclerotic arteries, by utilizing 1) an inflation testing, which employs the most physiological loading conditions ex-vivo and preserves the structural integrity of the artery, 2) high frequency US measurements, 3) high resolution MRI and 4) iFEM. By applying the developed iFEM pipeline successfully for the first vessel, the fibrous intima and the wall mechanical properties were estimated. The results successfully captured the nonlinear stiffening behavior and are in accordance with previously published data on atherosclerotic porcine iliacs [6] and for human arteries [2,8].

The currently-existing limitations of the study are planned to be addressed in the future steps of this work. More advanced hyper-elastic constitutive equations can capture the nonlinearity in a single pressure step simulation and even possibly further reduce the error achieved during the optimization process. Anisotropic constitutive laws can improve the results, which is possible to obtain with the developed pipeline as full-field deformation measurements are acquired. The future work will also include analyzing the remaining 25 cross-sections to obtain mechanical characteristics data of human atherosclerotic coronary plaque from a fairly sized sample population.

Although the developed approach is currently applied for ex-vivo mechanical testing, it holds the great potential to be used for in-vivo characterization as well. The plaque composition and geometry can be obtained similarly from MRI [9] and deformation measurements from US [10]. As such, the developed technique is promising to obtain patient-specific material properties in-vivo and aid rupture risk assessment.

INTRODUCTION

Contemporary coronary artery bypass grafting (CABG) uses autologous vessels to circumvent severely occluded regions of the vasculature to restore adequate cardiac perfusion [1]. Often patients with advanced coronary artery disease lack suitable graft tissues and many of these will undergo multiple bypass procedures [1,2]. Thus, a pressing-need exists for the generation of alternative bypass options. Whereas small caliber synthetic grafts experience thrombus formation and restenosis, tissue-engineered blood vessels (TEBVs) could be used to increase long-term graft patency due, in part, to the accurate matching of biochemical and mechanical properties [2,3]. TEBVs success, however, depends strongly on the chosen scaffolding material.

A proven technique for scaffold generation is through the decellularization of native tissues. Decellularization can be achieved via physical, chemical, or enzymatic approaches to completely remove cellular and nuclear material while retaining the native extracellular matrix (ECM). One such approach employs ionic and anionic detergents such as sodium dodecyl sulfate (SDS) and sodium deoxycholate (SDC). Comprehensive studies on how these agents impact the vessel's mechanical properties are currently lacking [5]. Since these mechanical characteristics depend on the abundance of existing ECM components such as collagen, elastin, and ground substances it is important to identify how these may be directly or indirectly altered during decellularization [1-5]. Our previous research identified the native porcine internal thoracic artery (ITA) as a superior candidate for bypass grafting due to its ideal mechanical and histological properties, thus we postulate that the porcine ITA would be an excellent scaffolding material for small diameter TEBVs [2]. The purpose of this study was to compare the ECM integrity and overall mechanical characteristics of

porcine ITAs following several chemical detergent concentrations used to remove cellular material.

METHODS

Tissue Preparation. Porcine ITAs, approximately 160 mm in length, were harvested from sows shortly after slaughter at a local abattoir and dissections performed immediately after harvest. Loose perivascular and adipose tissues were removed and arteries were stored in cold 1% phosphate buffered saline (PBS) until decellularization.

Decellularization. Porcine ITAs were rinsed in DI water for 24 hours and then decellularized according to previously identified protocols [5]. All experimental groups were placed in a solution containing the enzyme deoxyribonuclease I (DNase I) to break-down DNA. Vessels were then placed in a solution containing a PMSF antimycotic and an equivalent ratio of SDS to SDC but at varying ratios of total detergents to PBS so that the final concentrations of SDS-SDC in PBS were 6.0, 3.0, 2.0, 1.0, and 0.0% [5]. ITAs undergoing decellularization were then subject to three days of agitation in a specific detergent concentration to ensure complete and homogeneous processing. Other vessels were placed in a separate PBS solution to serve as a time-matched control. After completion of the decellularization treatment, the vessels were rinsed several times with PBS to elute excess detergent and cellular debris. Certain vessels were stained with DAPI and imaged and others used the Quant-iTTM PicoGreen® dsDNA reagent to quantify the residual double-stranded DNA (dsDNA). Western blots of α -smooth muscle actin (α -SMA), a cytoplasmic protein of smooth muscle cells, confirmed DAPI results.

Histology. Movat's Pentachrome staining was employed to identify smooth muscle, elastin, collagen, and glycosaminoglycans (GAGs) as red, black/brown, yellow, and blue colors, respectively [4].

Wiegert's elastic stain (not shown) was used for elastin quantification. Cross-sections of ITAs were paraffin-embedded and cut to approximately 6 μm in thickness. Staining was performed according to the manufacturer's instructions (Poly Scientific R&D Corp).

Mechanical Testing. Biaxial mechanical testing was carried out using a Bose Biodynamic 5270 device as described in [2]. Briefly, ITAs from each detergent concentration were cut into approximately 20 mm sections. Each vessel was then mounted into the testing chamber of the biaxial testing device and the chamber was filled with 1% PBS. The *in vivo* axial stretch ratio from the native ITA was determined when the force value remained pressure invariant. All decellularized vessels were tested at this ratio to facilitate comparisons across groups. Each vessel underwent five cycles of axial stretching and cyclic inflation as preconditioning. For data collection, the pressure was increased from 0 to 120 mmHg while the outer diameter and axial force were measured. Each test was conducted three times.

RESULTS

Decellularization. Porcine ITAs stained with DAPI are shown in Figure 1. Scoring revealed a decrease in cellular and nuclear material as the concentration of detergent increased. Results were largely confirmed with the PicoGreen DNA/RNA quantification kit (Control=21.7 \pm 14.2 ng/ml; 0.0% SDS-SDC=14.9 \pm 25.7 ng/ml; 1.0 to 6% SDS-SDC=undetectable). Western Blotting revealed the presence of α -SMA only in controls and 0% SDS-SDC.

Figure 1: DAPI of decellularized vessels for [A] PBS Control, [B] 0.0% SDS-SDC, [C] 3.0% SDS-SDC, and [D] DAPI quantification (Avg \pm STD, n=3 each). [E] Western blot for α -SMA

Histology. Light microscopy of decellularized vessels (Figure 2) confirm the absence of cellular material above 1.0% SDS-SDC. There was a notable decrease in GAG content (blue) that was progressive with detergent concentration. Surprisingly, a strong spatial dependency on anatomical location within the ITA emerged where proximal sections (Figure 2 E & F) have a greater medial thickness and number of elastic lamellae. Wiegert's stain also quantified the percent area of elastic fibers in decellularized vessels and the mean area fraction for the control, 0.0% SDS-SDC, and the 3.0% SDS-SDC vessels were 0.46 \pm 0.06, 0.44 \pm 0.18, 0.68 \pm 0.05, respectively.

Mechanical Testing. All specimens were tested at common axial stretches to facilitate comparisons between groups. Overall, the native and 0.0% vessels exhibited similar mechanical properties and the presence of detergents impacted the stiffness of all vessels in a concentration independent manner (Figure 3). That is, no obvious trends emerged between the varying SDS-SDC concentrations and mechanical

properties. Surprisingly, the anatomical location played a greater role in tissue mechanics; a finding that warrants further investigation.

Figure 2: [A] 6.0% [B] 3.0% [C] 2.0% [D] 1.0% [E] 0.0% SDS-SDC, and [F] PBS control. Sections shown from a single sow.

Figure 3: Native and decellularized vessels [A] pressure-radius and [B] circumferential stress-stretch. Avg \pm SEM (n=3 each)

DISCUSSION

The histomechanical properties of decellularized vascular scaffolds were investigated. We found that 1.0% SDS-SDC was sufficient for complete removal of cellular material without obvious ECM damage. Biaxial mechanical testing revealed that decellularized vessels were circumferentially stiffer, but stiffness did not depend on SDS-SDC concentration. Likewise, DNase I had no effect on mechanical properties. Ongoing work is being performed to investigate the length-dependent histomechanical properties and the impact of cryopreservation and recellularization.

INTRODUCTION

Collagen and elastin fibers are the two major load-bearing extracellular matrix (ECM) components in the arterial wall [1]. The ECM fiber orientation, distribution, and interactions largely define the passive mechanical properties of the arterial wall. Recent studies have provided interesting findings on the contribution of the individual ECM components to arterial mechanics [2, 3, 4]. Collagen and elastin fiber orientation through the arterial wall was characterized using both histological and multi-photon imaging methods. Results indicated that medial collagen fibers were arranged almost symmetrically around the circumferential direction and tended to be closer to the longitudinal direction in the adventitia [4]. Medial elastin fibers were found to have a transmural variation in fiber orientation in the media [3]. Reorientation of both elastin and collagen fibers was observed in to accommodating mechanical loading [2]. However, due to limited laser penetrating depth, sectioning of the tissue is required in order to image the fibers beneath the surface of the tissue.

The goal of this study is to understand the transmural variations in collagen and elastin fiber orientation distribution in intact arteries, and the contributions of ECM fibers to arterial biomechanics. Optical clearing method CUBIC (Clear, Unobstructed Brain/Body Imaging Cocktails and Computational analysis) [5] was adopted in order to increase the imaging depth in intact arterial tissue. Multi-photon microscopy was used to image the elastin and collagen fibers and their transmural variation in fiber orientation in the arterial wall.

METHODS

Sample preparation and optical clearing

Porcine thoracic aorta (12-24 month old) was obtained from a local abattoir. Upon arrival in the laboratory, aorta was carefully cleared from adjacent fat and cut open along the axial direction of the artery. Square

samples of approximately 2cm × 2cm were cut with one edge being parallel to the longitudinal direction and the other being parallel to the circumferential direction of the artery.

Samples were then chemically fixed by immersing them into 4% paraformaldehyde (PFA), where they were kept for 24 hours. Samples were then rinsed twice with phosphate-buffered saline (PBS) to washout any remaining PFA. In order to optically clear the samples, they were immersed in CUBIC clearing reagent with gentle shaking at room temperature for two hours. After that, the reagent was replaced every two days for a total duration of six days.

Multi-photon microscopy and image analysis

Samples were kept in the CUBIC clearing reagent while being imaged with a multi-photon microscope. An excitation wavelength of 800nm was used to generate two-photon excitation of fluorescence (525/45nm) from elastin and second harmonic generation (417/80nm) from collagen [2, 3]. Samples were imaged from both the intimal and adventitial side to capture the transmural structural characteristics of collagen and elastin fibers in the media and adventitia, respectively. Both sample sides were imaged to a depth of 210μm with 1μm spacing and a field of view of 277 × 277μm.

Z-stack images of elastin and collagen were acquired and the fiber orientation was extracted for every image using Directionality plug-in in FIJI (<http://Fiji.sc/Fiji>, Ashburn, VA). The program uses Fast Fourier Transform (FFT) to obtain the spatial frequencies of the image. The direction of the fibers is extracted by calculating the angle and the intensity of each spatial frequency in the FFT power spectra using edge-detector filters. The distribution functions at each imaging depth were combined into a three-dimensional (3D) image to study the transmural variation in elastin and collagen fiber orientation.

RESULTS

Representative fiber orientation distribution function of medial elastin (Figure 1A) and collagen (Figure 1B) is shown at three imaging depths of $40\mu\text{m}$, $100\mu\text{m}$ and $140\mu\text{m}$. Closer to the intima surface, at imaging depth of $40\mu\text{m}$, the two peaks near $\pm 90^\circ$ indicate that both elastin and collagen fibers are arranged mainly in the longitudinal direction. At imaging depth of $100\mu\text{m}$ and $140\mu\text{m}$, a peak appears around 0° which means that the fibers are more circumferentially oriented. Figure 2 shows the transmural variation in elastin and collagen fiber distributions from the reconstructed stacks of images in an imaging depth of $210\mu\text{m}$, where imaging depth of $0\mu\text{m}$ corresponds to an imaging scan close to the intimal surface. It can be seen that elastin fibers are arranged predominantly in the longitudinal direction closer to the intimal surface and then transitioned rather abruptly towards the circumferential distribution. Although not shown here, the medial collagen follows a similar transmural pattern as medial elastin.

Figure 1: Fiber orientation distribution function of medial elastin (A) and collagen (B) at imaging depths of $40\mu\text{m}$, $100\mu\text{m}$ and $140\mu\text{m}$. 0° corresponds to the circumferential direction and $\pm 90^\circ$ corresponds to the longitudinal direction.

Figure 2. Transmural variation in medial elastin fiber orientation distribution within an imaging depth of $210\mu\text{m}$.

In order to further understand the orientation of elastin and collagen fibers as a function of the imaging depth, the circumferential-to-longitudinal fibers ratio was calculated and plotted in Figure 3. This ratio is defined as the amount of fibers in the circumferential direction,

A_C , over the amount of fibers in the longitudinal direction, A_L . Specifically, A_C and A_L were defined as the areas under the distribution function from $0 \pm 20^\circ$ and $90^\circ \pm 20^\circ$, respectively [2]. For values less than 1, the fibers follow a longitudinally preferred distribution, while for values greater than 1, fibers are more circumferentially oriented. Our results show that medial elastin and collagen fibers distribution follow a very similar trend through the arterial wall. The fibers transitioned from longitudinally preferred orientation to mainly circumferentially oriented at about $70\mu\text{m}$ below the intima surface. Surprisingly, this transition happens rather abruptly, as shown by the steep increase in A_C/A_L . No clear trend was observed in the adventitial elastin and collagen fibers (results not shown).

Figure 3. Circumferential-to-longitudinal fibers ratio as a function of the imaging depth.

DISCUSSION

Here we studied the transmural variations in elastin and collagen fiber distributions using optically cleared samples and multi-photon microscopy. Optically cleared samples allowed a nearly fivefold increase in imaging depth from $40 - 60\mu\text{m}$ to more than $200\mu\text{m}$ without significant processing of the tissue, which could provide additional structural information of the ECM fibers in deeper layers of the arterial wall.

Our results show that both medial elastin and collagen fibers change their orientation throughout the arterial wall, from a longitudinally to circumferentially preferred orientation. The medial elastin and collagen fiber distributions follow a similar trend indicating the strong correlation of these two major load-bearing components in the arterial wall. The transmural transition in fiber orientation could be attributed to several functional reasons. The lumen surface of the arterial wall is subjected to shear stresses from the blood flow and the corresponding ECM fibers are longitudinally oriented to better accommodate such loading. On the other hand, the fibers in the medial layers of the artery are more circumferentially oriented to bear the large circumferential deformation from the pulsatile blood flow [3,4].

Future studies are underway to study the effect of the optical clearing method on the mechanical and structural properties of the arterial tissue and to understand the transmural variation in ECM fiber distributions with biaxial mechanical loading.

INTRODUCTION

Murine models of cardiac disease have played a crucial role in systematically exploring the contribution of underlying mechanisms toward disease pathophysiology¹⁻³. In this effort, *in vivo* imaging techniques have become an invaluable tool for assessing cardiac function, providing clinically-relevant metrics such as: ejection fraction, stroke volume, cardiac output, and left ventricular mass^{4, 5}. While high-field cine-MRI is often considered the gold-standard for studying cardiac function in mice due to its ease in imaging complex ventricular morphologies⁶⁻⁸, our group has recently developed and validated a high frequency four-dimensional ultrasound (4DUS) technique that provides higher spatiotemporal resolution, comparable cardiac volumetric measurements, and faster acquisitions compared to cine-MRI^{9, 10}.

Here we use our 4DUS data to develop a standard procedure for measuring myocardial deformations from volumetric endocardial and epicardial boundaries across the cardiac cycle, and subsequently use those to compare regional kinematics between animals. We apply this procedure to cohorts of wild-type mice and mice with genetically-induced cardiac hypertrophy and dysfunction, highlighting group-wise differences in temporal circumferential strain patterns.

METHODS

Animal Models: Six male mice with a genetically induced cardiac hypertrophy phenotype (*Nkx2-5^{l83P/+}*)¹¹, as well as a cohort of wild-type littermates, had 4DUS data acquired at 8 weeks of age. Following imaging at 8 weeks, mice from each cohort were sacrificed and excised hearts were weighed.

Ultrasound Imaging: All data was collected using the Vevo2100 high-frequency ultrasound system (FUJIFILM VisualSonics Inc, Toronto, Canada) with a 40 MHz center frequency transducer

(MS550D) and a linearly translating 3D motor. 4DUS data was created by collecting cardiac- and respiratory-gated planar image data at serial short-axis views across the left-ventricle (LV), and syncing data spatiotemporally in MATLAB (MathWorks Inc., Natick, MA).

Ventricular Boundary Definition: In order to set a standardized paradigm from which ventricular kinematics can be compared between animals, the following procedure was employed to define endocardial and epicardial boundaries:

1. 4DUS data is rotated to have the endocardial and epicardial apices, as well tissue between the aortic and mitral valves, all cross the same axis (Figure 1). This orientation defines the “kinematic axis”.
2. The through-plane location of the base, endocardial-apex, and epicardial-apex is manually tracked through the cardiac cycle.
3. Short-axis loops are extracted at positions corresponding to 0, 25, 50, and 75% the distance from the defined base to the endocardial-apex, thus mitigating changes in view due to through-plane motion (i.e. the relative position along the LV is maintained throughout the extracted cine-loop).

Figure 1. Three orthogonal views of 4DUS data demonstrating standard orientation and contours of the endocardial and epicardial boundaries. Both aortic valve (AoV) and mitral valve (MV) are noted on each long-axis view.

Figure 2. Circumferential strain (A) mapped to mouse-specific left-ventricular geometries across the cardiac cycle, and (B) as time-course plots, shown for a representative (top) control and (bottom) *Nkx2-5^{183P/+}* mouse at 8 weeks of age. All plots are scaled [-45,0] (%).

- For each cine-loop created in *Step 2*, six points around the kinematic axis (60° apart) are moved temporally to track the radial motion of each boundary (i.e. toward/away from the center of the LV chamber). Hobby-splines are drawn through the tracked points to ensure appropriate border definitions.
- Points from *Step 3* are then mapped to long-axis views at each 30-degree rotation around the kinematic axis, allowing users to further refine point-placements or spline-parameters.
- The finalized set of points and splines are used to interpolate a grid of standardized boundary locations for each respective time point: 40 equally-spaced long-axis positions from the LV apex to base by 40 positions circumferentially around the kinematic axis.

Circumferential Strain: For each of the 40 long-axis positions and time point across the cardiac cycle, the cumulative distance between each set of 40 circumferential points (i.e. slice perimeter) is calculated. Cauchy circumferential strain is then defined as:

$$Strain_t = \frac{L_t - L_0}{L_0} \quad [1]$$

where L represents the slice perimeter in millimeters at time point t .

RESULTS

The aforementioned procedure allowed us to quantify differences in circumferential strain between wild-type control and *Nkx2-5^{183P/+}* cohorts, which most notably occurred during systole and early diastole. Figure 2 displays these differences wherein lower magnitude strains (-30% vs. -45%), a less extensive systolic contraction wave from base to apex, and faster relaxation at the base of the heart are observed in the hypertrophic mice versus controls. These same trends are seemingly maintained when comparing time-courses averaged across each cohort (Figure 3). Of note, the differences between cohorts observed at the base of the heart during early diastole are not as prominent at the mid-ventricle or apex levels of the heart.

Figure 3. Time-course plots of circumferential strain averaged over (left) control and (middle) *Nkx2-5^{183P/+}* cohorts, respectively, and a plot (right) of the absolute difference between average time-courses (i.e. control - *Nkx2-5^{183P/+}*). Plots of averaged time-courses are scaled for circumferential strain [-45, 0] (%), and the absolute difference plot is scaled [-7, 0] (%). Notable differences are highlighted with (#1) a white line representing systole and (#2) a black oval closer to the base of the heart during early diastole.

DISCUSSION

By taking full advantage of information provided in 4DUS cardiac data and establishing a standard procedure for tracking local kinematics in the left ventricle, a comprehensive characterization of cardiac function can be obtained. This study focused on circumferential strain differences in a genetic model of cardiac hypertrophy (*Nkx2-5^{183P/+}*) and identified lower magnitude and less extensive systolic contraction waves in the hypertrophic hearts (Figure 3; #1). This is particularly interesting as these findings are from 8 weeks old; prior to when significant differences in global metrics of hypertrophy (e.g. LV mass) have been observed¹¹. This suggests that the effects of energy handling deficiency, induced in cardiomyocytes with the *Nkx2-5^{183P/+}* mutation, can be observed prior to significant ventricular hypertrophy and ejection fraction dysfunction¹².

Furthermore, the slower relaxation from peak systole seen at the base of the heart (Figure 3; #2) is suggestive of altered ventricular contractility. As blood flows into the ventricle from the left atrium, the compromised myocardium cannot resist the pressure from the initial inflow as well as wild-type controls. Taken together, the differences between cohorts could help better characterize the hallmarks of hypertrophy observed during disease progression.

Overall, these results show promise for the 4DUS technology and our standardized analysis paradigm to serve as a cost-effective and reliable tool for studying various mouse models of cardiac disease. Future work plans to both extend the breadth of kinematic metrics used and apply these techniques to additional cardiac disease models.

INTRODUCTION

Roughly 1 million Americans experience a heart attack each year [1]. Although the vast majority of patients survive the event, they are left with reduced cardiac function and an increased risk of heart failure [2]. This reduced cardiac pump performance is due in part to the immediate loss of functioning muscle and is exacerbated by the infarcted region distending and bulging during systole, thereby wasting energy. A wide variety of approaches have sought to mechanically reinforce the infarct zone to limit impairment of systolic function [3]. However, computational models and experimental studies have revealed that reinforcing the infarct also impairs the ability of the left ventricle (LV) to fill during diastole [4-6]. Overall, improvements in systolic function from reinforcement are offset by the reduction in diastolic function, resulting in little change in overall pump function.

As an alternative approach, we hypothesized that appropriately manipulating exponential passive material properties of the infarct could stiffen the infarct only during systole, and thereby improve systolic ejection without impairing diastolic filling. In this current study, we computationally tested this hypothesis using a previously developed finite element (FE) model of an infarcted canine LV.

METHODS

We utilized a previously validated FE model of the normal (baseline) and an acutely ischemic canine LV developed by our lab [7]. Briefly, an average geometry of the canine LV was generated based on CINE MRI scans from sixteen different dogs taken 48 hours post-infarction. A nearly-incompressible transversely isotropic Mooney-Rivlin (TIMR) material was used to simulate normal and ischemic myocardium, with fiber directions ranging from -60° in the epicardium to 60° in the endocardium. Active stress was calculated and generated along the fiber direction using a custom material plug-in. A large

anterior infarct was simulated by assigning 30% of the myocardium as an infarct that lacks active contraction. Active and passive material properties in the muscle region and passive material properties in the infarct region were optimized to match previously published experimental data [8], allowing us to simulate full pressure-volume relationships during a cardiac cycle.

To selectively stiffen the infarct during systole, we modified our fitted TIMR material parameters for the infarct region. The passive strain energy density is the sum of an isotropic (F_1), anisotropic (F_2), and penalty term to enforce incompressibility:

$$\Psi = F_1(I_1, I_2) + F_2(\lambda) + \frac{K}{2} [\ln(J)]^2 \quad (1)$$

where I_1, I_2 are the 1st and 2nd stretch invariants, λ is the fiber stretch, K is the bulk modulus, and J is the determinant of the deformation tensor. In this material model, the anisotropic passive fiber stress is evaluated as:

$$\lambda \frac{\partial F_2}{\partial \lambda} = \begin{cases} 0 & \lambda \leq 1 \\ C_3(e^{C_4(\lambda-1)} - 1) & 1 < \lambda < \lambda_m \\ C_5\lambda + C_6 & \lambda \geq \lambda_m \end{cases} \quad (2)$$

where C_3 and C_4 describe the exponential behavior during the toe region and initial engagement of fibers, C_5 describes the behavior once fibers are straightened and fully engaged, and C_6 enforces stress continuity at λ_m , the transition stretch between these two regimes. In our published model, λ_m was set to 10 so this transition never occurred. Herein, to preferentially stiffen the infarct at systolic pressures, we set $C_5 = 10000$ [kPa] and varied $\lambda_m = [1.2, 1.25, 1.3]$.

We simulated passive filling to calculate end-diastolic pressure volume relationships (EDPVRs). We generated end-systolic pressure volume relationships (ESPVRs) by applying the average pressure time course from the ischemia experiment and subsequently scaling this

pressure time course by 95% for 5 additional heart beats, corresponding to the expected pressure during occlusion of the inferior vena cava. We used the ED and ESPVRs to generate theoretical cardiac output curves by calculating the stroke volume at a heart rate of 106.7 [beats per sec], a systolic pressure of 85 [mmHg] and a range of filling pressures. All simulations were run using FEBio v.2.6.4 (<http://www.febio.org>).

RESULTS

Adjusting λ_m allowed us to selectively stiffen the infarct at high fiber stretches (in the range experienced by the fibers during systole) with limited impact on the infarct properties at low fiber stretches (in the range experienced by the fibers during diastole) (Fig.1). Specifically, smaller values of λ_m shifted the fiber stretch at which the stretch-stress curve transitioned into the stiffened region. The chosen value of $C_5 = 10000$ [kPa] led to ~10-fold increase in the maximum stiffness of the scar compared to the properties we previously determined for acutely ischemic canine myocardium.

Figure 1: Adjusting λ_m values leads to scar stiffening at high pressures. Plot of fiber stretch vs. stress for the original and new infarct material. Green lines represent varying values of λ_m .

Next, we tested whether changes in the infarct properties led to improved global systolic function without impairing diastolic filling (Fig.2). During passive inflation to 20 [mmHg], decreasing λ_m had little effect on the EDPVR. Conversely, decreasing λ_m shifted the ESPVR towards baseline and smaller end-systolic volumes. These shifts in the ESPVR increased the calculated cardiac output (Fig.3), indicating

Figure 2: Selectively stiffening the scar decreases end-systolic volumes without affecting end-diastolic volumes. Simulated end-diastolic (EDPVR) and end-systolic pressure volume relationships (ESPVR) for baseline (no scar), acute ischemia, and range of λ_m . Smaller values of λ_m led to bigger shifts towards baseline ESPVR.

enhanced LV function compared to the acute ischemia model. These benefits, however, were less substantial at higher end-diastolic pressures, where infarct stiffening did begin to affect filling.

Figure 3: Selective stiffening benefits LV global function. Theoretical cardiac output curves show a shift towards the baseline model, particularly at lower diastolic pressures.

DISCUSSION

In this study, we employed a computational approach to predict whether manipulating the passive material properties of a myocardial infarct could preferentially stiffen the infarct during systole and improve systolic function without impairing diastolic filling. We found that modifying infarct material properties to increase stiffness at high stresses shifted the ESPVRs, but not the EDPVRs, improving global systolic function without impairing filling. The increase in infarct stiffening allowed the remaining myocardium to pump more effectively, as shown by an increased cardiac output at matched diastolic and systolic pressures. This concept might provide a novel basis for designing synthetic patches or injection methods that could overcome limitations of previous attempts to mechanically reinforce infarcts.

One limitation of the simulations presented here is that they do not account for hemodynamic compensation mechanisms that could change in response to infarct stiffening. Constructing cardiac output curves at a fixed end-systolic pressure partially accounts for potential compensation by assuming that reflexes will maintain mean arterial pressure approximately constant. Fully understanding the impact of baroreflex regulation, however, will require coupling the presented FE model to a circulation model to account for compensations such as altered heart rate, systemic resistance, and others.

In conclusion, the computational study employed here suggests that preferentially stiffening the scar during systole is a promising approach for improving LV function following myocardial infarction.

INTRODUCTION

It is well-known that hypertension induces pathological remodeling in the left ventricle (LV). Specifically, hypertension has been shown to increase collagen volume fraction as well as passive stiffness in the heart [1, 2]. Hypertension is also known to affect the residual stress distribution in the LV—specifically, it decreases the opening angle [3]. Furthermore, we have recently shown that the interaction between myocytes and the collagen fiber network plays a key role in defining LV residual stresses [4]. For this reason, we hypothesize that hypertension also alters the inter-constituent mechanical interaction. To test this hypothesis, we have isolated the LV constituents of healthy and hypertensive rats, performed opening angle tests on them, and used this data to estimate possible forms of the interaction between the constituents in healthy and hypertensive tissue.

METHODS

Opening angle experiment - Whole hearts were extracted from 15 healthy (Sprague-Dawley, fed control diet) and 13 hypertensive (Dahl-Salt sensitive, fed 60% high fat diet) adult male rats. After the LV's were isolated, we obtained ring-shaped samples by cutting lateral slices from the whole heart. Then, the healthy and hypertensive LV's were split into three groups: intact tissue ($n = 5$, each), isolated collagen fibers ($n = 5$, each), and isolated myocytes ($n = 5$ healthy, 3 hypertensive). Samples from the intact tissue group were soaked in a Krebs buffer containing 2,3-butanediol, a myosin inhibitor, to relax the myocytes. Myocytes and collagen fibers were isolated through previously published protocols [4]. Then, classical opening angle tests were performed on all samples. The test consists of introducing a radial cut through the LV free-wall, allowing the sample to open and approach a nearly stress-free configuration. Each sample was allotted 90 minutes

to reach equilibrium, during which pictures of the sample were taken, then later used to measure the opening angle.

Modeling of interaction - A constrained mixture modeling framework was utilized to estimate the interaction between myocytes and collagen fibers in both healthy and hypertensive hearts. The inter-constituent interaction was modeled as an isochoric planar deformation—i.e. the collagen fibers “compress” or “stretch” the myocytes in the radial and circumferential directions. Briefly, we describe the interaction introducing a deformation gradient mapping from the unloaded configuration of the isolated constituents to the unloaded configuration of the intact tissue, Equations 1 and 2.

$$F^c = \text{diag} \left[\frac{1}{\alpha_c} \frac{\partial \rho}{\partial \rho_c}; \alpha_c \frac{\rho}{\rho_c}; \lambda_z \right] \quad (1)$$

$$F^m = \text{diag} \left[\frac{1}{\alpha_m} \frac{\partial \rho}{\partial \rho_c}; \alpha_m \frac{\rho}{\rho_c}; \lambda_z \right] \quad (2)$$

The interaction terms α_c and α_m represent the circumferential stretch due to the interaction of the collagen fibers and myocytes, respectively. We employed an isotropic exponential strain energy function to describe the mechanical behavior of each constituent. Then, the strain energy of the intact tissue was evaluated as the mass fraction-weighted average of the two constituents', Equation 3.

$$W^{tot} = \varphi_c [c_c (e^{k_c(l_1-3)} - 1)] + \varphi_m [c_m (e^{k_m(l_1-3)} - 1)] \quad (3)$$

Parameter estimation - The mechanical parameters, c_c , c_m , k_c , and k_m have been estimated by fitting experimental data from uniaxial ring tests of LV's collected from two healthy rats. Specifically, one ring was decellularized (isolated collagen fiber network), and one was treated

with collagenase (isolated myocytes). The mass fractions ϕ_c and ϕ_m were estimated by histological analysis or through literature review [1, 4, 5]. We assumed the mechanical behavior of the constituents is not altered by hypertension. Correspondingly, the only change with hypertension seen by our model will be mass fractions and interaction parameters.

After defining the parameter values in Equation 3, the model was used to find possible solutions for the interaction terms. Solutions were defined as combinations of α_c and α_m that allowed the model to reproduce the experimental results—i.e. to predict the correct experimental opening angle for intact tissue when appropriate tissue composition was considered. Two types of solutions will be presented here: a solution where $\alpha_m = 1$, and a solution where $\alpha_c = 1/\alpha_m$.

RESULTS

We found that the opening angle in the isolated collagen fibers was significantly higher compared to the intact tissue for both (healthy and hypertensive) groups of rats. The opening angle of the isolated myocytes was significantly lower than the intact tissue for the healthy rats ($p < 0.05$). However, this difference was not significant in the hypertensive rats ($p = 0.17$). Additionally, the intact tissue and the isolated collagen fibers of hypertensive LV's had a lower average opening angle than their respective healthy groups, however this difference was significant only in the isolated collagen fibers, Figure 1.

Figure 1. Comparison of opening angle between each experimental group. Error bars showing standard error (* represents $p < 0.05$).

We were able to fit material parameters to the ring test data well; the normalized root mean square deviation of both the isolated collagen fibers and myocytes was less than 5%. Our results show that the isolated collagen fibers were much stiffer than the myocytes, Figure 2.

Figure 2. Mechanical data and best-fit material parameters for isolated collagen fiber network and myocytes.

Based on histological analysis, we have determined $\phi_c = 0.1$ for healthy LV's. However, we do not currently have a measurement for this term in hypertensive LV's. While most studies report an overall increase in collagen area fraction with hypertension [1, 2, 5], there have

also been reports of no significant change [6]. For this study, we have used a range between the collagen area fraction measured for healthy rats and an upper limit found in literature, namely within the range $0.1 < \phi_c < 0.2$.

The “no interaction” ($\alpha_m = \alpha_c = 1$) solution was not valid for either the healthy or hypertensive models. Additionally, no solutions for the healthy and hypertensive were exactly equal. However, for the solution of $\alpha_m = 1$, the value of healthy α_c lies between the high and low values of the hypertensive α_c . For the solution of $\alpha_c = 1/\alpha_m$, though, as ϕ_c increases, the value for hypertensive α_m strays further away from healthy α_m .

Figure 3. Opening angle as a function of collagen inclusion shows the solutions for interactions of healthy (blue, CT) and hypertensive (red, HT) constituents. Left: solutions of the form $\alpha_m = 1$. Right: solutions of the form $\alpha_c = 1/\alpha_m$. The dots on each curve represent experimental measurements.

DISCUSSION

Our experimental results show that the collagen fibers seem to be the main contributor to residual stress within the LV, both in healthy and hypertensive hearts. However, it has been shown that although the collagen content may increase with hypertension, which might suggest an increase in the opening angle, the residual stress actually decreases. This has been illustrated both in the current study, despite having employed rats from two different strains, as well as a previous study on the intact tissue [3]. In this study, for the first time, we have shown that (1) the opening angle in the isolated collagen fibers also decreases with hypertension, while (2) the opening angle of isolated myocytes seems to not be affected by remodeling. A histological analysis of LV microstructure may help interpret these results.

The model showed that the interaction between myocytes and collagen fibers should not be ignored in either the healthy or the hypertensive LV. None of the solutions for the interactions terms that we have explored were common between the healthy and hypertensive models. Furthermore, it appears that the value of the interaction terms is highly affected by tissue composition. These results strongly suggest that with hypertension-induced remodeling of LV tissue, the interaction between the collagen fibers and myocytes is also changing. In the future, we will work to obtain constituent material parameters and collagen area fraction specific to the hypertensive LV.

BIOPRINTING 3D BREAST EPITHELIAL SPHEROIDS TO STUDY VASCULAR INTERACTIONS IN HUMAN CANCER

Swathi Swaminathan, Alisa Morss Clyne

Mechanical Engineering and Mechanics,
Drexel University, Philadelphia 19104

INTRODUCTION

Conventional 2D *in vitro* cancer cell culture fails to represent the tissue specific architecture, thereby providing a limited physiological model. Animal models recapitulate tissue architecture and whole organism physiology but may not accurately represent human disease. Therefore, physiologically relevant 3D human cancer models are a critical intermediary between conventional 2D *in vitro* culture and human disease. Biofabrication enables cells to be precisely deposited in a 3D structure, allowing improved spatial and temporal control over engineered tissue structure [1]. However, bioprinting based on layer by layer cell-bioink extrusion relies on rapid hierarchical cell self-assembly into 3D tissues. This self-assembly is time consuming and requires complex cellular interactions with extracellular matrix components, heterogeneous cell types and growth factors [2].

The objective of this study was to develop an entirely different approach to 3D tissue biomanufacturing. Rather than bioprint individual cells and wait for these cells to form their 3D architecture, we bioprinted multicellular building blocks (e.g., breast epithelial spheroids) to create a model tissue that could be used almost immediately. These pre-formed spheroids were then printed with endothelial cells to study chemotherapy response.

METHODS

Two breast epithelial cell lines were used. MCF-10A, an immortalized non-tumorigenic cell line that organizes into spheroids with a hollow lumen *in vitro*; and MCF10A-NeuN, an MCF10A cell line transfected to overexpress epidermal growth factor (EGF) receptor 2 (Neu/HER2/ErbB2), which yields a poor patient prognosis. Breast cell lines were cultured in DMEM/F12 with 5% horse serum, 20 ng/ml EGF, 10 µg/ml insulin, 10 ng/ml cholera toxin, 500 ng/ml hydrocortisone, and 1% penicillin-streptomycin. Breast cell lines were used to passage 25.

To create 3D breast spheroids, 4,000 breast epithelial cells were resuspended in medium with 20% Matrigel and seeded onto growth factor reduced Matrigel in an 8 chamber BioCoat Falcon Culture slide. Cells formed spheroids in 8 days. To grow endothelial networks, 5-10,000 red cell tracker labelled human umbilical vein endothelial cells (HUVEC) were added to Matrigel-coated wells in Endothelial Basal Medium-2. Cells formed tube-like structures within 6 hours.

3D breast spheroids were co-cultured with endothelial cells in two ways. First, the breast spheroids were carefully pipetted out of their wells and deposited onto the HUVEC networks. Alternatively, the 3D breast spheroids were bioprinted using a multi-nozzle solid freeform fabrication-based computer controlled direct cell writing system [3]. The system consists of three motion arms that allow micron-scale spatial control of material deposition as well as two screw driven motors that deposit biological material. An independent syringe heating enclosure provided temperature control of the bioink within the syringe. The bioink was composed of MCF10A and MCF10A-NeuN cells as either individual cells (200,000 cells/ml) or as spheroids and suspended in either Matrigel or collagen/alginate (3% alginate + 0.025% collagen in 0.9% sodium chloride). Bioink was microextruded using a screw-driven motor (1 mL/min, 25-gauge nozzle).

After 1 to 8 days, samples were fixed with 4% paraformaldehyde, blocked to prevent non-specific binding, and incubated with a primary antibody for integrin $\alpha 6$ (1:100, breast spheroids) or VE-cadherin (1:200, endothelium) overnight at 4°C. Samples were then incubated with an Alexa Fluor 488 secondary antibody (1:200) and Hoechst 33342 (10 µg/ml, nuclei) for one hour at room temperature. After thorough washing, samples were mounted on coverslips in Prolong gold antifade mounting agent and imaged in a Zeiss LSM 700 confocal microscope.

Cell viability in the presence of different doses of paclitaxel was assessed using resazurin. Conditioned medium from bioprinted

structures was transferred to a 96-well plate and incubated with 5% v/v resazurin (0.1 mg/mL) in phenol red-free DMEM medium for two hours at 37°C. Absorbance was measured in a microplate reader and data was collected at 570 nm using the Gen5 software.

RESULTS

We previously found that MCF10A cells killed HUVECs in 2D culture, while HUVECs prevented MCF10A spheroid formation when added into 3D culture. In this study, when pre-formed breast epithelial spheroids were pipetted on pre-formed endothelial networks, the spheroids preferentially attached to the endothelial networks and maintained network viability over 48 hours. Interestingly, over time the breast epithelial cells grew out of the spheroids and migrated along the endothelial networks. While MCF10A spheroids elongated over the endothelial networks after 72 hours of co-culture, MCF10A-NeuN spheroids elongated within 24 hours of co-culture (Figure 1) [4].

Figure 2: Bioprinted pre-formed spheroids maintained their morphology in both Matrigel and collagen/alginate. Inset (top right) shows hollow center plane of spheroids. Blue – nuclei and green – integrin $\alpha 6$. Scale bar = 100 μ m; Inset: Scale bar = 50 μ m.

were more resistant to Paclitaxel than individual breast cells, but co-culture with endothelial cells abrogated this effect (Figure 3).

Figure 3: Bioprinted preformed breast spheroids showed increased resistance to paclitaxel in comparison to individual breast cells, but co-culture with endothelial cells abrogated this effect. #p,0.05, ** p < 0.01, *** p < 0.001.

DISCUSSION

In this research, we showed for the first time that 3D cellular structures can be bioprinted while maintaining not only cell viability but also 3D architecture, polarization, and function. We bioprinted the 3D spheroids in alginate-based bioinks, which are largely inert other than the natural matrix proteins that we included. This shows that spheroids could likely be printed in a wide variety of bioinks, both natural and synthetic. We believe that 3D multicellular structure bioprinting has great potential to rapidly create tissue models, perhaps directly from patient cells, which better replicate the structure and function of the *in vivo* tumor microenvironment. Our method decreases the time between bioprinting and experimental assay from weeks to days; increases physiological relevance by allowing the investigator to more precisely control tissue architecture. In the future, we will bioprint breast spheroids onto an endothelial network or with microvascular fragments to create a vascularized breast cancer model.

ACKNOWLEDGEMENTS

We thank Dr. Mauricio Reginato for providing the breast cells.

While this technique demonstrated successful 3D co-culture of human breast epithelial and vascular endothelial cells, the method was limited in that spheroid location could not be controlled and Matrigel was still used. We therefore tested if the pre-formed breast spheroids could be bioprinted in Matrigel as well as less expensive, temperature insensitive bioinks such as collagen/alginate. We first tested whether individual MCF10A and MCF10A-NeuN cells would self-assemble into spheroids after printing in Matrigel or collagen/alginate. Although cell viability was maintained in both matrices, breast epithelial cells only formed spheroids in Matrigel but not in collagen- alginate bioink.

We then printed preformed breast spheroids in either Matrigel or collagen/alginate using the same printing parameters. After 48 hours, breast spheroids printed in either Matrigel or collagen/alginate maintained their 3D architecture, including the hollow lumen characteristic of MCF10A spheroids (Figure 2, inset in top right shows spheroid center plane). Bioprinted breast spheroids in either bioink maintained their 3D architecture for 96 hours (data not shown) [5].

Finally, we bioprinted both individual breast cells and the pre-formed breast spheroids in a grid structure with HUVECs to determine co-culture viability and chemotherapy response. In both cases, cells and spheroids were more than 80% viable. Interestingly, breast spheroids

FABRICATING 3D CELLULAR AGGREGATES VIA LASER DIRECT-WRITE BIOPRINTING: SIZE- AND SHAPE-CONTROLLED EMBRYOID BODIES AND TUMOR SPHEROIDS

INTRODUCTION

Multicellular 3D aggregates, such as embryoid bodies (EBs) and tumor spheroids, provide powerful *in vitro* models to study a wide range of biological processes for diagnostic and regenerative medicine applications. However, control of aggregate size and shape is necessary to recapitulate key *in vivo* parameters. For example, EB size has been shown to influence stem cell lineage specification [1–4], and the size of multicellular tumor spheroids (MCTSs) greatly affects model behavior: small spheroids (100-300 μm diameter) exhibit no gradient-related challenges in cell survival, larger sizes (500-1000 μm) often develop necrotic cores due to lack of sufficient nutrient/waste transport, and medium-sized spheroids (300-500 μm) develop biochemical gradients with discrete radial cell zones (*i.e.*, periphery cells are an active proliferating layer, and most inward are quiescent and/or hypoxic) [5,6].

Beyond size, the shape of cellular aggregates is also an important factor in model development. Size-related heterogeneity is, in part, due to spatiotemporal signaling effects, which are influenced by aggregate shape. Cellular aggregates are typically assumed to take on a spherical morphology, which is approximated by maximum intensity projection (MIP) images in the x-y plane using brightfield microscopy. However, recent evidence suggests that aggregate models can exhibit vastly different sizes and shapes, which can only be appreciated when analyzed in 3D [7]. Thus, both aggregate size and shape are crucial factors that can influence model behavior, with important implications in the development of the desired pathophysiological gradients [8].

Typical aggregate fabrication methods, *e.g.*, liquid overlay, hanging drops, provide modest control of aggregate size, and offer little-to-no control of aggregate shape. Herein, we aim to create size- and shape-controlled cellular aggregates (*e.g.*, EBs, MCTSs) using laser direct write (LDW) bioprinting, by patterning size-controlled cell-loaded microbeads that are then processed into core-shelled structures,

within which cells self-assemble to form 3D aggregates that grow to match the geometry of their printed shelled structure.

METHODS

Cell Maintenance. All experiments were conducted with either MDA-MB-231 human breast cancer cells (ATCC, Manassas, VA) or CCE Mouse Embryonic Stem cells (mESCs) (StemCell Technologies, Vancouver, BC, Canada). Tumor cells were cultured in Dublecco's Modification of Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum and 2 mM L- glutamine. Stem cells were grown in standard ES maintenance media with 15% fetal bovine serum, 1mM sodium pyruvate, 100 U mL⁻¹ penicillin/streptomycin, 2 mM L- Glutamine, 0.1 mM MEM non-essential amino acids, 10 ng mL⁻¹ leukemia inhibitory factor (LIF), and 100 μM monothioglycerol in DMEM high glucose. Cells were maintained in T-75 Flasks in a cell culture incubator (37 °C, 95% humidity, and 5% CO₂).

LDW Microbeads and Core-Shelled Structure Fabrication. LDW was utilized to 'single-step' fabricate and pattern alginate microbeads into arrays, or as voxels to produce larger continuous structures, as previously described [9]. Briefly, this technique uses two coplanar CAD/CAM controlled motorized stages: a print ribbon above an independently-controlled receiving substrate (**Figure 1a**). To print a bead, a pulse from an ArF excimer laser (193nm) volatilizes a sacrificial film on the underside of the print ribbon, ejecting a droplet of alginate suspending the biopayload (*i.e.*, MDA-MB-231 human breast cancer cells or CCE mESCs) from a transfer layer to the receiving substrate, where it is immobilized and crosslinked *in situ*. The droplet size is controlled by the beam diameter during deposition. For larger multi-bead structures, the between-droplet spacing is adjusted for overlapping voxels, and a continuous alginate structure is formed.

Core-shelled constructs were produced from printed-alginate structures by coating the printed beads with chitosan. This, in turn, created a polyelectrolyte-complexed layer of alginate and chitosan on the outside of the bead. Finally, sodium citrate is used to chelate the calcium crosslinking of the alginate bead, resulting in a polymeric shell surrounding a liquid core containing the cellular payload (**Figure 1b**). The encapsulated cells within these structures were then able to grow over the course of 14 days to produce MCTSs or EBs (**Figure 1c**).

Optical Coherence Tomography (OCT). OCT is a label-free, nondestructive/noninvasive imaging modality that enables 3D structural imaging of biological features with cellular resolution. OCT imaging was performed by a commercial spectral domain system (TEL220C1; Thorlabs Inc.). Cellular aggregates within core-shelled structures were visualized and quantified (*i.e.*, volume and sphericity) using Imaris image analysis software (v9.2, Bitplane USA, Concord, MA) [10].

Figure 1: Schematic of microbead LDW (A), processing into core-shelled structures (B), aggregate formation (C), and time-lapse of an array of alginate microbeads from day 0 (D), to 14-day EB (E).

RESULTS

Laser direct-write successfully fabricated and patterned large (400 μm) and small (200 μm) microbeads encapsulating cancer and stem cells in patterned arrays (600- μm centroid-to-centroid spacing) (**Figure 1d**). Consistent with prior work, arrays appeared to maintain pattern registry after conversion into core-shelled microcapsules [11]. Importantly, cancer cells and mESCs survived deposition from the print ribbon and processing into core-shelled microcapsule. Furthermore, within capsules, tumor cells and stem cells aggregated and self-assembled to form MCTSs and EBs, respectively, filling the entire capsule volume over 14 days (**Figure 1e**). It appeared that aggregate growth was confined to the geometry of the microcapsule shell, which determined the aggregate volume and shape. Resulting cellular aggregates appeared very densely packed, with a dark region attenuating light at the centroid.

Once LDW's ability to fabricate cellular aggregates from both cancer cells and mESCs was established, this work attempted to quantify the ability to control the size of the aggregate based on the core-shell structure dimensions. Three different core-shelled structures were fabricated (small microcapsule, large microcapsule, and micromat made of overlapping microbeads) and resulting 14 day aggregates were assessed with OCT and analyzed within Imaris (**Figure 2Ai-Aiii**). Core-shelled structures of different sizes produced aggregates of significantly different sizes, however cancer cells and mESCs within microcapsules of similar initial dimensions produced MCTSs and EBs of comparable volume (**Figure 2b**). Sphericity measurements (**Figure 2c**) revealed that both small and large mESC aggregates were highly spherical (0.986 ± 0.006 and 0.917 ± 0.017). Tumor aggregates similarly demonstrated

high sphericity in small microcapsules (0.976 ± 0.059), however this was significantly lower in large microcapsules (0.822 ± 0.049), and further reduced in the core-shelled micromats.

Figure 2: Volumetric scan of a 14-day EB grown in large (400 μm) capsule, collected via OCT and processed using Imaris analysis software (Ai-iii). Volume (B) and sphericity (C) of aggregates grown within small and large microcapsules and micromats, showing the ability to control aggregate size and shape via LDW.

DISCUSSION

For both multicellular tumor spheroids (MCTSs) and embryoid bodies (EBs), the aggregate size plays a key role in the phenotype of the individual cells, and the overall model behavior. This is, at least in part, explained by the development of nutrient (*e.g.*, oxygen and glucose) and cellular-signaling gradients within the aggregates. Thus, specific applications will require control of 3D aggregate size and shape to establish the desired pathophysiological gradients. Moreover, certain applications may demand precise aggregate positioning in the culture/construct to prescribe the desired homotypic/heterotypic cell signaling. Together, this spatial and geometric control is highly desired to create culture models that recapitulate key *in vivo* parameters. Herein, we demonstrate LDW's unique ability to create and spatially pattern size-controlled EBs and MCTSs. Overall, this bioprinting technique offers incredible promise for fabricating idealized *in vitro* models for mechanistic exploration, as well as tissue surrogates for a variety of diagnostic and regenerative medicine applications. Future work in this space will investigate the effects of aggregate size on cellular heterogeneity, a key factor in therapeutic resistance and differentiation.

FLUID-STRUCTURE INTERACTIONS AT DROP-DROP INTERFACE DURING DROP-ON-DEMAND PRINTING OF HYDROGEL-BASED SOFT MATERIALS

Cih Cheng, George T.-C. Chiu, Bumsoo Han

School of Mechanical Engineering
Purdue University
West Lafayette, IN, USA

INTRODUCTION

Hydrogel are widely used in numerous applications including healthcare, food, pharmaceutical, and cosmetic products [1], [2]. Moreover, recent advances in polymer sciences enable new emerging applications including smart sensors, stretchable and wearable electronics, and energy storage and conversion devices. To enable these new products as well as to improve current ones, it is crucial for manufacturing equipment and processes to have the capability of integrating these novel materials into three-dimensional (3D) parts with prescribed functional properties. However, hydrogel-based materials are very delicate and fragile to handle with conventional manufacturing methods.

Among various 3D printing techniques, drop-on-demand (DOD) printing shows great potential to address this manufacturing challenge. DOD printing may enable advanced additive manufacturing of functional soft materials by depositing hydrogel droplets with desired functional properties at desired positions with appropriate timing between adjacent droplets. However, it is currently extremely difficult to design DOD printing processes (i.e., when and where adjacent droplets should be deposited) due to limited mechanistic understanding of the behaviors of printed hydrogel droplets during and after deposition, which will eventually determine the functional properties of the printed products. These properties are elastic modulus, hydraulic conductivity and solute diffusivity, which are related to the microstructure of polymer matrix, specifically porosity. In contrast to liquid drop evaporation, gelation-dehydration kinetics of hydrogel ink droplet is poorly understood.

In the present study, we performed a computational study to establish a mechanistic understanding of the behaviors of hydrogel ink droplets during DOD printing processes for manufacturing of hydrogel

products. Specifically, we characterized the gelation of printed droplets and their concurrent and/or subsequent dehydration phenomena. This research is based on a hypothesis that a complex interaction between polymer matrix and interstitial water occurs during this dropwise gelation-dehydration as illustrated in Figure 1. The result of this interaction will determine the microstructural characteristics of polymers at intra-, inter-drop and inter-layer scales, ultimately the porosity of the hydrogel printed.

Figure 1: Schematic of intra-droplet fluid-matrix interactions during dehydration of a hydrogel droplet.

THEORETICAL BACKGROUND

Dehydration of two sequentially printed hydrogel droplets were computationally analyzed considering the drop-air and drop-drop interaction. Based on the one-droplet model developed in Han et al.[5], the fluid-matrix interaction in printed droplets were simulated using the consolidation equation and a boundary condition of balancing the vapor flux at the drop-air interface with the interstitial water flux. We assumed that gelation of hydrogel is a rapid process compared to dehydration process, so that gelation occurs instantaneously as droplets are deposited on the substrates. As illustrated in Figure 2, we formulated a

Figure 2: Computational Domain and Boundary Conditions.

boundary condition for the drop-drop interface to consider inter-droplet interaction as below:

$$\rho_w D \frac{\partial e}{\partial \hat{n}} \bigg|_{drop1} = \rho_w D \frac{\partial e}{\partial \hat{n}} \bigg|_{drop2} \quad (1)$$

This boundary condition represents the conservation of interstitial water flux between two droplets. At the interface, the water density and consolidation constant of the two droplets are assumed to be the same. Due to the pinning effect, the droplet diameter is assumed to remain constant during dehydration. These equations were numerically solved using a commercial finite element method (FEM) package (COMSOL Multiphysics). The consolidation equation was solved on the first droplet and subsequently the second droplet. The properties used in the computation are summarized in Table1 [3-9].

Table 1: Summary of the computational model

Parameters	Values
d (diameter of droplets)	500 μm
h (height of droplets)	250 μm
p (pitch)	200 μm
E (elastic modulus)	1000 Pa
K (hydraulic conductivity)	$1 \times 10^{-3} \text{ m}^2/\text{Pa}\cdot\text{s}$
ν (Poisson's ratio)	0.3
h_m (mass transfer coefficient)	0.01 m/s

RESULT

Figure 3 shows the dilatation contours and interstitial water flux vectors during dehydration of printed droplets. After a single droplet is printed (i.e., Step 1), a relatively high shrinkage (i.e., negative dilatation) is localized at the periphery of the droplet similar to the “coffee ring effect”, as shown in Figure 3(a). Dilatation increases from the periphery to the center. This implies interstitial water transports from the center to the periphery. Figure 3(b) shows the dilatation after deposition of the second droplet.

Figure 3: Droplet-dilatation and water flux during dehydration of printed droplets. (Contour plot at the substrate surface and cross-section contour plot with deformation gradient, i.e. water flux.).

The dilatation of the first droplet at the drop-drop interface significantly increases immediately after deposition of the second droplet. This suggests localized rehydration of the first droplet by the hydrated second droplet. A high degree of deformation is observed in the region of the drop-drop interface, indicating that rapid water transport occurs at the boundary of the two droplets. This change is thought to be caused by the large dilatation difference between a partly dehydrated droplet (1st one) and a fully hydrated droplet (2nd one). Accordingly, it is anticipated that high residual stress will be built up at the interface and may cause potential defects of the printed products. After the initially dehydrated drop has rehydrated, the interstitial water transport between two droplets is diminished at later time points (i.e., Figure 3 (c) and (d)). Evaporation becomes dominant in the 2nd droplet inducing outward water transport. Finally, the two droplets coalesce and dehydrate together like a single-drop case. The resulting two drops are not expected to have the same microstructural properties.

DISCUSSION

The present results suggest spatiotemporal variation of dilatation during curing (i.e., drying) of printed hydrogel, which is directly related to the porosity of polymer matrix, in printed drops. This variation could be explained by considering fluid-matrix interactions at the drop-drop interface. The drying process of droplets of various solutions, such as water, polymer suspension, blood, etc. has been well studied previously [10]. However, the most studies of droplet evaporation only focuses on one sessile droplet, which are not relevant to drop-drop interactions during DOD printing of hydrogels. The present computational model can provide a mechanistic explanation of the drop-drop interaction, and enable the prediction of spatiotemporal porosity, ultimately functional properties, of printed hydrogels.

DIRECTED SELF-ASSEMBLY OF 3D IN VITRO TISSUE MODELS USING DROPLET MICROFLUIDICS

INTRODUCTION

Vasculogenesis occurs in the developing embryo and results in a disorganized vascular network known as a plexus. By harnessing the cells' innate ability to self-assemble into vascular networks, we are able to fabricate large scale vascularized constructs of arbitrary geometries, allowing for a wide range of shapes and sizes and thus making this process ideal for various types of grafts or constructs [1]. A key feature of vascular self-assembly is that it closely recapitulates the *in vivo* processes of vasculogenesis and angiogenesis [2], especially in comparison to patterned models [3]. Physiological vascularized tissues display inherent heterogeneity in vessel size and extracellular matrix (ECM). We combined our bulk vasculogenesis-based method with a droplet-based 3D culture to achieve directed self-assembly whereby the cells are able to self-assemble in a quasi-deterministic manner based on environmental cues (Figure 1).

As a proof-of-concept of our customizable vascularized constructs, we have generated a 3D *in vitro* "minimal bone marrow niche." The bone marrow is a complex, heterogeneous structure that relies heavily on vascular signaling. It is the primary site of hematopoiesis, and in disease conditions, leukemogenesis. The architecture of the bone marrow is divided into two niches: the endosteal niche and the vascular niche [4]. Whereas it is tempting to consider these niches separately, there is evidence that a single hematopoietic stem cell (HSC) or leukemic stem cell (LSC) can be simultaneously regulated by cells of different niches [5]. We have developed an *in vitro* model that recapitulates both bone marrow niches. This minimal bone marrow niche incorporates osteoblasts and endothelial cells as each of these cells influence hematopoiesis and leukemogenesis. This platform allows for the assessment of cellular interactions and ECM properties in a complex pseudo-structured microenvironment. This directed self-assembly-based approach allows for assembly of vascularized microdomains with deterministic cell populations and defined matrix properties. The

stiffness and size of each droplet can be tuned to capture the heterogeneity of the *in vivo* tissue. Collagen is an ideal material for this application as it is the most abundant ECM protein in the bone marrow [6]. Accounting for the multifactorial influence of the bone marrow microenvironment will provide a more comprehensive understanding of HSC/LSC differentiation in the presence of stromal and vascular cells. As such, our model overcomes the limitations of single cell studies to investigate how the cells of the bone marrow niche work in concert to regulate hematopoiesis. These techniques can also be applied to the create large scale vascular networks.

Figure 1: Overview. (A) HUVECs embedded in a collagen gel self-assemble into a large scale vascular network called a plexus. (B) Seeding HSC/LSC-laden droplets with HUVECs results in a vascular bone marrow model. (scalebar= 200 μ m)

METHODS

Human umbilical vein endothelial cells (HUVECs) were cultured in EGM2, KG-1a (a leukemic stem cell line) were cultured in IMDM, and Saos-2 (osteoblast cell line) were cultured in McCoy's 5A. Collagen was freshly isolated from rat tails [3]. Each cell type was stained with a specific lipophilic membrane dye (Vybrant). KG-1a cells were encapsulated in collagen droplets using a flow-focusing droplet generator. Droplet size was modulated based on the flow rates of the dispersed and continuous phase. Microfluidic droplet generators were fabricated using standard photolithography approaches to generate SU-

8 silicon masters [7]. Replica molding and oxygen plasma treatment protocols were used to produce polydimethylsiloxane (PDMS)-glass microfluidic devices [8]. 3 mg/mL collagen was perfused as the dispersed phase, while Novec7500 fluorinated oil (3M) supplemented with 0.1125% Krytox 157 FSH oil (DuPont) served as the continuous phase. Droplet generation was imaged using a Fastec IL5 high speed camera. Collagen droplets were moved into media through solvent transfer and incubated overnight with the appropriate cells (HUVEC or Saos-2). Samples were imaged with a Zeiss confocal LSM880.

RESULTS

Using droplet microfluidics, we generated collagen droplets dispersed in a continuous phase of fluorinated oil (Figure 2). The flow-focusing device allowed for the creation of a range of droplet diameters by altering the flow rates. Resulting droplets were transferred from oil into media for cytocompatibility and subsequent culture.

Figure 2: Collagen droplets were generated through flow-focusing. (A) Droplet formation was captured using a high-speed camera (acquisition rate = 991 fps). (B) Cell-laden collagen droplets are formed in oil. (C) Droplets are monodisperse. (scalebar= 200 μm)

For initial studies in vascular self-assembly, collagen droplets were coated with HUVECs that were labeled with a lipophilic membrane dye. After individual droplets were coated with cells, the droplets were combined to aggregate them into larger constructs (Figure 3). This enabled the endothelial cells to proliferate and self-assemble a vascular network around the individual collagen droplets. The vascular lumens of the self-assembled constructs ranged in size, demonstrating that this method is effective at generating vessels at a variety of length scales.

Figure 3: HUVEC-coated collagen droplets form vascularized microtissues. Individual collagen droplets are coated with membrane dye-stained HUVECs (left). The droplets form aggregates leading to microtissues (center). The aggregates result in larger constructs containing lumens of varying sizes (right).

To generate a complex bone marrow tissue with microdomains consisting of vascular and endosteal niches, collagen droplets with an LSC line (KG-1a) encapsulated within were generated in the same fashion and coated with either HUVECs to mimic the bone marrow vascular niche or an osteoblast cell line (Saos-2) to mimic the endosteal niche. Cells were labeled with membrane dye prior to tissue generation, and confocal imaging confirms that the HUVEC and osteoblast-coated droplets containing the LSCs remained intact in culture (Figure 4).

Figure 4: Collagen droplets were used to generate a “minimal bone marrow niche.” (A) The vascular niche was modeled by coating LSC-laden droplets with HUVECs, and the (B) endosteal niche was modeled by coating LSC-laden droplets with osteoblasts. (C) Reflectance microscopy confirmed both niches formed surrounding the collagen droplets. (scalebars= 100 μm)

DISCUSSION

By harnessing the directed self-assembly of a droplet-based vascular network, we demonstrated a straightforward model that captures the heterogeneity of the bone marrow in an *in vitro* system. Existing *in vitro* bone marrow models are relatively straightforward and generally include two cell types (typically HSC/LSCs and osteoblasts) without accounting for the bone marrow vasculature. Given the important role the vasculature plays in the regulation of HSCs, models that do not incorporate vascular endothelial cells are missing critical soluble factors important for proper differentiation. 3D bone marrow models are proven to be superior to 2D models because soluble factors are prone to local accumulation [9]. Our 3D co-culture model consisting of LSCs, osteoblasts, and endothelial cells will recapitulate the complex interactions among the various bone marrow niches and can provide a mechanistic understanding of how neighboring cell-secreted chemokines impact LSC behavior.

This method can extend to the development of other vascularized tissue models by including other cell types. By incorporating defined regions of varying phenotypes, we can simultaneously capture multiple aspects of a heterogeneous tissue with regard to the vascular networks and the mechanical properties experienced by the cells. By exploiting and further controlling endothelial cells' tendency to self-assemble into networks, we are able to create networks of unprecedented size to study phenomena on varying length scales through vasculogenesis. Ongoing studies are focused on incorporating more stromal cells and expanding to other endothelial cell types.

INTRODUCTION

Ductal carcinoma in situ (DCIS) is an abnormal proliferation of premalignant luminal epithelial cells into the breast duct. Only 10-20% of DCIS cases progress from premalignant to malignant; however, there is no clinical tool to determine the likelihood of this transformation [1]. An *in vitro* ductal model of DCIS recapitulating *in vivo* progression to malignancy, by providing a clinical predictive tool, would significantly decrease morbidity and cost associated with prophylactic surgeries. Such a model has been difficult to create via conventional fabrication techniques. To address this, we use our previously developed Freeform Reversible Embedding of Suspended Hydrogels (FRESH) to 3D bioprint collagen-based scaffolds in complex, 3D geometries. Specifically, we FRESH printed full scale mammary ductal trees based on anatomical imaging data, as well as subcomponents of the ductal network to investigate cellular infiltration and remodeling of the engineered breast tissue constructs.

METHODS

Collagen scaffolds were FRESH bioprinted and then seeded with mammary cells. Briefly, FRESH works by embedding hydrogel bioink in a gelatin microparticle hydrogel support bath with yield stress behavior (fig. 1) [2]. Here, alginate and collagen type I bioinks were prepared as concentrated solutions of pre-polymers. For the hydrogel support bath, we utilized a gelatin microparticle slurry (20 μ m mean particle size) washed with CaCl₂ and Na-HEPES. 3D models were either generated or

Figure 1: Freeform embedding of suspended hydrogels 3D (FRESH) bioprinting. a) Cartoon demonstrating the Freeform Reversible Embedding of Suspended Hydrogels (FRESH) process. At 22 °C a hydrogel ink is extruded into a gelatin support bath and allowed to gel. After printing the support bath is thermoreversed at 37° C and the print can be retrieved.

derived from optical projection tomography imaging of mouse breast duct trees. Printing instructions were generated using the open-source slicing program Slic3r. 3D printing was carried out with a commercial desktop 3D printer fitted with custom open source syringe pump extruders. To extract printed constructs from the support bath, prints were released at 37°C to melt the gelatin microparticles and washed in a CaCl₂ Na-HEPES solution. All printing was conducted in sterile conditions or post-print sterilized with ethanol. Constructs were seeded with

MCF10A or primary human breast cells (from prophylactic mastectomies provided by collaborators at Magee-Women's Research Institute) and cultured for 14 days, after which they were fixed, stained, cleared with benzyl alcohol benzyl benzoate, and imaged using confocal fluorescence microscopy.

RESULTS

To demonstrate our ability to reproduce the full complexity of a breast ductal tree we printed a full-scale model generated from tomographic projection imaging (fig. 2a). This ductal tree had a collagen type I inner lumen surrounded by an alginate support structure. Reflectance confocal microscopy of the print surface showed geometric fidelity with the digital files (fig. 2b). To recapitulate a non-malignant breast duct, we printed a tubular construct from collagen type I and seeded it with healthy primary human breast cells (fig. 2c). Whole mount confocal imaging of these constructs reveals spreading and self-assembly into a confluent luminal and myoepithelial bilayer (fig. 2d, e). To

assess interactions of cancerous cells with our constructs, we printed an alginate reinforced collagen type I ductal end bud and seeded it with MCF10A cells (fig. 2f, g). Seeded cells produced confluent monolayers coating the end bud lumen (fig. 2h).

DISCUSSION

We have shown that we can utilize multi-material FRESH 3D bioprinting to produce complete ductal trees in full physiological detail. We have also demonstrated the printing of essential structural subcomponents of ductal trees, namely a ductal tube, and an end bud at relevant sizes compatible with cell seeding and whole mount fluorescence imaging. Additionally, we developed normal and malignant models by seeding constructs with either healthy human primary breast (from prophylactic mastectomies provided by collaborators at Magee-Women's Research Institute) or MCF10A cells. Together these steps move us closer to producing an *in vitro* model for studying progression of DCIS from premalignancy to malignancy that recapitulates the *in vivo* process.

INTRODUCTION

One of the major bottlenecks and cost drivers of cell-based therapies at this point is the manufacturing process that all too often is a scaled out version of the cumbersome manual laboratory procedures established during product development. Bioreactors have been adopted as an enabling technology for tissue engineering construct production, both for single cells and tissue culture. In contrast to static 2D culture in flasks or cell factories, bioreactors can incorporate sensors, allowing the identification and control of critical culture parameters such as temperature, pH, dissolved oxygen or the fluidic pattern (i.e. perfusion, mixing or agitation).

Integrating this information in order to monitor, control and optimize the bioreactor process requires the ability to combine different data sources, historic information as well as the already identified mechanisms of action of 3D tissue growth. In silico models (i.e. computer models) provide such a framework.

In this study, we describe the development of a perfusion bioreactor for cell expansion along with its digital twin, allowing for a precise monitoring, modeling and control of the cell culture process.

METHODS

A perfusion bioreactor was developed previously in our group, allowing for culture of cells in 3D printed scaffolds [1]. Seeding, harvesting, cell identity preservation and extracellular matrix production were investigated under various culture regimes (flow speed & refreshment regimes) [1-2]. A compact, benchtop version of the perfusion bioreactor set-up was recently developed [3], including connections for electronic and optical sensors at the chamber in- and outlet for environmental monitoring and control (Fig. 1). Scaffold filling, life/dead characterization, DNA content, overall glucose consumption and lactate production were tested to show the similarity

between the benchmark and compact system. All experiments were carried out with human Periosteal Derived Cells (hPDCs) seeded on 3D printed Titanium scaffolds (6mm ø, 6mm height) with either a diamond-shaped unit cell or a triple period minimal surface unit cell.

Figure 1: compact benchtop bioreactor. A: Illustration of the bioreactor housing with sensorized bioreactor chamber (right). B: Prototype of the bioreactor, highlighting the fluidic components of the recirculation loop and the internal configuration of the oxygenator

Based on observations made in a suite of experimental results obtained with a pilot version of the perfusion bioreactor set-up, a mechanistic computer model of the neotissue (cells + extracellular matrix) growth was developed [4]. The speed of neotissue growth (V_g) was observed to be influenced by local curvature ($g(\kappa)$), flow-induced shear stress ($f(\tau)$), oxygen ($h_1(C_o)$), glucose ($h_2(C_g)$) and lactate concentrations ($h_3(pH)$).

$$V_g = A_g \cdot f(\tau) \cdot g(\kappa) \cdot h_1(C_o) \cdot h_2(C_g) \cdot h_3(pH) \quad (1)$$

Neotissue growth was modeled in FREEFEM++ by means of the level set method whereby the neotissue growth was simulated by advecting the interface between neotissue and void space in the scaffold with the speed V_g defined as in Eq (1). Flow-induced shear stress was calculated from the Computational Flow Dynamics results. The other model variables were calculated based on Michaelis-Menten kinetics describing the spatio-temporal evolution of metabolic variables. Model convergence studies were executed to determine appropriate numerical implementation settings. The different model components were calibrated using in-house experimental data. Predictions on neotissue growth for two different triply periodic minimal surfaces (Gyroid, Dcup) were verified in a dedicated experimental set-up.

Finally, a reduced and reparametrized version of the model was developed (in MATLAB®) by homogenizing the equations over the scaffold volume. A reduction by 10^5 in computation time was obtained, allowing for rigorous single- and multiple objective optimization studies to determine bioreactor settings for maximal neotissue growth [5]. For this study, various evolutionary algorithms were used to perform the optimization.

RESULTS

Online monitoring of oxygen, glucose and lactate is now possible in the newly developed benchtop set-up. Comparing the results from the benchtop bioreactor and the benchmark showed no significant differences in terms of cumulative glucose consumption and lactate production (Fig. 2A), DNA content (Fig. 2B), Gene expression analysis showed similar gene signatures of the expanded populations in both systems.

Figure 2: Comparison compact benchtop bioreactor and benchmark. A: Cumulative lactate production over culture time. B: DNA quantification after 21 day culture.

Model predictions showed enhanced neotissue formation and lactate production for Gyroid scaffolds compared to Dcup scaffolds (Fig. 3A). Experimental results (Fig 3B) were quantified in 3D by contrast enhanced nanoCT imaging, confirming model predictions. The reduced model results (Fig. 3C) showed increased neotissue formation for frequent replacement of the bulk of the medium in the bioreactor. Taking into account the cost of culture (medium & labor

costs) shifted the optimal settings towards lower replacement frequencies and medium fractions.

Figure 3: Simulation results and model validation experiments. A: Simulation results for local oxygen concentrations and perfused fluid flow velocity in a Dcup (top) and Gyroid (bottom) titanium scaffold after 3 weeks of bioreactor culture. B: Life-dead staining of human periosteal cells cultured in the bioreactor for 3 weeks. C: Bayesian optimization of culture regime for maximum scaffold filling (color scale with red highest filling percentage) at 1 week.

DISCUSSION

The integrated development of a compact benchtop bioreactor along with its digital twin will provide, on the one hand, additional experimental read-outs for model credibility building and, on the other hand, the necessary real-world data for the development of real-time model-based monitoring and control algorithms for the culture process. This, in turn, will allow for the precise prediction and follow-up of neotissue formation in a 3D perfusion environment, which is an important step towards automation of cell expansion in the context of tissue engineering therapies.

INTRODUCTION

Pediatric anterior cruciate ligament (ACL) injuries are on the rise, increasing by 74% from 2001 to 2015 [1]. Concerningly, reinjury rates are 4-6 times higher in this population than in adults [2]. Additionally, there are differences in injury rates between sexes. Interestingly, females are at a higher risk of ACL tear than males during adolescence, but not during childhood [3]. Still, data is limited regarding the differences in maturation of the ACL between males and females throughout skeletal growth. In terms of orientation, data suggest increases in ACL-tibial plateau angle from birth to skeletal maturity in humans [4]. Sagittal and coronal ACL-tibial angles were significantly larger in females than in males (by ~2°) from 1 to 20 years of age, but no significant differences between sexes within individual age groups were found. ACL length has been shown to increase similarly in males and females through skeletal growth, diverging at adolescence where the ACL in males becomes longer than in females [5]. ACL cross-sectional area (CSA) has been found to be larger in males than females at skeletal maturity [6], but little data exists comparing the ACL CSA between males and females during growth. Little data is available investigating mid-substance CSA of the individual bundles (anteromedial (AM) and posterolateral (PL)) of the ACL during growth.

The porcine model is a common large animal model to study the musculoskeletal system, particularly the knee joint, and has been used to study the effects skeletal growth [7]. Our group has previously examined ACL orientation and size in female Yorkshire pigs [8]. Therefore, the objective of this study was to examine the orientation and size of the male porcine ACL throughout growth, and to compare these findings to previous data on the geometry and orientation of the female ACL throughout growth. We hypothesize that there are differences in ACL maturation between sexes, specifically that tissue orientation and size will diverge between males and females at adolescence.

METHODS

Hind limbs were collected from a total of 30 male Yorkshire pigs at 0 (newborn), 1.5 (early juvenile), 3 (juvenile), 4.5 (early adolescent), and 6 (early adolescent) months of age (n=6 per age group). Data was previously collected from the same number of female animals at the same ages [8]. All animals were cared for by the North Carolina University Swine Educational Unit, and all experimental protocols were approved by the North Carolina State University Institutional Animal Use and Care Committee. Hind limbs were harvested and the stifle joint was isolated from the animals immediately after euthanasia and prepared for magnetic resonance imaging (MRI). 0-month old limbs were imaged in a 9.4-Tesla Bruker BioSpec 94/30USR machine (Bruker BioSpin Corp, Billerica, MA) using a 3D fast low angle shot scan sequence (3D-FLASH, voxel size=0.1x0.1x0.1 mm). All other age groups were imaged in a 7.0-Tesla Siemens Magnetom machine (Siemens Healthineers, Erlangen, Germany) using a double echo steady state scan sequence (DESS, voxel size=0.42x0.42x0.4 mm). All joints were imaged at full extension.

Images were processed using commercial software (Simpleware). The angle of incidence of the ACL relative to the tibial plateau was calculated in the sagittal and coronal planes [8]. The AM and PL bundles of the ACL were segmented from all images, and exported as 3D models for size analysis using a custom MATLAB code. Bundle lengths were calculated as the length between the midpoint of the femoral and tibial insertions. Bundle CSA values were calculated as the average CSA of the middle 50% of each model. Statistical testing was performed using two-way ANOVA with age and sex as main effects and Tukey's post-hoc tests (JMP, $\alpha=0.05$).

RESULTS

MR images showed a general increase in size of the stifle joint and changes in the soft tissues within the joint (Fig. 1). Cartilage thickness and growth plate size greatly decreased relative to the size of the joint with increasing age.

Figure 1: Magnetic resonance images of male and female porcine stifle joints in the coronal plane at 1.5 and 6 months of age. Scale bars are 10 mm.

For both the coronal and sagittal angle of the ACL, statistically significant effects due to age, sex, and age-sex interaction were found ($p < 0.05$) (Fig. 2). Coronal angle increased by 18° and 28° from 0 to 6 months of age in males and females, respectively, and sagittal angle increased by 19° and 17° from 0 to 6 months of age in males and females, respectively ($p < 0.05$). Overall, coronal angle was 6° higher in females than males, pooled across ages ($p < 0.05$), and sagittal angle was 2° higher in males than females, pooled across ages ($p < 0.05$). Comparing data at specific age groups using post-hoc analyses, the coronal angle was 7° and 14° higher in females relative to males at 4.5 and 6 months, respectively ($p < 0.05$).

Figure 2: The orientation of the ACL relative to the tibial plateau in the coronal (A) and sagittal (B) planes. Statistical results of main effects shown in corner. Significance ($p < 0.05$) between sexes within an age group indicated (*). No age specific significance between sexes was detected in post-hoc analyses for sagittal angle.

Age, sex, and age-sex interaction also had statistically significant effects on CSA and length of both AM and PL bundles of the ACL ($p < 0.05$) (Fig. 3). Overall, all metrics increased with age ($p < 0.05$) and were larger in males than in females ($p < 0.05$). Comparing data at specific age groups using post-hoc analyses, AM length was 35% larger in males than females at both 1.5 and 3 months of age ($p < 0.05$). PL length was 52%, 39%, and 19% larger in males at 1.5, 3, and 4.5 months

of age, respectively ($p < 0.05$), and PL CSA was 41% greater in males at 6 months of age ($p < 0.05$).

Figure 3: Length (A) and CSA (B) of the AM and PL bundles of the ACL. Statistical results of main effects shown in corner. Significance ($p < 0.05$) between sexes within an age group indicated (*). No age specific significance between sexes was detected in post-hoc analyses for AM CSA.

DISCUSSION

In this study, we measured ACL orientation and geometry throughout growth in male and female pigs. Overall, all metrics increased with age, coronal ACL angle was higher in females than males, and ACL bundles were larger in length and CSA in males than females. The coronal angle and PL CSA data at the later age groups matched the literature describing steeper and smaller ACLs in human females than males after adolescence [4-6], partially confirming our hypothesis. However, we did not see a clear divergence in all metrics, particularly length, between males and females at early adolescence as originally hypothesized. This may be because the age range in this study is not broad enough to capture the differences in length between sexes throughout adolescence, since the oldest group is only at early to middle adolescence. In future work, we will study an additional age group to study late adolescence (18 months). The significant interaction between age and sex seen in nearly all metrics indicates that the manner in which the ACL grows with age is sex-dependent. Ongoing work will assess how sex-specific tissue properties may be related to differences in ACL injury rate between sexes during adolescence. Specifically, future work will be done to investigate this possibility by studying the biomechanical function of the ACL in males and females throughout growth.

DECORIN, ALONE AND IN TANDEM WITH BIGLYCAN, ALTERS VISCOELASTICITY IN AGED TENDONS

Ryan J. Leiphart, Snehal S. Shetye, Stephanie N. Weiss, Louis J. Soslowsky

McKay Orthopedic Research Laboratory, University of Pennsylvania, Philadelphia, PA, United States

INTRODUCTION

Risk of tendon injury increases with age, yet the age-associated changes to tendon tissue that lead to increased injury risk have yet to be elucidated [1]. Decorin (Dcn) and biglycan (Bgn) are small, leucine-rich proteoglycans (SLRPs) present in the tendon extracellular matrix that regulate collagen fibrillogenesis [2,3]. Both SLRPs are highly expressed during development, and conventional knockouts of either molecule impact tendon mechanical properties [4]. While knockout of decorin protects against age-associated reductions in tendon mechanical properties, acute deletion of biglycan or both SLRPs in mature tendons reduces mechanical and structural properties [5,6,7]. These results demonstrate that these SLRPs play a role in tendon homeostasis in addition to their role in development. However, the differential roles of these molecules in aged tendon homeostasis is unknown. Therefore, the objective of this study was to determine the effect of acute deletion of decorin, biglycan, or both SLRPs on aged tendon mechanics. Due to the negative impact of decorin during tendon aging and the positive impact of biglycan in tendon homeostasis, we hypothesized that acute deletion of biglycan would reduce tendon mechanical properties more than acute deletion of decorin, and that acute deletion of both SLRPs would result in similar mechanical properties to biglycan-deficient tendons.

METHODS

Animals: Female wild-type (WT) (n=6) and bitransgenic *Dcn^{flox/flox}* (n=11), *Bgn^{flox/flox}* (n=9), and *Dcn^{flox/flox}/Bgn^{flox/flox}* (n=15) mice with a tamoxifen (TM) inducible Cre were used in this study (IACUC approved). At 485 days old, mice received three consecutive daily TM injections (4mg/40g body weight) for Cre-mediated excision of targeted genes. Mice were sacrificed 30 days later (515 days of age). Patella-patellar tendon-tibia complexes were harvested from the left hind limb and prepared for mechanical testing as described [5].

Mechanical Testing: Uniaxial, viscoelastic testing was performed with an Instron 5848. The testing protocol consisted of 10 cycles of preconditioning, followed by stress relaxations at 3%, 4%, and 5% strain for 10 minutes. Following each stress relaxation, frequency sweeps of 10 cycles at 0.1, 1, 5, and 10 Hz were performed. A ramp-to-failure followed the final stress relaxation. Percent relaxation, dynamic modulus (E^*), and phase shift (δ) were computed for each stress relaxation and frequency sweep. Stiffness, modulus, maximum load, and maximum stress were quantified from the ramp-to-failure data.

Statistics: For all mechanical properties, one-way ANOVAs with Bonferroni post-hoc tests were used to compare across genotypes. Significance was set at $p < 0.05$, and trends were set at $p < 0.10$.

RESULTS

Quasi-Static Mechanics: No differences in CSA were observed between genotypes (data not shown). No differences in stiffness or maximum load were observed between genotypes (Fig 1). No differences in insertion or midsubstance modulus were observed between genotypes (Fig 2). *Dcn^{-/-}/Bgn^{-/-}* tendons had larger maximum stresses than *Dcn^{-/-}* tendons (data not shown).

Stress Relaxation: *Dcn^{-/-}/Bgn^{-/-}* tendons exhibited larger stress relaxations than WT and *Bgn^{-/-}* tendons at 3% and 4% strain (Fig 3). *Dcn^{-/-}* tendons exhibited a larger stress relaxation than WT tendons at 4% strain, and *Dcn^{-/-}/Bgn^{-/-}* tendons trended towards more stress relaxation than *Bgn^{-/-}* tendons at 5% strain.

Dynamic Mechanics: No differences in dynamic moduli were observed between genotypes at any strain level or frequency (data not shown). At 3% strain, *Dcn^{-/-}/Bgn^{-/-}* tendons had larger $\tan(\delta)$ values than WT tendons at all frequencies (Fig 4). *Dcn^{-/-}/Bgn^{-/-}* tendons had larger $\tan(\delta)$ values than *Bgn^{-/-}* tendons at 0.1Hz and 1Hz and trended towards larger $\tan(\delta)$ values at 5Hz. *Dcn^{-/-}* tendons trended towards larger $\tan(\delta)$ values than WT tendons at 5Hz and 10Hz. At 4% strain, *Dcn^{-/-}/Bgn^{-/-}* tendons had larger $\tan(\delta)$ values than WT tendons at 0.1Hz, 5Hz, and 10Hz (Fig 5). *Dcn^{-/-}/Bgn^{-/-}* tendons had larger $\tan(\delta)$ values than *Bgn^{-/-}* tendons at 0.1Hz and 5Hz and trended towards larger $\tan(\delta)$ values at 10Hz. *Dcn^{-/-}* tendons had larger $\tan(\delta)$ values than WT tendons at 1Hz and 10Hz, had larger $\tan(\delta)$ values than *Bgn^{-/-}* tendons at 1Hz, and trended towards larger $\tan(\delta)$ values than WT and *Bgn^{-/-}* tendons at 5Hz. At 5% strain, *Dcn^{-/-}/Bgn^{-/-}* tendons had larger $\tan(\delta)$ values than *Bgn^{-/-}* tendons at 0.1Hz and 1Hz (data not shown). *Dcn^{-/-}* tendons trended towards larger $\tan(\delta)$ values than *Bgn^{-/-}* tendons at 0.1Hz and 1Hz.

DISCUSSION

Induced knockout of decorin, biglycan, or both molecules in aged tendons did not impact quasi-static mechanical properties compared to WT tendons. Dynamic mechanical properties were also unaffected by genotype. Viscoelastic properties were most affected by both decorin knockouts, especially at low (3%) and intermediate (4%) strains. Deficiency of both decorin and biglycan led to increased viscoelasticity compared to WT and biglycan-deficient tendons at 3% and 4% strain. Deficiency in decorin alone led to some increases in viscoelasticity at the intermediate strain level compared to WT and biglycan-deficient tendons. The viscoelastic effects of decorin or decorin/biglycan deficiency were largely lost at the high (5%) strain level. These results run contrary to our hypothesis that deletion of biglycan would lead to

larger reductions in mechanical properties than decorin deletion and that double knockout tendons would have similar mechanical properties to biglycan-deficient tendons. Instead, knockout of both molecules led to large increases in viscoelastic properties, and some of these properties were increased with decorin deficiency alone.

Results demonstrate that decorin plays a larger role than biglycan in aged tendon mechanics. While no differences were observed between WT and *Bgn*^{-/-} tendons, *Dcn*^{-/-} tendons had increased viscoelastic properties compared to control tendons. While biglycan has been shown to impact mechanics in mature tendons, biglycan expression decreases with age [6,2]. This decreased expression may explain the negligible effect of biglycan deletion in aged tendons.

The structure-function role of decorin within the tendon matrix remains controversial. Conventional knockout of decorin impacts both quasi-static and viscoelastic properties of the patellar tendon [4,8]. Depletion of SLRP GAG chains in tail tendon fascicles, however, does not affect quasi-static and viscoelastic properties [9,10]. Results of this study support previous findings that decorin deficiency alters tendon viscoelastic properties at the tissue level.

The viscoelastic changes seen in decorin-deficient tendons were enhanced with the dual deletion of decorin and biglycan. Biglycan

expression has been shown to increase in response to induced deletion of decorin [11]. The *Dcn*^{-/-}/*Bgn*^{-/-} genotype eliminates this potential compensatory mechanism, which may explain the observed increases in viscoelastic properties in these tendons.

A limitation of this study is the small sample size used across groups, which may lead to certain parameters being underpowered. In addition, the mechanical changes observed lack a mechanistic explanation at this time. Future studies will analyze differential gene expression between these genotypes to better understand how decorin and biglycan together influence aged tendon mechanics.

This study reveals the role of decorin in the viscoelastic properties of aged tendons and demonstrates that biglycan may offset changes in these properties following the loss of decorin. These results provide further understanding of the role of SLRPs in the mechanical properties of aging tendons.

BATH OSMOLARITY ALTERS MULTISCALE MECHANICS AND DAMAGE IN TENDON

Ellen T. Bloom (1), Andrea H. Lee (1), Dawn M. Elliott (1)

University of Delaware
Newark, Delaware, USA

INTRODUCTION

Phosphate buffered saline (PBS) is a common choice for bathing solution in mechanical testing of biological tissue; however, even at physiological concentrations, the PBS bath causes increased hydration and decreased modulus in tendon and other tissues [1-3]. The physiological PBS bath also causes microstructural changes in tendon, by increasing collagen fibril diameter and interfibrillar spacing [3]. Beyond these observations, it remains unknown how a PBS bath solution may alter tendon multiscale mechanical behavior and damage. Our group has quantified tendon multiscale mechanics and damage, showing that microscale strain and sliding are related to tissue-level parameter changes after mechanical loading [4,5]. We hypothesize that increased tendon swelling and microstructural changes due to swelling in physiological PBS alter microscale sliding and increase tendon damage during tensile loading and that these effects can be mediated with a bath osmolality that maintains fresh tendon hydration. We have recently shown that by altering the osmolality of the bath using a combination of Tris-buffered saline (S) and 8% polyethylene glycol (PEG), which we defined as SPEG, the hydration and macroscale modulus of tendon is conserved compared to fresh tendon [2]. The objective of this study was to compare the effects of PBS and SPEG incubation on multiscale tendon mechanics and damage. The effect of bath solution on tissue mechanical behavior is critical knowledge that is necessary to interpret past work and design future studies.

METHODS

Sample Preparation: Rat tail tendon fascicles were harvested from 4-7 month-old female Long-Evans rats and tested in either physiological 0.15M PBS (n=8) or in 8% SPEG (n=7). Previous work showed that 8% SPEG maintains tendon's fresh frozen hydration and tensile modulus [2]. Following dissection, each sample was stained with 10 µg/ml 5-DTAF (Life Technologies).

Multiscale Mechanical Testing: Testing used an established protocol on a uniaxial device mounted on an inverted confocal microscope [4,5]. After gripping, a 0.1 N preload was used to define the reference length, 4 photobleached lines were made on the midportion, and each sample was preconditioned with 5 cycles to 2% grip strain. Testing included ramping each sample to 6% grip strain (baseline, i.e., pre-damage, Fig. 1A), holding for a 15-min relaxation, unloading to the initial length for a 40-min rest, then loading to failure (diagnostic, i.e., post-damage). All loading and unloading rates were 0.1%/s. Tissue-level parameters were calculated using displacement of ink markers measured via CCD camera (Fig. 1B, arrow).

Data Analysis: Tissue-level parameters were calculated via digital image correlation from the CCD images and included transition point, inflection point, and linear region modulus (Fig. 1A). The stress-strain curve from zero to the inflection point, here defined as the point where the curve shifts from strain-stiffening to strain-softening behavior [5],

Fig 1. (A) Representative loading curve showing Δ and tissue-level parameters; (B) configuration of sample in tester showing ink markers (arrows) and (C) photobleached lines during reference and deformed with loading.

was fit with a nonlinear constitutive model which optimized the transition strain and stress (end of the toe region) and linear region modulus [6]. These parameters were calculated for baseline and diagnostic ramps. Transverse strain was calculated from confocal images. To test the effect of bath osmolality between PBS and SPEG, a two-tailed t-test was used ($p=0.05$). To test for damage following mechanical loading (the difference between baseline and diagnostic) in each test (Fig. 1A), a two-tailed t-test was used ($p=0.05$).

Microscale parameters were measured using confocal images, from the deformation of photobleached lines, and included microscale strain (ϵ_r) and microscale sliding (γ) (Fig. 1C). Microscale strain was measured as the distance between the pairs of photobleached lines, and microscale sliding as the averaged tortuosity of the lines [4,5]. Non-recoverable sliding, a measure of microscale damage, was defined as the residual sliding that remained at the end of the 40-min rest period. An exponential decay function was fit to the microscale sliding recovery to quantify a time constant for sliding recovery.

RESULTS

Tissue-level Mechanics: At baseline, the SPEG group had a higher modulus compared to the PBS group (Fig. 2C), consistent with a previous study [2], and there was no difference between SPEG and PBS for transition and inflection point (Fig. 2A,B). At diagnostic, the modulus decreased compared to baseline for both SPEG and PBS, providing evidence that damage had occurred [4], however the modulus was no longer different between the two groups (Fig. 2C). At diagnostic, the transition strain was higher in SPEG compared to PBS. At diagnostic the inflection point strain increased for both groups compared to baseline, but there was no difference between SPEG and PBS. The transverse strain, measured from confocal images throughout the test, was significantly higher in SPEG compared to PBS immediately after loading ($t=0$), (Fig. 2D), however, there was no difference between the groups throughout the remainder of the test.

Microscale Mechanics: The microscale strain in the SPEG group was higher than PBS throughout loading, and was lower than PBS after unloading and throughout the recovery (Fig. 3A). Microscale sliding was not different between the SPEG and PBS groups and only partially recovered for both (Fig. 3B). Interestingly, the rate of the sliding recovery was significantly faster for SPEG (Fig. 3C), and the

Fig 2. (A-C) Tissue-level parameters during baseline and diagnostic. (D) Transverse strain fully recovered in both groups. Error bars show 95% CI and * # and + represent $p<0.05$, # and + between baseline and diagnostic within a group.

Fig 3. (A) Microscale strain and (B) sliding only partially recovered for both groups. (C) Time constant for sliding (SPEG $n=6$) and (D) non-recoverable sliding were smaller in SPEG samples. Error bars show 95% confidence interval and * represents $p<0.05$.

amount of non-recoverable sliding, a measure of microscale damage, was significantly lower for SPEG compared to PBS (Fig. 3D).

DISCUSSION

This study investigated the effect of bath solution on multiscale mechanics and damage in tendon by comparing PBS and SPEG, where the SPEG maintains fresh-frozen tissue hydration and physiological PBS swells the tissue. The tissue-level mechanical changes were consistent with previous work [1-3], as were the PBS group's tissue and microscale mechanics [4,5]. Importantly, we observed differences between PBS and SPEG in the tissue-level damage and the microscale mechanics. The increased ability of SPEG samples to recover microscale strain and sliding compared to PBS, suggests that swelling increases microscale damage. When tested in SPEG the sliding recovery is also faster (lower time constant) compared to PBS, suggesting that microscale viscoelasticity is affected by swelling. Whether this is due to fluid flow or intrinsic viscoelasticity is not yet known. Overall, these findings suggest that testing in PBS, where swelling is induced, not only affects the tissue-scale properties, but also affects the microscale mechanics, viscoelasticity, and damage.

This study shows that the osmolality of bath solution, which changes the sample hydration and tissue-scale mechanics, is important in tendon mechanical testing and also affects the microscale loading and mechanical damage. These tests were about 1 hour in duration and included a ramp, hold, and recovery. Previous work that has used physiological PBS as a bathing solution therefore likely swelled the tissue (depending on test duration), and those study results should be considered in light of the potential swelling effect. However, as long as appropriate controls were used to investigate the study hypotheses, reported findings are relevant. Future mechanical testing, particularly long duration tests such as cyclic fatigue, should consider using a SPEG bath solution with an osmolality that maintains fresh tissue water content.

MAGNETIC RESONANCE ELASTOGRAPHY OF THE HUMAN FOREARM DURING ISOMETRIC CONTRACTIONS

Daniel R. Smith (1), Andrea Zonnino (1), Peyton L. Delgorio (1), Raymond Duda (1), Fabrizio Sergi (1), Curtis L. Johnson (1)

University of Delaware
Newark, DE, USA

INTRODUCTION

Redundancy in the neuromuscular system enables humans to perform skilled motor tasks [1], though it is mostly unknown how the central nervous system manages and exploits redundancy, especially for fine motor tasks. Quantifying and analyzing the muscle co-activation could help in better understanding the mechanisms of fine motor control in neuromotor impairment. 40% of stroke survivors, or about two million United States citizens [2], are affected by upper motor neuron syndrome, which commonly leads to “abnormal coupling” of different muscle groups [3]. We propose to use magnetic resonance elastography (MRE) to study the coordinated action of multiple forearm muscles. MRE is a magnetic resonance imaging technique in which an external actuator generates shear waves that propagate through soft tissue. The wave motion is imaged with MRI, and then an inversion algorithm is used to solve for the tissue viscoelastic mechanical properties [4]. Other studies have shown the promise of using MRE to quantify the viscoelastic mechanical properties of skeletal muscle [5], including examinations of bicep muscle [6] and thigh muscle [7] stiffness with load or contraction, though forearm muscles and wrist torque contractions have yet been studied with MRE. Because viscoelastic properties of muscles are related to muscle force, as described by the short-range stiffness model [8], it may be possible to use MRE to ultimately estimate muscle force from viscoelastic properties. The purpose of this work is to quantify the mechanical changes to the forearm flexors and extensors measured via MRE in different isometric loading conditions (rest, flexion, extension).

METHODS

Subjects: We examined three healthy participants (2/1 M/F Age: 21-27) with a Siemens 3T Prisma scanner. Subjects laid headfirst and

prone in the bore of the scanner with their right arm in a forward posture in a custom device (Figure 1).

Figure 1: Experimental setup for the forearm MRE experiments

The custom device has three points of contact with the arm and hand: the passive driver for MRE under the belly of the forearm muscles; a strap to restrain the forearm; and a hand constraint against which force is applied during the experiments. A flexible MRI coil is constrained between the base of the device and the passive driver and then wrapped around the proximal forearm for imaging.

Imaging Protocol: MRE scans used an echo-planar imaging (EPI) MRE sequence with 3.0 mm isotropic resolution. Imaging parameters included: TR/TE = 1127/33 ms, FOV = 144 x 240 mm, 48 x 80 matrix, slices = 15. During MRE scans, vibrations were generated at 80 Hz using a pneumatic actuator (Resoundant) with a passive driver built into the custom forearm device. MRE scans were performed at three isometric contraction conditions (rest, flexion, and extension) with three repetitions of each series of contraction conditions. Two auxiliary isotropic T1-weighted anatomical scans (one acquired sagittally and one

acquired axially) were included for anatomical localization of individual muscles.

A follow-up experiment was performed on a single subject to observe muscle stiffness differences based on contraction intensity. MRE data was acquired with the participant instructed to perform wrist flexion and extension at both high and low torque levels. In this experiment we used a higher-resolution MRE scan with 2.0 mm isotropic resolution. Imaging parameters included: TR/TE = 2629/44 ms, FOV = 144 x 240 mm, matrix = 72 x 120, slices = 30. The higher resolution scans required three separate interleaved acquisitions to sample the entire displacement field necessary for mechanical property estimation, with the subject instructed to rest between contractions.

Analysis: We used a non-linear inversion algorithm (NLI) [9] to estimate the viscoelastic shear stiffness from the measured displacement fields (Figure 2). The stiffness is calculated from the complex shear modulus, $G = G' + iG''$, as $\mu = 2|G|^2/(G' + |G|)$. The shear stiffness describes the resistance of a viscoelastic solid to a harmonic shear forcing at the actuation frequency (80 Hz in this experiment).

Figure 2: A) Single slice of a T1-weighted anatomical scan of the forearm; B) the x, y, and z components of the wave motion in the same forearm slice; and C) the corresponding forearm stiffness map.

The T1-weighted anatomical scans were used to create regions-of-interest (ROIs) for each of the individual muscles with four flexors (flexor carpi radialis, flexor carpi ulnaris, flexor digitorum profundus, and flexor digitorum superficialis) and five extensors (brachioradialis, extensor carpi radialis brevis, extensor carpi radialis longus, extensor carpi ulnaris, extensor digitorum). We examined differences in muscle stiffness with contraction used a paired *t*-test after averaging each of the repetitions for each subject. We excluded MRE scans with low SNR from this analysis.

RESULTS

In the first experiment, we observed differences in the complex shear stiffness of the extensor muscles between rest (5.64 kPa) and both contraction conditions. The extensors significantly increased during extension (7.81 kPa; +38.5%; $p = 0.009$), and also increased during flexion, though this was not significant (6.65 kPa; +17.9 %; $p = 0.173$) across the subjects. We did not observe significant differences in the flexors between rest (5.91 kPa) and flexion (5.07 kPa; -16.5%; $p = 0.178$) or extension (5.21 kPa; -13.4%; $p = 0.122$) across the subjects.

Figure 3: Muscle stiffness changes at different contraction conditions: rest, extension, and flexion. A) Mean and standard deviation of stiffness across all extensor muscles for each subject and condition, and B) mean and standard deviation of stiffness across all flexor muscles for each subject and condition.

In the second experiment, multiple levels of contraction intensity resulted in an increased stiffness based on level of muscle activation (Figure 4). Both extensor and flexor muscles stiffened during agonist contraction, with greater stiffening at high torque. They also stiffened during antagonist contraction though to a lesser degree. These results are consistent with the previous experiment and revealed that flexor muscles likely behave similarly as extensor muscles, but with less overall stiffening during these contraction tasks.

Figure 4: A comparison of forearm MRE stiffness data from single slices through the flexor (top) and extensor (bottom) muscles during five activation states: high torque flexion, low torque flexion, rest, low torque extension, and high torque extension.

DISCUSSION

In this study, we observed stiffening in extensors whether they were acting as agonists or antagonists, though there appeared to be a higher stiffness, and therefore higher activation, during their agonist function. In this case, the extensor muscles act as we hypothesized: with increased stiffness during contraction, and more activation as agonists. Stiffening during antagonist function likely indicates co-contraction for stability during flexion. However, in the flexor muscles, we did not observe a significant change whether they were acting as agonists or as antagonists. The second experiment with multiple levels of contraction revealed that flexor muscles likely behave similarly as extensor muscles but with less overall stiffening. This observation is likely due to the use of higher imaging resolution for more accurate and reliable stiffness mapping. Additionally, this experiment indicated that stiffness during contraction is related to activation intensity, and likely force output. However, these scans took almost twice the time for data collection during each contraction state, which could introduce experimental challenges, such as muscle fatigue, due to the sustained contractile state. Future work will include exploring this possible limitation and counteracting it with accelerated data acquisition, as well the use of an MR-compatible force/torque sensor and visual feedback to control the level of contraction and correlate the levels of muscle stiffness to measurements of joint torque.

SEX-RELATED DIFFERENCES IN CARPAL ARCH MORPHOLOGY

Kishor Lakshminarayanan, Rakshit Shah, Zong-Ming Li

Cleveland, OH, USA

INTRODUCTION

Carpal tunnel syndrome (CTS) occurrence has a sex propensity with women being 3 times more likely to develop the condition [1]. One possible cause proposed for the higher incidence is that women have smaller wrist size than men [2]. The smaller wrist size in women also extends to a relatively smaller carpal tunnel cross-sectional area in women compared to men [3,4]. However, there was no sex-related differences in the relative carpal tunnel contents area [5]. Specifically, the relative median nerve cross-sectional area was not significantly different between the sexes [6]. The reduced available space for the tunnel contents in women could increase the likelihood of the median nerve getting compressed against the TCL. With median nerve being in close proximity to the TCL, investigating the sex-related differences in TCL-formed carpal arch morphology could provide insight into the higher incidence of CTS in women.

In addition to sex-related differences in carpal tunnel area, women have less compliant carpal tunnels compared to men [7]. Moreover, women have been shown to have a less elastic TCL than men [8] which may contribute to the reduced carpal tunnel compliance in women. Based on these evidences, it is possible that women have a predisposition for a reduced palmar bowing of the TCL compared to men. A less elastic TCL might not be able to palmarly bow adequately to accommodate for any reduction in available space for contents within the tunnel. Consequently, a reduced palmar bowing in women could make them more susceptible to median nerve compression by the TCL. However, to date, little is known about the differences in palmar bowing of the TCL between the sexes.

The purpose of this study was to determine whether the TCL-formed carpal arch would be different between healthy women and men at the distal and proximal carpal tunnel. The carpal arch was quantified

by palmar bowing (carpal arch height-to-width ratio). It was hypothesized that women would have smaller palmar bowing, especially in the distal tunnel.

METHODS

Twenty healthy young adults (10 women and 10 men) were recruited for the study. Subjects signed a written informed consent form approved by the Institutional Review Board before participating in the study. Subjects were asked to sit next to a testing table and place their right hand on the testing table with the shoulder abducted 30° and the elbow flexed 90°. The hand and wrist were then stabilized by a thermoplastic splint in a supine and anatomically neutral position

Fig. 1. Experimental setup for ultrasound imaging

(Fig. 1). Velcro® straps were used to secure the forearm, stabilize the four fingers in extension, and position the thumb in a naturally abducted position. An ultrasound system with a 18L6 HD linear array probe (Acuson S2000, Siemens Medical Solutions USA, Mountain View, CA, USA) was utilized for data collection. Ultrasound images were collected at the distal or proximal tunnel region. Three trials of ultrasonographic image collection were conducted at each tunnel level for each subject.

For each distal and proximal tunnel ultrasound image, the volar boundary of the TCL was manually traced along with the osseous attachment points (ridge of the trapezium and hook of the hamate at

distal tunnel and pisiform and scaphoid at proximal tunnel) using a custom LabVIEW program (Fig. 2). The traced TCL boundary and osseous insertion points were exported as calibrated image coordinates in mm for calculation of carpal arch width, and height. Arch width at distal or proximal tunnel was defined as the distance between the respective osseous attachment points of the TCL, and arch height was obtained as the maximal perpendicular distance of the TCL boundary points to the line along the arch width. The arch height was normalized with respect to the arch width as a palmar bowing index (PBI). The TCL tracing on the same image were performed three times and associated outcome data were averaged for statistical analyses.

Two-way mixed ANOVAs were used to determine the effect of sex (female and male) and location (distal and proximal) on the dependent variables of the arch height, width, and PBI. Post-hoc Bonferroni t-tests were used for all pairwise comparisons. Statistical analyses were performed using SigmaStat 4.0 (Systat Software Inc, San Jose, CA, USA). An α level of 0.05 was considered for statistical significance.

RESULTS

Arch height was significantly affected by the factors of sex ($p<0.001$) and location ($p<0.001$) (Fig. 3a), and their interaction was not significant ($p=0.918$). Females had significantly smaller arch height compared to men at both locations ($p<0.05$). At the distal tunnel, the arch height (0.9 ± 0.2 mm) for females was significantly smaller than the arch height (1.8 ± 0.4 mm) for males ($p<0.05$). At the proximal tunnel, females had an arch height of 4.3 ± 0.7 mm, which was significantly smaller than the arch height of 5.1 ± 0.6 mm for males ($p<0.05$).

Arch width was significantly affected by the factor of sex ($p<0.05$) but not location ($p=0.172$) (Fig. 3a). The interaction between sex and location also significantly affected the arch width ($p<0.05$). The arch width at the distal level (22.8 ± 1.1 mm) for females was not significantly different from the arch width (24.1 ± 2.3 mm, $p=0.09$) for males. At the proximal level, females had significantly smaller arch width compared to men (21.2 ± 1.4 mm vs. 24.4 ± 1.6 mm, $p<0.05$).

PBI as the arch height normalized with respect to the arch width was found to be significantly affected by the factors of sex ($p<0.05$) and location ($p<0.001$) (Fig. 3b), and their interaction was not significant ($p=0.154$). PBI was significantly smaller in females compared to males at the distal tunnel ($p<0.05$) but not the proximal tunnel ($p=0.465$). At the distal tunnel, females had a significantly smaller PBI of 0.04 ± 0.01 than the PBI for men which was 0.08 ± 0.01 ($p<0.05$). At the proximal tunnel, the PBI was not significantly different between the sexes (0.20 ± 0.03 for females and 0.21 ± 0.03 for males, $p=0.465$).

Fig. 2. Ultrasound images at each tunnel level (distal and proximal) for a representative male and female subject. The images reflect the selection for the traced TCL (solid line) and the landmark of interest - hook of hamate (H), ridge of the trapezium (T), pisiform (P), and scaphoid (S)

DISCUSSION

The evaluation of the TCL-formed carpal arch, and their differences between the sexes at the distal and proximal tunnels has

Fig. 3. The (a) arch width and height, and (b) palmar bowing index at the two tunnel levels (distal and proximal) for the two sexes (female and male)

delivered several key findings. The most significant of the findings is that females had a smaller palmar bowing than men. The palmar bowing (arch width-to-height ratio) had a pronounced reduction in females at the distal tunnel compared to the proximal tunnel. These findings support the findings of Monagle et al. [6] who reported a reduced palmar bowing in females compared to men at the distal tunnel level, but not at the proximal tunnel.

The reduced palmar bowing in females observed in our study could possibly be caused by the less compliant carpal tunnels in women compared to men observed by Li et al. [7]. The TCL being less elastic [9] but of similar thickness in women compared to men [9] may have contributed to the reduced tunnel compliance and consequently a reduced palmar bowing in women than men. Additionally, the pronounced reduction in palmar bowing at the distal tunnel compared to the proximal may have been contributed by the distal tunnel being narrower than the proximal [10], with the TCL being thicker distally [9-11] and less compliant than at the proximal tunnel [12].

The pronounced reduction in palmar bowing only at the distal tunnel in females compared to males show that women have a small and disproportionate TCL-formed arch. The small and disproportionate carpal arch observed in our study counter the debate that the females' naturally smaller wrists may predispose them to the development of CTS. The findings show that not just size difference but also sex-related differences inherent to the female anatomy makes women more susceptible to CTS than men.

Although women had smaller carpal tunnel area than men at both distal and proximal tunnels, the median nerve area at the distal tunnel was not different between the sexes [4]. In our study, the pronounced reduction in palmar bowing of the TCL in females could reduce the available space for the carpal tunnel contents including the median nerve at the distal tunnel. With median nerve being near the TCL and having no sex-related difference in nerve area at the distal tunnel, the reduced palmar bowing in females could predispose the median nerve to compression against the TCL. In conclusion, females having reduced palmar bowing than men, especially at the distal narrower end of the carpal tunnel might play an important role in higher incidence of CTS in women.

INTRODUCTION

Ultrasound is becoming a more popular tool for clinicians to diagnose musculoskeletal injuries (ie. tendon and ligament injuries). Currently, evaluation of tissue quality based on ultrasound images is mostly qualitative and depends on the user. Quantifying mechanical properties of tendons with ultrasound remains difficult [1]. Acoustic Radiation Force Impulse (ARFI) imaging is an ultrasound technique that generates a localized force onto the tissue of interest at a precise location and the resulting tissue displacement is measured [2]. Information about the resulting tissue displacement could lead to insights about the tissue's mechanical properties. ARFI imaging is primarily utilized for compliant, isotropic biological tissues such as the breast and liver to detect the presence of tumors [2,3]. However, the utility of ARFI imaging is not well understood for stiff, anisotropic biological tissues such as a tendon (tendon modulus in linear region: ~100s of MPa vs breast/liver ~kPa). Due to the high stiffness of tendons, ARFI imaging may only be possible at low loading levels, corresponding to the toe region of a stress-strain curve. However, to differentiate between damaged and un-damaged tendons, understanding the tendon modulus in the linear region is important. Furthermore, quantifying the mechanical properties of tendons with ultrasound techniques has not been established. Therefore, the objective of this study was to predict the tendon modulus in the linear region from ARFI data collected in the toe region of a stress-strain curve.

METHODS

Nine fresh-frozen cadaveric biceps tendons (55 ± 5 years) were harvested and prepared for tensile testing and ARFI imaging of the tendon midsubstance. The cross-sectional area of the tendon midsubstance was determined using a laser scanner (Next Engine, Desktop 3D Scanner, Santa Monica, CA, USA). For tensile testing, each

tendon underwent 1N preload, 1-10N preconditioning (10 cycles) and loaded to 30N. The ends of the tendon were clamped with custom soft tissue clamps and aligned for tensile loading in the materials testing machine (Instron, Model 5965, Norwood, MA, USA) and tendon midsubstance strain was measured with an optical tracking system (DMAS, Spica Technology, Kihei, HI, USA). The stress-strain data, representing the mechanical properties of the toe region, from loading the tendon to 30N was utilized for analysis.

For ARFI imaging, the tendon was loaded into a custom tensioning jig immersed in distilled water. For each tendon, ARFI images were acquired at 3 low stress levels within the toe region of the stress-strain curve (<1MPa and <20N) using a research ultrasound platform (Verasonics, VDAS V-1 Model, Redmond, WA, USA) and commercial linear array transducer (ATL L7-4). A localized radiation force at the tendon midsubstance was generated using a full-frame ARFI push (spatial resolution = 148 μ m) at the elevation focus of the transducer (25mm) for 1000 cycles at 5.2MHz. ARFI tendon displacement was tracked from post-ARFI push images and measured at the center area of the tendon to minimize boundary effects and used for analysis.

To predict the linear region modulus from toe region data, 4 steps needed to be accomplished. 1) Use ARFI tendon displacement data to predict the strain in the tendon. 2) Use predicted strain values and fit to the exponential approximation of a stress-strain curve to determine best fit model parameters. 3) Use model fit parameters to predict toe region modulus. 4) Use toe region modulus to predict linear region modulus. To validate our predictions, 6 of the 9 specimens were randomly chosen to establish the relationships. The remaining 3 specimens were used to validate predictions with experimental results.

Predict tendon strain from ARFI data: A linear regression was performed to determine the linear relationship between the measured strain acquired during tensile testing and ARFI tendon displacement

data. Equation 1 estimates tendon strain (ARFI strain) by describing the relationship between ARFI displacement data with increasing stress.

$$\text{ARFI Strain} = 1 - \frac{\text{ARFI Displacement}_{\text{Applied Stress}}}{\text{ARFI Displacement}_{\text{Lowest Applied Stress}}} \quad (1)$$

Similar to the classic strain equation (change in length divided by original length), Equation (1) evaluates the change in ARFI displacement with increasing stress with respect to ARFI displacement at the lowest applied stress.

Stress-strain curve model fit and relationship to toe region modulus: Using the estimated tendon strain from ARFI data (ARFI strain), equation 2 was utilized to approximate the stress-strain (σ - ϵ) relationship. Parameter A*B approximates initial stiffness [4]. A linear regression was then performed to relate A*B to the toe region modulus calculated from tensile testing. Toe region modulus was determined with a linear fit of the data up until 1% strain, maximizing the number of data points such that $r^2 > 0.9$.

$$\sigma(\epsilon) = A(e^{B\epsilon} - 1) \quad (2)$$

Predict linear region modulus: The mechanical testing protocol for the 9 specimens did not reach the linear region of the stress-strain curve (strain <3%). Therefore, a dataset of 16 previously tested fresh-frozen cadaveric biceps tendons were utilized to determine the relationship between the toe region modulus and linear region modulus. All specimens were non-destructively tested in tension and the tendon midsubstance reached the linear region of the stress-strain curve (strain >3%). Linear region modulus was determined with a linear fit from the end of the stress-strain curve, maximizing the number of data points such that $r^2 > 0.9$. A linear regression was used to establish the linear relationship between toe and linear region modulus. Significance was set at $p < 0.05$ for all relevant analyses.

RESULTS

Significant linear relationships were found for all steps in the process of predicting linear region modulus from toe region ARFI data. ARFI strain (defined in equation 1) was linearly related to the measured strain from tensile testing by a factor of 0.02 ($p < 0.05$, $r^2 = 0.562$). Average error between predicted ARFI strain and measured tendon strain was $63.6 \pm 45.9\%$. The toe region modulus was linearly correlated to parameter A*B by the relationship $y = 1.22x + 19.1$ (Figure 1). Predicting the linear relationship between the linear region modulus from the toe region modulus was also significant ($y = 4.5x + 14.7$, Figure 2). Comparing experimental results and predictions from the derived relationships, the magnitude of error for predicting model fit parameter A*B was $11.3 \pm 10.9\%$ and toe region modulus was $18.7 \pm 10.2\%$ (Table 1). Predicted linear region moduli ranged from 195.5 MPa to 299.7 MPa.

Table 1: Experimental data and model predictions from ARFI tendon displacement data

Tendon	A*B (MPa)		Toe Region Modulus (MPa)		Linear Modulus (MPa)
	Predicted	Actual	Predicted	Actual	Predicted
#1	34.8	38.8	63.7	91.4	273.9
#2	20.9	21.1	46.4	40.5	195.5
#3	39.4	50.9	69.4	78.1	299.7

DISCUSSION

The results of this study demonstrate the feasibility of predicting the linear region modulus of tendons from ARFI imaging data collected in the toe region using only linear relationships. Specifically, a strong relationship was found for predicting the linear region modulus once the toe region modulus is determined. Other ultrasound techniques such as shear wave elastography have only been able to describe relative changes in tendon stiffness [1,5]. All predicted values of toe and linear region moduli were physiologically reasonable. Preliminary tests indicated that ARFI imaging at stress levels in the linear region is not feasible since the tendon is too stiff for the acoustic radiation force to generate any measurable displacement.

Predicting tendon strain from ARFI displacement data was the limiting factor in terms of achieving the most accurate predictions (Equation 1). The equation chosen to estimate tendon strain (ARFI strain) from ARFI displacement data was chosen since it closely resembles the classic strain equation. Additionally, a linear relationship between ARFI strain and the measured tendon strain during mechanical testing was assumed. However, non-linear relationships may be needed to relate stress-strain with stress-ARFI displacement data since tendons are non-linear, viscoelastic, and transversely-isotropic. Nonetheless, errors less than 20% of the measured values for both model fit parameter A*B and toe region modulus are an encouraging first step.

This study serves as the foundation for future work in developing more sophisticated relationships to improve the accuracy of relating ARFI displacement data and tendon strain. With further development, ARFI imaging may be a viable approach to evaluate the linear region mechanical properties of tendons non-invasively and ultimately serve as a diagnostic tool for tendinopathies.

INTRODUCTION

Elastographic techniques, including both ultrasound elastography and magnetic resonance elastography (MRE) have great potential for non-invasive evaluation of the properties of soft tissues. MRE has been used to estimate parameters of linear elastic or viscoelastic material models in diverse tissues including skeletal muscle [1], liver [2, 3], and brain [4]. However, many biological tissues are nonlinear and anisotropic. Here we consider the use of MRE to estimate parameters of the Holzapfel-Gasser-Ogden (HGO) model, a simple and widely used nonlinear material model for fibrous biological soft tissues [5, 6].

MRE is based on MR imaging and analysis of shear waves in tissue excited by external vibrations. Typically, this tissue is assumed to be stress-free. For nonlinear materials, superimposing vibrations on a pre-deformed configuration alters the shear wave speeds due to changes in the linearized tissue stiffness. In this study we derived closed-form expressions for the relations between shear wave speeds and HGO model parameters in the reference (stress-free) and several pre-deformed configurations. These expressions were verified by analysis of displacement fields from numerical simulations. We demonstrate how these relationships can be used to estimate HGO model parameter values from MRE measurements of shear wave speeds.

METHODS

Theoretical values for wave speeds are found from the eigenvalue problem

$$\rho c^2 \mathbf{m} = \mathbf{Q}(\mathbf{n}) \cdot \mathbf{m}, \quad (1)$$

where $\mu = \rho c^2$ is the eigenvalue of acoustic tensor \mathbf{Q} , c is shear wave speed, \mathbf{n} is the propagation direction, and \mathbf{m} is the polarization direction vector of the wave. The acoustic tensor \mathbf{Q} can be expressed in Cartesian coordinates as:

$$Q_{ij} = A_{piqj} n_p n_q, \quad (2)$$

where \mathbf{A} is the (tangent) elasticity tensor which relates incremental strain and incremental stress.

In transversely isotropic fibrous materials, shear wave speed depends on both material properties and directions of propagation and polarization relative to fibers. For a given propagation direction, distinct eigenvalues of (1) correspond to speeds of “slow” and “fast” shear waves with different polarization directions. The slow and fast shear wave polarization directions in the reference configuration are:

$$\mathbf{m}_s = \frac{\mathbf{n} \times \mathbf{a}}{|\mathbf{n} \times \mathbf{a}|} \quad \mathbf{m}_f = \mathbf{n} \times \mathbf{m}_s \quad (3)$$

where \mathbf{a} is the fiber direction, \mathbf{m}_s and \mathbf{m}_f are the slow and fast polarization directions.

Figure 1 Waves of different polarization directions in transversely isotropic materials. (a) A “slow” wave involves displacements in the slow polarization direction, \mathbf{m}_s . (b) A “fast” shear wave involves displacement in the fast polarization direction, \mathbf{m}_f .

The HGO model is described comprehensively in [7]. It is defined by a strain energy density function containing volumetric (W_{vol}), isochoric (isotropic Neo-Hookean, W_{iso} , and anisotropic, W_{aniso}) terms:

$$W_{vol} = \frac{K}{2} (J - 1)^2, \quad W_{iso} = \frac{\mu}{2} (\bar{I}_1 - 3) \quad (4)$$

where K is the bulk modulus and μ is the shear modulus for small deformations. Many biological soft materials have shear moduli between 10^2 - 10^5 Pa, spanning acellular collagen and fibrin gels [8, 9] and muscle [10]. The anisotropic term can have different forms depending on fiber arrangement. The formulation proposed by Gasser et al. [11] accounts for the effects of fiber stretch in a single family of slender fibers with nonlinear properties and a distribution of orientations:

$$W_{\text{aniso}} = \frac{k_1}{2k_2} \{ \exp[k_2(\kappa \bar{I}_1 + (1 - 3\kappa)\bar{I}_4 - 1)^2] - 1 \}, \text{ for } \bar{I}_4 > 1 \quad (5)$$

We did not model the bi-linearity between fiber tension and compression ($\bar{I}_4 < 1$) in the HGO model.

Cauchy stress and (tangent) elasticity tensors in the HGO material are found by differentiating the strain energy density function:

$$A_{piqj} = F_{p\alpha} F_{q\beta} \frac{\partial^2 W}{\partial F_{i\alpha} \partial F_{j\beta}} \quad (6)$$

These tensors may be obtained in the reference or pre-deformed configurations; in general they depend on parameters μ, κ, k_1, k_2 , fiber angle ϕ , and pre-deformation (shear γ , e.g.). In each configuration, the acoustic tensor, \mathbf{Q} , may be found and used to determine wave speeds and directions from Eq. (1). These in turn also depend on the parameters of the model. Thus, in principle, shear wave speeds can be used to estimate HGO parameters.

Figure 2. Geometry of simulation domain. Green dashed lines represent vibrations in two perpendicular directions (X or Y). Red arrows show propagation direction along the negative Z-axis. Blue solid lines show fiber direction, where $\phi = 45^\circ$. One fiber family in (a) reference configuration and pre-deformed configuration of simple shear in the (b) XZ plane or (c) YZ plane.

For insight and efficiency of iterative parameter estimation methods, closed-form expressions that relate wave speeds to model parameters are highly desirable. Such expressions were determined from symbolic analysis of the eigenvalue problem (Eq. 1) for the pre-deformed configurations of Fig. 2b, 2c. Symbolic solutions were obtained with Matlab Symbolic Toolbox (Mathworks, Natick, MA).

$$c_{sxx} = \sqrt{\frac{\mu}{\rho} + 2 \frac{k_1}{\mu} \gamma_{xz}^2 M^2 \exp(M^2 k_2 \gamma_{xz}^2)} \quad (7)$$

$$c_{fxx} = \sqrt{\frac{\mu}{\rho} + \frac{k_1}{\mu} (N^2 + 6\gamma_{xz}^2 M^2 + 2\gamma_{xz}^4 k_2 M^2 (N^2 + 4\gamma_{xz}^2 M^2)) \exp(M^2 k_2 \gamma_{xz}^2)} \quad (8)$$

$$c_{syx} = \sqrt{\frac{\mu}{\rho} + 2 \frac{k_1}{\mu} \gamma_{yx} M (\gamma_{yx} M + N) \exp((\gamma_{yx} M + N)^2 k_2 \gamma_{yx}^2)} \quad (9)$$

$$c_{fyz} = \sqrt{\frac{\mu}{\rho} + \frac{k_1}{\mu} (N^2 + 6\gamma_{yz}^2 M^2 + 6\gamma_{yz} M N + 2\gamma_{yz}^2 (2\gamma_{yz} M + N)^2 (\gamma_{yz} M + N)^2) \exp((\gamma_{yz} M + N)^2 k_2 \gamma_{yz}^2)} \quad (10)$$

where (c_{sxx}, c_{fxx}) and (c_{syx}, c_{fyz}) are the slow and fast shear wave speeds for pre-deformations γ_{xz} and γ_{yz} respectively. The terms M and N are combinations of the dispersion parameter κ and the angle ϕ between the fiber and the propagation direction:

$$M = 2((1 - 3\kappa) \cos^2 \phi + \kappa); \quad N = (1 - 3\kappa) \sin 2\phi. \quad (11)$$

To verify analytical results, finite element (FE) simulations of shear wave propagation were performed using finite element software (COMSOL Multiphysics, Burlington, MA). Static pre-deformation and frequency-domain perturbation steps were performed in a cubic domain ($5 \times 5 \times 5$ mm³). The HGO model was implemented in COMSOL to

model elastic behavior; an isotropic loss factor of 0.1 was used to provide a small amount of viscoelastic damping. Frequency of excitation was 200 Hz, in order to provide multiple wavelengths in the domain. The domain was discretized into 5000 hexahedral elements. To demonstrate convergence, results were confirmed at higher resolution.

RESULTS

FE simulation results and theoretical predictions from the closed-form formulas for wave speed were compared for three conditions (no pre-deformation, simple shear in the XZ plane, and simple shear in the YZ plane). In Fig.3 below, the top row (panels a-e) displays c_f/c_0 , the normalized ratio between the fast wave speed and the isotropic, linear, shear wave speed $c_0 = \sqrt{\mu_0/\rho}$. Similarly, the bottom row (panels f-j) depicts the ratio c_s/c_0 . Parameters μ, k_1, k_2, κ , and γ_{yz} affect these ratios. Simulation results agree well with analytical predictions.

Figure 3. Relationships between fast and slow wave speeds and HGO model parameters (μ, k_1, κ, k_2) with simple shear γ_{yz} . Blue bars denote results from simulation; orange curves show analytical results. Default parameters are: $\mu_0 = 1000$ Pa, $\mu/\mu_0 = 1$, $k_1/\mu_0 = 2$, $\kappa = 1/12$, $k_2 = 5$, $K/\mu_0 = 10^4$, $\gamma_{yz} = 0.2$.

DISCUSSION

In materials that can be modeled as anisotropic, nonlinear, and nearly incompressible, slow and fast wave shear speeds can be measured from MRE and used to estimate parameters of the material model. In nonlinear anisotropic materials, unlike linear materials, pre-deformations in different directions may play an important role. Closed-form expressions for shear wave speeds in an HGO material, as functions of pre-deformation and material parameters, were derived and confirmed by numerical simulation. Wave speeds in different conditions (reference, or pre-deformation in simple shear in the XZ plane or YZ plane) showed excellent agreement between analytical predictions and simulation results. These results provide a new approach to parameter estimation for nonlinear material models of fibrous soft tissues.

SHOCK WAVE PROPAGATION IN BRAIN TISSUE

D. Keum, S. Assari, K. Darvish

Temple University
Philadelphia, PA, USA

INTRODUCTION

While Traumatic Brain Injury (TBI) continues to be the leading cause of accidental fatality [1], over the past decade, there has been a significant increase in the number of TBI incidents among military combat personnel [2] as a result of prominent use of Improvised Explosive Devices (IEDs). Previous studies have shown that brain tissue behaves like a nonlinear viscoelastic material. However, proposed material models were primarily developed for sports or motor vehicle injury applications [3]. Considering the nonlinearity and viscoelasticity observed in brain tissue, there has been an increasing need for better understanding of the material properties of brain tissue in higher loading rates.

The goal of this study was to enhance our understanding of the mechanical behavior of brain tissue at loading rates that resemble that of blast-induced TBI (BINT). A custom-designed high-rate shear test setup (HRS) was used to apply high-rate displacement rates that can cause a shear shock wave in brain tissue samples. The propagation of

the shear shock wave was investigated and compared with gelatin gel samples.

METHODS

Fresh bovine brains were used as test specimens because of their availability, having similar material properties as human brain [3], and their large size which makes extracting homogeneous samples more practical. The specimens were obtained from a local slaughter house with no visible damage to the brains. For maintaining their ionic balance and water content, the brains were kept in PBS solution immediately after purchase and kept at 5°C before testing that was conducted 3 to 6 hours post-mortem.

Cylindrical samples (n=6) were excised from 2 brain specimens from the corona radiata region approximately along the direction of axon fibers using an 8-mm diameter boring tool. Homogeneous samples with mainly white matter were selected for this study with approximately 10 mm height.

As it is schematically shown in **Figure 1.**, the test apparatus consisted of an actuator (piston) that was driven by a 2-in diameter shock tube with peak over pressure levels ranging from 150 kPa to 250 kPa. The sample was placed between two parallel plates (fixed with super glue) with the lower plate being pushed by the actuator. The top plate was connected to a 250 gram load cell (model 11, Honeywell) recorded at 50k samples/s and the sample deformation was recorded by a high speed camera at 10 kfps (Phantom v4.2, Vision Research).

Samples were tested with strain rate of bottom plate between 500 to 1000 s⁻¹ to investigate the shear wave propagation along the length of the sample. The deformation of the sample was captured using the high-speed video and quantified by tracking the markers placed along the length of the sample after image processing. Then the shear wave front was identified by a sharp change in angle of the markers with respect to

Figure 1. Schematic of the high-rate shear (HRS) test setup.

the vertical line. The effective shear wave velocity was calculated as the velocity of propagation of that sharp angle along the sample length.

The effective shear wave velocity was also calculated from the travel time of the shear force from the bottom plate to the top plate. This time period was measured in the recorded force-time history.

Gelatin gel has previously been used as a brain surrogate material. 5% and 10% gelatin gel samples with the same size as the brain samples were also tested to compare the characteristics of the shear wave propagation and their dependence on the material properties.

RESULTS AND DISCUSSION

The propagation of shear wave in a representative brain sample is shown in **Figure 2 top**. The corresponding force time history is given in the bottom figure, which shows the shear wave travel time, followed by a rapid rise in the force (about 0.5 ms) and then reducing to zero as a result of the sample failure.

Figure 2. (Top) Bovine brain tissue sample under high-rate shear deformation. The shear wave front propagating from the bottom plate to the top plate can be observed using high speed imaging. (Bottom) A representative shear force measurement is shown. The travel time of shear force from bottom plate to the top plate that is connected to the load cell is shown in this graph.

The shear wave speed is calculated at each marker location on the sample. **Figure 3 top** shows how the shear wave speed is changing as it propagates along the sample from bottom to top. As it can be seen, the shear wave speed is decreasing from about 4 m/s as it propagates along the sample and after about 50% distance it travels with an almost constant speed of about 2 m/s. The reported range of shear modulus for brain tissue, based on low to medium rate tests [4] is in the range of 2 to 4 kPa which corresponds to the shear wave velocity of 1.5 to 2 m/s. This range agrees with the constant elastic wave velocity obtained in this study. One possible explanation for reduction of the shear wave velocity could be that the wave is in the form of a shock wave at the initiation point and is therefore propagating faster than the elastic shear wave speed. The shear shock wave could have been generated because of the high rate loading input. The minimum displacement input velocity was about 6 m/s which is 3 times higher than the highest expected speed of elastic shear waves in brain tissue. The shock wave later disperses into elastic waves and its speed reduces. These results show that brain tissue is highly rate sensitive at strain rates that occur during BINT. Generation of shear shock waves could be crucial in causing injury in the tissue and further study is needed to investigate if the existing brain tissue material models can model such behavior in high rate loading conditions.

The results of gel tests showed that material properties not only affect the elastic shear wave velocity, they also affect the shear shock wave velocity (**Figure 3 bottom**). In the stiffer gel, the shear wave velocities were higher throughout the sample. The shock wave characteristics of 10% gel was very similar to brain.

In summary, the results of this study showed that shear shock waves can be produced in high loading rates that are experienced in brain tissue during BINT. The shockwave initial velocity and reduction of the velocity are properties of the material that need to be further characterized.

Figure 3. (Top) Calculated shear wave speed at different locations along the sample are shown for 5 representative bovine brain samples. (Bottom) Shows how the shear wave velocity can be different for different materials, here 5%, 10% gelatin gels in comparison with a bovine brain sample.

INTRODUCTION

Traumatic brain injury (TBI) is a recurring health concern, affecting as many as 2.8 million people each year in the US [1] and about 50% more especially amongst young athletes when unreported cases are considered [2]. Despite substantial research efforts in recent years, our physical understanding of how various brain substructures affect the progression of injury remains rather limited. Corpus callosum (CC), which is comprised of myelinated fibers is one of the regions of interest in mild TBI that has been poorly understood [3]. Hulkower *et al.* implemented diffusion tensor imaging (DTI) to identify fractional anisotropy (FA) abnormalities in the brains of TBI patients. They observed that white matter (WM) tracts such as CC, fornix, thalamus and hippocampus are among the most common brain regions with abnormal FA in the patients who suffered from TBI [4]. Hernandez *et al.* identified peak principal strain in the CC as one of the predictors of mTBI following a head impact [5]. Other studies also showed large amounts of strain near CC during impact, which hints at the importance of analyzing the link between the microstructural and mechanical properties of CC [6]. Myelin has been previously shown by Weickenmeier *et al.* to be a prominent factor in changing the WM stiffness [7]. Taking into account the importance of mechanical properties of the brain and how it affects the progression of injury, here we developed an experimental animal study in which the stiffness of CC in mice was decreased through local demyelination to investigate its role in response to mTBI. In the next step, we utilized a finite element (FE) simulation to

further analyze how mechanical stiffness variance of WM affect the strain patterns in the mice brain model

METHODS

Experimental animals and surgical procedures: In this study, we used young adult C57BL6/J mice (male; n=8; Jackson Laboratory) weighing between 25 and 30 g. All animal care, surgical and post-surgical procedures were IACUC-approved.

The animals were anesthetized with 3% sevoflurane and a midline incision was made at the top of their head. Stereotaxic equipment (calibrated relative to bregma) was used to drill a 2 mm hole into the skull. 1 μ L of a 1% lysolecithin solution - a toxic which has been previously shown to cause demyelination [8] - was injected into the CC of the first group of mice (n=4). In a similar procedure also 1 μ L PBS was injected into the CC of the second group of mice (n=4, control group). 3 days after the injection, mTBI was induced on the animals.

A modified weight drop (WD) impact acceleration model was used to induce mTBI [9]. A rod with a diameter of 3 mm and mass of 317 g raised to a height of 2.5 cm, was dropped at 1 mm rostral of coronal suture and 2 mm left of sagittal suture (Fig. 1A) of the mice which was anesthetized with sevoflurane and subcutaneously injected with lidocaine.

Mice were transcardially perfused 24 h after the WD. Dissected brains were incubated in formalin (24 h) then transferred to sucrose (48 h). Coronal brain sections (40 μ m) were obtained using a cryostat. Samples were stained with GFAP primary antibody (GFAP: Z0334, Dako) coupled to appropriate

secondaries in order to visualize damage localization and patterns of cell death. Fluorescent images were acquired and analyzed in ImageJ to quantify GFAP staining via a custom-made masking algorithm.

Finite Element Simulations: In order to replicate the effect of the change of stiffness on the patterns of injury in the mice brain, we utilized a murine FE model based on the atlas from the National High Magnetic Field Laboratory [10,11]. In this model a New Hookean material model using the properties in [12,13] was chosen. The brainstem and the bottom of the cortex of the FE model were pinned and a pressure of 10 N/mm^2 at 1 mm rostral of coronal suture and 2 mm left of sagittal suture was applied to the brain model. The responses for various k_{WM}/k_{GM} (white matter/ grey matter stiffness) were simulated and the strains developed in various regions of the brain were quantified.

RESULTS

We analyzed $n=8$ mouse brains and excluded one of the outliers from PBS injected group due to the issues with staining and fluorescence imaging. We observed a 27.1% increase in astrocyte activation in the body region of CC (*i.e.*, injection site) of subjects that experienced both the PBS injection and WD ($p=0.01$; Fig. 1B). Analyzing the regions above CC and near grey matter (GM), we did not observe substantial increase in astrocyte count of lysolecithin injected group (12.4% increase compared to the PBS injected group, $p=0.72$), which signals that more subjects are needed to be studied.

To further understand this phenomenon, we analyzed the strain patterns simulated in the FE model (Fig. 2). We observed that by varying k_{WM}/k_{GM} from 3.0 to 0.3 there is a significant change in the strain response (ϵ) pattern of the brain, from $\epsilon = 1.55 \times 10^{-1}$ to 1.93×10^{-1} , respectively.

Figure 1: Schematics of WD device and the inflammatory response of the mice brain. 1A) A modified WD model was implemented to induce a mild impact on the mice head. B) Immunofluorescent staining of the area surrounding the CC in coronal slices adjacent to the injection site (Red: reactive astrocytes (GFAP). Scale bar: $200 \mu\text{m}$).

Figure 2: Finite element simulation of the weight drop for various WM and GM stiffness ratios.

DISCUSSION

A comprehensive study into how varying mechanical properties of different brain sub-structures can affect TBI mechanism is crucial to better understand the role of each sub-region in injury mechanism. Here, we decreased the stiffness of CC thorough local demyelination, and observed significantly less astrocyte activation in the body of CC. Since the pediatric brain undergoes significant microstructural changes, including myelination [14], understanding the shielding effect of myelin in TBI could be crucial in understanding the injury mechanisms. Additionally, considering the vulnerability of CC to TBI especially amongst the children [15], this study further hints at the importance of understanding this region in injury patterns.

To further analyze our findings, we simulated this experiment with FE models. We observed that in the softest k_{WM} , the strain pattern is more diffuse, penetrating deep into the brain. This is in agreement with our experimental results, where we observed more diffuse astrocyte activation in demyelinated cases (Fig. 1B).

Our preliminary study further emphasizes the importance of studying how CC can affect injury metrics and hints that myelin in the CC acts as a mechanical shield to protect the brain from damage during mTBI.

Salt Lake City, Utah, USA

INTRODUCTION

Skull fracture is a common occurrence in both abusive head trauma and accidental trauma in children, but little is known about the intrinsic dynamic material properties of infant and toddler cranial bone. Early studies investigated quasistatic material properties of human infant bone and reported anisotropic and region-dependent results [1]. We previously evaluated infant and toddler skull at high strain-rates, but only tested specimens perpendicular to the dominant fiber direction [2]. In this study, we evaluate the dynamic material properties of the pediatric skull in the dominant fiber direction, and test the hypothesis that infant skull is a viscoelastic material.

METHODS

All human subject protocols were reviewed and approved by the Institutional Review Boards at the University of Utah and Primary Children's Hospital. Human cranial bone specimens were collected through autopsies performed by the Pathology Department at Primary Children's Hospital. Criteria for acceptance into the study were subjects ≤ 3 years old of age with no prior history of skull fracture, skull malformations, HIV, or hepatitis. Two cranial specimens, occipital and parietal, with the trabecular fibers oriented along the long axis of the specimen (parallel) were removed according to Figure 1 and frozen from each subject.

On the day of testing, frozen cranial samples were thawed to room temperature (25°C) in a phosphate buffered saline (PBS) solution. Samples were lightly machined under a constant drip of saline to produce a uniform thickness and shape, and tested within 1 hour of thawing.

Previously, we designed and validated a drop tower load frame to perform high-rate three-point flexural tests [2]. For this study, the drop tower was modified to reduce inertial effects, integrated with a higher

resolution laser displacement sensor (LK-G152, Keyence, Osaka, Japan), and instrumented with a new 25-lb load cell (Honeywell, Morris Plains, NJ) and amplifier (IAA100, Futek, Irvine, CA). The testing protocol and analysis were the same as previously reported [2], which were based on ASTM standard D790. Previously, we evaluated impact heights from 1, 2 and 3 feet. No significant differences with drop height were noted. Due to the limited number of specimens, only drops from 2 feet were used in this study. Per the ASTM standard, a minimum span to thickness ratio of 14:1 was maintained throughout the study.

Displacement (δ) and force (F) data were collected via laptop (MSI, New Taipei City, Taiwan) using a data acquisition system (Labview Signal Express 2015, National Instruments, Austin, TX) sampled at 10,000 Hz. A fourth order Butterworth low pass filter with a cut-off frequency of 800 Hz was used on each data set.

Figure 1: Specimen location and trabeculae fiber orientation.
Original skull image by Mikael Häggström, used with permission.

Elastic modulus (E) was calculated using the Bernoulli-Euler equation (1). Where $\left(\frac{F}{\delta}\right)$ is the force-displacement ratio during the linear elastic region of the three-point flexure test (Fig. 2), L is the span of the test, and I is the moment of inertia of the rectangular cross section of the specimen [3].

$$E = \left(\frac{F}{\delta}\right) \frac{L^3}{48I} \quad (1)$$

Figure 2: Force-displacement curve of a 4 week-old infant. F_{peak} and δ_{peak} are the maximum values for force and displacement, respectively. The diagonal red line represents the linear approximation used to calculate the bending modulus.

In-plane stress (σ_{xx}) was calculated using Timoshenko's corrected beam theory equation (2) which accounts for the radial tensile forces within the beam as a result of an applied concentrated load to the center of the beam [3].

$$\sigma_{xx} = \frac{3FL}{8wc^3}y - 0.133 \frac{F}{wc} \quad (2)$$

In this equation, F is the measured force, w is the specimen width, c is half the specimen thickness, and y is the location of interest on the outer surface of the specimen ($y = \pm c$). Ultimate stress (σ_{ult}) was calculated by using the maximum force (F_{peak} in Fig. 2) for F in equation (2).

Flexural strain (ϵ_f) for three-point bending was calculated from the relationship given by the ASTM standard D790.

$$\epsilon_f = \frac{5t\delta}{L^2} \quad (3)$$

Where δ is the deflection of the specimen, t is the thickness of the specimen. Ultimate strain (ϵ_{ult}) was selected as the flexural strain corresponding to the ultimate stress.

A correlation analysis was used to identify significant increases in E , σ_{ult} , and ϵ_f with age. A paired Student's t-test identified significant differences in material properties with region (parietal/occipital). A two-way ANOVA was used to identify significant differences in orientation (parallel vs. perpendicular) and region (parietal/occipital) when combined with data from our previous study [2]. Finally, parietal bone material properties were extracted from Kriewall and McPherson [1], Coats and Margulies [2], and the present study to evaluate the effects of rate and anisotropy on the material properties of human infant cranial bone. Significant differences were defined as $p < 0.05$.

RESULTS

Sixteen human pediatric cranial bone specimens were collected from 9 infant donors ranging from 32 weeks gestation to 10 months of age (Ave \pm SD: 9.053 \pm 17.78 weeks). Bending modulus (E) significantly increased with donor age ($p = 0.008$). Ultimate stress (σ_{ult}) also

increased with age, but variation was large and it did not reach significance ($p = 0.067$). E and σ_{ult} were generally higher in the parietal bone (E : 4807 \pm 2976 MPa; σ_{ult} : 108.5 \pm 42.28 MPa; Fig. 3) compared to the occipital bone (E : 3884 \pm 3016 MPa; σ_{ult} : 84.54 \pm 36.09 MPa), but this was not significant. E in infants < 1 month old was 10 times greater and σ_{ult} 8 times greater when tested parallel to the dominant fiber direction (E : 3471 \pm 1834 MPa; σ_{ult} : 90.12 \pm 23.70 MPa) compared to perpendicular to the fiber direction (E : 259.0 \pm 197.7 MPa; σ_{ult} : 17.65 \pm 21.27 MPa).

When data was combined with [1] and [2], E along the fiber direction was significantly greater than perpendicular to the fiber direction. This significant effect was stronger in infants < 1 month old ($p < 0.0001$) than in infants \geq 1 month old ($p = 0.025$). Strain-rate had a significant effect on E for infants \geq 1 month of age ($p < 0.026$), but not for infants < 1 month of age.

Figure 3: Bending modulus of parietal and occipital bones in infants < 1 month of age. Parallel data is from the present study and perpendicular is from [2]. * $p < 0.0001$ ** $p = 0.038$

DISCUSSION

In this study, bending modulus significantly increased with age. This is in agreement with other studies [1-2] and further supports the use of age-specific data when investigating pediatric head injury. The effect of specimen location when tested parallel to fiber orientation was not significant and differs from the effect of region (parietal/occipital) when tested perpendicular to fiber orientation [2]. This may be due to the low power from a small number of occipital specimens in the present study. Interestingly, strain-rate had no significant effect on modulus for infants < 1 month old, but modulus was significantly increased with increasing strain-rates for infants \geq 1-month-old. Adult skull exhibits a significant rate-dependence, and our findings may indicate the beginning of associated developmental changes from birth to adulthood.

Previous quasistatic studies report modulus is 3 times greater parallel to the trabeculae compared to perpendicular [1]. At high strain-rates, we found modulus was 10 times larger, signifying a rate-dependent effect on the anisotropy of the infant skull.

INTRODUCTION

During cranial impact with a large, rigid flat surface, the cranial point of contact bends inwards while the surrounding bone area bends outwards in a wave-like motion, resulting in cranial out-bending. Due to this globalized response of the skull, fracture location does not have to correspond to the place of contact [1] as demonstrated by Gurdjian et al. [2,3] in their pivotal stress coat and human head impact studies. This wave-like response of the head has more recently been observed by Fujiwara et al. [4] on occipital impacts of an anthropomorphic head model, demonstrating simultaneous cranial contractions of the occipital and frontal bones, with the parietal and temporal bones experiencing expansion, or out-bending. Interestingly, Griffen et al. [5] using case-based data demonstrates that occipital and frontal impacts result in transverse bilateral fractures of the temporal bone, with fractures perpendicular to the sagittal suture. Additionally, Weber et al. [6] using pediatric human specimens (0-8.2 months) demonstrates similar transverse bilateral fractures from a parieto-occipital impact in 1/15 impacts.

Bilateral fracture, i.e. symmetric fracturing over contralateral bones, is typically classified as a complicated skull fracture that is an indicator for child abuse [1]. The cause of these injuries is generally believed to be due to a crush scenario, or as a result of multiple impacts [1]. However, a detailed account of a therapist who witnessed an incident where a 6-week-old child fell backwards out of a stroller impacting the posterior midline (top) of the head on a stair, resulted in symmetric longitudinal bilateral fractures across both parietal bones, with fractures running parallel to the sagittal suture [7]. This case marks the first reliably reported instance of a single accidental impact resulting in bilateral fractures. Other cases attribute crush head injuries from being squeezed between two rigid surfaces such as a boot and the ground, or a body and a door resulting in similar bilateral fractures [8].

It is possible that a child's body weight can act as the opposing force in a crush-type injury from a head-over-heels fall.

As there are no known experimental studies that have consistently generated bilateral skull fractures, the purpose of the current study was to collect experimental evidence using infant porcine head specimens to test the hypothesis that cranial out-bending can produce direction-dependent bilateral fractures from top of the head impacts, back of the head impacts, and parieto-occipital impacts.

METHODS

A total of 30 infant porcine specimens (*Sus scrofa domestica*) from 1-22 days (4.0 ± 4.9 days) of age were collected from a local farm and frozen within 12 hours of death at -20°C . While frozen, the heads were removed from the body by cervical dislocation, labeled with age/head mass/specimen number, and remained at -20°C until testing. The specimens were thawed in room temperature 24 hours prior to the tests. All heads were screened by palpation of the scalp for pre-existing head trauma before each experiment. An approved IACUC exemption was obtained for the current study.

A custom drop tower was used in the current study to generate a single impact of the isolated heads against a flat aluminum plate (Figure 1) in three distinct locations of interest. The porcine head was impacted on top of the head at the posterior midline between both parietals ($N=10$), on the posterior right parietal bone as a parieto-occipital impact ($N=10$), and on mid-occipital ($N=10$) (Figure 2, row 1). From a preliminary study, the minimum drop height to produce fracture was $75.5 \pm 5.3\text{cm}$ for the parietal-occipital and top of the head impacts, and $116.8 \pm 2.5\text{cm}$ for the occipital impacts. These heights were therefore used in the current study. A single impact was performed for all specimens tested.

Figure 1: Experimental setup for infant porcine head impacts onto a flat plate.

The impact force generated by contact between the porcine skull and the impacting interface was measured over time with a 2500-lbf load transducer (model 1010AF-2.5K, Interface; Scottsdale, AZ) which was mounted below the fixed impact surface. The contact forces versus time were recorded at a sample rate of 10,000 Hz by a personal computer.

Following impact, the skull was palpated for fracture, and a viewing window was cut for photo documentation of the fracture patterns prior to heat maceration and cranial reassembly. All remaining soft tissues were removed by heat maceration of the skull in a mixture of water and laboratory detergent for four hours. After air-drying the bones, they were re-assembled and glued back together.

General Linear Model ANOVA in Minitab 16 (State College, PA) was used to analyze the impact energy, the overall peak contact force, the time to reach overall peak contact force, and the duration of impact time for each study group (top of the head impact, parieto-occipital impact, and mid-occipital impact). Statistical results were considered significant with $p < 0.05$.

RESULTS

Top of the head impacts generated 90% (9/10) longitudinal bilateral fractures (approximately parallel with the sagittal suture) in a mixed combination of both parietal and frontal bones (Figure 2, column 1, row 2). In contrast, back of the head impacts generated 60% (6/10) transverse bilateral fractures (approximately perpendicular to the sagittal suture) in both parietal bones and 20% (2/10) longitudinal fractures in both parietal bones. Of the occipital impacts 100% (10/10) had minor to extensive occipital fractures (Figure 2, column 3, row 2). The Parietal-occipital impacts produced 90% (9/10) fractures in non-impacted bones on both the impacted and non-impacted sides of the skull (Figure 2, column 2, row 2). Of these impacts, 78% (7/9) fractures into other bones were contiguous in nature, while 33% (3/9) were deflected diastatically along the suture and then continued into non-impacted bones. These patterns were similar to those from center-parietal impacts documented previously by this research team [9].

For the mechanical parameters of interest, the overall peak force (628.4 ± 227.9 N), time to overall peak force (4.9 ± 2.1 ms), and contact duration (13.7 ± 3.3 ms) were not statistically significantly

different between impact locations. As the required drop height to produce fracture was greater for occipital impact, the impact velocity (4.79 ± 0.05 m/s) and kinetic energy (7.7 ± 1.7 J) was greater for occipital impacts than those for the other impact locations. Parieto-occipital and top of the head impacts were not significantly different in terms of impact energy (5.1 ± 0.9 J) and drop velocity (3.85 ± 0.14 m/s).

Figure 2: Each column has its representative model of the porcine head orientation in contact with the flat plate (left), with the targeted impact location (red dot, right), and two representative skull reconstructions (with fracture lines in green) below.

DISCUSSION

The objective of the study was to determine if top of the head impacts, back of the head impacts, and parieto-occipital impacts onto a large, flat plate could produce bilateral cranial fractures consistently under a controlled, experimental setting using the infant porcine head specimens. The results of the current study showed that the head drop tests not only consistently produced bilateral skull fractures, but the fracture orientations also demonstrated a directional dependency to the impact location. Impacts to the top of the head consistently produced longitudinal bilateral fractures, as demonstrated in the Arnholtz et al.' case [7], while impacts to the back of the head as well as a small number of parietal-occipital impacts produced transverse bilateral fractures, supporting those observed in the Weber study [6] and Griffen et al. study [5].

It is important to note that this experimental fixture simulated a single-impact crush injury of the head where the weight of the guide trolley was included into the impact mass of the head. This study provides convincing evidence that a single head impact can produce symmetric cranial fractures in multiple bones, and that while bilateral fractures can be diagnostic of an abusive event, it may also be a symptom of an accidental head-over-heels fall that may result in a crush-type injury. Caution should be taken in interpreting these results for the pediatric subject, as the overall geometry, cranial thickness, and material properties specific to the infant porcine skull may influence the resulting fracture patterns.

INTRODUCTION

In 2011, after reviewing scalar on-field kinematics data leading concussion clinicians concluded “Recent studies suggest that a concussive injury threshold is elusive, and may, in fact, be irrelevant when predicting the clinical outcome”.¹ In 2014 the Institute of Medicine concluded that “Available studies of head injury biomechanics have identified the importance of linear and rotational movements of the head in injury causation...” and “there are currently inadequate data to define thresholds for linear and rotational acceleration specifically associated with concussions...”.²

It is likely that higher fidelity estimates of spatial and temporal impact parameters will clarify the currently unclear impact dose-response relationship.

The aim of this study was to investigate spatial and temporal estimates of head impact doses collected with a laboratory-calibrated impact monitoring mouthguard (IMM) system in American football. We first calibrated the IMM system in n=751 laboratory American football tests against instrumented Reference headforms. Next, we analyzed time-synchronized video and IMM data collected during n=445 player-games of high school and collegiate American football. Summary statistics on all impacts were synthesized. Cases where a player sustained impacts during a single play, or during a cumulative game’s-worth of plays, and on video was demonstrably witnessed to meet the NFL’s “No-go” criteria were analyzed in-depth.

METHODS

The IMM is an impact monitor that is instrumented with twelve channels of linear acceleration measurement at 3.2kHz (“12a”, **Figure 1**) and has been described elsewhere.^{4,5} Each IMM has an embedded flexible circuit board contained within FDA-grade mouthguard material. The IMM also includes a microprocessor, battery, wireless

charging, onboard storage and wireless data offload.

Figure 1. The Impact Monitoring Mouthguard (IMM) System.

To evaluate the quality of IMM impact estimates, we compared their spatial and temporal outputs versus instrumented Reference headforms in the laboratory for all tested directions/locations combined. For this comparison we used published head impact dosimeter validity specifications³⁻⁶. Laboratory calibration tests (n=751) generated first harmonic frequency content in the range of 20-100Hz, like what is seen on the field of play.⁴ Impacts were delivered using a linear pneumatic impactor and Hybrid III headform with fixed mandible (n=434) or articulating mandible (n=132), as well as using a pendulum with NOCSAE headform and fixed mandible (n=185).

After calibrating the IMM system against Reference in the laboratory, a total of 2851 video-verified head impacts were retrospectively identified from 445 player-games. Players with zero

head impacts during a game were not included in this analysis. Each event was time-synchronized to 30fps video collected of each game. Any events collected when the athlete was not being impacted in the head were identified as false positives and discarded. The remaining true positive events were scrutinized based on published methods to confirm a head impact occurred in the video and the computed motion was physically realistic and matched the video.⁷

RESULTS

In the laboratory testing, head impacts for IMM versus Reference fit a linear model close to the ideal form; $IMM=0.97*REF+1g$, $R^2=0.97$ (Figure 2). Non-trivial processing algorithm, adequate IMM coupling to dentition, knowledge of sensor positions and orientations with respect to Reference, and calibration of individual sensor outputs were required to achieve this level of accuracy.

Figure 2. Comparison of IMM versus Reference in Laboratory.

During on-field data and video analysis, there were approximately 13,000 triggering events captured, with $n=2851$ true positives confirmed after hardware and software filters were applied, along with the time synchronized video (Table 1).

# Video-verified Impacts	# Player-games	Average # Impacts/game		Impact Location ⁸	
2851	445	6.4		58% to Front, 30% to Sides	
Median PLA (g)	Median PAA (rad/s ²)	Median PLV (m/s)	Median PAV (rad/s)	Median KE Transfer (J)	Median RWE
21	1600	1.5	12	6	0.00002

Table 1. Summary from $n=2851$ Video-Verified Head Impacts

There were four (4) players with coronal plane impacts during a single play, three (3) players who sustained cumulative sagittal plane impacts during a game identified as “No-Go” candidates⁹

DISCUSSION

We found an average of 6 to 7 video-verified head impacts per player-game in this study, which is in line with published video-verified studies¹⁰ and approximately one order of magnitude lower than published studies without video verification.¹¹

For the four players with “No-go” single play impacts, all impacts were to the side of the players’ heads. Coronal plane impact sensitivity has been a hypothesized clinical injury mechanism¹² and our results support that hypothesis. However, other studies have pointed to top and front of head impacts as being the most dangerous.¹

The single play computed kinematics were in the top 5% of all impacts. We did not see high PLA/PAA impacts without obvious player “No-go” observations. This finding disagrees with other studies that have reported high PLA/PAA impacts without any demonstrable “No-go” observations¹³.

Also observed in single play “No-go” impacts, the kinetic energy transfer (40J to 110J) was an order of magnitude higher than the median (6J). This makes sense, as computational models predict substantially higher brain stress and strain when kinetic energy transfer is high in an impact^{14, 15}. On the contrary, the RWE metric¹⁶ was low for three of the four “No-go” single play impacts. This also makes sense as RWE values increase exponentially on a logistic regression above critical PLA and PAA values of $\sim 120g$ and 6000rad/s^2 . The PLA/PAA values in our analysis were generally lower than RWE critical values.

For the three players with “No-go” cumulative impacts, 75% of cumulative impacts were to the front of the players’ heads. The total KE transfer, 100J to 320J, was 1-2 orders of magnitude higher than the median value of 6J. Although the number of subjects is modest, this result could point to a spatial and temporal – within one gameday – tolerance to head impact in the frontal direction. It was interesting that the cumulative RWE was low for the “No-go” cumulative players. This can be explained by the fact that most of the cumulative impact doses had negligible RWE since only 15% of cumulative impacts were above 40g PLA or 3000rad/s^2 PAA.

INTRODUCTION

Most complex forms of congenital heart disease (CHD) require surgical repair during infancy [1]. A common post-operative complication of these early surgeries is branch pulmonary artery stenosis (PAS) [2-6] which is associated with both acute and chronic morbidity and mortality [7-9]. Catheter interventions with intravascular stenting are a first line therapy for post-surgical PAS in older patients and with technological advances this therapy is now being used in infants and small children. Little is known about the acute and chronic consequences of early stent therapy for treatment of post-surgical PAS occurring early in life or the capabilities of 4D Flow MRI to longitudinally define consequences of stent interventions with serial dilations in a porcine PAS model. We hypothesize that early stent interventions will allow for normal pulmonary vascular and lung parenchyma growth and normal branch PA flow distribution.

METHODS

Isolated left PAS was created in neonatal piglets (n=6, 5.4 kg) by suturing a short segment of 4.0mm Gore-Tex tube graft around the proximal left PA (LPA). Cardiac catheterizations with pre and post intervention MRI occurred at 6 (LPA stent), 12 (LPA stent dilation) (n=3). At 20 weeks all animals (n=9) had catheterization and imaging. From cone-beam CT angiography (Dyna CT) data sets the pulmonary arteries were segmented. Areas from centerlines were calculated for the RPA, LPA and six similar first order branch arteries. MRI was performed on a 3.0T scanner using the 4D Flow MRI sequence PC-VIPR (Phase Contrast Vastly Under sampled Projection Imaging) [10]. 4D Flow MRI quantitatively and qualitatively assessed cardiac and vascular blood flow. Analysis planes and streamlines are shown in Fig2D. Cardiac index (CI) is cardiac output (CO) normalized by bodyweight. LPA flow percentage equals LPA flow divided by CO measured in the MPA. Alveoli counts were obtained from R and L lung tissue samples. Statistical analysis is performed using ANOVA with post hoc hypothesis testing correcting for multiple comparisons.

RESULTS

RV, MPA and LPA pressures were similar in the interventions and sham controls while the stenosis controls had increased RV and MPA pressures with lack of pulsatility in the LPA (Table 1).

Figure 2A is a representative Dyna CT image the pulmonary vasculature of the three study groups. LPA 1st order branch artery areas (Fig 2B) were similar in sham and interventions, both of which were larger than the stenosis controls. RPA 1st order branch areas demonstrate the opposite trend (Fig 2C).

Figure 1: Experimental timeline showing stenosis surgery, LPA stenting, balloon dilation and final imaging for the early intervention group. Sham and stenosis controls only have imaging at 20 weeks.

Figure 2: 3D renderings of the pulmonary vasculature show altered stenosis morphology, **B.** Stenosis decreases the LPA 1st order branch areas and intervention increases the LPA 1st order branch areas to normal, **C.** Stenosis increases the RPA 1st order branch areas and intervention decreases the RPA 1st order branch areas to normal, **D.** 4D Flow MRI data is lost in the stent, but flow is still able to be analyzed proximal and distal to the stent, **E.** CI is greater in intervention animals than sham, **F.** Stenosis decreases LPA flow and intervention increases LPA flow, but not to normal levels, **G.** Longitudinal LPA flow percentage shows intervention improves LPA flow initially, then LPA flow remains constant.

Table 1: Pressure catheterization measurements

	Sham	Stenosis	Intervention
RV Pressure (mmHg)	29/8	40/10	29/6
MPA Pressure (mmHg)	30/15	39/18	29/14
LPA Pressure (mmHg)	29/17	15/13	23/14

The mean number of L lung alveoli were similar in sham and interventions and both were increased compared to stenosis controls. No differences were noted for the R lung alveolar counts (Fig3). Abnormal bronchiolar arterioles with significant medial hypertrophy and lack of normal pulmonary arterioles were present in the stenosis controls.

CI is greater in the intervention group than the sham group (Fig2E). Intervention improves LPA flow percentage compared to stenosis controls, 37% vs 9% ($p < 0.01$) (Fig2F). Intervention LPA flow percentage is still impaired compared to sham controls, 37% vs 54%. The initial intervention increase LPA flow percentage from 17% to 34%, then remains relatively constant (Fig2G) despite stent dilation at 12 weeks and additional time for growth.

Figure 3: Representative lung histology for **A.** Sham, **B.** Stenosis, **C.** Intervention, showing that **D.** intervention preserves left lung alveoli

DISCUSSION

In this animal model of surgical PAS, early stent intervention normalized R heart pressures, was associated with a trend towards improved growth of the first order branches of the LPA and allowed for improved pulmonary development, as demonstrated by normal L lung alveolar counts and normal appearing pulmonary arterioles. Despite “successful interventions” percentage of L lung pulmonary blood flow was significantly decreased compared to sham controls. This persistent flow discrepancy did not compromise cardiac output as estimated by MRI imaging.

More broadly, this study demonstrates the capability of 4D-flow MRI to comprehensively examine the acute and chronic effects of minimally invasive interventions. While MRI signal is lost due to the stent material artifact, flow can still be quantified proximal and distal to the stent. For longitudinal studies looking at the time course of an intervention, 4D flow MRI is non-invasive unlike heart catheterization and provides greater information than other non-invasive modalities like ultrasound and nuclear medicine perfusion scans.

Future work will include additional PA stenting animals ($n=10$ total) compared to sham and untreated stenosis controls and analyze ventricle function using 4D flow metrics of kinetic energy and vorticity.

INTRODUCTION

Congenital Heart Defects (CHDs) occur in approximately 1% of all live births and are the leading cause of mortality in infants and small children[1]. Malformations of the left ventricle are among the most serious of CHDs. It has been established that altered hemodynamics can lead to the development of CHDs, especially malformations of the left ventricle such as Hypoplastic Left Heart Syndrome (HLHS); however, the specific mechanism by which hemodynamics affects ventricular growth is still poorly understood [2, 3]. The fetal heart grows primarily through proliferation of cardiomyocytes (CMs) [4]. Endothelial secreted neuregulin-1 (NRG) has been suggested as a potential therapeutic target to promote CM proliferation [5]. Recently, it has been shown that ECs secrete NRG in response to mechanical and biochemical cues [6]. *We hypothesized that fluid shear stresses may modulate communication between endothelial cells (ECs) and CMs, and that altered shear stress in congenital pathologies may affect CM proliferation.*

METHODS

To assess the proliferative effects of NRG on cardiomyocytes we exposed neonatal rat cardiomyocytes (NRCMs) cultured on either tissue culture plastic or tissue culture plastic coated with solubilized fetal cardiac extracellular matrix (ECM) to exogenous NRG. NRCMs were cultured with serum-free media containing either 200 ng/mL of NRG, 100 ng/mL of NRG, or no NRG. After 24 hours and 5 days, cells were fixed with 4% paraformaldehyde, labeled with anti-cardiac α -actin and anti-Ki67 (a proliferative marker), and imaged using an Olympus IX81 fluorescent microscope. Custom pipelines developed in CellProfiler (Broad Institute, Cambridge, MA) assessed proliferation of cells.

We then assessed shear effects on ECs alone, using a custom-built macroscale cone-plate shearing device, capable of applying controlled,

pulsatile flow to human endothelial cells. ECs were seeded on glass coverslips 48 hours prior to device installation. The device was filled with endothelial cell growth medium 2 (EGM-2) (Lonza Inc., Basel, Switzerland), and ECs were exposed to steady, oscillatory, and physiological (healthy and unhealthy) pulsatile shear stress. After shear exposure, media was collected, and coverslips were removed. ECs were fixed in 4% paraformaldehyde and labeled with either anti-VE-Cadherin or anti-neuregulin-1. Images of VE-Cadherin stains loaded into custom pipelines developed in CellProfiler (Broad Institute, Cambridge, MA) were used to assess EC eccentricity, spread area, aspect ratio, and orientation with respect to the flow.

As a preliminary experiment to assess communication between ECs and CMs, we utilized a transwell assay. Human ECs seeded were seeded on transwell membranes positioned above NRCMs seeded on TCP. ECs were placed on an orbital shaker and exposed to shear stress for 24 hours. CMs were fixed in 4% paraformaldehyde, stained with anti-cardiac α -actin and anti-Ki67, and imaged using an Olympus IX81 fluorescent microscope. Custom pipelines developed in CellProfiler (Broad Institute, Cambridge, MA) assessed proliferation of cells.

In a separate experiment, we generated 3D printed models of patient specific geometries. We used these 3D models to more accurately replicate the flow inside a complicated, patient-specific left ventricle geometry. As a proof of concept, we first used an adult left ventricle geometry extracted from a patient specific CT scan. Models were modified to include cutouts for the installation of engineered tissue constructs. Constructs, seeded with human adult cardiac fibroblasts, were installed in the 3D printed model and cultured for 24 hours in serum containing medium. Currently, we are working on applying realistic flow waveforms to cells installed in the models to more accurately replicate flow inside a ventricle.

RESULTS

Figure 1: (A) Representative images of cells stained with DAPI for nuclei (blue), α-actinin for CMs (green), and the proliferation marker Ki67 (red). (Scale Bar = 100 μm). (B) The percentage of α-actinin+ cells. (C) Fold change of α-actinin+ cells with respect to cells fixed after 24 hours. (n = 4 per group). * = p < 0.01 compared to TCP at 0 ng/mL. # = p < 0.01 compared to fECM at 100 ng/mL.

First, we assayed the proliferative effects of NRG-1 on NRCMs seeded on either solubilized fetal cardiac extracellular matrix, or tissue culture plastic (Figure 1A). We observed a significant increase in positive staining for cardiac α-actinin in NRCMs treated with 100 ng/mL of NRG1 cultured on TCP compared to NRCMs treated with no NRG on TCP (Figure 1C). We did not see significant changes in positive stains cardiac α-actinin in NRCMs cultured on solubilized cardiac fetal ECM.

We then sought to expose monolayers of ECs to controlled physiological levels of shear stress to better quantify EC phenotype and protein expression. A custom-built cone-plate shearing device (Figure 2A-B) exposed monolayers ECs to pulsatile shear stresses. Eccentricity measurements (Figure 2C) and immunofluorescent images (Figure 2D-E) verify that our device can successfully culture ECs under sheared conditions. Additionally, positive stains for NRG (Figure 2E) verify the ECs are expressing NRG under sheared conditions. We then used a

Figure 2: Photograph (A) and schematic (B) of cone-plate viscometer. (C) Percentages of ECs in each eccentricity range under static or shear stress culture conditions. (D-E) Representative images of ECs after 24 hours of static culture or shear stress culture. (D) VE-Cadherin (red). (E) NRG expression (red). Direction of flow is left to right (Scale Bars = 100 μm).

transwell experiment to assess how CMs may respond to ECs exposed to shear stress. We observed trends in proliferation of NRCMs in response to ECs in a transwell exposed to shear stress (Figure 3A-B).

We have started preliminary experiments to address complicated flow-induced shear stresses that arise from patient specific geometries. Patient specific ventricle geometries extracted from CT scans were 3D printed. Engineered tissue constructs containing cardiac fibroblasts (CFs) were installed into the 3D printed models and cultured for 24 hours. For future studies, engineered constructs containing CMs, ECs, and CFs installed in 3D printed ventricle models will be connected in a pulsatile flow loop to assess how specific flow patterns may modulate cellular communication. Results from these studies will be presented.

Figure 3: (A) Percent of CMs that are proliferating in response to ECs in a transwells under either static culture or sheared culture (n=2 per group). (B) Representative images of CMs staining for Ki67, alpha-actinin, and DAPI. (SB = 50 μm).

DISCUSSION

The significant increase in cells expressing cardiac α-actinin observed in cells on TCP treated with exogenous NRG (Figure 1C) suggests that NRG expression is important for understanding CM proliferation, and thus fetal ventricular growth. We have designed a cone-plate shearing device capable of culturing ECs under sheared conditions. Under sheared conditions, these ECs are expressing NRG (Figure 2E). Furthermore, increased trends in cells expressing cardiac α-actinin in response to ECs exposed to shear stress (Figure 3) suggest that there is communication between ECs and CMs that is modulating CM proliferation; however, additional studies with controlled shear stresses are necessary to evaluate significance and to elucidate the mechanism of EC-CM communication. Finally, we have manufactured a patient-specific ventricular model with cell cutouts for the installation of 3D engineered tissues. This model is capable of culturing cells in static conditions and culturing cells in a pulsatile flow loop.

ACKNOWLEDGEMENTS

We thank Dr. Sitaram Emani and Boston Children's Hospital for their expertise on congenital heart defects and for providing us with MRI images of fetal hearts.

INTRODUCTION

Peripheral pulmonary artery stenosis (PPAS) is a relatively rare form of congenital heart disease (CHD) found in < 1% of CHD patients, but frequently found in association with Alagille and Williams syndromes. PPAS is characterized by stenoses in the central and peripheral pulmonary arteries (PAs) and results in disparity in left vs. right lung perfusion, right ventricular (RV) hypertension, and ultimately RV failure [1]. Since the stenoses are frequently distal and complex, most centers favor catheter-based interventions despite unfavorable outcomes, including unchanged RV pressures, risks of vessel dissection, aneurysm formation, rupture, and even death [2, 3, 4]. Furthermore, the pathophysiologic features of the PAs, including medial thickening, nonparallel arrangement of smooth muscle cells, and elastin deficiency, place these patients at a uniquely high risk of in-stent stenosis and thus reintervention [5, 6]. More recently, comprehensive surgical reconstruction of PPAS, or patch augmentation of all stenoses in the main, branch, lobar, and segmental arterial levels, has been shown to significantly reduce RV pressures with low morbidity and mortality [1].

To our knowledge, no studies have investigated hemodynamic conditions following catheter-based angioplasty and/or stenting in Alagille or Williams patients. While previous computational fluid dynamics (CFD) studies have modeled the post-operative hemodynamics following surgical reconstruction of PPAS in Alagille patients [7, 8], they lacked validation against post-operative PA and RV pressures, the primary indicators of success in PPAS repair. In this study, we aim to investigate the hemodynamics enabling surgical reconstruction to outperform stent placement for PPAS repair in Alagille and Williams patients, and further, to provide patient-specific predictions of stenoses that should be surgically patched in order to achieve normal RV pressures and balanced lung perfusion. We hypothesize that unlike surgical reconstruction, catheter-based interventions fail to reduce the large resistance associated with diffuse stenoses in the distal pulmonary vascular bed and therefore fail to reduce the PA and RV pressures.

METHODS

Using the open-source software SimVascular (simvascular.org) and computed tomography (CT) scans, we generated 3D anatomical models of the pre-operative PAs of a 13-year-old male Alagille patient and a 7-month-old male Williams patient, both of whom underwent surgical reconstruction at Lucile Packard Children's Hospital at

Stanford. A healthy adult PA inflow waveform scaled to each patient's cardiac output was prescribed at the inlet, and a 3-element Windkessel model was prescribed at each outlet to model the downstream vasculature not resolved by CT. Hemodynamic simulations were performed with a backflow-stabilized 3D Navier-Stokes solver. Fluid-structure interaction was incorporated via the coupled momentum method [9] with an elastic modulus of 1.5×10^6 dyn/cm² for the PAs.

An automated tuning framework was developed to iteratively identify all boundary conditions (BCs) necessary to achieve patient-specific pre-operative systolic, diastolic, and mean pressures at the main PA (MPA), left main PA (LPA), and right main PA (RPA) measured via cardiac catheterization—a total of 9 target pressures. In particular, a 0D lumped parameter circuit was designed as a surrogate model of the 3D fluid domain. In each iteration, Nelder-Mead optimization was first performed on the 0D surrogate model parameters and 3D outlet BCs to match the CFD-simulated and catheterization-measured pressures, respectively (Figure 1), before another CFD simulation was run using the newly optimized 3D outlet BCs. The log barrier method (Equation 1) was implemented to ensure physiological tuning ranges:

$$\tilde{\phi}(\vec{x}) = \phi(\vec{x}) - K \sum_{i=1}^m \ln[-g_i(\vec{x})] \quad (1)$$

where $\phi(\vec{x})$ and $\tilde{\phi}(\vec{x})$ are the original and modified cost functions, K is a scalar multiplier, m is the total number of inequality constraints, and each $g_i(\vec{x}) \leq 0$ is an inequality constraint. The optimized 3D outlet BCs were distributed to all outlets with the assumptions that all downstream vessels in the RPA or LPA form parallel circuits, and that each outlet resistance is inversely proportional to the outlet area [10].

Surgeon-guided virtual surgery will be performed to reconstruct post-operative anatomies, and simulated post-operative outcomes will be validated against cardiac catheterization data as well as available lung perfusion data. Finally, virtual stent placement will be performed on the pre-operative models, and simulated outcomes will be compared to those of virtual surgical reconstruction. In either case, adaptive outflow boundary conditions [7] will be determined using a structured tree model [11, 12] and the assumption that arteries respond to flow perturbations by maintaining wall shear stress levels [13].

RESULTS

The automated tuning framework successfully minimized the cost function in all tuning iterations for the 0D surrogate model parameters

and 3D outlet BCs (Figure 2). Correspondingly, the severe pre-operative PA pressure drops across proximal stenoses in both patients were accurately captured: $\Delta P_{MPA-RPA} = 29 / 3$ mm Hg (systolic/ diastolic, mean) and $\Delta P_{MPA-LPA} = 39 / 0$ mm Hg in the Alagille patient (Figure 3A); $\Delta P_{MPA-RPA} = 106 / 21$ mm Hg and $\Delta P_{MPA-LPA} = 98 / 11$ mm Hg in the Williams patient (Figure 3B). No pre-operative lung perfusion scan was available for the Williams patient, but the highly skewed PA flow distribution was accurately captured in the Alagille patient: 68% R / 32% L. Post-operative results will also be presented.

Figure 3: Pre-operative systolic PA pressures in the (A) Alagille and (B) Williams patients.

DISCUSSION

Given the severely stenotic and hypoplastic PA morphology, drastic pressure drops across stenoses, and skewed lung perfusion in Alagille and Williams patients, outlet BCs for hemodynamic simulations are particularly challenging to identify such that all patient-specific clinical targets are achieved. In this study, an automated tuning framework was designed to tune outlet BCs of PA hemodynamic

simulations to patient-specific systolic, diastolic, and mean MPA, RPA, and LPA pressures. While automated tuning has previously been performed for coronary hemodynamic simulations [14], our framework is easily generalizable to different 0D lumped parameter circuit designs and even other non-PA vascular physiologies. Importantly, it also allows for tuning to hemodynamic quantities within arbitrary regions of the 3D domain rather than the outlets alone.

The outcomes of PPAS repair vary widely from complete repair to early or late mortality associated with complications such as vessel dissection, aneurysm formation, and rupture. CFD simulations provide a unique platform for computational patient-specific surgical planning, in which patient-specific anatomical models are altered to represent different interventional cardiology techniques, and the post-interventional hemodynamics are assessed in each case. Previous studies investigating hemodynamic conditions following surgical reconstruction of PPAS in Alagille patients were only validated against post-operative lung perfusion scans [7, 8]. Our ability to accurately predict post-operative outcomes would suggest the potential to identify all stenoses that need to be addressed in order to achieve normal PA pressures and balanced lung perfusion. Such predictions would prove particularly valuable to cardiothoracic surgeons by providing a model-based tool and possibly improving surgical outcomes.

While our study investigates the immediate post-interventional PA hemodynamic conditions following catheter-based angioplasty and surgical reconstruction of PPAS, arteries are known to respond to flow perturbations through acute adaptation as well as chronic growth and remodeling [13]. One limitation is therefore the inability to assess the long-term growth and remodeling processes in the pathophysiologic vascular wall that underlie in-stent stenoses in Alagille and Williams patients. Other limitations include the lack of post-operative CT scans for anatomical validation and the small patient cohort. Nonetheless, our study is the first to lend insight into the post-interventional hemodynamics enabling surgical reconstruction to outperform stent placement for PPAS repair in both Alagille and Williams patients.

ACKNOWLEDGEMENTS

This study is supported by the National Science Foundation Graduate Research Fellowship and the Stanford Graduate Fellowship in Science and Engineering. CFD simulations were performed using Stanford Research Computing Center's Sherlock cluster and the Extreme Science and Engineering Discovery Environment (XSEDE), which is supported by National Science Foundation grant number ACI-1548562.

INTRODUCTION

There are 1.3 million people in the United States who survived into adulthood who were born with congenital heart defects. Single ventricle physiologies account for 9-12% of congenital heart anomalies¹. Single ventricle patients undergo a series of palliative procedures during the early years of life, resulting in a reconstructed cardiac circuit known as Fontan physiology. In these patients the single fully-formed ventricle actively drives blood through systemic circulation and passively draws blood through pulmonary circulation². These patients commonly encounter numerous long-term complications, such as early-onset congestive heart failure, thrombosis, arrhythmias, and protein losing enteropathy². The complications in this cohort of patients results in an annual clinical treatment and management cost in excess of \$1 billion³. Improvements to surgical techniques have brought the post-operative mortality rate to under 5%² but the 10-, 20-, and 30- year survival rate is only 74%, 61% and 43%, respectively⁴. Pharmaceutical and surgical advances have slowed for Fontan patients. Heart transplantation is the best option if the patient can survive the waiting period.

It has theorized a pressure boost of 1-5mmHg in the pulmonary arteries is adequate to alleviate many of these complications, and there is a growing interest in the use of blood pumps as a bridge to therapy or transplant^{2,5}. Currently available blood pumps have limited utility for these patients because they are large and primarily designed to support systemic circulation in adults. A major constraint of current pumps that limits their usefulness for Fontan patients are designs with rigid blades that have a fixed diameter. The rigid blade designs prevent minimally invasive insertion and require off-design operation to adapt the pump to the unique pressure generation needs of the Fontan circuit. Off design use leads to irregular flow patterns, inefficient performance, and blood damage. The presented study investigates the use of flexible blade, cage, and diffuser designs to begin working toward the design of a minimally

invasive blood pump with blade pitch adjusting capabilities. The design in development will be inserted into the surgically created Fontan connection and have an impeller with three raised blades, a protective cage with four helical fibers, and a diffuser. A rigid version of the design, seen in Figure 1 below, has been optimized through computational modeling and benchtop experimental testing.

Figure 1 Fontan Blood Pump in Development

METHODS

Using one-way fluid-structure interaction (FSI) computational studies completed in ANSYS 15.0, the implications of blade deformation on blood damage and pump performance were investigated. For the flexible impellers, we considered biocompatible materials of construction of nitinol, polyurethane, and silicone. We investigated operating conditions of flow rates between 2.0-4.0 L/min and rotational speeds of 3000-9000 RPM. Blood was defined as a Newtonian fluid with a density of 1050 kg/m³ and a dynamic viscosity of 3.5 cP. The shear stress transport turbulence model was used when solving the physics of the fluid domain. Material constants for the biocompatible impeller and cage materials investigated were found in the scientific literature. In the one-way studies, the fluid pressure on the surface of the impeller was calculated using computational fluid dynamics (CFD). Next, the surface pressure was exported and used to determine impeller deformation using finite element analysis (FEA).

Finally, the deformed impeller geometries were exported from the FEA software package and imported back into the CFD software to assess the impact of deformation on pressure generation, blood damage index, and fluid streamlines. The results for the undeformed and deformed cases were compared.

In another set of one-way FSI studies, the level of predicted deformation was calculated for cages and diffuser made of steel, nitinol and polyurethane at flow rates of 2.0 and 4.0 L/min at rotational speeds of 2000, 3000 and 4000 RPM. These studies were completed both with and without a rotating impeller at the center of the model.

To ensure the meshes used for all computational studies were of high quality, mesh independence studies were completed for all domains and the standard mesh quality metrics of skewness, aspect ratio, Jacobian ratio, and element quality were used. Blood damage index was predicted using an experimentally derived power law relationship, seen in Equation 1 below, that relates the shear stresses experienced by red blood cells and the residence time within the pump domain⁶.

$$BDI = \int_{inlet}^{outlet} 1.8 \times 10^{-6} \cdot \tau^{1.991} \cdot dT^{0.765} \quad (1)$$

RESULTS

It was found that rotational speed, and not flow rate, is the largest determinant of impeller deformation. The maximum deformation occurred at the blade trailing edge. The models predicted the maximum impeller deformation for nitinol to be 40nm, Bionate 80A polyurethane to be 106um, and silicone to be 2.8 mm, all occurring at 9000 RPM from 15 kPa of fluid pressure on the trailing edge of the impeller blade. Figure 2 shows impeller deformation as a function of rotational speed for the three materials investigated. Figure 3 is a visual representation of silicone impeller deformation at 9000 RPM. The undeformed impeller is represented by a wireframe outline. Blade deformation is largest at the trailing edge blade tip. Blood flow is left to right in the image.

Figure 2 Impeller deformation by rotational speed

The effect of silicone deformation on pump performance was significant, particularly at rotational speeds above 5000 RPM where a decrease in pressure generation of more than 10% was observed for all rotational speeds. Despite the loss in pressure generation, the calculated pressure increase exceeded the level required to alleviate Fontan complications. The estimated blood damage observed for all materials tested at all operational conditions remained below the level that is acceptable for blood pumps.

When analyzing cage and diffuser deformation, steel deformed less than a millimeter, nitinol deformed on the millimeter scale and polyurethane deformed on the centimeter scale. The steel and nitinol models retained their shape despite deformation and polyurethane became highly distorted.

DISCUSSION

These studies began to illuminate the effects of flexible material deformation on pump performance, with the goal of developing an

Figure 3 Silicone impeller deformation at 9000 RPM.

intravascular, collapsible, pitch adjusting blood pump for Fontan physiology. Pump collapsibility will allow minimally invasive percutaneous deployment. Pitch adjustment will allow the operating conditions of the pump to be matched with specific patient needs so optimum operating conditions can be maintained to increase efficiency and decrease irregular flows and blood damage.

When analyzing impeller deformation, nitinol deformed on the nanometer scale, polyurethane deformed on the micrometer scale and silicone deformed on the millimeter scale. An increase in rotational speed had the greatest impact on the level of deformation. This information will be leveraged in future composite designs to select the optimal materials to ensure collapsibility and pump performance. More flexible materials, like silicone, allow increased collapsibility but also have deleterious effects on pump performance at high rotational speeds.

Blood damage was predicted to be below the acceptable threshold for all materials and operating conditions. The effect of significant impeller deformation on blood damage was inconsistent and requires additional investigation. The calculated impeller deformation reduced blood damage metrics in some circumstances and the reduction could be leveraged in the future with additional investigation to full characterize the system. These results support the continued development of an axial-flow, mechanical assist device as a new clinical therapeutic option for patients with dysfunctional or failing Fontan physiology

INTRODUCTION

The heart is the first organ to function in vertebrates, initiating contractions shortly after heart tube fusion. Immediately after formation, the valveless heart tube is able to drive blood forward throughout the embryonic body through a series of contractions initiated by a confluent monolayer of myocardial cells. This layer compresses a layer of cardiac jelly that is sandwiched by the myocardium and endocardium. The valveless pumping mechanism at this stage has received significant attention over the past decade where studies have investigated the potential of peristalsis or impedance pumping, by studying contractile mechanics and blood flow. However, mechanical properties of this stage are rarely considered, limiting the ability to identify the pumping mechanism. Here, we have developed a computational Multiphysics model to study the interplay between mechanical properties, contraction, and blood flow. We validate our results through experiments involving a zebrafish heart (30 hpf).

METHODS

In the simulation, the heart-like model was developed to represent the zebrafish heart at stage 26-30 hpf. This heart tube model consists of two-layers, myocardium and cardiac jelly, with the assumption that the endothelium is relatively compliant and can be neglected. The heart tube diameter is defined as 0.05mm with a length of 0.18mm. The cardiac jelly thickness is 10-15 μm and the myocardial thickness is 3-4 μm .

Arbitrary Lagrange Eulerian formulation is used to simulate the Navier–Stokes equations. Five different pumping mechanisms were studied: 1,2) peristaltic with exponential and sinusoidal contraction function, 3,4) impedance with exponential and sinusoidal contraction function, and 5) the biological pumping based on muscle contraction. Myocardial contraction was implemented by imposing an external load function. No-slip boundary conditions were applied at the fluid–

structure interface. The outlet pressure is a 0D model, involving a function of flowrate and peripheral vascular resistance. Pressure at the inlet of the fluid domain was set to zero.

The range of model parameters were found from published studies. Yet, there is a severe deficiency of reliable data due to accessibility and experimental limitations. Therefore, a sensitivity analysis was performed to find the dependence of cardiac output on the model parameters. Sensitivity analyses for each parameter were conducted to narrow the range of values to have a 0.04 mm^3/min cardiac output. Parameters are shown in table 1. To assess the ideal pumping mechanism, we also calculated the efficiency for each type.

In the experiment, heart wall motion was characterized at the following cycle (T) fractions; .2T, .4T, .6T, .8T, and T. Blood velocity was also computed through spatiotemporal kymographs. All experiments on embryonic zebrafish are approved by IACUC at CSU. Selected embryos were dechorionated and placed in a solution of E3 egg maintenance media for holding. Individual embryos were moved to a glass bottom coverslip and embedded in 1.5% low-melt agarose to arrest movement for imaging, performed on an inverted microscope system (Olympus IX73 with 20X objective and the optical resolution of 0.37-0.45 microns) using a high-speed camera (Photron Fastcam Mini UX100) at 1600 frames per second and 45 $\mu\text{m}/\text{pixel}$.

RESULTS

To validate the pumping mechanisms, the experimental velocity measurement is compared with the three defined pumping mechanisms (peristaltic, impedance and biological). The biological pumping mechanism is based on the calcium flux in the mouse cardiac muscle and within agreement with mouse muscle isotonic contractions [1, 2]. The motion is also shown in Fig. 1 and the pattern of contraction agrees best with experimental patterns in a zebrafish.

Table1. The parameters values for the sensitivity analysis

Parameter	Unit	Value	Range
Myocardium thickness	μm	3.5	3-4
Cardiac jelly thickness	μm	12	10-15
Heart length	μm	180	-
Diameter	μm	50	-
Blood density	kg/m^3	1035	1035-1045
Blood viscosity	Pa.s	0.004	0.003-0.004
Wave speed	mm/s	0.4	0.1-0.8
vascular resistance	Pa.s/m^3	2×10^{12}	$1-4 \times 10^{12}$
Wave length	μm	180	0.1L-1.5L

The velocity is compared between simulations and experiments to assess which pumping mechanism flow best matches experimental flow. Simulations of impedance and peristaltic pumping mechanisms divert from experiments by 31% and 26%, respectively. Alternatively, there is good agreement between the biological mechanism and experimental results (11%, which is within the experimental measurement error). In biological pumping, contraction starts near the inlet, traveling as a wave to the middle of the heart when the contraction is still occluding near the outlet.

FIGURE 1: Heart wall motion (myocardium and cardiac jelly) during one cardiac cycle for biological pumping

As the mechanical properties of the zebrafish embryonic heart are unknown in early development, the stiffness of each wall layer was also studied, assuming a Hookean material as a first order approximation. Values are assumed to be reasonably estimated when the simulation cardiac output matches experiments. As shown in Fig. 2(a) the valid range for the cardiac jelly elastic modulus is 10-30 pa. Increasing the elastic modulus 3 times, decreases the cardiac output by 17% for biological pumping and 28% for impedance and peristaltic pumping. Fig. 2(b) shows the modulus of the myocardium is larger than the cardiac jelly with a value of 25 to 40 Pa Increasing the myocardium elastic modulus by 60% decreases the cardiac output by almost 22%.

Energy loss is further calculated to determine what pumping mechanism is most efficient. Peristaltic pumping has the highest energy loss which is 3.2 times larger than impedance pumping. The biological pumping mechanism can provide sufficient cardiac output with the least energy for the wall motion. The energy loss in biological pumping is higher than in impedance pumping but lower than in peristaltic. Impedance pumping mechanisms have the least energy loss but also their cardiac output is not as high as the two other pumping mechanisms.

(b) FIGURE 2: Elastic modulus of (a) myocardium (b) cardiac jelly for different pumping mechanisms

DISCUSSION

In the present work, we used experimental and numerical methods to study the mechanics and efficiency of the zebrafish embryonic heart tube (30hpf). We found that the elastic modulus of the cardiac jelly is lower than the myocardium. Our values are close to those measured in the chicken embryonic heart tubular stage (stage HH 10/11), where Zamir et al. found 6-24 Pa for cardiac jelly and 30- 120 Pa for the myocardium [3-6]. We studied different pumping mechanisms and introduced the biological pumping mechanism which is not necessarily an impedance or a peristaltic pump. The energy efficiency of each mechanism is also studied to find the most efficient pumping mechanism. When subjected to peristaltic pumping, the heart tube produces a proper cardiac output, but the wall motion is not valid and is also inefficient. Velocity changes in time for impedance pumping is not in agreement with the experimental results. The impedance pump also does not provide the necessary cardiac output. As compared to peristaltic and impedance pumping, our proposed biological pumping produced the highest cardiac output with the least amount of energy loss, indicating that it accurately describes pumping seen in the embryonic heart tube. Through an understanding of pumping mechanics and material properties, it is possible to quantify the complex stresses that exist during embryonic heart development and to determine how these stresses contribute to normal morphological development or to cardiac malformation in the form of a congenital heart defect.

INTRODUCTION

Past investigation found that fluid mechanical forces influenced cardiovascular development and abnormal flow conditions could lead to congenital heart malformations,¹ which is clinically a leading cause of birth defect related deaths.² We utilized a previously established 4D high-frequency imaging technique³ on HH25 chick embryos (just before septation), tracked the cardiac motion with a novel motion tracking algorithm, which could enable wall strain calculations, and performed flow simulations to understand the hemodynamics.

METHODS

3 embryonic hearts were studied. Cine-ultrasound images were obtained at multiple planes spaced evenly. Images for more than 20 cardiac cycles were averaged into 1 cardiac cycle via quadratic mean to create contrast between tissue and blood (none was naturally present), in accordance to our previously established imaging technique.³ A novel cardiac motion tracking algorithm was utilized, where a cyclic motion model was curve-fitted to displacement fields calculated by pair-wise 3D image registration for all consecutive time points. Dynamic mesh computational fluid dynamic (CFD) simulations were then performed to obtain flow fields and flow stresses. Doppler velocity measurements were obtained at the outflow tract and used to determine boundary conditions. From the motion tracking algorithm, the cardiac wall strains could be calculated. From the flow simulations, wall shear stresses (WSS) characteristics were determined. Systolic ejection work done was also calculated, using embryonic cardiac pressure values reported in the literature.⁴

RESULTS

Figure 1A demonstrate that the cardiac motion tracking algorithm worked very well, and tracked ventricular volume matched manual

segmentations in a test case very well. At HH25 (4.5 days old), the embryonic hearts had a single primitive ventricle and two joined primitive atria with atrial appendages (figure 1B).

Figure 1: (A) Ventricular volume vs time, comparing manual segmentation and automatic tracking. (B) Ventral view of embryonic heart. (C) Ejection fraction of cardiac structures. (D) Cardiac wall strain rate at two time points.

The atria were found to have lower stroke volume and ejection fraction than the ventricle. Interestingly, however, the atrial appendages were found to be highly contractile, having higher ejection fraction than even the ventricles. The appendages occupied only about 15.7% of the atria's diastolic volume but contribute about 27.0% to the total atrial stroke volume. Strain mapping in Figure 1D demonstrates that the atrial appendages underwent the highest strains within the atria, and had strain magnitudes comparable to the ventricle. Ejection work done calculations in figure 2 further demonstrated that the atrial appendages accounted for 40% of work done by atria. These suggested that the embryonic atrial appendage might have the role of fluid pumping in the embryonic heart.

Figure 2: The Work done by the different chamber of the heart.

Analysis of the CFD flow fields demonstrated that during late ventricular diastole (atrial systole) the ventricle could directly drew inflow from the veins, without the aid of the atria (figure 3). Further, Figure 2 demonstrated that the ejection work done by the ventricle was 1 order of magnitude higher than that of the atria, most likely because the ventricle pumped against high pressures but the atria did not. This suggested that the atria pumping function was not essential for providing circulatory energy. Instead, we propose that the atria pumping would be important for creating flow and WSS stimuli to ensure normal heart development. This was supported by literature evidence where surgical manipulation of the atria was shown to cause abnormal remodeling of the ventricle,⁵ and knocking out contractile function of the atria was found to be embryo-lethal, due to the failure of the cardiac cushions, heart valves and septation to form properly⁶.

Figure 3: CFD flow field results. (A) Ventricle systole and ejection via the outflow tract, and atria diastole and filling. (B) Ventricular diastole and atria systole, resulting in high flow through the atrioventricular junction. (C) At late atria systole / ventricular diastole, direct atrial inflow towards the ventricle occurred.

Consequently, it would be important to understand flow WSS in the embryonic heart. Figure 4 shows the WSS waveforms and spatial patterns for a typical embryonic subject. Significant spatial temporal variations were found, and the atria and ventricle experienced elevated

WSS during different times of the cardiac cycle. The highest WSS were observed at the ventricular outlet, the atrioventricular junction, and the septating mid-line between the two atria and the two ventricles. High WSS were thus imposed on the locations where the cushions and developing septum were, and could be important stimuli required for proper valve and septum development.

Interestingly, the right atrial appendages were found to have a high retention of blood fluid, as could be demonstrated by particle tracking analysis. Blood in this appendage merely moved in cyclic linear motions within the length of the appendage and were seldom washed out. Due to this phenomenon, significant oscillatory shear index is found in the right atria as well.

Figure 4: (A) Averaged WSS across a cardiac cycle. (B) WSS during mid-systole. (C) WSS during mid-diastole. High WSS at sites where valvulogenesis and septation will occur.

DISCUSSION

Our study results suggested that the atrial appendage were interestingly highly contractile in the embryonic heart, and played out-sized role in contributing to atrial blood pumping, both in terms of stroke volume and energy contributions. To date, the function of the atrial appendages were not known, although in adults with fibrillation, they have a high tendency to experience blood clots. Surgical ablation or occlusion of the appendages in these adults have resulted in no harmful effects on patients. It was thus interesting to find the embryonic atrial appendage taking up the fluid pumping role.

However, our flow field and flow energy study has pointed out that the atria do not have substantial contribution towards circulatory energy. The ventricle seemed to be capable of drawing flow directly in from the veins, bypassing the atria. We thus hypothesize that the atria pumping would be important to provide the suitable flow mechanical force stimuli for proper development in the heart. As discussed above, there are literature evidence that disruption of atrial pumping would cause abnormal ventricular,⁵ and cushions development,⁶ supporting our hypothesis. Our WSS investigations demonstrated that the atrioventricular junction and septating tissues protruding into the cardiac lumen has higher WSS, and this could be an important stimuli for their development, leading to valvulogenesis and septation.

INTRODUCTION

Pulmonary Hypertension (PH) is a progressive pathophysiological condition that emerges as high blood pressure in the pulmonary vasculature and ultimately results in right ventricular failure [1]. Symptoms of pulmonary hypertension are vague and can include shortness of breath, fatigue, weakness, angina, and syncope [2]. PH is categorized into 5 groups, and the focus of this study is group 1- Pulmonary Arterial Hypertension (PAH).

Significant remodeling and narrowing of pulmonary arteries results in increased mean pulmonary arterial pressure (mPAP) and pulmonary vascular resistance (PVR) [3]. Pulmonary arterial hypertension is diagnosed based on a mean pulmonary arterial pressure (mPAP) ≥ 25 mmHg and a pulmonary arterial wedge pressure (PAWP) ≤ 15 mmHg measured during a right heart catheterization (RHC) [1]. Other measurements include: systolic and diastolic PA pressure (sPAP, dPAP) and cardiac output (CO). Parameters of RV function include end-systolic elastance (Ees), arterial elastance (Ea), and RV-PA Coupling [4]. Additional testing can include an echocardiogram, a chest CT and a Magnetic Resonance Angiogram (MRA) [3].

Current clinical assessments of vascular structure from CT imaging are labor intensive and have not been directly related to RV function. The aim of this study is to 1) develop methods to quantify pulmonary vascular structure from cardiac MRAs and 2) to investigate associations between vascular structure and RV function in patients with PAH.

METHODS

Patients with a clinical MRA were retrospectively selected from the University of Arizona's PH registry. The final analysis was performed on patients that had undergone both a RHC and a clinical MRA. Patients

were categorized into two groups: PAH (mPAP ≥ 25 mmHg and a PCWP ≤ 15 mmHg) and Control (mPAP ≥ 25 mmHg).

Exported DICOMS MRA Images were imported into SimVascular (2018.05.23), an open source software package for cardiovascular modeling [5]. The principal artery, anterior artery, anterior basal artery, and medial basal artery were segmented (Figure 1) as previously described [4]. Branches were modeled from their origin to their end, following the path of the largest diameter.

Figure 1: Volume renderings of the pulmonary vasculature in a representative A) Control and B) PAH patient. C) and D) Wire representations of the principal pathway, anterior artery, anterior basal artery, and medial basal artery.

Once the arteries were segmented based on volume renderings (Figure 1A, B; yellow-segments), the raw data was exported and analyzed using a custom code in MATLAB (v2018). The custom code determined the diameter, and cross-sectional area (CSA) of each segmentation along each artery. To get a representative diameter for segments along each artery, the measured diameters were averaged for the region between each branch (Figure 2A, segments 1 to 7). The pathlength of each artery was determined as the sum of the distance between each of segmentations along the artery.

Hemodynamic Equations

$$PVR = (mPAP - PAWP)/CO$$

$$stroke\ volume\ (SV) = (mPAP - PAWP)/CO$$

$$PA\ Ca = SV/(sPAP - dPAP)$$

$$Ees = (P_{max\ iso} - sPAP)/SV$$

$$Ea = sPAP/SV$$

Pulmonary vascular resistance and PA compliance (PA Ca) were calculated as measures of functional changes in the pulmonary circulation. Single-beat analysis were used to measure RV function with Ees, Ea, and the ratio Ees/Ea (RV-PA coupling). Data are presented as mean \pm standard deviation and an Analysis of Variance test with a Tukey HSD post hoc analysis were used to determine the difference in PA diameters between patient groups. Linear regressions were used to determine the correlation coefficients. Correlations were considered significant when the p-value is less than 0.05.

RESULTS

Twenty patients were selected for analysis (10 controls and 10 PAH) but three patients were excluded from the final analysis due to missing RHC data (Control N=2) or poor quality MRA images (PAH: N = 1).

The pulmonary arteries in both patient groups were segmented using the same segmentation and visualization settings (Figure 1). The average diameter from each of the segments in the principal pathway was compared between groups (Figure 2). Patients with PAH had significantly larger diameters in the first three segments of the principal pathway compared to control patients (Figure 2B). The average pathlength for the principal pathway was the same for both controls (201.31 mm \pm 30.87 mm) and PAH (208.87mm \pm 34.10 mm) patients. There were no significant differences in diameter or pathlengths in the anterior artery, anterior basal artery, and medial basal artery between groups (Data not shown).

Figure 2: A) Cross sectional area (CSA) as a function of the pathlength in control and PAH. B) Comparison of the average diameter in each segment between groups. * p < 0.05 vs Control

As expected, patients with PAH have increased mPAP, increased PVR and decreased PA Ca compared to control patients (Table 1). RV function is significantly reduced in patients with PAH with increased arterial afterload and decreased RV-PA coupling. Patients with PAH have a significant increase in mPAP, PVR, pulse pressure (PP), Pulmonary arterial compliance (PAC), arterial elastance (Ees), and arterial elastance (Ea). However, PAH Patients experienced a significant decrease in RV-PA Coupling. There was a non-significant correlation between PVR and the MRA measured ($r^2 = 0.16$, $p = 0.07$)

and no correlation between PA Ca and the MRA measured ($r^2 = 0.01$). Right ventricular afterload had no correlation with PA diameter ($r^2 = 0.1$) but Ees/Ea had a non-significant correlation and RV-PA coupling also significantly correlate with the average PA diameter ($r^2=0.16$, $p = 0.07$).

Table 1: Hemodynamic Results. Data presented as mean \pm standard deviation.

RHC Data	Control	PAH	p-value
	N = 8	N = 9	
mPAP (mmHg)	17 \pm 4	52 \pm 7	<0.001
PAWP (mmHg)	7 \pm 2	7 \pm 4	0.871
CO (L/min)	5.5 \pm 1.5	4.9 \pm 1.2	0.345
PVR (mmHg)	1.9 \pm 0.6	9.9 \pm 0.3	<0.001
PA Ca (ml/mmHg)	4.9 \pm 1.3	1.3 \pm 0.6	<0.001
Ees (mmHg/ml)	0.8 \pm 0.5	0.9 \pm 0.4	<0.001
Ea (mmHg/ml)	0.4 \pm 0.1	1.4 \pm 0.4	<0.001
Ees/Ea	2.1 \pm 1.0	0.7 \pm 0.3	<0.001

DISCUSSION

It is feasible to use clinical MRA images to quantify pulmonary vascular structure in patients with and without pulmonary hypertension. Patients with PAH having increased PVR and PA diameters compared to control patients. These results are in keeping with previous findings that have found increased PA diameters in PAH patients from CT scans [6]. MRA imaging has lower resolution than traditional CT imaging but provides the benefit of allowing for the quantification of the dynamic motion of the right ventricle and RV volumes in the same scan as the pulmonary vascular structure. Limitations in imaging resolution is a potential reason for why there were no significant differences in the length of the principal pathway between control and PAH patients.

Increased pulmonary vascular resistance in patients suggest that there is a decrease in the diameter of the vasculature. Our results show PAH patients have increased PA diameters that is likely due to the increased operating pressure (mPAP: 52 \pm 7 mmHg) compared to control patients (mPAP: 17 \pm 4 mmHg). There were no detectable differences between patient groups in the anterior artery, anterior basal artery, and medial basal arteries. We are limited in our ability to detect changes in smaller distal pulmonary vessels due to the resolution of MRA images.

Previous studies have found increased PA diameters significantly associate with mortality [6,7]. Our data suggests there is potentially a correlation between PA diameter and PVR and RV-PA coupling. Our data suggests pulmonary vasculature structure in combination with RV function could be used to further investigate the development and progression of RV failure.

INTRODUCTION

Fetal cardiac anomalies are diagnosed through fetal echocardiography (echo) and are among the hardest fetal anomalies to characterize *in utero*. It has been suggested that these defects may originate from blood flow patterns through the developing heart or from a genetic basis[1]. Therefore, visualizing the intra-cardiac flow distributions during gestation may be helpful to understand fetal cardiac anomalies. *In vitro* four dimensional flow magnetic resonance imaging (4D Flow MRI), a technique that combines patient-specific 3D printed geometries with MRI, has been successful in children and adults to model specific hemodynamic states to improve surgical techniques as well as study system efficiency[2,3]. Recently, we showed the success of applying 4D Flow MRI to fetal life by using patient-specific 3D printed heart models at two gestational ages, 28 and 30, to visualize intra-cardiac flow profiles[4]. This previous study was the first to 3D print geometry from a fetal echo, and was the second reported 3D printed model from an echo[5]. The purpose of this study was to validate this modeling technique for intra-cardiac flow analysis by quantitatively comparing *in vitro* patient specific fetal flow distributions measured with 4D Flow MRI with those reported in literature.

METHODS

One fetal echo, deemed to be developing normally at 32-weeks' gestation was analyzed with IRB approval. The ultrasound was segmented and designed in Mimics/3-Matic (Materialize, Leuven, Belgium) to represent the cardiac lumen (Figure 1a,b). Any unclear valve or heart anatomy, likely due to acoustic shadowing or fetal movement, were created based on the mean fetal measurements from literature at 32-weeks' gestation. Multiple 2D cross section measurements from Mimics were compared with the 3D volume

(Figure 1b) created in 3-Matic to minimize error due to smoothing and model post-processing. A wall and connectors were added (Figure 1c) leaving a cavity representing the flow lumen and the life size model was 3D printed (Form 2, Formlabs Inc, Somerville, MA).

Figure 1: a) Fetal echo of the normal fetus at 32 weeks gestational age. b) Right anterolateral view of the segmented fetal heart model (cm). Cylinders added to the segmented vasculature represent average vessel size at the given age. c) 3D printed model of (b).

For *in vitro* assessment the heart model (Figure 1c) was connected to a positive displacement pulsatile pump at 1 L/min of water (BDC PD-1100, BDC Laboratories, Wheat Ridge, CO) and imaged using a clinical 1.5T MRI scanner with a head coil (Signa HDxt, GE Healthcare, Waukesha, WI). Appropriate resistance was applied to the outlet pulmonary arteries[6]. Post-processing of the 4D Flow MRI data was done and the intra-cardiac flows were visualized and quantified by placing planes in the vessel of interest in EnSight (CIE, Apex, NC). Intra-cardiac flow distributions (Aorta (Ao), pulmonary artery (PA), ductus arteriosus (DA), foramen ovale (FO), left and right pulmonary arteries (LPA+RPA)), were compared against percent flow distributions found in literature[7,8]. All flows were measured with planes with the following exceptions: DA flow was calculated by

subtracting Ao flow before and after the DA; FO flow was calculated by subtracting PA flow from inlet flows (IVC+SVC+Ductus Venosus (DV)). All literature values represented the mean for that gestational age.

RESULTS

The fetal echo successfully incorporated the heart anatomy. The following vessel and valve diameters were slightly modified based on dimensions reported in literature: LPA, RPA, LPV, RPV, FO, DV and mitral, tricuspid, aortic and pulmonary valve diameters[9-13]. Segmentation, post-processing, and 3D printing were successful to create a physical model of a patient-specific 32-week fetal heart (Figure 1c).

In-vitro analysis with 4D Flow MRI produced consistent flow patterns throughout the whole anatomy and conserved mass (Figure 2a). There is evident flow through the other fetal shunt, the DA (insert) to bypass the pulmonary vessels, as illustrated in the insert of Figure 2a. Significant flow can also be seen passing from the RA to the LA through the FO, as denoted by the white arrow (Figure 2b), consistent with the normal shunting of blood through the fetal heart.

Figure 2: a) Velocity streamlines (m/s) from *in-vitro* 4D Flow MRI.

Blood enters the RA from the SVC and IVC (not pictured), followed by the RV, then accelerates out the (PA). Flow exiting the PA joins the Ao via the ductus arteriosus (DA). Peak velocity is observed approaching the DA (insert). b) Visualization of blood flow across the (FO) is illustrated and denoted by the white arrow.

Figure 3: Illustration of intra-cardiac flow distributions from literature [7,8] and the *in-vitro* 3D-printed fetal heart model.

Quantitative analysis of flow distributions were consistent with flows reported in literature (Figure 3). Aortic and pulmonary valve flow are an average of two values reported in literature (41.4% and

42.6%, and 58.6% and 56.9% respectively), the other distributions were only reported by one source[7,8].

Flow values are reported as percentage of total cardiac output. These flows were found to be 16% through the FO, 58% through the PA, 42% through the Ao, 29% through the DA and 29% through the PA. Internal consistency of 4D Flow MRI measurements has been previously determined as 8%[14]. Therefore, no significant differences were found between intra-cardiac flows in literature and those from the *in-vitro* assessment of the 3D printed patient-specific fetal heart.

DISCUSSION

Results from this study in conjunction with our previous study suggest that the presence of the DV plays a key role in the intra-cardiac blood flow across the FO, consistent with literature [4,6].

Since *in-vivo* values were unavailable for this patient, literature values of the 50th percentile flow distribution at 32-weeks' gestation were chosen. Therefore, a potential limitation of this study is if modeled heart was not the 50th percentile, and future work will take the growth percentile into account.

Although this heart model is a passive representation of the fetal heart, it has shown to provide reliable intra-cardiac flow distributions. Other limitations such as estimating the exact sizes of the anatomy and using water instead of blood are present but are not believed to be significant. Future work will include analysis of more normally developing hearts at various gestational ages to determine the consistency of this modeling technique to estimate flow patterns *in-vivo*. Additionally, the continued advancement of new flexible materials with 3D printing will allow for more flexible materials to be used to better represent the beating heart.

As mentioned by Ruedinger et al., this modeling technique can be helpful for parents to better understand the fetal anatomy, especially when a fetal cardiac anomaly is present. This study supports the use of 3D printing a patient-specific fetal heart as well as *in-vitro* 4D Flow MRI to analyze intra-cardiac flow distributions in fetal life. This information, in conjunction with diagnostic routine could be valuable to physicians and parents to better understand complex flow regimes, such as in cases of fetal cardiac anomaly.

INTRODUCTION

Abdominal aortic aneurysm rupture is a major health concern and is associated with significant mortality. At the extracellular matrix (ECM) level, an increase in elastase and collagenase levels eventually make the aortic wall weak. Ultimately the wall ruptures when the forces applied exceed the material strength of the vessel. In this study, we investigated the application of an organic polyphenolic compound called pentagalloyl glucose (PGG), which has shown beneficial cardiovascular effects in humans [1], can assist in stabilizing the arterial tissue by crosslinking the extracellular matrix proteins (i.e. elastin), and can potentially assist in suppression of aneurysm growth. To assess PGG interaction with arterial tissue ECM, we evaluated murine abdominal aortic specimens treated with or without PGG through pressure-inflation testing. We hypothesized that the application of PGG *in vivo* will improve the biomechanical characteristics of the abdominal aorta wall and will prevent further damage from enzymatic actions.

METHODS

Aneurysm Mouse Model – Animal studies were performed following IACUC approval at Purdue University. Eleven male C57BL/6 mice at 8-10 weeks of age underwent laparotomy under sterile conditions and the abdominal organs were retracted outside the abdomen to expose the aorta. To induce aneurysms, 5.0 mg/mL pancreatic porcine elastase (PPE) was topically applied to the infrarenal aorta for 5 minutes while 0.2% beta-aminopropionitrile was continuously administered via drinking water beginning 2 days prior to surgery and extending the length of the study. After elastase treatment, 7 of the 11 animals received a PGG (0.06%) topical treatment on the abdominal aorta as an aneurysm preventive measure and the 4 remaining mice received a saline solution (control). Aortic expansion was monitored via high frequency ultrasound (Vevo2100, FUJIFIM

VisualSonics) on a weekly basis (prior to surgery and post-surgery up to 4 weeks). Animals were sacrificed four weeks post-surgery and their abdominal aortas were dissected and utilized for pressure inflation testing.

Figure 1: Experimental setup for pressure-inflation testing. The inset shows the specimen view from the top.

Pressure Inflation Testing – Pressure inflation tests were performed using the free-end technique to analyze the deformation of the vessels when subjected to intraluminal pressures [2]. The experimental set up (Fig. 1) consisted of a high-resolution camera (Basler Inc., Germany) mounted on an inverted microscope (Olympus, Center Valley, PA), while the specimens were mounted on 500- μ m-diameter stainless steel cannulas with machined grooves placed in a vessel chamber (LSI, Burlington, VT). Specimens were secured at both ends with 6-0 sutures and the chamber was filled with clear PBS

(Sigma-Aldrich Inc., MO). A syringe pump (Chemyx, Stafford, TX) was utilized to pressurize the specimens at room temperature and the syringe filled with food dye + PBS for detecting rupture or leaks in the specimen. Pressure changes were recorded using a digital pressure transducer (Omega Inc., Norwalk, CT).

Data Collection & Analysis – As shown in Fig. 2, the undeformed configuration of each specimen was captured by dissecting a small segment of the infrarenal aorta. From the captured images, wall thickness (t) and outer and inner radii (r_i) were measured. A perfusion rate of 0.5 mL/min was used until burst pressure was achieved. Simultaneous pressure data and images were recorded via a custom LabVIEW® program. Using the Vision Assistant® package from LabVIEW®, suture to suture distances (axial deformation) and external diameter changes (circumferential deformation) of the specimens were measured.

Figure 2: Schematic of experimental protocol and data collection procedure.

Mean circumferential and axial Cauchy stresses, along with Green strains for finite deformation, were calculated using Eqs. (1) - (4),

$$\sigma_{\theta} = \frac{Pr_i}{t} \quad (1)$$

$$\sigma_z = \frac{Pr_i}{2t} \quad (2)$$

$$E_{\theta} = \frac{1}{2} (\lambda_{\theta}^2 - 1) \quad (3)$$

$$E_z = \frac{1}{2} (\lambda_z^2 - 1) \quad (4)$$

where P is the applied transmural pressure. From the stress-strain curves, biomechanical parameters such as the elastic modulus (slope of the linear portion of the curve), maximum stress, and maximum strain were recorded for each specimen orientation (i.e. axial or circumferential).

Statistical Analysis – Data were expressed as mean \pm std. deviation for all biomechanical parameters. To test for significant differences, unpaired t-tests were applied across the groups (saline vs. PGG). Data was considered significant at $p < 0.05$.

RESULTS

Biomechanical analysis of the murine abdominal aorta specimens revealed a stiffer response from PGG-treated specimens compared to the controls. There were no significant differences in the biomechanical parameters in the circumferential orientation. In the axial orientation, the elastic modulus of the control specimens was lower, but non-significant, than the PGG treated specimens (Fig. 3A; $p = 0.11$). The maximum stress achieved by PGG treated specimens (88.6 ± 18.0 kPa) was nearly 3.43 times greater than the control specimens (25.8 ± 4.8 kPa) (Fig. 3A; $p < 0.001$). However, the maximum strain was lower in

the specimens from the PGG group compared to the saline group (Fig. 3C) (0.110 ± 0.018 mm/mm vs. 0.078 ± 0.008 mm/mm; $p < 0.001$).

Figure 3: Biomechanical parameters derived from the axial direction of the murine abdominal aorta specimens. *denoted level of significance at $p < 0.001$.

DISCUSSION

In this investigation, we utilized a peri-adventitial application of PGG to the murine abdominal aortas as a preventive measure prior to elastase-induced pathological changes. The observed biomechanical changes in the PGG-treated specimens may be due to the crosslinking activity of the polyphenol *in vivo*. PGG forms cross-links across ECM proteins, especially elastin and collagen, and forms a stabilized arterial matrix that enhances its biomechanical strength. Future studies are needed to determine if (i) a topical application is the best method for suppressing aneurysm growth, (ii) the increase in stiffness due to PGG treatment is dose dependent, and (iii) the PGG will be effective in suppressing small diameter aneurysms in a clinical setting.

INTRODUCTION

Analysis of peripheral venous pressure (PVP) waveforms is a novel method of monitoring intravascular volume, especially in cases of hemorrhage. [1][2] However, the PVP signal can potentially be confounded by parameters other than volume status, such as anesthetic agents. We hypothesized that inhaled anesthetics may have an impact on the PVP signal in the pediatric patient undergoing elective surgery for craniosynostosis, where isoflurane is used as an anesthetic agent.

During craniosynostosis surgery, prematurely closed sutures on the skull are opened, and moderate to severe hemorrhage from scalp vessels occurs routinely. The depth of the patient's anesthesia both in the hemorrhagic and non-hemorrhagic portion of the surgery is controlled by altering the minimum alveolar concentration (MAC) of isoflurane, where a higher MAC corresponds to a higher dosage of the anesthetic. This study determines if MAC influences the PVP waveform, and then utilizes machine learning to predict MAC given an arbitrary PVP waveform.

METHODS

Data Acquisition: Data were collected at Arkansas Children's Hospital from nine sequential patients undergoing surgery for craniosynostosis. PVP waveforms were continuously collected from patients using a 24-gauge Insite N-Autoguard peripheral intravenous (PIV) catheter (Becton Dickinson Infusion Therapy Systems) which was connected to a Deltran II pressure transducer (ADInstruments) through a 48-inch arterial pressure tubing. [1] Two patients were discarded

due to missing data relating between real operation time and its equivalent *LabChart* time.

Algorithm Development: Due to interference in the PVP waveform from device motion, system set-up error, PIV location, and sensitivity to movement, incisions, and breathing, an algorithm was developed using *MATLAB* to pre-process the data and remove unwanted parts of the waveforms.

First, the entire PVP waveform was sampled at a rate of 100Hz from *LabChart* for each patient. After sampling the waveform, the PVP data was exported into a custom *MATLAB* program along with the corresponding MAC value for every PVP value. The program allows the user to select the time period in which to analyze the data with the algorithm, and the number of standard deviations from the mean waveform value that will serve as the upper and lower bounds of the cleaned data. The algorithm takes sections of the PVP data at a user-selected length of time to analyze. For every section of the PVP waveform signal, the mean value of the data in that section was calculated, and if any data points in that time section exceeds above or below the user-defined number of standard deviations, then the entire section of data is removed. This method is illustrated in Figure 1 below. The algorithm goes through the entire PVP waveform, which can be up to 4 hours long, removing sections of the data that are unwanted. After cleaning the data, the final waveform is exported, and transformed into the frequency domain before statistical analysis.

Figure 1: Data Pre-processing algorithm.

Statistical Analysis: Before performing the statistical analysis, the PVP waveform was separated into 10-second segments based on which MAC group they fell into. There were n MAC groups that were assigned a group number $n > 0$ when MAC fell between $n-1$ and $n-0.1$. For example, if MAC ranged between $[0-0.9]$, then it would be classified as MAC group 1. In Table 1 below, the MAC groups for each patient are listed.

Table 1: MAC groups for each patient.

	MAC group #
Patient 3	1, 2, 3
Patient 4	1, 2, 3
Patient 5	1, 2
Patient 6	1, 2
Patient 7	1, 2, 3, 4
Patient 8	1, 2, 3, 4, 5, 6
Patient 9	1, 2, 3, 4

After grouping the PVP waveforms, a multivariate analysis of variances (MANOVA) test was applied using *R Studio* for each patient. The independent variable for the test was MAC group and the dependent variable was the PVP waveform, with 50 frequency variables.

Finally, each patient's PVP data was loaded into the machine learning system, which utilized a k-nearest neighbor test to predict if the PVP data was from MAC group 1 and 2. For the test, $k=1$ and 70% of the patient's data was used for training, and 30% was used for testing the system.

RESULTS

Because of its robustness, the Pillai's Trace was utilized as the test statistic for the MANOVA test, with $\alpha=0.05$. The results of the test are shown in Table 2 below.

Table 2: MANOVA results.

	df	df_{error}	F	$partial \eta^2$	$p-value$
Patient 3	50	231	4.60	0.499	<0.01
Patient 4	50	221	3.02	0.406	<0.01
Patient 5	50	249	2.79	0.359	<0.01
Patient 6	50	571	17.30	0.602	<0.01
Patient 7	50	101	2.86	0.586	<0.01
Patient 8	50	110	7.26	0.768	<0.01
Patient 9	50	226	3.71	0.450	<0.01

The results from the k-nearest neighbor test are shown below in Table 3. The correct and incorrect predictions are shown as fractions out of the total number of 10-second segments.

Table 3: K-nearest means prediction results.

	Correct Prediction	Percent Correct	Incorrect Prediction	Percent Incorrect
Patient 3	66/82	80%	16/82	20%
Patient 4	55/67	82%	12/67	18%
Patient 5	89/90	98%	1/90	2%
Patient 6	143/186	77%	43/186	23%
Patient 7	27/35	77%	8/35	23%
Patient 8	23/28	82%	5/28	18%
Patient 9	64/82	78%	18/82	22%

DISCUSSION

Our study found that there is a significant relationship between the dosage of inhaled anesthetic and the PVP waveform. The PVP waveform increases as the MAC increases. We were also able to show that the machine learning system was able to accurately distinguish between the PVP waveforms of each MAC group and predict the correct MAC for an arbitrary PVP at least 77% of the time. Isoflurane is a known potent vasodilator, and our results indicate that the subsequent changes in vascular resistance are reflected in the venous circulation and thus PVP signal as well. Future research in PVP waveforms should take into account any anesthetic agents the patient has received, and this clear relationship should be considered in any future application of PVP signal technology. These results are also useful for the development of a novel anesthesia monitor for children, as the only current device of this kind is a bispectral index monitor which only assesses the depth of anesthesia.

INTRODUCTION

Pulmonary hypertension (PH) is a fatal disease that has an incidence of 15-50 people per million with a median survival of 2.8 years [1]. PH is characterized by endothelial dysfunction, including reduced vasodilation and increased inflammation in blood vessels partially due to decreased nitric oxide (NO) bioavailability [1]. In addition, PH lungs show increased glucose uptake and glucose-mediated protein post-translational modifications such as protein O-GlcNAcylation [2,3].

NO is produced by activation of endothelial nitric oxide synthase (eNOS) through eNOS phosphorylation at the Ser-1177 site [4]. eNOS activity can also be modified at this same site by O-GlcNAcylation [5]. eNOS O-GlcNAcylation may decrease eNOS phosphorylation and consequently decreased endothelial NO bioavailability [5,6]. Protein O-GlcNAcylation occurs through the hexosamine biosynthetic pathway (HBP), which produces the critical substrate UDP-GlcNAc. The addition and removal of O-GlcNAc from target proteins is performed by O-GlcNAc transferase (OGT) and O-GlcNAcase (OGA), respectively [5].

Statins have shown positive effects in many cardiovascular diseases via improved endothelial cell function and anti-inflammatory effects [7]. Animal studies using statin treatment have shown success in reversing pulmonary vascular remodeling but the exact mechanism responsible is unknown and human studies have been inconclusive [8-10]. *In vitro*, statins increase endothelial cells eNOS and reduce cell glucose metabolism via glycolysis [9,11]. We hypothesized that statins reduce eNOS O-GlcNAcylation to promote eNOS phosphorylation and NO bioavailability. To investigate this hypothesis, we treated HUVEC with fluvastatin *in vitro* at varying concentrations and time durations and measured total and GlcNAcylation eNOS by Western blot.

METHODS

Human umbilical vein endothelial cells (HUVEC) were cultured in Endothelial Growth Medium-2 (EGM-2) supplemented with 10% fetal bovine serum, 1% penicillin-streptomycin, and 1% L-glutamine. 300,000 cells/mL were seeded on collagen coated plates. Experimental treatment began when samples reached confluency 48 hours later.

HUVEC were treated with supplemented EGM-2 with or without 500 nM fluvastatin for 24 or 48 hours. In some cases, 100 μ M ATP in PBS was added for 1-minute following fluvastatin treatment to investigate eNOS phosphorylation. Following treatment, samples were analyzed via Western Blot. Samples were washed with cold PBS and scraped off in ice-cold lysis buffer (20 mM EDTA, 2 mM NaVO₄, 2 mM PMSF, 50 mM NF, 10% glycerol, complete protease inhibitor (Roche), pH 7.4). Next, samples were needle lysed, and centrifuged in 4°C at 13,000 RPM for 10 minutes. Supernatant was collected and the protein content of all samples was normalized via BCA assay. Sample proteins were separated by SDS-PAGE on a 4-12% Bis-Tris gel (Life Technologies) and transferred to nitrocellulose membranes using the Invitrogen iBlot system. Membranes were blocked with a 5% BSA in PBS-T solution for 1 hour. Membranes were incubated overnight with primary antibodies for protein O-GlcNAcylation, p-eNOS, eNOS, OGT, OGA, and β actin, followed by a horseradish peroxidase conjugated secondary antibody for 2 hours at room temperature. Protein bands were detected using an enhanced chemiluminescence kit (Western Lightning, PerkinElmer) and visualized with a Fluorchem digital imager (Alpha Innotech). Protein band intensities were quantified using AlphaEase FC software. Student's t-test was used to compare experimental groups (*p<0.05, **p<0.01, ***p<0.001).

RESULTS

We first measured eNOS quantity and protein O-GlcNAcylation in HUVEC exposed to fluvastatin at varying doses (Figure 1) and for increasing times (Figure 2). eNOS O-GlcNAcylation significantly decreased ($*p<0.05$) while total eNOS significantly increased ($*p<0.05$) when HUVEC were treated with 5 μ M and 10 μ M fluvastatin (Figure 1A and 1B, respectively).

Figure 1: Endothelial cells treated with higher fluvastatin concentrations showed a significant decrease in eNOS O-GlcNAcylation (A) and increase in eNOS (B) as compared to untreated cells. HUVECs were treated with 0, 100 nM, 500 nM, 1 μ M, 5 μ M, or 10 μ M fluvastatin for 24 hours. ($*p<0.05$, $**p<0.01$, $***p<0.001$).

We next tested whether a lower fluvastatin dose (500 nM) would affect eNOS at longer time points, since concentrations only up to 1 μ M are possible in human circulation after standard drug dosage [10]. eNOS O-GlcNAcylation, normalized to either β actin or total eNOS, decreased ($***p<0.001$) after both 24 hours and 48 hours of fluvastatin treatment (Figures 2A and 2B, respectively). Total eNOS also increased ($**p<0.01$) after both 24 hours ($**p<0.01$) and 48 hours ($***p<0.001$) of fluvastatin treatment (Figure 2C).

Figure 2: HUVEC treated with 500 nM fluvastatin for 24 and 48 hours showed a significant decrease in eNOS O-GlcNAcylation and increase in eNOS as compared to untreated cells ($*p<0.05$, $**p<0.01$, $***p<0.001$).

We next investigated whether the decrease in eNOS O-GlcNAcylation due to fluvastatin treatment increased eNOS phosphorylation (Figure 3). HUVEC treated with fluvastatin and then stimulated with ATP showed a significant increase in peNOS compared to HUVEC that were not treated with fluvastatin when samples were normalized to β actin (3A, $*p<0.05$). However, the effect was not significant when samples were normalized to total eNOS (3B, $p>0.05$). This suggests that the increased peNOS in fluvastatin treated cells is due to increased eNOS expression and that eNOS O-GlcNAcylation may not affect ATP-induced eNOS phosphorylation.

Figure 3: HUVEC treated with 500 nM fluvastatin for 24 hours and stimulated with 100 μ M ATP (F(A+)) showed a significant increase in peNOS compared to controls stimulated with ATP (C(A+)) when normalized to β actin but not when normalized to eNOS ($*p<0.05$, $**p<0.01$, $***p<0.001$).

DISCUSSION

We now show that fluvastatin decreases eNOS O-GlcNAcylation, which may contribute to its positive effects in cardiovascular disease. Our results do not suggest that reducing eNOS O-GlcNAcylation via fluvastatin increases eNOS phosphorylation. However, whether reduced eNOS O-GlcNAcylation restores eNOS function and NO bioavailability in diseases such as PH warrants further investigation. The effect of statins on other diseases with increased O-GlcNAcylation, such as hyperglycemia in diabetes, should be explored in the future.

INTRODUCTION

The two atrioventricular heart valves (AHVs), the mitral valve (MV) and tricuspid valve (TV), facilitate proper cardiac blood flow through opening and closure of soft tissue leaflets. These soft tissue leaflets are supported during closure by the chordae tendineae (CT), preventing prolapse of the leaflet into the atria. However, when the chordae tendineae fail to prevent leaflet prolapse regurgitation can occur. Currently surgical methods include chordal replacement using an expanded polytetrafluoroethylene (ePTFE) suture. However, the materials used in the chordal replacement have a higher elastic modulus than the native CT which can lead to regurgitation recurrence [1]. Refinement of these surgical procedures can be informed through characterizations of the native CT's mechanics.

Previously studies have performed quantifications of the CT's stress-stretch response as an *individual* segment, rather than as a functioning *group* [2-3]. In *individual* CT testing, the CT were separated from the leaflet and papillary muscles points of attachment before mechanical testing. However, by analyzing the chordae mechanics as a *group* structure by preserving the points of attachment, a mechanical characterization may be made which better represents how the CT operates *in vivo*. Further, limited information exists on the mechanics of the CT of the TV. This study addresses the need for mechanical characterizations of the CT as a *group* structure, which will be useful in computational modeling and therapeutics refinement.

METHODS

Tissue Preparation: Healthy porcine hearts (80-140 kg, 1-1.5 years of age) were retrieved from a local slaughterhouse. For group CT testing, the thickest, strut CT of the mitral valve anterior leaflet (MVAL) and tricuspid valve anterior leaflet (TVAL) were excised with their papillary

muscles and leaflet points of attachment preserved, obtaining one group from the left (LG) and right (RG) of the leaflet apex (**Fig. 1a**).

Figure 1: (a) The CT group was excised from the valve, preserving leaflet and papillary muscle points of attachment and tested (b) using a tine-based approach, as opposed to (c) schematic of the clamping mechanism used in the individual CT testing [2-3].

Mechanical Testing: In group CT testing, specimens ($n=7$ for each group) were mounted to a commercial biaxial testing system (BioTester – CellScale Biomaterials Testing) using tines which pierced the papillary muscles and leaflet sections (**Fig. 1b**). This tine-based testing

method allows for freedom of movement for the chordal points of attachment at the papillary muscles and leaflet, as opposed to a clamping-based method (**Fig. 1c**) where those interactions are not adequately considered. Fiducial markers were placed on the CT segment for data image correlation (DIC)-based strain calculation.

CT groups were mechanically tested by: (i) a preconditioning step of 15 loading and unloading cycles, targeting a force of 1.4N and 1.2N for the MVAL and TVAL CT tissue groups, respectively, and (ii) a mechanical testing step of 15 additional loading and unloading cycles. The preconditioning step was performed to exercise the tissue to its *in vivo* configuration [4]. The testing forces employed were used due to their similarity to physiologic loading in the respective valves [5-6]. Chordal diameters were measured using a microscope.

Data Analyses: For calculating stress chordal diameters were used assuming a circular, uniform cross-sectional area. Tissue stretch was quantified using DIC techniques to obtain time-dependent fiducial marker positions. Marker positions were used to find the three components of CT stretch: (i) the preconditioning stretch (λ_0^1), (ii) the total tissue stretch (λ_0^2), and (iii) the mechanical stretch (λ_1^2).

Statistical Analyses: Physical quantities were determined for statistical significance using SAS 9.4. One-way ANOVA was used to determine significance between CT groups of the same valve. Two-way ANOVA was used to determine significance between left and right CT groups, and MVAL and TVAL CT groups, with the interaction term also considered. A p-value <0.05 was considered statistically significant, while a p-value <0.10 was deemed nearly statistically significant.

RESULTS

The diameters of the MVAL CT tissue groups were found to be 30-60% thicker than the TVAL CT tissue groups. Specifically, the MVAL-RG diameters were nearly significantly higher than the MVAL-RG (p=0.059). Also, the MVAL CT diameters were found to be significantly higher than the TVAL CT thicknesses (p<0.001).

CT tissue groups followed the non-linear, exponential force-displacement trend expected of soft tissues (**Fig. 2**) [7]. The mean preconditioning stretches (**Fig. 3a**) of the MVAL CT tissue groups were found to be significantly higher than the TVAL CT tissue groups (p=0.014). The RG was found to have a nearly significantly higher preconditioning stretch than the LG (p=0.068). Additionally, the mean preconditioning stretches of the MVAL RG were found to be nearly significantly higher than the MVAL LG (p=0.081).

Figure 2: The force-displacement responses of the (a) MVAL-CT tissue groups (n=6) and (b) TVAL-CT tissue groups (n=7).

From the total tissue stretches (**Fig. 3b**), the MVAL CT tissue groups experienced significantly higher total tissue stretch than the TVAL CT groups (p=0.018). Nearly significant difference was found between the LG and RG (p=0.083). From mechanical stretches, no statistically significant differences were found (**Fig. 3c**).

Figure 3: The (a) preconditioning stretch, (b) peak stretch, and (c) mechanical stretch of the CT group. Values are reported as the mean \pm SEM. Notation: *, statistical significance; **, near statistical significance; N.S.S, not statistically significant.

DISCUSSION

This study provides a unique characterization of the MVAL and TVAL CT which considers the effects of the points of attachment on observed CT mechanical properties, rather than characterizing *individual* CT segments. Further, this study contributes to the limited research of the right-side CT. In a previous study [3] testing *individual* strut CT of the MV and TV to a 1MPa stress it was found that the MV CT had an approximate 6.5% strain and the TV CT had an approximate 1.5% strain. In our study testing CT *groups*, at a 1MPa testing stress the MV and TV CT were found to have an average strain of $13.1 \pm 3.2\%$ and $20.7 \pm 3.0\%$, respectively. Comparing to previous studies it can be seen the preservation of the chordal points of attachments provides new, unique information about the chordal mechanics.

This study has some limitations. For instance, there was some CT shear/torsional stress in uniaxial mechanical testing due to improper planar alignment of the specimen. However, this stress can be considered negligible as the CT segment recovered its *in vivo* functional state after approximately 10 loading/unloading cycles where axial stretch was the dominant stretch mode. Using the information found in this study, computational models of the AHVs may be refined to inform therapeutic refinement using characterizations which represent CT function *in vivo*, as compared to characterizations of *individual* CT.

INTRODUCTION

From 2010 to 2017, 439 children, among the 4,731 children on the transplant list, died while waiting for a heart. [1] There is a clear shortage of hearts available for transplant and a need for a pediatric bridge-to-transplant device.

To meet this need, a pneumatic, pulsatile pediatric ventricular assist device (PVAD) has been developed by Penn State and is shown in Figure 1. While animal studies have been encouraging, thrombus formation has been observed, which remains a problem in ventricular assist devices. Previous studies have shown that surface roughness of the segmented poly-(ether polyurethane urea) (SPEUU) seamless blood sac can lead to the aggregation of platelets in a fibrin matrix.

Figure 1: The Penn State pediatric ventricular assist device developed at the Penn State College of Medicine. [2]

The goal of this research is to study surface irregularities in relation to the presence of platelet and fibrin deposits, which will provide insight into why thrombosis occurs here.

METHODS

Twelve ovine studies have been completed at the Penn State Hershey Medical Center with the PVAD implanted in the animal for a target of 4 to 6 weeks. An explanted blood sac was characterized for each study. Immunofluorescent labeling and confocal microscopy were used to identify the presence of platelets and fibrin on the surface of the blood sac. These structures were confirmed with environmental scanning electron microscopy (ESEM). Biological structures were enzymatically degraded from the surface, and optical profilometry was used to characterize the surface topography of each blood sac. All images were taken in a snake-like pattern shown in Figure 2.

Figure 2: Samples from each blood sac were cut to a size of 4 mm by 3 mm. The microscopy and profilometry images were correlated using the numbering scheme presented. [3]

The roughness average (Ra), an average of all values on the roughness profile, the root mean squared (RMS), an average deviation from the roughness average center line, and the Swedish height (H), a roughness average of the middle 90% of the data, were collected for each sample. An overview of these methods is shown in Figure 3. A non-implanted SPEUU blood sac was used as the control and was analyzed with the same methods. Images taken from confocal, ESEM, and optical profilometry were correlated for each sample, as shown in Figure 4. Based on these images and the surface roughness parameters, the relationship between thrombus deposition and surface topography was determined.

Figure 3: Overview of explanted sac protocol. [3]

Figure 4: (A) Sample confocal microscopy, (B) ESEM, and (C) optical profilometry images taken from a macroscopic clot on the surface of the Penn State PVAD blood sac. [3]

RESULTS

Explanted sacs were analyzed by studying the correlated images. In total, 5 macroscopic deposits were found on 4 of the 12 sacs studied. There were also 26 microscopic deposits found across all of the 12 sacs studied. Macroscopic deposits were visualized without the use of a microscope, where the microscopic deposits were revealed upon use with the confocal microscope.

A diagram of the PVAD is shown in Figure 5, with locations for all deposits identified and later analyzed.

Figure 5: Map of all deposits found across the 12 sacs analyzed. In total, (A) there were 22 microscopic deposits with 5 macroscopic deposits found on the front of the sac, and (B) 4 microscopic deposits found on the back of the blood sac.

The topography of each sac was analyzed by the size of the deposit to compare the roughness in regions of macroscopic deposits, microscopic deposits, and the control. The RMS value for the five macroscopic deposits observed was 16% greater than that of the 26 microscopic deposits and 76% greater than the control. Similar trends were observed for the roughness average (Ra) and Swedish height (H).

Figure 6: Comparing average RMS, Ra, and H values for macroscopic clots, microscopic clots, and a control sac.

DISCUSSION

There was greater sac surface roughness in regions of larger thrombus deposition. The majority of the deposits were found in the transition from the inlet and outlet ports to the main body of the sac.

The surface roughness parameters are higher for macroscopic and microscopic clots than for the control samples. A two-factor t-test ($\alpha = 0.05$) was conducted to determine the significance of the findings. The difference between the macroscopic deposits and the control was significant for RMS, Ra, and H. The difference between the microscopic deposits and the control was also significant for RMS, Ra, and H. The differences between macroscopic and microscopic deposits were not statistically significant for any surface roughness parameter.

These data provide a procedure for determining the relationship between thrombus deposition and surface topography in the Penn State PVAD. Areas of higher surface roughness on the SPEUU seamless blood sacs could promote deposition of platelets and fibrin. Future studies could add more statistical significance to the results found for these 12 sacs and provide a more complete map of deposit locations.

INTRODUCTION

The vascular system plays the essential role of delivering oxygenated blood to tissues throughout the body, and when it fails dire consequences are seen. For example, aortic aneurysms that rupture kill more than 15,000 people per year¹. Even more troubling, the incidence of aortic aneurysm has tripled in the U.S. during the past 30 years¹. Aortic dissections discovered after they occur are deadly (~20% of patients die before reaching hospital). Both aneurysm and dissection are aberrant mechanical events, and understanding of how and why they happen is crucial to prevention, diagnosis, surgical interventions, and therapeutic development. While aortic dissections can occur in different regions of the aorta, there is a disparity in the prevalence of where they happen, with the most common starting in the ascending thoracic aorta and extending to or beyond the aortic arch². Thus, we hypothesize there are characterizable regional differences in the mechanics of the aorta.

The goal of this study was to determine the properties of the wild-type (WT) mouse aorta along its entire length through the excision and uniaxial testing of ring specimens. A finite element (FE) model of a ring-pull test was regressed to experimental data to determine mechanical properties. In the past, ring-pull experimentation could not be used to elucidate mechanical properties directly because the ring pulls had to be treated as uniaxial tests, which they are not. With improved methods for solving FE problems, however, particularly for contact problems, it is now possible to use inverse methods to solve for mechanical properties in such systems. The overall questions addressed by this work were whether aortic mechanical parameters could be reliably ascertained from ring-pull experiments, how they change in different regions, and how they affect macroscopic behavior under *in vivo* like conditions (i.e., inflation with physiologic pressures).

METHODS

Sample Preparation

The heart and attached aorta were dissected from adult WT mice (age 8 -16 months) between the iliac bifurcation and top of the arch. The aorta was cut at its root away from the heart and sectioned into alternating ~0.5mm and ~2mm wide rings (Figure 1). Samples 0.5 mm in width were used to establish the average wall thickness and inner/outer diameter of rings. Rings 2mm in width were measured and used for the ring-pull tests. Ring inner diameters varied between 0.97 and 1.19mm.

Figure 1: A. Aorta and approximate cut locations; B. Cut rings; C. Top-view of ring; D. Side-view of ring on pulling apparatus

Ring-Pull Test Protocol

The 2mm wide rings were placed onto a custom fixture, consisting of a pair of thin wires (0.5mm in diameter) inserted through the lumen of the aorta sample⁴. Each fixture was attached to a load cell and oriented so that the pull was uniaxial. Rings were preloaded to an elliptical shape to keep them from moving on the fixture. Rings were pulled at a rate of 2mm/min until failure³. Figure 2 shows the dimensions used and a schematic of the test.

Figure 2: Ring-pull test geometry and schematic
FE Ring-Pull Simulation and Parameter Optimization

A computational model of the ring-pull experiment was created in FEBio. The wire rod in the test was treated as a rigid body, and the tissue ring was treated as an uncoupled solid mixture, with neo-Hookean behavior and an exponential power law to account for two different fiber populations—located at +45 and -45 degree orientation in the circumferential-axial plane (1)^{3,5,6}.

$$W = c_1(I_1 - 3) + \frac{\xi}{2\alpha} * (e^{0.5\alpha(\lambda^2 - 1)^2} - 1) \quad (1)$$

W is the total strain energy density function of the tissue; c_1 the constant for the neo-Hookean nature of the tissue; I_1 is the first invariant of the deformation gradient; ξ is the fiber bundle modulus; α is the exponent representing non-linearity; and, λ is the stretch of the tissue. A custom code was developed that used the Nelder-Mead simplex algorithm to optimize the parameters c_1 , ξ , and α to match experimental force/displacement data.

Because the simulation involves a contact problem, more setup was required to get the correct results. At the start of the simulation, the tissue was placed precisely in contact with the wire. This requirement added a layer of complexity to the problem, and a custom code was created to take a template FE model file, filter out the tissue nodal positions, scale them to the dimensions of the specific ring used in the experiments, shift them into exact contact with the rod, and output a correct simulation file specific to each ring sample. The contact was specified to be a sliding interface between the rod and the inner ring surface, neglecting friction between the surfaces. The augmented Lagrangian method with two-pass automatic penalty was used with a penalty factor of 2 and a gap tolerance of 0.01.

RESULTS

The optimized parameters from ring-pull simulation are shown in Figure 3 along with a representative fit. The constant scaling the neo-Hookean portion (c_1) dominates in low-strain regions, as fiber stretch has not yet come into play. Parameters α and ξ govern the behavior of fibers, and come into play in larger strain regions where non-linear stress/strain relationships are present. The general trend of the data shows increasing fiber stiffness and nonlinearity as we move around the arch from the aortic root toward the upper portion of the thoracic aorta. Parameters were also determined from a uniaxial fit to the experiment data, which yielded α values two orders of magnitude larger (0.585 to 1.338), c_1 values decreasing from nearly the same values for the first two rings (0.0145, 0.00747 MPa) to nearly zero for the last two rings, and ξ values an order of magnitude smaller (0.00724 to 0.0507 MPa) than those determined from the optimization shown in Figure 3b.

Figure 3: A. Representative fit of FE force-displacement with experimental data B. Optimized parameters for ring-pull tests

Figure 4 shows a heat map of the 1st principle stress for a representative simulation. The stress tends to concentrate on the luminal side just past the contact point of the rod. The geometry along the rod and just beyond the contact patch becomes wider along the luminal surface, as has been observed in experiments.

Another important aspect of this simulation is the implementation of contact. The contact gap was maintained to be less than 5% of the initial wall thickness with typical values <1%. The contact pressure along the surface increased from zero to ~2.5MPa under large strains.

Figure 4: Stress concentration in tissue during ring-pull
DISCUSSION

The optimization of model parameters using the simplex method provided a reasonable fit to the experimental data (average RMSE of 4mN). This is significant because the simulation does not make the uniaxial assumptions made when one simple curve fits the constitutive model. This is highlighted in Figure 4, where stress concentrates along the tissue surface in contact with the wire rod, which is something not accounted for in uniaxial extension. The uniaxial fit to the data predicted much different parameters compared to the optimization done in this study, typified by much more nonlinear fibers and very little influence of the neo-Hookean ground substance. Thus, determining model parameters through FE optimization is more appropriate than treating these experiments as uniaxial extension.

It is clear that different regions have different behavior (i.e., have different model parameters) (Figure 3b). A general trend is seen where the fiber parameters become more prominent and nonlinear as we move along the aorta, whereas the neo-Hookean component (elastin matrix, ground substance) remains relatively constant. It is hard to draw conclusions, however, based on the limited sample size.

Future work on this project will include adding to the dataset of WT mouse aortas to distinguish behaviors between groups (e.g., male vs. female, old vs. young). The results from this study will serve as the basis for a new FE model of mouse aorta expansion during inflation, accounting for the regional variation measured here.

A COMPUTATIONAL STUDY OF THE ROLE OF THE PERICARDIUM ON CARDIAC FUNCTION IN NORMAL AND HYPERTENSIVE HEARTS

INTRODUCTION

The heart and lungs operate as a single functional unit [1]. Efficient operation of the cardiopulmonary system requires coordinated performance of the left (LV) and right ventricles (RV). Pulmonary arterial hypertension (PAH) causes an increase in pressure and subsequent growth and remodeling in the RV. While the pericardium has been shown to impact LV and RV interdependence, the effect of the pericardium on ventricular interaction and organ-level cardiac function in a hypertensive heart remains unexplored [2]. We recently developed finite-element (FE) rat heart models (RHM) of both normal and hypertensive specimens using extensive imaging and pressure-volume datasets [3]. In this work, we extended our biventricular RHMs to account for the effect of pericardial sacs and used the models to investigate the alterations in systolic and diastolic ventricle interaction and function from a normal to hypertensive state. We used the extended models to test the hypothesis that the gradual dilation of the RV throughout the development of PAH compromises the integral of the pericardium, which is to act as a mechanical constraint against pathological changes in heart size [4].

METHODS

We developed two implementations of the FE biventricular RHM based on extensive datasets from normal and post-hypertensive rat hearts in order to simulate and understand the local and organ-level remodeling of the RV in response to PAH. Additionally, we implemented model-specific pericardia to investigate the role of the pericardium with respect to ventricular function in both normal and hypertensive hearts.

PAH Animal Model

A total of 8 male Fischer-344 rats were used in this study. The hypertensive group (PAH, n=4) received a moderate dose of

monocrotaline (MCT) by subcutaneous injection to induce PAH. The control group (n=4) received an equivalent volume of saline. At four weeks post MCT injection, terminal pressure-volume (P-V) measurements were collected and the harvested hearts were imaged by a cardiac MRI scan. FE biventricular RHMs (Fig. 1) were constructed and validated using imaging datasets and in-vivo hemodynamic measurements collected at the Texas Heart Institute.

Figure 1: FE models of control (left) and PAH (right) murine hearts (green) and pericardia (yellow).

Finite Element Model

An anisotropic hyperelastic constitutive model was used for both myocardium and pericardium. Myofiber direction was mapped to the FE mesh from reconstructed diffusion tensor imaging. The fibrous structure of the pericardium was assumed to have a similar distribution as that of the epicardium of the heart.

$$\mathbf{S} = \mathbf{S}^{passive} + \mathbf{S}^{active} \quad (1)$$

A stress decomposition approach to was used to describe the passive and active behaviors of the tissue (1), where

$$\mathbf{S}^{passive} = \frac{\partial W^{dev}}{\partial \mathbf{E}} + \mathbf{S}^{vol}$$

$$\mathbf{S}^{active} = T_{Ca^{+2}}(t) \frac{1 + \beta(\lambda - 1)}{\lambda^2} \mathbf{N} \otimes \mathbf{N} \quad (2)$$

and where T_{Ca} is the contractility parameter, \mathbf{N} is the fiber direction, and β is a constant. W^{dev} is the deviatoric strain energy.

Inverse Modeling

The RHM passive and active behavior was determined through an inverse modeling approach to match the organ-level hemodynamic measurements. Passive stiffness was determined by matching the end-diastolic point in the model to in-vivo measurements. The active contraction parameter, T_{Ca} , was determined by minimizing the error between model behavior and the acquired pressure-volume (PV) loop.

Addition of the Pericardium

Pericardia were modeled as hyperelastic thin FE shells adjacent to the epicardium. Interaction between the pericardium and the epicardium is modeled as a frictionless sliding contact.

Several numerical experiments were conducted with the RHMs with and without pericardium in both control and hypertensive states and the following relationships were evaluated: (i) RV and LV volumetric inflation to assess the diastolic function of each ventricle, (ii) the influence of a varying chamber size in one ventricle on the end-diastolic pressure and peak-systolic pressure of the other to assess diastolic and systolic ventricular interdependence, (iii) complete P-V loops over one cardiac cycle to assess change in organ-level cardiac function.

Figure 2: RV and LV end-diastolic pressure-volume relationship in control and PAH hearts with (dashed) and without (solid) pericardium.

RESULTS

We found that the addition of the pericardium does not have a significant impact on the stroke volume (SV) of the control RHM, while it decreased the SV of the RV in the hypertensive heart. Addition of the pericardium resulted in a slight decrease in the contractility of the RV necessary to maintain cardiac output in the normal heart, whereas a significant increase in contractility was noted in the PAH model (Fig.

3). This may be due to the overall decrease in RV diastolic filling that we observed in the comparison of RV diastolic filling with and without pericardium. In addition, we found a significant lack of biventricular interaction during systole in the PAH heart with pericardium.

DISCUSSION

Results for the normal heart were consistent with previous studies of the functions of the pericardium and effects of pericardiectomy [2]. Notable changes in the end-diastolic volume are present in the RV with the addition of the pericardium in both control and PAH hearts. The slight decrease in the contractility of the control RV with pericardium and a significant increase of contractility seen in the PAH RV suggest that the major role of the pericardium, which is to act as a mechanical constraint to pathological variations in heart size, has been chiefly compromised in the hypertensive heart [4]. Results show little change in the LV function in both models, implying the presence of the pericardium does not biventricular interaction in either diastole and systole.

Figure 3: RV and LV contractility over the cardiac cycle of control and PAH hearts with (dashed) and without (solid) pericardium.

Further investigation in to the adaptation of the pericardium in hypertension are necessary to conclusively determine changes in the pericardium's adaptive function. The major assumption of this work was that the pericardium itself does not undergo remodeling due to PAH. Our investigation was limited by the lack of tissue experimentation examining fibrosis in the pericardium in response to PAH; future work will address these restrictions.

The presence of the pericardium is understood to impact cardiac output and ventricular interaction. Models such as those used in this study could inform the development of therapies for complex comorbidities in structural heart disease.

INTRODUCTION

With recent clinical evidence showing the immense benefit of endovascular treatment for acute ischemic stroke (AIS) with proper patient selection, a need has emerged to further optimize this procedure to minimize patient harm¹. While the primary goal of the AIS endovascular catheter treatment is to reestablish bulk flow to the occluded artery, it is unknown whether the catheter introduces additional cerebral hypoperfusion during deployment. With sensitive cerebral tissue already in an ischemic state (also known as penumbra zones) due to inadequate oxygen and glucose levels to sustain neuronal survival, additional hypoperfusion, even for a small duration, could impact long-term brain tissue recovery in localized regions. The purpose of this computational study is to quantify endovascular catheter induced hypoperfusion across patient populations during middle cerebral artery (MCA) thrombus removal procedures.

A 1D-lumped parameter network (LPN) cerebrovascular model², designed with cerebral autoregulation, CO₂ reactivity, cerebral spinal fluid (CSF) generation/reabsorption, and intracranial pressure dynamics can be used to study the hypoperfusion effects of an endovascular device, specifically catheters used for thrombus retrieval, on arterial blood flow in the brain. The 1D portion of the model is built upon the cross-sectionally averaged Navier-Stokes equations coupled to elastic arteries. The LPN represents the intracranial vascular bed dynamics through an electrical circuit model design. Static vascular beds are characterized through constant resistors to influence blood flow distribution as well as CSF generation/reabsorption, venous resistance, and cortical collateral vessels. Cerebral active flow compensation such as autoregulation and CO₂ reactivity utilizes dynamic resistances that model physiological behavior based around myogenic vasodilation or vasoconstriction. Overall, the LPN represents the intracranial space, and is constrained by the fixed volume balance of the Monro-Kellie doctrine between blood flow, CSF, brain tissue compliance, and intracranial

pressure. Ultimately, after a characteristic analysis and two-step Adams-Bashforth numerical solve, the cerebrovascular model outputs average arterial area, flow velocity, and pressure across the entire arterial network. The 1D-LPN model design facilitates aorta to cerebral circulation coverage, specializes in rapidly capturing flow rerouting and systemic flow dynamics, and can actively account for physiologic cerebral flow disruptions that deviate from baseline flow with autoregulation compensation. Additionally, the model has the ability to evaluate the hypoperfusion influence of both patient-specific and surgical parameters within an endovascular procedure, making it a reasonable model to study endovascular device hypoperfusion effects across a wide spectrum of parametric possibilities³. Understanding the influence of these parameters has implications for endovascular device design in ischemic stroke and works towards quantifying the potential undesired cognitive impact of endovascular device deployment.

METHODS

In order to study the effects of the catheter on blood flow within the cerebral network, the 1D-LPN model was first tuned to account for the change in arterial area where the catheter is present during surgery. The model areas were first tuned along specific vessels according to clinically-relevant catheter sizes (catheter diameter: 3mm, microcatheter diameter: 0.9mm)⁴. As shown in **Figure 1a**, for an occlusion in the right middle cerebral artery (RMCA), the catheter takes the path indicated by the blue line. The catheter pathways represent the typical endovascular routes neurointerventionalists take to reach the left or right middle cerebral arteries. To properly capture the flow effects of the endovascular device placement within the 1D vessel framework, an annular area-reduced vessel equivalent was calculated. Here, it is assumed that the catheter is positioned within the center of an artery to form an annular geometry producing a different flow effect from a general reduction of vessel area. For the equivalent area-reduction

calculation, Eq. (1), target vessel radii were calculated by equating flow between the standard and annular section Poiseuille's Law.

Figure 1: a) Visual representation of endovascular device path (in blue) within the 1D portion of the cerebrovascular model². b) Breakdown of the simulation scenarios for one endovascular pathway. Colors correspond to parameters varied in the study.

To provide unpressurized target areas to the cerebrovascular model, the percent difference between an artery's simulation area and its target area was used as a measure of tracking the artery's tuning progress. Along the way, visualization and data collection methods were implemented to track the progress of each artery through iterations, and a conditional gain system was created to make the updates between each iteration more robust.

Once the model was fully tuned to account for the presence of the catheter, parametric simulations were run. Specifically, 160 parametric simulations were run for each endovascular pathway, accounting for 40 different levels of MCA occlusion, endovascular catheter presence, and cerebral autoregulation ability (see **Figure 1b**). The 40 difference occlusion sizes ranged from 0 to ~100% (2.5% apart), with 0 representing a non-occluded artery and ~100% being the most extreme case. The catheter was treated as a binary parameter - it was either present or not present. Autoregulation was also treated as a binary parameter; either indicative of healthy young autoregulation or completely impaired global autoregulation ability. Looking at autoregulation ability as healthy (complete autoregulation ability) and completely impaired (no autoregulation ability) offers the best- and worst-case autoregulation abilities. From these simulations, flow values were extracted and averaged after steady-state (periodicity) was reached. These values were then compared against the flow value of the occlusion-free and catheter-free simulation case in order to determine the percent blood flow loss.

In an ischemic event, there is a reduction of blood flow in a localized area of the brain. By considering clinically determined flow thresholds for defining selective neuronal loss (between baseline and underperfused), penumbra (significantly underperfused and at-risk), and infarct (dead) tissue, rough approximations for tissue damage at particular occlusion sizes can be determined³. While these zones are highly dependent on ischemic duration, they provide context for the hypoperfusion degree needed for observable ischemic damage.

RESULTS

Overall, the presence of the catheter was found to decrease flow in the RMCA across all occlusion sizes and autoregulation abilities as shown by the difference in the dashed and solid lines in **Figure 2**. For occlusion sizes of approximately 45-75%, the catheter resulted in a significantly greater hypoperfusion effect than completely impaired autoregulation. However, for occlusions that were predicted to cause tissue to be in the upper penumbra region (75-90%), the flow effects of the catheter and autoregulation were comparable. Lastly, for occlusion sizes associated with infarct ($\geq 90\%$), the loss of autoregulation had a more devastating effect than the presence of a catheter, but the greatest hypoperfusion effect here is due to the occlusion itself. In addition to looking at flow within the RMCA, flow values for the other major cerebral arteries were investigated. Within the occlusion hemisphere, the neighboring right posterior cerebral artery (RPCA) flow was unaltered and the right anterior cerebral artery (RACA) experienced increases (+6%) or decreases (-15%) in flow depending on autoregulation ability and presence of the catheter.

Figure 2: Comparing RMCA percent blood flow loss due to catheter presence and autoregulation ability across occlusion sizes.

DISCUSSION

The endovascular catheter considered does contribute to MCA vascular bed hypoperfusion by decreasing MCA baseline flow by an additional 6 - 42% depending on the degree of MCA occlusion and autoregulation ability. Additionally, for MCA occlusion size of 42 - 90%, blood flow decrease due to the endovascular catheter is stronger than the impact of completely impaired autoregulation ability. While this study provides evidence that endovascular devices do significantly impact vascular bed perfusion during MCA thrombus removal, the cognitive consequence is unknown. Future work will focus on incorporating variations in cerebral circle topology, cortical collateralization ability, and various catheter sizes into the parametric study. Additionally, the authors plan to consider the neurological cost of this flow decrease by approximating the relationship between hypoperfusion degree, hypoperfusion duration, and subsequent neurological injury.

ALTERATION OF THE MECHANICAL RESPONSE OF PORCINE TRICUSPID VALVE ANTERIOR LEAFLETS FOLLOWING EXPOSURE TO DE-IONIZED WATER

Margaret M. Clark, Samuel D. Salinas, Rouzbeh Amini

Department of Biomedical Engineering
The University of Akron
Akron, OH, USA

INTRODUCTION

The biomechanical properties of the tricuspid valve (TV) leaflets have been quantified previously [1,2]. To minimize the effects of osmotic pressure on the mechanical responses of the tissues, in the abovementioned studies, isotonic phosphate buffer saline (PBS) were used for tissue storage and during the course of the experiments. While the effects of hypo- and hyper-osmolarity have not been particularly studied in cardiac valves, the mechanical response of other soft tissues has been shown to be sensitive to the osmotic pressure [3-5]. As such, our laboratory and many other investigators have used isotonic solutions whenever conducting experiments on cardiac valves.

In a recent published experiment, however, pulsatile flow of de-ionized (DI) water was used in ex-vivo hearts to stimulate cardiac valve motion [6]. Interestingly, the authors did not find any significant differences in the study outcomes using DI water. The objective of our study was to further examine the effects of DI water on the mechanical response of TV leaflets using a more controlled bench-top method, i.e. the biaxial mechanical testing approach. We *hypothesized* that the mechanical response of the porcine TV anterior leaflets obtained from biaxial tensile loading experiments will be different when the samples are immersed in DI water as compared to those immersed in PBS.

METHODS

Fresh porcine hearts were obtained from a local slaughterhouse and transported in chilled PBS solution. Upon arrival of the samples in our laboratory, the TV anterior leaflet was dissected (n=9). The average thickness of the leaflet was measured before it was trimmed to a custom 3D printed phantom [1]. While the sample was lined up in the anatomical radial and circumferential directions and placed in the custom phantom, suture lines were attached to the leaflet to be mounted on a biaxial loading machine according to previously established

methods [1]. Four fiducial markers were glued on the leaflet in order for the biaxial testing machine to track the deformation of the tissue. For the control test, five loading protocols were conducted while the tissue is immersed in PBS. The five protocols were performed similar to our previous published work [1], with a maximum stress of 127 kPa which roughly represented right ventricular pressure of 30 mmHg. The loading machine software reported the forces applied to the tissue, from which the stresses were calculated according to the following equations

$$\sigma_{rr} = \frac{F_r}{A} \quad (1)$$

$$\sigma_{cc} = \frac{F_c}{A} \quad (2)$$

where σ_{rr} and σ_{cc} are the normal stresses in the radial and circumferential directions, respectively; F_r and F_c are the tensile forces exerted on the tissue in the radial and circumferential directions, respectively; and A is the cross-sectional area of the trimmed square-shape TV leaflet specimen. The specimen was then removed from the biaxial machine and placed in DI water for 2 hours. The leaflet was trimmed again to the custom phantom before biaxial loading protocols, in which DI water was used as the immersing solution. For this study only the equibiaxial stress-strain data were used and analyzed. However, data from the other four protocols were stored properly for future analysis. For the equibiaxial cases, strain values were calculated from the positional data of the fiducial markers using an internally-developed MATLAB script as described previously [1]. To determine the changes in the tissue samples following DI water exposure, the circumferential and radial strains of the control experiments at the 85 kPa equibiaxial stress were compared to their post-DI-exposure values using paired Student's t-tests ($p < 0.05$ indicating significant difference).

Figure 1: The average radial and circumferential mechanical responses for pre- and post-DI exposure of the TV anterior leaflet for the equibiaxial loading protocol. Shaded regions represent standard error (n=9).

RESULTS

Visual examination of the equibiaxial stress-strain data (Fig. 1) shows that the average tissue strain decreased following exposure to DI water in the radial direction. The leaflet strain in the circumferential direction, however, appeared to be only slightly different from pre- to post-DI water exposure (Fig. 1).

We further examined the strain values at 85 kPa equibiaxial stress, which is an estimation for the physiological right ventricular pressure value of 25 mmHg (previously approximated using the law of Laplace [1]). As shown in Fig. 2, we found a significant difference between the values of strains in the radial direction for the samples that only immersed in the PBS and those of the same samples after exposure to DI water. However, no significant difference was observed in pre- and post-DI exposure strains in the circumferential direction.

It is noteworthy that the immersion in the DI water resulted in the tissue physically expanding due to osmotic swelling. As such, the samples had to be trimmed to the controlled size before biaxial mounting as shown in the visual representation in Fig. 3.

Figure 2: The comparison of the strain of the TV anterior leaflet immersed in PBS compared to that of the same samples after exposure to DI water at a stress level of 85 kPa. The error bars represent standard error (n=9). The asterisk represents significant difference.

Figure 3: Swelling of a representative anterior TV leaflet specimen following submersion in DI water. For comparison, the custom-made phantom used for trimming the sample is included. The upper left extension of the leaflet is used to reference the radial from the circumferential direction.

DISCUSSION

In this study we examined whether the DI water would be an acceptable alternative for storage and handling of heart valve tissues before and during biomechanical testing, as compared to commonly used isotonic PBS. Not only did we observe physical changes (i.e. expanding and thickening) in tissues due to swelling, we also found out that the mechanical response of the tissue significantly changed after exposure to DI water. In our strain examinations, we only observed significant changes in the radial direction. Nevertheless, due to the tensorial nature of the strain, any significant change in only one of the components of the strain tensor indicates a significant difference in the overall state of the deformation.

In their recent study [6], Pierce et al. measured the indentation response of the mitral valve annulus and its surrounding tissues in two sample groups: one submerged in DI water for three hours and one submerged in isotonic saline solution for the same amount of time. Unlike our observations, they did not find any significant difference between the two groups. One should be cautious in extending the conclusions of our multiaxial testing of heart valves to uniaxial indentation of the annular tissue. Nevertheless, we suspect that a small sample size, and consequently a large variability in the measured values of the indentation forces might have led to the conclusion of Pierce and colleagues.

In summary, consistent with our initial hypothesis, we found out that DI water immersion significantly impacted the biomechanical properties of the TV anterior leaflet. As such, isotonic solutions, such as PBS, are more suitable mediums for storage and handling of valvular tissues in experiments in which the biomechanical response of the leaflets plays an important role.

ON THE DISTRIBUTION OF AORTIC VALVE CUSP CALCIFICATION

Varshini Guhan, Megan Heitkemper, Dr. Lakshmi Dasi

(1) Department of Biomedical Engineering
The Ohio State University
Columbus, Ohio, United States

INTRODUCTION

Aortic valve stenosis is the buildup of calcification in the cusps of the aortic valve, which limits valve mobility and function. This disease has a high mortality rate in the elderly population and can become severe over the course of one year, thus taking the patient's life before an aortic valve replacement can be performed. In one study, aortic valve stenosis had a significantly low first-year survival rate, at only 60% [1]. The exact mechanism of calcification formation in a stenotic aortic valve is unknown and explanations for the disease have varied in the past few years [2]. It is important to understand the root cause of this condition to better treat aortic stenosis patients.

The Right Posterior Sinus (RNS) is the sinus in the aortic valve, which does not have a coronary artery stemming from it, thus interchangeably referred to as the non-coronary cusp. The other sinuses, the Left Posterior Sinus (LPS) and the Anterior Aortic Sinus (AAS), have the left and right coronary arteries stemming from the cusps respectively. These areas are also referred to as the left coronary region and right coronary region respectively. Towards the goal of better understanding and treating aortic stenosis, the objective of this study is to identify areas of high deposition of calcification, and which sinuses if any, have a higher tendency to collect calcium on its cusps. Thus, this research aims to explore the distribution of calcification volume present on the cusp of each region.

METHODS

The study population included 29 senior patients (> 64 yrs.) with average age of 80 years old at The Ohio State University Wexner Medical Center between January 2014 and September 2018. The pre-procedural patient specific aortic root, calcium nodules and cusps were segmented for each of the 29 patients from computed tomography (CT) images using Mimics Research 18.0 (Materialise, Belgium). The calcification nodules of each patient were then identified as attached to one cusp (LCC, RCC, or NCC) and the volume of calcium deposited on

the cusps was determined. Each cusp was assigned a colour during the modeling process to help easily distinguish the calcification lesions visually (as shown in Figure 1). The mean and standard deviation of the calcification volume for each cusp was used to determine if there were any significant differences between two particular regions. A Mann-Whitney U-test was carried out to compare mean calcification volume between two different regions and identify significant differences between each pairing; p-values were calculated between the left- and right-coronary regions, the left- and non-coronary regions, and right- and non-coronary regions. The p-values identified how calcification buildup was distributed among the three leaflets (LCC, RCC, or NCC).

Figure 1: Constructed Calcification Geometries on Native Aortic Valve Cusps Using Mimics Research 18.0

RESULTS

The average volume of calcification was found to be significantly higher for the Right Posterior Sinus than the Left Posterior Sinus or the Anterior Aortic Sinus. As shown in Figure 2, the average of the calcification on the Left-Corony Cusp is 29.10 cm³ higher in amount than the calcification found on the Right-Corony Cusp. The NCC had an average of 228.26 cm³ of calcium, while the LCC and RCC had 107.95 and 137.05 cm³ respectively (Figure 2). The calculated standard deviation of calcification on the NCC, LCC, and RCC is 184.39, 116.52, and 150.71 cm³ respectively. The p-value analyzing the LCC and RCC data was 0.36393 (Figure 2), which is larger than the significance factor of 0.05, thus showing that there is no significant difference between the measurements taken in the LCC and in the RCC. Between the regions with the presence of a coronary artery (AAS and LPS) and the Right Posterior Sinus, the p-values were shown to 0.0183 for the LCC and NCC and 0.00233 for the RCC and NCC (Figure 2). Both p-values of 0.0183 and 0.00233 were under the significance factor of 0.05, which indicated that there was a significant difference between the calcification found in the left-/right- coronary regions and the non-coronary region. These results show that NCC collects a higher amount of calcifications than the RCC and LCC.

Figure 2: Average calcification volume on Left-Corony Cusp, Right-Corony Cusp, and Non-Corony Cusp

DISCUSSION

The results show that the Non-Corony Cusp has a significantly higher volume of calcification than the Left- and Right-Corony Cusps. The results had high standard deviations and the standard deviation of the calcification volume on the NCC was higher than the other two standard deviations, as shown with the overlapping error bars in Figure 2. However, both the p-values for the difference in calcification between left- and non- coronary regions and right- and non-coronary regions were less than the significance level of 0.05, indicating that there is a significant distinction between calcification present in the left- and right-coronary regions and the non-coronary region. This follows the widely accepted notion that the non-coronary region has a more stagnant

blood flow due to the absence of a coronary artery, which allows for a greater amount of unwanted calcification.

The experiment and process of data imaging clearly showed the tendency of calcium to deposit in the Right Posterior Sinus over the two sinuses (Anterior Aortic and Left Posterior) that gave rise to a coronary artery. There is more flow present in the sinuses which have an outlet through which the blood would move. An increase in flow rate leads to lower calcium deposition, since the constant motion of the blood does not allow the calcium to adhere to the cusps. Thus, we can consider the idea that the blood flows through the Anterior Aortic Sinus and the Left Posterior Sinus without depositing as much calcium on the cusps due to the presence of the coronary arteries emerging from these sinuses, as opposed to the higher amount of calcification build up in the right posterior sinus, which lacks a steady flow of blood through the sinus.

This data analysis focuses on the averages of the calcification in each region for the patient population as a whole, rather than focusing on the differences in calcification volumes between the non-coronary region and the left- and right-coronary regions for an individual patient. This allows for a better depiction of the scale in which the data was collected; the amount of calcification in each individual case varies significantly, so it is important to understand the size difference in relation to how much calcification was present. In the future we will calculate the calcific ratio between each of the three leaflets for individual patients, which could eliminate possible discrepancies between the average trend portraying the calcification on the NCC to be higher than the buildup on the LCC and RCC.

In the future, the images of the patients' aortic valves in the mid-systolic position could be used to collect observations and form patterns about the regions of the cusps in which calcium is deposited. This can be used in future research correlating the amount of calcification with the shape of the calcium formation in the aortic sinuses. These measurements can also be used to predict the risks of calcification and the way in which calcium deposits for future cases of aortic valve stenosis.

In sum, we have shown that the regions in which the cusps are located has a significant effect on the amount of calcification formation. This knowledge could be used towards further understanding and treating aortic stenosis.

ACKNOWLEDGEMENTS

INTRODUCTION

The atrioventricular heart valves are located between the atria and the ventricles and facilitate blood flow between the chambers. Valvular heart diseases are one typical example of cardiovascular lesions, such as valve regurgitation (blood backflow), stenosis (narrowed valves due to hardening of leaflets) and atresia (completely blocked blood flow). These conditions can be fatal and often require valve repair or replacement. Comprehension of these valvular diseases is reliant on thorough characterization of heart valve structures for use in computational models. Our lab has focused on computational modeling of heart valves, specifically the tricuspid valve, to simulate how various pathological scenarios typically associated with regurgitation affect the biomechanical function. A thorough materials characterization of valve leaflet tissue is crucial to facilitate a more precise model.

Previous models and studies of mechanical behavior of heart valves have only examined the stress distribution throughout the entire thickness of intact leaflets [1]. However, it has been shown the leaflets have four layers that contribute in different ways to the mechanics of the whole leaflet. Previous studies determined that different layers of aortic valve tissue possessed different mechanical behavior because of their distinct microstructure constituents [2]. The objective of this research is to determine if the atrioventricular heart valves possess similar layer-specific variance to the aortic valve. We will accomplish this by micro-dissecting atrioventricular valve leaflets and subjecting the tissue samples to various loading ratios. We ultimately aim to improve our computational model of heart valves to better patient-specific treatment methods and save lives.

METHODS

Tissue Preparation: Porcine hearts are dissected to obtain the mitral valve anterior leaflet (MVAL) and tricuspid valve anterior leaflet

(TVAL). The leaflets are then placed in a freezer for 24 hours. A micro-dissection procedure is then used to dissect the MVAL into the atrialis/spongiosa, fibrosa, and ventricularis layers and the TVAL into the atrialis/spongiosa and fibrosa/ventricular layers. These combinations result from the spongiosa and ventricularis layers being too thin to separate from the other leaflet layers. In brief, the tissue (MVAL or TVAL) is first placed on a wax plate, with the ventricularis facing upwards, and stretched to its full size using surgical pins. Then, a scalpel is used to make a small incision separating the atrialis/spongiosa (A/S) layers from the remaining tissue. Thin-pointed tweezers are then used to peel the A/S layer away from the tissue with an ophthalmic scissor also used to sever any significant connections between the two layers (**Fig. 1**). The MVAL tissues are then flipped over with the ventricularis side facing upwards to also remove the ventricularis layer. Then, samples are labeled and briefly stored in phosphate-buffered saline before mechanical characterization.

Figure 1: Microdissection of the Atrialis/Spongiosa and Fibrosa/Ventricularis layers of tissue

Biaxial Mechanical Characterization: The tissue sample is then removed from the container, the thickness is measured three times, and then it is mounted to the biaxial testing machine (Cellscale Biomaterials Testing,). A surgical pen is then used to create a four-node fiducial marker array for subsequent image-based strain calculations. Finally, the tissue undergoes various loading ratios (Fig. 2) for mechanical characterization.

Figure 2: (top) a mounted tissue sample with markers applied, (bottom) a sample of the set of force protocols for layer specific tests

RESULTS

Results for the peak total tissue stretches of the two TVAL layers and three MVAL layers are presented in Fig. 3. Due to increased peak total tissue stretches of the atrialis/spongiosa layer compared to other layers in both the TVAL and MVAL, this study suggests that the atrialis/spongiosa layer is this most extensible layer of tissue in both mitral and tricuspid valve tissue. According to previous studies of mechanical behavior of tricuspid valves, the intact TVAL exhibits fewer peak total tissue stretches than the atrialis/spongiosa, but greater peak total tissue stretches than the fibrosa/ventricularis layer [1].

Figure 3: Circumferential and radial peak total tissue stretches in the layers of the TVAL and MVAL

Results for stress versus stretch of the two TVAL layers and three MVAL layers are presented in Fig. 4. The atrialis/spongiosa layer exhibited greater anisotropic behavior in both the TVAL and MVAL

compared to other layers. While the atrialis/spongiosa layer exhibits a great deal of anisotropy, the mechanical behavior of the other layers of both TVAL and MVAL tissue appear to be nearly isotropic.

Figure 4: Circumferential and radial stress versus stretch curves for the layers of the TVAL and MVAL under 1:1 force loading

DISCUSSION

This study is the first of its kind to quantify the mechanical response of the different layers of the atrioventricular heart valves. With other studies having supported the anisotropic nature of intact heart valve leaflets, the results of this study indicate that the atrialis/fibrosa layer of tissue contributes significantly to the anisotropy of heart valve tissue [1]. However, considering that the intact TVAL was more compliant than the fibrosa/ventricularis layer and stiffer than the atrialis/spongiosa layer, it is evident that all three tissue layers influence the valve's mechanical behavior.

According to histology performed on our tissue samples, the atrialis/spongiosa layer of the TVAL was made up of similar portions of collagen and elastin (45% and 43%, respectively.) Additionally, the atrialis/spongiosa and ventricularis layers in the MVAL were made up of over 50% elastin. In order to understand how these microstructural components contributed to the differing mechanical behavior of the layers of valvular tissue, a study should be performed on tissues with elastin and collagen removed.

Altogether, the mechanical data obtained in this study can be used to improve existing computational models of heart valves. This will contribute to better treatment options, thus improving prognoses, increasing patient quality of life, and ultimately saving lives.

A STUDY OF PRESSURE DYNAMICS ACROSS A STENOTIC ORIFICE

Tori Burton (1), Hoda Hatoum (1), and Lakshmi Prasad Dasi (1)

Columbus, Ohio, USA

INTRODUCTION

Aortic stenosis (AS) affects approximately 2% of people over the age of 65 and is classified as the narrowing of the aortic valve often caused by calcium buildup on the leaflets of the valve¹. This stenosis causes a substantial pressure drop across the aortic valve which means the heart has to work harder to pump blood to the entire body. The two common methods of characterizing the severity of AS are echocardiography or cardiac catheterization². Catheterization gives direct pressure measurements but is a highly invasive procedure, so echocardiography is the clinically accepted approach. Unlike catheterization, an echocardiogram is only able to quantify the pressure gradient across the valve indirectly using the simplified Bernoulli equation and is not able to capture the recovery of pressure that occurs downstream in the aorta. Accurate assessment of the workload is crucial towards better timing of intervention and management of patients with AS². Most recent efforts to develop better models still utilize the Bernoulli's principle²⁻⁴. In Bernoulli's equation, velocity and pressure are related in terms of kinetic and potential energy, respectively. So as fluid velocity increases at the stenosis as a result of a narrowed cross-sectional area, static pressure decreases. As the velocity decreases again, the reverse is true, and pressure is restored. The pressure of the fluid will theoretically recover as the diameter of the conduit increases distally to the vena contracta; however, energy loss due to friction makes it impossible to fully recover. It is therefore important to examine the limitations of Bernoulli's principle as it pertains to unsteady effects, as well as frictional effects before sophisticated models may be developed. The objective of this study is to assess the spatio-temporal variations of static pressure along a streamline through a stenotic orifice under physiological aortic conditions.

METHODS

The hemodynamics were assessed across an orifice chamber of area 0.6cm² placed upstream and in series with a 21mm Medtronic Hancock II surgical aortic valve (SAV) in the aortic position of a left heart simulator flow loop. The working fluid used in the experiment was a mixture of water and glycerin with viscosity and density similar to those of blood. A Millar catheter was inserted axially into the orifice chamber in order to take pressure measurements at various longitudinal distances from the insertion point. The flow loop was run continuously under physiological pressure and flow conditions (cardiac output = 5 L/min; heart rate = 60 beats per minutes; systolic to diastolic pressures = 120/80 mmHg) while data were recorded for 50 cycles per measurement location. Measurements were taken every 0.5 cm, starting at 14cm and moving back to 0cm. Distances of 0-3cm represent the measurement points upstream of the orifice and 3.5-14cm lie downstream, as shown in Figure 1 below.

Figure 1: Schematic side view of orifice chamber; red dots represent points of measurement; blue arrow represents direction of flow.

RESULTS

Figure 2 shows pressure versus time for three different positions: before the stenotic orifice, immediately after, and about 10cm downstream. Both systole and diastole are included in order to observe the entire cardiac cycle. The pressure upstream of the orifice at position

1cm is exceptionally higher than both 5cm and 13cm and remains higher for the duration of systole; however, all points in the chamber experience similar pressure changes during diastole.

Figure 2: Variation of pressure with time over 1 full cardiac cycle.

Pressure versus longitudinal position is depicted in Figure 3. The times shown are every 0.05 seconds for the duration of systolic flow in order to isolate positive flow conditions. Static pressure is high before the orifice (located at 3.0cm) and drops immediately after. Pressure is then recovered slightly, but never reaches its initial value. The data shown in Figure 3 is a comparison of pressure and position using an ensemble average of individual pressure values per point in time.

Figure 3: Variation of pressure with distance from stenotic orifice; red dashed line denotes the mid-orifice location; yellow contour in the inset figure highlights area of data (systolic flow).

DISCUSSION

Figure 3 reveals a fair amount of information regarding pressure based on distance from a stenotic orifice. At the start of systole (0 seconds), the pressure measurements are relatively low and remain low throughout the duration of systolic flow. This can be attributed to the fact that the velocity has only begun to increase following diastolic flow. At the very end of systole (0.45 seconds), pressure is even lower than at the onset of systole and follows an almost completely linear curve with little to no changes in pressure throughout the length of the chamber. In contrast, the intermediate times (0.15-0.30 seconds) possess a disparate curve with an extremely high initial pressure (>200 mmHg) that drops below 75 mmHg immediately distal to the stenotic orifice and finally slightly recovers to less than half its initial pressure (~100 mmHg). These results are reasonable based on the understanding of the direct

relationship between velocity and orifice area which causes the fluid velocity to increase significantly at the orifice. Again, Bernoulli's equation explains the relationship between velocity and pressure— as velocity increases, static pressure decreases. The pressure recovery that occurs downstream from the stenotic orifice is the result of velocity slowing as the area of the conduit is increased and it does not continue to recover fully to the initial pressure because the velocity plateaus approximately 5cm after the valve; consequently, the static pressure reaches its maximum recovery value. Focusing only on these intermediate time points, the vena contracta is an important piece of data to analyze and there are very slight discrepancies between its location based on the data; however, the majority of the intermediate time point curves place the vena contracta at ~4 cm.

Figure 4: Normalized Pressure vs Distance Curves

Figure 2 is a depiction of 3 full cardiac cycles at 1, 5, and 13 cm. During systole, the pressure at a point just before the orifice (1cm) increases significantly. The pressure at a point further downstream from the orifice (13cm) stays relatively low, increases a tiny bit, and decreases once again. In contrast significant turbulent fluctuations may be observed at 5cm position. In order to verify the validity of the Bernoulli's principle, the normalized pressure drop was plotted (Figure 4). Figure 4 reveals several important points when normalized with respect to the velocity at the orifice (V_o) and pipe (V_p). Firstly, the pressure at the orifice is significantly different from that predicted from Bernoulli and this may be attributed to the flow acceleration in time as well as non-insignificant energy losses. Further pressure never recovers to a normalized pressure difference less than 1.0 except at the end of systole. This may indicate that even simplified Bernoulli may be severely under-predicting the true pressure drop across the orifice. The implications of these findings need to be further explored in a stenotic aortic valve model. Further studies are necessary to develop new empirical models that can capture the true severity of workload without being limited to the evident limitations of the Bernoulli equation when applied even to an idealized orifice.

A STUDY OF THE EFFECTS OF AN INCREASED BEAT RATE ON THE PENN STATE PEDIATRIC VENTRICULAR ASSIST DEVICE

INTRODUCTION

Congenital heart disease is the leading cause of infant death annually, with nearly 40,000 cases in the United States alone [1]. A heart transplantation is often the only treatment option for these patients, despite the high average organ transplant waiting list mortality rate of 13% [2]. Ventricular assist devices (VADs) have proven to be effective in treating heart failure in adult patients. The growing success of VADs lead to the design of pediatric ventricular assist devices (PVADs) which were adapted for the smaller anatomical features of pediatric patients. Therefore, the Penn State 12cc pneumatic, pulsatile PVAD (Figure 1) was developed. This device can be used as bridge-to-transplantation by reducing the mechanical load experienced by the heart while increasing the cardiac output.

Figure 1: Schematic for the implantation of the Penn State PVAD in an infant [3]

One of the major issues surrounding cardiac assist devices is the development of thrombosis. Flow visualization techniques can be used to assess the risk of clotting in certain regions of low flow or shear. Prior *in vitro* studies of the Penn State PVAD have examined hemodynamic parameters with a beat rate of 75 bpm [4], however, infant heart rates typically range from 100 to 180 bpm [5]. This study aims to examine the effects of an elevated beat rate on the Penn State PVAD by quantifying the fluid dynamics using particle image velocimetry (PIV).

METHODS

An acrylic model of the Penn State PVAD was used in order to provide an optically clear surface for visualization. This model was placed in a mock circulatory flow loop (Figure 2) consisting of compliance and resistance components to obtain physiologically relevant conditions.

Figure 2: Mock circulatory loop for PVAD [6]

A 40% hematocrit, non-Newtonian blood analog was created to mimic the viscoelastic behavior of blood by matching the nonlinear kinematic viscosity and elasticity. The flow and pressure waveforms for the 75 bpm and 125 bpm were matched to mimic flow in a healthy infant. To ensure complete ejection and filling, the systolic duration was set to 43% for the 75bpm case and 47.5% for the 125bpm case. The outlet pressure in the vessel corresponds to an aortic pressure of 90/60 mmHg. For both cases, the flow rate was set to 1.0 L/min.

PIV was used at three different planes (7, 8.2, and 11 mm) within the PVAD (Figure 3). The 0 mm reference plane started at the furthest edge of the inlet valve. Data were collected for 16 time points, including the complete systole and diastole of the PVAD.

Figure 3: Parallel planes used for flow analysis [4]

RESULTS

In both cases, the cycle begins with a strong inlet jet which transitions into a solid body rotational flow (Figure 4A). Two jets can be observed, one for the major orifice and one for the minor orifice of the tilting disk valve. The velocity of the major and minor inlet jets, during the 125 bpm case, was higher than the jets at the 75 bpm case. The 125 bpm case has a maximum velocity of 1 m/s, whereas the 75bpm case only reaches 0.7 m/s.

Figure 4: Comparison between the 75 and 125 bpm conditions during A) pump filling (33% diastole) and B) ejection (71% systole)

The strong inlet jet creates recirculation within the device. This recirculation is stronger at the higher beat rate and lasts for an extra 20% of diastole. As the pressure within the sac increases, the recirculation region transitions towards the outlet valve and an outlet jet forms (Figure 4B). The outlet jet for the 75 bpm case is slightly stronger than the 125 bpm case.

DISCUSSION

At a higher beat rate, there was an overall increase in the strength of the inlet jet. This resulted in a stronger recirculation region that lasted for a longer percentage of diastole. The strong recirculation reduces stagnation and washes the walls of the device to prevent clotting. By increasing the beat rate, the flow within the device creates more favorable conditions for reducing clotting.

These results are consistent with previous studies showing that an elevated beat rate reduces the risk of thrombosis in the Penn State PVAD. The data support the claim that the device could be used as a bridge-to-transplant in pediatric patients, as it has favorable conditions under varying, pediatric heart rate, flow rate and pressures.

CONCLUSION

The comparison of flow within the Penn State 12cc PVAD at a higher beat rate can help to predict how the device will behave under normal conditions, considering pediatric heart rates typically range from 100 to 180 bpm. The stronger inlet jet and recirculation region suggests that the PVAD is less susceptible to clotting when operated under normal pediatric conditions. Future studies could examine the effects of increased beat rate on flow with the PVAD, confirming some of the flow observed in this study.

HEMODYNAMICS OF CORONARY ARTERIAL ANEURYSMS IN KAWASAKI DISEASE — AN IDEALIZED ANEURYSM MODEL

INTRODUCTION

Kawasaki disease (KD), a vasculitis of unknown etiology typically occurring in infants and young children, is the leading cause of acquired heart disease in childhood in developed countries. Approximately 20-25% of patients may eventually develop coronary artery aneurysms (CAAs) if not treated within ten days of disease onset. Unlike cerebral or abdominal aorta aneurysms, which pose a risk of rupture, CAAs are threatening in their potential for inducing thrombus formation, resulting in myocardial infarction and sudden death [1].

Current American Heart Association (AHA) guidelines for risk stratification rely on aneurysm size alone as the criterion for initiating systemic anticoagulation; however, studies suggest risk may also depend on hemodynamic parameters such as time averaged wall shear stress (TAWSS), residence time (RT), and oscillatory shear index (OSI), which are not available through image data alone [2,3]. Indeed, CAAs' complex geometries, as well as aneurysm shape, number, and location, may all contribute to abnormal hemodynamics and correlate with patient outcome.

Patient-specific hemodynamic simulations can non-invasively supply informative hemodynamic parameters for better thrombotic risk assessment; however, existing studies have been limited in patient cohort size and struggle to quantify effects of aneurysm shape on local hemodynamics. With such limitations in mind, existing patient-specific models can be augmented by introducing artificial aneurysms of specified length and diameter, to achieve a systematic evaluation of relationship between CAA shape, size, and position on local hemodynamics. Ultimately, elucidating the relationship between hemodynamics and aneurysmal shape characteristics may underlie more powerful risk stratification methods to support clinical decision-making regarding initiation of anticoagulation therapy.

METHODS

Idealized Aneurysm Models

Existing AHA aneurysm classification for small, medium, and giant CAAs serves as a guide to proceed from body surface area-normalized Z-score to an estimated maximal diameter for a given coronary vessel [4]. Using aneurysmal shape index (ASI), defined as the ratio of aneurysmal length to maximal lumen diameter,

$$ASI = \frac{L}{d_{max}} \quad (1)$$

we produce a set of aneurysms according to a range of lengths and diameters. Beginning with an existing patient-specific model of the aorta and coronary vasculature, we prescribe length and diameter to guide smooth, radially symmetric deformations to generate idealized artificial aneurysms at specific positions (examples in **Figure 1b**). This aneurysm generation pipeline and simulation post-processing rely on functionality from the Visualization Toolkit Package (VTK) package.

Computational Hemodynamics

Each new generated aneurysm model is processed in Simvascular [5], an open source software enabling patient-specific cardiovascular simulation. Using Tetgen [6], an open source package for mesh generation included in Simvascular, we generate a tetrahedral finite element mesh. The Simvascular solver then computes a numerical solution to the time-dependent Navier-Stokes equations governing blood flow. Blood is modeled as an incompressible Newtonian fluid (density=1.06 g/cc, dynamic viscosity=0.04 dynes/cm²) and walls are assumed to be rigid in all cases.

Systolic myocardial contraction increases intra-myocardial pressure, transiently increasing distal coronary resistance substantially and causing coronary flow to be out of phase with systemic flow. Specialized boundary conditions coupling intra-myocardial pressure to coronary flow are required to replicate this complex physiology in the

numerical model. We achieve this with a closed-loop, Lumped Parameter Network (LPN) modeling the heart and distal vasculature, which imposes boundary conditions with tunable parameters to produce physiologically accurate cardiac output, heart rate, blood pressure, and flow distributions. For idealized models described in this work, LPN parameters are kept constant to better isolate the effects of aneurysmal geometry on hemodynamics. **Figure 1** shows the full pipeline, proceeding from baseline model to artificial aneurysms and simulation results over isolated aneurysm regions.

RESULTS

Idealized aneurysms of 3 representative shape index values (ASI = 2, 4, 6) were generated for 5 diameters (z-score = 6, 8, 10, 12, 14) at positions along the right coronary artery (RCA) and left anterior descending (LAD). Hemodynamic simulation results were isolated over aneurysmal regions to identify the effects of shape, size, and position on local hemodynamic conditions. Idealized aneurysm models show consistent variation in distribution of hemodynamic parameters as Z-score increases, as seen in **Figure 1c**. TAWSS distribution varies consistently with ASI while holding Z-score constant. As in **Figure 2**, percentage of area exposed to low TAWSS increases with ASI at all Z-scores. Similar trends are observed in aneurysm cases in the LAD.

DISCUSSION

It has been shown that TAWSS over aneurysmal regions is associated with risk of thrombosis, and that a decision boundary based on percentage of aneurysm surface area exposed to low TAWSS is more predictive of thrombosis than aneurysm diameter for KD patients [7]. Thus, we assess the distribution of TAWSS over the surface as one potential surrogate for hemodynamic behaviors that may underlie thrombosis. Results exemplified by **Figure 2** show that aneurysm diameter alone may not be sufficient to predict local hemodynamic variables such as TAWSS. We observe that aneurysms similar in diameter but with different aspect ratios can furnish substantially different hemodynamic environments. In some cases, smaller diameter aneurysms with higher ASI (fusiform shape) even produce lower TAWSS values than more saccular aneurysms with larger maximum diameter. We show that a combination of aneurysm shape and length, in addition to other potential factors such as vessel curvature and aneurysm position, may contribute to local hemodynamic behaviors. Correlation between aneurysm hemodynamic and geometric features suggests potential to link clinical measurements easily obtained from echocardiography or other routine imaging modality, with patient outcome. Such approaches may form the basis for more sophisticated geometry-based risk stratification methods supporting clinical decision-making in assessment of KD patients.

INTRODUCTION

Approximately 1 out of every 10,000 children are born with a single ventricle congenital heart disease [1]. The Fontan operation palliates the effects of this disease and allows these children to live long into adulthood. The operation allows systemic venous blood to bypass the non-functional right ventricle and provide blood directly to the pulmonary circulation. With new preoperative methods and procedure improvements, the survival rates for Fontan patients has increased to over 85% at 20 years post-operation [2]. This means there is an increasing patient population entering adulthood and beginning to experience a pathology known as Failing Fontan. This chronic disease can be divided into three categories of symptoms: (1) ventricular dysfunction, (2) systemic complications of Fontan physiology, and (3) chronic Fontan failure [3]. All three decrease the quality of life for the many patients suffering from this disease.

The goal of this project is to investigate the fluid dynamics in an implantable blood pump that will provide mechanical support for patients with failed Fontan circulation. The flow will be quantified using particle image velocimetry (PIV).

METHODS

To study the fluid dynamics within the pump a flow loop was constructed to obtain pressure head versus total flow rate (HQ) curves and to image specific flow regions under steady flow conditions. The loop consisted of a single inlet, single outlet reservoir and tubing that connects the reservoir to the two inlets and single outlet of the acrylic Fontan Pump model (shown in Figure 1). Pressure transducers (Merit Medical, Jordan, UT) were inserted near each of the inlets and at the outlet to monitor pressure within the system and calculate the pressure drop across the pump. An external flow probe (Transonic Medical, Ithaca, NY) was used to determine total flow rate through the system

and through each inlet. A 60-40 flow split was maintained between the inlets representing the inferior vena cava (IVC) and superior vena cava (SVC), respectively, by varying resistance on the SVC tubing. This flow split mimics the physiological conditions the pump would experience after implantation. A Newtonian blood analog composed of water, glycerin, and sodium iodide replicated the viscosity of 40% hematocrit blood and the refractive index of acrylic, producing a kinematic viscosity of 3.57 cSt.

Figure 1: A) Side view of Fontan pump for the SVC and IVC inlets. B) Top view of the Fontan pump for the outlet, both denoting the centerline PIV plane of interest.

Next, we established pump operating conditions for PIV using the blood analog properties, properties of blood, and the HQ curves (Figure 2). The point of interest highlighted in Figure 2 represents ideal operating conditions for the model, an axial speed of 4000 RPM, total flow rate of 5 LPM, and a pressure head of 30 mmHg.

Figure 2: HQ curves of the implantable Fontan pump (optimal operating condition designated by arrow).

Non-dimensional parameters were used for proper comparison of pump flow fields. The parameters used to determine operational conditions for the acrylic model were the pump Reynolds number (Equation 1) and flow coefficient (Equation 2):

$$Re_{pump} = \frac{\rho \omega D^2}{\mu} \quad (1)$$

$$C_v = \frac{Q}{\omega D^3} \quad (2)$$

Where ρ is density, ω is rotational velocity of the rotor, μ is dynamic viscosity, D is characteristic diameter, and Q is flow rate. To match these non-dimensional parameters to the target operating condition, the pump was operated at 4282 RPM and at a total flow rate of 5.35 LPM. This non-dimensionalization was carried out for each operating point along the HQ curves in Figure 2.

Finally, a camera (TSI, Inc., Shoreview, MN) and PIV laser (Quantel, Bozeman, MT) were mounted orthogonally above and parallel to the pump, respectively, to visualize the PIV planes perpendicular to the camera through the centerline of the two pump inlets and the outlet (Figure 1). PIV data were collected at the extreme operating conditions of the HQ curves. The outlet plane required two sets of images to capture the entire region, one near the rotor blades at the volute exit and one further downstream. One thousand image pairs were collected in each region and processed using Insight 4G (TSI, Inc., Shoreview, MN) and Tecplot Focus (Tecplot, Bellevue, WA).

RESULTS

The PIV data show standard flow fields expected from the pump operating under steady inlet conditions. As demonstrated in Figure 3, the flow was 2D axisymmetric through the centerline of the SVC inlet. The velocity increased significantly from an average of 0.18 m/s at the entrance to 0.54 m/s as it tapered to the rotor blade passage region and pump volute

Figure 3: Mean PIV flow data at the centerline of the SVC inlet for 4280 RPM and 2.14 LPM.

The velocity field was relatively constant throughout the outlet. However, there was a region at the top of the flow field in Figure 4 that shows near zero velocity flow. This may have been a result of the 3D flow at this point with the fluid exiting the rotor passage region moving out of the 2D PIV plane.

Figure 4: Mean PIV flow data at the centerline of the outlet for 4280 RPM and 5.35 LPM.

DISCUSSION

These preliminary results provide an initial understanding of the hemodynamics within the Fontan pump. The experimental data will also be used to help validate CFD simulations. Mean velocities observed in the PIV data approximately match calculations based on average flow rate and geometry. A seam in the acrylic model at the center of the outlet ($X = 33$ mm) may have caused the inconsistency observed in this part of the flow field. Future data collection in the pump will include planes offset from the centerline to gain a better understanding of flow through the entire 3D geometry. Finally, this study was limited to steady boundary conditions, which may not be accurate for predicting how the pump will perform *in vivo*.

HETEROGENEITY AND ANISOTROPY IN THE MICROSCALE ENERGY DISSIPATING PROPERTIES OF THE KNEE MENISCUS

INTRODUCTION

The synovial joint of the knee is essential for shock absorption and joint lubrication during locomotion. For high frequency activities, such as running and jumping, the shock absorption function is governed by the fluid flow-induced poroelasticity of cartilage [1], in which, the interstitial fluid pressurization arises due to the densely packed, highly negatively charged aggrecan in the cartilage extracellular matrix (ECM) [2]. Besides articular cartilage, the meniscus is also a key functional unit of the knee joint, enhancing congruency, providing direct load transmission to the cartilage [3] and increasing joint stability [4]. Like cartilage, the meniscus also exhibits pronounced time-dependent mechanical properties [5]. However, the meniscus ECM has a distinctive structure and composition, marked by a type I collagen-dominated outer region that gradually transitions into a type II collagen and aggrecan-rich inner region [6]. Our recent studies suggested that the structure and mechanical behavior of the meniscus ECM is highly heterogeneous and anisotropic [5]. It is unclear, however, if or how, the meniscus contributes to the poroelastic energy dissipation of the joint in a region- and orientation-specific manner. Such knowledge is important, given that meniscus injury often occurs during high frequency activities, and is a common cause of post-traumatic osteoarthritis. Thus, a more in-depth understanding of meniscus biomechanics will provide new benchmarks for documenting disease progression and developing regenerative strategies. The objective of this study was to investigate and detail the microscale energy dissipating mechanical behavior of the meniscus, with a focus on the tissue structural heterogeneity and anisotropy.

METHODS

Sample preparation. Medial menisci were harvested from adult bovine (18–30 months old) knees. The outer one-third (outer region) and inner one-third (inner region) were dissected and embedded in O.C.T. Blocks from both regions were cryo-sectioned in the transverse or coronal plane at the thickness of 10- μ m to produce both horizontal and vertical sections from the outer and inner zones.

Histology. Safranin-O/Fast Green staining was applied to assess tissue-level collagen structure and the distribution of sulfated glycoaminoglycans (sGAGs, mostly from aggrecan).

AFM Nanorheometric testing. The microscale energy dissipating mechanical properties were determined using a custom-built AFM-nanorheometer with microspherical tips ($R \approx 12.5 \mu\text{m}$, $k \approx 2 \text{ N/m}$) and a Dimension Icon AFM, followed by our established procedures [7]. Specifically, a 2-3 nm random binary sequence displacement was superimposed onto the $\sim 1 \mu\text{m}$ static compression during a 100-sec ramp-and-hold. The dynamic force, F^* , and depth, D^* , as a function of frequency (1-1000Hz) was extracted via discrete Fourier transform. The complex dynamic modulus magnitude, $|E^*|$, and phase angle, δ , were derived via the Taylor expansion of Hertz model [8]. The self-stiffening ratio was obtained by the ratio of $|E^*|$ at high (900-1000 Hz, E_H) versus low (1-3 Hz, E_L) frequencies.

sGAG Depletion. Enzymatic removal of chondroitin-sulfate GAGs (CS-GAGs) via 1 U/ml incubation in chondroitinase ABC for 30 min was performed to observe the role of GAGs in the inner vertical region.

Statistical test. One-way ANOVA followed by Tukey-Kramer post-hoc analysis was used for statistical testing, with $\alpha = 0.05$.

RESULTS

Histology showed the more fibrous nature of the meniscus outer zone, marked by the prevalence of circumferentially aligned collagen fibers. The inner zone had apparently higher staining for the sGAGs, signifying a higher concentration of aggrecan (Fig. 1a). AFM nanorheometric testing detected substantial heterogeneity and anisotropy in the microscale properties, marked by the distinctive frequency spectra of $|E^*|$ and δ among test regions and orientations (Fig. 1b). As a result, the moduli, E_L and E_H , self-stiffening ratio, E_H/E_L , and maximum phase angle, δ_m , varied significantly between inner and outer zones, and between horizontal and vertical sections. Overall, the moduli and phase angles were higher on the vertical sections than horizontal sections (Fig. 1c). For the vertical sections, while the moduli, E_L and E_H , were both higher in the outer region, the inner region showed higher E_H/E_L and δ_m , indicating a greater contribution of energy dissipating behavior in those regions. Removal of CS-GAGs resulted in a significant reduction of E_H/E_L , maximum phase angle, δ_m , and both E_H and E_L illustrating the contribution of CS-GAGs to the overall energy dissipative properties in the inner region (Fig. 2).

DISCUSSION

This study highlights the distinct microscale energy dissipating mechanical properties of the meniscus ECM. In particular, greater time-dependence was found in the vertical sections. According to the literature, at the deformation length scale of the AFM-nanorheometric test (contact radius $\sim 2 \mu\text{m}$), the time-dependence and energy dissipation are primarily governed by poroelasticity [9]. On the vertical sections, the loading axis is parallel to the collagen fiber axis, resulting in compression of collagen fibrils with lateral confinement from adjacent fibrils and proteoglycans residing in the interfibrillar space [6]. In comparison, in the horizontal section, the loading axis is perpendicular to the fiber axis, which leads to local uncrimping or sliding of the fibrils. Therefore, given that proteoglycans are more confined by laterally constrained compression, indentation in the vertical direction allows for a higher degree of fluid pressurization, and thus, more pronounced energy dissipating time-dependent behavior (Fig. 3).

For vertical sections, while the outer region was stiffer due to the more organized collagen fibers, the inner zone exhibited a higher degree of energy dissipation. Such contrast shows the importance of aggrecan in the microscale energy dissipation of the meniscus. This contrast possibly suggests that the collagen fibers have limited contributions to the poroelastic energy dissipation. It also indicates that, during high frequency loading, the meniscus mainly dissipates energy in its aggrecan-rich, compressive load-bearing inner zone. On the other hand, the highest δ_m ($16 \pm 2^\circ$, mean \pm S.E., measured in the IV region), was much lower than bovine cartilage ($36 \pm 2^\circ$, [2]), indicating that the contribution of the meniscus to knee shock absorption is secondary to that of cartilage.

INTRODUCTION

Collagen is central to many soft tissues, and it is therefore of great interest to characterize and understand its microstructure [1]. Substantial efforts have been devoted to this endeavor by us [2,3] and others [4,5]. Many of these studies have analyzed collagen microstructure based on histological sections [1,2,5]. Sections have several benefits, such as the specificity afforded by labels and stains, the opportunity to easily isolate the tissues of interest, and the potential to share materials with pathology labs. Sections, however, have an important limitation: they provide only 2D information of the 3D collagen microstructure. Some have proposed to address this limitation by applying the 2D techniques in stacks of sections [6]. Although better, these are still not truly 3D.

We recently introduced a 3D analysis technique based on polarized light microscopy (3D-PLM) that allows quantifying both in-plane and out-of-plane angles of collagen fibers on a thin histological section [7]. Our goal in this study was to demonstrate the use of 3D-PLM to quantify collagen microstructure in 3D. Specifically, we focus on two aspects of microstructure that are of great importance to eye tissue mechanics and development, namely, collagen fiber crimp tortuosity and lamellar layering in the limbal region. To demonstrate the power of this technique, we compare measurements of microstructure between eyes of young and old eyes. We then also compare the 3D measurements with those obtained using the more traditional measures in 2D.

METHODS

3D fiber orientation quantification –We utilized the 3D-PLM technique described in detail elsewhere [7]. Briefly, tissue sections were imaged using polarized light under 4 different polarization states. Analyzing the changes in pixel intensity between the four polarization states, we calculated both in-plane and out-of-plane fiber orientation.

Figure 1 (a) Example longitudinal section of a normal human eye; (b) Close-up of the limbus region to illustrate collagen fiber organization. (d) Further close-up showing fiber waviness or crimp and lamellar structure. (c) Schematic of the analysis of a collagen fiber (blue line) in 3D or 2D projection (brown line).

Collagen fiber tortuosity – The tortuosity was calculated as the ratio of the path length along a tortuous fiber and the straight end-to-end length between two endpoints. For a small segment of a fiber, the length is calculated as $L_{OP} = L_{IP} / \cos(\phi)$, where L_{OP} is the true (or out-of-plane) length of a fiber segment, L_{IP} is the projected (or in-plane) length in X-Y plane, ϕ is the out-of-plane fiber orientation. For the 2D tortuosity was calculated using only in-plane fiber path lengths, (Fig 1d, brown). For the 3D tortuosity, we used out-of-plane fiber orientation to estimate the length along a tortuous fiber (Fig. 1c, blue).

3D fiber structure measurement in limbus of human eyes – We performed both 2D and 3D tortuosity measurements in the limbus region of sagittal sections of a young eye (9-month-old) and an old eye (97-year-old). The de-identified human eye sections were prepared in accordance with the tenets of the Declaration of Helsinki and the Health Insurance Portability and Accountability Act. The limbus regions of both human eye sections were imaged with a 10X strain-free objective, and the images were analyzed with 3D-PLM. We traced manually the collagen fibers following the fiber bundles to include at least two crimp periods (brown line in Fig. 1d). We performed a 2-sample t-test to test for a significant difference between the crimp tortuosity in limbus of young and old eyes. Fiber tortuosity measurements were then used to calculate a stretch-based collagen recruitment curve.

RESULTS

Fig. 2 shows example color-coded in-plane and out-of-plane fiber orientation maps in limbus of both young and old eyes. Collagen fibers in the young eye are more tortuous and show more crimp than in that of the old eye. The line profile of the out-of-plane angle revealed that the young eye has thinner lamellae, as discernible by the higher frequency of the angle oscillations.

Figure 2 Example in-plane and out-of-plane fiber orientation maps of young and old eyes. Colors and brightness represent local fiber orientation and retardance, respectively. Profiles of out-of-plane orientation (c and f) along the black lines in b and e show that the young eye had thinner lamellae.

Figure 3 Tortuosities in both eyes, in 2D and 3D. Below each label are shown the mean and SD. Tortuosities decreased with age and were underestimated by 2D analysis.

Tortuosities measured in 3D were 11.4% and 11.1% larger than in 2D for young and old eyes, respectively (Fig 3). As expected, tortuosity decreased substantially and significantly with age ($P<0.0001$) [8]. Though the change was larger in 2D measurements (5.2%) than in 3D (4.5%). Tortuosity had a larger spread in young eyes and in 3D measurements, than in old eyes and 2D measurements. Fig. 4 shows the predicted stretch-induced collagen fiber recruitment in the limbus region.

Figure 4. Stretch-induced collagen fiber recruitment in the limbus region. All cases exhibited sigmoid-shaped curves, but recruitment rates varied substantially. In both young and old groups, 3D crimp measures predict that the collagen fibers would be fully recruited at a substantially higher level of stretch than the 2D measures.

DISCUSSION

We have demonstrated that the application 3D-PLM to quantify collagen fiber microstructure from histological sections produces substantial and significant differences in the measurements. The results show that more conventional 2D tortuosity measurements underestimate 3D tortuosity by about 10%. This difference, while apparently small, should not be misunderstood as being negligible. Predicted fiber recruitment curves show that the difference will have a very substantial impact on the tissue mechanics. Collagen fiber crimp is the basis for the nonlinear mechanical behavior at the macroscale, in a process of stretch-induced stiffening called fiber recruitment [1].

Our results also show that the overall trend of age-related differences in collagen fiber tortuosity previously reported [8] still holds. This suggests that while 2D tortuosity measurements may underestimate 2D values, they may still capture the essence of the parameter, at least for limbus crimp. Similarly, both 2D and 3D measures predict a lower stretch level for full fiber recruitment in the old eyes. Using the out-of-plane angle analysis, we confirmed that the density of lamellae (or the number of lamellae per unit thickness) is higher in younger than in older eyes. We suspect that this is because young lamellae are developing and have not reached full thickness.

Overall, we have shown that the imaging and analysis technique of 3D-PLM provides valuable information on collagen crimp and lamellae layering. The technique can be applied to measure other aspects of microstructure, and for other collagenous tissues.

INTRODUCTION

Blast-induced traumatic brain injury (bTBI) present complex challenges to the military. Such injury can cause multisystem, life-threatening injuries, and blast survivors suffer a range of acute and chronic negative health consequences. The emphasis of our research is on harnessing the neuroprotective and anti-inflammatory properties of non-psychoactive cannabinoids for the treatment of blast injury with or without concomitant hemorrhage. Previous studies have shown that activation of the cannabinoid receptor type 2 (CB2) may have neuroprotective effects [1]. In this study we investigated whether administration of O-1966, a CB2 receptor agonist, before injury has any effect on the recovery of the motor functions of rats after mild bTBI.

METHODS

A compressed-gas driven shock tube was used to replicate bTBI in rats (**Figure 1**). The test apparatus consisted of a small tube diameter (50 mm) opening that allowed targeting only the head of the animal [2]. It was verified that the overpressure in thorax and abdomen were negligible. Prior to the blast exposure, animals were anesthetized with isoflurane and the head was secured and oriented for dorsal exposure in a custom holder. A rapid overpressure of 270 kPa was applied for a duration of 1.6 ms to induce mild bTBI [3]. The animals were exposed to either single blast or triple blast exposures. In the multiple exposure case, there was a 3-hour wait time between each exposure.

Sprague-Dawley wild-type rats (male, average 300 grams), were used for this study and divided randomly into three test groups of Treatment with O1966 (injury+medication), Sham (only anesthesia), and Vehicle

(injury+non-therapeutic injection). O-1966 was administered at 5.0 mg/kg IP.

The motor function of rats was assessed using the rotarod experiment [4]. A commercial rotarod (LE8500, PanLab Harvard Apparatus) was used for four rats at a time. The testing was divided into two phases of baseline training and post injury evaluation. The baseline training was done for 5 days that are indicated as days -7 to -3. The animals were then allowed to rest for two days (weekend, days -2 and -1). Any drug injection and then the bTBI test was done in day 0. The Post-injury phase of the rotarod test was done on the animals for 4 days after the injury (days 1 to 4). The test result is given as the speed in revolutions per minute (rpm) at which the animal falls off the rotating rod (Speed at Fall or SAF). The rotarod device was used in the accelerating mode that

Figure 1. The Compressed-Gas Driven Shock Tube (**A**) showing the driver section (1), diaphragm location (2), driven section (3), and the animal holder (4). The custom-made animal holder (**B**) minimizes the acceleration induced brain injuries and allows for different exposure orientations (**C & D**).

changed the speed gradually from 4 rpm to the maximum of 40 rpm. The animals that did not show any training, i.e., their SAF value did not increase during the 5-day baseline period, were excluded from further data analysis.

The number of animals that are reported in this study are n=8 for treated with O1966 (5 single and 3 triple hits), n=9 for Sham (3 single and 6 triple anesthesia), and n=11 for Vehicle (6 single and 5 multiple hits).

RESULTS AND DISCUSSION

The results are summarized in **Figure 2** which show the mean SAF values with standard error of the mean as error bars. As can be seen, in the training period, the animals started at about 10 rpm and reached to about 30 rpm. The training pattern is generally increasing asymptotically, which indicates that the 5-day training period was enough. This is consisted with previous studies [4].

The post-injury data shows that there is almost no difference in Sham SAF, as expected, but there is reduction of SAF in injured animals (both O1966 and Vehicle) in days 2 and 3 followed by recovery in day 4. Based on these preliminary observations, quantitative comparisons were made between day 2 (maximum effect of injury) and day -3 (maximum training before injury).

Figure 2: Rotarod performance for all groups. **Top:** bTBI and treated with O-1966. **Middle:** Sham control group that were anesthetized only. **Bottom:** Vehicle group with bTBI and non-therapeutic injection. Both drug and Vehicle animals were exposed to either a single (blue) and triple (red) shock waves.

For quantitative comparison, *t* test was used with 5% probability as the threshold of statistical significance. When comparing the effect of injury, there is reduction in SAF (**Figure 2, bottom**) for both single ($p=0.08$) and triple ($p=0.14$) hit cases although they are not statistically significant. For treated animals (**Figure 2, top**), the difference is almost the same for single hit case ($p=0.09$) but it is much closer to pre-injury for the triple hit case ($p=0.49$).

Based on the observation mentioned above, a comparison was made between single and triple hit cases at day 2 after injury. The results showed that the difference is more in the Vehicle case with triple hit resulting in 7 rpm less ($p=0.07$). This difference in the O-1966 case is less (4 rpm) with $p=0.57$ and is close to sham (3 rpm) with $p=0.70$.

In summary, the result of this study shows that treatment with O1966 can improve recovering from multiple blast exposures but was not effective in mild blast TBI with single hit. Multiple exposure resulted in more severe injury and made CB2 receptors more responsive to O1966. In the future, the effect of O1966 dosage on injury severity needs to be investigated.

This study showed that rotarod results were sensitive to indicate the effect of the injury and the drug. The effect of injury was maximized at 2 days after the injury and the animal almost recovered fully recovered after 4 days. Since statistical significance could not be achieved with the number of samples used here, more data is needed to improve the statistics of this work and verify the preliminary conclusions.

DRONE BLADE INDUCED SKIN LACERATION AND EYE INJURY RISK; AN INVESTIGATION OF SKIN AND EYE SURROGATE MODELS

Lauren A. Duma, Mark T. Bergonia, Barry Miller, Stefan M. Duma

Institute for Critical Technology and Applied Science
Virginia Tech
Blacksburg, Virginia, United States

INTRODUCTION

As the use of drones becomes increasingly popular and more widespread, the number of drone related injuries has the potential to increase. Drone accidents have caused a variety of injuries, including skin lacerations, open globe eye lacerations, and head injuries leading to unconsciousness. [1]

Possible skin surrogates that can be used to test drone injuries include cadaver skin, porcine skin, porcine eyes, and chamois. Frozen cadaver skin has proven to be ineffective, due to ice crystal formation and rapid decay. [2] This limits cadaver skin from displaying realistic biomechanical properties. Human volunteers have been used; however, given extreme injury risk, this is not a viable option. [3] Porcine skin has been used in other experiments and has shown similar structure to human skin. [2] Chamois, or synthetic skin, has also been shown to represent qualities similar to human skin. [4]

The objective of this study is to assess and analyze the ability of drones to cause laceration injuries, and to study and compare the effectiveness of skin and eye surrogates, including porcine skin, porcine eyes, and chamois, as viable and appropriate replacements.

METHODS

A total of eight experiments were performed. Two drones were selected for testing: the Phantom 4 Advanced and the Air Hogs Axis 200. For the Phantom 4 Advanced, each surrogate type, chamois, porcine skin, and porcine eye, was tested twice. For the Air Hogs Axis 200, the porcine eyes were tested twice.

The Phantom 4 Advanced had blades 9.42 inches long (total length) and 1.221 inches wide, with the thickest point on the blade being 0.1005 inches. The blade tip was 0.454 inches wide, and 0.0410 inches thick. The Air Hogs Axis 200 had blades 6.278 inches long (total length) and 0.7085 inches wide, with the thickest point on the blade being

0.0280 inches. The blade tip was 0.437 inches wide and 0.0250 inches thick. Blade velocity was calculated using rotational velocity and blade length at the tip.

High speed video was used to record the blades of each drone at maximum throttle coming into contact with chamois, porcine skin, and porcine eyes. The video camera model was the Phantom Miro LC321S with 768 x 576 resolution, recording at 6,100 frames per seconds, and 20 microsecond exposure for skin tests or 40 microsecond exposure for eye tests. A custom slider table was used to preform each test. Each drone was secured to a platform, while the skin or eye surrogate was moved into the blades a measured distance and for a specific amount of time (Figures 1 and 2). The surrogates were each mounted to ballistic gelatin. The condition of the skin surrogate was recorded before and after the experiment.

Figure 1: Aerial view of the skin laceration tests. The chamois skin surrogate (shown), mounted to ballistic gelatin, was moved into contact with the Phantom 4 blade at maximum speed.

Figure 2: Side view of the testing setup for the eye impact tests. The porcine eye surrogate (shown), mounted to ballistic gelatin, was moved into contact with the Phantom 4 blades at maximum speed.

RESULTS

The rotational velocities for the Phantom 4 in tests 1 through 6 ranged from 7944 rpm to 8423 rpm (Table 1). The Air Hogs Axis 200 had a rotational velocity of 2181 rpm, significantly less than the Phantom 4. This corresponded to a similar difference in blade tip speed with the Phantom 4 ranging between 3,118 ft/s to 3,306 ft/s compared to the Air Hog blade tip speed of 571 ft/s.

Table 1: Rotational blade velocity of each test performed.

Test Number	Drone	Surrogate Type	Rotational Velocity	Blade Tip Speed
1	Phantom 4	Chamois	7944 rpm	3118 ft/s
2	Phantom 4	Chamois	8209 rpm*	3222 ft/s
3	Phantom 4	Porcine skin	8115 rpm	3185 ft/s
4	Phantom 4	Porcine skin	8209 rpm*	3222 ft/s
5	Phantom 4	Porcine eye	8423 rpm	3306 ft/s
6	Phantom 4	Porcine eye	8354 rpm	3279 ft/s
7	Air Hogs	Porcine eye	2181 rpm	571 ft/s
8	Air Hogs	Porcine eye	2181 rpm*	571 ft/s

*Average rotational velocity was taken from matched experiments if not enough video frames were available.

The chamois and porcine skin surrogates displayed similar results when coming into contact with the Phantom 4 blades. In tests 1 through 4, both surrogates had a minor scrape with no laceration (Table 2). For example, in test two, the chamois had a visible scrape after coming into contact with the Phantom 4 blade (Figure 3). The porcine eye surrogates had varied results when impacted with the Phantom 4 and Air Hogs Axis 200 blades. The porcine eyes hit by the Phantom 4 blades displayed far more extreme injuries. For example, in test 5, the porcine eye had a total globe rupture (Figure 4). The porcine eyes impacted by the Air Hogs Axis 200, however, only experienced partial corneal abrasions.

Table 2: Observed injury results of each test performed.

Test	Observed Injury
1	No laceration, minor scrape
2	No laceration, minor scrape
3	No laceration, minor scrape
4	No laceration, minor scrape
5	Total globe rupture within 6 strikes
6	Full thickness corneal laceration, no globe rupture
7	10% corneal abrasion
8	20% corneal abrasion

Figure 3: The chamois skin surrogate after making contact with the Phantom 4 blade in test 2. A minor scrape with no full thickness laceration was observed.

Figure 4: The porcine eye surrogate after making contact with the Phantom 4 blade in test 5. After 6 strikes, there was a total globe rupture.

DISCUSSION

The chamois and porcine skin did not prove to be viable skin surrogates. The Phantom 4 Advanced drone has caused severe skin lacerations that have required stitches, while no lacerations. The porcine skin and chamois did not reflect this, as only minor scrapes were observed.

In contrast, the porcine eye proved to be a viable eye surrogate. For the Phantom 4 Advanced tests full globe rupture was observed as was also seen in the field. Also, the Air Hogs Axis 200 tests resulted in minor corneal abrasions and no full lacerations. This is to be expected from the smaller toy drone.

The total globe rupture that results from the Phantom 4 coming into contact with someone's face has lifelong consequences. Because recovery from a total globe rupture is unlikely, this injury would result in permanent blindness.

Future work with drone blade injury risks should include more variables such as speed, diameter, and blade thickness. Future testing could also include experimentation with different skin models that might have thinner epidermises.

INTRODUCTION

More than 100,000 anterior cruciate ligament (ACL) injuries [1] and approximately 74,000 collateral ligament injuries [2] occur each year in the United States alone. Recently, the incidence of ligament injuries has been increasing at a higher rate in children and adolescents than in their adult counterparts [3], but treatments for these young patients continue to be based upon research in skeletally mature subjects [4]. Previous studies have found that graft rotation during ACL reconstruction surgeries has an immediate effect on biomechanical function [5]. Our group has previously found differences in the shape of the ACL bundles between different age groups and bundles using magnetic resonance imaging (MRI) [6]. However, it is unclear whether these changes in tissue morphometry also correspond to changes in the orientation of the individual highly-aligned collagen fiber networks within the tissue. In order to tease out such changes, an *in situ* analysis of collagen fiber behavior within ligaments and tendons is needed. This work is further motivated by previous studies, which have assessed the orientation of the anteromedial (AM) and posterolateral (PL) bundles of the ACL at their femoral and tibial insertion sites by dividing the tissues into small bundles [7]. While this previous study directly measured the fibrous bundles of the ACL and found orientation changes at the insertion sites based on anatomical location, it did not characterize the behavior of the fibers in the midsubstance of the ligaments. The objective of our study was to directly analyze the collagen fibers in major ligaments and tendons along their length in the porcine stifle joint, and to compare the fiber paths between tissues and at two joint flexion angles: full extension (~40° in the pig) which is the flexion angle from our MRI scans, and 60° of flexion which is a more common position in previous literature reporting ACL rotation [8]. In order to do so, we collected points along surface collagen fibers in the patellar tendon (PT), medial collateral ligament (MCL), lateral collateral ligament

(LCL), and the AM and PL bundles of the ACL in a juvenile porcine model at both 40° and 60° knee positions. We plan to measure the difference in orientation of the fibers relative to the bulk tissue. We are continuing this work by developing a curve fitting system to quantify fiber orientation relative to the bulk tissue.

METHODS

Hind limbs from juvenile (2.5 month old) female Yorkshire cross-breed pigs (n=6) were collected. Tissue was removed from the femur and tibia up to the joint space and a fiberglass epoxy was applied to the bones in order to interface with clamps on a biomechanical robotic system. Testing was performed using a 6 degree-of-freedom universal force sensing robotic system (KUKA, SimVtro). Additionally, we took MRI scans of juvenile porcine stifle joints (7T Siemens MRI scanner, double echo steady state scan sequence, 0.42x0.42x0.4 mm voxels) and created 3D models of all tissues of interest using commercial software (Simpleware, Synopsys) (Fig. 1A). These 3D models were analyzed to obtain measures of bulk tissue rotation [6].

For the *in situ* testing, a passive path was determined from full extension (~40° of flexion) to 60° of flexion. 5-7 fibers were identified on the PT, MCL, and LCL and 8-12 points along each fiber were recorded (Fig. 1B, 1C) with a 3D point digitizer (MicroScribe) at both 40° and 60° of flexion. All remaining soft tissue other than the ACL as well as the medial femoral condyle were removed, and the digitization procedure was performed on 4-6 fibers within the AM bundle of the ACL in both positions. Lastly, the AM bundle was removed and the procedure was repeated for approximately 4-6 fibers on the PL bundle of the ACL at 40° and 60° of flexion.

Fiber points were imported into MATLAB as isolated points which were translated into 3D scatterplots (Fig. 1D). These plots were created

for individual fibers and all fibers from an individual tissue we superimposed into plots for further analysis.

Figure 1: 3D renderings were created of porcine stifle joints featuring soft tissues of interest (A). Diagram of the tissues of interest and anatomic points that were collected in this experiment (B). Points were collected running along several collagen fibers on the tissue surfaces (C). Points from individual collagen fibers were plotted in 3D space (D).

RESULTS

In the LCL, MCL, and PT, fibers were relatively linear in nature and there was little to no overlap in the tracks created by the individual fibers (Fig 2). In comparison, the fibers within the AM and PL tissues appeared less linear than those in the other tissues (Fig 2). The fibers from the AM and PL bundles were more irregular, in that the paths created by the fibers varied in the planes normal to the primary axis of the ligament. Additionally, there was more variance in the paths created between digitized points for the AM and PL bundles in comparison to the paths created in the LCL, MCL, and the PT. The LCL, MCL, and PT tissues were made of fibers that were aligned to the primary direction of the tissue, with little crossover between fibers and little variance from a straight line (Fig. 2).

Figure 2: Fibers for the tissues of interest from a representative joint at full extension (40° of flexion in the pig) after rotation onto the anatomical longitudinal axis. Dots indicate points digitized along the fibers with separate fibers depicted as different colors.

DISCUSSION

In this study, we were able to use an *in situ* approach to assess the rotation of collagen fibers along the surface of several ligaments and tendons in the porcine stifle joint at multiple flexion angles. For the LCL, MCL, and PT, the fibers followed similar paths within a single tissue, although small fiber-to-fiber variation could be seen. For the AM and PL bundles of the ACL, we observed much higher degrees of fiber-to-fiber variation. This matches visual observations of fiber orientation noted during the digitization process. These observations are further strengthened by a preliminary analysis in which fiber points were fit to second degree polynomial curves. Although we have been able to model the fibers using this approach with high correlation coefficients ($R^2 > 0.992$) across tissues, the fit was better in tissues such as the LCL, MCL, and PT where less fiber rotation occurred. Interestingly, in our initial analysis, flexion and extension of the joint did not have a noticeable impact on fiber orientation, despite previous studies reporting both fiber and morphometric changes due to knee flexion angle changes in both human and porcine joints [6-8]. This discrepancy may be due to differences in the ranges of flexion angles studied [6-8].

Ultimately, our goal is to develop a non-invasive MRI-based method to assess fiber rotation within ligaments and tendons. To do so, we will compare the pitch and angles of fiber rotation via MRI and our direct *in situ* method using a single set of joints, allowing direct comparison of the methods. Ongoing efforts will involve developing a method to fit points onto MRI-based surfaces in order to track the rotation of both fibers and bundles in a 3D coordinate system. These measurements will be validated using our direct *in situ* method. Interestingly, the non-linear appearance of point maps for the AM and PL bundles of the ACL found in the current study correspond with our early MRI-based findings, where we found ~57° rotation of the primary axis of the AM bundle and ~55° rotation of the primary axis in the PL bundle. Additionally, a future direction involves dividing the tissues into regions and comparing regional fiber patterns. We also plan to expand this study to include early juvenile and late adolescent groups in order to assess potential differences in fiber alignment during growth. Overall, this work represents an initial step toward a method to noninvasively assess fiber rotation, which may better inform surgical interventions and enhance our understanding of ligament and tendon structure.

INTRODUCTION

Tendons act as one of the most important parts of a human's musculoskeletal system, as they are the connectors between bone and muscle. The compositional and organizational properties of tendons determine their ability to provide adequate mechanical function. While the collagen matrix is known to provide high tensile strength, relatively little is known about how the non-collagenous components of a tendon, and more specifically elastic fibers, influence its mechanical properties [1-3]. Elastic fibers are composed of elastin deposited onto a microfibrillar scaffold and exist predominantly in the interfascicular matrix (IFM), which is located between collagen fascicles and may link them together [1, 4]. Elastic fibers have been suggested to provide important mechanical roles in tendon; for example, they may allow a tendon to recoil after being loaded. Clinically, understanding the effect of elastic fibers on the mechanical properties of tendon could facilitate future research on diseases such as Marfan Syndrome and Williams Syndrome, both of which stem from mutations to elastic fiber-related genes [5]. More in-depth understanding would allow clinicians to help patients with elastic fiber deficiencies in a more informed and effective manner.

However, there is little experimental evidence on how elastic fibers affect the tensile mechanics of tendon. Previous research using genetically modified mouse models has suggested that elastin has an effect on a tendon's mechanical properties, but the effect was less than initially anticipated. Because of the vast difference in tendon size between mice and larger animals, the distribution of the elastin within the tendon and IFM may also be quite different [3]. Therefore, comparing the contribution of elastin in larger tendons with a prevalent IFM may better elucidate how elastin functions under tensile load in tendon.

In order to isolate the mechanical effect of elastic fibers, comparisons can be made by testing tendons, with and without enzymatic elastin degradation treatment, under the same loading conditions. Previous studies have used elastase to determine the effects of elastin digestion on the quasi-static mechanical properties of tendon and ligament; however, no studies to date have investigated changes to viscoelastic properties in tension with elastase treatment [3,6]. In this study, bovine long digital extensor tendon (LDET), which is functionally analogous to the human tibialis anterior tendon, was used as a representative tendon for large species. The purpose of this study was to utilize mechanical testing before and after elastase incubation to determine the role of elastin on the viscoelastic mechanical properties of tendon.

METHODS

Bovine LDETs were acquired from a local abattoir and frozen at -20° C until use. Before testing, samples were thawed at room temperature for 30-60 minutes. Cross-sectional area of each tendon was measured using a non-contact laser scanning device. Samples were loaded in custom clamps gripped between pieces of sandpaper to ensure minimal slipping occurred. Clamps were placed in an Instron 5542 Testing Machine, a 0.5 MPa preload was applied, and the gauge length was then measured using calipers. Once the gauge length and preload were determined, samples were preconditioned using ten cycles to 6% strain and subsequently tested in stress relaxation for ten minutes at 6% strain followed by triangular loading waveforms to 2, 4, and 6% strain to assess hysteresis (Figure 1). Following testing, the clamps were removed and incubated in either PBS (controls) or 3.5-4 units/mL elastase solution for 24 hours while maintaining a constant gauge length. Both control and test solutions contained 0.1 mg/mL soybean

trypsin inhibitor to prevent digestion of collagen. Following incubation, the clamps were reloaded into the Instron and the tendon was loaded using the same protocol as the pre-incubation test. Changes in mechanical parameters after PBS or elastase incubation are reported.

Figure 1: (a) A LDET sample loaded in the custom-made clamps. Samples were loaded in tension in the Instron 5542. **(b)** A time versus displacement graph for the testing protocol. The protocol for the pre and post incubation tensile testing protocol included 10 cycles of preconditioning at 6% strain, followed by a 10-minute stress relaxation at 6% strain and hysteresis curves to 2, 4 and 6% strain.

In between experiments, the enzyme solution was filtered using a hollow fiber filter with a maximum pore size of 0.1 μm to remove released tendon fragments and prevent bacterial growth in the solution. For elastase-treated samples, the activity of the elastase solution was measured daily [7] and additional elastase was added as necessary to ensure constant activity across all samples.

RESULTS

Elastase treatment altered the viscoelastic and quasi-static mechanical properties of LDETs compared to PBS treated controls (Figure 2). In control samples, peak stress, equilibrium stress, and relaxation time (i.e., time to reach 50% of total relaxation) values remained relatively constant after incubation, while percent relaxation decreased after incubation (Figure 2d). In contrast, both the peak and equilibrium stress significantly decreased after elastase treatment (Figure 2b,c). Moreover, the relaxation time significantly decreased (Figure 2e), and percent relaxation remained slightly closer to the pre-incubation values following elastase incubation (Figure 2d).

Hysteresis at 2% strain and linear modulus values also decreased after elastase treatment relative to controls (not shown). The transition strain increased after both PBS and elastase incubation, although the effect was significantly great in elastase treated samples (not shown).

DISCUSSION

Our preliminary results show that digestion of elastin significantly altered the viscoelastic properties of tendon. despite making up only 1-2% of tendon weight [4]. These changes were likely due to the fact elastin is a protein in elastic fiber in tendon. Although it makes up a small percentage of a tendon's dry weight, its function is unique and quite different than collagen, the major component of tendon [4]. When the elastin is digested the tendon's structural mechanisms relaxe, hence the change in viscoelastic properties. Elastin-dependent results are also intriguing when considering the function of the LDET in bovine hooves.

Figure 2: (a) A plot of stress normalized to pre-incubation values during the stress relaxation period versus time. **(b)** The change of peak stress during the stress relaxation period. **(c)** A plot of the change of equilibrium stress before and after incubation. **(d)** Difference in percent relaxation during stress relaxation. **(e)** Change in relaxation time which is time to reach 50% relaxation.

Like the tibialis anterior tendon in humans, the LDET is a positional tendon, meaning the tendon is not strained with the same magnitude or as frequently as a more energy-storing tendon [8]. This difference in function has previously been shown to relate to differences in mechanical properties and elastin content in functionally distinct tendons [8]. However, significant changes were still observed after elastase incubation, which suggests that elastin plays a significant role in the positional tendon's function. Further research will determine if elastase incubation has a larger effect in energy-storing tendons.

Ultrasound shear wave Elastography of the Anterior Cruciate Ligament

INTRODUCTION

About 250,000 Anterior Cruciate Ligament (ACL) reconstructions are performed every year in the US, resulting in an annual health care cost exceeding \$2 billion [1]. ACL injury typically occurs in the physically-active young population. The incidence of ACL injury is greater in males due to greater exposure to physical activity, however, the relative risk of injury per exposure is 2 to 8 times greater in females [2]. Long-term effects of ACL rupture include strength asymmetries, residual pain, and osteoarthritis. Specifically, 50% of individuals who continue playing competitive sports, will develop OA after an ACL repair [3]. ACL ruptures occur when forces, sometimes within physiological limits, exceed the strength of the ACL, which may be compromised due to micro-damage caused by repetitive loading, hormonal effects, genetic factors, or cell-driven abnormal processes. Therefore, in-vivo measurement of changes in the mechanical properties of the ACL can provide valuable information for the evaluation of risk of injury and prevention of ACL injuries. Evaluation of ACL is commonly done using MRI [3], which is expensive and only provides information about size and structure. Ultrasound shear wave elastography (SWE) is an imaging technique designed to non-invasively measure the shear modulus of soft tissues [4]. The objective of this study was to evaluate the repeatability of SWE for quantifying the ACL shear modulus in healthy individuals.

METHODS

To compare the ability of ultrasound of localizing the ACL, a comparison between MRI and B-mode ultrasound was performed in a healthy individual (male, 29 years old). A T2-weighted MR image (Siemens Prisma, 3T, TE: 60 ms, TR: 2000 ms) with fat saturation was performed with the knee bent at 90 degree flexion. B-mode ultrasound images (Verasonics, Vantage 128, L7-4) were obtained from the same individual with the knee also at 90 degree flexion.

The ultrasound elastography method was implemented in a research scanner (Verasonics, Vantage 128). Unique characteristics of our elastography method, compared to commercial scanners, are the ability of precisely locating the push pulses at the insertion of the ACL to create a mechanical wave that propagates along the ACL and the ability of measuring the wave speed when the wave is propagating in a diagonal direction rather than horizontally.

To evaluate the repeatability of the SWE technique and the effect of knee flexion, fifteen healthy patients (Mean age \pm SD, 21.13 \pm 1.25; Mean BMI \pm SD, 22.14 \pm 5.06) were recruited in this study. All subjects had a dominant right leg. During the measurement, the participants were asked to lie supine with the knee joint in three different positions: 90 degree flexion in the knee, 120 degree flexion in the knee, and fully flexed knee posture, where the tibia is perpendicular to the patient bed (Fig 1). An angle adjustable knee brace was used to secure the knee. The ultrasound transducer was placed between the patella and the tibia plateau and the measurements were performed in both knees. To evaluate day-to-day reliability, the same procedures were repeated on two different days with an interval of at least two days.

Figure 1: Experimental setup for the ACL SWE when the participant is at: (a) 90 degree of flexion in the knee (b) 120 degree of flexion in the knee (c) fully flexed knee posture.

RESULTS

The comparison between the knee MRI and ultrasound images shows that it is possible to the distal portion of the ACL using ultrasound.

Figure 2: MRI image of the ACL (left), Ultrasound image of the ACL (right)

The shear wave propagation within ACL is shown in Fig. 3. There was not a significant difference between the shear wave speed in dominant and nondominant leg. The shear wave speed increased with increasing the knee flexion and putting more tension on the ACL.

Figure 3: The shear wave (red) propagation of the ACL at different time steps: (a) 5 ms, (b) 20 ms, (c) 40 ms, after transmitting push pulses.

The shear wave speeds within ACL at each posture are shown in Figure 4. The Between-days intraclass correlation (ICC) (95% CI) for the ACL shear wave speed was 0.83 (0.74-0.89), suggesting excellent reliability. The standard deviation and standard error of the mean at each posture is shown in Table 1.

□

Figure 4: Shear wave speed within ACL increased with increasing of the knee flexion (mean \pm standard deviation)

Table 1: Standard deviation (SD) and error of the mean (SEM) at different postures for the ACL measurements.

Flexion angle	SD, SEM (m/s)
90 degree	0.23, 0.09
120 degree	0.91, 0.37
Fully flexed	1.63, 0.67

DISCUSSION

The present study investigated the reliability of the SWE technique for evaluating ACL shear modulus in healthy individuals. The results suggest that ultrasound SWE could be a repeatable tool for quantifying the change in ACL shear modulus. The shear wave speed within ACL is increased with increasing the flexion of the knee, suggesting that ultrasound SWE is sensitive to the loading of the ACL. The correlation is significant because it provides the changes in mechanical properties of the ACL in motion. Studies have shown that the ACL provided more than 80% of anterior restraining force from 30° to 90° of knee flexion, while other ligamentous structures such as the medial joint capsule, the iliotibial tract, and the medial and lateral collateral ligaments provided no relevant secondary restraint to this motion [5].

There are several mechanisms responsible for change in the mechanical properties of ACL. Jones et al. [6] found a correlation between the mechanical properties of the ACL and stiffness, bodyweight, and physiological loading. Ultimate failure load was found to have a significant correlation with bodyweight whereas there was no statistical difference of stiffness at different ages. Non-contact modes of failure, such as tensile or torsional ruptures and tears, are also important in decisions for surgical reconstruction of the ACL [6]. SWE can be used to track these mechanisms that alter the mechanical properties of the ACL.

Our proposed protocol for evaluating the ACL shear modulus using SWE offers several potential applications for trainers, coaches and practitioners. It may also potentially improve ACL reconstruction surgery and current rehabilitation protocols. This method is safe and non-invasive, which allows evaluation of the ACL directly in patients. This technology opens new avenues of research for evaluating the different tissues used as ACL grafts, and their adaptation after surgery. First, it can be used as a potential tool for evaluating the health status of the ACL and early detection of injury for future sports medicine applications. For example, it could be used to routinely monitor the ACL of athletes during a season in order to understand if an ACL is injured or if it has a higher risk of injury. Second, it could also be applied to evaluate the degree of injury. Several studies have shown that allografts are more likely to fail at the points of insertion compared to autografts [7]. Third, there is controversy regarding the choice of hamstring versus patellar tendon autografts [7]. SWE may help medical doctors identify the optimal intervention strategy, monitor the recovery process and the effect of the treatment. This may potentially reduce the probability of patients who develop OA and minimize the costs of procedures and rehabilitation. This information can also be carried into other injuries and ligament repairs for further impact on society.

The limitation of this study is that our sample for healthy individuals consisted only students under the age of 25 with a normal BMI. Future studies will focus on evaluating patients with a ruptured ACL and ACL reconstructions. In conclusion, SWE could be a reliable tool for quantifying the changes in ACL shear modulus.

INTRODUCTION

Osteoarthritis (OA) is the most common joint disorder in the United States, affecting over 27 million adults (1). Risk factors for OA include age, obesity, previous injury, and genetic predisposition. The prevalence of OA is predicted to increase as the US population grows older, potentially affecting 25% of adults by the year 2020 (1). The cellular mechanisms of OA progression are poorly understood and current treatments for OA involve joint replacement and pain management. OA is characterized by the degradation of articular cartilage. During the development of OA, the stiffness of the extracellular matrix (ECM) of cartilage decreases due to a degradation of both collagen type 2 and proteoglycans (2). This progression involves a shift in the balance of anabolic factors, that buildup the ECM, and catabolic factors that break down the ECM. The mechanosensitive Transient Receptor Potential Vanilloid 4 (TRPV4) channel conducts calcium and responds to mechanical force, osmolarity, and chemical stimulation. The TRPV4 channel has been shown to play a crucial role in the development and function of cartilage (3). While altering matrix stiffness changes the function and phenotype of mesenchymal stem cells, few studies have investigated the role of altering matrix stiffness on chondrocyte phenotype and function. Therefore, I postulated that the loss of cartilage ECM stiffness would alter the function and phenotype of chondrocytes. The goal of this project was to determine how ECM stiffness influences TRPV4 activity, chondrocyte cytomechanics, and function. Here we show that decreasing the ECM stiffness, modeled by poly(ethylene-glycol) (PEG) hydrogels, reduces the ability of the TRPV4 channel to respond to osmotic challenge.

METHODS

PEG-DA/RGDS Hydrogels: Polyethylene-glycol diacrylate (PEG-DA) was used as the polymer for the hydrogel; Hank's Balanced Salt

Solution (HBSS) with calcium and magnesium was used as the buffer; Lithium phenyl-2,4,6-trimethylbenzoylphosphine (LAP) was used as the photoinitiator. Peptide H-Arg-Gly-Asp-Ser-OH (RGDS, Bachem, Torrance CA), a fibronectin derived cell adhesion peptide, was used for cell attachment. Varying weight percentages of PEG-DA were added into solution to alter the stiffness of the polymerized gel. Hydrogels were made by the Slater Lab at University of Delaware. Hydrogels were tested compressively on an Instron Single Column Tabletop Model Testing System (Model 5943, Norwood MA) to determine the Young's Moduli at different weight percentages of PEG-DA. Weight percentages of 14.1% PEG-DA represents a healthy cartilage stiffness of 350kPa, 9.8% PEG-DA an intermediate model at 175kPa, and 5.2% an osteoarthritic stiffness model at 35kPa were used in these studies.

Cell Culture: Chondrocytes, murine ATDC5 chondrogenic cells (Sigma Aldrich) were cultured on the hydrogel surface. Chondrocytes were grown in DMEM/F-12 50-50 media supplemented with 10% Fetal Bovine Serum (FBS) (Atlas Biologicals) and 1% Penicillin/Streptomycin (Hyclone).

Calcium Imaging: Experiments were conducted as previously describes (4,5). All experiments were conducted at room temperature to avoid temperature-sensitive spontaneous TRPV4-mediated calcium oscillations. Cells were loaded with Fluo-4 (Life Technologies) before being recovered in either HBSS or in 100nM GSK2193874 (GSK219), a TRPV4 antagonist. Cells were challenged with 50% Hypotonic Swelling (HTS) after a 1-minute baseline was recorded.

Cytoskeletal Immunostaining: ATDC5 cells were cultured for 48 hours and then serum starved for 24 hours, as previously described. Actin was stained with Phalloidin-iFluor 488.

Statistical Analysis: One-way or Two-way ANOVAS were used to determine significance, with Tukey-Kramer's post-hoc test used to compare between groups. p-values < 0.05 were considered significant.

RESULTS

Graham et al. have shown that compressive and tensile moduli decreases in OA cartilage explants (4). However, how this decrease in mechanical properties of cartilage alters osmosensation of chondrocytes has yet to be studied. TRPV4 is a key osmosensor in chondrocytes, as knock-out of the channel significantly attenuates the response of chondrocytes to osmotic pressure and dynamic load (5). Thus we investigated how altering ECM stiffness changed TRPV4 channel activity. Studies from our lab indicate that polymerization of the actin cytoskeleton can regulate TRPV4 activity. Additionally, decreasing the stiffness of the ECM leads to decreased actin polymerization in cells. Here, we confirm that a decrease in stiffness of the ECM leads to the formation of fewer actin stress fibers (Fig. 1). As the stiffness of the gels was decreased, the intensity of the stain and actin stress fiber formation diminish.

Figure 1: Immunofluorescent staining of ATDC5 cells on PEG hydrogels. A.) 5.2% Osteoarthritic stiffness model with low actin stress fiber formation and low levels of staining, B.) 9.8% Intermediate stiffness model, C.) 14.1% Healthy stiffness model with increased actin fiber formation and high intensity of the stain. n= 1.

Previous results from our lab indicate that increasing actin stress fiber formation attenuates TRPV4 mediated calcium influx. However, the decrease in actin polymerization on the lower PEG-RGDS gels significantly lessened the response of ATDC5s to hypotonic challenge (Fig. 2). To confirm the role of TRPV4 in altered chondrocyte calcium response to changes in stiffness, GSK219 was used to inhibit TRPV4 on the PEG-DA models. When intracellular calcium influx was normalized to the baseline, significant differences between the models materialize (Fig. 2A). Cells grown on the 350kPa gels, representative of healthy cartilage, show significantly higher responses to HTS when compared to cells grown on both the 175 kPa (intermediate) and 35 kPa (OA) gels (Fig. 2B). Additionally, ATDC5 cells grown on the 175 kPa gels show a significantly greater response to HTS when compared to cells grown on the 35kPa gels. Interestingly, inhibition of TRPV4 with GSK219 significantly suppressed the response of cells to HTS when they were seeded on the healthy and intermediate gels, only. When the area under the curves were analyzed, a similar trend to the peak over baseline responses is seen. Chondrocytes grown on the healthy and intermediate gels have a trend of GSK219 inhibiting the responsiveness of the cells to HTS.

DISCUSSION

Our findings show how ECM stiffness alters TRPV4 activity in chondrocytes. Cytoskeletal staining demonstrated that cells displayed higher actin stress fiber formation on the healthy stiffness model than on both the intermediate and the osteoarthritic stiffness models. Actin stress fibers contribute to the mechanosensitive ability of the TRPV4 channel, with our results indicating that as the stiffness of the ECM decreases, the response of chondrocytes to HTS is suppressed in a TRPV4-dependent mechanism. Han et al have shown that proteoglycan rich microdomains have lower ECM strain, which corresponded to a higher calcium baseline (2). Here, our data confirms that the calcium baseline of ATDC5 chondrocytes is significantly increased as the matrix loses stiffness. Furthermore, cell morphology was altered depending on matrix stiffness, with the appearance of increased cell spreading and cytoskeleton organization on the higher stiffness gels.

Although previous studies from our lab indicate that actin stress fiber formation attenuates calcium influx, our hydrogel models may provide a more physiologically accurate model of chondrocyte behavior. The results suggest that there is an optimal range of calcium stimulation which promotes healthy chondrocyte function, and deviations above or below this range can have adverse effects. Our data indicates that ECM stiffness contributes to the regulation of calcium stimulation and cytoskeletal organization. The balance of TRPV4 activity may play a key role in the progression of OA, as other studies indicate ablation or over-activation of TRPV4 both cause deleterious effects on the phenotype of chondrocytes (2,5). Further studies will explore the role of ECM stiffness on TRPV4 and chondrocyte function through investigating the role of TRPV4 stimulation on these gels and the role of modulating the stiffness on anabolic and catabolic gene expression. This information could provide new ways to target OA progression and improve therapies for OA patients.

INTRODUCTION

Asthma, characterized by chronic airway inflammation, airway obstruction, and lung remodeling, is one of the most prevalent chronic lung diseases in the US [1]. Lung remodeling causes an increase of the airway wall thickness and a decrease in lumen size in severe asthmatics [2]. The changes in geometry due to remodeling or obstruction result in alteration of airway resistances and respiratory patterns [3]. Due to the high variance in airway geometry of asthmatic patients, it is important to develop a framework to quantify the morphometric differences between asthmatic and healthy patients and correlate these findings to clinical and inflammatory metrics. Understanding the changes in morphology due to asthma may be a key factor to better diagnostics [4]. The main goals of this study are to develop and test a framework to quantify lung morphometry in healthy and asthmatic patients and to compare severe, mild to moderate, and healthy groups to each other. We extract airway lengths, radii, and bifurcation/gravitational angles from 3D realistic CT-based airway models and then study the inter subject variability between each severity group.

Figure 1. Model rendering for the healthy subject (green) compared to the severe asthmatic subject (red).

METHODS

Our group created airway geometries for 3 healthy, 5 mild-moderate, and 6 severe asthmatic patients from high-resolution CT scans acquired at Total Lung Capacity (TLC) (Fig. 1). The

demographic information is presented in Table 1. Centerlines for each model were extracted in SimVascular [5] in form of discrete points in space with minimum inscribed sphere radius associated with each point.

Table 1. Demographic information
in form of mean \pm standard deviation.

	Gender	Height (cm)	TLC volume (ml)
Healthy	1 m, 2 f	167.7 \pm 8.4	4697 \pm 1894
Moderate	3 m, 2 f	175.8 \pm 9.9	6333 \pm 928
Severe	5 m, 1 f	180.0 \pm 4.1	7304 \pm 310

Next, centerline data was imported in Matlab to reconstruct and analyze the geometry (Fig. 2). Data exported from SimVascular were in the form of discrete points in a list format. For each point, we obtain the XYZ coordinate location and the minimum inscribed sphere radius. The developed Matlab code separates the points into individual branches and connects them together to form a complete lung geometry.

Figure 2. The process of reconstructing centerline geometry for a moderate asthmatic subject. A. 3D rendering of the model. B. Centerline points extracted and assigned to branches. C. Branches are joined together.

After the geometry is fully reconstructed, the algorithm computes the total length of each airway branch. Next, we determine the average, maximum, and minimum radius for each branch from the minimum inscribed sphere radius associated with each point. We identify the key anatomical regions of interest and recorded and compared values for these regions.

Finally, we compute the main bifurcation angle at the location where the trachea splits into the main right and left bronchi (Fig. 3). To do this, we determine the best fit lines through the centerline points in all three dimensions, using a total least squares analysis for the left main bronchi, the right main bronchi, and the trachea. From these lines, we find the total angle of bifurcation (angle α) and the bifurcation angle between the trachea and main right and left bronchi (angles β and γ).

Figure 3. Angle of bifurcation measurements.

RESULTS

We found the average airway radii for healthy, moderate, and severe asthmatic groups. Radii data was normalized by subject's lung volume to account for differences in lung size between subjects and is plotted in Fig. 4. Error bars represent inter-subject variability. We choose to plot the radii by anatomical region to correlate results with defects measured with HP ³HE MRI data in future studies.

We observed a higher variability in healthy subjects due to a limited sample size and an outlier in form of a female subject with a low TLC lung volume of 2487 ml. The variability of height is also greater in the healthy subjects, and height is known to correlate with lung dimensions, increasing radii range.

Figure 4. The average airway radii normalized by volume at different anatomical regions. Region definitions: trachea (1), right main bronchus (2), right superior lobar bronchus (3), right superior to middle conducting bronchus (4), right middle lobar bronchus (5), right inferior lobar bronchus (6), left main bronchus (7), left superior lobar bronchus (8), and left inferior lobar bronchus (9).

We also found the average airway length for the same key anatomical regions with an exception of trachea for the three groups in Fig. 5. Trachea is excluded from the length analysis because only the lower portion of the trachea geometry was modelled for this study. We observed that the airway average length and variability doesn't seem to change significantly with asthma progression.

Figure 5. The average airway length measured at different anatomical regions of the models.

For the given models we also obtained bifurcation angles, as illustrated in Fig. 3 for the three groups. We observed an increase in variability of the total angle of bifurcation with asthma progression. There is also an increase in average total bifurcation angle for the moderate group compared to the healthy group.

Table 2. Angles of bifurcation across three groups in form of mean \pm standard deviation.

	α (degrees)	β (degrees)	γ (degrees)
Healthy	87.99 \pm 5.55	145.02 \pm 21.85	125.58 \pm 20.14
Moderate	102.56 \pm 13.39	119.32 \pm 13.33	135.91 \pm 11.99
Severe	87.68 \pm 16.25	129.53 \pm 13.93	143.08 \pm 8.28

DISCUSSION

Using the framework described above, we successfully acquired length, as well as average, maximum, and minimum radius for the key airways of 6 severe, 5 moderate, and 3 healthy patients. We determined that the average airway radius normalized over volume appears to decrease with asthma progression. However, the airway length between the groups doesn't seem to change significantly with asthma progression. The total angle of bifurcation and its variability seem to increase with asthma progression. Our findings align well with previously documented airway constriction and increase of bifurcation angle in severe asthmatic patients [6]. We plan to increase our sample size and analyze correlations with physiological parameters in future studies.

CONTRIBUTIONS OF COLLAGEN II, LAMININ, AND FIBRONECTIN TO VITREORETINAL ADHESION IN HUMAN EYES

Joseph D. Phillips (1), Christopher J. Creveling (1), Brittany Coats (1)

(1) Mechanical Engineering
University of Utah
Salt Lake City, Utah, USA

INTRODUCTION

Vitreoretinal adhesion plays an important role in ocular health and pathologies. In aging eyes, the vitreous undergoes syneresis and gradually separates from the retina, often resulting in posterior vitreous detachment (PVD). In an incomplete PVD, lingering vitreoretinal attachments exert tractional forces on the retina, causing sight-threatening damage such as macular holes and edema [1]. However, vitreoretinal adhesion mechanisms are not well understood. Previous research suggests that collagen as well as non-collagenous proteins, such as laminin and fibronectin, are critical components of the vitreoretinal interface modulating adhesion, and are often the targets of pharmacologic vitreolysis to induce a full PVD [2]. However, proteins have not been quantified, nor do we know their contribution to vitreoretinal adhesion. The objectives of this study were to (1) quantify collagen II, fibronectin, and laminin at the vitreoretinal interface and identify differences by region and with age, and (2) identify correlation of each protein density with regional vitreoretinal adhesion. These data will, for the first time, provide quantitative data regarding the regional mechanisms of adhesion at the vitreoretinal interface.

METHODS

A custom rotational peel test system was used to measure the adhesive strength between the vitreous and retina in human eyes ($n=26$) as described in [3] and shown in Figure 1. Maximum and steady state peel force were measured in the equator and posterior regions of each eye. After the peel test, specimens of unpeeled retina were collected from regions adjacent to the peeled retina. The vitreous was collected with each specimen to ensure an intact vitreoretinal interface. The specimens were then placed into a fixative solution of 1% buffered formaldehyde and 1.25% glutaraldehyde.

Following fixation, 3-4 micron sections were cut from each specimen and stained for collagen II, laminin, and fibronectin using

Figure 1: Image of the custom peel test system described in [3]. The retina is peeled from the vitreous as the device rotates.

immunohistochemistry (IHC). Digital images of each stained vitreoretinal specimen were acquired on an automated slide scanner (ZEISS Axio Scan, ZEISS, Oberkochen, Germany) and processed by a custom MATLAB program (The MathWorks, Inc., Natick, Massachusetts). The custom program segmented the image by color based on a k-means clustering algorithm, and the user identified the protein in the image. The protein density was calculated as a unitless pixel ratio by dividing the total number of stained pixels in the image by the geometric pixel length of skeletonized retina. An example image showing the segmented protein pixels and the skeletonized retinal length is shown in Figure 2.

Collagen II, laminin, and fibronectin are known to be present at the vitreoretinal interface [2]. Stained pixels were only accounted for in the density calculation if they were considered part of the vitreoretinal interface. Images with no stain were assumed to be due to processing artifacts and excluded from the analysis.

Figure 2: IHC image of a human retina from the posterior of a 70-year old donor. Collagen II (C) is shown in red at the vitreoretinal interface separating the retina from the vitreous (V). The retina is converted into a skeletonized line (S) to estimate retinal length.

Paired Student's t-tests were used to determine significant differences in protein density between regions of the eye (equator and posterior pole). We previously reported a significant decrease in equatorial and posterior pole adhesion after 60 years of age [3], so these analyses were performed first with all ages combined, and then repeated for individuals ≤ 60 years of age and those >60 years of age. Finally, collagen II, laminin, and fibronectin density were statistically correlated with the maximum peel force measured adjacent to each specimen. A p-value <0.05 was considered significant.

RESULTS

Collagen II was significantly greater in the equator (9.22 ± 5.53) than in the posterior pole (4.24 ± 1.71 , $p=0.024$), and did not significantly change with age. Laminin and fibronectin exhibited interesting age- and region-dependent trends. Specifically, there was no difference in laminin density between the equator or posterior pole until after 60 years of age (Figure 3A). At this age, laminin in the posterior pole (3.69 ± 2.23) decreased to levels lower than the equator (5.10 ± 2.36). Conversely, fibronectin in the posterior pole was greater than the equator (5.51 ± 2.50 vs 3.31 ± 1.46), but decreased after 60 years of age in the posterior pole to equal density in the equator (Figure 3B). The trends with laminin and fibronectin were not statistically significant due to limited specimens in some groups.

Collagen II significantly increased with increasing maximum peel forces ($p=0.02$, Figure 4A,B), but only in the posterior pole. Interestingly, laminin significantly increased with increasing maximum peel forces ($p=0.01$, Figure 4C,D), but only in the equator. Fibronectin had a positive correlation ($r=0.50$) with maximum peel force in the posterior pole, but this trend was not significant ($p=0.25$).

DISCUSSION

In this study we quantified collagen II, laminin, and fibronectin at the vitreoretinal interface, and identified age and region-dependent differences. Further, we found significant region-dependent correlations of proteins with adhesion force that suggest different mechanisms of adhesion between the equator and the posterior pole.

Collagen II was significantly greater in the equator compared to the posterior pole and did not change with age. This corroborates observations made in previous studies [4]. Interestingly, collagen II correlated with vitreoretinal adhesion in the posterior pole, but not the equator. This supports theories of differing mechanisms of adhesion between the equator and posterior pole. In the posterior pole, collagen fibers running anterior to posterior may penetrate the inner limiting membrane (ILM) to tether the vitreous to the retina. This is corroborated by the data in the present study and from our previous study [3] which

Figure 3: (A) Laminin and (B) fibronectin density by age for each region. Error bars represent standard error.

Figure 4: Correlation of collagen II (A,B) and laminin (C,D) density to maximum vitreoretinal peel force in the equator and posterior pole.

found ILM rupture was significantly higher in the posterior pole after peeling compared to the equator, despite requiring lower adhesive forces for failure. We believe the increased ILM rupture is due to collagen fiber pull-out.

In the equator, only laminin density was significantly correlated to vitreoretinal adhesion, even though this region had higher amounts of collagen II compared to the posterior pole. This suggests sheet-forming adhesive proteins, such as laminin, create adhesion between the vitreous and the retina in the equator. Fibronectin also increased with maximum peel force in the equator, but the trend was not significant. Therefore, fibronectin, and potentially other proteins, may also contribute to vitreoretinal adhesion in the equator.

RAPID QUANTITATIVE ASSESSMENT OF POSTURAL CONTROL FUNCTION FOR MILD TRAUMATIC BRAIN INJURY: EVALUATION OF A PORTABLE FORCE PLATE DEVICE

Jonathan P. VanPaepeghem, Kunal Dave, Liying Zhang

Biomedical Engineering
Wayne State University
Detroit, MI, United States

INTRODUCTION

As reported by the Center for Disease Control and Prevention (CDC), concussions, also known as a mild traumatic brain injury (mTBI), are a major public health disorder.¹ A recent report estimated between 1.6–3.8 million sports-related mTBIs occur annually in the U.S. alone, but this number is likely greater due to underreported mTBIs arising the failure of injury recognition.² It is reported nearly 250,000 U.S. military service members were diagnosed with a mTBI since 2000, yet this number is also believed to be underestimated due to underreporting.³ Unfortunately, those with acute mTBIs often have subjective, nonspecific complaints and only undergo a routine physical exam. The only way such mTBIs can be diagnosed is through expensive testing and/or subjective clinical evaluation. In a military environment, mTBI results are interpreted by relatively small numbers of highly trained health care providers, resulting in delays in diagnoses and treatment. Currently there is no effective measurement tool that can be administered quickly and accurately by a broad range of medical staff in multiple environments to assist in diagnosing mTBIs and help provide consistent, objective evidence-based care.

The Balance Error Scoring System (BESS) is the most commonly used postural control evaluation tool for sports-related mTBIs. It assesses an individual's ability to maintain balance based on information from the vestibular systems and somatosensory signals that the brain receives from the muscles and joints. The BESS is an emerging tool for sideline mTBI evaluation, as it allows for postural assessment in the absence of instrumented balance devices.⁴ When conducting a BESS test, the subject is asked to position themselves in three stances: double-leg stance, single-leg stance, and a tandem stance in a heel-to-toe fashion. All three stances are performed on both a firm surface and again on a foam surface, with the eyes closed during a 20-second trial. During each trial, the test administrator will count each of the six errors that may occur and a final score is provided at the end of the six trials

(errors include opening of the eyes, lifting hands off the iliac crests, stepping or stumbling and falling out of position, lifting the forefoot or heel, abducting the hip $> 30^\circ$, or failing to return to the test position in more than 5 seconds.⁵

While it has been reported that the BESS has moderate to good reliability to assess static balance, it faces multiple limitations when administered independently.⁶ The test is extremely subjective with high test-variability, and is subject to the skill of the observer administering the test.^{5,7} In addition, discerning a false positive from an intentioned act is difficult for the observer to detect with the naked-eye. The SiM – 1000 Portable Force Plate⁸, is a computerized balance assessment device designed for athletic teams and health care professionals to quickly and objectively diagnose a mTBI. It is a FDA Class 1 balance assessment medical device. The SiM – 1000 utilizes accurate, durable, and reliable automotive sensor technology to detect weight sway through various mechanical measures, and is also robust and portable, weighing only 35 lbs. Previous studies have reported that the SiM – 1000 provides objective balance data with a high correlation to the visual BESS.⁸ This portable device has the potential to provide quick, objective early identification of mTBIs on the sideline and in a military setting. However, sufficient research is needed to establish its utility. The current study was conducted to further verify the accuracy of the balance score obtained between the SiM – 1000 device and the visual BESS on a healthy population.

METHODS

Research was conducted on a total of twenty-six university students between the ages of 19 and 33 years (mean \pm SD = 23.8 ± 3.56) who volunteered to perform the test. Before each test, subject sex (23 male, 3 female), weight (71.6 ± 13.3 kg), height (173.9 ± 7.34 cm), and known medical conditions relating to postural instability were recorded for potential use in future research. Subjects were fully informed of the

proper positioning for each stance of the BESS test and instructed to remove their shoes for each of the trials. Each test subject completed all six 20-second trials of the BESS test while standing on the SiM – 1000 Portable Force Plate. Each subject was video recorded with an iPhone 7 for the duration of the six trials.

After the completion of all trials, the overall BESS and individual stance scores output by the SiM program were recorded. The recorded video for each subject was analyzed and the number of errors were manually counted and recorded in compliance with the BESS protocol.⁵ The total and individual stance scores output by the SiM program were then correlated with the associated manual scores from each video in order to determine the efficacy of the SiM program. Linear regression analysis was used to correlate the SiM program and manual scores for each of the six individual stances and total scores from all subjects.

Trials were also completed in which a subject intentionally committed errors during each stance to determine if the SiM program can discern between intentional and legitimate errors. The SiM program output parameters including Lateral Sway Length, Anterior-Posterior Sway Length, Vector Sway Length, and Vector Sway Velocity were also analyzed to determine how the program defines errors.

RESULTS

The total SiM scores and manual scores for each of the twenty-six subjects is shown in Figure 1. The coefficient of determination of the linear regression was $R^2 = 0.6005$. When plotting the SiM scores and manual scores for the individual stances, it was found that the single-leg foam test score had the poorest R^2 value of the six stances ($R^2 = 0.3715$, individual stance avg. $R^2 = 0.6226$). The SiM score for the single-leg foam tests were found to be consistently lower than the manual scores.

Figure 1: Correlation of Total BESS Score (SiM vs. Manual)

Figure 2: Vector Sway Length Plot with Indicated Peaks

Figure 2 shows the peaks of the Vector Sway Length plot of the single-leg foam stance that occurred at the same instant manual errors were recorded from the video analysis. The initial peak present at 2-seconds correlated with a minor sway in which the subject abducted the hip $> 30^\circ$, and the two prominent peaks occurring at 5- and 8-seconds correlated with foot taps on the platform. It was found that among all of the output parameters, the peaks and timing of the Vector Sway Length plot correlated well with when a subject came out of position and tapped the platform with their foot.

When the intentional errors of opening the eyes, lifting the hands off the iliac crests, and abducting the hip $> 30^\circ$ were committed in each of the stances, the SiM program usually did not award an error. This was verified by the Vector Sway Length measure. When the intentional errors of stepping or stumbling and falling out of position, lifting the forefoot or heel, or failing to return to the test position in more than 5-s were committed, the SiM program did award an exact number of errors.

DISCUSSION

The findings suggest that the correlation between the total BESS score automatically reported by the SiM program and total score recorded manually via video analysis is sufficient. In general, the SiM program can effectively detect the errors of stepping or stumbling and falling out of position, lifting the forefoot or heel, or failing to return to the test position in more than 5-seconds, regardless of whether or not a trained administrator was conducting the test.

When the errors of opening of the eyes, lifting hands off the iliac crests, and abducting the hip $> 30^\circ$ were committed deliberately by the test subject, an error score was likely to be awarded by the manual BESS method. When using the SiM, the Vector Sway Length measured by the load cell effectively detects the stability or minimal sway that was present during the act and does not usually award what would be considered an intentional error. This demonstrates that the SiM can provide a more accurate and consistent evaluation of postural imbalance.

When analyzing the SiM program scores for the individual stances, a discrepancy was found with the detection of “simultaneous” errors. When two detectable errors are committed within one-second or less from another, the SiM program only awards one error, while the manual scoring protocol would award two discrete errors.⁵ Thus, it is evident that the SiM program defines “simultaneous” as any number of errors that occur within one-second or less from another. According to the BESS manual, “simultaneous” errors are only counted as a single error, but no time interval limit between the two consecutive errors was specified.⁵ The interval between “simultaneous” errors in BESS tests requires further clarification. It is feasible that the Vector Sway Length history analyzed by the SiM can assist medical professionals with improving the definition of “simultaneous” errors.

The peaks of the Vector Sway Length plot were a strong indicator of errors in most trials, but it is unclear how the SiM program specifically assigns those errors (the threshold level is unreported). For the single-leg foam stance, the SiM consistently underpredicted the scores, suggesting the error threshold setting for this case should be improved.

The SiM – 1000 Force Plate device is unique in that it is portable, durable, weather resistant, and produces consistent objective BESS scores. Future studies are required to verify the SiM using a large sample population and research should investigate the correlation between SiM BESS scores, symptoms, and clinical history data following mTBIs.

INTRODUCTION

Poly(vinyl alcohol) (PVA) hydrogels are often used in wound healing due to their biocompatibility, biodegradability, and their hydrophilic nature. Their unique ability to absorb a substantial amount of water in comparison to their dry weight allows for elevated nutrient transport, controlled fluid exchange, and possible pain relief. Graphitic carbon nitride (g-C₃N₄), a photo-responsive biomaterial, can be used as a filler in PVA hydrogels to create a non-toxic electrostatic polymer that promotes an antimicrobial solution at the injury site and accelerates the healing process. The selection of an ideal concentration of g-C₃N₄ will depend on how this filler influences the mechanical properties of the film. A film that is too strong will cause atrophy of surrounding tissues from stress shielding, while a film that is too weak may result in mechanical failure.

The objective of this study is to determine the mechanical effect of adding varying amounts of g-C₃N₄ filler to PVA based films. It is expected that increases in the filler concentration will increase the film's stiffness, strength, and durability.

METHODS

Thin films were fabricated by combining 1.5 g of PVA with 15 mL of H₂SO₄ (0.5 M), which was then stirred at 95 °C until dissolution of the material occurred. Different weight percentages of carbon nitride filler (0, 0.67, 3.33, and 6.67%) were then added to 4.5 mL of dH₂O and sonicated for 15 minutes resulting in four test groups. These percentages were selected because they demonstrate antimicrobial activity. The g-C₃N₄ mixture was added to the PVA solution and stirred. The resulting mixture was then processed and casted forming the final product. Relative crystallinity of the PVA films was quantified by using Fourier

transform infrared spectroscopy to measure the area ratio of two vibrational modes (A_{1140}/A_{1127}).

Uniaxial tensile experiments were performed on the thin films using a mechanical testing system (Fig. 1A). The films were submerged in 0.9% saline solution at room temperature for 24 hours prior to punching the specimens into dog bone shaped coupons (Fig. 1B, left). Coupon dimensions were based on industry standards for polymer films (ISO 527-3),¹ and emery cloth tabs were applied to the coupons using cyanoacrylate to prevent slipping. Tabbed specimens were loaded into an E10000 mechanical test system (Instron, Norwood, MA) with an average grip-to-grip length of 16.2 ± 1.0 mm (Fig 1A).

Figure 1: Mechanical testing setup and analysis. A) Specimens were immersed in a saline bath and pulled in tension (white arrow). B) Each specimen was punched in a left) dog bone shape to right) promote failure in the midsubstance of narrow gauge region (within the white dashed lines).

A preload of 0.05 N was applied, and front and side images were taken with a digital camera. The test chamber was filled with 0.9% saline solution at room temperature (21.8 ± 0.3 °C) and the coupon was allowed to equilibrate in the saline bath for ten minutes before being pulled to failure at 1% strain/s. All analyzed specimens failed in the midsubstance (Fig 1B, right), except for four specimens in the 0% group that failed near a grip. Eight specimens were tested in each group (0, 0.67, 3.33, and 6.67%), for a total of 32 tests.

The experimental data was analyzed with a custom MATLAB script. Image processing methods² were used to calculate specimen width (0.35 ± 0.05 mm) and thickness (0.26 ± 0.04) in the narrow-gauge region. Engineering stress and engineering strain curves were generated for all tests (Fig. 2). Tensile strength and failure strain were calculated at the ultimate tensile stress, energy density to failure, which is a measure of durability, was calculated as the area under the stress-strain curve, and tensile modulus, a normalized measure of stiffness, was calculated as the linear slope of the stress-strain curve. The effect of carbon nitride filler on tensile strength, failure strain, energy density to failure, and tensile modulus was determined using a MANOVA, followed by Bonferroni post-hoc tests for multiple comparisons.

Figure 2: Stress-strain curves of representative specimens from each group with different percentages of carbon nitride filler.

RESULTS

The 0.67% group had an average increase in tensile strength, failure strain, and energy density to failure of 67%, 45%, and 130%, respectively, when compared to the 6.67% group. ($p < 0.05$) (Fig. 3A, 3B, 3C).

Figure 3: Mechanical testing results. A) Increasing C_3N_4 concentration decreased tensile strength, B) decreased failure strain and C) decreased energy density to failure. D) Increasing C_3N_4 concentration had no significant effect on tensile modulus. * = significant difference between C_3N_4 content.

Linear modulus and linear stiffness showed no significant differences between sample groups (Fig. 4D) ($p < 0.05$).

Changes in tensile strength at each concentration level of C_3N_4 were reflected by similar changes in relative crystallinity (Fig. 4).

DISCUSSION

The mechanical properties of thin film PVA hydrogels were influenced by the concentration of C_3N_4 filler. Specimens with increased filler concentrations exceeding 0.67% had reductions in tensile strength, failure strain, and energy density to failure while tensile modulus remained unchanged (Fig. 3). Structural changes in crystallinity were followed by functional changes in mechanical behavior, suggesting that mechanical properties can be controlled by adjusting the ratio of crystalline and amorphous regions during film fabrication (Fig. 4).

Figure 4: Comparison of the relative crystallinity and tensile strength at each weight percent of carbon nitride filler.

The results from this study did not support our hypothesis, as mechanical integrity was decreased when adding filler above a threshold of 0.67%. One explanation is that above a threshold the filler may cause material disorganization and plane slippage^{3,4}. The average tensile strength of the pure PVA films in the present study was 5.4 MPa, which is comparable to human skin tissue (2–15 MPa)⁵, but is considerably less than studies by Wang et al. and Liang et al. that reported tensile strengths of 20 MPa and 50 MPa, respectively^{6,7}. This may be due to variations in PVA fabrication methods and mechanical testing techniques. For instance, unlike previous studies, the present study tested specimens in a saline bath to more closely simulate physiological conditions. Another distinction of our mechanical test protocol was the reporting of failure location (i.e. midsubstance vs. grip). In the present study, all analyzed specimens failed in the midsubstance, except four specimens in the pure PVA group. This indicates that the tensile strength and failure strain of the pure PVA specimens may be slightly underestimated relative to the specimens with carbon nitride filler added to the PVA. In summary, this study developed and applied an accurate test methodology to determine the mechanical influence of graphitic carbon nitride filler on PVA films.

INTRODUCTION

Asthma is a chronic airway disorder that causes physical and conformational changes within the airways of affected subjects [1]. Factors including ventilation heterogeneity, airway remodeling, and mucus plugging make it difficult to deliver therapeutics to obstructed airways, resulting in inadequate dose concentrations in some patients. The prescription of dose concentrations based on generalized data has led inhaled drug therapies to be ineffective for 10-15 percent of patients, leading to uncontrolled asthma [1]. Patient-specific data must be taken into consideration. To better understand respiratory mechanics and the deposition of inhalant therapy particles throughout the airway tissues a unique work flow was developed to generate 3D airway models for computational simulations, reflecting realistic and patient-specific geometry. Following our previously-developed simulation pipeline [2], these models will be employed to investigate airflow and particle disposition patterns and to optimize regional drug targeting.

METHODS

CT scans at two lung states, Total Lung Capacity (TLC) and Functional Residual Capacity (FRC) were collected, and a Hyperpolarized (HP) ³He MRI scan was conducted at FRC + 14% TLC. Models were created in TLC because narrowing of airways in FRC prevented successful selection of all the necessary branches needed for simulation.

Figure 1. Initial geometry obtained in SimVascular (A) and model after airways have been trimmed and extruded in Blender (B) of a patient with severe asthma.

To create patient-specific models, thoracic CT scans at TLC were uploaded as DICOM data into the program Slicer, where

the images were compounded and saved as a VTK file. The VTK was then loaded into an open source software SimVascular [3]. In SimVascular, the airways were selected using the 3D region growing function. A seed was placed in an open airway, and the program grew the region to find nearby airways based on a defined threshold. We aimed to select a minimum of 38 branches. From the HP ³He MRI data, segmental volume defect percentages (SVDPs) were calculated for 19 lung segments in total, 9 in the left lung and 10 in the right lung. For each segment, we needed the segmental feeding airway (SFA) to have two subsegmental daughter branches in order to couple the SVDPs with the SFAs.

Selecting the 38 necessary branches, between 60 and 90 segment selections were created and then unioned together to form the geometry of the initial model (*Figure 1A*). The selection process was particularly challenging in patients with severe asthma due to the extreme narrowing of branches and the presence of mucous plugs and fully collapsed airways. Patient CT data was referenced to confirm the location of plugs and collapses, allowing us to create an accurate model of the patient's remodeled airway tree.

After the initial geometry was established, the 3D model was cleaned and trimmed in the modeling program Blender. Disconnected airways, excess generations, and sharp edges were removed. The remaining branches were trimmed to have flat faces perpendicular to the airway (*Figure 1B*). These faces were then extruded outward to resolve the effect of the SVDP outlet boundary conditions for the simulations.

The simulations required a high-quality mesh, which Blender was incapable of providing as it decreases the mesh quality of the model. Therefore, we choose to use the 3rd party software, OpenFlipper, to improve the surface remesh, generating a higher-quality model with more elements from which a volume mesh could then be extracted.

Next, the models were moved into the program Paraview where they were scaled down to the size of the equivalent models in FRC based on a calculated scalar factor γ (1).

$$\gamma = \sqrt[3]{\frac{V_{FRC}}{V_{TLC}}} \quad (1)$$

where V_{FRC} and V_{TLC} are the volumes of the lung at FRC and TLC, measured from the CT scans. The scaling step allowed us

to use HP ^3He MRI data collected in FRC for simulation analysis.

Back in SimVascular, the model was labeled based on the 19 established segmental feeding airways. Patient models often differed in location and size of branches, as well as in number of bifurcations. Once labeled, the final mesh was created. A total surface and volume mesh resulted in a final model with between 9 and 14 million elements, which could then be used for airflow and particle deposition simulations.

RESULTS

Models were successfully created in TLC for 17 patients. Of the 17 patients, 7 were severe asthmatics, 7 were mild or moderate, and 3 were healthy. Between the severe asthmatics there was visible variety in morphometric features. Differences were present in airway size, ellipticity, bifurcations, and gravitational angles, likely due to the remodeling that occurs as a result of the chronic respiratory illness (results not shown here). There was noticeably less variety in the airway structures of healthy and moderately affected patients. The scaling step of the workflow was evaluated by airflow simulation comparisons. A full model at FRC was created for one severe asthmatic subject. Due to the extreme narrowing of relaxed-state airways, this could only be achieved for one subject.

Figure 2. Simulation results for pressure distribution in airways of models in TLC (A), TLC scaled to FRC (B), and FRC (C) for one patient with severe asthma. Pressure gradient in $\text{cm H}_2\text{O}$.

For this subject, fluid dynamics simulations were performed at TLC, FRC, and TLC scaled to FRC ($\gamma = 0.8$, Figure 2). The boundary conditions for all three gas flow simulations were set based upon the SVDPs calculated from the HP ^3He MRI data. Because the MRI data was most reflective of the FRC state, the FRC model simulations were viewed as the control. When the airway resistances in the unscaled TLC model were compared to the FRC model, the 3D resistance in FRC was more than twice the resistance in TLC (Table 1). However, the scaled model matched the FRC resistance much more closely, suggesting that the simulation on the scaled model is more representative of normal breathing conditions. The greatest improvement was seen for the left upper, right upper, and right middle segments (Fig. 2), while scaling resulted in less change in the left and right lower segments.

In reality, the airways should not scale uniformly from TLC to FRC, particularly with disease presence. Therefore, it will be impossible to model FRC with high accuracy, as demonstrated by the regional differences in pressure gradients (Fig. 2). Considering this limitation, the scaling step of our workflow is justified because we achieve values closer to those found for the

FRC simulations, specifically the measures that are most important in the clinic (e.g. airway resistance and dosimetry).

Table 1. Airway resistance in airflow simulation for models in TLC, FRC, and scaled to FRC. Models were generated from data of one severe asthmatic with SVDP 17.17 ± 15.34

Model	3D Resistance ($\text{cm H}_2\text{O}\cdot\text{s/ml}$)
TLC	1.90 E-03
FRC	4.60E-03
SCALED TO FRC	4.40E-03

DISCUSSION

Asthma is typically controlled by direct delivery of therapeutics to the lung via inhalation. Due to airway remodeling, many patients with severe asthma may not respond to prescribed dosages. With the ultimate goals of predicting lung mechanics and optimizing drug delivery and dosage, a novel workflow was developed to generate airway models with patient-specific geometry which could then be utilized for airflow and particle deposition simulations. The progress in accurate modeling is considered the first step towards our goal of understanding how asthma affects patients in unique ways.

The number and quality of airways that could be achieved for each model were limited by the resolution of the initial CT scans. Many of the outer airways were only a few pixels wide and could not be detected by the semi-automated 3D region-growing functions. As MR imaging and CT resolutions advance, it may become possible to measure defects and produce models that extend beyond the segmental areas, better capturing the realistic patient-specific geometry of the airways. We are also interested in including extra-thoracic airways in future studies, as that would allow us to capture the laryngeal jet and associated turbulence in the simulations.

By creating a database of realistic 3D airway models from individuals of different ages, genders, and asthma severities, we will have the means to test deviation from expected respiratory variations in the future. A database of models and simulation results would provide insight into pathological flow characteristics and airway mechanics in asthmatics, which could improve disease classification and lead to more successful treatment options for treatment-resistant asthmatics. So far, we have successfully created 17 models from patient CT scans in TLC and performed simulations using HP ^3He MRI data. We aim to create a database of 60 models.

WATER SPORT HEAD INJURIES; ABILITY OF HELMETS TO REDUCE HEAD IMPACT ACCELERATIONS

Brock G. Duma, Mark T. Begonia, Abigail M. Tyson, Casey L. Charron, Stefan M. Duma

Institute for Critical Technology and Applied Science
Virginia Tech
Blacksburg, Virginia, USA

INTRODUCTION

As watersport popularity grows, the number of head injuries, including concussions, is increasing.[1] Each year there are over 7,000 tubing related injuries treated in a hospital, of those nearly 2,000 are head injuries .[2] For participants under 20 years old, the leading head injury mechanism is contact with another person (Figure 1). Head injury risk could potentially be lowered, if the participants utilized a helmet. The purpose of this study was to evaluate the biomechanical performance of watersport helmets and to investigate the potential of watersport helmets to reduce head injury risk in tubing.

Figure 1: Watersport activities with multiple people can result in head injuries from contact with participants.

METHODS

Ten helmets were selected as a representative subset of all available watersport helmets, and two samples of each helmet were tested. A total of 28 tests were performed with 24

helmeted, and four controls at 2 m/s and 4 m/s with impacts to the side and rear for each speed (Figure 2). The helmets are from wakeboarding, kayaking, water skiing, and women's lacrosse. A custom impactor was used to test the helmets under head-to-head conditions which are known to be associated with the highest risk of concussion in tubing. The impactor consists of two NOCSAE head and Hybrid III neck configurations on 16 kg sliding masses to represent the head, neck and torso of 50th percentile participants. The struck head was instrumented with a triaxial angular rate sensor and three linear accelerometers. For each testing configuration, both rotational and linear head accelerations were recorded.

Figure 2: Side view of the testing configuration for the 2 m/s rear impact with the Pro-Tec helmet as the subject matter.

RESULTS

All of the tests with helmets resulted in lower head accelerations compared to the control tests that simulated bare head impacts. For example, in the 2 m/s side impact condition the control test resulted in 71g and 5,595 rad/sec² while the ten helmeted tests resulted in 15 +/- 3 g (range 11 to 22), and 1221 +/- 297 rad/sec² (range 780 to 1,864). In the 2 m/s rear impact condition, the control test resulted in 66g and 4,395 rad/sec² while the ten helmeted tests resulted in 14 +/- 4 g (range 8 to 18.9), and 1,090 +/- 204 rad/sec² (range 624 to 1,1430).

In the 4 m/s side impact condition, the control test resulted in 180g and 12,746 rad/sec² while the ten helmeted tests resulted in 67 +/- 23 g (range 31 to 109), and 5641 +/- 1,759 rad/sec² (range 2,494 to 7,912) (Figure 2 and Figure 3). In the 4 m/s rear impact condition, the control test resulted in 169g and 10,896 rad/sec² while the ten helmeted tests resulted in 42 +/- 16 g (range 23.2 to 79), and 3,158 +/- 839 rad/sec² (range 1,605 to 4,752).

Figure 2: Peak resultant linear acceleration values (g) for the top speed of 4 m/s in the side impact direction.

Figure 3: Peak resultant rotational acceleration values (rad/s²) for the top speed of 4 m/s in the side impact direction.

DISCUSSION

The women's lacrosse helmets had the lowest linear and rotational accelerations in every configuration tested (Figure 4).

In the 4 m/s side impact tests, their accelerations were more than 50% less than the average for the watersport helmets, and less than 20% of the control impact accelerations.

Figure 4: Hummingbird (left) and Cascade (right) women's lacrosse helmets were the best performing helmets.

All watersports helmets reduced both linear and rotational accelerations for all test configurations. In the 4 m/s control tests, very high accelerations were observed and would most likely result in head injury as they correspond to a 99% risk of concussion [3]. Although the 2 m/s helmet tests resulted in very low acceleration values, the control values for the unhelmeted tests were high and underscore the importance of both a low speed and higher speed test configuration. But in particular, the Hummingbird utilized a unique soft shell design which helped it perform the best in every configuration that we tested, except the 4 m/s rear impact in which the Cascade performed the best. The Cascade helmet had an unusually large rear pad, which allowed for the lower accelerations. Because of the results gained from the Hummingbird tests, this type of soft shell helmet might be recommended for use in watersport activities in particular tubing activities with multiple participants on a tube.

Interestingly, the price of a helmet was not correlated to performance, with the most expensive helmet resulting in the highest accelerations for the helmeted tests. This trend has been observed in other helmeted sports as well. Data from these tests can help consumers make informed decisions.

A limitation of this study is that not all water sport helmets were tested. A sample of eight types of water sport helmets were tested based on the most popular purchased helmets from Amazon. It is possible that other helmets would test differently, but wearing helmets while performing watersports will dramatically reduce head impact accelerations.

ACKNOWLEDGEMENTS

The authors thank our good friend Brett Stoner and his unfortunate water sport head injury for motivating this study.

THE INFLUENCE OF RADIOGRAPHIC PROJECTION ANGLE ON VISUALIZATION OF THE SUBTALAR JOINT

INTRODUCTION

A thorough understanding of subtalar joint morphology is needed to diagnose hindfoot pathology, to develop pre-operative plans for reconstructive surgeries, and to evaluate the success of treatment [1,2]. Recently-published data suggest that the posterior facet of the subtalar joint has a major impact on the evolution of hindfoot disorders, including planovalgus deformities and ankle osteoarthritis [3]. Thus, there is a clinical need to evaluate the appearance of the posterior facet and the orientation of the subtalar joint relative to other anatomic landmarks of the hindfoot. Recently, the general appearance of the posterior facet as well as the subtalar inclination angle (SIA) and calcaneal slope (CS) were assessed on weightbearing CT scans [3]. The SIA and CS measurements were measured in three coronal slices of weightbearing CT scans within the anterior, middle, or posterior regions of the posterior facet [4,5]. Although weightbearing CT scans have become common for assessment of foot and ankle disorders in recent years, conventional radiographs are still the standard for imaging the hindfoot [6]. A formal consensus regarding normative values for these measurements on conventional radiographs has not yet been reached, which has slowed progress towards standardizing diagnoses based on evaluation of plain film radiographs. Furthermore, current radiographic measurement methods are shown to be sensitive to intra- and inter-observer agreement. The subtalar joint is arguably more complex in shape than the tibio-talar joint, and thus, even subtle changes in the position of the foot and ankle and X-ray equipment are likely to alter the general appearance of this structure as well as affect measurements of the SIA and CS. However, studies have not assessed how foot position and orientation of the X-ray equipment affect measurements of the subtalar joint in a systematic manner. The purpose of this study was to determine how changes in the radiographic equipment beam projection angle from horizontal (tilt) and axial rotation of the foot influenced subtalar joint measurements. In addition, the subtalar joint line was projected on three-dimensional (3-D) models of the calcaneus to investigate whether the visible area of the posterior facet changes across different foot positions. We hypothesized that the position of the foot and X-ray equipment impacts the assessment of the subtalar joint.

METHODS

Participants

Informed consent was provided by a total of 27 healthy volunteers. Inclusion criteria included individuals 40 to 70 years of age that did not have any previous medical history of foot or ankle injury and/or surgery.

Computed Tomography Collection and Image Processing

Each participant underwent a weight bearing CT scan (Planmed Verity, Planmed Oy, Helsinki, Finland; 0.2 mm slice thickness, 1 mm

slice interval) of their foot and ankle with their calcaneus aligned in reference to the second metatarsal for a parallel alignment relative to the scanner's anterior-posterior axis. The CT images were segmented to generate 3-D surfaces representing the tibia, fibula, talus and calcaneus bones (Amira, v6.0.1, Visage Imaging, San Diego, CA, USA). Surfaces were smoothed and decimated to reduce segmentation artifact. Next, digitally reconstructed radiographs (DRRs) were generated of each bone surface by projecting the CT image data to a plane representing the desired view. A total of 25 DRRs were created to represent views with different positions of the foot and radiographic projection angle. Here, we began with an antero-posterior (AP) view, defined by no rotation of the foot and no simulated downward tilt of the X-ray beam. Iterative combinations of internal rotation of the foot and simulated downward tilt of the X-ray beam ranging from 0 to 40° (10-degree increments) yielded 25 possible permutations, resulting in 675 DRRs for the cohort.

Radiographic Measurements of the Subtalar Joint

The SIA was measured on each DRR and was defined as the angle between the surface of the talus and the posterior facet of the calcaneus [1]. The CS was also calculated and was defined as the angle between a line from the medial to the lateral boarder of the posterior facet to a vertical line [5]. A custom MATLAB script (Version R2017b, MathWorks, Natick, MA, USA) loaded DRR views individually and guided the reader through measurements of SIA and CS, automatically calculating angles based on the user-defined line defining the joint lines. The SIA and CS were measured at two different times, separated by 2 weeks, to assess intra-observer agreement. Measurements obtained by an orthopaedic surgeon were compared to those made by a scientist to establish an estimate for inter-observer reliability.

Projection of the Posterior Facet Relative to the Joint Line

The joint line visualized on the DRR views was projected onto the posterior facet and was evaluated by defining virtual anatomical landmarks around the perimeter of the articular surface (Fig.1). First, six anatomic landmarks of the posterior facet of the subtalar joint (calcaneal side) were defined in the CT image data as virtual beads and included the: (1) antero-medial point, (2) medial point, (3) posterior point, (4) superior point, (5) lateral point, and the (6) antero-lateral point. The positions of these virtual beads were defined mathematically using the second principle of curvature to isolate the perimeter of the posterior facet (PostView, v2.1.0, FEBio, Salt Lake City, UT). Once the bead locations were established, their placement was used to quantify direction and magnitude of anatomical bead locations relative to the visualized joint line in each of the 25 DRR views (Fig 1A). A rotation sequence for the appropriate internal rotation and simulated downward

tilt of the X-ray equipment was applied to each 3-D calcaneus model containing the defined anatomical beads in MATLAB (Fig 1C). The custom MATLAB script used the points to perform a curve fit of the joint line in that projection view and sequentially calculated the six anatomical beads' direction and magnitude from the joint line within the calcaneal articular surface based on nodes within the 3-D surface model.

Figure 1: (A) Six virtual landmark beads and projected joint line. (B) DRR projection (30° of ankle internal rotation and 40° of simulated downward tilt of the X-ray beam) with six virtual beads. (C) MATLAB figure of calcaneus rotated into the 30/40-degree position; the black joint line was defined as a curve fit with the red stars representing six virtual bead locations.

Statistical Analysis

Inter- and intra-observer agreement was assessed using the two-way random intraclass correlation coefficient (ICC) and presented with a 95% confidence interval (95% CI) for SIA and CS measurements. Agreement was considered very good for an ICC > 0.80; good with an ICC = 0.61 – 0.80; moderate with an ICC = 0.41 – 0.60; fair with an ICC = 0.21 – 0.4; and poor with an ICC < 0.20 [7].

RESULTS

Radiographic Measurements of the Subtalar Joint

Across the 25 DRR viewing perspectives, SIA measurements ranged on average from 3.8 to 20.9° (Table 1) and CS measurements ranged on average from 54.8 to 105.8°. Simulated downward tilt of the X-ray beam decreased the mean SIA. The mean SIA and CS also changed when the foot was internally rotated when compared to a constant simulated beam tilt. The lowest ICC values were evident at the AP view of the foot without any downward tilt or rotation (SIA inter-observer agreement 0.368, CS inter-observer agreement 0.184). For the other views, the reliability ranged from 0.416 to 0.967 (SIA) and from 0.586 to 0.996 (CS).

Table 1: SIA Measurement of the Subtalar Joint Posterior Facet

SIA		Internal Rotation				
		0°	10°	20°	30°	40°
		Mean (SD)	Mean (SD)	Mean (SD)	Mean (SD)	Mean (SD)
Tilt	0°	12.0 (6.1)	14.0 (6.3)	18.2 (5.6)	20.5 (5.5)	20.9 (5.3)
	10°	9.9 (5.9)	12.4 (6.0)	14.4 (5.1)	15.3 (4.7)	15.2 (4.9)
	20°	8.7 (5.3)	9.0 (5.8)	9.2 (5.1)	9.5 (4.8)	9.9 (5.3)
	30°	4.4 (2.7)	4.5 (3.3)	4.4 (3.1)	5.0 (3.4)	5.5 (4.7)
	40°	3.8 (3.4)	3.6 (2.8)	3.8 (3.1)	4.4 (3.5)	4.3 (3.3)

Projection of the Posterior Facet Relative to the Joint Line

The visible area where the joint line was projected onto the posterior facet changed between the different viewing perspectives (Fig 2). While on an AP view of the foot and ankle the posterior area of the posterior facet was visible, a slightly more anterior area was visible when the foot was internally rotated. Simulated downward tilt of the X-

ray beam also changed the visible area of the posterior facet from a posterior (without downward tilt) to more anterior (40° downward tilt).

Figure 2: Projection of the posterior facet on 3D models of the calcaneus. (A) Internal rotation (without downward tilt of the X-ray beam) demonstrates a curved joint line projected onto the posterior facet, the visualized joint line begins posteriorly and moves anteriorly. (B) Simulated downward tilt (at 40° internal rotation) of the X-ray beam shows a more anterior aspect of the posterior facet of the subtalar joint.

DISCUSSION

This study assessed the influence of various DRR projection views with different internal rotations of the foot and simulated downward tilt of X-ray equipment on the visualization of the subtalar joint. The major findings were a) measurements describing the alignment of the subtalar joint (SIA and CS) changed between different viewing perspectives, and b) changes in DRR projection visualized a joint line on different aspects of the posterior facet articulating surface. Understanding the radiographic appearance of the posterior facet in healthy individuals on DRRs is important to identify pathologic changes among symptomatic, diseased ankles. Studies using weightbearing CT scans have shown that the configuration of the posterior facet may have an impact on the evolution of ankle osteoarthritis [2,5]. To our knowledge, DRRs generated from weightbearing CT scans have not been assessed for the purpose of evaluating how changes in the alignment of the X-ray equipment could affect visualization of the subtalar joint. Use of DRRs is advantageous because it allows for computer-controlled projections, thus preventing errors that would otherwise be present if standard X-ray equipment was used for this study.

Based on our results, we recommend 20° of internal rotation of the foot to assess the posterior aspect of the posterior facet, while a combined 20° internal rotation of the foot and 40° downward tilt of the X-ray beam is likely best for assessing the anterior aspect of the posterior facet. With a better understanding of the projection of the subtalar joint, clinicians will be better-equipped to make meaningful interpretations of the morphology of hindfoot on conventional radiographs, thus providing reliable diagnoses for their patients.

INTRODUCTION

For over two decades, computational models of human body—such as the Toyota THUMS model— have been used in automobile safety [1]. These models rely on accurate material properties for each tissue. However, the compressive behavior of skeletal muscle is not fully understood, particularly regarding the differences in muscle response to *in vivo* loading conditions [2]. It is likely that *in vivo* muscle experiences a variation between confined and unconfined volumetric boundary conditions, but nearly all previous studies investigating passively compressed tissue have focused on muscle in unconfined compression (UC) [2, 3]. One study has investigated muscle under anisotropic semi-confined compression [4], however none have studied muscle in fully confined compression (CC). Thus, we have investigated the effects of volumetric boundary conditions (UC and CC) on the stress relaxation of skeletal muscle. Moreover, a finite element model simultaneously characterizing muscle behavior in both boundary conditions is explored.

METHODS

Using an impermeable steel well, transverse oriented plugs ($\phi = 6.4\text{mm}$) of porcine tibialis anterior (TA) from six animals were subject to CC stress relaxation tests. Two testing configurations were employed with $n=8$ for each: fast-compression (strain rate = $15\%/s$, $\epsilon = 15\%$) and slow-compression (strain rate = $1.5\%/s$, $\epsilon = 1.5\%$). Similarly, transverse oriented cubes (thickness = $7.9 \pm 0.5\text{ mm}$) of TA from six animals were exposed to stress relaxation tests under UC in two testing configurations with $n=8$ for each: fast-compression (strain rate = $40\%/s$, $\epsilon = 40\%$) and slow-compression (strain rate = $5\%/s$, $\epsilon = 5\%$). All samples relaxed for 400s after compression. Data was collected by a 10N Instron load cell at 100 Hz. Testing was completed within eight hours of sacrifice to reduce the effects of rigor mortis. Muscle samples

were hydrated by physiological buffer solution. First Piola-Kirchoff stress and nominal strain were determined through post-hoc analysis of initial specimen dimensions.

Three-dimensional finite element models of UC and CC geometries were developed in Abaqus (Dassault Systèmes). The UC geometry was reduced to a quarter of the sample by symmetry with 175 first-order 8-node hexahedral elements (type C3D8RH). This model was compressed by rigid platen and reaction force on platen was divided by initial area to acquire first Piola-Kirchhoff stress. The CC geometry was reduced to a two-dimensional axisymmetric model of cylinder with 96 first-order 4-node quadrilateral elements (type CAX4RH). Displacement was prescribed for top surface and as no lateral expansion occurred, first Piola-Kirchhoff stress was determined directly from model output. Displacements in both fast compression models simulated the slight experimental overshoot applied by the Instron.

A quasi-linear hyper-viscoelastic material formulation was chosen to model the behavior of skeletal muscle subject to both CC and UC. The model utilized third degree Yeoh form [5] of a polynomial hyperelastic strain energy density function ($\Psi(\mathbf{C})$) (Equation 1).

$$\Psi(\mathbf{C}) = \sum_{i=1}^3 C_{i0} (\bar{I}_1 - 3)^i + \sum_{i=1}^3 \frac{1}{D_i} (J - 1)^{2i} \quad (1)$$

Here C_{i0} and D_i are material parameters, \bar{I}_1 is defined as $\bar{I}_1 = \bar{\lambda}_1 + \bar{\lambda}_2 + \bar{\lambda}_3$ where $\bar{\lambda}_i = J^{-\frac{1}{3}} \lambda_i$ (λ_i are the principle stretches), and J is the volume ratio. A Prony series viscoelastic model (Equation 2) was applied to the shear (\bar{I}_1) and volumetric (J) responses in Equation 1.

$$K(\tau) = K_{\infty} + \sum_{i=1}^4 K_i e^{-\tau/\tau_i^K} \quad G(\tau) = G_{\infty} + \sum_{i=1}^4 G_i e^{-\frac{\tau}{\tau_i^G}} \quad (2)$$

Here $K(\tau)$ is the time dependent bulk modulus and $G(\tau)$ is the time dependent shear modulus. K_∞ and G_∞ model long-term bulk and shear modulus respectively. τ_1^K and τ_1^G are time constants ($\tau_1^G = \tau_1^K = 0.05s$, $\tau_2^G = \tau_2^K = 1s$, $\tau_3^G = \tau_3^K = 20s$, $\tau_4^G = \tau_4^K = 400s$). A power law model ($y = Ax^{-B}$) was also fit to all relaxation data to characterize and compare relaxation behavior between testing groups.

The finite element model consisted of fourteen parameters (6 hyperelastic, 8 viscoelastic). Parameter identification was achieved by a nonlinear least-squares deterministic optimization (*lsqnonlin* in MATLAB). The error function (Equation 3) was minimized to simultaneously fit experimental UC and CC fast-compression data (t_{peak} is time of peak experimental stress). UC and CC slow-compression data was then predicted by this optimized model.

$$error = \sum_{t=0}^{t_{peak}} t * (\sigma_{model} - \sigma_{exp}) + \sum_{t=t_{peak}}^{401} \frac{(\sigma_{model} - \sigma_{exp})}{t} \quad (3)$$

RESULTS

Figure 1: Average stress relaxation curves for (A) CC fast and slow compression (B) UC fast and slow compression with standard deviation

Figure 1 shows that despite lower strain levels, muscle was stiffer in CC than in UC (p -value<0.001). In both UC and CC, muscle stiffness increased with strain rate ($p=0.02$ for CC, $p=0.03$ for UC), which is consistent with previous studies [2]. Fitting the power law model ($R^2=0.96$) shows that relaxation behavior differed with boundary condition at both strain rates ($p<0.001$ for slow compression, $p=0.042$ for fast compression). Relaxation was independent of strain rate in UC ($p=0.47$), whereas it depended on strain rate in CC ($p=0.030$) (Table 1). The FEA model provided excellent simultaneous fits to CC and UC fast-compression data (Figure 2 A-B) (Table 2). Optimized parameters (Table 3) were used to calculate initial shear modulus (0.044 kPa) and initial bulk modulus (42.6 kPa). Approximately two thirds of muscle instantaneous shear and bulk moduli relaxed with the first time constant (0.05s) for both CC and UC (Table 3). The model showed acceptable validation for UC and CC slow-compression (Figure 2C-D, NRMSE UC 10.65%, CC NRMSE 9.02%).

Table 1: Power law B-parameter values \pm SD for different groups

	CC Fast	CC Slow	UC Fast	UC Slow
B value	0.23 ± 0.06	0.15 ± 0.07	0.32 ± 0.08	0.35 ± 0.04

Table 2: Error values for model-experiment comparisons

Error Type	UC	CC
Peak error	0.05%	4.72%
NRMSE	1.71%	0.85%

Table 3: Optimized finite element model parameters

Parameter Type	Parameter	Optimized value
Hyperelastic (MPa)	C ₁₀ , C ₂₀ , C ₃₀	2.22e-5, 1.32e-4, 3.16e-5
Hyperelastic (MPa ⁻¹)	D ₁₀ , D ₂₀ , D ₃₀	46.99, 1.29, 10e10
Shear Coefficients	G ₁ , G ₂ , G ₃ , G ₄	0.68, 0.13, 0.097, 0.077
Bulk Coefficients	K ₁ , K ₂ , K ₃ , K ₄	0.62, 0.091, 0.093, 0.17

Figure 2: Average fast-compression experimental data (solid black) and optimized model (dashed red) with SD for (A) CC and (B) UC. Average slow-compression experimental data (solid black) and model predictions (dashed red) with SD for (C) CC and (D) UC.

DISCUSSION

This study presents new data of passively compressed muscle under different volumetric boundary conditions (UC versus CC) along with a quasi-linear hyper-viscoelastic finite element analysis. While a previous viscoelastic approach successfully modelled stress relaxation of muscle in UC [3], this study simultaneously fit stress relaxation data of muscle in CC and UC, thus providing greater accuracy for the volumetric behavior of skeletal muscle.

Since muscle's bulk modulus is three orders of magnitude larger than its shear modulus, muscle shows great resistance to volumetric deformations. This supports previous findings of near incompressibility of muscle [2, 4]. The validation for CC slow compression suggests that there may be a mechanism in addition to viscoelasticity that dictates muscle stiffness and stress relaxation under volumetric deformations. The impermeable walls of the CC testing well may trap intramuscular fluid within the muscle. This boundary condition—along with previous studies showing non-negligible permeability of skeletal muscle [6]—suggests that pressurization of incompressible fluid may contribute to the stiffness of muscle in CC. Such a model may induce non-linearity in the relaxation behavior of muscle in compression.

It is not yet entirely clear how differences in strain level and rate attribute to data presented in Figure 1. Studies at higher strain levels are required, nevertheless this study provides a robust model that effectively characterizes compressive behavior of skeletal muscles in different volumetric boundary conditions.

INTRODUCTION

Deep space flight or cancer treatment can expose bone tissue to a high dose of ionizing radiation, which has been linked to increased fracture risk [1], [2]. However, the mechanisms leading to increased risk are not well understood. For example, experiments on mice exposed to ionizing radiation *in vivo* have shown altered bone micro-architecture in the mouse vertebral body without altered strength [3]. Since mechanical behavior is expected to correlate with micro-architecture, such discordance suggests that ionizing radiation *in vivo* may uniquely alter the vertebral body micro-mechanics [4]. To gain insight into this issue, we investigated how local deformation, load transfer mechanisms, and initial failure location in the mouse vertebra are altered following *in vivo* exposure to a whole-body clinically-relevant dose (5Gy) of ionizing radiation. In addition to providing insight into *in vivo* radiation effects, this study can illustrate the structure-function relationship within the vertebral body, in particular the role of changes in micro-architecture on whole-vertebra mechanical behavior.

METHODS

Twenty-seven 17-week-old male mice (C57BL/6J) were randomly divided into two groups. One group (N=14) was not exposed to any radiation (control) and the other (N=13) was irradiated by acute 5Gy γ -radiation (¹³⁷Cs source). Both groups were sacrificed after 11 days. The L4 and L5 vertebrae were excised from all mice and the vertebral bodies were isolated. The L4 vertebral bodies were then subjected to a uniaxial compressive monotonic mechanical test to measure whole-vertebral body stiffness and ultimate force (strength). The L5 vertebral bodies were scanned with micro-computed tomography (μ CT) at an isotropic resolution of 10 μ m after which trabecular and cortical tissue were manually segmented for each μ CT slice. Those images were then analyzed for various micro-architectural parameters. (L5 vertebral bodies were also subjected to fatigue mechanical test, data not reported.)

The μ CT images were also analyzed by 3D linearly elastic finite element analysis. Each voxel-based finite element model (10 μ m element size, 8-noded cubic elements; bone tissue Young's modulus 10 GPa, Poisson's ratio 0.3 [5]) was subjected to a 0.5% apparent compressive strain (FEAP Ver8.3). Three major outcomes were defined: 1) the 90th percentile of the maximum and minimum principal strains in the trabecular and cortical compartments as well as the whole vertebral body; 2) the trabecular load fraction, defined as the ratio of axial force in the trabecular bone to the whole vertebral body, calculated at each transverse slice; and 3) the ratios of high-risk cortical bone to total cortical bone, of high-risk trabecular bone to total trabecular bone, and the high-risk cortical bone to high-risk trabecular bone. The high-risk tissue was quantified by first normalizing the maximum and minimal principal stresses of each element by its tensile (61 MPa) or compressive (150 MPa) yield stress, respectively, then taking the higher absolute value. Elements within the top 10% of values were classified as "high-risk", and were further classified either in tension or compression [5].

For statistical analysis, we compared results between the control and irradiated groups using unpaired t-tests (JMP Pro Ver14.0); significance was assumed at $p < 0.05$.

RESULTS

For uniaxial compression testing (on L4), there was no significant effect of ionizing radiation on either vertebral strength ($p = 0.55$, Fig.1a) or stiffness ($p = 0.97$, Fig.1b).

By contrast, there was a significant effect of ionizing radiation both on measurements of trabecular micro-architecture ($p < 0.01$) and on the 90th percentile values of the principal strains ($p < 0.01$). Following radiation, the trabecular bone volume fraction and (Fig.1c) the connectivity density decreased (Fig.1d), and the trabecular separation (Fig.1e), thickness, and SMI (not shown) increased. These difference in

Figure 1: (a-b) Whole-bone mechanical testing and (c-f)

Mean \pm 95% CI (confidence interval) (*: $p < 0.01$)

trabecular micro-architecture indicated a transformation from a well-connected plate-like structure towards a sparser rod-like structure. The 90th percentile of principal strains in the trabecular bone (Fig.3a and 3b) were lower for the irradiation group, implying that the trabecular tissue was less likely to fail after exposure to radiation. On the other hand, cortical thickness (Fig.1f) and the 90th percentile of principal strains in the cortical compartment were not altered by radiation ($p > 0.5$).

With respect to the trabecular load fraction, at all transverse sections of the vertebral body the trabecular load fraction was lower following irradiation ($p < 0.05$) (Fig.2). While the overall load sharing behaviors before and after radiation exposure were similar, the load fraction was significantly lower at each transverse section following radiation exposure.

Consistent with these trends, the high-risk cortical fraction (ratio of high-risk cortical bone to total cortical bone) was significantly higher following irradiation ($p < 0.01$) (Fig.3c), but the high-risk trabecular fraction was significantly lower following irradiation ($p < 0.01$) (Fig.3d). Since the high-risk tissue was defined with consideration of asymmetric

Figure 2: Load fraction of trabecular bone along caudal

Figure 3: (a-b) Principal strains in the trabecular bone and

Mean \pm 95% CI (*: $p < 0.01$)

failure criteria, the location of high-risk tissue should indicate where the initial failure would occur when the whole vertebral body was overloaded. Prior to irradiation, around 6% of trabecular bone and 16% of cortical bone were subject to initial failure, and these values were found to be 4% for trabecular bone and 20% for cortical bone after irradiation. Therefore, it can be inferred that the radiation shifted the initial failure region from the trabecular bone to the cortical shell.

DISCUSSION

These results indicate that clinically-relevant doses of ionizing radiation altered the morphology of the trabecular bone in the mouse vertebral body — and the micro-mechanics throughout the vertebral body — without altering overall stiffness or strength. These morphological changes are likely attributed to effects of radiation on osteoclast and osteoblast activity, which can alter the trabecular micro-architecture [2]. Given changes in the micro-architecture of trabecular bone, the vertebral body reduced the maximum and minimum principal strains in the trabecular bone and shifted more load and initial failure risk to the cortex. Such changes in the micro-mechanics after radiation treatment effectively preserved the whole-bone level stiffness and strength. Thus, we have demonstrated how the mouse vertebral body can adapt its micro-architecture for biomechanical preservation.

INTRODUCTION

Retrospective analysis of computed tomography (CT) scans via CT-based patient-specific finite element analysis (FEA) is proposed for increased accuracy of fracture risk prediction. Patient CT scans are frequently limited to the proximal femur. However, full femur anatomy more accurately defines the patient-specific femoral coordinate system (PSFCS) than proximal femur anatomy [1]. Statistical shape modelling (SSM), based on cadaveric databases, can be used to estimate full femur anatomy [1]; and therefore, PSFCS can be defined for CT scans of the proximal femur. Using this approach has been shown to result in increased predictive accuracy [1]; however, this technique is not recommended when surface errors exceed 1.5 mm in the proximal region [2]. Sex differences in femoral angle are well documented [3] and may be relevant for increasing the accuracy of PSFCS estimates. The aim of this study was to quantify the accuracy of the estimated PSFCS for a previously untested cadaveric dataset by sex.

METHODS

Materials and CT Scanning: This study was conducted on 24 cadaveric femurs from 7 women (aged 43-61) and 5 men (aged 55-63). CT scans were captured on a GE Discovery CT750 HD CT scanner at the Wisconsin Institute for Medical Research. Scan settings were 120 kVp, 1.25 mm slice thickness, 0.625 mm slice spacing, variable current, and monochrome2.

Segmentation and Statistical Shape Modeling: Femurs were segmented using Mimics v19.0 (Materialise, Leuven, Belgium). Two geometries were created: a full femur model (Fig. 1a), and a proximal 1/3 femur model (Fig. 1b). SSM was conducted using MAPClient software [4]. An iterative closest point algorithm aligned the center of the segmented mesh of the proximal 1/3 model (yellow) with an averaged left or right SSM femur mesh (red) (Fig. 1c). The averaged

proximal femur was replaced with the full femur (red) from the cadaveric database (Fig. 1d) and a full femur shape (yellow) was estimated via SSM (Fig. 1e). The actual full femur (grey) and the estimated full femur (yellow) can be visually compared (Fig. 1f).

Figure 1: Full femur estimate from the proximal 1/3 femur for PSFCS definition: (a) Specimen full femur; (b) specimen proximal 1/3 femur; (c) aligned specimen proximal femur (yellow) and statistical shape cloud from MapClient cadaveric database (red); (d) specimen proximal femur (green) and averaged full femur (red); (e) specimen full femur estimate (yellow) with specimen proximal femur (green) and averaged full femur (red); (f) specimen full femur (grey) and full femur estimate (yellow); (g) center of femoral head; (h) posterior condyle surfaces; (i) knee center estimate; (j) lateral coordinate; (k) PSFCS.

Coordinate System Definition: The PSFCS was defined for actual and predicted full femurs using the same process in 3-Matic v13 (Materialise, Leuven, Belgium) [1]. The origin was defined at the center of the femoral head, using the analytical fit tool with a sphere (Fig. 1g). The coordinates of the most posterior surface of the two condyles were visually identified (Fig. 1h). The knee center was estimated as their midpoint (Fig. 1i). The x-axis was defined along the unit vector through the origin and the knee center estimate. The y-axis was defined as the laterally directed (Fig. 1j) unit vector, orthogonal to the x-axis and coplanar with the origin, the knee center, and the posterior condyles. The z-axis was defined by the cross product of the x- and y-axes (Fig. 1k).

Vectorial Analysis and Statistics: Vectorial analyses of the PSFCS for the actual and the predicted femurs were conducted in MATLAB 2018b (Mathworks, Natick, MA, USA). The distance vector between the femoral head center and the knee center estimate was calculated for the PSFCS of each femur. The angle, K, between the two resulting distance vectors (x-axes) was determined for each patient (Fig. 3). Additional distance vectors (y-axes) between the femoral head center and the lateral coordinate were determined and the angle, L, between them was calculated (Fig. 3). The Euler angles were calculated between the actual femur predicted femur coordinate systems. A Student's one-sided t-test was conducted on the angles.

RESULTS

The distance between the center of the femoral head and the knee center estimate was under-predicted and poorly correlated with the actual distance (men: slope 0.16, $R^2 = 0.017$; and, women: slope 0.43, $R^2 = 0.020$, Fig. 2). Angle K was less than 10° for all femurs, while angle L ranged from 7° to 60° for all femurs (Fig. 3). These and Euler angles are summarized in Table 1. Angle L ($p = 0.051$) and Euler angle Θ_x ($p = 0.028$) for women were larger than for men.

Figure 2: Correlation between the predicted versus the actual femur length from the center of the femoral head to the center of the knee. Male femurs are blue plus signs and female femurs are red circles, dashed line.

Table 1: Mean and standard deviation for K, L, and Euler angles

Group	Men	Women	Combined
Angle K	$4.48^\circ \pm 2.47^\circ$	$4.19^\circ \pm 2.16^\circ$	$4.16^\circ \pm 2.24^\circ$
Angle L	$12.0^\circ \pm 8.89^\circ$	$20.2^\circ \pm 14.6^\circ$	$16.3^\circ \pm 12.6^\circ$
Θ_x	$0.5^\circ \pm 9.2^\circ$	$8.7^\circ \pm 16.3^\circ$	$9.4^\circ \pm 18.4^\circ$
Θ_y	$0.3^\circ \pm 2.2^\circ$	$0.8^\circ \pm 2.0^\circ$	$1.2^\circ \pm 3.0^\circ$
Θ_z	$-0.3^\circ \pm 2.3^\circ$	$0.2^\circ \pm 2.8^\circ$	$-0.2^\circ \pm 3.6^\circ$

Figure 3: Angle K, between the actual and predicted femur length vectors for all specimens (x-axes). L – M and L – W, reflect the difference between the actual and predicted y-axis for men and women, respectively. Euler angle Θ_x (X – M and X – W). Male femurs are blue plus signs and female femurs are red circles.

DISCUSSION

This study quantified the accuracy of the estimated PSFCS for this dataset. The combined Euler angles for these femurs are comparable with prior studies (Table 2); however, this dataset does display more variation in Θ_x . The largest errors were found in the y-axis estimates (angle L), especially when differentiating by sex (Table 1). The errors in y-axis estimates and the larger Θ_x for women demonstrate a need for further investigation on additional patients.

Table 2: Euler Angle Comparison between Studies

Euler Angle	Qasim et al. [1] n = 95, all female	Zhang et al. [2] n = 13	Current n = 24
Θ_x	$12^\circ \pm 7^\circ$	$7.7^\circ \pm 4.0^\circ$	$9.4^\circ \pm 18.4^\circ$
Θ_y	$7^\circ \pm 3^\circ$	$2.6^\circ \pm 1.0^\circ$	$1.2^\circ \pm 3.0^\circ$
Θ_z	$3^\circ \pm 3^\circ$	$7.5^\circ \pm 4.2^\circ$	$-0.2^\circ \pm 3.6^\circ$

Further study for determining a more accurate method for deriving PSFCS for use in patient-specific FEA is necessary. PSFCS estimates from the proximal femur may be improved by using: (a) sex-specific averaged SSM femur mesh; (b) the closest femoral match from the cadaveric database; or (c) additional proximal femur anatomical landmarks. In summary, SSM provides an important and promising start towards deriving PSFCS for the retrospective study of CT scans for femur strength prediction.

INTRODUCTION

Elastin, collagen, and smooth muscle cells are primary components that comprise the microstructure of arteries and contribute to the vessel mechanical behavior. During the course of the cardiac cycle, varying loading configurations are imposed on the vessel wall, causing each microstructural component to experience different amounts of combined loading. While macroscopic mechanical behavior, such as anisotropy, has been observed in vessel studies [1], the contribution of each individual constituent to the overall vessel mechanics is still relatively unclear. Selectively removing components via enzymatic digestion allows demarcation between constituent contributions to various loading configurations. Previous studies have presented a wealth of uniaxial data [2], but a deficiency in shear testing. Testing shear loading configurations is highly important, as many disease etiologies begin between the artery layers [3]. Despite much progress in understanding vessel mechanics, there remains a need to explore the role of each arterial component, in order to grasp the underlying mechanisms behind important vascular diseases. Here, we use enzymatic digestion to explore the role of collagen and elastin on the mechanical composition of porcine abdominal aortas in uniaxial and shear lap loading configurations. These two test protocols were chosen to evaluate both normal and shear stress effects on the tissue.

METHODS

Tissue samples were dissected from porcine abdominal aortas obtained from pigs sacrificed as part of separate, IACUC-approved studies at the UMN Visible Heart Laboratory.

Collagenase and elastase solutions were prepared (500 U ml⁻¹, Type IV, Worthington Biochemicals, NJ, USA, and 10 U ml⁻¹, porcine pancreatic elastase, Worthington Biochemicals, NJ, USA, respectively) in 1X Dulbecco's phosphate-buffered saline solution (Quality

Biological, MD, USA). Samples were thoroughly cleaned and incubated at 37 °C for 1, 3, 5, 7, or 9 hours [4]. Tissue was completely submerged in buffered-media and thoroughly washed in 1X PBS following treatments. Small samples from each artery segment were collected after each study for later histological review.

Tissue thickness was measured using calipers by taking six measurements at different positions along the artery and calculating an average thickness. All cylindrical arteries were cut open along their lengths to produce planar sections. Once oriented in the circumferential (θ) and longitudinal, 'axial' (z), directions, these were then dissected into uniaxial and lap samples (Figure 1).

Figure 1: Uniaxial and Lap test geometries.

Uniaxial and lap data were collected using a Microbionix Uniaxial Tester (University of Minnesota, Tissue Mechanics Lab) with a 5 N load cell. After samples had been mounted, the load cell was zeroed, and the

actuator arm was moved so reach an 0.2 N pre-load. Samples were then pulled to failure at a constant rate of 0.045 mm/s. To maintain tissue hydration during the experiments, samples were placed in a 1X PBS bath at room temperature.

Stress and strain of uniaxial samples were calculated by finding the force over the original cross-sectional area of the neck and by the displacement divided by the original sample length, respectively. For lap samples, the average shear stress was calculated as the force divided by the original overlap area of the sample.

RESULTS

Control data (Figure 2) was used to establish baseline stress and strain values in the absence of matrix degradation enzymes and validate the testing methods. As expected, the circumferential direction showed greater stiffness in both the uniaxial and the lap tests. In the subsequent examination of the digested samples, we focused on the failure point, defined as the maximum stress, and we calculated the average failure stress and failure strain.

Figure 2: A) Uniaxial and B) Lap tests on control samples.

The average failure stresses and strains are shown in Figure 3. After an initial rise in failure stress at the 1-hour time point, especially in the uniaxial tests, further digestion led to a gradual decline in failure stress indicative of a degraded collagen matrix. The early strengthening can be attributed to a preliminary cross-linking of amino acids located near the enzyme binding sites in the collagen [5]. This effect was most notable in the circumferential direction. The failure strain showed little effect of digestion except for a rise in failure strain for the axial lap tests following long-time elastase digestion (Fig. 3D).

An additional observation, whose significance is not clear, is that while control lap samples in both orientations, as well as digested lap samples in the circumferential direction, failed in the overlap region, but digested samples failed in the sample arms. Since the arms of a lap sample are in extension during the test, this shift in the location of the failure point may be driven by weakening of the tissue in uniaxial extension as seen in Figure 3A. Similarly, the drop-in failure stress during lap testing (Figure 3C) is not an indication of weakening in shear but rather a consequence of extreme weakening of the arms.

Figure 3: A) Failure stress and B) Failure strain in uniaxial tests. C) Failure stress and D) Failure strain in lap tests. Points are mean \pm 95 confidence interval.

DISCUSSION

Much is understood about the biological and biomechanical mechanisms that contribute to vascular disease progression, but much also remains unknown. There is a lack of available tissue from the onset of vascular disease to its end stages, making ex-vivo digestion experiments a critical substitute. This study examined the contributions of collagen and elastin to the failure behavior of the tissue in both shear and uniaxial extension.

Collagen and elastin degradation for uniaxial testing showed very similar results for circumferential direction, but a failure stress of half for axial when using elastase. Failure strains remained similar for the two. There is an opposite trend for lap samples, with a decrease in circumferential failure stress for elastase, but no measurable trend for the axial tests.

There are, of course, other biomacromolecular and cellular components that contribute to vascular mechanics. Future mechanical testing will focus on cell contributions to artery microstructure by decellularization testing and incorporating computational models to improve understanding of microstructure behavior.

INTRODUCTION

The tricuspid valve (TV), located in the right side of the heart, has been historically under-treated in the clinical setting due to assumptions that functional tricuspid regurgitation (FTR) will regress after treatment of left-sided lesions [1]. Recent studies have contradicted these assumptions and demonstrated that FTR often continues to progress after the repair, worsening the overall prognosis [2]. In addition to left heart disease, TR may result from right heart dilation in congenital heart disease, primary pulmonary hypertension as well as an increased pressure-volume load seen in single ventricle patients. Thus, the TV has become of great focus in the past 5-10 years with emphases on more accurate assessment of FTR and determination of the optimal treatment time. However, proper assessment of FTR can be difficult, especially for patients who have less than moderate FTR [3-4]. Furthermore, current methods utilize various medical imaging modalities for these assessments, such as 2D/3D echocardiography, that provide key information regarding the TV geometry but no information regarding the TV mechanical environment. Therefore, the objective of this study is to develop a finite element framework for the TV to address these limitations. Specifically, this framework will provide enhanced information about key geometrical and mechanical quantities associated with pathological valves to assist clinicians in the assessment of FTR.

METHODS

Finite Element Model Geometry: The finite element (FE)

model geometry was generated in two steps. First, the TV annulus and chordae tendineae geometries were obtained from micro-CT image data of an ovine TV fixed in the closed position. Second, the leaflet geometry was created using a previously-published parametric model for the TV [5], represented by cubic B-spline surfaces and curves [6]. These geometries were then combined (**Fig. 1**) using the ABAQUS CAE interface.

Figure 1: Schematic of the finite element geometry.

FE Simulations: FE simulations were performed using the ABAQUS explicit dynamic solver. Both the valvular annulus and papillary muscles were assumed to be fixed to prevent rigid body motion. Transvalvular pressure of 25 mmHg (40 mmHg for the pulmonary hypertension scenario) was applied to the ventricular side of the leaflets for 0.4 seconds, which is the approximate duration of systole, to simulate systole. The leaflets were represented by a simplified isotropic material model:

$$\psi = c_0(I_1 - 3) + c_1(e^{c_2(I_1 - 3)^2} - 1) \quad (1)$$

wherein c_0 , c_1 , and c_2 are the material model constants, and I_1 is

the first invariant of the right Cauchy-Green deformation tensor. The chordae tendineae were assumed to be nonlinearly elastic with a Young's modulus of 40 MPa and Poisson's ratio of 0.30.

A series of numerical studies were performed to investigate the effect of various pathologies typically associated with FTR on quantitative values described in the next sub-section. The specific scenarios were pulmonary hypertension (PH) and annulus dilation (AD) with a flattened annulus.

Simulation Results Post-Processing: Results from the different scenarios underwent extensive post-processing to quantify key geometrical and mechanical quantities. The geometrical quantities of interest were those typically quantified in the clinical setting, specifically the leaflet tenting height, tenting area, and coaptation height (Fig. 2). For the mechanical quantities, the von Mises stress and maximum in-plane Green-Lagrange Strain (MIPE) were averaged for all elements of the leaflet geometry, and qualitative comparisons were made between the contours.

Figure 2: Schematic of the geometrical metrics.

RESULTS

FE simulation results presenting the von Mises stress and MIPE contours for the healthy, PH, and AD scenarios are provided in Fig. 3. The von Mises stress was observed to increase in the central area of the leaflets from ~75 kPa in the healthy scenario to ~125 kPa in the PH scenario, while the AD scenario remained around ~75 kPa with differences in the contour. Similar trends were observed for the MIPE.

Figure 3: Simulation results of the healthy, pulmonary hypertension (PH), and annulus dilation (AD) scenarios.

Results for the geometrical and mechanical quantities are provided in Fig. 4. The geometrical quantities generally varied between the coaptation considered. The PH scenario showed a consistent decrease in the tenting height and increase in the coaptation height when compared to the healthy simulation. Moreover, the AD scenario resulted in an increase in all geometrical quantities for the AL-SL and PL-SL coaptations. The PH scenario had a larger increase in mechanical values compared to the AD scenario.

Figure 4: Geometrical and mechanical quantities from the study scenarios. The x-axis labels stand for different leaflet coaptations (e.g., AL-PL is the coaptation between the anterior and posterior leaflets). Black: Healthy; Blue: PH; Green: AD.

DISCUSSION

This study is the first of its kind to determine the effects of PH and AD using an FE framework. However, a previous study by Casa et al., [7] determined the individual and combined effects of PH and AD *in-vitro*. The trends observed in the geometrical quantities are comparable to the previous *in vitro* study with differences in the effect of PH on the PL-SL coaptation. Overall, the numerical changes for PH and AD were larger in the *in-vitro* study but were within the same order of magnitude. Differences between the two studies could stem from the choice of valve. The *in-vitro* study used excised porcine valves whereas this study used a parametric representation of the TV leaflets with real annulus and chordae geometry.

Our findings could improve the understanding of how PH and AD affect TV function. TV coverage index (TV leaflet length / TV tenting area) is currently used as a marker for PH [8] and this could be expanded. Moreover, the developed framework opens new avenues for patient-specific *in-silico* modeling, which could significantly benefit the clinical setting. For example, the framework could use a patient's geometry to aid with the assessment of the valve's status. This would be of great value when making decisions about the need for TV repair at the time of cardiac surgery for other lesions. Furthermore, the framework could also be used to guide patient-specific therapeutics.

INTRODUCTION

Many biomechanical diseases, such as heart valve stenosis, tendon tears, and arterial aneurysms, cause impairment in organ function via alterations and remodeling in tissue microstructure. Consequently, prior studies have examined the microstructure of healthy and diseased tissues [1]. Methodologies for microstructural analysis include histology, small angle light scattering (SALS), polarized light microscopy (PLM), and second-harmonic generation (SHG) imaging, among others. However, these techniques are incapable of capturing the *dynamic* nature of tissue microstructure and the collagen fibers therein. In collagenous tissues, such as the tendon and heart valves (HVs), the orientations and dispersion of the load-bearing collagen fibers dynamically adjust in response to mechanical loading [2]. In this study, we developed and validated a novel integrated system consisting of a biaxial tester and a polarized spatial frequency domain imaging (pSFDI) device to quantify load-driven changes to collagen microstructural architecture in tissues.

METHODS

Birefringent Microstructural Scattering Theory: Collagen fibers exhibit birefringence, i.e., a polarization-dependent refractive response. For a single fiber with coplanar polarization, the refractive index depends upon the fiber orientation (θ_f) relative to the polarization of the light (θ_p). The reflected light intensity (I) of the fiber under co-polarized illumination and capture is described by Eq. (1).

$$I = a_0 + a_2 \cos(2(\theta_p - \theta_f)) + a_4 \cos(4(\theta_p - \theta_f)) \quad (1)$$

This birefringent relation between I , θ_f , and θ_p is further visualized in **Figure 1** with an example fiber angle of 90° and typical fitting Fourier series coefficients (a_0, a_2, a_4) as observed for collagen fibers.

Figure 1: Schematic of the reflected intensity response of a collagen fiber at $\theta_f = 90^\circ$ under co-polarized illumination and capture (T. Axis ~ Transmission axis of the polarizer).

This reflected intensity response holds for clusters of collagen fibers as well. In brief, the average orientation of a group of collagen fibers (θ) can be calculated as the θ_p where the reflected intensity is at its maximum. Additionally, the spread of the group of fibers can be represented via the degree of anisotropy (DOA) metric [3]:

$$DOA = 1 - \left[\frac{a_0}{(a_0 + a_2 + a_4)} \right] \quad (2)$$

pSFDI System Theory: In pSFDI, a projector generates patterned images, according to spatial frequency domain imaging (SFDI) theory, and projects these images through a polarizer and onto a sample. The reflected light then passes through the same polarizer and is captured by a camera. To acquire the intensity response of the sample, the polarizer is incrementally rotated through 180° with an image captured at each increment. The pixelwise θ and DOA can be calculated by fitting Eq. (1) to the intensity response at each pixel and applying the fit coefficients to Eq. (2) (**Fig. 2a**).

Figure 2: (a) Schematic showing the passage of light through the fundamental components of the pSFDI system, and (b) image of our integrated pSFDI and biaxial testing systems.

The Integrated System: Our group integrated a commercial biaxial tester (CellScale Biomaterials Testing, Canada) with a vertically-mounted pSFDI system to produce a combined opto-mechanical testing system (Fig. 2b). The testing sequence is controlled by in-house LabView programs and data/image analyses were performed in Python.

RESULTS

Tendon Tissue Testing: For validation, we performed uniaxial mechanical testing on a strip of bovine tendon with a 50° preferred fiber orientation, a width of 18 mm, and a thickness of 0.75 mm (Fig. 3).

Figure 3: (a) Raw testing images, (b) θ predictions, and (c) DOA predictions for a tendon sample under 0% and 3% strains.

The θ prediction of 50° was accurate for both unloaded and loaded states, despite the appearance of some bands associated with 150° false predictions in the loaded tendon (Fig. 3b). On the other hand, the DOA predictions exhibited substantial load-dependency, with the domain-average DOA increasing from 0.145 for the unloaded tendon to 0.188 for the loaded tendon (Fig. 3c).

HV Leaflet Testing: We also used our system to examine the dynamic collagen microstructural architecture within a porcine mitral valve anterior leaflet (MVAL) with a thickness of 0.87 mm. We conducted a standard biaxial mechanical preconditioning protocol to restore the tissue's *in-vivo* behavior, then characterized the MVAL microstructure without loading (Fig. 4c) and under equibiaxial loading of 1.0 N (Fig. 4d).

Figure 4: (a) Schematic of the MVAL testing region, (b) image of the mounted MVAL with directions marked (R: radial, C: circumferential). Predicted θ (dashed lines) and DOA: (c) without loads and (d) under an equibiaxial load of 1.0 N.

The fiber orientation predictions showed a strong bias toward the circumferential tissue direction but minor load-dependency, with domain-averaged θ of 177.1° prior to loading and 176.4° after loading. This bias manifested in the non-uniform dilation of the loaded tissue, with stretch of 29.7% in the radial direction but only 18.6% in the circumferential direction. In contrast to θ , the DOA showed a substantial response to external loads, with domain-averaged DOA increasing from 0.045 to 0.085 with applied loading. We also found subtle spatial variance in both the fiber orientation and DOA predictions.

DISCUSSION

The highly-uniform collagen orientation predicted in bovine tendon agrees with the known longitudinal fiber architecture. The increase in DOA we observed in the loaded tendon confirms intuition and suggests potential uncrimping of the collagen fibers with applied loads. For the HV leaflet tissue, our findings suggested that the loaded fibers: (i) are predominantly oriented in the circumferential direction and (ii) exhibit substantial spatial heterogeneity are supported by a mechanical study that found spatial differences and an increased circumferential stiffness in the MVAL mechanical response [4]. Although our study is the first to examine the fiber architectural changes in the full HV leaflet under biaxial loading, a prior study utilized SHG imaging and found microstructural load-dependency in the superficial layer [5]. Our study provides richer information to establish that MVAL load-dependency extends through the leaflet thickness. The similarity of tendon and MVAL microstructural predictions from this study to prior results validated the systemic capacity and opens doors to new research explorations, including: (1) novel applications in structural constitutive modeling, (2) understanding of the impacts of connective tissue disease on microstructure dynamics, and (3) improved microstructural analysis of fibrous biomaterials and engineered tissues.

INTRODUCTION

Head injuries commonly occur after bicycle accidents, with rates up to 2/3 for severely injured cyclists [1]. Appropriate head protection could contribute in the prevention of these head injuries. To determine the requirements for appropriate head protection, knowledge about the injury mechanisms is needed. Much effort has already been done to establish head injury criteria for multiple injury types, commonly using finite element head models (FEHM) [2]. However, no consensus about a good predictor with a corresponding threshold has been found.

At the same time, within the framework of accident reconstruction, real-life accidents are a potential source of valuable information, as they allow to study severe human head injuries in realistic situations. In order to investigate the head response in these real-life accidents, a work-flow based on validated multi-body (MB) models and a FEHM has already been used [3]. The available information about the true situation in these accidents has a varying accuracy. Besides, the pedestrian and bicycle MB models have many variables [4, 5]. Both aspects lead to uncertainty on the reliability of the outcome of the MB simulations. No quantification of the uncertainty introduced by the reconstruction of real-life bicycle accidents without car collision was found in literature.

Therefore, it is the aim of this study to assess the added value of using the validated MB models and FEHM to study real-life bicycle accidents. Two topics will be discussed in particular. The first one is the quantification of the uncertainty introduced by the use of MB software, which is used to obtain the head kinematics from real-life unhelmeted bicycle accidents without car-collision. The second part considers the possibility to correctly predict the diagnosed Acute Subdural Hematoma (ASDH) and brain contusions, based on finite element analysis (FEA), with the MB head kinematics as input, and the current knowledge about injury predictors and their corresponding thresholds.

METHODS

Parametric study of MB simulations For five real-life bicycle accidents, whereof the accident and injury description was collected at the University Hospital of Leuven, an initial simulation was set up based on a validated 50th percentile male MB model in MADYMO [5]. A trial and error approach was used. It was required that the impact place of the simulations corresponded to the description. Thereafter, two types of parametric studies, based on six input variables (see table 1), were performed. The peak resulting angular acceleration ($\alpha_{Peak,Res}$) was taken as output variable, as it was found to be linked to the injury mechanisms [2]. The influence of each input variable was investigated for three cases by considering the maximal change in $\alpha_{Peak,Res}$ per variable and per case, with respect to the initial simulation, and univariate linear regression. A methodology based on an orthogonal array and multivariate linear regression was applied to the other two cases. Besides, based on the subset of simulations leading to the correct impact place, the uncertainty on $\alpha_{Peak,Res}$ was quantified. The head kinematics with the minimal and maximal $\alpha_{Peak,Res}$ were selected for each case as input for the FEA, together with those of the initial simulation.

Head impact FEA The KTH FEHM, adapted to study brain contusion and ASDH due to ruptured bridging veins (BV), was used to perform the analysis in LS Dyna based on the obtained head kinematics. The maximal engineering strain of all BV and the relative motion damage measure (RMDM) were investigated as predictors of ASDH [6]. For brain contusion, the maximal principal compressive and tensile true strain were assessed using strain injury thresholds of 0.20 and 0.25 [7, 8]. After comparing the results of the predictors to each other, they were compared to the medical information in a qualitative way. The ability to distinguish injured and uninjured cases was assessed and the correctness of the predicted locations was considered.

Table 1: Input variables of the parametric study and the corresponding ranges. Feet-pedals and Hands-handlebars indicate the strength of the connection between the feet and the pedals and between the hands and the handlebars, respectively.

Parameter	Range	Step
Position pedal hub	-20° to 20° w.r.t. initial position	10°
Position upper body	Ca. 25° to 60° w.r.t. vertical line	8.64°
Speed	60% to 140% of initial speed	20%
Saddle height	-6 cm to 6 cm w.r.t. initial height	3 cm
Feet-pedals	60% to 140% of initial strain	20%

RESULTS

Parametric study of MB simulations Although the maximal change in input variable differed often strongly from case to case, there was at least one case with a maximal change larger than 70% in $\alpha_{\text{Peak,Res}}$ for each input variable (see table 2). The number of significant univariate linear relations and the number of significant terms in the multivariate relations were limited and the variables leading to the significant relations and terms were case dependent. Next, based on the subset of simulations leading to the reported impact place, the smallest maximal change on $\alpha_{\text{Peak,Res}}$ was ca. 30%.

Table 2: Overview of the maximal changes for $\alpha_{\text{Peak,Res}}$ per input variable. The maximal change per case from the subset of simulations with the correct impact place is given as well.

Case	Upper body	Pedal hub	Feet-pedals	Hands-handlebars	Speed	Saddle height	Correct impact
1	60%	72%	8%	96%	42%	60%	72%
2	64%	26%	0%	43%	51%	63%	42%
3	81%	38%	80%	92%	84%	83%	52%
4	NA	NA	NA	NA	NA	NA	33%
5	NA	NA	NA	NA	NA	NA	232%

Head impact FEA For ASDH due to ruptured BV, the predicted injury locations and distinction between injured and uninjured cases of the maximal BV strain and RMDM were similar. The predicted brain contusion locations for the strain measures were comparable on a general level as well. The comparison with the medical information suggested for both head injury types that using the head kinematics of the initial simulations led to a correct distinction between injured and uninjured cases, with a true strain threshold of 0.20 for brain contusions. This was no longer true when looking to the simulations based on the minimal and maximal $\alpha_{\text{Peak,Res}}$. While the predicted location of ASDH agreed well with the medical information, the brain contusion locations had a limited agreement.

DISCUSSION

Parametric study of MB simulations The high maximal change for each input variable in at least one case, indicated that all input variables had a relevant importance. That small changes in the input variables can imply large maximal changes in the rotational head acceleration, was also noticed before [4]. However, the relevance of the input variables for a particular bicycle accident varied and it is not ensured that all important variables were taken into account.

Next, with the considered sample size, no general trends in the influence of the uncertainty on the initial situation and the relative importance of the input variables could be established using uni- or multivariate linear regression. One study that performed regression based on a parametric study of MB simulations was found [9]. However, as the linear velocity instead of $\alpha_{\text{Peak,Res}}$ was used as output, the results of the study are not transferrable. It is, therefore, suggested that more cases should be considered in order to gain further insight.

Besides, the smallest maximal change in $\alpha_{\text{Peak,Res}}$ was ca. 30% for the subset of simulations with the correct impact place, implying a minimal uncertainty of 30% on $\alpha_{\text{Peak,Res}}$. However, this uncertainty indicates a minimum and is only valid for the considered cases and ranges of variables, so caution is warranted. Including more cases is needed to expand the insight in the uncertainty that could be expected in general.

Other limitations related to the parametric studies, next to the limited number of cases, are the user-dependence of the simulation set-up, the assessment of the estimated impact place and the use of a 50th percentile male model for all cases.

Head impact FEA Based on the medical information, the injured cases could be separated well from the uninjured ones for ASDH due to BV rupture and brain contusions, based on the head kinematics of the initial simulations. The threshold distinguishing the victims diagnosed with BV rupture from those without, i.e. a maximal BV strain of ca. 0.14, is situated at the lower boundary of the experimentally determined BV rupture strains [10]. This implies that the threshold might be realistic. However, the threshold should be interpreted as upper boundary of the safe region, rather than as an indication of BV rupture. For brain contusions, the maximal principal strain threshold of 0.20, situated within the range of thresholds proposed before, allowed to correctly distinct the victims with and without brain contusion for the initial simulations [7, 8].

For BV rupture, the injury locations were predicted quite well. Caution should, however, be taken, as the reliability of the location prediction with the FEHM was questioned before [11]. Considering brain contusions, the locations were determined in a suboptimal way, due to the lack of CT scans. Moreover, the correspondence with the medical information was limited.

Besides, the dependence of the ability to distinct harmed from unharmed victims on the use of the minimal, initial or maximal MB simulation, stresses the risk of the uncertainty related to using MB software for the reconstruction of real-life bicycle accidents.

Conclusion By using the head kinematics from the initial MB simulations as input for the FEA, the presence of ASDH due to ruptured BV and brain contusion was correctly predicted for the five real-life accidents, despite the uncertainty on the initial situation and the lack of consensus on the injury predictors and thresholds. The work-flow, therefore, has the potential to contribute in head injury research. However, further improving the characterization of the uncertainty and the use of CT scans to assess the injury locations, is required to improve the insight in the reliability of the results obtained with this work-flow.

INTRODUCTION

Neck and back pain have high incidence and costs, and the spinal facet joint and its capsular ligament have roles in pain [1-3]. Yet, how mechanical signals are transduced to painful ones is still unclear. Previously considered non-injurious loading [4,5] is increasingly being shown to induce mechanical and biologic dysfunction, including ligament laxity and pain responses. Studies of effects of such loading on the microstructural scale report collagen disorganization [6,7], suggesting the possibility for injury and/or dysfunction at the cellular level. Further supporting that hypothesis, repeated loading even below thresholds for pain and injury produces pain and changes in ligament structure [6,8]. Because collagen organization is dictated by macroscopic ligament stresses and strains, and mediates neuronal responses [9,10], defining microstructural effects of macroscale loading applied after an otherwise non-injurious exposure is needed to define pain mechanisms.

This study used a collagen gel system [7] to study effects of repeated stretch on mechanics and collagen organization. All gels underwent stretch that has been previously defined to be non-injurious, inducing strains (~8%) below the threshold for pain and lasting structural damage [7]. To test whether the collagen microstructure is disorganized or damaged, a second stretch was applied either at the same non-injurious magnitude or at a magnitude (~17% strain) known to activate neurons [7]. During loading, force, strain and circular variance (CV) were measured to define macromechanics, regional kinematics and collagen organization with fiber alignment maps [7,11,12].

METHODS

Gels underwent repeated non-injurious stretches, or a non-injurious stretch followed by an injurious one. Gels were made using a solution (2mg/ml) of rat tail Type I collagen (Corning), formed in a 12-well plate [7], and incubated at physiological conditions to set overnight and then cut into a 21mmx8mm strip. A matrix of markers was placed on the surface to define elements and track deformations (Fig. 1) [6]. Gels were submerged in a PBS bath and clamped in a planar test machine (574LE2; Test Resources). Each gel underwent a uniaxial stretch (1.5mm; non-injurious; NI) at 0.5mm/s, was held for 2s, returned to its reference unloaded state (AfterNI) and held for 10s (Fig. 1). A

Figure 1: Gels underwent two consecutive stretches, with imaging data analyzed at designated events. The image shows a gel at Stretch2(I) with grid, element and corresponding MPS.

set of gels (n=5) received a second NI stretch (Fig. 1); another set (n=5) underwent a second stretch (3mm; injurious; I) at the same rate (Fig. 1). Force and displacement data (200Hz) were synchronized with imaging (Phantom v9.1; Vision Research; 500fps; 568x568pixels²) that tracked the markers. Polarized light imaging acquired fiber alignment maps [7,11] at: unloaded (ref), Stretch1 (NI), AfterNI, Stretch2, and after Stretch2 (Fig. 1).

From the imaging data, maximum principal strain (MPS) and CV were calculated to define changes in local kinematics and collagen fiber organization during the stretches and holds. Using marker displacements and the LS-DYNA software (LSTC), elemental MPS at each event was calculated [12]. CV at each element also was calculated from the alignment maps at each event. Separate paired t-tests compared force, strain, and CV between each matched event for each group.

RESULTS

Imaging data were unavailable for a gel in each group. For all gels, the force (11.46 ± 8.93 mN), strains ($7.96 \pm 3.43\%$) and CV (0.087 ± 0.19) at the first NI stretch are not different ($p > 0.2$). Both force and MPS at the second NI stretch are significantly lower ($p < 0.05$) than at the first NI stretch (Fig. 2). In contrast, force and MPS at the higher (3mm) injurious Stretch2 are both increased significantly ($p < 0.03$) over matched Stretch1 values (Fig. 2).

Figure 2: Peak force and MPS for groups at each event show both are significantly increased for injurious Stretch2 (S2(I)) (* $p < 0.03$) and decreased (* $p < 0.05$) for non-injurious Stretch2 (S2(NI)).

The CV at the injurious Stretch2 (0.003 ± 0.003) is also significantly higher ($p < 0.01$) than its corresponding Stretch1 (0.002 ± 0.001), indicating that the collagen fibers are becoming more disorganized as the fibers are becoming less aligned with each other (Fig. 3). In addition, the CV for a non-injurious Stretch2 (0.185 ± 0.25) is significantly different ($p < 0.05$) from corresponding CV values at the first NI stretch (0.23 ± 0.30). Taking all gels together, there is no difference ($p > 0.2$) in CV at the first NI stretch (0.087 ± 0.19) from the corresponding reference CV value (0.084 ± 0.20).

DISCUSSION

The fact that CV at the first NI stretch is not different from the corresponding reference CV value implies that a single non-

Figure 3: Histograms of fiber alignment for the gel in Fig. 1 showing tighter fiber angle clustering at non-injurious Stretch1, but more disorganization (larger spread of angles) at Stretch2.

injurious stretch is not enough to cause microstructural changes. This is supported by the finding that Stretch1 induces strains (Fig. 2) below the threshold for unrecoverable strain, laxity and collagen disorganization [4,6,7]. However, a second similar stretch does change the collagen network microstructure, which is evidenced by compromised load capacity and increased deformations and fiber disorganization (Figs. 2 & 3). In the context of ligament pain, changes in collagen fiber organization directly mediate and align with neuronal activation and signaling [4,6,7,13]. Although effects of repeated loading on neurons was not evaluated here, comparable non-painful facet capsule stretch exposures *do* induce pain when repeated within 2 days in vivo [8]. Further, the fact that the second NI stretch produces collagen disorganization, which is known to occur at the same strains as neuronal pERK upregulation [7], suggests the possibility for pain generation, despite strains at that second stretch ($6.4 \pm 3.1\%$) being decreased compared to the first stretch ($7.9 \pm 4.1\%$) (Fig. 2). Since pERK can be induced through cellular deformation [14,15], it is possible that such activation occurs even at lowered strains. Future studies incorporating neurons in these collagen gels will help with direct assessment of their mechanical and physiological responses and the relationships between these and physiologic preconditioning or sensitization that may occur as a result of repeated exposures.

INTRODUCTION

Biomechanical analysis of human injury response and injury tolerance data may require the use of normalization or scaling method due to the variability between the human test subjects. For most biomechanical testing, data are scaled to the 50th percentile adult male. Scaling techniques based on equal stress-equal velocity technique were often used to scale these experiments done on human surrogates (e.g. volunteers, cadavers) to human population of different ages and genders, to establish injury thresholds. The equal stress-equal velocity method assumes a constant mass density and constant modulus of elasticity between subjects and a scaling factor is determined by assuming geometric similarity [1]. The development of Brain Injury Criteria (BrIC) [2] was based on human head finite element (FE) modeling of the experimental brain injury in animals by scaling the head kinematics of the animals (rhesus monkeys, baboons and miniature pigs) to the FE human head model. The accuracy of equal stress-equal velocity scaling method used in above process is questionable as it solely based on the mass difference without considering the anatomical, geometrical differences between the heads and brains of the animals. It was reported that scaling law works for elastic material but not for viscoelastic materials of the brains of similar geometry [3]. The objective of the current study was to evaluate and demonstrate the issues of not considering geometrical and anatomical differences between human and animal head with the use of the mass scaling method in the development of human brain injury criterion. To achieve the goal, both primate FE head model and human head model were used to simulate the experimental data directly or using scaling method to scale the head kinematics from the monkey to the human and from the monkey to the monkey with different brain mass in order to assess the geometric effect

on the resulting brain responses and potential injury severity predicted by the models.

METHODS

FE head models: Evaluation of scaling techniques was studied by comparing the brain tissue response predicted between three head models simulating animal test conditions based on mass scaling method. Model 1 was a detailed rhesus monkey (*macaca mulata*) head model developed recently and scaled to the brain of the monkey subject used in each of the three experiments. Model 2 represented a large size monkey by scaling the Model 1 to approximate the brain mass of the Global Human Body Models Consortium (GHBMC) 50th percentile adult male head model [4] that was recently updated. Model 3 was the GHBMC M50 head model. Figure 1 shows the three models used for the evaluation and comparison of the resulting brain responses.

Figure 1: Models used for evaluating the scaling techniques based on mass of the brain

Scale factors and scaling the head rotational loading: The scaling factor to scale the Model 1 mesh to Model 2 was determined based on

mass scaling method and the factor is 1.95. The mass of the rhesus monkey brain model was 109 g. The experimental case simulated was based on reported monkey head rotational experiments on diffuse axonal injury [5,6]. The head rotational acceleration used for the input to Model 1 was the unscaled original monkey experimental loading. For model 2, the input used for Model 1 was scaled based on the mass of brain of the Model 2 which has a similar mass as the GHBMCM50 head model. For Model 3, the input was the same as that used for the Model 2. The Ommaya's mass scaling method to scale the rotational acceleration was applied [7]. To scale the input 1 to the input 2, the magnitude of the angular acceleration of the monkey test data was scaled by 0.263 while the time duration was by 1.95. Figure 2 shows the angular acceleration, velocity and calculated angular displacement for the two inputs.

The material models and associated properties for monkey models were based on the GHBMCM50 head model (v5.0). Maximum principal strain (MPS) and Cumulative Strain Damage Measure (CSDM) were examined between the models for subcortical white matter, corpus callosum (CC) and brainstem structures, the common structures observed for Diffuse Axonal Injuries (DAI) in experimental models. All simulation was performed using LS-DYNA MPP R8.1.

Figure 2: Input profiles: Input 1 for Model 1 and input 2 for Model 2 and Model 3

RESULTS AND DISCUSSIONS

Maximum principal strain: The monkey model with monkey experimental input (Model 1, Input 1) and scaled monkey model with scaled original input to brain similar to the human (Model 2, Input 2) yielded similar MPS results for the structures involved in DAI with a variation of 8%, 1% and 0% respectively, for the brainstem, the corpus callosum and the subcortical white matter. The GHBMCM50 model (Model 3, Input 2) with scaled input from monkey to M50 yielded much different MPS with 48%, 48% and 45% variations respectively at the corresponding three brain structures, as compared to the Model 1 as shown in Figure 3. The peak strain in the monkey model occurred earlier than that in the scaled monkey model. It is due to the input of shorter duration used for the monkey model and a longer duration input for the scaled monkey model due mass scaling applied to scale the peak rotational acceleration and associate duration.

Figure 3: Comparison of MPS resulted from the three models

MPS contours predicted for the brainstem, CC and subcortical white matter from three models are depicted on Figure 4. The strain distribution, location and patterns in the same structure were nearly identical between the monkey brain and the scaled monkey to the mass

of human brain, because the two models had the identical geometry while the mass scaling is valid. In contrast, the human head model exhibited different response pattern and strain localization than the monkey model and scaled monkey when compared to that of human brain mass model.

Figure 4: MPS contours predicted from the three models

Cumulative strain damage measure: The peak CSDM volume percentages at 0.5 MPS predicted by the scaled monkey model showed slight deviation at 6%, 10%, 4% and 12% more or less than those predicted by the monkey model in the whole brain, brainstem, corpus callosum and white matter, respectively. The GHBMCM50 model predicted 50%, 50%, 33% and 67% less CSDM than the monkey model at the corresponding structures, respectively using the input that was scaled from animal experimental data.

CONCLUSIONS

The similarities in biomechanical responses (MPS and the CSDM) experienced by the brain of various structures from the monkey model and the scaled monkey model demonstrate that mass scaling technique works well within the species of identical anatomy and geometry. The profound differences in MPS and CSDM results found when using scaled experimental data simulated by the human head model and the experimental data simulated by the same animal model suggests that the scaling method used in the development of new brain injury criterion [2] is unreliable owing to the geometrical, shape and neuraxis differences between the two species. The primate model developed for this study can be applied to develop tissue-level response correlates for various brain injury severities and be translated to the human head model such as the GHBMCM50 head model in order to improve its capability of establishing reliable brain injury criteria.

DETERMINATION OF TISSUE LEVEL INJURY THRESHOLD FOR OCULAR TRAUMA BY FINITE ELEMENT ANALYSIS

Kunal Dave, Liying Zhang

Biomedical Engineering Department
Wayne State University
Detroit, MI, USA

INTRODUCTION

There are over 2.5 million traumatic eye injuries that occur each year in the United States. Ocular injuries can occur from sports related impacts, in automobile crashes and by high speed projectiles from fireworks and BB guns. With the increase in use of weapons releasing fragments, the rate of eye injuries has increased to higher level as compared to total military injuries. The improved understanding of mechanism of ocular injury in blunt impact may help design improved protective device for eye protection. A number of blunt impact tests have been conducted on human eye specimens but the reported injury was limited to globe rupture. The experimental studies on porcine eye reported anatomical and pathological injury to the cornea, lean and retina tissues in blunt and blast loading conditions. The morphological and anatomical features of the porcine eye were very similar to those of the human eye. Finite Element (FE) modelling of traumatic event can serve as a powerful tool to study biomechanical process and tissue response of ocular injury at various conditions. In earlier studies, kinetic energy was reported as an injurious parameter for globe rupture. However, kinetic energy is incapable of providing information on the responses of various ocular tissues to injury and the injury localizations. The objectives of this study were to 1) develop and validate a detailed FE porcine eye model, 2) simulate a number of experiments to quantify the local tissue response parameters for various types of ocular injury including corneal abrasion, lens dislocation, retinal damage and globe rupture, and 3) develop injury threshold risk curves for various ocular trauma.

METHODS

FE eye model development: The geometric information of the porcine eye was taken from the literature [1-3]. The finite element mesh

of the porcine eye was developed using Hypermesh 13 (Altair Engineering, MI). The model consists of all essential components of the eye including the cornea, sclera, aqueous humor, iris, lens, zonules, ciliary body, retina, choroid, and vitreous humor (Figure 1). The cornea and sclera tissue were modeled as non-linear elastic materials. The aqueous humor, vitreous humor and retina were modelled as viscoelastic materials. The iris, lens, zonules, ciliary body, and choroid were modelled as linear elastic materials. The FE eye model was constructed with over 12,500 solid hexahedral elements and over 850 shell elements with an average resolution being 0.6 mm. All simulations were carried out using LS-DYNA MPP Version 971 R8.1 (LSTC, CA).

FE eye model validation: The FE eye model was first subjected to a validation against corneal displacement measurement from BB (0.345-gram, 4.5-mm diameter, $v=62.3$ m/s) impact experiments [4]. The model predicted corneal indentation, equatorial variation, and longitudinal variation of the globe were compared with test results. The objective rating software CORA was used to assess the correlation [5]

Figure 1: FE eye model

Ocular injury predictor and risk function development: The mode was applied to simulate a total of 86 tests reported in the literature using different blunt impact projectiles as mentioned in Table 1 [6-8].

The biomechanical response parameters predicted by the model were related to the observed injuries. The maximum principal stress predicted at the cornea-sclera junction component and at corneal apex along with the pressure in the central vitreous were monitored for globe rupture. The displacement, strain rate and product of strain and strain rate were calculated at corneal apex for predicting corneal abrasion. Maximum principal stress and maximum principal strain predicted at retina in macular region was monitored for retinal damage. For lens dislocation, strain rate and product of strain and strain rate were predicted at the center of lens just behind aqueous humor. Logistic regression analysis was performed to assess various tissue-level response predictors for predicting risks of globe rupture (86 cases), lens dislocation (N=15), retinal damage (N=15) and corneal abrasion (N=13). The Area Under the Receiver Operating Characteristic (ROC) Curves (AUC) were used to evaluate relative predictability, sensitivity and specificity of the regression models for predicting various ocular trauma.

Table 1: Blunt impact simulations

Type of Injury	Number of Cases Simulated	Type of Projectile	Diameter of Projectile(mm)	Mass of Projectile(gm)	Velocity Range(m/s)
Globe Rupture (86 cases) {6}, {7}, {8}	11	Airsoft Ball	6	0.12-0.2	67-115
	20	Paintball	17.3	3.2	68-108
	4	Delrin Impactor	19.9	112.55	8-9
	5	Plastic Rod	7.62	0.35	5-20
	19	Foam	4.5-12.5	0.04-0.50	16-149
	4	Aluminium Rod	9.25-11.16	3.57-5.19	28-37
	8	BB Pellet	4.37-4.5	0.345	62-96
Lens Dislocation & Retinal Damage {6}	15	Steel Projectile	6.35-45.5	2.6-45.5	4-38
Corneal Abrasion {7}	13	Foam	12.5	0.15-0.50	18-87

RESULTS

Validation results: The corneal displacement calculated by the FE eye model from BB pellet impact was 8.2 mm matching the experimental value reported by Delori et al 1969 (Figure 2). The CORA rating was 0.84 which implied a good correlation of the temporal response of the corneal displacements between the model prediction and experimental measurement.

Figure 2: Experimental validation of FE eye model

Logistic regression for determining ocular injury thresholds: For cases of globe rupture, the pressure in the vitreous humor and maximum principal stress in the sclera and cornea were predicted to be constantly higher in the case with globe rupture than that without globe rupture. The prediction of high stress location was consistent with the experimental observation where the limbus region (cornea-scleral junction) was the common site of failure in globe rupture cases. For the logistic regression models, the AUC values based on cornea maximum principal stress, vitreous pressure and normalized impact energy were 0.995, 0.876, and 0.986, respectively for predicting globe rupture. The AUC value based on the principal strain rate, product of strain and strain rate in the lens and the impact energy were 0.94, 1, 1 for lens dislocation. For the retinal damage, the AUC values based on retina stress, retina

strain and impact kinetic energy were 1, 1 and 0.97, respectively (Figure 4). The AUC values based on cornea displacement, product of strain and strain rate and impact kinetic energy were 0.925, 0.925, 0.95, respectively, for predicting corneal abrasion.

Figure 3: Injury risk curve for globe rupture

Figure 4: Injury risk curve for retinal damage

DISCUSSION

An anatomically detailed finite element porcine eye model with all essential intraocular tissues has been developed and validated against corneal displacement response. The model has been used to simulate 86 blunt ocular impact experiments. The direct correlations between the biomechanical response parameters predicted by the model and the pathological damage location observed in experiments can help improve our understanding of the mechanism of various ocular injury types based on local tissue responses. The injury predictors and associated damage threshold functions have been established to predict the risk of corneal abrasion, retinal damage, lens dislocation and globe rupture from blunt impacts. The corneal abrasion and globe rupture (100%) would occur when the maximum principal stress exceeds 1.2 MPa in cornea and 10 MPa in limbus, respectively. The retinal damage would occur when the maximum principal stress or maximum principal strain exceeds 19 MPa or 0.2. The future work will apply the FE porcine eye model to understand the mechanism of blast-induced ocular trauma and develop tissue level threshold for blast induced ocular injury.

INTRODUCTION

Lisfranc injuries of the mid-foot are challenging to identify during initial evaluations because the common measurements to indicate their presence are small and the mechanism of injuries often include other injuries in the foot. Untreated Lisfranc injuries result in severe discomfort and pain (1). When the diastasis (separation) between the medial cuneiform and second metatarsal is greater than 2 mm, surgery to repair the joint is indicated. However, historically, these surgeries have a low satisfaction rate with patients (2). Recent literature has compared a range of surgical repairs with conflicting recommendations on which procedure provides the optimal environment to promote healing and avoid implant failures (2-4).

This study applies computational modeling, both rigid body and finite element analyses, to compare the stability and stress contours associated with three different repair procedures: open reduction and internal fixation (ORIF) with endobuttons, ORIF with cortical screws, and arthrodesis with cortical screws. The focus is to identify the procedure that results in the most stable joint after the surgery, which has been related to better outcomes (5). The use of computational models allow for a common anatomy to be used for the different procedures and provide more extensive measurements without having to rely on cadaveric or patient studies. The ultimate purpose of this work is to help practitioners in selecting the optimal procedure for patients.

METHODS

Computerized tomography scans of a healthy foot were used to generate 3D solid models of the individual bones. The bones were imported into the 3D design software SolidWorks (Dassault Systemes, Waltham MA) and positioned in 30° plantar flexion, the position believed to put maximal stress on the Lisfranc joint (3). Ligaments were modeled as tension only elements across the bones and were provided

with *in situ* strain in the original rigid body of this injury (6). Using a previous cadaver study that was loaded with axial compression of 343 N (7), the model validated the cadaver results for a healthy foot and a foot with a ligamentous Lisfranc injury (cut Lisfranc and intercuneiform ligaments).

With the computational rigid body model validated on cadavers, the three repair procedures were simulated. For the ORIF with endobuttons case, two tension only elements were added to represent the fiberwire spanning from the medial cuneiform and the second

Figure 1: A) AP view of endobutton (illustrative) tension only elements. B) AP view of two screws used for ORIF with screws. C) AP view of arthrodesis fixation

metatarsal as well as the medial cuneiform and the intermediary cuneiform (Figure 1A). The ORIF with screws model used rigid bodies for the screws which were placed in a similar orientation as the endobuttons (Figure 1B). The arthrodesis case used five screws and was based on that used in previous clinical studies (Figure 1C) (4). Screw-bone interfaces were treated as bonded contacts. For all these simulations, muscle forces were incorporated in the rigid body model to simulate muscle activation for standing in 30° plantar flexion (8,9). Each model was loaded with the same axial compression of 343 N after which three diastasis measurements were recorded. From each rigid body simulation, contact forces and ligament/muscle forces were extracted in order to perform a finite element analysis (FEA) in ANSYS Workbench (ANSYS, Canonsburg PA) for the stresses generated during the loading (Figure 2).

All three surgical repair models tracked the dorsal, interosseous, and plantar separation (diastasis) between the medial cuneiform and second metatarsal, relative to the healthy, unloaded foot. These separations were compared to both a healthy and injured model that have previously been validated to determine the ability of the surgery to reverse the excessive instability in the joint after injury.

Figure 2: ANSYS FEA study of the arthrodesis procedure with forces applied shown with red arrows.

RESULTS

When comparing the diastasis measurements throughout the Lisfranc joint (Figure 3), the endobutton procedure reduced the plantar and interosseous diastasis seen in the injured model; however, the dorsal aspect of the joint closed while the plantar aspect opened relative to the healthy foot. The screws and arthrodesis repairs greatly reduced the amount of diastasis and provided values closer to a healthy model.

Figure 3: Diastasis measurements of the Lisfranc joint for the healthy, injured, and three repair models

The stresses in the bone and hardware for the ORIF repair showed one area of yielding in the screw spanning the Lisfranc joint. The arthrodesis procedure did not show any areas of yielding though stresses were high in similar regions as for the ORIF repair. In the ORIF case, the yielding was isolated to a small region of the screw threading. Other regions of the screw shaft showed high stresses.

Figure 4: von-Mises stress contour (MPa) on screw spanning the Lisfranc joint in the ORIF procedure

DISCUSSION

A major indicator of successful Lisfranc surgical repairs is the ability for the procedure to reduce movement in the joint following surgery (5). This study demonstrated how screw fixation techniques are better in preserving joint diastasis between the medial cuneiform and the second metatarsal when weight bearing. While the endobutton procedure exhibited some improvements over an injured foot, the non-rigid nature of the wires and their placement allowed separation along the plantar portion of the joint. Some studies that have recommended endobutton fixation have praised that the non-rigid fixation technique allows for earlier mobilization and full weight bearing (10).

One concern with screw fixation is implant failure. The finite element analysis for ORIF screw fixation procedures showed a region of yielding in the screw threads (stress greater than 827 MPa for Ti-6Al-4V screws). Both ORIF and arthrodesis procedures exhibited other regions of high stress which could be susceptible to fatigue failure. However, these stresses may be caused by the bonded contact condition set between the screws and bone which may be overly restrictive to motion.

Based on the need to re-establish anatomical fixation after a Lisfranc injury (either temporarily with ORIF or permanently with arthrodesis), screw fixation provides the best stability. Weight bearing and activities should be controlled however, because of the potential for implant failure during initial healing. As fusion occurs in the arthrodesis case or as tissue healing occurs for ORIF with screws, the risk of implant failure should reduce. Ultimately, this computational approach supports previous clinical studies that show less diastasis with screw fixation techniques (3,11) and points to reasons for implant failure (12). This study shows the ability of computational models to help inform on outcomes of different surgical procedures in a cost effective manner. It also demonstrates the flexibility of these types of studies where variations in patient anatomy is controlled.

INTRODUCTION

Osteoarthritis (OA) is a degenerative disease of the articular cartilage (AC). During OA, the structural constituents of AC, proteoglycans (PGs), sulfated glycosaminoglycans (sGAGs) and collagen, are lost. This results in decreased fluid retention, reduced modulus, and reduced energy dissipative capacity [1-4].

Quantitative magnetic resonance imaging (qMRI) techniques can distinguish healthy from osteoarthritic cartilage by identifying altered cartilage composition or structure. Commonly used techniques include delayed gadolinium-enhanced MRI of cartilage (dGEMRIC) and transverse T_2 relaxation. dGEMRIC is a contrast-enhanced method that produces longitudinal relaxation (T_{1Gd}) maps sensitive to sGAG content [5-9]. T_2 maps do not require contrast [4, 5, 10-13]. Multi-component Driven Equilibrium Single Shot Observation of T_1 and T_2 (mcDESPOT) is a contrast-free method that provides measurements of both bound water fraction (F_{PG}) and T_2 , with relatively short scan times [14]. mcDESPOT has been shown to have high sensitivity for detecting cartilage degeneration in human knees [14], suggesting its utility in predicting material properties for computational modeling [14].

Given that both qMRI metrics and material properties are governed by AC structure and composition, qMRI may allow for non-invasive estimates of material properties. However, previous studies have revealed confounding results with correlations between commonly measured qMRI metrics (i.e., T_{1Gd} and T_2) and cartilage material properties varying widely from weak to strong [4,5,10-12]. Thus, more recently developed qMRI techniques may allow for more accurate estimates of cartilage material properties. Given the promise of mcDESPOT, the aim of this study is to evaluate the association between mcDESPOT metrics (i.e., F_{PG} and T_2) and macroscale AC material properties.

METHODS

In this study, location-specific F_{PG} and T_2 values were correlated with AC mechanical properties (Fig. 1). Acquired tissue samples underwent mechanical testing for macroscale mechanical properties. The associations between material properties and qMRI mapping values

Fig. 1. Overview of methods to correlate qMRI parameters with material properties.

were evaluated using Pearson correlation coefficients.

TISSUE ACQUISITION. Frozen human cadaveric knees were obtained through Science Care, Inc. (Phoenix, AZ) with selection criteria including individuals less than 60 years of age; body mass index less than 25 kg/m²; no prior history of knee injuries, pain, or arthritis; and no prior knee surgeries. After acquisition, specimens were frozen at -20°C. Samples were thawed and patellae were removed for imaging.

QUANTITATIVE MR IMAGING. Baseline scans of cadaveric patellae were acquired using the mcDESPOT sequence on a 3.0 T scanner (Discovery MR750; GE Healthcare, Waukesha, WI) using an

In vivo MRI Precision 8 Channel Wrist Array Coil (GE Healthcare, Waukesha, WI). Patellae were submerged in DPBS with protease inhibitors throughout imaging. F_{PG} and T_2 were calculated [14]. Following sample dissection, patellae were reimaged to determine regions of interest (ROIs). MatrixUser (Fang Liu, University of Wisconsin-Madison, Madison, WI) was used to first segment bone from AC in baseline MR images. This mask was used to register the baseline qMRI and post-dissection morphological MR images using Elastix (University Medical Center Utrecht and contributors). ROI-specific qMRI values were found by segmenting plug ROIs on the qMRI maps.

MECHANICAL TESTING. Cylindrical samples (6 mm diameter) were removed from the resected cartilage surfaces and frozen at -20°C . Sample thickness was measured using a current-based micrometer. Mechanical testing was conducted on a tabletop test machine with a 1000 g load cell (TA Instruments 3230-AT, New Castle, DE). Twenty-three samples from 5 human cadaveric patellae were tested. Samples were loaded between two glass platens. Samples were tare loaded to 3 g for 5 minutes, then axially loaded at 1 Hz to 10% engineering strain for 10 cycles. Data were processed using MATLAB (MathWorks, Natick, MA). The loading stress-stretch curve was fit to an exponential (Eq.1), with the derivative providing the tangential modulus at zero strain (Eq. 2):

$$\sigma = A(e^{B(\lambda-1)} - 1) \quad (1)$$

$$d\sigma/d\lambda|_{\lambda=1} = AB \quad (2)$$

Where A and B are material constants, σ is 1st Piola-Kirchhoff stress, and λ is stretch. Dissipated energy per cycle was calculated as the area between the loading and unloading stress-strain curves using trapezoidal numerical integration.

STATISTICAL ANALYSIS. Pearson correlation coefficients were calculated between the material properties and mcDESPOT metrics with statistical significance defined as $p < 0.05$. Correlations were split into the following groups: strong ($0.5 < |R| < 1.0$), moderate ($0.3 < |R| < 0.5$), weak ($0.1 < |R| < 0.3$), and very weak or none ($0 < |R| < 0.1$).

RESULTS

High-resolution T_2 and F_{PG} maps were acquired for patellar cartilage (Fig. 2). Mechanical properties and qMRI were correlated (Fig. 3). F_{PG} was strongly correlated with both initial modulus and dissipated energy (Fig. 3A, C). T_2 was moderately correlated with both initial modulus and dissipated energy (Fig. 3B, D).

Fig. 2. Representative qMRI maps across patellar AC. The articular surface is down, lateral is to the left.

DISCUSSION

The purpose of this study was to evaluate correlations between mcDESPOT metrics and bulk mechanical properties. The strength of correlations between qMRI and mechanical properties in this study was consistent with previous literature. Our findings indicate improved correlations between qMRI mapping values and mechanical properties over previous non-contrast methods, but weaker correlations compared to contrast-enhanced MRI. Correlations between T_2 and mechanical properties have varied from poor to strong strengths. While some studies found weak to moderate strength correlations between various mechanical properties such as Young's, equilibrium, and instantaneous

Fig. 3. Correlations between mechanical properties and qMRI for initial modulus versus F_{PG} (A), initial modulus versus T_2 (B), dissipated energy versus F_{PG} (C), dissipated energy versus T_2 (D).

moduli ($0.1 < |R| < 0.5$) [5,10,11], others found strong correlations with Young's modulus ($0.70 < |R| < 0.80$) [4,12]. The correlations in the present study between material properties and T_2 are consistent with these previous studies. In comparison to $T_{1\rho}$, the strength of correlations with both T_2 and F_{PG} indicates that contrast-enhanced imaging may provide more accurate estimates of AC material properties as compared to non-contrast enhanced MRI. $T_{1\rho}$ correlations range from weak to strong between Young's, equilibrium, and instantaneous moduli ($0.03 < |R| < 0.81$) [4,5,10,12], stronger than correlations with non-contrast enhanced parameters.

Interestingly, correlations between F_{PG} and material properties were stronger than correlations between T_2 and material properties. Previously, F_{PG} has been shown to be strongly related to PG content [15,16]. Thus, the strong correlations likely reflect the influence of PGs on both the modulus and dissipative capacity of cartilage. Overall, these results suggest that mcDESPOT offers an improved method versus T_2 alone for contrast-free estimation of cartilage material properties.

In conclusion, this study successfully leveraged a novel non-contrast enhanced MR modality that correlates well with mechanical properties. Correlations can be used to provide mechanical context for mcDESPOT-based evaluation of cartilage health, or for computational modeling with subject-specific cartilage material properties.

CHARACTERIZATION OF SHEAR WAVE SPEED-STRESS RELATIONSHIP IN COLLATERAL LIGAMENTS

Jonathon L. Blank (1), Joshua D. Roth (1), Darryl G. Thelen (1,2)

INTRODUCTION

Dissatisfaction rates after total knee arthroplasties (TKAs) exceed 18%, amounting to 700,000 patients per year [1][2]. Overly tight collateral ligaments, which can contribute to pain and stiffness, are often linked with patient dissatisfaction [3][4]. Therefore, collateral ligament tension is an important mechanical variable that affects surgical outcomes. Surgeons are currently reliant on indirect subjective approaches, e.g. laxity testing, for balancing collateral ligaments in the operating room. We are investigating the use of shear wave tensiometry to directly assess ligament tension, and thereby enable surgeons to more objectively position TKA components.

Shear wave tensiometry is a non-invasive approach for gauging axial stresses in soft tissues. Our prior work has shown that shear wave speed squared is proportional to applied stress in tendons [5]. The purposes of this study were to (1) determine if the shear wave speed-stress relationship extends to ligaments, and (2) compare load-dependent wave speeds between the lateral and medial collateral ligaments (LCL and MCL), which exhibit substantially different geometries.

METHODS

Three lateral and three medial collateral ligaments were collected from large (>120 kg) pigs. Collateral ligaments from large pigs have been previously shown to have an axial loading response similar to that of human collateral ligaments [6]. Each ligament was isolated by removing proximal and distal bone blocks, with ligament-bone insertions left intact. Once secured in aluminum cups using a potting material, the ligaments were subjected to a cyclic load using an electrodynamic testing system (MTS Systems Corporation, Eden Prairie, MN). After pre-conditioning (50 seconds of cyclic loading

between 30 and 300 N at 1 Hz), the specimens underwent 10 loading cycles from 30 to 300 N at 1 Hz. During loading, shear waves were excited in each ligament using a piezoelectric actuator to impulsively tap the ligament. Transverse tendon velocity was measured using laser vibrometers (Polytec, Inc., Irvine, CA) at two points spaced 5 mm apart (Fig. 1). Ligaments were kept moist and intact during the testing

Figure 1: Shear wave speeds were captured using laser vibrometers and a piezoelectric tap applied transversely to the ligament (left). Shear wave speed (c) is measured using the time delay between two successive laser vibrometer velocity signals.

procedure. Three cyclic loading trials for each specimen were analyzed for the purpose of this study, accounting for a total of nine trials for each type of collateral ligament.

For each tap, the induced shear wave speeds were computed by measuring the time delay between arrival of the wave at the two successive laser points (Fig. 1) [5]. Average axial stresses during the loading were computed by approximating the cross-section of the LCL as an ellipse and the cross-section of the MCL as a rectangle. The average cross-sectional areas were 13.6 mm² for the LCL and 19.4 mm² for the MCL.

Stress and wave speed data were grouped according to ligament type (i.e. LCL or MCL) for analysis. For each ligament type, linear regression was conducted with the stress as the independent variable and the squared wave speed as the dependent variable. A follow-up regression was performed to determine whether the intercept and slope of the squared wave speed-stress relationship were different between ligament types. This follow-up regression included data from both ligament types (Y_i, X_i), an indicator variable for ligament type (D_i), and an interaction term ($X_i D_i$) (Eq. 1).

$$Y_i = \alpha + \beta X_i + \gamma D_i + \delta(X_i D_i) + \varepsilon_i \quad (1)$$

RESULTS

The average squared wave speed of both the LCL and MCL increased monotonically as the axial stress in the ligament was increased (Fig. 1). There were moderately strong linear relationships between squared shear wave speed and stress in both the LCL and MCL ($R^2 = 0.67$ and 0.65 , respectively). The slope of the linear fit was significantly greater in the MCL ($2.15 \text{ m}^2/\text{s}^2/\text{kPa}$) than in the LCL ($1.87 \text{ m}^2/\text{s}^2/\text{kPa}$), ($p < 0.0001$). However, there was not a significant difference between the intercepts of these two regression fits ($p = 0.7$).

Figure 2: Squared wave speed and stress relationship for the lateral and medial collateral ligaments (LCLs and MCLs). Plotted are the mean (\pm s.d.) wave speeds within 1 MPa bins. The dashed lines indicate the linear fits determined from each regression that included data from all three LCL/MCLs.

DISCUSSION

Our study shows that ligament shear wave speed increases with axial stress in a predictable manner. This observation suggests it may be

feasible to use shear wave tensiometers [5] to gauge ligament tension, and thereby enable surgeons to more objectively balance ligament loads in TKA procedures.

We did observe a slight difference in the slope of the squared wave speed-stress relationship between the LCL and the MCL, with the MCL exhibiting higher wave speeds at a given stress. This difference may be attributable to the differing cross-sectional geometries of the ligaments. The MCL has a sheet-like cross-section which can give rise to a non-uniform distribution of axial stress across its width. This non-uniformity creates local regions of fibers that are at a higher axial stress than the average axial stress used in this study. Therefore, it is possible that the higher wave speeds measured in the MCL were indicative of this higher localized stress. In contrast, the LCL has a rope-like cross section, which should lead to a relatively uniform axial stress across its width and a local stress similar to that of the average stress.

Shear wave speeds at low loads were similar between the two ligaments. This result might be attributable to the direct dependence of wave speed on material properties (specifically the tissue shear modulus and effective density) in an unloaded state [5]. Both the LCL and MCL are ligamentous bundles of collagen fibers oriented in the direction of loading, and thus may be expected to have consistent material property values across different specimens.

The precise nature of the wave speed-stress relationship in ligaments did differ from that previously seen in tendons. In particular, we observed higher wave speeds in ligaments than tendons at a given stress. This result may, in part, be attributable to different wave speed measurement approaches. Our prior study used high frame rate ultrasound to measure the vibration frequency of standing waves in axially loaded tendons [5]. In contrast, this study used laser vibrometry to measure the arrival time of transient waves in ligaments. There were also slight differences in boundary conditions. Tendons were isolated and fixed in clamps [5], whereas this study retained the ligament-bone insertions to better reflect *in situ* conditions. We are continuing to investigate how these experimental factors may influence the measurement of wave propagation in tissues.

The findings of this study suggest that human collateral ligaments with dissimilar geometries may exhibit different shear wave speeds, and thus stresses, under the same axial load. Moving forward, results from this study can be used to better interpret stresses in collateral ligaments from *in situ* shear wave speed measurements. Overall, these findings motivate the further development of an intraoperative sensor to guide ligament balancing in total knee arthroplasties with the ultimate goal of improving surgical outcomes and patient satisfaction.

ACKNOWLEDGEMENTS

This project was funded with continued support from NIH (EB024957 and 2 T32 AG 213-27) and specimens were procured from the University of Wisconsin-Madison Department of Animal Sciences.

TRIBOCORROSION BEHAVIOUR OF METALLIC IMPLANTS: A COMPARATIVE STUDY OF COCRMO AND Ti6ALV4

Mihir V. Patel, Edward Cudjoe, Jae Joong Ryu

Mechanical, Industrial & Manufacturing Engineering Department
Youngstown State University
Youngstown, OH 44555 USA

INTRODUCTION

Prosthetic implantation has been successful to restore mobility and increase the function of the diseased joints [1]. Modular design of joint replacements are most widely used due to ease of anatomic customization [2]. However, the modular interface such as stem-head interface of total hip joint replacements (THR) as shown in Figure 1 is continually subjected to wear and corrosion. The bearing components of THR are usually made out of polymers, metals, and ceramics. Metal alloys such as titanium-alloys (Ti6Al4V) and cobalt-chromium-alloys (CoCrMo) have manifested their long useful life due to superior mechanical strengths and electrochemical stability during active articulations in human bodies [3].

Figure 1. Modular Total Hip Joint Replacement (THR)

Ti6Al4V has been chosen for an orthopedic implant material owing to its inertness in the biochemical environment with mechanical strengths. CoCrMo alloys exhibit its good chemical stability with superior mechanical properties as summarized in Table 1. The greater hardness of CoCrMo results in desirable wear resistance and the oxide layer effectively protect the surface from corrosion attack. However, previous clinical studies and in vitro simulations of tribocorrosion presented the contrary results, i.e. cobalt chromium implant surface showed higher wear rate than the titanium implant surface, despite higher hardness of cobalt chromium surface than titanium surface [3-4].

Table 1. Mechanical Properties of Ti6Al4V and CoCrMo

Materials	Yield Strength (MPa)	Ultimate strength (MPa)	Hardness (HRC)
Ti6Al4V (F136)	924	1000	33
CoCrMo (F1537)	958	1338	45

This tribocorrosion damage mechanism is a multifactorial process involving mechanical properties, loading conditions, and environment. Tribocorrosion of orthopedic implants is a crucial issue and has been found to significantly limit the useful life of the implants. Wear and fretting corrosion in artificial joints result in the formation of soluble and particulate debris that can migrate in locally or systemically and induce a cascade of inflammatory events that may ultimately result in bone loss (osteolysis) and subsequent implant failure [5]. It is evident that enhancing the durability and reliability of total joint replacements is a critical engineering problem that affects society and the economy. In spite of the widely appreciated magnitude of this problem, there remains a critical gap in the knowledge base that centers on the complex multifactorial damage mechanism of modular interfaces of implants. The current article reports the tribocorrosion of Ti6Al4V and CoCrMo to compare and understand the complicated process of the alloys. Findings from this research will help predict the overall life-cycle of metallic orthopedic implants under fatigue loadings at the modular joint replacements for the vast application for biomedical devices.

METHODS

Cyclic reciprocation of a 3mm-diameter spherical alumina pin (Nanovea, CA) was employed on the smooth implant alloys to simulate fretting fatigue motions at the modular interfaces. Reciprocating motion was performed at 1 Hz and 1800 cycles. The implant alloys were fabricated into rectangles to the final dimensions of W1.0mm x H2.54mm x L22.95mm using the electric discharge machining. The

1.0mm x 2.54mm surface was polished to the average roughness $R_a = 13.8$ nm and $R_a = 17.5$ nm for Ti6Al4V and CoCrMo, respectively. The alloys were exposed to phosphate buffer saline solution (PBS) during fretting contact to observe surface damage response accelerated by environmental corrosion. A custom-built liquid cell was manufactured and placed on the high resolution stage of Mechanical Tester (Nanovea, CA) to control reciprocating motions. Two different normal loads were applied to simulate elastic range fatigue contact at 143 mN and 300 mN. Open circuit potential (OCP) changes were monitored during cyclic reciprocations of the alumina sphere. Potentiodynamic polarization resistance (PPR) were measured to identify corrosion responses without mechanical stimuli through the potential range from -1 V to 1.5 V with a slow scan rate 0.2 mV/s. Saturated calomel (reference) electrode was immersed in the PBS electrolyte. The alloy sample (working electrode) and platinum wire (counter electrode) were connected to potentiostat controller (Gamry Instruments, PA). The experimental apparatus was represented in Figure 2.

Figure 2. Schematic of the fretting corrosion test system

RESULTS

Open circuit potential measurements were performed in a sequence of (1) dwell: exposure in PBS for 10 min without fretting; (2) fretting corrosion: rubbing in PBS for 30 min; and dwell: again exposing in PBS after fretting was ceased. Ti6Al4V surface showed two stages of oxide recovery. Shortly after sliding contact was initiated, the potential decreased sharply and in the midrange of the sliding potential was gradually decreased at both high and low normal loads. However, CoCrMo potentials continuous increased and the oxide recovery finally began after the fretting was ceased. Ti6Al4V presented the more load sensitive behaviors. The potential change with the greater normal load at 300 mN was doubled compared to potential change with 143 mN, while CoCrMo fretting corrosion responses depicted the comparable potential change with both levels of normal loads. Therefore, it described that the electrochemical enhancement of titanium oxides would be superior to that of chromium oxides.

Figure 3. OCP measurement for Ti6Al4V and CoCrMo at different contact normal loads

Table 2 summarized the parameters from dynamic polarization curves presented in Figure 4. The higher current density of CoCrMo would indicate rapid initiation of corrosion process of CoCrMo in the most of the potential. The lower corrosion current (I_{corr}) of Ti6Al4V indicates that the corrosion rate of the surface without fretting is less

than corrosion rate of CoCrMo. Therefore, it was elucidated that Ti oxide provides more protection than Cr oxide from corrosion attack [6].

Table 2. Parameters from potentiodynamic polarization curves

Materials	I_{corr} (A cm^{-2})	E_{corr} (V)
Ti6Al4V (F136)	3.10E-7	-0.40
CoCrMo (F1537)	2.09E-6	-0.332

Figure 4. Potentiodynamic Polarization scan at 0.2 mV/s

DISCUSSION

The oxide layer on Ti6Al4V is more noble and lesser prone to corrosion when mechanical stimulus was combined with corrosion attack compared to CoCrMo surface. Ti6Al4V surface actively enhances the corrosion resistivity. Although CoCrMo possesses the superior mechanical properties with greater hardness and ductility, when the surface is exposed to a corrosive environment, the electrochemical damage was accelerated. However, the rapid passivation of Ti6Al4V illustrated the fast oxide layer reformations even during the active fatigue sliding contact. The greater normal contact loads would induce more significant electrochemical damage on Ti6Al4V. Figure 5 summarizes that the damage process would be by the competition between deteriorative mechanical abrasion and atomic dissolution and beneficial enhanced passivation by residual strains [7].

INTRODUCTION

Sclera biomechanics are intimately tied with diseases such as glaucoma and myopia [1, 2]. Hence, there has long been an interest in developing constitutive models of ocular tissues [3, 4]. These models, however, do not explicitly incorporate some key aspects of the tissue microstructure, such as the fiber waviness or crimp (Figure 1). As collagenous tissues, their biomechanics are dependent on the underlying fibers, and in particular their waviness or crimp [1, 5]. Using polarized light microscopy, we recently reported that collagen crimp tortuosity in human sclera decreases significantly with age [1]. It is important to understand how the decreased crimp tortuosity influence the mechanical response of the eye to elevated IOP.

Our goal was to incorporate the microstructural information of collagen fibers into a constitutive model and to derive the stiffness of collagen fibers and the surrounding matrix. We subsequently examined the effects of aging on the derived mechanical properties.

Figure 1: Wide-field view of the limbus region using polarized light microscopy (adapted from Jan et al. [1]). The wavy pattern of the collagen fibers is clearly discernible. The close-up images show the periodic waviness analyzed in this work.

METHODS

Overall method strategy: using polarized light microscopy, we imaged axial whole-globe sections of human eyes. Collagen crimp morphology in the posterior sclera was quantified through tortuosity. The tortuosity was incorporated into a microstructure-based constitutive model. By fitting the experimentally measured stress-stretch curve in the same scleral region [6], we then derived the age-dependent stiffness of collagen fibers (C_5) and the surrounding matrix (C_1).

Age-dependent collagen crimp in the posterior sclera: following Jan et al. [1], we analyzed 7 axial whole-globe sections from 3 normal eyes of 3 human donors, with 40, 72 and 97 years old, respectively. Sections were imaged using polarized light microscopy at a resolution of $0.73 \mu\text{m}/\text{pixel}$. We quantified collagen fiber tortuosity in the posterior sclera. The distribution of crimp tortuosity for all three age groups is shown in Figure 2.

Figure 2: Boxplots of collagen crimp tortuosity in the posterior sclera of the three human eyes donors analyzed.

Collagen microstructure-based constitutive model: the mechanical response of the sclera were modeled using a fiber-based constitutive equation of the form

$$W = W_{fiber} + W_{matrix} \quad (1)$$

where W is the total strain energy density, W_{fiber} is the strain energy density of the collagen fibers, and W_{matrix} is the strain energy density of the surrounding matrix.

The strain energy density equation for the collagen fibers was modeled using the form [3]

$$\lambda \frac{\partial W_{fiber}}{\partial \lambda} = \begin{cases} 0 & \lambda \leq \lambda_m \\ C_5(\lambda - \lambda_m) & \lambda > \lambda_m \end{cases} \quad (2)$$

where λ_m is the collagen crimp tortuosity, λ is the fiber stretch, and C_5 is the stiffness of the straightened fibers.

The strain energy density equation for the surrounding matrix was modeled as a Mooney-Rivlin solid which has the form

$$W_{matrix} = C_1(I_1 - 3) + C_2(I_2 - 3) \quad (3)$$

where C_1 and C_2 are material constants defining the stiffness of the matrix and I_1 and I_2 are the first and second invariants of the right Cauchy-Green deformation tensor (non-directional measures of material deformation). In this work, C_2 was set to zero which is analogous to a neo-Hookean formulation.

RESULTS

Figure 3 shows the age-dependent stress-stretch curves of the posterior sclera predicted by our collagen microstructure-based constitutive model and by the inflation test experiments reported by Coudrillier and colleagues [6]. The derived stiffness of the collagen fibers and of the surrounding matrix with aging are shown in Figure 4.

Figure 3: Age-dependent stress-stretch curves of the posterior sclera predicted by our collagen microstructure-based constitutive model simulation (dashed lines) and by the inflation tests (solid lines) [6]. The measured nonlinear stress-stretch behavior of the posterior sclera and the stiffer response with aging were captured well by our collagen microstructure-based constitutive model.

Figure 4: Model-predicted stiffness of collagen fibers (top) and the surrounding matrix (bottom) with aging. With aging, the stiffness of the collagen fibers increased linearly, and the stiffness of the matrix increased exponentially.

DISCUSSION

Our goal was to incorporate the experimentally-derived microstructural information of collagen fibers into a constitutive model and to derive the stiffness of collagen fibers and the surrounding matrix. We then further examined the effects of aging on the derived mechanical properties.

Our collagen microstructure-based constitutive model predicted a nonlinear stress-stretch behavior of the posterior sclera at three ages, consistent with the experimental measures [6]. Note that the fiber stiffness is at least one order of magnitude larger than the matrix stiffness. As a result, the tissue-level stiffness should be dominated by the stiffness of collagen fibers. Importantly, in our constitutive models, the collagen fibers were assumed as linear elastic. The predicted nonlinear stress-stretch behavior of the posterior sclera is caused by the process of fiber recruitment based on the tortuosity. To the best of our knowledge, this is the first report of the use of microstructural properties to derive a nonlinear stress-stretch behavior of scleral tissue.

We also found that the stiffness of collagen fibers increased linearly, and that of the matrix increased exponentially with aging. Similar stiffening effects of collagen fibers with age have been reported in the literature for the cornea [7] and the sclera [8, 9] using various experimental techniques. However, the effect was attributed to the accumulation of nonenzymatic glycation-type cross-links with aging [10]. Inverse models have also been used to suggest age-related changes in sclera properties, including compliance and fiber crimp.[11] Those findings, however, were based on experimental measurement of deformations, without direct measurements of crimp. Unfortunately, no studies yet have measured the stiffness of the matrix and its changes with aging. Further studies are necessary to elucidate the causes for matrix stiffening and its potential role in eye physiology and pathology.

In summary, we incorporated the experimental microstructural information of collagen fibers into a constitutive model and then derived the age-dependent stiffness of collagen fibers and the surrounding matrix of the posterior sclera. Findings from this work can help reveal the role of microstructure on eye physiology, in aging, and in biomechanical-related diseases, such as glaucoma.

INTRODUCTION

Platelets are fundamental to maintaining the integrity of the cardiovascular system. Despite and/or because of their efforts, cardiovascular-related disease is the leading cause of death in the developed world, through heart attack and stroke often resulting from platelet responses to non-physiological hemodynamic environments. Limited understanding of the mechanisms behind platelet biophysics that lead to binding, activation, and spreading further limits the ability design blood-contacting devices without inducing a thrombotic response. To mitigate these risks, patients with current generation blood-contacting devices are treated with systemic anticoagulant and antiplatelet therapies that must be carefully modulated to avoid bleeding complications. Under high flow, however, these therapies exhibit limited efficacy, and can have serious side effects leading to drug-related deaths. Lastly, platelet function is tightly linked to bleeding disorders, e.g. Gray platelet syndrome, of which the cause of many have yet to be explained. Overall, platelets play a key role to the health of our cardiovascular system.

At the core of these platelet responses, is an ability to sense and respond to their mechanical environment through chemical signaling. This ability, known as mechanotransduction, is critical to many fundamental cell functions. However, unlike many other cells, the area of platelet biophysics has received limited attention, with most focus on the study of platelet-surface interactions and the proteins are involved. However, these studies do not provide an explanation for how platelets respond under flow or how they actively respond to mechanical forces. In our recent work, we found a decision-making process in platelets that appears to be force dependent, where platelets choose to both bind and spread or to detach.

By developing a computational model of platelet biophysics, combined with key experiments, it will be possible to identify dominant

biophysical pathways that platelets use to sense surrounding forces in the context of flow and their binding substrate. Results may help in the design of medical devices like blood pumps, artificial heart valves, stents, et cetera. Better understanding of when and how platelets bind can lead to discovery of currently unused targets in biophysical pathways, which can be used for the development of novel antiplatelet therapies, while possibly helping us to understand and treat unexplained bleeding disorders.

METHODS

Model - A stochastic model was made to show platelet binding to a stiff surface. The model is a modified version of the one proposed by Bangasser et al. 2017 [1]. The model has been modified to more accurately depict the activation of integrin $\alpha_{IIb}\beta_{III}$ and subsequent platelet spreading. Additional forces were added to the model simulating flow conditions. Parameters for the model were collected from the literature and through platelet experiments described below. Finally, a sensitivity analysis was performed to determine what characteristics of a platelet play a key role in force sensing

Platelet Isolation - Whole blood was collected with written consent and IRB approval into 5ml Monoject blood collection tubes with 0.5ml 3.5% buffered sodium citrate (Covidien LLC, Mansfield, MA). Acid-Citrate-Dextrose and Apyrase (New England Biolabs Inc., Ipswich, MA) was further added. Platelets were resuspended into Tyrodes-Albumin Buffer (TAB) after 2 centrifugation steps with PGI₂ (Cayman Chemical Company, Ann Arbor, MI). The final platelet concentration was checked using a Hemavet hemocytometer (Drew Scientific, Miami Lakes, FL) and was adjusted to 3×10^8 with the addition of more TAB.

Retrograde Flow - Actin retrograde flow is the flow of actin towards the granulomere, which is caused by elastic resistance of the

cell membrane to the extension of the actin fiber. This value is measured for a more complete picture of the internal forces acting on a platelet as it spreads. This was determined by allowing washed platelets to spread on a fibrinogen (an $\alpha_{IIb}\beta_{III}$ counterreceptor) coated surface, with the subsequent addition of a solution containing fibrinogen-coated 1 micron diameter beads (Invitrogen). The rate at which a bead moved along the platelet body was determined.

Spreading Validation - To confirm rate of $\alpha_{IIb}\beta_{III}$ usage, and quantify actin polymerization and filopodial growth, isolated platelets were placed on glass coverslips with and without fibrinogen at different concentrations of fibrinogen. Image series were taken covering the full length of spreading, from the landing of the platelet on the surface until spreading had completed. The spread time was calculated, and the rate of spreading found.

Flow in Whole Blood - Once the model was validated for static conditions an additional force was added to simulate flow conditions. This was subsequently verified experimentally by flowing whole blood at a known shear rate in a microfluidic device containing a strip of fibrinogen. The created tether was monitored to determine growth rate and break point or time to fully spread, depending on the applied shear.

RESULTS

Platelets spread at a rate of 14.6 ± 3 nm/s, reaching a fully spread state at 296 ± 8 s. This spreading rate validates actin polymerization and $\alpha_{IIb}\beta_{III}$ -fibrinogen kinetics. Total internal reflection fluorescence microscopy (TIRFm) was used to assess separation distance, Fig. 1. Beads on a spread platelet had a speed of 7.7 ± 1.7 nm/s and 7.7 ± 1.6 nm/s. Rate of retrograde flow increased in the presence of CK666, an inhibitor of actin assembly by actin-related protein Arp2/3 complex, and decreased in the presence of blebbistatin, which inhibits myosin II. In both cases, variability of retrograde flow increased. These results incorporate the rate of myosin contraction and retrograde actin polymerization, which are used to validate parameters in our model.

Figure 1: Left: Platelets binding to 100 µg/ml fibrinogen (labeled in purple) under flow with a wall shear rate of 600 s⁻¹. Middle: Platelets spreading with TIRFm images. Right: Retrograde flow bead tracks.

The rate of spreading as seen in the model was very similar to the found rate of spreading for platelets. With the additional force added to the model, the model spread rate and time were found to be like the median range of shear rates. At very high and very low shear rates the model did not match the experimental times.

DISCUSSION

Here, we present a model for platelet spreading under flow on elastic surfaces, with experimental validation. Based on parameters such as force of fluid flow, wall shear rate, actin extension rate and myosin contractile forces, we can predict platelet activity, including

clutch engagement rate. The combined results tell us net spreading forces, total platelet body movement per time point, and allow us to gain insight into overall platelet responses in static or flow conditions.

Figure 2: Model of actin cytoskeleton extension. 1) On and off rate of α_{2bb3} binding fibrinogen. 2) Myosin motor force, actin polymerization, and motor stall force. 3) Surface stiffness. 4) A_{2bb3} material properties, number of integrins, and bond rupture force.

Under static conditions, platelets attach and spread. However, under flow, platelets react differently, perhaps in a force dependent manner. Under flow, after initial binding via a discrete adhesion point, the platelet body will pull away in the direction of the flow, after which, they sometimes spread and sometimes detach. This model is designed to look at how flow changes adhesion based on forces acting on the platelet, and should work in both constant and pulsatile flows conditions.

Previous work has shown that under static conditions, as surface stiffness increases, so do the platelet contractile forces [2]. Our research supports this and suggests that the same principle is occurring under flow. However, flow can overcome these contractile forces, resulting in the extension of a platelet body into the flow direction, as a result of slipping 'biological clutches.'

This work is a preliminary assessment of a model for platelet spreading on surfaces. It will need to be expanded to incorporate more initial parameters, with the aim of giving us more complete output data, such as rate of spreading found from actin extension rate, platelet motility, found from platelet adhesion strength and surface stiffness.

Overall, we have developed a model that is providing insight into platelet active responses to changes in force based on kinetic binding rates, actin polymerization rates, and myosin contraction rates. Combined, this model and experiments provide a first step toward elucidating complex platelet responses under flow. Identification of these processes will provide new insight into potential targets for antiplatelet therapies to prevent heart attacks and stroke. They may also give us new insight into still unexplained bleeding disorders.

INTRODUCTION

Measurement of the force produced by individual muscles is critical for understanding muscle physiology, how body motion is produced and controlled, how injuries affect muscle function, and how body function is affected by muscle pathologies. However, measuring the force produced by individual muscles non-invasively remains an unmet challenge in biomechanics. The motion of most joints in the body is produced by the simultaneous action of several muscles. The resultant force (or torque) from the action of all the muscles crossing the joint can be measured using dynamometers (i.e., Biodex) or calculated from motion capture data. However, there are an infinite number of combinations of individual muscle forces that can result in the measured torque. Current attempts to estimate individual muscle force often require convoluted combinations of additional experimental modalities, theoretical models, and assumptions that may be valid only for specific muscle groups under specific conditions. Surface electromyography (sEMG) may be used to measure the activation of an individual muscle. However, calculating force from sEMG measurements requires the measurement of many other parameters and frequent calibration due to low signal-to-noise ratio, differences in tissue electrical properties among individuals, and surrounding conditions [1].

A major challenge in the study of the relationship between shear modulus and muscle force is the ability of measuring the force from a single muscle at the time. This cannot be done by voluntary muscle contraction since joint motion is typically produced by the simultaneous contraction of several muscles. Neuromuscular electrical stimulation (NMES) has been previously used to induce contraction of single muscles in-vivo [2]. NMES can be delivered using surface electrodes or acupuncture needles. The advantage of surface electrodes is the non-invasive nature of the procedure, while needles have a more localized

effect. The objectives of this study are to evaluate changes in the shear modulus of the *Tibialis anterior* (TA) muscle and the surrounding muscle in the lower leg when the TA is stimulated using NMES and to compare the two delivery methods (surface and needle electrodes). Results from this study can help determine whether the combination of NMES and Shear wave elastography can be used to analyze single muscle contraction.

METHODS

Six healthy participants (Four male and two female; Age 22.5 ± 1.378 ; BMI 24.85 ± 5.57) were recruited for this study. They were asked to lie down in a natural position on their back with their legs extended out. From the proximal end of the tibia, approximately 4 inches (~10.2 cm) and 6 inches (~15.2 cm) were measured and marked with a marker. Two acupuncture needles of 30 gauge and 30 mm in length were inserted at the marked spots. Similarly for the surface NMES procedure, two electrode pads were placed at the same location. The pads and needles were attached to the Electrical Muscle Stimulator (Quattro 2.5) device via NMES leads. The ultrasound transducer (Verasonics) was placed on the lower leg using the fixture. Figure 1 shows the initial setup for needle and surface NMES.

Figure 1: Initial Setup on the lower leg

Five unstimulated baseline values of shear wave speed for the top layer of the TA muscle were collected through the SWE method. The NMES device was then slowly ramped up to the maximum tolerable intensity (1 mA for needle and 40 mA for surface NMES) to contract the muscle at a frequency of 50 Hz and the duration of 300 μ s on a constant mode. Once stimulated, five shear wave speed values were collected once again from the top layer of the TA muscle. The procedure was repeated for the lower layer of the TA muscle. Additionally, the change in shear modulus of the *Peroneus Longus* (PL) muscle, the *soleus* muscle, and the *Tibialis Posterior* muscle was also collected during stimulation to verify that the surrounding muscles are not being contracted in this procedure by changing the position of the transducer on the lower leg and keeping the needles in at the same position. A short break was given between contractions to allow the patient to rest in order to avoid fatigue in muscles.

RESULTS

In the case of surface electrodes, the shear modulus of the TA and surrounding muscles increased as plotted in Figure 4. On average, the values of shear modulus increased from 11.96 ± 8.01 to 65.04 ± 122.37

Figure 2: B-mode and shear modulus color map (kPa) of the TA muscle (top), Soleus Muscle (middle), and the PL Muscle (bottom), before (left) and during (right) NMES

Figure 3: Graphical representation of the changes in shear modulus in the muscles using needle electrodes

Figure 4: Graphical representation of the changes in shear modulus in the muscles using surface electrodes

DISCUSSION

The results suggest that it is possible to stimulate a single muscle using needle electrodes. Conversely, the use of surface electrodes resulted in the stimulation of surrounding muscles, which is possible due to the larger surface area of the electrode pads. In the case of needle electrodes, the variability in the results could arise from factors, such as the depth of the needle and the placement of the needle. As it can be seen in Fig. 3, the lower (deeper) portion of the TA muscle experienced a smaller increase in shear modulus during electrical stimulation. This could be caused by inconsistent needle depth. Needles were placed following the typical protocol for electroacupuncture. However, the variability could still be present because the size of the TA muscle differs from person to person. Surface NMES produced a more intense contraction of muscle (higher modulus) probably due to the larger electrical current applied.

Several recent studies have suggested a linear relationship between individual muscle force and its shear modulus ($F-\mu$ relationship) during isometric muscle contraction. These measurements have been performed in the Abductor Digiti Minimi muscle, which is the only muscle producing little finger abduction torque. The Abductor Digiti Minimi is one of the few examples in the body of joint motion controlled by a single muscle. Therefore, the ability of experimentally measuring forces from individual muscles is instrumental for evaluating $F-\mu$ relationships in other muscles. Additionally, the mechanistic principles behind the $F-\mu$ relationship are presently unknown. For this reason, it is unknown why the proportionality constant of the $F-\mu$ relationship varies across muscles and across individuals, preventing *a priori* estimation of individual muscle force. $F-\mu$ relationship may be modulated by muscle pennation angle and muscle volume, which are important muscle properties playing a role in force production. The effect of muscle pennation angle and muscle volume on the $F-\mu$ relationship will be evaluated in future studies.

In conclusion, needle stimulation is a technique that allows studying the contraction of individual muscles using shear wave elastography. However, it seems to produce a lower intensity of muscle contraction.

INTRODUCTION

Recent studies have demonstrated high incidences of poor outcomes and implant failure in total ankle replacement patients [1]. Currently, no test methodology exists to sufficiently quantify the degree to which these implants replicate normal ankle mechanics during the dynamic activities of daily living. Quantifying these responses are key to understanding how these implants affect foot and ankle function, and how future implants can be improved. Biomechanics research on living subjects is limited to what can be measured non-invasively. Consequently, post mortem human surrogates (PMHS) remain the gold standard for human biomechanical measures. Nevertheless, PMHS lack the passive tone and muscle activation that drive the torque-generating muscle tension across the joints of the foot and ankle during gait. In an effort to address this shortcoming, several research groups have developed robotic gait simulators that allow dynamic muscle forces to be applied to the foot during gait [2,3]. This study demonstrates the capability of a six degree-of-freedom robotic gait simulator design capable of applying full body weight (BW) at near-normal gait speeds with real-time extrinsic muscle control, as well as its potential utility for investigating biofidelic foot and ankle dynamics.

METHODS

The major components of the robotic gait simulator are the serial robot, tendon actuators, coordinate digitizing arm, motion analysis system, and a six degree-of-freedom load cell (6-DoF) (Figure 1).

The 6-DoF position and force/torque controlled serial robotic test system was used to drive previously collected in vivo tibia kinematics. The PMHS specimen was affixed to the end-effector of the robot through rigid urethane potting at the proximal tibia. Prior to testing, multiple points on the PMHS limb were digitized and used to generate

a specimen-specific ankle coordinate system with respect to the robot's coordinate system.

Figure 1. a-c: a. Specimen before toe-off. b. Motion tracking data applied to simulate foot motion. c. Model of entire system.

Nine linear actuators were used to pull tension in each the following nine tendons: (1) Achilles, (2) Tibialis Anterior, (3) Tibialis Posterior, (4) Flexor Hallucis Longus, (5) Flexor Digitorum Longus, (6) Extensor Hallucis Longus, (7) Extensor Digitorum Longus, (8) Peroneus Longus, and (9) Peroneus Brevis. These tendons represent the largest contributors to gross foot and ankle motion, especially with regards to Plantarflexion and Dorsiflexion [4]. Muscle force time-

histories were generated based on percent activation and physiological cross sectional area.

The single PMHS right lower extremity used for the study was disarticulated at the knee from a 46-year-old donor (99.3 kg, 175.3 cm). Approximately 150mm of the proximal tibia was denuded to allow for connection to the end of the robot. Additionally, a 50 mm window of skin was removed from around the circumference of the ankle just above the medial malleolus in order to expose the tendons of each of the extrinsic muscles inserting in foot. Each actuator was then affixed to its respective tendon using polyester surgical thread by means of a Krakow stitch. By virtue of the very high tension required, the Achilles was attached using a custom aluminum cryoclamp. Retroreflective motion tracking arrays were attached to the following bones: tibia, fibula, calcaneus, talus, navicular, cuboid, first metatarsal, and fifth metatarsal.

Four body weight (BW) conditions were tested: 25%, 50%, 75%, and 100%. For each BW, a target ground reaction force (GRF) time-history was used to optimize the tibialis anterior force during heel strike, superior position of the tibia during midstance, and Achilles force during toe-off. Each BW condition had 8-12 optimization runs, with 3 experimental runs each. Testing took place over the course of 4 days.

Figure 2. Actual and Desired GRF Target

Data collected can be separated into two main categories, force and moment data from the walking platform, and bone kinematics from the motion tracking arrays. Platform load cell data is reported in the ankle coordinate system and did not require substantial post processing.

Marker arrays were digitized in a pretest CT scan along with the rest of the specimen in order to establish a rigid body transformation between each marker array and its respective bone. During testing, a laboratory reference frame was established using motion-tracking targets attached to the plane of the walking platform. All of the motion capture data is reported in this lab reference frame, with the anterior direction being +X, medial direction being +Y, and superior direction being +Z. Using the established transformations, motion-tracking trajectories are applied to all of the marker arrays and their bones, respectively.

RESULTS

The robotic gait simulator imposed known tibia kinematics from previous human volunteer gait data, as well as estimated extrinsic muscle force time-histories [3] on a PMHS lower extremity. Vertical displacement was modulated according to observed GRF to represent the effects of different body weights during gait.

The system was able to trace the GRF approximately within 10% of the input target (Figure 2). Increasing body weight led to observed changes in global foot kinematics. The calcaneus everted 6 degrees under 100% BW versus only 2 degrees for the 25% BW trial. Likewise, the navicular was observed to compress 18 mm inferiorly toward the ground plate during the 100% BW, while only compressing 15 mm under 25% BW (Figure 3).

Figure 3. [TOP] Drop in longitudinal arch height as measured by Z excursion of the navicular. [BOTTOM] Change in hindfoot varus/valgus as measured by rotation about calcaneus x axis.

DISCUSSION

The robotic gait simulator was able to reproduce gait-like motions of a PMHS lower extremity. Ground reaction forces and tibia kinematics from living subject 3D motion tracking were accurately reproduced. Further, the gross motion of the foot was consistent with translations and rotations reported in the literature [5]. As we were interested in understanding the effect of body weight on foot function, the relative motions of the calcaneus and navicular were of particular interest. For increasing levels of axial load, it was observed that the hindfoot had increasing amount of valgus tilt (negative rotation about the x-axis). Likewise, increasing load led to the centroid of the navicular moving inferior (negative translation in the z-axis). These trends are consistent with those reported previously for living subjects and are characteristic of the longitudinal arch of the foot spreading and compressing with every larger amounts of axial loads [5].

The 100% BW trials deviated during toe-off from the expected trends. This was due to the foot sliding posteriorly during toe-off, suggesting that the imposed anterior-posterior (AP) and medial-lateral (ML) tibia kinematics needs to be tuned during optimization runs to match human volunteer gait data.

Further specimens are needed to investigate whether or not these trends are consistent. Additionally, further investigation into mitigating shear AP and ML sliding of the foot, as well as improving the optimization scheme to reduce the approximately 10% model error.

In order to improve clinical outcomes, implants must be better at replicating the complex characteristics of the dynamic activities of daily living. This system represents the first step towards integrating all necessary components, muscle effects, positional effects, and dynamic effects to replicate precise in vivo bony kinematics.

INTRODUCTION

Muscular impairments are at the heart of numerous orthopaedic and neurological conditions. However, rehabilitation protocols for these conditions are generally not subject-specific and the results of the protocols can be mixed [1]. Neuromusculoskeletal (NM) models may improve rehabilitation effectiveness by allowing researchers and clinicians to evaluate the proposed intervention on a computational model of the subject prior to beginning rehabilitation. Neuromusculoskeletal models' accuracy have traditionally been evaluated on their ability to match calculated joint inverse dynamics loads. However, due to the muscle redundancy problem (more muscles than degrees of freedom), there are infinite combinations of muscle forces that produce the same joint moments. Therefore, matching inverse dynamics moments does not guarantee that the individual muscle force predictions are accurate. This is a challenge if muscle force predictions are to be used to make rehabilitation decisions.

Intramuscular pressure (IMP) is the interstitial fluid pressure within a muscle. Animal studies have shown IMP to have high correlations with muscle force [2]. Therefore, IMP provides a minimally invasive opportunity to verify muscle force predictions from neuromusculoskeletal models.

This study examined the effect of four muscle models on the correlation between predicted muscle force and IMP. These muscle models were included in a subject-specific neuromusculoskeletal optimization. This study is one of the first studies in humans to assess the accuracy of muscle force predictions from musculoskeletal models.

METHODS

Prior to participation in this study, the subject signed informed consent documents approved by the Mayo Clinic Institutional Review Board. The subject was a 26-year old female (height: 174.3 cm, weight: 62.8 kg). The subject laid on her back with her foot secured to a custom

torque cell dynamometer. In order to isolate ankle plantar/dorsiflexion as the single degree of freedom the subject's ankle axis was aligned with the axis of the dynamometer. Additionally, a wooden block was inserted under the subject's foot to invert the subject's foot 20°. This isolated the subject's tibialis anterior as the sole plantarflexor by reducing other plantarflexor muscles' ankle flexion moment arm. Surface EMG electrodes were placed over the tibialis anterior, soleus, medial gastrocnemius, and lateral gastrocnemius. A fine-wire EMG electrode was inserted into the tibialis anterior. Finally, a fiber-optic IMP sensor was inserted into the tibialis anterior parallel to the muscle fibers. The subject performed 21 total trials. The trials were three dorsiflexion Maximum Voluntary Contractions (MVCs) in each of three positions: with the foot dorsiflexed 5°-10°, in a neutral position, and plantarflexed 20°; three ramp to max effort trials in the same three positions; and finally, three plantarflexion MVC trials in the neutral position. The plantarflexion MVC trials were necessary to calibrate ankle plantarflexor muscles in the neuromusculoskeletal model. Each trial was cut to reflect the time from 250 ms before the onset of ankle torque to the maximum torque. The 250 ms buffer was added to account for the electromechanical delay. Trials were removed from consideration if there was a significant negative region in the IMP (possibly indicating cavitation) or if there was a sudden spike in the IMP greater than the max in any other trial.

The neuromusculoskeletal model used in this study is a modified version of a previously published EMG-driven model can optimize parameters for subject-specificity. The optimizable parameters are EMG to activation parameters, tendon slack length, ideal fiber length, muscular geometry, and tendon compliance if a compliant tendon model was used. The model's cost function encourages agreement with measured joint inverse dynamics loads and generic moments generated

by passive muscle force as reported in literature. Finally, a term that encouraged agreement between muscle force predictions and measured IMP could be turned off and on. The model was reduced to nine muscles and two degrees of freedom (ankle plantar/dorsiflexion and subtalar rotation). To avoid local minima in the optimization, six optimizations were performed alternating between optimizing the EMG to activation parameters; tendon slack length, ideal fiber length, and tendon stiffness in the compliant tendon case, and muscle geometry. Finally, all parameters were adjusted at once to conclude the optimization.

Four muscle models were used in this study: rigid tendon with one fiber type, rigid tendon with fast and slow twitch fibers, compliant tendon with one fiber type, compliant tendon with fast and slow twitch fibers. Compliant tendon models were based on Millard et al [2]. Models with fast and slow twitch fibers were based on Wakeling et al [3].

RESULTS

Tables 1-3 present the results of the four optimizations. In general, subject-specific parameters led to higher force predictions-IMP correlations than the initial generic neuromuscular parameters. Additionally, important features of the IMP curves were captured in the predicted forces (Figure 1).

Two-fiber type muscle models had higher correlations with the measured IMP than their matched single fiber muscle models. However, two fiber type models had worse moment matching results than their matched single fiber type models. Results were mixed when comparing rigid tendon muscle models to compliant tendon models. The rigid tendon model performed better when a single fiber was used while the compliant tendon model led to significant improvement when two muscle fibers were used.

Adding a term to the cost function that encouraged higher correlation between predicted muscle force and measured IMP predictably led to higher correlations. However, this optimization also improved moment matching results. While the improvements were minor for rigid tendon models, significant improvement was observed for compliant tendon models.

Table 1: Performance of Muscle Models Blinded to IMP

	Initial R ²	Final R ²	RMS (Nm)	MAE (Nm)
Rigid Single Fiber	0.8307	0.8518	4.196	3.1527
Rigid Two Fiber	0.8524	0.8707	5.9331	4.3889
Compliant Single Fiber	0.8317	0.8211	4.6499	3.7353
Compliant Two Fiber	0.8542	0.8689	5.0139	3.7977
Performance of Muscle Models are Aware of IMP				
Rigid Single Fiber	0.8307	0.8621	4.1765	3.1509
Rigid Two Fiber	0.8524	0.8769	5.925	4.349
Compliant Single Fiber	0.8317	0.8556	4.3351	3.2713
Compliant Two Fiber	0.8542	0.8747	4.9922	3.752
Percent Improvement in IMP-Aware vs. IMP-Blind Case				
Rigid Single Fiber	-	1.2%	0.5%	0.1%
Rigid Two Fiber	-	0.71%	0.1%	0.9%
Compliant Single Fiber	-	4.2%	6.8%	12.4%
Compliant Two Fiber	-	0.7%	0.4%	1.2%

DISCUSSION

All muscle models had high average correlations between predicted force and measured IMP. This indicates that while there are

infinitely many muscle force solutions, EMG-driven neuromusculoskeletal models can accurately predict muscle forces.

Figure 1: Agreement between scaled predicted tibialis anterior force (red) and measured IMP (black)

This work presents evidence that a two-fiber type model more accurately reflects muscle force production than a single fiber type model. Two-fiber type models had 4% higher correlations with IMP than single fiber type models. This is remarkable because the only difference between the single-fiber and two-fiber models were that the fast and slow twitch fibers in the two-fiber models had separate activations and maximum contraction velocities. These led the two fibers to operate at different points on the force-velocity curve. This provides strong evidence that treating the electromyographic signal as a single signal is not bio-fidelic. Even small changes like assigning two maximum contraction velocities to the high and low frequency components of the EMG signal yielded significant improvements in muscle force matching. However, despite better muscle force matching, two-fiber type models had worse moment matching results than single fiber type models. This may be a result of EMG scaling problems. A single EMG scale term was used to scale both activations in the two-fiber models. At low levels of activation, like those in the antagonist movements used here, fast twitch fibers should be preferentially activated because of the low muscle force required. However, currently both EMGs are proportionally scaled up, leading to an underestimation of the joint moment. Future work will give each fiber separate EMG scaling factors. It is expected that at that point two-fiber models will have better moment matching than their matched single fiber models.

The higher correlations from the two-fiber type models suggest that for muscle producing significant force, a two-fiber type model more accurately represents muscle force production.

Finally, the table shows that adding a cost function term that encourages muscle force predictions to match IMP not only increases force-IMP correlations, but also improves moment matching. This improvement is most significant for compliant tendon models. This supports the idea that IMP is a good surrogate for muscle force predictions because predictions more similar to IMP also yield more realistic moments.

INTRODUCTION

Breastfeeding is universally accepted as being beneficial for infants. During initiation of breastfeeding, the infant latches onto the mother's nipple and areola, and the nipple extends as far as the infant's hard-soft-palate junction (HSPJ). The infant moves his tongue and mandible in an up and down motion to extract milk. As previously reported by our lab, the anterior tongue moves as a stiff body while the posterior tongue exhibits peristaltic motion [1]. Ankyloglossia, also known as tongue-tie, is a condition where the lingual frenulum, that connects the tongue to the bottom of the mouth, is thicker, shorter, or stiffer than usual. This limits the motion of the tongue and can impede feeding. Tongue-tie is currently treated with a frenectomy, a surgical intervention where the lingual frenulum is slightly cut to allow for better motion of the tongue. However, the use of frenectomies for the treatment of tongue-tied infants has been controversial due to the absence of objective measures to indicate the need for a frenectomy. While frenectomies are not highly invasive or risky surgeries, they do cause slight injury and discomfort to infants and should not be performed unless necessary and beneficial [2]. The goal of this study was to objectively quantify tongue kinematics for evaluation of potential parameters that may detect changes and improvements in breastfeeding due to frenectomy.

METHODS

We recruited 6 mothers with tongue-tied infants scheduled for frenectomies. Ultrasound videos were taken with an ultrasound transducer placed under the infant's chin. Mid-sagittal ultrasound clips were recorded for about 10 seconds immediately before and after frenectomy. The experimental protocol has been approved by the IRB committee and mothers signed informed consent. Follow-up surveys were given to caregivers to help assess effectiveness of the frenectomy.

The analysis was conducted on the clearest of the ultrasound video segments from before and after frenectomy using the MATLAB code developed in our lab [1]. First the videos were separated into frames. The palate and tongue were tracked on each frame using the active contours method (i.e., snake). Reduction of noise due to breathing of the mother, infant, and technician was done using registration with respect to the hard palate as the hard palate does not deform during breastfeeding. Polar coordinates were placed on the registered images to allow tracking of the local motion of the tongue along each polar line. This resulted in a time dependent signal of local tongue motility during breastfeeding (i.e., distance vs. time). Then we applied Fast-Fourier transform (FFT) to explore the dominant frequencies, and auto-covariance to analyze the periodicity of tongue motility.

RESULTS

The ultrasound video clips were analyzed using MATLAB. Computation of the infant's tongue-motility about the polar lines was used to represent the local dynamics of the tongue in the mid-sagittal plane. The results shown are from breastfeeding immediately before and after the frenectomy procedure. The time dependent local motility for a representative subject is shown for the anterior (Figs. 1a,b) and the posterior tongue (Figs. 1c,d). The frequency spectrum obtained by FFT is depicted in Figs. 1e, f and the periodicity characteristics obtained by the auto-covariance of the time-dependent motility signal at each tongue location is shown in Figs. 1g, h. The dominant frequencies from both the pre- and post-frenectomies were 2.34 Hz. It can be seen that there was more of a periodic motion evident post-frenectomy in both the anterior and posterior tongue motion and the dominant frequency was more defined post-frenectomy. The representative data shown in Fig. 1 demonstrated improvement after the frenectomy. However, improvements were not seen in all the analyzed scans.

Figure 1: (a, b, c, d) Time dependent signals of tongue motion before and after frenectomy. (a) and (b) Motion of the anterior tongue; (c) and (d) Motion of the posterior tongue; (e) and (f) FFT of the tongue motion; (g) and (h) Auto-covariance of tongue motion.

DISCUSSION

The present study is based on objective analysis of ultrasound video clips recorded during breastfeeding to explore the periodicity of the tied tongue before and after frenectomy. While breastfeeding has been studied through the use of ultrasound in the past [3], the method used here is one of the first to utilize registration with respect to the hard palate in order to reduce the noise and mitigate errors from movement of the ultrasound videos. The hope was that by using a reproducible, quantifiable method of analysis, this would allow us to get closer to objectively answering the long controversial questions: Are there significant differences seen in the tongue motion of tongue-tied babies versus non-tongue-tied babies and if there are differences, is the frenectomy effective in treating these differences?

Other studies have shown improvements due to frenectomies in adults or babies using visual images [4] or by visually analyzing ultrasound videos [3]. This study is different in that it uses a quantifiable and reproducible procedure to analyze the ultrasound videos. However, while the results presented here showed an improvement after frenectomy, this was not apparent in all of the analyzed videos. It is

unclear if this is due to the method itself, due to the fact that the post-frenectomy videos were taken immediately after surgery when there may have still been an open wound, or because the frenectomies themselves were unsuccessful. To answer this question, we will use the responses from surveys completed by parents about the improvements in feeding a few weeks after the surgery. This way we can determine if the computational results match the anecdotal evidence.

INTRODUCTION

The cerebral aneurysm is an abnormal ballooning of the cerebral artery and its rupture causes subarachnoid hemorrhage. In the process of intravascular treatment for the cerebral aneurysm, stent deployment into parent artery of aneurysm is one of popular approaches. There are two types of stents for treatment; laser-cut stent and braided stent, and both of them are mainly used to assist coil embolization to prevent the coil removal to the parent artery. In particular, the braided stent consisting of multiple metallic wires is one recently proposed for expecting high flexibility. Furthermore, it is widely known that deployment of the braided stent can act to divert blood flow in the parent artery from the aneurysm [1].

In clinical use, however, there is a critical issue of the braided stent deployment that incomplete stent expansion often occurs especially in the cases that the deployment into the aneurysm with curved parent arteries [2][3]. This under expansion induces blood flow stagnation in the gap between the stent and the arterial wall, which may promote thrombosis and embolization of the parent artery. Conversely, over expansion of the stent to avoid the stent malfunction brings abnormal contact force to the arterial wall, which might induce arterial inflammation and changes of the arterial shape. To assist surgeons to achieve complete stent expansion with appropriate contact force in each clinical case, understanding of the mechanical characteristics of the braided stent with considering mechanical properties of wires constituting the stent and these mechanical interactions is hopeful.

The present study develops a mechanically-consistent computational model of braided stent. Mechanical behavior of the wires constituting the stent are expressed by a set of beam elements in finite element manner and these multiple contacts with friction are treated in computation. Numerical example demonstrates two cases of the stent deployment simulation with different arterial geometries.

METHODS

Computational stent modeling Here we consider mechanical model of the wire constituting the braided stent. The wire was assumed as a thin slender beam which obeys Kirchhoff's rod theory [4], and thus the elastic energy of the wire per unit length, U is derived by integrating the stretching, bending and torsional elastic energies, given by

$$U = \frac{1}{2} [k_s \varepsilon^2 + k_t (\kappa_1 - {}^0\kappa_1)^2 + k_b (\kappa_2 - {}^0\kappa_2)^2 + k_b (\kappa_3 - {}^0\kappa_3)^2] \quad (1)$$

where k_s , k_t and k_b is the stretching, torsional and bending stiffness, ε is the axial strain, κ_1 , κ_2 and κ_3 is the degree of twist and curvatures and ${}^0\kappa_1$, ${}^0\kappa_2$ and ${}^0\kappa_3$ is those in the reference state. Internal forces of the wire were obtained from eq. (1) based on the minimum energy principle. Each wire was discretized to be a set of two-node beam elements and these deformation including finite rotations was treated by the corotational beam element formulation [5]. Multiple contacts between wire-arterial wall, catheter and wire itself were detected by the method of our previous study [6] and treated by expressing repulsive force in normal direction and tangential frictional force based on [4]. Note that the arterial wall and catheter were assumed to be rigid.

Following these internal and contact forces, algebraic form of the equation of motion of the stent is finally given by

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{C}\dot{\mathbf{U}} + \mathbf{F}_{\text{int}}(\mathbf{U}) = \mathbf{F}_{\text{ext}}(\mathbf{U}, \dot{\mathbf{U}}), \quad (2)$$

where \mathbf{U} is the displacement vector of all nodes of wires, \mathbf{M} is the mass matrix, \mathbf{C} is the damping matrix, \mathbf{F}_{int} is the internal forces and \mathbf{F}_{ext} is the contact forces. Stent motion during deployment into arteries was expressed by solving eq. (2) iteratively by explicit Newmark-type predictor-corrector scheme with adaptive time stepping [7].

Setup for numerical examples Numerical example of the stent deployment simulation into arteries was conducted. We constructed the braided stent consisting of 24 wires with the diameter of 0.04 mm. Outer diameter and total length of the stent were set to 5 mm and 22.7 mm, respectively, and assumed wires are made from Co-Cr alloy with Young's modulus of 225 GPa and shear modulus of 95 GPa. Each wire was discretized by 100 nodes. An initial state of the braided stent for the numerical simulation is shown in Fig. 1. We set a wire shape at the reference state to the single helical shape with constant curvatures and torsion.

Two cases of stent deployment into arteries were conducted using different arterial geometries with the radius of 4 mm. Idealized arterial geometries of the straight and 2-D curved shapes with the curvature radius of 12 mm were constructed. The catheter was set to be a straight tube with a diameter of 0.7 mm.

The stent was packed into the straight catheter by the method of [8] and this catheter with the stent was set on the centerline of each artery. In case of the 2-D curved artery, the catheter with the stent was quasi-statically deformed to fit the centerline of the catheter to that of the 2-D curved artery. The stent was deployed into each artery by gradually pulling the catheter.

RESULTS

Snapshots of the deployment process of the braided stent into the straight and curved arteries are demonstrated in Fig. 2. The stent was deployed around the arterial wall from the distal end as the catheter was pulled in both cases. In the case of the straight artery, the stent expanded uniformly to the arterial wall from the distal end (Fig. 2 left). On the other hand, in the case of the curved artery, the stent expanded along the inside of the artery and contacted on the inside of arterial wall (Fig. 2 middle-right). After deployment, a gap between the stent and the arterial wall locally occurred outside the curved artery (Fig. 2 bottom-right).

Figure 3 shows the spatial distribution of the contact forces between the stent and the arterial wall. In the case of straight artery, contact forces were distributed locally in the longitudinal direction whereas uniformly in the circumferential direction. On the other hand, in the case of curved artery, contact forces concentrated on the inside of the curved artery. Magnitude and deviations of the contact force in each case was evaluated by box plot (Fig. 4) and these differences were assessed by Mann–Whitney U test. Magnitudes of the contact forces were same order in both cases, whereas that in the case of curved artery was significantly higher than those in the case of straight artery.

SUMMARY

The present study proposed the computational model of the braided stent taking into account of the mechanical characteristics of wires constituting the stent and these mechanical interactions. Two cases of numerical examples of stent deployment in a straight and a curved artery were conducted. Results exhibited that the stent expanded uniformly in the circumferential direction in case of the straight artery whereas located on inside in the case of the curved artery and relatively strong contact force was generated inside of the artery. These results successfully demonstrated that the present computational model of the braided stent is capable to represent mechanical behavior of the stent during deployment into arteries. Moreover, because mechanical properties of the wire can be handled in the present model, the present model has a potential to evaluate effects of number of wires and wire mechanical properties on the mechanical characteristics of the braided stent. For this perspective further numerical experiment may be helpful to improve design of the braided stent and its performance assessment.

INTRODUCTION

Cerebral palsy (CP) is a non-progressive neurologic disorder of movement and posture that affects approximately 2 in every 1000 children in the United States [1]. Of these children, 40% have unilateral or hemiplegic CP, with abnormal tone, decreased strength, dystonia, and other muscle impairments impacting movement on one side of the body [2].

Constraint-Induced Movement Therapy (CIMT) is an evidence-based treatment for children with hemiplegic CP [3]. CIMT uses a constraint, typically a rigid cast, to restrict motion of the unimpaired hand, forcing the child to use their impaired hand during therapy and daily life. While CIMT has been shown to improve hand function, the protocols are often variable and results are only measured in the clinic [4, 5]. CIMT is both time and resource intensive for the children, their families, and providers. Understanding the extent to which casting influences hand use both in therapy and in daily life, as well as the outcomes after therapy are critical to optimizing treatment protocols.

Wearable technology, including accelerometers, has been used to quantify hand movement and evaluate hand function for both children with CP and adult stroke survivors [6, 7]. The goal of this research was to use accelerometry metrics to quantify hand use in clinical and home environments before, during, and after CIMT for children with CP and compare it to typically-developing (TD) peers.

We hypothesized that (1) impaired hand use would increase during CIMT, both at home and in the clinic, and (2) that increased impaired hand use during CIMT would be associated with enhanced bimanual use in daily activities after CIMT.

METHODS

We recruited seven children with hemiplegic CP undergoing CIMT (age: 6 – 10yr, 5 boys/2 girls) and seven TD children (age: 6-11yr, 1 boy/6 girls) from a pediatric tertiary care facility.

Per the institution's CIMT protocol, the unimpaired hand of each child in the CP cohort was placed in a cast for three weeks. Unilateral hand training of the impaired hand occurred in the clinic for 2 hours/day, 4 days/week. On Fridays, the cast was removed and the children received bimanual training for 2 hours before replacing the cast. The CP cohort wore ActiGraph GT9X Link (*ActiGraph Corp.*, Pensacola, FL) tri-axial accelerometers on both wrists for 3 consecutive days during three time periods: 1-week before, during, and 6-8 weeks after CIMT. Functional tests (grip strength, lateral pinch strength, and Box & Blocks) and the Canadian Occupational Performance Measure (COPM) were completed before and after CIMT. Box & Blocks was used to test manual dexterity and the COPM is a ten-point scale, used to assess how satisfied each child felt he/she was meeting their self-identified goals. The TD cohort did not receive therapy, but wore the Actigraph accelerometers on both wrists for three consecutive days at home, on three occurrences temporally aligned with the CP cohort time periods.

Accelerometry data were downloaded using 1-second activity counts and analyzed using the use ratio (UR) and magnitude ratio (MR) [6, 7]. The UR is the amount of active time of the impaired hand divided by that of the unimpaired hand (eqn. 1); it is used to assess frequency of hand use. A UR of one indicates the same frequency of movement between each hand, a number greater than one is indicative of more impaired hand use, and a number less than one indicates more unimpaired hand use. The MR is the natural log of the impaired hand

vector magnitude of acceleration in the three directions (i.e., $x^2 + y^2 + z^2$) divided by that of the unimpaired (eqn. 2). Values outside of the range ± 7 were set to ± 7 to constrain the range of values, similar to prior research [6]. MR is a metric used previously to describe magnitude of hand use in individuals recovering from neurologic injury [6]. Results were compared using paired t-tests between CIMT subjects and unpaired t-tests to compare between cohorts.

$$UR = \frac{\text{Hours of Non-Dominant/Impaired Hand Use}}{\text{Hours of Dominant/Unimpaired Hand Use}} \quad (1)$$

$$MR = \ln\left[\left(\frac{\text{Non-Dominant/Impaired Magnitude}}{\text{Dominant/Unimpaired Magnitude}}\right)\right] \quad (2)$$

RESULTS

The UR or MR were similar across time periods for the TD cohort, averaging 1.0 ± 0.0 and -0.3 ± 0.3 , respectively. Before therapy children with CP used their impaired hand less ($UR = 0.87 \pm 0.2$, $p=0.27$) and with a lower magnitude ($MR = -1.2 \pm 1.2$, $p=0.19$) compared to the TD cohort first data collection (Figure 1).

Figure 1: Use ratio (A) and magnitude Ratio (B) for the typically developing (TD) cohort and cohort of children with cerebral palsy (CP), before, In-Therapy (during CIMT while working with a therapist), Out-of-Therapy (during CIMT while doing activities outside of therapy, i.e. school), and after CIMT. The dashed lines represent equal hand use; 1 for the use ratio and 0 for the magnitude ratio.

During CIMT while working with a therapist (in-therapy), frequency and magnitude of movement of the impaired hand compared to the unimpaired hand increased significantly compared to pre-CIMT values, with average in-therapy UR of 1.6 ± 0.2 ($p=0.0003$) and MR of 2.8 ± 0.5 ($p=0.0001$). Children with CP also significantly increased these values during CIMT while out-of-therapy, with average UR of 1.4 ± 0.1 ($p=0.0004$) and MR of 1.9 ± 0.4 ($p=0.0006$). However following CIMT, children fall back to baseline values for both frequency (0.8 ± 0.1 , $p=0.32$) and magnitude (-1.9 ± 0.4 , $p=0.30$) of impaired hand use.

After CIMT, the CP cohort scored higher on impaired hand functional measures: grip strength increased by 8.3 ± 7.3 ($p=0.05$), lateral pinch increased 5.2 ± 3.5 ($p=0.03$) and the number of blocks transferred in 60 seconds increased by 4.3 ± 5.1 ($p=0.11$) blocks. Furthermore, children rated their performance on being able to reach their self-identified goals by 3.7 ± 2.4 ($p=0.00005$) points higher following CIMT (measured by the COPM).

DISCUSSION

The combination of increased UR and MR levels during therapy with increased functional gains following CIMT suggests that children are gaining unimanual skills as a result of CIMT. However, the subsequent drop to baseline values in the accelerometry metrics after CIMT suggests that these gains are not maintained outside of the clinic.

Similar to this study, other studies have shown improved functional scores measured in the clinic [8]. Coker-Bolt and colleagues (2017) performed a similar study, where children with CP wore two accelerometers before and after a 1-week, 30-hour CIMT intervention. The study reported that five of 12 children showed gains in accelerometry values one to two weeks after CIMT [7]. In the present study, all participants returned to baseline values 6-8 weeks after CIMT. These results may suggest that immediately following CIMT there is an opportunity to employ new strategies to help children transfer unimanual skills gained in CIMT into greater impaired hand use outside of the clinic, such as remind-to-move therapy, bimanual interventions, or other interventions.

ACKNOWLEDGEMENTS

We thank the Seattle Children's Hospital Academic Enrichment Fund, Seattle Children's Hospital Occupational Therapists, and the CIMT team for their help integrating this research into clinical care.

INTRODUCTION

Gradual loss of kidney function typically progresses to end stage renal disease, in which the kidneys are no longer able to filter out excess waste and fluids. To combat the accumulation of toxic levels of waste, electrolytes, and fluids in the body, hemodialysis is performed, in which blood is removed from the arterial system, filtered externally by a dialyzer, then reintroduced into the venous system.

Hemodialysis often requires an arteriovenous graft, a synthetic tube connecting an artery to a vein, as an access site for removal and return of blood. These grafts have relatively high rates of morbidity because they trigger thrombus formation at the venous anastomoses by perturbing blood flow fields beyond the physiological range of vessel wall shear strain rates [1-5]. Wall shear strain rates below the healthy physiological range (<50 1/s) can lead to thrombus formation by allowing coagulation factors to accumulate, while rates above the physiological range (>1000 1/s) can do so by allowing platelet aggregation [6]. Despite these major patient care issues, the role of graft shaping and placement on flow fields has not been quantified, and the possibility that graft design could be tuned to improve these flow fields has not been explored.

We hypothesized that the placement of and shaping of an arteriovenous graft affects the flow fields at the venous anastomosis. We performed a series of computational fluid dynamics simulations that supported this hypothesis. Results revealed ways that arteriovenous graft design can be optimized to reduce risk factors.

METHODS

We estimated the pulsatile flow field of blood in an arteriovenous system with a graft in place through pressure-based, transient computational fluid dynamics (CFD) simulations. A back of the envelope estimate of the Reynolds number, prompted us to use a

viscous, laminar model. A series of idealized, straight arteriovenous grafts were constructed in commercial CAD software (DesignModeler, ANSYS, Canonsburg, PA) based upon the typical arterial and venous presentations. The venous attachment was simulated at 90° , 60° , 45° , 30° , 15° and 13° . Additionally, a tailored venous anastomosis was developed, with geometry designed to constrain wall shear rates in the vein to stay within physiological ranges. This was done by modifying the shape on the distal insertion to manipulate the entering arterial blood to have similar dynamics to the venous blood.

Figure 1: Meshing of the simple arteriovenous graft model

A computational mesh was generated using ANSYS Fluent (ANSYS, Canonsburg, PA). Care was taken to ensure that discretization was not distorted in regions of high curvature and at

edges. For each simulation, mesh size was refined until convergence was reached, following standard procedures [7]. An inflation mesh was set at the wall to ensure complexities at the boundary layer could be resolved. Figure 1 shows the geometry and meshing of the arteriovenous graft model.

Blood was modeled as a non-Newtonian fluid following the Navier-Stokes equation. The Bird-Carreau constitutive law was used to represent the non-Newtonian, pseudo-plastic nature of blood, as is appropriate for oscillatory flow with high Womersley number. The inlet condition for the artery was based on velocity wave forms measured in the radial and brachial arteries [8] [9]. For the arterial and venous outlets an outflow boundary condition was used to model the downstream effects that are present in the circulatory [10] [11].

RESULTS

Blood entering a vein from an arteriovenous graft perturbed the venous flow fields. These perturbations varied with anastomosis. For severe angles, boundary layer separation occurred immediately distal to the anastomosis. This led to pathologically low shear rates at the location on the vein wall. Elevated shear strain rates were evident near the distal end of the graft insertion. The incidence of pathological flow fields could be modulated by altering the anastomosis entry angle (Figure 2), including undesirable features such as high shear rate at the distal end of the graft and boundary layer separation on the vein wall.

Figure 2: Cross sectional view of the various venous anastomoses showing the blood shear strain rate fields 30% of the way through the cardiac cycle. (a) Graft following optimization. (b) 90°, (c) 60°, (d) 45°, (e) 30°, (f) 15°, and (g) 13°. White arrows, peak shear strain rates on the wall; black arrows, flow separations

To quantify the degree to which blood flow was perturbed pathologically over one heart beat, the shear strain rate was recorded at each of the mesh cells on the vein wall for each time point, normalized with respect to area, and visualized on a histogram (These normalized distributions revealed an important role for the insertion angle in determining the fraction of the vein wall that experienced pathological shear strain rates. As evident from the logarithmic representation of area fraction in Figure 3, a, the small fraction of blood flow that was outside of the physiological range increased as the venous anastomosis insertion angle increased to 90°.

The analysis of standard venous anastomoses indicated that standard graft design cannot introduce arterial blood into the venous system without creating areas of excessively low and excessively high wall shear rate. We studied an optimized anastomosis. For this design, an intact boundary layer was maintained. Data in Figure 3 suggested that the optimized anastomosis reduced instances of shear rate outside the physiological range.

Figure 3: Shape optimization ameliorates pathological flow fields.

DISCUSSION

The shear strain rate fields at the vein wall play an important role in maintaining vessel health. Prior work has shown that shear rate above and below the physiologically healthy range can lead to thrombosis. The implantation of a foreign artifact such as a graft creates an environment that is at risk for wall shear strain rates in the pathological range. We showed here that the passage of arterial blood flow could be controlled by the specific geometry of an anastomosis to reduce the prevalence of pathological wall shear strain rate. These results are important as they show that anastomosis insertion angle, an aspect of graft implantation that a physician typically has control over, has a direct impact on shear environment. Insertion angle optimization can reduce the incidence of pathologically high and low shear rates on the venous walls

Even following anastomosis insertion angle optimization, the flow fields could not be tailored to eliminate all unhealthy shear. The unique optimized anastomosis, however, maintained the boundary layer across the threshold from the graft to the vein wall, and substantially reduced the vein wall area over which pathological shear strain rates were observed. Results support the idea that relatively minor changes to graft design can make substantial progress towards achieving safer grafts.

FLOW THROUGH SOFT TISSUE EQUIVALENTS: MEASURING THE HYDRAULIC PERMEABILITY OF COLLAGEN GELS

Christopher S. Vidmar, Brittany L. Fisher, Victor K. Lai

Department of Chemical Engineering
University of Minnesota-Duluth
Duluth, MN, USA

INTRODUCTION

Interstitial flow is a vital phenomenon in physiology. Interstitial flow helps the transport of nutrients and wastes between cells [1], helps lymphatic regeneration [2], and affects the production rates of vascular smooth muscle cells [3]. Understanding the roles and processes of interstitial flow will aid in drug delivery and can be used in the advancement of tissue engineering, where the permeability of these tissue equivalents affects the transport of nutrients through the tissues. Despite this significance, little is understood about fluid flow through the interstitium. Specifically, fibrous materials in the interstitium create a high resistance to hydraulic flow [3]. Collagen is one of the primary fibrous materials in the interstitium. There are many models that estimate the permeability of collagen gels, such as the Carmen-Kozeny equation [4], Happel's model [5], and more complex computational models [6]. However, there are very few reported experimental values of collagen permeability. One such example is [7], where the hydraulic permeability of collagen was measured as a function of collagen concentration. To our knowledge, however, such permeability studies have not been extended to investigate other variables such as collagen fiber alignment or other fiber types (e.g. fibrin, collagen-fibrin co-gels). Here, we present a method for measuring the hydraulic permeability of a collagen gel. This experimental setup can be modified to account for other variables, such as collagen densities, fiber alignments and pressure dependence.

METHODS

Apparatus: Figure 1 shows the experimental setup made of a 30" long, ½" diameter PEX tubing calibrated to measure the change in height. A valve controls the volumetric flow rate through the sample. A

smaller piece of PEX tubing holding the sample is connected to the bottom of the valve. The top of the apparatus is filled with water.

Figure 1. Apparatus used to determine permeability. Full length of the PEX tubing is not shown for clarity

Collagen Type I Preparation: 4 mL of 1.98 mg/mL collagen type 1 was prepared. In a 15 mL centrifuge tube, 816 μ L of 1M HEPES buffer solution, 104 μ L of 1M NaOH, 400 μ L 10x of Minimum Essential Medium Eagle (MEM), and 40 μ L of 200 mM L-Glutamine. 2640 μ L of 3mg/mL collagen I rat tail (ThermoFisher Scientific, Waltham, MA) was added with a frozen pipette. The solution was mixed and transferred to a 4", ½" diameter PEX tube with parafilm one on end. The gel was incubated at 37°C for 30 minutes before testing.

Permeability measurement: A piece of Scotch-Brite™ is rolled up and placed in the bottom tube. Water flows through the apparatus as the change in height versus time is measured. To find hydraulic permeability (κ), the hydraulic resistance (R) of the Scotch-Brite™ is determined using Darcy's Law (eq. 1):

$$Q = -\frac{\kappa A}{\mu L} \Delta P = \frac{1}{R} \Delta P = \frac{1}{R} \rho g \Delta h \quad (1)$$

Where Q is the volumetric flow rate, μ is the viscosity of water, A and L is the cross-sectional area and length of the sample respectively, ΔP is the pressure change, ρ is the density of water, g is gravitational acceleration, and Δh is the change of the water height. The volumetric flow rate can be written as the change in height per unit time (eq. 2):

$$Q = \frac{dV}{dt} = A \frac{d(\Delta h)}{dt} = \frac{1}{R} \rho g \Delta h \quad (2)$$

Combining eq. (1) and (2), this differential equation can be solved to give eq. (3):

$$\Delta h = \Delta h_0 \exp\left(\frac{-\rho g t}{R \cdot A}\right) \rightarrow \ln(\Delta h) = \frac{-\rho g}{R \cdot A} t + \ln(\Delta h_0) \quad (3)$$

Once the resistance of the Scotch-Brite™ is determined, the Scotch-Brite™ is transferred to the PEX tube containing the collagen sample. The collagen is moved to sit above the Scotch-Brite™ to hold the collagen in place. The height of the collagen sample is measured. Water is run through the sample, compressing the collagen sample until the collagen reaches a steady height. The collagen is then measured before and after the tests to ensure there is negligible compressive effect during the tests. Nine total runs are done for the collagen sample. The hydraulic resistance acts in series, allowing for the calculation of the hydraulic resistance of the collagen (R_{collagen}) from the resistance of the Scotch-Brite™, $R_{\text{Scotch-Brite}}$:

$$R_{\text{series}} = R_{\text{scotch brite}} + R_{\text{collagen}} \quad (4)$$

Comparison with Happel's model: The calculated permeability is compared to Happel's model for flow through an array of cylinders using the following equations [5]:

$$\kappa = \frac{2}{3} k_{\perp} + \frac{1}{3} k_{\parallel} \quad (5)$$

$$k_{\perp} = \frac{a^2}{8} \left[\ln\left(\frac{1}{\sigma}\right) - \frac{1}{\sigma} \frac{1-\sigma^2}{1+\sigma^2} \right] \quad (6)$$

$$k_{\parallel} = \frac{a^2}{8} \left[4 - \sigma + \frac{1}{\sigma} \left\{ 2 \ln\left(\frac{1}{\sigma}\right) - 3 \right\} \right] \quad (7)$$

Where k_{\parallel} is the flow through parallel cylinders, k_{\perp} is flow through perpendicular cylinders, a is the collagen fibril radius of 50 nm and σ is the solid volume fraction. The compressed collagen was estimated to have a concentration of 9.9 mg/mL, and a σ value of 0.007 was found using a bulk collagen density of 1.41 g cm⁻³.

RESULTS

Permeability Measurements: A representative plot of $\ln(\Delta h)$ versus time is shown in Figure 2 below. The data is fitted with a linear trendline according to Eq. (3). The slope from the Figure 2a (left) is combined with equation 4 to calculate flow resistance of Scotch-Brite™, allowing for the permeability to be found, which was 2.1651x10⁻¹⁰ m². The slope from Figure 2b (right) is used to calculate the total hydraulic resistance. The resistance due to the collagen sample can then be found through equation 4, and the permeability of the collagen sample was found to be 9.49x10⁻¹¹ ± 2x10⁻¹¹ m².

Figure 2. $\ln(\text{height})$ versus time for a sample of just Scotch-Brite™ (left) and of one containing both Scotch-Brite™ and collagen (right). The permeability of the collagen gel, 9.49*10⁻¹¹ m² is calculated from the slope of the right graph.

Comparison with Happel's Model and Other Works: Figure 3 shows a large discrepancy between all three methods, as the permeability values are orders of magnitudes away from each other.

Figure 3. Graph comparing permeability values. The measured value reported here is higher than both Happel's Model and the one reported by Ramanujan, et al. [7]

DISCUSSION

The permeability of Scotch-Brite™ was calculated to be 2.16 x 10⁻¹⁰ m², which is on the same order of magnitude as the literature value of 5.03 x 10⁻¹⁰ m² [8]. It is unknown how tightly wound the Scotch-Brite™ was while in the apparatus, which could lead to some variations with the permeability values.

The discrepancy with the Happel model could be due to the assuming that the collagen fibers are an array of rigid cylinders, which does not accurately replicate the collagen network. In addition, the Happel model does not account for molecular interactions between the collagen fibers and the fluids. The discrepancy seen with the value reported in Ramanujan, et al. could be due to different gel preparation techniques, which may drastically alter the network morphology (e.g. connectivity, fiber diameter, etc.). For the experimental set-up described here, near-wall flow likely contributed to a higher permeability. The major discrepancies seen in Figure 3 suggest the need for more accurate methods to experimentally determine collagen permeability to validate the various predicated values from theoretical models.

INTRODUCTION

Expiratory central airway collapse (ECAC), defined by >50% collapse of large airways during expiration, resulting from either cartilaginous weakening or redundancy of the posterior membranous wall of the trachea, is an increasingly recognized disorder associated with cigarette smoking and chronic obstructive pulmonary disease (COPD) [1]. Pathophysiology of ECAC is multifactorial and the biomechanics of airflow in the trachea could be an important factor resulting in the progression of the disease. With improving our understanding of ECAC as the motivation, this study aims to establish a computational methodology to comprehensively investigate the biofluid mechanics in healthy and diseased patient-specific trachea.

Studying the airflow characteristics in human airways has gained a renewed interest in recent years due to potential patient treatment options. Understanding fluid mechanics of airflow remains a challenge due to the complexity of human lungs and their individual characteristics. Computational fluid dynamics (CFD) simulation is one way to study and understand the flow through complex airways [2]. While earlier CFD investigations adopted engineering simplifications such as idealized geometry, advancement in computational efficiency and noninvasive technology now allow researchers to study respiratory flows in a patient-specific manner [3]. Previous studies have utilized patient-specific trachea models with various mesh sizes, use of flow extensions, and a wide range of inlet and outlet boundary conditions [2,3,4]. However, none of the studies have conducted the assessment and comparison of CFD simulations of respiratory flow with the use of different velocity profiles as the inlet boundary condition.

In this study, we specifically explore the effects of different idealized inlet flow assumptions on CFD simulations using patient-specific trachea models. We aim to ascertain if the velocity profile affects the CFD-derived wall shear stress (WSS) results from the

trachea. We compare the simulations in patient-specific tracheas to discern the differences in the wall shear stress parameters with different flow conditions at the inlet. Thus, the objective of the present study is two-fold, to simulate 1) nominal tidal flow (tidal breathing) as shown in Figure 1a and 2) steady flow both using the different inlet velocity conditions of a flat profile as seen in Figure 1b and a parabolic profile as seen in Figure 1c. We aim to compute flow field metrics such as wall shear stress variations along with Time-Averaged Wall Shear Stress (TAWSS) and Oscillatory Shear Index (OSI) from these simulations.

Figure 1: a) Tidal flow; b) Flat profile; c) Parabolic Profile

METHODS

Geometry Extraction and Processing: The 3D geometry of five patient-specific healthy tracheas obtained from the computed tomography (CT) scans were smoothed and clipped with 3D slicer (V4.8.1; www.slicer.org) as shown in Figure 2a. The processed model was saved into Standard Tessellation Language (STL) format. Then, Solidworks (solidworks corp., Waltham, USA) was used to simplify the inlet and outlet boundaries of the trachea model as shown in Figure 2b. **CFD Methodology and Boundary Conditions:** The trachea model was imported to ICEM CFD (ANSYS Inc., Pennsylvania, USA) where an unstructured mesh was generated with a mixture of prism and tetrahedral elements using the octree mesh method as shown in Figure 2c. The prism boundary layer having 6 concentric rows with a growth

factor of 1.11 was used. Depending on the size of the trachea model, the number of elements varied from 600,000 to 1,000,000 and the element size was set around 1% of the inlet diameter. The file from ICEM CFD was exported to fluent format for use in flow simulations.

ANSYS-Fluent (ANSYS Inc., Pennsylvania, USA) flow solver was used for steady and transient laminar flow model simulations. The boundary condition for the inlet portion which is near the mouth was given a velocity boundary condition using a user defined function (UDF) and an outlet condition was prescribed with a pressure of 1 atm. The velocity boundary condition was selected from the healthy adult data having tidal volume of 500ml with 12 breaths per minute [5]. From this data from a healthy adult, a blunt (flat profile) and a parabolic profile velocity boundary condition was formulated and implemented for two different simulations in both steady and transient case. A pressure-based solver with a simple pressure-velocity coupling scheme and a second order spatial discretization of pressure and momentum was used for each simulation in ANSYS-Fluent. Continuity and velocity residuals values were set to $1 \times e^{-3}$ as a convergence criterion.

Figure 2: a) Smoothed and clipped trachea geometry with 3D slicer; b) Simplified geometry with Solidworks; c) Mixture of prism and tetrahedral elements with details of prism layers

Metrics Evaluated: WSS and TAWSS parameters were calculated using the definitions shown below and the spatial average was obtained for each case. After, all of the 5 patient case values were averaged for comparison between steady flow and tidal flow. The overall distribution of OSI through the trachea wall was used to qualitatively assess the oscillatory nature of the flow.

$$\vec{\tau}_w(WSS) = \mu \frac{\partial u}{\partial y} \quad (1)$$

$$TAWSS = \frac{1}{T} \int_0^T |\vec{\tau}_w| dt \quad (2)$$

$$OSI = 0.5 \left(1 - \frac{\left| \int_0^T \vec{\tau}_w dt \right|}{\int_0^T |\vec{\tau}_w| dt} \right) \quad (3)$$

RESULTS

Figure 3 below illustrates the steady flow simulation of the wall shear stress variation in a flat and parabolic inlet velocity profiles for one of the five cases. The spatial average of the WSS over the trachea was calculated to be 0.05 Pa (flat profile) and 0.08 Pa (parabolic profile) for the case shown in Figure 3, which is a 60% difference in average wall shear stress between the inlet conditions.

Figure 3: Wall shear stress variation in steady flow simulation a) Flat Profile; b) Parabolic Profile

Figure 4 illustrates the time-averaged wall shear stress (TAWSS) and oscillatory shear index (OSI) variation for a flat and a parabolic velocity inlet boundary condition for the same case as in Figure 3. The

spatial average of TAWSS over the trachea was calculated to be 0.03 Pa (flat profile) and 0.05 Pa (parabolic profile) for the case shown in Figure 4, which is a 67% difference between the inlet conditions. Qualitatively, it was observed that the OSI was higher for the parabolic inlet conditions (Figure 4b) than for the flat inlet conditions (Figure 4a).

The spatially averaged WSS and TAWSS for all 5 cases were averaged and tabulated in a bar graph as seen in Figure 5. Furthermore, the overall results of steady flow WSS is greater than the tidal flow TAWSS for both flat and parabolic profile velocity inlet conditions.

Figure 4: TAWSS and OSI variation in tidal flow simulation a) Flat profile; b) Parabolic profile

Figure 5: Comparison showing TAWSS and WSS averaged over 5 healthy tracheas

DISCUSSION

In this study, it is observed that the use of a simplified velocity profile influences the WSS, TAWSS and OSI results for both steady and tidal flow cases. Using different inlet profiles as boundary conditions, produces variations in the wall shear stress distribution (Figure 4 and 5) which could prove important for understanding patient breathing flow dynamics. The current study distinguishes the flow metrics like WSS, TAWSS and OSI for different inlet conditions and distribution patterns from those described in previous studies [3]. This type of study where processing medical imaging and integrating with CFD analysis for derivation of flow field metrics will help improve the better understanding of airflow dynamics through patient-specific tracheas. While this study is a good first step, there are some limitations. First, the bifurcation at the carina was not considered and it could have an influence on the results obtained. Second, the compliant nature of the trachea was not modeled and a rigid trachea was used for this study.

INTRODUCTION

Mechanical loads, such as tension, compression, and shear, can stimulate growth and remodeling in musculoskeletal soft tissues. In order to test and validate theories that describe this mechanobiological response, bioreactors have been designed to apply various loading conditions to cellularized constructs during an *in vitro* culture period. Conventional bioreactors are limited to applying mechanical loads along one preferred axis [1, 2], but biaxial bioreactors can simultaneously apply tensile and compressive loads, which mimic the physiological loading environment of connective tissue. A novel application of biaxial bioreactors is to apply controlled states of planar stress in order to study the effect of strain energy, which is the stored energy from deformation, on cellular behavior. Furthermore, strain energy can be decomposed into hydrostatic and distortion (deviatoric) energy, which is related to volume change and material distortion, respectively. Tissue distortion has been linked to changes in the structure and function of tendon and ligament [3], yet the specific impact of distortion energy on tissue remodeling has not been quantified due to challenges in applying targeted levels of strain energy to cellular constructs. Therefore, a need exists to develop an experimental methodology that can apply varying levels of distortion, while maintaining a constant strain energy density, to understand how distortion specifically influences the cellular activity, matrix structure, and mechanical function of cellularized constructs. By identifying the specific mechanical mechanisms that trigger cells to remodel and repair, scientists and physicians will be better able to treat and prevent connective tissue disorders.

The objective of this research is to validate a novel method of subjecting 3D collagen constructs to differing magnitudes of distortion energy while maintaining a targeted strain energy density. We hypothesize that combined loads will increase distortion energy relative to single tensile or compressive loads.

METHODS

Setup. The biaxial bioreactor consists of a horizontal and vertical actuator to apply tensile and compressive forces, respectively, a culture chamber to contain specimens of varying lengths, and a camera housed at the base of the bioreactor for tracking localized specimen deformation (Fig. 1). To control the applied tensile and compressive forces, a custom LabVIEW program was previously developed using a force feedback control loop to dynamically regulate the position command sent to the bioreactor actuators [4].

Figure 1: Biaxial bioreactor.

Construct Preparation and Applying Complex Loads. Type-I collagen sponges (DSM, Exton, PA) were speckled with water insoluble black ink using a commercially available DIC stamp (Correlated Solutions, Irmo, SC). The sponges ($n = 3$) were then cut into dog-bone shaped specimens using a custom designed punch and hydrated in water overnight. Once fully hydrated, the specimens were subjected to five different loading conditions: only tension (T), only compression (C), equal tension and compression (T/C), compression with low magnitudes of tension (LT/C), and tension with low magnitudes of compression (T/LC) applied by the bioreactor. Before testing, specimen dimensions were measured. Preloads of 0.05 N in tension and 0.025 N in compression were applied, depending on the loading condition. Friction was reduced between the tissue platform of the bioreactor and the

specimen interface by applying a clear, biocompatible lubricant (Miller-Stephenson Chemical Company, Danbury, CT). Engineering stress, σ , was calculated along the x- and z- axes using force sensor data ($\sigma_y=0$). Engineering strain, ϵ , was calculated along the x- and y-axes by tracking the speckle patterns on the specimens using digital image correlation (DIC; Fig. 2), while strain along the z-axis was determined based on encoder values from the compressive actuator.

Specimens were preconditioned in tension for ~900 cycles to apply tensile strains between 6-8%. At the end of preconditioning, the tensile elastic modulus was calculated as the stress-strain slope, where the average strain was calculated from DIC in the region of interest (ROI; Fig. 2). Strain energy density was determined as the area under this stress-strain curve (Fig. 3A). Next, the compressive loading condition was applied to the same specimen and the compressive modulus was measured. Using the compressive modulus, a compressive force was selected to apply the targeted strain energy density measured in tension.

For the combined loading T/C group, the tensile modulus and compressive modulus were used to select tensile and compressive forces that each applied half of the total targeted strain energy density. In addition, the tensile and compressive forces for the T/LC group were selected to equal 2/3 and 1/3 of the total targeted strain energy density, respectively. Similar calculations were then conducted for the LT/C group. The loading conditions for these tests can be plotted with respect to principal planar stresses, σ_A and σ_B (Fig. 3B). For all loading conditions, additional tests were performed to minimize the percent error between the actual and targeted strain energy density by adjusting the applied forces. To calculate distortion energy, total strain energy density, W , was decomposed into hydrostatic and distortion components (Eq. 1). A one-way ANOVA with a Tukey-Kramer post-hoc test was used to detect differences in distortion energy between the five loading conditions. A paired samples t-test was used to determine whether test iterations reduced the error in applying targeted strain energy values.

$$W = \frac{1}{2}(\sigma:\epsilon)_{hydrostatic} + \frac{1}{2}(\sigma:\epsilon)_{distortion} \quad (1)$$

Figure 3: Bioreactor methods. A) Representative stress-strain plot. B) Principal planar stresses (σ_A , σ_B) for all loading conditions.

RESULTS

The bioreactor was able to accurately apply a single magnitude of strain energy density to specimens that were subjected to various loading conditions (Fig. 4A). The average error in applying a targeted strain energy density was reduced from $11 \pm 4\%$ to $4 \pm 3\%$ when using an iterative approach (Fig. 4A; $p = 0.002$). The combined loading conditions experienced the greatest distortion energy, where these groups were on average 53% and 160% greater than the only tension and compression group, respectively (Fig. 4B). However, only the compression group was determined to be significantly different than the combined loading conditions ($p < 0.05$).

Figure 4: Bioreactor results. A) Error in applying the targeted strain energy density determined from only tension tests to four other loading conditions. B) Distortion energy (* = significantly greater than compression).

DISCUSSION

In this study, strain energy density was successfully controlled in collagen matrices subjected to different loading conditions in a biaxial bioreactor. These results demonstrate that the bioreactor can be used to accurately control the application of planar stress for varying amounts of distortion while maintaining a constant strain energy density (Fig. 3B). Distortion energy was largest for combined planar loads, which supports our hypothesis and is consistent with mechanical theory. However, there was little variation in matrix distortion between the combined loading conditions, which suggests that distortion is insensitive to varying magnitudes of simultaneously applied tensile and compressive loads.

To our knowledge, this is the first experimental study to 1) control total strain energy density in a localized region of a 3D construct and 2) measure distortion energy in 3D constructs. This required the novel implementation of an algorithm to predict the strain energy density being applied in a ROI based on moduli values. In order to measure the actual strain energy density in the ROI, where planar stresses were applied, a camera was inserted under the bioreactor. Using DIC, we were thus able to confirm that tension was homogeneously transferred through the gauge region of the construct while compression was simultaneously applied (Fig. 2). This study gives us confidence that we can apply controlled levels of shear (i.e. distortion) throughout the volume of a ROI in a 3D matrix. More importantly, these results will allow us to test new mechanobiology theories based on strain energy, which can potentially unify existing theories that only account for single directional loads (i.e. only tension, only compression) [5]. A future experiment will use this newly validated method to investigate the effect of dynamic distortion on fibroblast-seeded constructs during culture.

INTRODUCTION

Cartilage injuries represent one of the most common intra-articular knee injuries [1]. Focal lesions jeopardize normal fluid pressurization, altering strains, and initiating a vicious chemo-enzymatic and mechanical cycle of cell dedifferentiation/death and degradation of adjacent ECM, propagating the defect area and concluding in joint-wide osteoarthritis [2]. Prior attempts have sought to restore mechanical integrity of damaged cartilage via genipin cross-linking or material-based resurfacing [3-4]. While showing some promise, these options present concerns regarding toxicity and durability of the engineered interface, respectively. In this study, we developed a modified hydrogel system (methacrylated hyaluronic acid) that intercalates within the cartilage ECM and can undergo photo-induced crosslinking following diffusion into the tissue (**Fig 1A**). The purpose of this study was to optimize the delivery system, focusing on the effect of material concentration, application time, and degree of crosslinking on the ability of the biomaterial to infiltrate into defected cartilage surfaces and restore cartilage mechanical function.

METHODS

Material Synthesis: Hyaluronic acid (HA; 75kDa) was methacrylated (~50% modification) and conjugated with fluorescent peptides (FITC) for tracking. The material was oxidized with sodium periodate to introduce aldehydes (~30% substitution), which can form covalent linkages with exposed amines in damaged tissue [5].

Assessment of UV Penetration: The ability of UV light to penetrate into cartilage tissue was first investigated. Juvenile bovine trochlear cartilage plugs (12mm diameter) were sectioned parallel to the articular surface at thicknesses ranging from 10 μ m to 300 μ m. Samples were placed on glass slides and hydrated with phosphate buffer solution (PBS). A UV lamp was positioned above a radiometer

and set to an initial irradiance of ~10 mW/cm². Cartilage samples of varying thickness were placed between the radiometer and the UV lamp, and irradiance was measured.

Figure 1. (a) Schematic showing the application of material to the defect surface, diffusion into the cartilage, and UV-mediated cross-linking to form an intercalated network within the tissue. (b) Irradiance as a function of cartilage thickness. n=5-10 per thickness.

Material Infiltration: Juvenile bovine trochlea plugs (6mm diameter) were excised, and the superficial zone of these samples was removed to represent a focal defect. Material solution (1%, 4% or 10%) was applied for 1, 5, or 10 minutes, followed by 10 minutes of UV-crosslinking and serial rinsing in PBS. In addition to these fresh “focal defects,” material penetrance into degenerated defects was evaluated by digesting additional plugs in 0.1% collagenase at 37°C for 30 minutes. Digested plugs were subjected to a 1% material

solution for 1, 5 or 10 minutes, followed by UV crosslinking. All plugs were sectioned perpendicular to the articular surface to obtain axial cross-sections (20µm thick). Chondrocyte nuclei were visualized with DAPI, and biomaterial was visualized via the covalently linked FITC peptide. Fluorescence intensity was quantified as a function of cartilage depth. The cartilage surface was defined as the point at which fluorescence intensity reached 20% of maximum, and the infiltration depth was determined as the point at which fluorescence intensity fell below 20% of the maximum value (**Fig 2** – red lines).

Surface Mechanics: Finally, the ability of the intercalated material to alter the mechanics of the cartilage surface was investigated. Juvenile bovine trochlear cartilage plugs were retrieved and the superficial zones were removed. Half of these plugs were digested in 0.1% collagenase for 30 minutes, while the remainder were maintained in their naïve state. A 1% material solution was applied to the surface of plugs for 5 minutes, followed by 10 minutes of UV crosslinking and PBS-rinsing. Surface mechanics were evaluated by atomic force microscopy (AFM) to obtain elastic moduli. Borosilicate glass colloidal tips (5µm diameter) attached to cantilevers ($k \sim 1.5$ nN/nm) were used to generate force maps (~16 sites per region, ~10 µm/s) at various locations along each surface of the sample. Indentation curves were sampled at 1.5 Hz, with a force trigger of 750 nN and were fit to the Hertz model to extract elastic moduli (E).

Statistical Analysis: Irradiance versus cartilage thickness data was analyzed with a linear regression fit. Infiltration and AFM data were analyzed by two-way analysis of variance (ANOVA) with post-hoc Tukey's tests ($p < 0.05$).

RESULTS

Radiometer readings as a function of cartilage sample thickness are depicted in **Fig 1B**. The baseline irradiance without cartilage (11.29 mW/cm²) steadily decreased with increasing sample thickness, falling below 50% of the initial intensity at a cartilage thickness of 300µm (4.83 mW/cm²). Extrapolating a linear fit of irradiance versus cartilage thickness ($R^2 = 0.8699$, $p < 0.0022$) suggests that irradiance will completely dissipate at a cartilage depth of 509.1 µm.

Biomaterial application and cross-linking showed that material infiltrated and intercalated within the cartilage matrix (**Fig 2A**).

Figure 2. (a) Fluorescence imaging of non-digested samples with 4% material solution applied for 1, 5 and 10 minutes. (b) Normalized fluorescence intensity as a function of depth. (c) Material infiltration data for non-digested samples for 1, 4, 10% solutions for application times of 1, 5, 10 minutes (n=5). (d) Material infiltration into digested and non-digested samples for 1% material solution (n=10).

Furthermore, intensity peaked at approximately 25 µm in the 1-minute and 5-minute application groups, followed by a gradual decline (**Fig 2B** – left/middle). Conversely, for the 10-minute application, intensity remained elevated to depths approaching 200 µm (**Fig 2B** – right). Average penetration depth for non-digested samples (**Fig 2C**) showed a general trend of increasing depth of penetration with increasing application time, with the exception of the 1% solution. Overall, two-way ANOVA indicated a statistically significant impact of both material solution percentage ($p < 0.0001$) and application time ($p = 0.004$), with infiltration increasing with both variables. All application combinations showed infiltration greater than 200 µm (**Fig 2C**). Infiltration also increased with application time for the digested samples (**Fig 2D**), and digestion increased infiltration by 9.9-24.1% across the three application times ($p = 0.07$).

Figure 3: Elastic moduli from AFM analysis of non-digested and digested samples without material and with 1% material solution.

Elastic modulus of non-digested cartilage without material was 84.4 ± 29.2 kPa, and showed a 54.1% decrease in modulus following digestion ($p < 0.0001$; **Fig 3**). Biomaterial application and crosslinking provided a 22.1% increase ($p = 0.07$) in non-digested samples. This enhancement was more pronounced in digested cartilage, with a nearly 3-fold increase in elastic modulus (33.9 to 94.3 kPa, $p < 0.0001$).

DISCUSSION

The results of this study demonstrate the ability of our HA hydrogel to intercalate and incorporate into both defected (nondigested) and degenerated (digested) articular cartilage. Crosslinking of the hydrogel is likely governed by the penetrance of UV light into the tissue, as well as material concentration and application time, impacting the depth of retained material. More importantly, this system displayed effective fortification of the damaged interface, restoring degenerated samples to mechanical properties matching native tissue. These findings may have implications for the treatment of both focal and degenerated cartilage defects, both mechanically for load support, and biologically for chondrocyte health. While these biological implications have not been studied here, future experiments will elucidate the impact of material application on cellular and tissue response.

INTRODUCTION

Cell and bioactive molecular gradients are critical for tissue development, maturation, and function. In articular cartilage, cell number decreases from the superficial zone (SZ) to the deep zone (DZ). Cell shape, orientation, and biologic activity also vary through the depth, and contribute to the depth dependent mechanical properties of cartilage [1]. To recapitulate this zonal cell distribution and matrix properties, studies have layered hydrogels of different stiffnesses [2] or containing different zonal chondrocyte subpopulations [3, 4]. While such layered scaffolds are an improvement over homogenous scaffolds for cartilage tissue engineering, the sharp transitions in these constructs are not physiologic and may be susceptible to failure under physiologic loading.

Towards the development of engineered cartilage with continuous spatial variation in cellular composition, this study developed and validated a method to spatially pattern particles and/or cells in a *single* hydrogel. To do so, hyaluronic acid (HA) hydrogel precursor solutions were supplemented with a clinically used paramagnetic contrast agent, Gadodiamide, to increase the magnetic susceptibility of the fluid. Based on previous literature [5-8], we hypothesized that diamagnetic particles (i.e. cells) suspended in the HA solution would be repelled from a nearby permanent magnet and would accumulate in areas of lower magnetic field strength in a computationally predictable manner.

METHODS

Experimental setup. The magnetic cell positioning setup included (i) one permanent magnet (15/16" diameter x 1/2" thick, $B_{\text{max}} = 13,200$ Gauss; K&J Magnetics, Inc.), (ii) a glass slide, (iii) a polydimethylsiloxane (PDMS) ring with an inner 4 mm diameter, and (iv) a PDMS cover (**Fig. 1**). The PDMS ring was positioned 3.8mm above the central axis of the magnet on the glass slide.

Figure 1. Schematic of permanent magnetic setup and gel fabrication. (A) A solution containing particles/cells, Gadodiamide, and hyaluronic acid is injected into a PDMS ring. (B) UV light is used to crosslink the hydrogel and stop movement of particles/cells.

Gel fabrication. A 1% w/v methacrylated hyaluronic acid (MeHA) solution [9] with 0.05% photoinitiator (Irgacure) was combined with 200 mM Gadodiamide (Gd; Omniscan) and fluorescent polystyrene microspheres (10 μm diameter; 250,000 beads/mL). 20 μL of MeHA – beads – Gd solution was pipetted into the PDMS ring and covered. After either 1 minute, 3 minutes, 5 minutes, or 10 minutes of magnetic field exposure, the solution was crosslinked with UV light ($\lambda = 365$ nm; intensity: 10 mW/cm²) for 10 minutes. Gels fabricated with cells used juvenile bovine mesenchymal stem cells (2 million/mL) labeled with CellTracker Far Red. Samples were cut diametrically after UV exposure and were imaged with an inverted fluorescent microscope.

Modeling and simulation. The magnetic field throughout a 2D cross section of the hydrogel (R: 0-2mm, Z: 0-1.3mm) was computed at each point on a 20 μm spaced rectangular grid in COMSOL. Magnetic field values and their respective derivatives were exported into a custom

MATLAB script to plot the movement of polystyrene beads (10 μm in diameter, 1.05 g/mL density) over ten minutes with a time step of 5 seconds. The molar magnetic susceptibility of gadolinium-based paramagnetic solutions is $3.2 \times 10^{-4} \text{ M}^{-1}$ [7]. The following equations were solved in MATLAB with the variables defined in Table 1.

Governing equations – adapted from Durmus et al. [7].

$$\mathbf{F}_{mag} + \mathbf{F}_{drag} + \mathbf{F}_{bouyant} + \mathbf{F}_{grav} = m\mathbf{a} \quad (1)$$

$$\mathbf{F}_{mag} = \left(\frac{V\Delta\chi}{\mu_0}\mathbf{B} \cdot \nabla\right)\mathbf{B} \quad (2)$$

$$\mathbf{F}_{drag} = 6\pi R\eta f_D \mathbf{v} \quad (3)$$

$$\mathbf{F}_{bouyant} = V\rho_f \mathbf{g} \quad (4)$$

$$\mathbf{F}_{grav} = V\rho_c \mathbf{g} \quad (5)$$

Table 1. Variables used in model.

Var	Description	Units	Value
V	Bead volume	μm^3	523.6
$\Delta\chi$	Magnetic susceptibility of bead – Magnetic susceptibility of fluid	none	$\chi_c = 0$ $\chi_f = 6.4 \times 10^{-5}$
B	Magnetic induction	T	Calculated from COMSOL
μ_0	Mag permeability of free space	NA^{-2}	1.2566×10^{-6}
r	Radius of bead	μm	2.5-20
η	Dynamic viscosity of uncrosslinked hydrogel	$\text{Pa}\cdot\text{s}$	$10^{-2} - 10^1$
f_D	Drag coefficient	none	1 [7]
v	Velocity of bead	m/s	Calculated
m	Mass of bead	g	5.5×10^{-7}
a	Acceleration of bead	m/s^2	Calculated
ρ_f	Density of fluid	g/mL	1.081 (measured)
ρ_c	Density of polystyrene bead	g/mL	1.05
g	Gravitational acceleration	m/s^2	9.8

RESULTS

The stray B-field was modeled in COMSOL across half of the 2D cross section of the hydrogel (**Fig. 2A**). As expected, the field strength decreased along the Z-direction and was relatively constant along the R-direction, given that the gel was significantly smaller in diameter than the magnet. Overall the field strength ranged from 0.28T to 0.34T through the depth of the gel.

Using the MATLAB particle movement model, a parameter sweep was carried out for particle radius (r: 2.5 μm -20 μm) and fluid viscosity (η : 10^{-2} - 10^1 Pa·s) (**Fig. 2B**). Increasing radius increased drag force, while also increasing magnetic force, such that particles with a greater radius were more responsive to the applied field. Increases in viscosity slowed particle movement. To validate the model, polystyrene beads of uniform size and density were used. The model output (**Fig. 2C**) was strikingly similar to the experimental data acquired (**Fig. 2D**). As predicted, particles moved away from the magnet placed underneath the Gd-meHA solution. After 3 minutes of magnetic field exposure, there was a clear gradient of particles within the hydrogel. After 10 minutes, most beads had reached the top of the gel, similar to the model.

After validating the computational model, fluorescently labeled cells were mixed into the Gd-meHA solution and subjected to the same magnetic field as in Figure 2. In control gels, the cells were evenly dispersed throughout the depth, as expected (**Fig. 3**). After applying the magnetic field for 5 minutes before crosslinking, there was a clear gradient from the top to the bottom of the constructs, as shown in the fluorescence intensity plot.

Figure 2. B-field modeling and particle movement. (A) COMSOL model of the magnetic field in a 2D cross section of the hydrogel. **(B)** Path of particle over 10 minutes in B-field based on radius or viscosity of fluid. **(C)** Simulation of polystyrene bead movement. **(D)** Experimental data of polystyrene bead movement.

DISCUSSION

These data demonstrate that negative magnetophoresis may be used to pattern cells in 3D space for potential interface tissue engineering applications. A wide array of stray B-fields can be designed with additional permanent magnets. This technique is advantageous over other magnet-based methods that require iron oxide particles to be tethered to or phagocytosed by cells, since iron particles can negatively affect cell differentiation [8]. Additionally, the computational model may be used to expedite experimental work focused on patterning objects of known density and diameter in a paramagnetic fluid. This work lays the foundation for future studies focused on long-term culture of engineered constructs with spatial cell gradients to investigate how cell density influences tissue mechanics and cell-cell interactions.

INTRODUCTION

The well-established role of hemodynamics in cardiovascular disease [1] makes the study of cardiovascular flows of wide interest. Here we apply for the first time a method based on complex networks (CNs) theory [2] to investigate and characterize quantitatively the complexity of cardiovascular flows. The rationale lies in the ability of CNs to explore the complexity of physical systems, such as 4D cardiovascular flows, in a synthetic and effective manner. CN-based approaches have already proven useful for data-driven learning of dynamical processes that are hidden to other analysis techniques. In detail, a dataset of 10 patient-specific computational hemodynamics models of human carotid bifurcation (CB) is considered here. Quantitative metrics derived from CNs theory are applied to two fluid mechanics quantities describing the intricate intravascular hemodynamics. These are (1) the so-called axial velocity, i.e. the blood velocity component aligned with the main flow direction, as identified by the vessels centerline, and (2) the kinetic helicity density, a measure of pitch and torsion of the streaming blood. The obtained results suggest the potency of CNs in unveiling fundamental organization principles in cardiovascular flows.

METHODS

Ten patient-specific computational hemodynamics models of CB from the Vascular Aging-The Link That Bridges Age to Atherosclerosis (VALIDATE) study are considered. An overview of the methods is provided in **Figure 1**. Briefly, vascular geometries and flow rates at inflow and outflow boundaries were acquired from contrast-enhanced angiography and phase-contrast MRI. The common carotid artery (CCA) geometry was reconstructed from the thoracic segment, where possible, to well above the bifurcation. On the reconstructed models, uniformly discretized tetrahedral computational

grids were generated, and unsteady-state computational fluid dynamics (CFD) simulations based upon the finite elements method were carried out [3-4]. Additional details are provided elsewhere [3-4].

Figure 1: Schematic diagram of the proposed integrated CFD/CNs approach and explanatory example of a CN.

The full-length models were then truncated normal to the branch axis at sections located 7, 2 and 5 radii along respectively the CCA, the external (ECA) and internal (ICA) carotid artery (CCA7, ECA2 and ICA5 sections, respectively, in **Figure 1**), to ensure a consistent spatial extent across all cases [4]. To describe the complexity of intravascular hemodynamics, two fluid mechanics quantities are considered, axial velocity (V_{ax}) and kinetic helicity density (H_k). In detail, V_{ax} is representative of the main flow direction and was calculated by projecting the velocity vector field along the local vessel centerline [5]. The pseudoscalar H_k , defined as the internal product between velocity and vorticity vectors, is considered here due to the recognized

atheroprotective significance of helicity in the CB [4] and, in general, in the evolution and stability of both turbulent and laminar flows. Here CNs are applied to the time-histories of these quantities at each grid node along the cardiac cycle to unveil fundamental organization principles in the CB hemodynamics. In graph theory, a CN is a network with significant patterns of connection between its elements and nontrivial topological features (an explanatory example is presented in **Figure 1**). The CN is defined by a set of nodes $V = 1, \dots, N$ and a set of links E between nodes $\{i, j\}$. In this study the nodes of each CN are represented by the grid points of the finite element mesh used to perform the CFD simulations. For each CB model, the network is built by applying a correlation criterion [6-7]: for each pair of nodes $\{i, j\}$ of the discretized fluid domain, the linear Pearson correlation coefficient R_{ij} is calculated between time-histories of V_{ax} and H_k . Then, the corresponding network is built up based upon the constraint that a topological link between nodes i and j does exist if and only if R_{ij} is greater than a threshold value \hat{R} . The threshold values are set equal to the median of the overall R_{ij} distributions ($\hat{R}^{V_{ax}}=0.55$, $\hat{R}^{H_k}=0$). The obtained network is represented by its adjacency matrix:

$$A_{ij} = \begin{cases} 0, & \text{if } \{i, j\} \notin E \text{ or } i = j, \\ 1, & \text{if } \{i, j\} \in E. \end{cases} \quad (1)$$

A_{ij} contains all the information about node connectivity: $A_{ij}=1$ if a link does exist between node i and node j ($R_{ij} > \hat{R}$); $A_{ij}=0$ elsewhere. On the built up networks, we calculated the following several CNs metrics: (1) the *degree centrality* (DC_i) of node i , defined as the fraction of nodes of the network directly connected to node i (the so-called first neighborhood of node i); (2) the *diameter* D of the network, defined in terms of number of links as the maximum value of the shortest path length between nodes i and j (**Figure 1**, in red); (3) the *Average Euclidean Distance* (AED_i) [6] of node i from all its first neighbors $n(i)$. AED provides a quantitative evaluation of the length of persistence of the correlation of hemodynamic structures inside the vascular domain, and their main direction of propagation. Intravascular structures characterized by high AED keep their correlation high within a large spatial distance, on the other hand for low AED structures the correlation vanishes within a shorter distance.

RESULTS

The volumetric maps of the V_{ax} degree centrality DC are presented in **Figure 2** for all the investigated CB models. In general, for V_{ax} high DC values characterize the nodes in the CCA, while nodes located at the carotid bulb present lower DC values. In most cases, high correlation among V_{ax} time-histories is restored distally to the flow divider, in ECA and ICA. On average, the value of the network diameter D is equal to 4 (range 3-5) for the ten investigated cases. Notably, the models presenting the highest and the lowest value for D are the same presenting respectively the highest and lowest value of carotid flare, a measure of the geometric expansion of the carotid bulb and known trigger of flow disturbances. The volumetric map for AED metric for a representative model is also displayed in **Figure 2**. In detail, AED map reveals that V_{ax} time-histories of nodes located close to CCA7 and ICA5 sections are characterized by a neighborhood that expands on a distance equivalent to 3 CCA7 diameters ($dCCA7$) or more, while shorter AED characterize nodes located in the carotid bulb. The CN-based analysis on H_k highlighted in all the models that two balanced, distinguishable positively/negatively correlated regions emerge from the distribution of DC values, which represent the detailed picture of those counter-rotating helical flow structures visualized and described in terms of integral quantities in previous studies [4]. All H_k networks are characterized by $D = 2$, i.e. the most

distant nodes are separated only by a two-links path. Lastly, from the AED results, it emerged that H_k time-histories with the largest AED (equal to 3.5 $dCCA7$) are located close to the CCA7 and ICA5 sections. Interestingly, in general helical flow structures exhibit shorter AED values, i.e., shorter length of persistence of the correlation, in the bulb region, similarly to what was observed for V_{ax} .

Figure 2: Volumetric maps of DC for all the ten V_{ax} networks, and volumetric distribution of AED for one representative model.

DISCUSSION

The CNs analysis on V_{ax} allows one to isolate two distinct regions, i.e., an “undisturbed” hemodynamic region vs. a “disturbed” hemodynamic region. The former presented high DC and AED values, physically implying that in that region forward flow dominates and V_{ax} time-histories are highly correlated, and this correlation is kept for large distances. The “undisturbed” hemodynamic region represents the largest fraction of the nodes, as DC values are $>80\%$. On the other hand, the “disturbed” hemodynamic region corresponds to the carotid bulb, where the propensity to plaque formation is stronger. There, only a smaller fraction of nodes is highly correlated (lower DC values), expanding for an AED of about one CCA7 diameter. The observed correspondence between metric D and the carotid flare suggests that the expansion at the bifurcation, markedly contributing to break up the topological links of the network, is the putative mechanism of correlation dispersion of V_{ax} . As far as H_k is concerned, CNs analysis emphasizes the presence of two distinguishable, balanced counter-rotating helical structures [4] as an emergent feature in CB hemodynamics, showing that in the bulb helical patterns maintain correlation on a much shorter distance than elsewhere. This aspect confirms (in such a way that can be measured in terms of persistence length of the correlation within the fluid domain) the role of the carotid sinus in promoting complex flow structures. In conclusion, the proposed integrated CFD-CN-based approach has the potential to provide a more complete picture of the intravascular flow complexity/disturbances, quantifiable in terms of persistence length of correlated hemodynamic quantities.

INTRODUCTION

In order for personalized computational models to have predictive or diagnostic value for the individual, it is essential that real-world data describing the individual case are assimilated into the model. In the field of 3D computational haemodynamics (CH), data can be obtained on a range of different aspects of the individual in question, in various modalities. These data vary in terms of the difficulty involved in their assimilation into the model; this is primarily due to the differences in the available state-of-the-art assimilation technologies available in each case.

For example, in personalized CH, accurate representation of an individual's blood vessel geometry and structure – via segmentation from 3D medical image volumes – is relatively advanced, accurate and fast, and is supported by specialized tools such as CRIMSON [1]. Similarly, the imposition of data such as known volumetric blood flow waveforms on CH models is well-supported. The reason for these is that these categories of data can be imposed directly upon our model. These directly-imposable data types can be considered to constitute a first class of data.

In the present work, we are interested in values which can be measured, but which represent emergent properties of the model, rather than values which can be imposed directly. These represent a second class of data; one which must be assimilated indirectly, by adjusting other aspects of the model until they are reproduced by the model, rather than by direct imposition. This second class is much more difficult to deal with, it is not clear in advance how a model should be adjusted in order to achieve the reproduction of the data in question. General principles may be known (if X is increased then Y will get closer to the desired value), but the exact magnitude of the necessary adjustments to X are much more difficult to determine.

In general, an educated trial-and-error approach can be taken, guided by general principles, but more systematic – and ideally, automated – methods are required.

In the present work, we discuss some methods for data assimilation which can be applied to patient-specific CH models, in order to determine appropriate parameters for the model's boundary conditions. These are described by zero-dimensional lumped parameter network (LPN) models, which have a number of electronic-circuit-analogous component parameters which must be determined, so the parameterization procedure fundamentally amounts to making patient-specific estimates of the properties of the zero-dimensional vascular bed representations (see the electrical circuit models in Figure 1 or 2). The Class II data that we will make use of will be blood pressure and flow measurements recorded within the domain of the model, and we will know that the parameters are appropriate when the simulated results reproduce this target data. We have a particular interest in Kalman filtering based approaches [2, 3].

METHODS

We developed a novel Kalman filtering based approach for determining the appropriate boundary condition parameters in a variety of cases. Our approach was to create a CH model geometry, determine some physiologically-appropriate LPN boundary condition parameters, and perform a “forward” simulation in order to generate some target pressure and velocity waveforms within the domain; this is Class II data. We then reset the model boundary condition LPN parameters to some generic, incorrect values, and run the data assimilation procedure, filtering for these parameters, and assess how well the filtering approach manages to: 1) recover the original parameters, and 2) reproduce the data observed in the forward simulation.

Our novel techniques as part of the Kalman filtering process were required in order to filter the complex LPN models that modern CH studies necessitate. For example, in the present work we made use of the arbitrary boundary condition model toolbox present in CRIMSON [1], which allows users to assemble custom arbitrary LPNs from a toolbox of circuit components. In order to support the arbitrary nature of such circuits, a novel mathematical approach was required.

Specifically, Kalman filtering in this context proceeds by generating a series of perturbations of the current LPN parameter state. Each member of this series is called a *particle*, and each particle represents a complete copy of the whole simulation state, differing only in terms of the perturbed parameters. Each particle is then advanced forward in time by one time-step, under the time evolution described by the incompressible Navier-Stokes equations, the produced pressure and flow values compared with the target data, and then the particles are recombined to create an *a posteriori* estimate of the model state, including a best new estimate of the target LPN parameters.

The requirement for a novel mathematical approach as part of this is due to the arbitrary nature of the LPN models. Unlike classical three-element Windkessel models, which have been determined using Kalman filtering previously [3], an arbitrary LPN model will have internal, time-dependent pressure states which are not directly determinable from the pressure at the 3D model's boundary. These states require careful consideration in the context of the filter, because each particle must contain internal an LPN state which is compatible with the perturbed parameters. If this is not the case, then the particles will exhibit inconsistent behavior over time, as if a series of shocks or discontinuities are delivered to the model, and the Kalman filtered estimates will not converge.

For this reason, after the generation of each particle, we introduce an update step to the filtering procedure, in which we update the LPN's internal state so that it is self-consistent, before it is stepped forward in time. However, because the pressure and flow at the 3D interface are both known variables at this point in time, the linear system representing the LPN circuit is overdetermined, and therefore solutions generally do not exist, and the internal LPN state cannot be found. Therefore, we "deconstrain" the values of the internal LPN pressures from the previous time-step, which are state variables in the presence of capacitance units due to the dP/dt term which occurs in the capacitor equation. This is philosophically justified because the particle has no true previous time-step, as the parameters have just been generated, and the available internal state belongs to what is really a different model, with a different parameter set.

In general, this approach leads to an underdetermined linear system. The solution to this problem is to make use of both the overdetermined and underdetermined linear systems simultaneously, by finding a least-squares solution to the overdetermined linear system, constrained by the requirement that it must satisfy the equations of the underdetermined system, too. Filtering can then proceed as normal for CH models [3].

RESULTS

Results are shown for the filtering of a single Windkessel (Figure 1), and for a coronary model (Figure 2). We see that the filter does a good job of finding appropriate values for the parameters, with some discrepancies which will be discussed later. Not shown is the fact that the target pressure and flow waveforms (one of each) are well recovered by the model with the final parameters found by the filter.

DISCUSSION

It is worth noting that the parameters are not necessarily recovered precisely. This is due to two factors. The first is that there may be multiple possible parameter sets which explain the observed input

Figure 1: Filtering a 3-element Windkessel model. Standard deviations for the estimate of each parameter are shown shaded.

Figure 2: Filtering a 5-element coronary model. Standard deviations for the estimate of each parameter are shown shaded. Target values are shown as dashed lines of the appropriate color.

data, indicating that the parameters are not all directly identifiable, at least not without more data. This may have implications for LPN design, or for the data requirements for creating an accurate model. The second is that the model may end up in a state where the data is no longer achievable, regardless of the parameters, because of the current location of the system in pressure-velocity state space. To overcome the latter problem, it is sometimes sufficient to terminate the filtering procedure, save the final parameter estimates, then restart the whole filtering approach (resetting the state space), but this time starting with the saved parameter estimates.

The outcome of this work shows, for the first time, the automatic determination of parameters in some complex lumped parameter network models in CH. This required the development of a new mathematical and philosophical approach to the internal state of the LPNs within each particle, and will support automatic parameter determination in real-world models.

DEVELOPING A SCALABLE OPEN-SOURCE SOLVER TO SIMULATE HEMODYNAMICS IN THE HUMAN PULMONARY VASCULATURE

INTRODUCTION

Employing computational methods to simulate pulmonary blood flow permits the assessment of complex multivariate interactions between the arterial wall, blood stream, and the right ventricle. Characterizing patient-specific pulmonary hemodynamics can possibly aid in devising novel custom-made treatments for pulmonary diseases. Moreover, simulation-based diagnosis presents a promising approach to circumvent invasive diagnostic procedures such as right heart catheterization. However, a dependable scalable software platform is imperative in this regard. This work elucidates the conception and development of a scalable in-house computational fluid dynamics (CFD) solver undertaken to simulate patient-specific hemodynamics in the pulmonary vasculature. The CFD solver contributes toward our long-term goal of characterizing aberrant hemodynamics and blood-tissue interactions engendered by pulmonary hypertension (PH).

METHODS

The CFD solver was developed using open-source C++ libraries available in OpenFOAM – v5.0 distribution. OpenFOAM works on the collocated finite-volume formulation for numerical representation of the equations governing fluid motion and the message passing interface (MPI) method for parallel computing. The open-source toolbox features a range of numerical schemes, methods and turbulence models. Our code follows the PIMPLE algorithm to evaluate the conservative form of three-dimensional Navier-Stokes equations. The PIMPLE algorithm is a combination of Issa's [1] Pressure-Implicit with Splitting of Operators (PISO) algorithm and Patankar's [2] Semi-Implicit Method for Pressure-Linked Equations (SIMPLE). At its core, the PISO algorithm is used, which decouples the pressure and velocity fields, and linearizes the convection term. SIMPLE contributes by allowing under-relaxation to ensure convergence within each time step. OpenFOAM's

hierarchical structure allows us to switch off the contribution from SIMPLE by setting the relaxation factors to 1; this option is availed in our simulations. The governing equations are the Navier-Stokes equations for isothermal incompressible flows, i.e. Eqs. (1) and (2),

$$\nabla \cdot \mathbf{u} = 0 \quad (1)$$

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} = -\nabla p + \nabla \cdot [(\nu)(\nabla \mathbf{u} + \nabla \mathbf{u}^T)] \quad (2)$$

where \mathbf{u} is the fluid velocity vector, p is the density-normalized or kinematic pressure, and ν is the kinematic viscosity of the fluid.

Figure 1: Flow chart of PIMPLE solution procedure used in OpenFOAM. $nOuterCorr$ is the number of outer corrector loops; and $nNonOrthoCorr$ is the number of non-orthogonal pressure corrector loops.

Equations (1) and (2) are evaluated using the pressure-velocity coupling methodology, which can be described in three steps: (1) momentum predictor, (2) pressure solver, and (3) momentum corrector.

The solver performs multiple iterations within a given time step and equation under-relaxation between each iteration is allowed for stability. The algorithm (see Figure 1 **Error! Reference source not found.**) allows automatic time step adjustment to maintain a stipulated CFL number.

Velocity and pressure data were recorded with a Volcano catheter in eight PH patients at Allegheny General Hospital (Pittsburgh,). The data was normalized with respect to the mean of the distributions. Inlet centerline velocity adjusted with the cardiac output and mean pulmonary arterial pressure (*mPAP*) were used as dimensional factors to generate quasi patient-specific waveforms. A resistance structured-tree outflow boundary condition, proportional to the outlet radius, was applied at each outlet cross-section. The outlet resistances were dynamically adjusted to achieve the patient-specific pressure waveform at the inlet. This transient resistance boundary condition ensured the time lag between velocity and pressure waveforms typical of the human circulation in large arteries.

The iterations were conducted on a parallel architecture using Intel's Knight Landing (KNL) nodes on Stampede-2 at Texas Advanced Computing Center (TACC), University of Texas at Austin. It is a Linux environment with Omni-Path network with a fat tree topology and a 100 GB/s bandwidth disk system. Each node comprises of 68 cores, 96 GB of DDR RAM, and 16 GB of high speed MCDRAM. Static mapping library, SCOTCH, was used to decompose and distribute the simulation domain among the processors, while ensuring minimum inter-processor boundaries. To ensure accurate flux evaluation at the inflow/outflow boundaries, all mesh elements belonging to a single boundary surface were constrained to be allocated to a single processor. This constraint obviated the occurrence of inter-processor boundaries at the inlet/outlet faces.

RESULTS

The total run time for simulating pulsatile blood flow through a patient-specific vasculature was approximately 200 hours on 32 cores. The run time was reduced to 48 hours when the same simulation was run on 128 cores. Beyond this point, increasing the number of cores ensued insignificant changes to the run time (see Figure 12). The hemodynamics were simulated under a Newtonian fluid assumption [3]. We observe a decreasing pressure distribution from the inlet to the outlet during the accelerating phases of the cycle ending at peak systole. Subsequently, a reversed pressure gradient is observed until the end of diastole. The pressure distribution obtained between peak systole and end diastole are the outcome of a prevailing decelerating incompressible flow. The PIMPLE algorithm evaluates pressure by substituting the velocity field into the pressure-Poisson equation. Thus, the pressure field is obtained as a product of the existing velocity distribution. In transient situations, this protocol is indeed expected to yield a pressure gradient reversal. Moreover, geometric influences occurring on account of the simulation domain also impact the velocity and pressure fields. These effects are articulated in the form of spatially oscillating pressure gradients.

DISCUSSION

There are several commercial and open-source software available for simulating large artery hemodynamics. ANSYS provides a reliable and highly validated infrastructure; however, the economics of software licenses poses a critical bottleneck. Open-source software is, to a large extent, custom made for specialized applications. To this end, a third-party user experiences a steep learning curve working with the available boundary conditions, computational models, numerical schemes, and their optimal combinations. Limited documentation and material models for the fluid domain limits universal applicability. In this work,

we utilized the widely validated OpenFOAM C++ libraries whose community-based support has evolved over the years to provide basic to advanced levels of troubleshooting. The next phases of this work involves conducting hemodynamic simulations on multiple patient-specific pulmonary vasculatures. Correlations obtained between simulation-based indices and clinical data will contribute towards our long-term goal of identifying non-invasively detectable biomarkers of a developing PH condition.

INTRODUCTION

Computational fluid dynamics (CFD) analysis of biomedical systems is often performed with stationary boundaries due to the complexity. However, significant boundary motion is observed in the majority of anatomies (blood vessels, ventricle, heart valve, cerebrospinal fluid, etc) and medical devices (artificial heart valves, ventricular assist devices, etc) that are studied with CFD. In most commercial CFD solvers using boundary fitted tetrahedral meshes, the additional complexity of moving boundaries is due to deformation of the initial CFD mesh as the boundary moves, which deteriorates mesh quality and requires remeshing which is both computationally expensive and induces additional numerical error [1]. Immersed boundary (IB) methods are another common approach to moving boundaries and don't require remeshing [2]. In IB and other Eulerian methods the grid size is limited which is also not ideal as the solution may not be fully converged [1]. A third approach to moving boundaries is the use of cut-cell meshes, in which the cells at the boundary are cut into polyhedra to match the shape of the boundary. With cut-cell meshes, remeshing moving boundaries is very efficient as the Cartesian interior mesh remains the same and only the boundary mesh is altered [1]. Cell faces will remain orthogonal, resulting in greater numerical stability than a mesh with skewed cells.

Another benefit of cut-cell meshes is that solution adaptive mesh refinement (AMR) may be applied every time step due to efficient remeshing. Cut-cell meshes have been used in a small number of aortic valve and mechanical heart valve (MHV) simulations [3]. AMR has been used extensively for internal combustion simulations [4] but has not yet been used on a biomedical system. Additionally, the performance of cut-cell meshes compared to other methods and the effectiveness of AMR has not been investigated for biomedical flows with moving boundaries.

This study focuses on flow in a MHV, a medical device used to treat heart valve disease. MHVs are long lasting but known to have high rates of thrombus formation [5]. MHVs are frequently studied with CFD as thrombus formation is highly related to fluid-dynamics within the valve. We aim to compare the performance of MHV CFD using 1. tetrahedral meshes, 2. cut-cell meshes and 3. cut-cell meshes with AMR. We hypothesize that cut-cell meshes perform more efficiently than tetrahedral meshes and that AMR will improve the efficiency of cut-cell meshes.

METHODS

We simulate flow in a 19mm bi-leaflet MHV (CryoLife, Kennesaw, GA) using experimentally measured flowrates and pressures as boundary conditions (BCs) from an *in vitro* flow loop. Leaflet motion is imposed using measurements from video recordings. Only systole is simulated as leaflet motion is obscured by the valve ring during diastole. The fluid is an incompressible 60-40 glycerol-water mixture with a viscosity of 0.0146 Pa sec and a density of 1167 kg/m³.

Cut-cell mesh CFD is performed with CONVERGE (Convergent Science, Madison, WI) using a PISO algorithm. An adaptive time-step algorithm uses a CFL like condition to prevent a boundary moving more than half a cell length in a single time step. Cell sizes range from 4mm to 250µm.

Tetrahedral mesh CFD was attempted with FLUENT (ANSYS Inc, Canonsburg, PA) using a SIMPLE algorithm as PISO was found to be unstable in simulations with stationary leaflets. In FLUENT simulations with moving leaflets could not be performed due to poor mesh quality (cell skewness > 0.99) in regions of the valve with 10-100µm gaps.

AMR is implemented with CONVERGE. Refinement is based on

Figure 1: A. Geometry of 19mm MHV and aortic root with BCs for inflow, outlet pressure and leaflet rotation. B. Meshes at different resolutions and AMR settings. 2.5 cm/sec sub-grid AMR refines within the valve while 0.5 cm/sec AMR also refines distal to the valve.

the sub-grid field (ϕ') or difference between the actual field (ϕ) and resolved field ($\bar{\phi}$) [6]

$$\phi' = \phi - \bar{\phi}. \quad (1)$$

The sub-grid field is defined by an infinite series,

$$\phi' = -\frac{dx_{[k]}^2}{24} \frac{\partial^2 \bar{\phi}}{\partial x_k \partial x_k} + \frac{1}{2} \frac{dx_{[k]}^2}{24} \frac{dx_{[l]}^2}{24} \frac{\partial^4 \bar{\phi}}{\partial x_k \partial x_k \partial x_l \partial x_l} + \dots, \quad (2)$$

however in practice only the first term is used to approximate the sub-grid field as an infinite series cannot be evaluated

$$\phi' \approx -\frac{dx_{[k]}^2}{24} \frac{\partial^2 \bar{\phi}}{\partial x_k \partial x_k}. \quad (3)$$

When the sub-grid field is above a specified level a cell is refined into 8 identical cells and if the sub-grid field below $1/5^{\text{th}}$ the specified level the embedding is released. The refinement level is an integer determining how many times a cell can be refined. Velocity is chosen as the variable to monitor for refinement and sub-grid field values of 2.5cm/sec and 0.5cm/sec are both analyzed. A variety of base grid sizes are simulated from 8mm-2mm and using a refinement level of three.

CFD accuracy is evaluated at a point between the leaflets (Fig2B, red circle) and in the valve wake (Fig2B, black square) using the L_1 norm of the axial velocity over time. Total error (Fig2A) is the average error at these two points. The 250 μm mesh without AMR is considered the converged solution. CPU-time is calculated by taking the simulation wall time and multiplying by the number of cpus used in the calculation. A numerical method is more efficient if the performance curve (error vs cpu time) is shifted to the left, i.e. greater accuracy for the same cpu time.

RESULTS

Performance curves for cut-cell mesh simulations show that the 0.5 cm/sec sub-grid AMR is the most efficient (Fig2A). For simulations using approximately 10^4 sec cpu time, 0.5 cm/sec sub-grid AMR simulation (2mm base grid) has an L_1 error six times less than a simulation not using AMR (500 μm base grid). The 2.5 cm/sec sub-grid AMR performs worse than no AMR.

The reason for the poorer performance of the 2.5 cm/sec sub-grid AMR can be seen when looking at meshes At a 2.5 cm/sec sub-grid the AMR algorithm refines cells along the valve leaflets (Fig1B). Looking at error within the valve leaflets (Fig2B), 2.5 cm/sec sub-grid AMR outperforms no AMR simulations, and at comparable cpu times has similar error to 0.5 cm/sec sub-grid AMR. 2.5 cm/sec sub-grid

Figure 2: A. The performance curves for total error show that an AMR sub-grid of 0.5 cm/sec is the most efficient. B. Within the valve both AMR sub-grids perform more efficiently than no AMR. In the valve wake, 0.5 cm/sec is more efficient than no AMR while 2.5cm/sec is less efficient than no AMR.

AMR does not refine cells in the valve wake (Fig1B) and performs worse than simulations without AMR in this location (Fig2B).

DISCUSSION

Heart valve simulations have used cut-cell meshes [3] but not AMR. These simulations did use boundary layer mesh refinement which could be used with AMR to further improve performance. AMR has been used in tetrahedral mesh simulations [7] but these simulations had rigid boundaries. In previous tetrahedral studies, AMR was only performed at the end of a simulation, not at every time step which decreases the potential benefit of AMR. It is important to note that performance depends on AMR settings.

A key limitation is that leaflet motion was prescribed instead of solved with fluid-structure-interaction (FSI). Future work will investigate AMR using FSI. We were also unable to perform tetrahedral mesh CFD so a comparison of tetrahedral and cut-cell meshes cannot be made. Others have reported increasing gap sizes in heart valve geometries to preserve mesh quality [8] and while this is a solution, the nonlinear response of flow to gap-size ($O(h^3)$) makes this approach undesirable unless a porous media or other approach is used to limit flow.

We found that AMR can improve CFD performance in a MHV with moving leaflets. A 400k cell simulation with AMR can be run on a desktop computer and has error less than 0.5cm/sec (70cm/sec peak velocity) compared to a 5M cell simulation run on a cluster. In addition to FSI, future work will investigate AMR performance in other anatomies and medical devices as well as the performance of cut-cell mesh AMR compared to tetrahedral meshes and IB methods. We also look to validate MHV CFD and 4D Flow MRI of MHVs against particle image velocimetry.

UNCERTAINTY QUANTIFICATION OF OUTFLOW BOUNDARY CONDITIONS ON PRESSURE QUANTIFICATION IN AORTORENAL ARTERY SYSTEM

Huidan (Whitney) Yu^{1,2}, Monsurul Khan¹, Hao Wu¹, Xiaoping Du¹, Alan P. Sawchuk²

INTRODUCTION

Image-based computational hemodynamics (ICH) has emerged as a new method for noninvasive quantification of a full wealth dynamic information of blood flow in human vessels. Such a capability gives rise to a promising patient-specific aid in clinic to either diagnose the true degree of hemodynamic abnormality or predict the therapeutic/surgical benefits to patients for various cardiovascular diseases. In recent years, a unique computational platform [1], named *InVascular*, as schematized in Fig. 1, has been developed, validated, and applied for the assessment of true severity of renal arterial stenosis (RAS) [2] and the prediction of

angiography (CTA) and Doppler ultrasonography (DUS) data. Integrating unified lattice Boltzmann method [1, 4] for both image segmentation and computational hemodynamics through a seamless connection with GPU (Graphic Processing Unit) parallel computing technology [5], *InVascular* enables exceptionally fast computation to establish correlation between trans-stenotic pressure gradient and volumetric reduction of renal artery, from which the hemodynamic severity contributing to the blood flow resistance in the diseased renal artery can be determined [2]. Such data are not readily available from the current standard clinical measurements. While it is encouraging that the non-invasive computational pressure has a good agreement with the invasive pressure measurement in aortic, left, and right renal arteries, referred to p_a , p_{lr} , and p_{rr} , of five clinic cases, the reliability of the computational results needs to be further addressed noticing that there exist various uncertainties in the entire process from image acquisition to 4-D hemodynamics (Fig. 1). Since only a segment of a vessel anatomy can be included in ICH due to the limit of computational power, boundary conditions (BCs) at inlets and outlets play critical roles to achieve reliable computational results. In *InVascular*, we choose 3-element WindKessel (WK3) model as outflow BCs. Three parameters, representing vessel compliance (C), proximal resistance (r), and distal resistance (R), form a lumped vessel network to close the blood flow loop. Due to lack of patient-specific data, the three parameters are determined empirically based on the physiological hemodynamics in aortorenal artery system. It is well known that uncertainty always exist in any modeling and simulation process [6]. Uncertainties due to the inaccurate data of local blood flow rate, vessel hardness, blood viscosity, etc. can affect the accurate determination of the three parameters. We therefore treat the parameters as random variables and quantify their effects on the output variables, i.e. the blood pressure values of p_a , p_{lr} , and p_{rr} , through uncertainty quantification (UQ).

optimal implant of left ventricle assist device [3] utilizing patient's CT

METHODS

A patient case (male, 64) with existing CTA and DUS image data is selected from a previous research project [2] that was for the validation of *InVascular* to quantify 4-D pressure in aortorenal artery system (Fig. 1). The computed pressure waves in one cardiac cycle of p_a , p_{lr} , and p_{rr}

Table 1. WK3 model parameters (r, R, C) for out BCs at the exits and validated systolic pressure of aorta, left and right renal arteries.

Vessel	Values	r (dynes · s/cm ⁵)	R (dynes · s/cm ⁵)	C (cm ⁵ /dynes)	Systolic pressure (mmHg)
Aorta (a)		108.12	3386.38	1.0e-5	155.80
Right renal artery (rr)		3306.39	8505.96	4.8e-6	141.72
Left renal artery (lr)		2879.76	7386.06	5.4e-6	144.61

have been compared to the corresponding invasive measurement with very good agreements, demonstrating the reliability of *InVascular* for the non-invasive pressure quantification. Table 1 shows the three parameters (r, R, and C) used in the WK3 model for outflow BCs as well as the validated systolic pressure in the aortic, right renal, and left renal arteries. In this study, we quantify the effects of the uncertainty of the outflow BCs on the *in vivo* systolic pressure quantification for this patient case. The input and output variables are the three parameters at three exits and systolic pressure values, denoted by x_i ($i=1-9$) and y_j ($j=1-3$), respectively. We assume that the input variables are independently and normally distributed. Their means are shown in Table 1. Their standard deviations are determined by coefficients of variation of 3%. This means that the standard deviations of the input variables are 3% of their means. Since the uncertainty in the input variables is not significant, we use the FOSM (First Order Second Moment) method [7, 8], which is accurate when the standard deviations are small. The required derivatives, $\partial y_{ij} / \partial x_j$ with $i=1-3$ and $j=1-9$, are computed using the finite difference method.

RESULTS

FOSM uses a linear approximation and all input variables are normally distributed. Thus, the three output variables are also normally

Table 2 95% confidence intervals of model predictions

U □ Results Outputs	Mean (μ_y)	Standard deviation (σ_y)	95% confidence Interval
$y_1 (p_a)$	155.80	1.3743	□153.05,158.55□
$y_2 (p_{rr})$	141.72	1.1149	□139.49,143.95□
$y_3 (p_{lr})$	144.61	1.1224	□142.37,146.86□

distributed. The distribution parameters of the output variables are shown in Table 2. For a normal distribution, the 95% confidence interval is approximately determined by the mean plus and minus two standard deviations [9]. The 95% confidence intervals of the pressure values of p_a , p_{rr} , and p_{lr} quantified via *InVascular*, are therefore [153.05, 158.55], [139.49, 143.95], and [142.37, 146.86], in mmHg, respectively, given the uncertainty in the outflow BCs. The coefficients of correlation between the three pressure values are $\rho_{a-rr} = 0.8969$, $\rho_{rr-lr} = 0.8497$, and $\rho_{a-lr} = 0.9474$. The correlations are positive and strong. This means that if any pressure value increases, it is likely that the other two pressure values will increase. With the means, standard deviations, and coefficients of correlation, the joint probability density of the three output variables is also fully defined.

The UQ analysis indicates the following.

- The pressure values of p_a , p_{rr} , and p_{lr} are random variables because they depends on random WK3 parameters.
- UQ produces a family of output variables (predictions) instead a point prediction. For this case study, the complete joint distribution of the pressure values is obtained.
- The joint distribution provides not only the average pressure values, but also their standard deviations, which are a measure of uncertainty.
- The three pressure values are strongly correlated, and the correlation is positive.
- The 95% confidence levels of the pressure values provide the likelihood that the actual values could occur. This can help us make more reliable decisions based on the simulation result.

DISCUSSION

Computational quantification of trans-stenotic pressure gradient using non-invasive ICH is a promising new means to replace the invasive catheter-based measurements currently in clinic practice. Such a new capability is significantly meaningful for more quantitatively determining the severity of arterial stenosis and the necessity of interventional therapy to avoid the patient's discomfort and to reduce the medical cost. It is inherently patient-specific thus expected to impact on precision medicine for cardiovascular diseases as stenosis can occur in all the major vessels, not only renal arteries in the current study but also coronary, cerebral, and iliac arteries that are being investigated. However, due to the existence of various uncertainties in medical image acquisition, image segmentation, computational models, and inflow and outflow BCs, the reliability of the computational quantification has been a big concern. Little knowledge about how the variability of key data and models due to unavoidable uncertainties would affect the accuracy of the ICH outcomes has been gained so far. As the very first step, we have focused on how the systolic pressure in aorta and renal arteries are affected by the uncertainties in the outflow BCs through the variations of the parameters representing the proximal and distance resistance and vessel compliance in WK3 model. Our study has demonstrated the benefits of considering uncertainty in the process of modeling and simulation. We have moved to the next step of the study, in which around 10 patient cases with different degrees of RAS observed from CTA are studied. We will investigate more sources of uncertainty and obtain more accurate uncertainty information about the model input variables. More advanced and more accurate UQ methods, such as Saddle-point Approximations, are being introduced.

INTRODUCTION

Cardiovascular disease (CVD) accounted for more deaths in the United States every year than any other cause of death since 1918, and was the underlying cause for 30.8% of all deaths in the United States in 2013 [1]. With regards to CVD, arterial stiffness is of clinical significance as an independent predictor of cardiovascular morbidity and mortality in hypertensive patients, type 2 diabetes, end-stage renal disease, and in elderly populations [2]. Arterial stiffness can be measured using noninvasive methods that obtain the arterial pulse wave velocity (PWV), which has been traditionally related to arterial stiffness using the Moens-Korteweg equation (MKE) [3]. However, the MKE assumes that the vessel is infinitely long, straight, isolated, and cylindrical with a wall that is elastic, isotropic, linear, homogeneous, and thin, which contains a homogenous, incompressible, and nonviscous fluid [3, 4]. While the qualitative relationship between stiffness and PWV in the MKE is useful, these assumptions are not realistic *in vivo* as arteries are highly curved, branched, and surrounded by adjacent tissue, and the vessel wall and blood are non-linear, viscoelastic, and heterogeneous [4]. As a result, there is a need for modeling software that can accurately calculate the PWV under physiological conditions.

FEBio is a free, open-source finite element software (febio.org), that was developed specifically for the biomechanics and biophysics communities [5]. It already offers many constitutive relations suitable for biomechanics such as nonlinear, anisotropic, heterogeneous, hyperelastic, and viscoelastic materials that may undergo remodeling, damage, chemical reactions, and solute transport. Recently we formulated and implemented a novel 3D fluid-structure interaction (FSI) solver in FEBio based on mixture theory where the FSI domain was described as a mixture of fluid and solid constituents that have distinct motions [6]. Our FSI formulation did not require stabilization

methods to achieve good convergence, producing a compact set of equations and robust code implementation that was validated and verified against a wide range of problems.

This study illustrates how the FEBio FSI solver can be utilized to accurately measure PWV of models of varying complexity and assumptions. A PWV benchmark problem of a flexible tube was compared with FEBio results to show accuracy in idealized cases [7]. The PWV for same model was solved for at different values for the wall stiffness to compare with expected values. Finally, the PWV was calculated for a realistic carotid artery problem with non-Newtonian blood, heterogeneous, nonlinear, and anisotropic thick wall, with surrounding adipose tissue.

METHODS

For the flexible tube problem [7], the model consisted of a cylinder with length $L=100$ mm, inner diameter $D=20$ mm, and wall thickness $t=2$ mm. Both ends have a symmetry boundary condition. The inlet is prescribed a step pressure of 5 kPa to initiate the pulse wave. The wall is Neo-Hookean with $E=1$ MPa, $\nu=0.3$, and $\rho_s=1000$ kg/m³. The fluid is Newtonian with bulk modulus $K_f=2.2$ GPa, $\rho_f=1000$ kg/m³, and viscosity $\mu=0.004$ Pa·s. The tube was modeled as a quarter cylinder with 20,520 linear elements and 23,111 nodes.

Then using the same model, different values for E were used in order to observe how the PWV from FEBio correlated with the MKE, which is shown in Eq. 1 [4].

$$E = \frac{2R\rho_f}{t}PWV^2 \quad (1)$$

PWV was also compared to a more accurate equation that allows for thick walls and compressible fluid. In-house Matlab code plotted fluid pressure along the center axis onto a spatiotemporal map, where the PWV was then calculated at the half-height of the pressure increase.

Finally, the PWV was calculated in a realistic bifurcated carotid artery example, originally used as a FSI example problem [6]. In this model, the arterial wall was an anisotropic, heterogeneous, multi-layered, and fiber-reinforced composite described by Holzapfel's material model with material parameters obtained from carotid arteries from cadavers [8], and the blood was a non-Newtonian Carreau fluid [9]. Adipose tissue was assumed to be a neo-Hookean material [10]. To initiate the pulse wave, the outlet pressure and inlet velocity were raised to physiological levels representing diastole (10.6 kPa and 0.1 m/s respectively) and allowed to equilibrate before a step increase in the velocity, representing systole (0.5 m/s). The PWV was calculated before the bifurcation. This model had 271,933 linear elements and 59,673 nodes.

RESULTS

The comparisons of the results for the PWV test problem between FEBio and literature are shown in Fig. 1, where centerline pressure values were taken at 5 different time points [7,11]. Overall there was good agreement between FEBio and literature results.

Figure 1: Centerline pressure of flexible fluid-filled tube.

The PWV of same models at different stiffness values were compared with the MKE and equation from Greenshields (GE) [7]. The results are documented in Table 1. FEBio PWV showed good agreement with GE, and followed the expected trends with MKE.

Table 1: PWV at different E for flexible fluid-filled tube.

Stiffness (MPa)	FEBio (m/s)	MKE (m/s)	Error (%)	GE (m/s)	Error (%)
0.5	6.432	7.071	9.03	6.204	3.68
1	8.802	10.000	11.98	8.774	0.32
2	12.416	14.142	12.20	12.408	0.07
4	17.541	20.00	12.29	17.547	0.03
10	27.473	31.623	13.12	27.741	0.97

Finally, the PWV was calculated from the realistic bifurcated carotid artery. The artery mesh and the surrounding subcutaneous adipose tissue, is shown in Fig. 2. The pulse wave propagated through the carotid artery before the bifurcation and then reflected as it hits the junction, which is illustrated in Fig. 3. The PWV of the artery (calculated before the bifurcation) was 13.59 m/s. Clinically, the PWV of the carotid artery was 9.84 ± 3.86 m/s and 10.68 ± 3.29 m/s for geriatric people (average age ~69) without and with carotid atherosclerosis respectively [12].

DISCUSSION

This study illustrates how FSI in FEBio can be used to accurately calculate PWV both in idealized and realistic artery models. With the

fluid-filled elastic tube model, FEBio was in agreement with literature results (Fig. 1), which verified that FEBio can be used to model the propagation of the pulse wave in simple cases. Observing the PWV change at different E for this model (Table 1), the good agreement with the GE demonstrates that FEBio PWV behaved as expected under different conditions. FEBio and MKE did not agree as well most likely due to unacceptable simplifying assumptions, although FEBio followed anticipated trends. For the physiological artery model, the incident pulse wave was observed to both reflect at the junction and be transmitted to the two branches as expected (Fig. 3) [4]. The calculated PWV was within range, although at the higher end of the clinical PWV for elderly patients with and without carotid atherosclerosis. However, this was reasonable as the wall material properties were obtained from donors who were older than those in the clinical study (76.8 average age), most of whom had varying degrees of atherosclerosis [8]. Thus, from these results, in addition to its many material models and features, FEBio can be a powerful and versatile tool for modeling pulse wave propagation in arteries. Future potential applications include, for example, patient-specific studies and artery wall material characterization. Currently, studies are ongoing that use FEBio to model PWV in phantoms to complement experimental results obtained using ultrasound to observe the effect of stenosis formed by plaque.

INTRODUCTION

The intraventricular flow structures generated during the diastolic phase are believed to facilitate the filling of the heart, mass transport and momentum by keeping the blood moving throughout the diastolic phase and smoothly redirecting the flow towards the outflow tract [1]. The intraventricular flow dynamics are influenced by structural/anatomical alterations of the left ventricle (LV) cavity and changes in cardiac physiology [2]. Consequently, researchers are highly interested in the effect of the adaptation of the LV to the flow dynamics. The LV flow has an intrinsic complex three-dimensional and unsteady structure. However, *in vivo* imaging methods are still limited in terms of temporal and/or spatial resolution and are often complemented and/or validated by *in vitro* or *in silico* methods. Until now, *in vitro* flow investigations were primarily performed in 2D or pseudo-3D, where the volumetric flow was reconstructed from a series of planar measurements. We believe, however, that LV flow analyses would highly benefit from the application of an instantaneous volumetric measurement technique.

The goal of our present work is to investigate the evolution of the 3D intraventricular flow structures downstream of a biological valve mounted in a compliant LV model. The flow is investigated by means of a truly volumetric particle-based imaging technique; a 3D multi-camera imaging system is used to record time-resolved images of tracer particles within the investigated volume. The Shake-The-Box (STB [3]) Lagrangian Particle Tracking (LPT) algorithm is employed to reconstruct individual particle tracks during the cardiac cycle. The FlowFit data assimilation algorithm [4] allows for the interpolation of the scattered LPT results onto a regular grid and for the extraction of the 4D relative pressure field.

METHODS

An anatomically realistic LV is mimicked by means of a flexible membrane driven by a programmable pump (Vivitro Systems, Inc., Victoria, BC, Canada). The 0.5 mm thick membrane was manufactured by painting silicone layers onto a 3D printed mold; the geometry of the mold was based on the mean shape of 150 computed tomography patient segmentations [5]. The LV membrane is immersed in a Plexiglas ten-sided polygon tank and connected via the valve holders (figure 1a), where the aortic and the mitral valve are placed. The atrial and aortic chambers are connected via an adjustable resistance and fixed to the tank lid. The tank is connected to a pulsatile pump that generates semi-sinusoidal volumetric changes in the tank and consequently induces a loop of inflow and outflow in the LV.

Figure 1: (a) CAD view of the nine-sided tank. 1-2: valve holders, 3-4: mitral and aortic valve position, 5-6: atrium and aortic blocks, 7: aortic pressure catheter. (b) Sketch of the 3D imaging system (top view).

To minimize optical distortion, a fluid mixture with the same refractive index as the silicone membrane was used (table 1). The fluid was seeded with Fluorescent Rhodamine-B coated particles. The 3D

imaging system was designed to simultaneously acquire four different views of the LV model using only two high-speed cameras (Imager Pro HS 4M, PCO, Kelheim, Germany) with a custom-made image splitter that was placed in front of each camera (figure 1b). A volume of approximately $80 \times 110 \times 70 \text{ mm}^3$ was illuminated by a double-cavity Nd:YLF laser. A long-pass filter was mounted in front of a macro lens (100 mm, Samyang Optics co Ltd., Korea) to selectively capture the fluorescent light scattered by the particles. The calibration of the camera system was performed by imaging a 3D calibration target located at the center of the investigated domain along the viewing direction (Z axis). The target calibration yielded an average error of 0.2 pixels; the volume self-calibration [6] technique was employed to reduce the residual calibration error down to less than 0.02 pixels. The measurements were performed during two consecutive cardiac cycles of 857 ms at a sampling rate of 2 kHz, resulting in 1714 recordings.

The recording sequence was processed using the Shake-The-Box algorithm [3]. STB enables the reconstruction of single particle tracks in 3D over long time-resolved sequences of recordings from a multi-camera imaging system. The method makes use of the Iterative Particle Reconstruction (IPR [7]) to reconstruct the 3D particle locations. An initial phase where tracks are identified over the first few realizations is followed by the prediction of the particle location at subsequent recordings; the predicted location is then corrected by means of an image matching scheme. Subsequently, the scattered position, velocity and acceleration measurement provided by the STB are interpolated onto a regular 3D grid by the FlowFit data assimilation algorithm [4] where a system of cubic B-splines is used to represent the velocity and pressure fields. By leveraging physical constraints derived from the Navier-Stokes equations, the spatial resolution is increased beyond the sampling offered by the tracked particles. The spatial gradients (such as vorticity, Q-criterion and viscous stress) can be evaluated analytically from the B-spline functions.

LV silicone membrane	Thickness: 0.5 mm
	Refractive index: 1.413
Mitral and aortic valves	25 and 19 mm biological valve
Hydraulic settings	Pseudo-sinusoidal -70 BPM
	Stroke volume: 50 ml
Fluid: 60% glycerol 40% water	$\eta=17,7 \text{ mPa}\cdot\text{s}$ $\rho=1160 \text{ kg/m}^3$
Seeding: Rhodamine-B	Diameter: 20-50 μm
Imaging system	CMOS 4MP camera sensor
	Laser: 30 mJ/pulse (per cavity)

Table 1: Relevant setup and processing parameters

RESULTS

Figure 2 (a-b) shows approximately 7000 individual particle tracks during the inflow (a) and outflow phase (b); the tracks are visualized in the 3D domain by plotting the velocity vectors (color-coded by the vertical velocity) at the instantaneous particle locations along 18 subsequent recordings. The biological valve induces a strong trans-mitral jet directed towards the anterior wall of the LV, with a vertical velocity (V_y) of up to 1.3 m/s. The topology of the inflow jet is characterized by a crossed flow path, where the outflow fluid crosses the inflow path during the ejection phase (fig 2c). In physiological conditions the intraventricular flow path is looped [8] as shown in (fig 2d). The vortical structures induced in the LV cavity are visualized by iso-surfaces of Q-criterion (fig 2e). Multiple vortices are formed during the filling phase, similar to the vortices generated from a cylinder with an inclined exit. Figure 2f depicts the iso-surface of velocity magnitude colored by the pressure field relative to an offset

P_0 . In further processing P_0 is estimated via direct pressure measurement inside the LV model via a thin catheter.

Figure 2: (a-b) Particle tracks over 18 recording during the diastolic and systolic phase, respectively, colored by vertical velocity component (along the Y axis). (c) Transversal cross-section colored with velocity magnitude. MV mitral valve, AV aortic valve. The dashed line depicts the crossed flow path. (d) Looped flow path in a healthy heart. (e) Vortex structures: iso-surface of Q-criterion (at 9350 s^{-2}) and contours of velocity magnitude in the XY plane at $Z= -5 \text{ mm}$. (f) Iso-surface of velocity magnitude color-coded with the relative pressure.

DISCUSSION AND CONCLUSION

To the best of our knowledge, this is the first in vitro study to provide time-resolved Lagrangian 3D intraventricular flow patterns and relative pressure within a flexible LV model downstream of a biological valve. The preliminary results showed the formation, evolution and dissipation of the vortical structures during the diastolic phase. Considering that the implemented 3D imaging setup provides time-resolved access to the full velocity gradient tensor, we consider that this setup is an ideal tool for validation of numerical simulations and medical imaging.

INTRODUCTION

In the lack of information on the preferred method of bifurcation stenting in peripheral arterial disease (PAD) patients, further experiences with hemodynamic analysis are required to gain understanding of the underlying mechanisms implicated in ISR formation using different bifurcation stenting arrangements in peripheral arteries.

The aim of this study is to quantify altered hemodynamics due to virtual implantation of the most commonly used double-stent bifurcation stenting techniques including T, Culotte (CUL) and Crush (CRU) in a model of a below-the-knee bifurcation. The model of popliteal bifurcation generated from representative vascular dimensions is used for subsequent computational fluid dynamics (CFD) analysis. Time averaged wall shear stress (TAWSS) and oscillatory shear index (OSI), were quantified as hemodynamic indicators of disturbed flow responsible for ISR formation. The results of this study can help endovascular interventionalists in the selection of a suitable strategy for PAD treatment.

METHODS

For bifurcation models, the geometry of the popliteal artery which branches into anterior tibial artery and tibio-peroneal trunk is used to construct different configurations of stenting techniques. The geometric characteristics used for creating these models are given in **Error! Reference source not found.** For virtual stent implantation, the Bx Velocity device (Johnson & Johnson Interventional System, Warren, NJ, USA), was selected due to their major application in the treatment of below the knee arteries. The stent geometry information was

reconstructed from optical microscopy images [1] as well as available manufacturer's product catalogue most of which can be find in [2].

All grid discretization were generated using ICEM 14.5 (ANSYS Inc., Canonsburg, PA, U.S.A). The geometric models were meshed using the hybrid tetrahedral-prismatic layer elements with regards to the information provided in our previous study [3]. Convergence testing was first carried out on mesh density, and then continued to time step size and residual level for all models through transient simulation to ensure the reliability and stability of the grid solutions. The robust GCI methodology is used to evaluate the uncertainties involved in each solution in accordance with our previous study [3]. After all, a total number of 8683951, 8301933 and 7915173 elements were used to discretize the model of CUL, CRU and T techniques, respectively. A time step of 0.001s was deemed most feasible to sufficiently resolve the complex hemodynamic flows yielding the average courant number less than 1. RMS residual level equals to 10^{-4} was used as a convergence criteria. Simulations were run for 3 consecutive cycles and only the results from the third cycle were used for analysis to avoid transient start-up effects.

The blood was assumed to be a Newtonian and homogeneous fluid with a density of 1060 kg/m^3 and a viscosity of 0.0035 Pa.s. The peak Reynolds number for all flows ensures a laminar fluid model for all cases. The walls were assumed to be rigid, nonporous and smooth as the arterial wall thickens due to calcified atherosclerotic plaque accumulation. A physiological triphasic flow waveform obtained from the proximal segment of popliteal bifurcation was imposed as an inlet MB boundary condition while the flow rate profile through the anterior tibial artery was applied at the distal MB outlet. A zero static pressure

condition was imposed at the SB outlet to meet flow continuity. ANSYS CFX 16.2 (Canonsburg, PA, USA) was utilized for simulation.

Table 1: Design characteristics used for regenerating 3D digital models of stented bifurcated popliteal artery.

Geometric Characteristics	
Proximal MB diameter (mm)	4.5
Distal MB diameter (mm)	3.9
SB diameter (mm)	2.5
Bifurcation angle	60°
Oversize ratio	10%
Stent strut width × thickness (mm)	0.013 × 0.14
(fully embedded strut protrusion)	
Stent Profile	Rectangular

RESULTS

TAWSS was considered to capture the significant difference between the models. The fluctuations in WSS was evaluated through the use of OSI. The results on using these two metrics to address the adverse hemodynamics within these three models are displayed in Figure 1. Looking at the distal MB and the SB, similar patterns for low TAWSS and high OSI were observed for all models, mainly confined to the near-stent strut and over the outer wall of the SB proximal to the ostium.

Figure 1: (Left column) Adverse TAWSS and (Right column) OSI contour plots along the arterial wall for T, CUL and CRU models.

The noticeable difference in distribution of these two hemodynamic indices is observed at the PM segment varying depending on the different insertion of additional stent into the artery. In the proximal MB, increasing areas of low TAWSS and high OSI are noted for CUL as compared to CRU. This is due to the in-stent recirculation caused by the presence of the additional layers of struts, more pronounced in CUL where the second layer localised all around the PM segment. Another distinct difference obtained was that the low OSI value localised at the location of carina in T model, is extended to the lateral walls at the ostium of CUL and CRU, indicating minimal variation in WSS throughout the cycle.

DISCUSSION

The results of this study indicated that each bifurcation stenting technique has distinct impact on the flow patterns shown through adverse TAWSS and OSI metrics, known to influence ISR. The deleterious interaction of additional layers of struts in CRU or CUL provided some disadvantages, most notably the highest risk of ISR in CUL followed by a less significant one in CRU. However, CUL and CRU demonstrated the most favourable results in preserving the bifurcation ostium patency as the least adverse events and thus ISR was obtained for this region due to the better SB ostial coverage provided by multiple layers of struts.

In this study, due to the marked difference in the diameter of PM and DM segments, the geometric variation in the PM and SB segments resulting from the concentration of one or multiple layers of struts for T, CUL and CRU, did not appear to impact the near-wall flow condition in the DM segment. Thus, all stented models seem to expose to adverse hemodynamic condition similar to each other. This indicates the same chance of the exposure of this segment to the likely mild ISR across all techniques. However, a more pronounced difference is observed in the results of [4] in a model of the coronary artery throughout the SB and DM segment between T, CUL and CRU techniques, emphasizing different performance of these techniques in terms of ISR formation in coronaries and peripheries when the major geometrical configuration such as the lumen diameter and the bifurcation angle and the inflow properties differs between the two arteries.

Among all considered double-stent models, T showed to provide a balanced haemodynamic environment that eliminated the adverse effect of multiple layers of struts within the PM segment while maintaining the flow condition throughout the SB and DM segment similar to the other techniques. However, as the coverage of the SB ostium in this technique is not as good as CUL or CRU, more of the ostial area can be exposed to potential restenosis, also shown through the localisation of adverse TAWSS and high OSI within more of the ostium section. Therefore, this technique is not suited to lesions which involve the ostium and the proximal SB.

INTRODUCTION

Embolic coils treat intracranial aneurysms (IAs) by inducing blood stasis inside the IA, leading to its thrombotic occlusion, but 20.8% of coil-treated IAs are incompletely occluded at treatment follow-up [1]. Computer simulation of coiling and aneurysmal flow could help predict treatment outcomes *a priori*, but it requires accurate modeling of coils and their deployment. We previously developed a finite element method (FEM)-based virtual coiling technique to investigate effects of different treatment strategies on aneurysmal hemodynamics [2]. Here, we (1) improved the pre-shape and mechanical properties of modeled coils and (2) tested how coiling simulations compared with experimental coil configurations. Being highly dynamic, actual coil configurations are practically irreproducible in simulation, which makes validating coiling simulations challenging. Thus, we developed a new experimental approach for validating coiling simulations. We fabricated 4 physical phantoms based on two patient-specific IAs and deployed 1 or 2 coils in each phantom. To characterize coil configuration, each treated phantom was solidified into a block and sanded down into 5 sequential cross-sections, on which we measured coil density and lacunarity (spatial uniformity). In order to compare our original and improved virtual coiling methods, we simulated the experimental deployments 9 times with different initial conditions in the simulations, using our original and then the improved method in each phantom geometry. The resulting 72 virtually treated phantoms were sectioned into planes to match the experimental phantom cross-sections. Results from both methods agreed well with experiments, with the improved method having better agreement.

METHODS

Improvements to Coil Pre-Shape and Mechanical Properties Coils have a multiscale geometry with three levels: primary wire, secondary spring-like structure, and tertiary pre-shape [3]. As in our original

coiling method, we simplified the coil's complex geometry in the improved method in this study: the coil's primary wire was not modeled and its secondary spring-like structure was modeled as a series of linked, tubular finite element beams. In our original coil method, "random", three-dimensional parametric curves were adopted as the coil's tertiary pre-shape, as demonstrated in Figure 1A. In our improved coil model, we improved the modeling of the coil's pre-shape. Coil pre-shapes are proprietary, but coil patents are publically available, which contain illustrations of pre-shapes. As the basis for our pre-shape model, we selected the pre-shape in Figure 5A of U.S. Patent No. 6,322,576 24 (here, Figure 1B) and modeled it in Solidworks [4]. In our original coil model, we assumed that the coil's beam elements' elastic moduli (E_b , G_b) were the same as the coil's platinum primary wire (E_w and G_w). In the improved coil model, we considered the influence of the coil's spring-like structure and calculated spring-inspired beam properties (E_b and G_b) by equating beam stiffness to spring stiffness (i.e. compressive, shearing, and flexural) to calculate "effective" beam properties [5].

Figure 1: Original and improved coil pre-shape models. A. The original pre-shape model was a "random" spherical 3D curve generated by parametric equations. **The improved pre-shape model** was created by virtually mimicking the mechanical winding of the coil's secondary structure around a complex-shaped mandrel (the "tree-like" structure).

Figure 2: Overview of the experimental approach to extract and characterize coil configuration from the coiled phantoms.

and in each phantom, we modeled the physical coil deployments 9 times using both our original and improved modeling methods. The virtually treated phantoms were sectioned into 5 planes matching those extracted from the experiments, and virtual coil distributions were quantified. To compare the simulation results with experiments, coil distribution quantifications were plotted together and analyzed. To obtain a “volumetric” (or 3D) representation of coil configuration resulting from each deployment, we summed the values of CD and L of each deployment over the 5 cross-sections. To quantify distances between the volumetric experiment and simulation points in order to compare the accuracy of the both simulation methods, we standardized CD and L such that they were on the same scale. Then, we calculated 3 Euclidean

Figure 3: Examples of virtual coiling results from the original (green) and improved (blue) methods in virtual Phantom A2. Only 4 of the 9 virtual deployments are shown for each method.

Experimental Approach to Evaluate and Validate Coiling Methods In order to experimentally validate our virtual coiling methods, as well as determine if the improved method had better accuracy than the original method, we developed an *in vitro* approach to extract and characterize the geometry of coil configurations in patient-specific IA phantoms. To obtain real coil configurations to validate our coiling method, we deployed one or two coils in two phantoms each of two patient-specific IAs. These 4 coiled phantoms were solidified in epoxy and sanded to extract 5 intra-aneurysmal cross-sections from which coil configuration was characterized and quantified. Specifically:

1. To create physical phantoms of the aneurysm models, we 3D printed plastic molds (positive) of their *stl* files and created optically clear silicone phantoms (negative) from them, using our previously developed phantom fabrication technique [6].
2. To obtain coil configuration from the coiled IA phantoms, we extracted 2D cross-sections by solidifying the phantoms in epoxy, sanding them down sequentially in planar cross-sections, and stepwise imaging the coil containing cross-sections [7].
3. To characterize coil configurations, we binarized the 2D cross-section images and quantified coil distributions on them using coil density (CD) and lacunarity (L) (spatial uniformity) [8].

A flowchart summarizing this experimental approach is shown in Figure 2.

To compare and validate our virtual coiling methods, we modeled each physical phantom and in each phantom, we modeled the physical coil deployments 9 times using both our original and improved modeling methods. The virtually treated phantoms were sectioned into 5 planes matching those extracted from the experiments, and virtual coil distributions were quantified. To compare the simulation results with experiments, coil distribution quantifications were plotted together and analyzed. To obtain a “volumetric” (or 3D) representation of coil configuration resulting from each deployment, we summed the values of CD and L of each deployment over the 5 cross-sections. To quantify distances between the volumetric experiment and simulation points in order to compare the accuracy of the both simulation methods, we standardized CD and L such that they were on the same scale. Then, we calculated 3 Euclidean distances, namely d_{Min} , d_{Max} , and d_{Avg} .

RESULTS

As an example of physically deployed coils in an IA, treated Phantom A2 is shown in the middle of Figure 3. Images of the 5 cross-sections – the result of sanding this coiled phantom – are also shown. For virtual coiling results in the virtual phantoms, Figure 3 shows 4 of the 9 simulated

deployments by both modeling techniques in Phantom A2. The top row of Figure 4 shows binarized images of cross-section 2 (S_2) of Phantoms A1 and A2, together with the CD - L graphs for this cross-section. The bottom row of Figure 4 shows volumetric CD and L . The graphs show that the improved method produced volumetric realizations closer to the experimental realizations in the four phantoms. Figure 6 shows the results of the Euclidean distance calculations. Figure 6A illustrates the concepts of the 3 Euclidean distances, using the results of Phantom A2 as example. Figure 6B plots bar graphs of these distances resulting from the 2 virtual coiling methods for the 4 phantoms.

It is clear from Figure 6B that d_{Min} , d_{Max} , d_{Avg} are consistently smaller for the improved method than for the original method. This result was the same in the other 3 phantoms. In

other words, regardless of what distance is considered, the improved method better captures the physical reality than the original method.

DISCUSSION AND CONCLUSION

In this study, we improved the coil model in our FEM-based virtual coiling method and developed a validation approach to test if the improvements led to more accurate coiling simulations compared to experiment. Our results indicate that while both the original and improved methods agreed well with experiments, the improved method had consistently better agreement. This suggests that the model improvements were necessary to increase the accuracy of the virtual coiling method.

INTRODUCTION

Image-based computational tools have helped gain insights into clinical diagnosis and treatment decisions for cerebrovascular diseases like intracranial aneurysms (IAs) [1]. However, these tools have failed to translate into the clinical workflow to aid the clinicians in decision-making. One of the big bottlenecks for the lack of translation is the segmentation of patient's medical image to create 3D vascular model. Currently, the segmentation processes in the computational tools are either manual or semi-automatic [2-5]. In both these segmentations, it is necessary to clean-up the final 3D model, and correctly distinguish between vasculature and imaging artifacts during the processing. This manual interaction with the image is highly time-consuming and subjective, which makes segmentation a big bottleneck in the computational tools. Therefore, if computational tools are to be translated into the clinic, the segmentation has to have the following features: automated, objective, efficient and anatomically accurate. To that end, in this study we propose an automated workflow for segmentation of 3D medical images using group morphology and convolution neural networks (CNN). Furthermore, with digital subtraction angiography (DSA) being the gold standard for IA examinations [5], we show the application of our workflow, by training and validating our model on 45 patient-specific 3D DSA images of aneurysm patients. We quantified dice similarity coefficient (DSC) of our model on an independent test dataset (n=5), which quantifies the similarity of our workflow's predictions as compared to the ground truth (manual segmentation).

METHODS

The flowchart of the proposed automated segmentation workflow is shown in Figure 1. The workflow consists of four steps: (1) pre-processing, (2) patch-extraction and CNN predictions, (3) image-binarization, and (4) post processing. In the first step, we take the complete (512^3 voxels) or partial (localized to major arteries susceptible to aneurysms) 3D cerebrovascular image, and use group morphological erosion-dilation process to eliminate erroneous imaging artifacts. In step 2, smaller patches are extracted from the cleaned image and a pre-trained CNN predicts the probability of each voxels in the patch being part of vasculature. In step 3, these predictions are binarized into either 1 (vessel) or 0 (background). This binarized image is further cleaned up

Figure 1: Workflow for automated segmentation of 3D vascular images, combining 3D CNN with group morphology operations.

Figure 2: Proposed 3D U-Net for predicting vessels and background.

to get rid of any disconnected branch to give a fully connected network of desired vasculature. The following section provides details on the methods used in each step.

Pre-processing using erosion-dilation

We used group morphological opening (erosion followed by dilation) to remove erroneous imaging artifacts. This method first 'erodes' the objects smaller than the structuring element and then dilates to restore the shape of the remaining objects for artifact removal.

Patch extraction and CNN architecture

For training, the pre-processed image was divided into smaller patches with 50% overlap. Overlap amongst patches helps maintain continuity in data [6] and increases the number of training samples. For prediction, repeated values in overlapping patches were weighted-spline averaged for patch fusion [6]. As shown in Fig. 2, U-Net architecture is

used for the CNN, which is a well-established 3D CNN for biomedical image segmentation [7].

Image binarization based on Otsu's thresholding

The predictions from the CNN network are real numbers between 0 and 1, separating background from vasculature. To binarize these predictions a generalizable Otsu's thresholding method [8] is employed, which objectively maximizes the between-class variance of the classes.

Post-processing using morphological binary area opening

Morphological area opening was used to remove unattached artifacts in the CNN predictions to yield cleaner final segmentation.

Proof of concept study

Steps 1 and 3 in our automated workflow were derived mathematical formulations, which have been established and tested in other applications [9]. However, step 2 involves a 3D CNN, which required training to test the feasibility of our complete segmentation workflow. To that end, we collected 3D DSA images of 50 aneurysm patients to train (n=40), validate (n=5) and test (n=5) the feasibility of the computational workflow.

For this study, from the collected images we used only the regions encompassing the major arteries susceptible to aneurysms from the collected images. For showing feasibility of the workflow, a pipeline without the pre-processing step was implemented and tested. Moreover, the patch fusion for predictions were done by simple averaging.

Training & testing of the CNN model

For the CNN training and testing, first, the patient specific 3D DSA were manually segmented inside the pre-extracted ROI. The segmented surface were voxelized using the open-source mesh voxelization algorithm [10] and converted to binarized 3D volumes.

The CNN model was trained using the patches pre-extracted from the ROI. Different patch sizes were tested to evaluate the trade-off between accuracy and memory requirements. The percentage overlap for predictions was also varied to evaluate the trade-off between accuracy and the computational cost. For the model training, a hybrid of binary cross-entropy and Dice Similarity Coefficient (DSC) was used as the loss function [6]. As DSC was used as one of the contributor of the loss function, only patches with atleast one '1' label in the ground truth were used for the training [6]. The models trained for varying patch sizes and % overlaps were evaluated by comparing the DSC.

PRELIMINARY RESULTS

The performance of the models' training using 16^3 , 32^3 and 64^3 sized voxel patches with 50% overlap on the training and validation cohort is shown in Fig. 3. The convergence of the models in the training and testing cohort can be observed from the progression of the loss function and DSC towards a plateau after ~700 epochs.

Optimum patch-size and overlapping voxels

Figure 3: Loss and dice similarity coefficient for different patch of training models. Results showed that a patch size of 32 voxels provided best training.

The performance of the models on complete images of the validation cohort can be seen in Fig. 4. The graphs indicate the sensitivity analysis of the model to patch size and % overlap used for the predictions. A patch-size of 64 incrementally yields the highest DSC. Overlap of 87.5% yielded the highest DSC for varying % overlap. But considering the time taken to predict results at such high overlap %,

an overlap of 50% is ideal. A higher % overlap results in incremental difference in the performance, but exponentially increases the time required for the prediction.

Figure 4: Dice coefficient and computational efficiency of using different overlaps of the patch size during training.

With an ideal patch-size of 64 and ideal % overlap of 50% along with post-processing, the model yielded a DSC of 0.919 ± 0.0342 on the testing cohort (n=5). A representative case from the testing cohort has been shown in Fig. 5. With only 40 cases used for training, the model was able to segment the major arteries but misses out on some minor arteries as can be seen in Fig. 5.

Figure 5: Comparison of automatically segmented image from the proof of concept study (training n=40) with manual segmentation for a representative 3D DSA

DISCUSSION

This proof of concept study for automated segmentation of cerebral vasculature from 3D DSA images produces a DSC of 0.919 ± 0.0342 on the independent testing cohort, when trained and validated on 40 and 5 cases, respectively. Furthermore, for predictions on the testing cohort, we found that optimum path-size of 64 and % over-lap of 50% gave the best trade-off between accuracy and computational cost. We found that our model missed smaller arteries during the predictions, which might due to the limited number of cases available for training (n=40). With a higher number of cases, we believe that our workflow would be able to capture these smaller arteries and be more robust. Thus, our tool has the ability to be potentially used in a clinical setting to provide reliable and quick segmentation for further analyses.

CONCLUSIONS

This work gives a feasibility study of the concept of using group morphological operations along with deep learning on the major cerebral artery segmentation to achieve automatic, objective, computationally efficient and accurate segmentation that can be used for accurate analysis downstream of the analysis pipeline.

INTRODUCTION

In aortic dissection (AD), an aortic wall tear results in a false lumen formation, leading to complications such as aneurysm growth, rupture, end-organ malperfusion and hypertension [1]. Hemodynamics are highly complex, with a wide range of velocities and chaotic flow. Thus, the study of this pathology can be greatly benefitted by numerical and physical modeling, the latter relevant in CFD validation studies. However, despite great advances in patient-specific physical models [2-4], representation of wall mechanical properties is still a challenge. The purpose of this study was to present the feasibility of a flexible AD model fabrication and in vitro testing for flow assessment.

METHODS

Model Design and Fabrication

A virtual 3D geometry was created by extruding the cross-section of an AD taken from medical data (Mimics, 3-matic; Materialise; Leuven, Belgium) (Fig. 1A). Connectors were added at the inlet and outlets. The inlet section was combined into a single channel while each outlet was kept isolated (Fig. 1B).

The geometry was 3D printed (fused deposition modeling) using polyvinyl-alcohol (PVA) and placed in a PMMA casting box [2]. Sylgard 184, a PDMS silicone (The Dow Company; Midland, MI), was used as the model material, due to its refractive index and material properties, loosely comparable to common cardiovascular tissues [4]. Sylgard components were mixed (10:1 ratio) and degassed in a vacuum chamber (-80 kPa, 45 minutes) to remove air bubbles before pouring into the mold to cure. The PVA core was then manually removed after softening by soaking in hot water. The final model is shown in Fig. 1C.

Optical Imaging

A high-speed camera system (Phantom v341, Vision Research, Wayne, NJ), equipped with 60 mm f/2.8D lenses (Nikon Inc.,

Melville, NY), was set up to visualize model walls [5]. A 42% water-58% glycerol solution ($\rho = 1.14 \text{ g/cm}^3$, $\mu = 0.01017 \text{ Pa-s}$) was used to match Sylgard 184 refractive index ($n = 1.41$), and was circulated using a pulsatile flow pump (BDC Laboratories, Wheat Ridge, CO). The model walls were imaged for approximately 1 s.

Figure 1: A) Virtual 3D geometry of the extruded AD cross section; B) idealized AD model as a casting insert; C) finalized silicone AD model.

Images were used to measure the length of both the true and false lumens (TL, FL) from a lateral view (Fig. 2). Change in length was recorded at several time points, using in vitro peak systole as the reference.

4D Flow MRI

MRI scanning was performed in a clinical 3T scanner (Discovery MR 750, GE Healthcare, Waukesha, WI) using a 5-pt phase contrast vastly undersampled isotropic projection (PC-VIPR) [6] sequence. Scanning parameters were FOV 320 x 320 mm, TR/TE = 6.15/2.0 s, FA 8, slice thickness 1.25 mm, Venc = 80 cm/s. Cardiac gating was used to align the data acquisition with the pulsatile flow profile. The data was reconstructed with 14 time steps and corrected for motion and noise.

Figure 2: Lateral view of AD model from high-speed camera, indicating length measurements.

MR images were processed (EnSight; CEI Inc, Apex, NC) to visualize velocity distribution at cross planes, velocity streamlines and vectors. Time-resolved magnitude images were used to measure area of FL and TL at a plane located at the longitudinal center of the model along the cardiac cycle (ImageJ; public domain, NIH).

RESULTS

Optical Imaging

Resulting length measurements from high-speed camera images show some change in length of the lumens (mean strain 3.22% for FL and 0.1% for TL), thus demonstrating some flexibility or flap movement, represented especially on the FL.

4D Flow MRI

Fig. 3A shows velocity magnitude distribution throughout the model. Velocities were higher in the TL compared to the FL. Furthermore, velocity streamlines show completely retrograde flow in the FL; some of the flow exits the FL through the inlet bifurcation to enter into the TL (Fig. 3B). Velocity vectors show high magnitudes in the TL, exhibiting a non-parabolic profile (Fig. 4).

Area measurements in time-resolved magnitude images throughout the pumping cycle show variations that resulted in a mean strain of 3.50% for the FL and 3.20% for the TL.

DISCUSSION

The fabrication methods in this study show the feasibility of a 3D printed model with flexible walls. Several manufacturing process aspects can be optimized to achieve in vitro wall properties appropriately representing cardiovascular pathologies. Modifications of the flap and surrounding silicone block geometry could allow more deformation. Future work will also focus on a more patient-specific geometry. The fabrication methods here described provide a model with the transparency apt for particle image velocimetry, allowing highly accurate CFD and 4D Flow MRI validation.

This study was successful in using a pulsatile in vitro system in combination with the flexible model, which contrary to other flexible resin models, was able to withstand working pressures and flow conditions. Existence of a FL produces chaotic and retrograde flow, usually present in ADs. The use of 4D Flow MRI allows the study of velocities throughout the model. With geometries and wall properties

that more closely represent in vivo tissues, models can be used to systematically study FL hemodynamics in vitro.

Figure 3: A) Velocity distribution along the AD model; B) velocity streamlines.

Figure 4: Velocity vectors at the longitudinal center of the AD model, at in vitro peak systole.

Both optical imaging and magnitude image measurements demonstrate transverse change in area of the lumens. The FL exhibits a higher strain. The lower resolution in MRI magnitude images is a limiting factor, as well as some subjectivity in contouring and measuring boundary definition. The TL strain measured in optical images was low compared to magnitude image measurements. This could indicate bulk movement along with the flap towards the FL or deformation in the other dimension of the cross plane. However, both techniques resulted in evidence of in vitro wall movement.

INTRODUCTION

Flow diverter (FD) is a self-expanding, densely woven stent mesh implanted across the neck of an intracranial aneurysm (IA) as an effective endovascular treatment device. By diverting the blood flow away from the aneurysm and into the parent artery, the FD aims at inducing stasis inside the IA, which causes thrombotic occlusion of the aneurysm and thus excludes it from the circulation. Despite the unique effectiveness of FD in treating challenging IAs such as giant, wide-necked and fusiform aneurysms, approximately 25% of FD-treated aneurysms do not occlude within 6 months of treatment.[1] For such unoccluded cases, persistent blood flow in the aneurysm may expose it to thrombotic complications and latent risk of rupture.[2]

Studies have shown that residual filling of the FD-treated IAs reflects ineffective flow diversion of FD in the unoccluded cases.[3,4] Paliwal et al. have found that FD treatment outcome is dependent on the post-treatment hemodynamics [3], which in turn depends on the geometrical parameters of the implanted FD. Therefore computer modeling of FD implantation using “virtual stenting” techniques along with computational fluid dynamics (CFD) could potentially aid clinicians in treatment planning.[5-8]

For a virtual stenting algorithm to be integrated into the clinical workflow, it needs to be able to accurately and rapidly simulate the FD treatment in patients. Previously, we developed an FEA-based high fidelity virtual stenting (HiFiVS) technique, which accurately captures the physics of FD deployment processes.[5,6] However, the computational cost associated with this method is high.

Recently we developed two fast virtual stenting techniques—virtual stenting workflow (VSW) and ball sweeping (BS). The VSW is a dynamic algorithm based on pseudo-physical forces for expansion of a generic simplex mesh in the parent artery.[7] Although it has been used in many clinical studies, [3,9] the modeling technique has not been properly validated. The only validation of VSW was a comparison of post-treatment CFD results for a porous Enterprise stent—not FD—in a patient-specific IA, against CFD results of post virtual stenting using the HiFiVS technique. The HiFiVS technique itself was rigorously validated in terms of deployed FD geometry [6]. Since FDs are composed of a much larger number of braided wires than the Enterprise stents, the VSW simulations of FD deployment still have to be geometrically and hemodynamically validated against experiments.

To further reduce computation, the BS technique takes a very different approach by skipping expansion and collision detection.[8] Being a static algorithm, BS sweeps a maximally inscribed sphere along the parent artery to directly generate a stent surface. However, since BS completely lacks the physics, it is unclear whether it can accurately represent the actual FD deployment. Thus, it is imperative to validate BS to investigate whether it can still provide accurate FD deployments in patient-specific IAs.

Clearly, there is a need to validate the accuracy of both VSW and BS algorithms for simulating FD deployment against experimental data. This was the purpose of this study.

METHODS

We employed VSW and BS algorithms to simulate the deployment of pipeline embolization device (PED) in three representative patient-specific aneurysm models: two internal carotid artery (ICA) aneurysms (one 7 mm and one 17 mm) and one anterior cerebral artery (ACA) aneurysm (10 mm). We physically deployed a PED in each of the phantoms of these IAs and evaluated the accuracy of the virtually deployed PED geometry against the experimental results. We also validated the CFD-derived post-treatment flow in the virtually treated IAs against particle image velocimetry (PIV) measurements in the phantoms.

Validation Workflow – As shown in Fig.1 we segmented the DICOM images of the selected IAs. Next, we 3D printed Vero models of these IAs and used them to fabricate silicone phantoms using the lost wax technique.[10] One PED (ev3, Chestnut Medical, Menlo Park, CA) was deployed in each phantom by an experienced neurointerventionalist. We captured the geometry of the deployed PEDs in the silicone phantoms using bright field imaging and performed image processing to calculate the porosity and pore density. Furthermore, to measure post-treatment hemodynamics, we performed PIV experiments on the treated phantoms and measured the IA velocity on a 2D plane. Next, we imaged the phantoms to obtain their 3D geometrical models and modeled the FD deployment using VSW and BS algorithms. The porosity and pore density of the virtually implanted devices were calculated and compared against the experimental results. We also performed CFD on the virtually treated IAs to obtain the velocity field in each aneurysm and compared them against PIV measurements.

Figure 1 Validation workflow

Geometric and Hemodynamic Parameters – We captured the experimental and virtual deployed PEDs (for both VSW and BS) from sagittal and transverse views and divided each one to 3 zones: “proximal”, “neck”, and “distal.” We further divided each zone to 4 patches, totaling 12 patches for each IA. These patches matched between experiments and virtual models. We calculated porosity and pore density for each patch, and quantified the absolute errors in these metrics between experiment and both VSW and BS. These errors were averaged over all the patches across all 3 IAs in each zone, which resulted in a single average error for each algorithm at each zone. A student’s t-test was performed on the errors to determine whether there was a statistical difference between the two algorithms at each zone.

In addition to geometrical parameters, we calculated the post-treatment average IA velocity at the PIV plane from both CFD and PIV velocity fields. We also calculated the average 2D inflow velocity at the neck. For each of the hemodynamic metrics, we calculated the error between PIV and CFD for each algorithm and performed student’s t-test to determine if there was statistical difference between them.

RESULTS

Geometrical Accuracy – Figure 2 shows the deployed PED in the 3 IA models from experiments and the two virtual stenting modeling techniques. Qualitatively, the VSW results match experiments better than BS. In particular, the virtual FDs simulated by BS show large and irregular bulges at the IA neck, which are absent in the physically

Figure 2 Experimental and virtual deployments in 3 IA models

Figure 3 Average errors in porosity (a) and pore density (b) at the 3 zones for VSW and BS deployment. * indicates $p < 0.05$

deployed FDs. To quantify the accuracy of the algorithms in recapitulating the FD geometry, we calculated the porosity and pore density of the PED patches. As shown in Fig. 3, VSW had lower average porosity errors ($p=0.589$ at proximal, $p=0.593$ at neck, $p=0.692$ at distal) with smaller standard errors, and lower average pore density errors ($p=0.003$ at proximal, $p=0.049$ at neck, and $p=0.004$ for pore density) with smaller standard errors, compared to BS.

Hemodynamic Accuracy – We compared the CFD-calculated flow fields on virtually treated IA models against the PIV measurements on

a representative plane in each PED-treated phantom. Figure 4 shows that CFD flow field on both VSW- and BS-treated IAs qualitatively captured the PIV measurements basic flow patterns in terms of the inflow jet location, the number and location of the vortices in the aneurysm, and the overall flow pattern. However, quantitative comparison of IA average velocity (Fig. 5-a) and 2D inflow velocity (Fig 5-b) shows higher accuracy for VSW in all IAs, albeit not statistically significant ($p=0.167$ for IA velocity and $p=0.105$ for 2D inflow velocity).

Figure 4 Post-treatment flow fields from PIV experiment and simulations

Figure 5 IA average velocity and average 2D inflow velocity calculated from CFD and experiment. Percent errors are shown on top of the bars.

DISCUSSION AND CONCLUSION

The VSW algorithm outperformed BS in capturing the PED geometry. Pore density from VSW had significantly less error compared to BS. Porosity from VSW was also smaller albeit not significantly. Moreover, in terms of hemodynamics, VSW-treated IAs had average less error than BS-treated cases IA velocity and 2D neck inflow velocity, calculated from CFD, but these did not reach statistical difference. The computational time performance of the two algorithms need to be evaluated in the future.

ADHESION EFFECT ON LOCALIZATION OF DEFORMABLE MICRO-PARTICLES IN BLOOD FLOW

INTRODUCTION

The margination and adhesion of micro-particles (MPs) have been Margination, defined as the migration of a particle in blood flow towards the periphery of the blood vessel, allows the particle to come close to the endothelium, and then adhere to the vessel wall [1]. It is of significant importance to understand such physiological processes for curing relevant diseases. For example, in the inflammation process, margination of leukocytes towards the vessel wall is the precondition for an organism to perform defence functions, such as adhering to vascular endothelium and transmigration into the tissues. In atherosclerosis, the thrombosis, formed by the clot, is caused by the margination and accumulation of numerous platelets responding quickly to events on the vessel wall, e.g. injury. Additionally, margination has extensive applications in microfluidic devices for the removal of pathogens and the separation of cells [2].

METHODS

We use the lattice Boltzmann method and molecular dynamics to solve the fluid dynamics and particle dynamics (including red blood cells (RBCs) and elastic MPs) in blood flow, respectively. Additionally, a stochastic ligand–receptor binding model is employed to capture the adhesion behaviours of elastic MPs on the vessel wall. The schematic is shown in Figure 1.

RESULTS

Margination probability is used to quantify the localization of elastic MPs at the wall. Two dimensionless numbers are considered to govern the whole process: the capillary number Ca , denoting the ratio of viscous force of fluid flow to elastic interfacial force of MP, and the adhesion number Ad , representing the ratio of adhesion strength to

viscous force of fluid flow. We systematically vary them numerically and a margination probability contour is obtained. We find that there

Figure 1 Transport of elastic MPs in blood flow. (a) Computational model of margination and adhesion of elastic MPs in blood flow. The zoomed panels give the detailed adhesion behaviour of an elastic MP under a stochastic ligand–receptor binding effect. (b) Schematic of transport process of an elastic MP from the centre of the bloodstream (denoted (C)) to the cell-free layer (F), and then reaching the adhesion layer.

exist two optimal regimes favouring high margination probability on the plane Ca – Ad . The first regime, namely region I, is that with high adhesion strength and moderate particle stiffness; the other one, region II, has moderate adhesion strength and large particle stiffness (see Figure 2).

Figure 2 Contours of margination probability on the Ca – Ad plane

DISCUSSION

We conclude that the existence of optimal regimes is governed by the interplay of particle deformability and adhesion strength. The corresponding underlying mechanism is also discussed in detail. There are three major factors that contribute to the localization of MPs: (i) near-wall hydrodynamic collision between RBCs and MPs; (ii) deformation-induced migration due to the presence of the wall; and (iii) adhesive interaction between MPs and the wall. Mechanisms (i) and (iii) promote margination, while (ii) hampers margination. These three factors perform different roles and compete against each other when MPs are located in different regions of the flow channel, i.e. near-wall region. In optimal region I, adhesion outperforms deformation-induced migration; and in region II, the deformation-induced migration is small compared to the coupling of near-wall hydrodynamic collision and adhesion [3].

INTRODUCTION

Image based computational fluid dynamics (CFD) has the capability to enhance medical imaging outcomes, investigate complex biomechanics phenomena and improve clinical decision making [1-4]. Image based CFD has been applied to many cardiovascular diseases like coronary artery stenosis [1], congenital heart defects [2,3] and cerebral aneurysms [4]. Numerical and computational resource advances allow the use of patient specific vessel wall stiffness in fluid-structure interaction (FSI) [5] and patient specific reduced order modeling of the distal vasculature [6] not directly available from medical imaging. Using FSI with patient specific vessel stiffness is important for accuracy as CFD simulations assuming rigid walls have been shown to overestimate wall shear stresses and fundamentally alters the physics of pulsatile flow as waves will be propagated at infinite speed. Reduced order modelling of the distal vasculature has been shown to improve velocity field accuracy. While patient specific vessel wall and distal vasculature properties are important for accuracy, previous methods to define these patient specific boundary conditions (BCs) are based on pressure measurements [7,8]. Tonometry can be used to measure pressure in the carotid and iliac arteries for estimating pressures in aortic simulations but invasive catheterization is required to measure pressure in other cardiovascular.

The goals of this abstract are: 1. Describe a method for defining patient specific BCs from non-invasive 4D Flow MRI, 2. Validate this method for an *in vitro* model, 3. Demonstrate the feasibility of defining patient specific BCs from 4D Flow MRI *in vivo*.

METHODS

Our noninvasive method to determine patient specific BCs from 4D flow MRI is motivated by cardiovascular physics and physiology

(Fig1). First, pulse wave velocity (*PWV*) is used to determine the vessel stiffness (*Eh*, *E* is elastic modulus and *h* is wall thickness).

$$Eh = \frac{PWV^2}{\rho D} \quad (1)$$

PWV is calculated as the slope of flow versus area in early systole [9]. This is derived from wave intensity analysis (WIA) where flow rate (*Q*) and vessel cross-sectional area (*A*) are decomposed into forward and backwards travelling waves. It can be derived from conservation laws that *PWV* is equal to the ratio of incremental changes in either forward or backward traveling waves. The difficulty is that to decompose waves into forward and backward travelling components *PWV* must be known. Fortunately, in early systole it is appropriate to assume that there are only forward travelling waves and thus *PWV* is calculated as the ratio of incremental changes in *Q* and *A*.

$$PWV = \pm \frac{dQ_{\pm}}{dA_{\pm}} \approx \frac{dQ}{dA} \Big|_{t \in \text{early systole}} \quad (2)$$

Once stiffness is known from *PWV*, the pulse pressure in the vessel can be calculated from the systole to diastole artery area change using the Law of Laplace [10]. Distal compliance (*C*) can then be calculated from *Q* and the pulse pressure (ΔP).

$$\Delta P = \frac{\sigma_{\theta\theta} h}{R_{dia}} = \frac{E \epsilon_{\theta\theta} h}{R_{dia}} = \frac{Eh}{(1-\nu^2)R_{dia}} \left(1 - \sqrt{\frac{A_{dia}}{A_{sys}}} \right) \quad (3)$$

$$C = \frac{\Delta V}{\Delta P} = \frac{(Q_{sys} - Q_{dia})(t_{sys} - t_{dia})}{\Delta P} \quad (4)$$

Lastly, an exponential decay is fit to vessel area during diastole. The exponential time constant (τ) is assumed to be the distal vasculature time constant and used to calculate resistance $R = \frac{\tau}{C}$. While τ for area will not be the same as τ for pressure, vessel area is a function of pressure and should provide an estimate of τ .

FSI is performed for half a cardiac cycle to rapidly estimate stiffness as *PWV* is not affected by initial transients. Vessel stiffness is

Figure 1: A. Flow chart describing the algorithm to determine patient specific conditions from 4D Flow MRI. An initial iterative loop is used to rapidly match PWV, then a second loop matches RAC and τ , **B.** Geometric models of the *in vitro* phantom and the *in vivo* PAS. Original geometry is opaque while the deformed geometry is shown as transparent. **C.** Error plots of the *in vivo* PAS showing the convergence of PWV, RAC and τ over the course of 7 FSI simulation iterations. The simulation is considered to match 4D Flow MRI when error is less than 10%.

Table 1: FSI Validation Against Benchtop Measurements

Measurement	Benchtop [11]	FSI	Error
PWV (cm/sec)	93 ± 2	102	10%
Max Disp (mm)	1.73 ± 0.02	1.98	15%

modulated until error between measured and simulated PWV is less than 10%. Next, four heartbeats are simulated to reach a periodic solution. Compliance and resistance are modulated until relative area change (RAC) and τ error is less than 10%.

The method is applied to an *in vitro* phantom of pulsatile flow in a latex tube (Fig1B) [11] and validated compared to benchtop measurements. MRI is obtained on a 3.0T scanner using 4D Flow MRI PC-VIPR (Phase Contrast Vastly Under sampled Projection Imaging) [12]. Flow rates are calculated from velocity fields and vessel areas from complex difference images. FSI is performed with the open source software Simvascular [5, 13]. After validation an *in vivo* subject specific simulation of a porcine pulmonary artery stenosis (PAS) (Fig1B) is performed. BCs from the PAS are then applied to the same anatomy with a virtually placed stent to simulate catheter based intervention. The results of the virtual intervention are compared to 4D Flow MRI measurements taken immediately before and after intervention in the porcine PAS.

RESULTS

FSI displacements (Fig1B) agree with MRI measurements. FSI and 4D flow measurements for *in vivo* PAS (Fig1C) converge to the 10% error criterion for PWV at the second iteration, τ at the fourth iteration and RAC at the seventh iteration. This is a comparable number of total iterations to methods using pressure [7,8]. FSI shows reasonable agreement with benchtop measurements (Table 1). Virtual intervention accurately predicts post-intervention LPA flow percentage 9% error versus 4D Flow MRI. There is error between FSI and 4D Flow MRI for the stenosis which could be due to difficulty segmenting an accurate stenosis geometry.

DISCUSSION

Using 4D flow MRI to determine FSI BCs enables implementing advantages of patient specific simulation in enhancing information from medical imaging, surgery and intervention planning, and basic science research without the risks associated with catheterization. Realistically, a cardiologist will only perform invasive catheterization when necessary for treatment or diagnosis. For patient specific simulation to be widely applicable, methods for non-invasively determining BCs need to be developed and validated.

This method may not give as accurate of simulated pressures, particularly mean pressure, as approaches which use pressure catheterization to determine BCs. For an incompressible liquid such as

Figure 2: A. Virtual intervention predicts stenting decreased MPA pressure and **B.** accurately predicts LPA flow percentage.

blood, only pressure gradients drive flow not the mean pressure. For applications looking at local flow quantities such as velocity, wall shear stress or pressure gradients fitting BCs to vessel wall motion could provide more accurate results as the flow will now be solved for more accurate time resolved geometry. For other applications such as quantifying ventricular afterload in a closed-loop simulation, accurate mean pressures are important.

Flow and areas measured from 4D Flow MRI can determine vessel wall stiffness and distal vasculature bed resistance and compliance. The ability to determine BCs for patient-specific simulations without invasive catheterization increases the ability to couple FSI and 4D Flow MRI for translational and basic science studies of cardiovascular disease and eventually clinical decision making. Future work will validate this method in additional *in vitro* phantoms against high speed camera strain measurements [15] as well as apply this technique to other vascular anatomies.

DIFFERENCES IN PARENT ARTERY GEOMETRY BETWEEN ACOM AND MCA ANEURYSMS

F. Mut (1), M. Lawson (1), J. R. Cebal (1)

INTRODUCTION

Understanding the mechanisms of aneurysm formation and evolution towards rupture or stabilization is important to improve patient selection for treatment or conservative observation as well as for improving procedures and devices [1].

Hemodynamics is thought to be involved in the process of aneurysm formation, and in particular high flows and wall shear stress have been implicated in the initiation of intracranial aneurysms [2]. Although hemodynamics is also thought to influence the progression and rupture of cerebral aneurysms, its role in these mechanisms has not been clearly established [3].

It is well known that aneurysms selectively form at arterial bifurcations in or around the circle of Willis and that aneurysms at different locations have different rupture risks and may rupture at different sizes [4].

Aneurysms at the anterior communicating artery (ACOM) are fed by the A1 segments of the anterior cerebral artery (ACA), while aneurysms at the middle cerebral artery (MCA) bifurcation are fed by the M1 segment of the MCA. Both, the M1 and A1 branches are supplied by the internal carotid artery (ICA), which at its terminus bifurcates into the ACA and MCA. Thus, if hemodynamics influences aneurysm formation (and subsequently aneurysm evolution), it is reasonable to hypothesize that the ICA bifurcation of patients with ACOM aneurysms may be different from those of patients with aneurysms at the MCA bifurcation.

Therefore, the aim of this study was to compare the geometric characteristics of the ICA bifurcation between patients harboring aneurysms at the ACOM and patients with aneurysms at the MCA bifurcation, and between ruptured and unruptured aneurysms at these two locations.

METHODS

Aneurysm Data

Patients with aneurysms in the anterior communicating artery or the middle cerebral artery were selected from our database of patient-specific computational fluid dynamics (CFD) models. The requirement for inclusion was that the entire segments of the internal carotid artery from the ophthalmic artery to the ICA terminus, the M1 segment of the MCA from the ICA terminus to the MCA bifurcation, and the A1 segment of the anterior cerebral artery from the ICA terminus to the ACOM origin were included in the vascular model. A total of 66 patients with MCA aneurysms (46 unruptured, 21 ruptured) and 55 patients with ACOM aneurysms (24 unruptured, 32 ruptured) were included in the study.

Vascular Data

Patient-specific vascular models previously constructed from 3D rotational angiography images and stored in our database [5] were used to quantitatively characterize the geometry of the M1, A1 and ICA ophthalmic-terminus arterial segments, as well as the ICA bifurcation.

Vessel skeletons are automatically constructed using an advancing front method that starting from the vascular model inlets and outlets iteratively places maximally inscribed spheres along the vessel axes until no more spheres can be placed, or the skeleton connects to another skeleton node. In a subsequent step arterial branches containing no skeleton nodes are identified and new starting points are automatically added, and the advancing front process is repeated. With this approach, it is possible to automatically skeletonize branches such as the ACOM or PCOM connecting independent arterial trees into an arterial network. Skeletons are oriented from the vascular model inlets towards the

outlets (the orientation of communicating arteries is arbitrary). In a second step, the vascular model and the network skeleton are loaded into a graphical tool that allows the user to manually edit the skeletons to correct any topological defects, create new branches if missing, delete undesired branches, split or join branches, re-orient the skeletons, and finally label different anatomical arterial branches and bifurcations, such as the M1, A1 and the ICA ophthalmic-terminus branch and ICA bifurcation.

Arterial Characterization

Once the arterial branches have been skeletonized and labeled, their geometries are characterized by computing the following quantities: a) length – pathline or geodesic length along the branch, b) diameter – mean diameter of the inscribed spheres along the branch skeleton, c) tortuosity – ratio of geodesic length and Euclidean distance between end points, d) tapering – mean rate of change of arterial diameter along arterial branch, and e) eccentricity – average of maximum over minimum diameter of cross sectional cut normal to the branch. Similarly, arterial bifurcations (ICA in this case) are characterized by computing the angles between the parent branch (ICA) and each of the daughter branches (M1 and A1), and between the daughter branches; as well as ratios of the branch characteristics a-e) of A1 segments over M1 segments of each ICA bifurcation.

Data Analysis

Geometrical characteristics of A1, M1 and ICA segments and the ICA bifurcation were statistically compared using the Mann-Whitney test between patients harboring ACOM aneurysms versus patients harboring MCA bifurcation aneurysms, as well as between ruptured and unruptured aneurysms of these two groups of patients. The p-values were adjusted for multiple comparisons using the Benjamini-Hochber (BH) method. Differences were considered significant if $p < 0.05$. Statistical analysis was carried out using R.

RESULTS

Comparisons between the mean values of the geometrical characteristics of the ICA bifurcation branches between patients with ACOM and MCA aneurysms are graphically summarized in Fig. 1. This figure shows the ratio of the mean values computed over the ACOM aneurysm group over the mean values computed over the MCA aneurysm group.

Figure 1: Comparison of geometric characteristics of the ICA bifurcation between patients with ACOM vs MCA aneurysms.

These results indicate that patients harboring aneurysms at the ACOM tend to have larger A1 diameters ($p=0.0374$), lower tapering of the A1 ($p<0.0001$), and larger tapering of the M1 segment. Conversely, patients with aneurysms at the MCA bifurcation tend to have larger tapering of the A1 ($p<0.0001$) and smaller A1 diameters ($p=0.0374$), and smaller tapering of the M1, although this latter association was not significant after adjustment for multiple testing ($p=0.0201$, before adjustment; $p=0.0925$, after adjustment).

No significant differences were found between ruptured and unruptured ACOM aneurysms, while ruptured MCA aneurysms had marginally shorter A1 segments than unruptured MCA aneurysms ($p=0.0506$).

DISCUSSION

In summary, the findings of this study indicate that the aneurysm feeding branch (A1 for ACOM aneurysms; M1 for MCA aneurysms) tends to be of larger diameter and with less tapering than the opposite branch of the ICA bifurcation (M1 for ACOM aneurysms; A1 for MCA aneurysms), which also tends to have larger tapering. These findings seem to confirm our expectations that anatomical configurations and geometries of the ICA bifurcation favor increased flows towards the side where the aneurysms formed compared to the opposite side of the ICA bifurcation.

This observation could explain why aneurysms tend to form at one location in one patient and at a different location in other patients, i.e. perhaps the patient's anatomical characteristics favor the creation of adverse hemodynamic environments due to changes in the systemic circulation which could result in wall damage at one location in some patients and in other patients at other locations.

No major differences were found between the ICA bifurcation characteristics of ruptured and unruptured aneurysms at each location, which suggests that the geometry of the parent artery likely influences the location where aneurysms form, but not whether they rupture or not. After formation, the evolution of the aneurysms is likely influenced by the intra-aneurysmal hemodynamics (studies have shown differences between ruptured and unruptured aneurysms, or between stable and unstable aneurysms [6]), which is largely determined by the aneurysm shape and its exact location on the parent artery but not so much of the geometry of the proximal parent artery.

INTRODUCTION

In patients surviving the acute period after aortic dissections (AD), the dissected descending aorta may progress to aneurysm formation (20-50% within 1-5 years^[1]). Understanding which patients are likely to develop aneurysms can affect early disease management and long-term clinical outcomes.

Disturbed fluid dynamics is known to be a key factor in the onset and progression of vessel wall pathological remodeling that leads to decreased wall strength behind AD pathogenesis^[2].

Purpose of this study is to analyze flow patterns and assess blood-vessel interactions by mean of computational fluid dynamics (CFD)-based indices and geometric features as potential risk factors for aneurysmal degeneration of the dissected descending aorta.

METHODS

Multidimensional non-linear growth analysis, assessed on multiple planes across aortic length, was carried on follow-up images of 22 patients with residual dissected descending thoracic aorta after surgery for type A. Patients with a rapidly expanding aorta (maximum growth > 5mm/year^[3]) were compared to patients with a stable aortic size. CFD simulations were performed on patient-specific geometries obtained from CTA images early after surgery for type A aortic dissection.

Time-Averaged Wall Shear Stress (TAWSS), Oscillatory Shear Index (OSI) and Relative Residence Time (RRT) (equations 1,2,3), were computed to quantify local hemodynamic disturbances^[4] and correlated with aortic growth. Flow entering the FL at peak systole was evaluated as a percentage of the total flow in the thoracic aorta.

$$TAWSS = \frac{1}{T} \int_0^T |WSS(s, t)| dt \quad (1)$$

$$OSI = 0.5 \left[1 - \left(\frac{|\int_0^T WSS(s, t) dt|}{\int_0^T |WSS(s, t)| dt} \right) \right] \quad (2)$$

$$RRT = \frac{1}{(1-2 \cdot OSI) \cdot TAWSS} \quad (3)$$

RESULTS

CFD simulations indicate that flow patterns in the dissected aortas are very complex and disturbed, presenting flow separation and recirculation affected by the entry tear size and location

All patients showed low velocities in the false lumen (FL) and higher values in the true lumen (TL), especially in the narrowed region distal to the entry tear.

The TAWSS is uniformly low (< 0.4Pa) in the ascending aortas and the outer surface of the FL, with a region opposite to the tear presenting elevated TAWSS (> 1.5Pa) as consequence of flow impingement on the wall (figure 1). High TAWSS were mostly located at the tear edge, with rapidly growing dissections showing higher peak TAWSS over an increased area combined with larger diameter at first scan and higher FL flow rate (figure 1). Patients with rapid growth also presented an increased tortuosity of the aorta.

Slow recirculating flow associated with prolonged RRT was found in the retrograde expansion of the FL favoring thrombus formation.

The pressure distribution on the aortic wall was also evaluated from CFD results at different times during the cardiac cycle (figure2). The higher systemic pressure in the FL causes the true lumen to collapse during diastolic peak. The systolic phase (systolic peak and mid-systolic

deceleration) presents the opposite situation showing higher pressure in the TL. Patients prone to rapid aortic growth, however, exhibit a different trend, with higher pressure in FL compared to the TL also during mid-systolic deceleration and consequently for most of the cardiac cycle. Red circles in figure 2 highlight the contours showing higher pressure in the vessel region that was subject to enlargement (at the level of the inferior left pulmonary vein on axial view).

Figure 1: CFD-based analysis is reported for three of the patients in the population. Velocity profiles are reported at systolic peak in the top row with the red arrow pointing at flow impingement on the FL wall. TAWSS luminal distribution is shown in the bottom row. Bottom arrows indicate increasing tortuosity and aortic growth.

DISCUSSION

The management of aortic dissection disease is restrained by our understanding and ability to predict each patient’s clinical course. Current clinical practice and several studies have indicated the FL patency to be a risk factor for long-term complications and aneurysmal degeneration, but there is no patient-specific criterion that can reliably predict rapid aortic growth. Our results suggest that CFD-based hemodynamic indices help the characterization and quantification of local flow disturbances, with high shear stress patterns correlating with rapid growth. Flow rate and pressure differences between the lumens maintain a patent FL promoting aortic expansion associated with worse long-term outcomes. CTA images used in the study represent a limitation: they don’t provide patient-specific flow information and they were not electrocardiographically gated, showing the dissection flap position as a time-weighted average of the configuration during diastolic and systolic phase. Local hemodynamics and the characterization of flow patterns are critical factors that may help understand which flow features promote changes in the vessel patho-physiology. The employment of CFD may be a valuable tool to investigate which flow conditions play a role in the progressive weakening of dissected aortas and provide a rationale for

risk stratification by identifying a subgroup of patients that may benefit from early intervention.

Figure 2: Pressure distribution on the aortic wall for three of the patients during three phases of the cardiac cycle, namely systolic peak, mid-systolic deceleration and diastolic peak (from top to bottom). The red circles highlight the pressure contours in the area subject to enlargement for this specific patient.

INTRODUCTION

Type B aortic dissection (TBAD) is a serious clinical emergency which can lead to complications such as aortic aneurysm, rupture or malperfusion syndromes. Thoracic endovascular repair (TEVAR) can effectively treat this disease. Image-based computational fluid dynamics (CFD) has been widely used to evaluate hemodynamics in dissected aortas and after TEVAR. However, most computational models used simplified inlet and outlet boundary conditions, due to the lack of patient-specific flow and pressure measurements, and validation of computational results against *in vivo* measurements is scarce.

The aim of this work is to evaluate TEVAR hemodynamic performance by making use a newly developed CFD methodology for patient-specific analyses based on 4D flow magnetic resonance imaging (MRI) and pressure measurements acquired pre-TEVAR. Results for pre- and post-TEVAR hemodynamics were compared and validated against available *in vivo* measurements.

METHODS

The study was conducted on a TBAD patient (59-year old, female) who presented aneurysmal dilatation in the thoracic false lumen (FL) and was treated with TEVAR in chronic phase [1]. Doppler wire (DW) pressure measurements were taken during TEVAR procedure, before and after stent deployment. CT (computed tomography) images were acquired before and 3 months after TEVAR and were used to reconstruct the pre- and post-TEVAR geometries. The 12-month CT follow-up of this patient was also available. The geometric models included the supra-aortic branches, the superior mesenteric, celiac, renal and iliac arteries, and were discretized into unstructured meshes of about 6 (pre-TEVAR) and 4 (post-TEVAR) million elements.

For both pre- and post-TEVAR models, a full set of patient-specific boundary conditions was obtained using the pre-TEVAR 4D flow MRI data and DW pressure measurements. Through-plane time-varying velocity profiles were extracted from the pre-TEVAR 4D flow MR images and mapped onto the 3D global coordinates of the computational model inlet using an in-house Matlab tool [2]. 3-element Windkessel models were used at each model outlet, with their parameters being tuned using the pre-TEVAR DW pressure measurements, and flow distribution obtained from the 4D flow MRI data [3]. Simulations were run in ANSYS CFX, where the described boundary conditions were implemented via user-defined profile data and FORTRAN subroutines. Blood was modelled as an incompressible Newtonian fluid, and flow was assumed to be laminar.

RESULTS

CFD results were validated against 4D flow velocities and *in vivo* DW pressure measurements, showing good qualitative and quantitative agreement, with a maximum difference between CFD-predicted and DW-measured pressures of 11 mmHg. Fig. 1 shows comparisons between pre- and post-TEVAR pressure distributions. In the Pre-TEVAR model, FL and true lumen (TL) pressures were comparable in the aortic arch and started to differ from mid-descending aorta, with FL pressure being higher. After TEVAR only a small percentage of flow entered the abdominal FL. Hence, TL pressure was higher than in the FL at mid-systolic acceleration and deceleration. Overall, CFD results predicted a reduction in pressure after TEVAR, which was consistent with the *in vivo* pressure measured by DW (see comparisons in Fig.1). Flow in the pre-TEVAR thoracic FL was characterized by stagnation and recirculation, particularly at the first entry tear level where a large persistent recirculation region was present. On average 56% of the aortic flow

entered the thoracic FL, of which 26% re-entered the TL through the re-entry tear. Post-TEVAR, the thoracic FL was completely thrombosed with only a small percentage of flow entering the abdominal FL. Overall, the aortic flow was well organized. 40% of the aortic flow entered the FL, of which only 10% entered the abdominal FL, while most of it was diverted to the right renal artery. The reduced FL flow post-TEVAR caused an increase in TL velocity, with a substantial increase in flow eccentricity and vorticity. In addition, FL enlargement caused a local narrowing in the TL which persisted after TEVAR and resulted in high velocities and elevated WSS there.

Figure 1: Comparison of pre- and post-TEVAR peak systolic pressure distributions. At the top, *in vivo* DW pressure measurements (in mmHg) are reported, along with CFD-predicted pressures. Stars mark the level where pressures were measured.

To highlight dominant flow features, Fig. 2 shows cycle-averaged velocity contours. At the re-entry tear pre-TEVAR flow is directed from the FL to TL, this is reverted after TEVAR, due to occlusion of the first entry tear by the stent-graft. At T8-9 level, a dominant anticlockwise vortical structure is observed in the pre-TEVAR FL, while the TL presents an almost uniform velocity profile. At this level, the post-TEVAR aorta shows complete thrombosis of the FL and considerable remodeling of the TL with a highly eccentric velocity profile. At T12-L1, the pre-TEVAR aorta presents an almost uniform velocity distribution in the FL, while the TL shows considerable spatial variation, with distinct high and low velocity regions. The post-TEVAR TL is significantly remodeled with a relatively uniform velocity distribution. At L3-4, flow in the pre-TEVAR TL and FL shows dominant vortical structures. While the FL is still patent in the post-TEVAR aorta, velocities in the TL are higher than those in the pre-TEVAR TL, and significantly higher than those in the post-TEVAR FL.

DISCUSSION

Hemodynamics has a fundamental role in the development and progression of TBAD, and in TEVAR outcomes and complications. Computational methods have been widely employed to study hemodynamics in aortic dissection. However, the limited availability of patient-specific flow data led to the common use of idealized boundary conditions, particularly post-TEVAR, when 4D flow cannot be used due to artefacts caused by the metal stent-graft. In this study a 4D flow MRI-based methodology was developed for detailed analysis of post-TEVAR hemodynamic performance using 4D flow and DW pressure data acquired before TEVAR. To validate the proposed methodology, CFD results were compared against 4D flow MRI data

and *in vivo* DW-measured pressures, demonstrating a good agreement. Particularly, the pressure decrease after TEVAR was well captured by the CFD model. This suggested that boundary conditions extracted from pre-TEVAR data could be used for post-TEVAR hemodynamic assessment. This allowed for comparison of pre- and post-TEVAR hemodynamics.

Figure 2: Mean velocity contours for a sagittal section at the re-entry tear (RET) level and at three different cross-sections along the aorta. T8-9, T12-L1, and L3-4 are the levels of the spine (T=thoracic, L=lumbar). For the sagittal view, velocity vectors are shown; while for the cross-sections the projection of the velocity streamlines is shown, with arrows indicating the flow direction.

Pressure distribution plays a key role in aortic dissection, determining FL expansion and rupture, and being crucial for TEVAR outcome. Pressure analysis showed that TEVAR successfully reduced the absolute mean and maximum pressures, along with the central pulse pressure, suggesting that TEVAR could decrease the workload for the heart. Large recirculation regions were observed in the FL at the first entry tear (pre-TEVAR) and re-entry tear (post), suggesting the possibility of further FL thrombosis at these locations. Results also showed that flow through the re-entry tear was strongly affected by TEVAR, with only 10% of thoracic FL flow entering the abdominal FL post-TEVAR, while the rest was diverted to the right renal artery. This raised concerns about the distal organ and limb perfusion, as the dissection extended to the right iliac artery. Indeed, the 12-month follow-up CT scan showed FL thrombosis with partial occlusion of the right iliac artery [1]. In addition, a substantial increase in TL flow eccentricity and vorticity was observed post-TEVAR. Despite these features are common in healthy aortas, high values have been linked to atherosclerosis. Therefore, this finding should be further investigated.

Overall, our methodology allowed for detailed comparison of pre- and post-TEVAR hemodynamics in a TBAD patient. The comparison highlighted several changes in the TL hemodynamics and predicted the possibility of further thrombus formation and distal organ malperfusion, which were confirmed by clinical follow-ups.

INTRODUCTION

Aortic valve (AV) diseases are a leading cause of heart failure, and a significant risk factor for thoracic aortic aneurysm and dissection. Surgical AV replacement (SAVR) and transcatheter AV implantation (TAVI) can relieve cardiovascular symptoms, but have also been linked to negative wall remodeling [1]. Despite the long recognized role of local hemodynamic factors in wall remodeling [2], computational studies of patient-specific hemodynamics after AV replacement are rare [3]. Even fewer studies compared the hemodynamics before and after valve replacement, or SAVR with TAVI.

The aim of this work is to present a comprehensive evaluation of the hemodynamic function of different aortic valve replacement procedures, in comparison with healthy and pathological aortic hemodynamics.

METHODS

The study cohort included: a healthy volunteer, 3 patients with severe aortic valve stenosis who underwent SAVR with two-leaflet mechanical (MV1 and MV2) or biological (BV) valves, and a TAVI case. For the two MV cases, pre-operative data were available and analyzed (P1 and P2, respectively). Ethical and institution approvals were obtained (Wales REC, 14/WA/1225 and 16/NI/0160) for this study and all patients gave their informed consent.

Magnetic resonance (MR) imaging and phase-contrast MR images (PC-MRI) were acquired with a 1.5T Philips Achieva system. PC-MRI data were acquired at two transverse sections, with one located in the aortic root and another in the proximal descending aorta. Patients' central pressure was measured 30 min prior to the MR scan. Patient-specific models of the thoracic aorta and aortic branches were reconstructed from MR images by using Mimics (Materialise). Geometric models were discretized using structured meshes (0.9-2.7

million elements). Three-directional velocity profiles were extracted from the PC-MRI measurement in the aortic root, and were mapped to the inlet of the computational model for each patient [4], allowing for a patient- and valve-specific representation of the inlet boundary condition. 3-elements Windkessel models were applied at all the model outlets, with model parameters adjusted to fit each individual patient [5]. These boundary conditions were implemented in ANSYS CFX for flow simulations, which assumed the flow to be laminar and blood as a Newtonian fluid.

RESULTS

Inlet velocity profiles extracted from PC-MRI data were analyzed to obtain maximum flow velocity in a cardiac cycle, and to calculate flow displacement (FD) at peak systole [6]. Table 1 reports a summary of the obtained quantitative results. Comparison of inlet velocity maxima shows that all cases except TAVI present higher values than HV, with the highest peak velocity found in AV stenosis (P2). SAVR reduced the maximum flow velocity in MV1 and MV2. All patients had higher levels of flow displacement than the healthy control (HV), indicating moderate or marked flow eccentricity in the ascending aorta.

Fig.1 shows instantaneous velocity streamlines at two time intervals. Compared to the well-organized streamlines in HV, flow in P1 and P2 was highly asymmetric especially in P2 where a strong jet developed from the AV and impinged on the outer curvature of the ascending aorta. After AV replacement, both MV1 and MV2 showed an overall improvement in flow patterns, with reduced maximum velocity and flow eccentricity, although a weakened flow jet could still be seen along the outer curvature, together with flow recirculation at the inner wall. Similarly, BV was characterized by eccentric flow and a prominent flow jet from the inlet, mainly due to asymmetric valve

opening. Amongst all the analyzed cases, TAVI hemodynamics showed the most similarity to that of HV.

Table 1: Quantitative results obtained from PC-MRI and CFD analyses. V_{\max} = maximum inlet velocity; FD = flow displacement; TAWSS = time-averaged wall shear stress (values given for mean and maximum in the ascending aorta); HFI = helicity flow index.

Subject ID	V_{\max} (m/s)	FD	TAWSS mean (Pa)	TAWSS max (Pa)	HFI
HV	1.06	0.05	1.51	4.31	0.47
P1/MV1	2/1.8	0.11/0.1	3.5/2.5	11.2/8.3	0.42/0.42
P2/MV2	2.8/1.7	0.13/0.11	3.4/2.5	10.4/14.3	0.31/0.44
BV	2	0.19	2	7	0.29
TAVI	0.8	0.09	1.3	3.3	0.36

Mean and maximum values of time-averaged wall shear stress (TAWSS) in the ascending aorta are reported in Table 1, while distributions are shown in Fig.2. Compared to HV, all cases except TAVI showed more spatial variations in TAWSS. Comparisons of pre- and post-operative TAWSS values for the MV patients suggested a reduction in the mean TAWSS in the ascending aorta (-29% for MV1, -27% for MV2), but an increase in the max TAWSS in MV2 (+38%). All cases had lower helicity flow index (HFI) values compared to HV (Table 1). In addition, MV cases showed a normalization of HFI which increased by 42% in P2 before and after operation.

Figure 1: Comparison of instantaneous velocity streamlines at peak systole (T1) and mid-systolic deceleration (T2).

DISCUSSION

In the present work, state-of-the-art image-based patient-specific CFD was used to study aspects of aortic hemodynamics after different aortic valve replacement procedures, SAVR and TAVI. Our results showed that some degree of normalization in aortic hemodynamics was achieved in all patients, regardless of the procedure employed. Nevertheless, flow eccentricity was more pronounced and maximum velocities and WSS were higher in the SAVR than the TAVI cases and normal control. Overall, it is clear that hemodynamic features are patient and prosthesis dependent.

The observed high velocity jet along the ascending aorta outer curvature may increase the risk of aneurysm formation and dissection, while the marked flow recirculation might cause valve thrombosis [7]. Reduced HFI values with respect to the healthy control also suggest increased lipid penetration and reduced oxygen transport at aortic wall [8], which could promote aortic wall disease. In addition, it is likely that deviations from normal will lead to increased ventricular afterload, which could delay ventricular remodeling.

Overall, our results confirm that abnormal flow features are a key contributor to the fact that after aortic intervention patients continue to be at higher risk of aortic events, despite correction of their valve pathology.

Figure 2: TAWSS maps in the ascending aorta. The ascending aorta (from the model inlet to the root of the first branch) was cut along the inner curvature and unfolded.

ACKNOWLEDGEMENTS

Hemodynamic Characteristics Associated with Cerebral Aneurysms Evolution

Seyedeh Fatemeh Salimi Ashkezari (1), Fernando Mut (1), Juan R. Cebal (1)

(1) Bioengineering Department
George Mason University
Fairfax, VA, USA

INTRODUCTION

A cerebral aneurysm is an abnormal dilation of a cerebral artery in the brain. It is estimated that approximately 2-5% of the general population have at least one cerebral aneurysm [1, 2].

While many studies have identified aneurysm growth as a strong risk factor for prospective rupture, the pathophysiology by which aneurysms evolve is poorly understood. Hemodynamics is thought to be an important factor in the progressive degeneration and remodeling of the aneurysm wall. However, the specific changes in the aneurysm flow conditions during its evolution are not yet fully understood [3].

As a matter of fact, to determine the growth rate of unruptured aneurysms it is necessary to follow-up the aneurysms for a long period of time so that significant growth could be observed. However, many clinicians recommend treating aneurysms that have enlarged during follow-up observations, which leads to fewer longitudinal follow-up imaging data being available to study the aneurysms' evolution and possible associated hemodynamic variables.

The objective of this work was to study the changes in hemodynamic characteristics of cerebral aneurysms during their evolution and to investigate whether those changes are different between aneurysms in different locations.

METHODS

A total of 66 cerebral aneurysms at three locations, anterior communicating artery (ACOM), posterior communicating artery

(PCOM), and middle cerebral artery (MCA) were selected from our databased and studied with image-based computational fluid dynamics (CFD).

For each aneurysm, two synthetic sequences approximating the aneurysm geometry at three earlier stages were generated by (a) shrinking the aneurysm sac with a Laplacian smoothing function while keeping the aneurysm neck fixed (Fixed Neck), and (b) shrinking the aneurysm sac and diminishing the aneurysm neck size at each stage (Growing Neck). CFD simulations were carried out for each aneurysm and each simulated evolution stage in the generated sequences under similar flow boundary conditions.

A total of 19 hemodynamic parameters were computed to characterize and compare the hemodynamic environment, flow intensity, spatial complexity, and temporal stability at different stages and between different aneurysms. Wall shear stress (WSS) distributions in two aneurysms, one with a fixed neck and another with a growing neck are illustrated in Figure 1.

RESULTS

The main findings of this study are summarized in Figure 2. This figure presents the average rate of change of different hemodynamic variables for aneurysms with growing and fixed necks in the three locations considered. Statistical analysis (Paired t-test) was performed to explore differences in the rates of change between the two modes of evolution. For each parameter, a p-value less than <0.05 signifies that growing neck

had a greater average rate of change than the fixed neck (indicated with a “*” in Fig. 2).

As aneurysms enlarged, the inflow rate (Q) increased in aneurysms with growing necks, and decreased in aneurysms with fixed necks. The concentration of the inflow jet (ICI) increased in both, but increased faster in aneurysms with growing necks. On the other hand, the mean velocity (VE), and wall shear stress (WSS Mean) decreased as the aneurysms enlarged in both fixed neck and growing neck simulations, but they decreased faster for fixed neck cases. In addition, the mean oscillatory shear index (OSI Mean), corelen (a measure of flow complexity), and podent (a measure of flow instability) increased as the aneurysms enlarged, but their rate of change were not significantly different between growing and fixed neck cases. Similar overall hemodynamic changes were observed for aneurysms at all three locations considered.

Figure 1: WSS distributions in aneurysms and arteries resulted from simulating the aneurysm evolution. Figures show (a) fixed neck, meaning shrinking aneurysm and keeping the neck fixed and (b) growing neck, shrinking both aneurysm and the neck.

Figure 2: Ratios of rates of change of hemodynamic variables of growing neck over fixed neck aneurysms. Statistically significant differences ($P < .05$) are indicated with an asterisk. Bars with diagonal patterns show positive average rates of change in growing neck and negative average rates of change in fixed neck. Bars with solid fills present positive average rates of change in both fixed and growing neck cases, and checked bars illustrate negative average rates of change in both modes of evolution.

DISCUSSION

Hemodynamics is believed to play a driving role in the pathogenesis of cerebral aneurysms. The goal of this work was to study the changes in the aneurysm flow condition that take place as the aneurysm evolves. We focused on three locations, and observed differences in the evolution of flow characteristics of aneurysms with fixed and growing necks. We found that similar changes occurred in most hemodynamic characteristics (except for aneurysm inflow rate) but these changes occurred at different speeds depending on whether the neck of the aneurysm was fixed or enlarging.

In a previous study Chung et al. [4] found that compared to stable unruptured aneurysms, ruptured aneurysms had faster flows, more complex flow patterns, and more concentrated and oscillatory shear stress distributions, when controlling for aneurysm location.

In our study, we observed that as the aneurysm grows, the flow velocity and wall shear stress tend to decrease, and this decrease occurs faster in aneurysms with fixed necks. The flow complexity, instability, and oscillation tend to increase, but there was no significant difference in the speed of increase between aneurysms with growing and fixed necks. Additionally, the inflow rate increased in aneurysms with growing necks and the inflow jet became more concentrated as the aneurysm enlarged. These observations suggest that aneurysms with fixed necks may evolve towards a flow environment characteristic of stable aneurysms faster than aneurysms with growing necks, thus perhaps placing aneurysms with growing necks at a higher risk of destabilization and rupture.

INTRODUCTION

Carotid stenosis is the leading cause of ischemic stroke [1]. Carotid auscultation is routinely used in the clinical practice to screen for the presence of bruit as a marker for asymptomatic carotid stenosis. The carotid bruit stems from unstable flow downstream of the stenosis. However, auscultation is strongly operator dependent. Carotid bruit also presents itself as skin vibrations, due to the propagation of stenosis-induced instabilities as mechanical waves. A Laser Doppler Vibrometer (LDV) would hence potentially allow us to infer the presence of flow instabilities by measuring skin vibrations. The aim of this study is to evaluate the proof-of-principle of LDV-based stenosis detection in a patient-specific model of a stenosed carotid artery, yet accounting for the varying flow rate, flow split and degree of stenosis that one may encounter *in-vivo*. We applied a computational fluid dynamics (CFD) strategy and then compared our findings with *in-vitro* LDV recordings, previously performed on a replica of a stenosed bifurcation [2], for validation purposes.

METHODS

Computer tomography angiography images of a 75-year old patient with severe stenosis (76%) in the internal carotid artery (ICA) were segmented to obtain a model of the carotid bifurcation. Later, manipulation of the geometry allowed to reconstruct the healthy lumen [3] and to obtain four additional stenotic models with varying degree of stenosis (56%, 66%, 86%, 96%) [4]. The six models were meshed using VMTK with a spatial resolution of $\Delta x_{mean} = 1.92 \cdot 10^{-4}$ m, previously found to be adequate [5]. The common carotid artery (CCA) flow rate and the ICA flow split boundary conditions (BCs) were set according to clinical data [6, 7]. Including only plausible scenarios, a total of 19 simulations were run. As such, Q_{CCA} varied from 145 to 529 ml/min, and Q_{ICA}/Q_{CCA} flow split from 11.9 to

70.8%. Blood was modeled as Newtonian fluid with $\nu = 3.3 \cdot 10^{-6} \text{ m}^2/\text{s}$. We ran the simulations for three cardiac cycles with time step $\Delta t = 5 \cdot 10^{-5} \text{ s}$ using the 2nd order finite-element CFD solver *Oasis* [8]. The pressure traces of the last two cycles were extracted from the centerline point located one CCA diameter downstream of the stenosis throat. The traces were then high-pass filtered to retrieve only its fluctuating components [9]. The logarithm of the time integral of their power was used as measure of the intensity of flow instabilities I_{FI} , as shown in equation (1).

$$I_{FI} = \text{Log}_{10} \left(\int_{0 \text{ Hz}}^{10 \text{ kHz}} \text{Power}_{\text{high-pass filtered pressure}} \right) \quad (1)$$

We evaluated the impact of Q_{CCA} , Q_{ICA}/Q_{CCA} , Q_{ICA} , $\text{Area}_{\text{stenosis}}$, $\text{Velocity}_{\text{stenosis}}$ and $\text{Reynolds}_{\text{stenosis}}$ on I_{FI} of the stenosed models by means of linear regression analysis.

Furthermore, the Q-criterion, defined as in equation (2), was used to visually identify vortexes in the simulations run on the six models with average degree-specific Q_{CCA} and Q_{ICA}/Q_{CCA} .

$$Q = \frac{1}{2} \left[|\vec{a}|^2 - |\vec{s}|^2 \right] > 0 \quad (2)$$

The experimental data were LDV recordings of the displacement of the skin-mimicking foil put on top of the ultrasound gel (mimicking the neck's soft tissues) in which the compliant replica of the stenosed bifurcation was embedded. The flow conditions applied to the *in-vitro* model were in the same range as the boundary conditions of the subset of CFD simulations for which Q_{ICA}/Q_{CCA} was kept constant while Q_{CCA} varied between 145 and 529 ml/min. To ease the comparison, the same post processing was applied to the experimental (EXP) data.

RESULTS

All factors have a positive relationship with I_{FI} . The poorest predictor for the presence of flow instabilities was the stenosis severity, which could only account for 12% of the variation in the data. The Reynolds number at the stenosis throat was the best predictor for I_{FI} (Figure 1).

Although the magnitude of CFD data is not the same range as the EXP data, since we are comparing two different physical quantities, the trend is remarkably consistent.

Figure 1. The positive relationship between I_{FI} and $Reynolds_{stenosis}$ holds for CFD as well as for EXP data.

A qualitative comparison of the vortical structures of the several degrees of stenosis is provided in Figure 2. The 56% to 76% stenoses harbor more intense flow instabilities than the 86% stenosis. The extremely severe 96% stenosis, on the other hand, does not harbor any instability, and neither does the healthy subject model.

Despite the $Reynolds_{stenosis}$ of the healthy-subject model is comparable to the one of the 86% stenosis and 20% larger than the 56% stenosis, no unstable flow can be detected in the ICA.

DISCUSSION

The aim of this study was to explore the relationship between the degree of stenosis, inlet flow rate, and flow split with the intensity of the downstream flow instabilities. Our validated CFD methodology allowed us to identify vortexes in the moderate and severe stenoses (56% – 86%), which quickly dissipated further downstream. Of note is that the 96% stenosis did not harbor any flow instabilities because of the extremely low, but physiological, $Reynolds_{stenosis}$. This suggests that an absence of flow instabilities does not imply the absence of a stenosis. Similar conclusions were drawn by a clinical study on asymptomatic carotid patients, where they found the sensitivity and specificity of auscultation for extreme stenoses to be only 26% and 49%, respectively [10].

Given the high comparability of the CFD and EXP data, we expect the LDV to behave similarly to the routinely used clinical methodology (auscultation), but with tool-aided consistency. Naturally, the absolute values of I_{FI} did not match when comparing the data from *in-vitro* and computational setup since they are from two different physical quantities. Nonetheless, our finding is that the pressure from the rigid-wall CFD simulations can be used as a surrogate measure for wall vibrations. That being said, pressure traces from fluid structure interaction simulation (FSI) would perhaps have been even better correlated. Of note is also that intra-arterial pressure measurements were available from *in-vitro* recordings. The catheter was, however, found to affect the downstream-stenosis flow field, thereby making the comparison with CFD data unfeasible.

Furthermore, from the *in-vitro* experiments we observed that the LDV also detected changes in flow rate. For extreme severe stenosis

the flow is expected to redistribute to the remaining vessels. Therefore, by comparing the LDV inferred flow rate on both carotid arteries, it could be possible to detect unilateral stenosis and hence improve the sensitivity of the technique.

Currently running clinical studies will provide data to verify our findings.

Figure 2. The healthy model and the 96% stenoses do not harbor flow instabilities, whereas the moderate and severe stenoses do.

INTRODUCTION

The left atrial appendage (LAA) is a pouch that is extruded laterally from the left atrium¹. Atrial fibrillation (AF) decreases the contractility of the left atrial appendage (LAA). The rapid fluctuation of electrical pulses caused by AF leads to decreased blood velocities that result in stagnation of blood in this area leading to conditions that are associated with thrombosis. If the formed thrombus embolizes, it can lead to stroke that currently affect over three million people in the United States². Normal blood flow at the apex of the LAA, the most lateral portion, allows blood to fill and empty out of the apex each cycle. However, this also worsens over time due to the weakening of surrounding muscle fibers¹.

Patients with AF are frequently treated by cardioversion, a procedure where electrical shock is administered to the heart to restore sinus rhythm. However, cardioversion is contraindicated if the patient already has a thrombus formed in the LAA for risk of systemic embolization. Currently, to identify if the patient has LAA thrombus, transesophageal echocardiography (TEE) and cardiac computed tomography (CT) are performed. TEE is a semi-invasive procedure where an ultrasound probe is run through the esophagus to collect real time images of the LAA as well as velocity measurements throughout the cardiac cycle. CT is used by injecting a contrast agent in the patient and identifying regions of low contrast indicating low blood flow or thrombus that does not allow diffusion of the contrast agent.

Blood velocity in the LAA has been shown to be strongly related to thrombus formation³. However, it is still not considered a factor sufficient to prescribe anticoagulants and is only measured using the invasive test of TEE. The aim of this study is to develop a computational framework to non-invasively predict the risk of thromboembolism through assessing flow stasis in the LAA.

METHODS

As a part of an IRB approved study, high resolution cardiac CT images of four patients (3 with AF and 1 without AF) were collected throughout the cardiac cycle. Patients 1-3 were in sinus rhythm and patient 4 was in atrial fibrillation at the time of the scan. Patients 3 and 4 showed signs of blood stasis/thrombosis on CT images as evident by the presence of LAA filling defect (lack of contrast opacification) in the apex of the LAA that was dense in patient 4 and mild in patient 3. Figure 1 shows CT images of each patient indicating this evidence.

Figure 1: (1-2) No filling defect suggesting no blood stasis/thrombus, (3) soft filling defect suggesting moderate blood stasis/thrombus, (4) dense filling defect suggesting severe stasis/thrombus.

4D CT reconstructions were created using Mimics Research 18.0 (Materialise, Belgium). Each LAA was then discretized in 3-Matic Research 13.0 (Materialise, Belgium). The 4 segmented LAAs are shown in Figure 2. 1-2 are LAAs that had no detection of blood stasis or thrombus formation from CT scan analysis and 3-4 showed signs

blood stasis/thrombus formation. CFD analysis was then performed using Ansys CFX 17.1 Academic (Canonsburg, PA) to create a velocity map within each LAA. Each LAA 1-4 had the following number of tetrahedral volume elements respectively: 376056, 197617, 429434, and 519839. The boundary conditions consisted of an inlet velocity at the orifice that was measured using the 4D CT volume change. Each simulation used blood material properties with density of 1060 kg/m³ and dynamic viscosity of 0.00278 kg/m-s.

Figure 2: LAA segmented geometry of all four patients.

RESULTS

Figure 3 shows the velocity contour maps for all four LAAs. The colors range from red to blue, red being the maximum velocities and blue being the lowest velocities. Areas that show gray coloring indicate zero velocity. LAAs 1 and 2 show minimal areas with low blood velocities. LAAs 3 and 4 have large areas at the apex with very low or zero blood velocities and had evidence of blood stasis or thrombus formation. Table 1 shows the apex and maximum velocity measurements and maximum shear stresses for each LAA from the CFD analysis. LAA 1 did not have AF and showed the highest maximum velocity and shear stress of 64.4 cm/s and 3.20 Pa respectively. LAA 2 did have AF but did not show signs of thrombus formation or blood stasis and had a lowered maximum velocity of 39.7 cm/s. LAA 3 had AF and showed signs of thrombus formation or blood stasis and had an even lower maximum velocity and shear stress compared to LAA 2. LAA 4 was in AF during the CT scan and showed signs of thrombus formation and blood stasis. It also showed the lowest velocities of 0 cm/s at the apex and maximum of 1.96 cm/s with the lowest maximum shear stress of <0.01 Pa.

Figure 3: LAA velocity map results of four patients, (1-2) no stagnation or thrombus detected, (3-4) detected stagnation/thrombus with low blood velocities.

Table 1: LAA apex velocity and maximum shear stress measurements for each patient.

LAA Number	History of AF	Heart rhythm at time of scan	Stagnation/Thrombus	Apex Velocity (cm/s)	Max Velocity (cm/s)	Max Shear Stress (Pa)
1	No	Sinus	No	3	64.4	3.20
2	Yes	Sinus	No	3	39.7	0.79
3	Yes	Sinus	Yes	0.2	13.6	0.11
4	Yes	AF	Yes	0	1.96	<0.01

DISCUSSION

The average LAA outflow velocities in normal subjects ranging from 80 ± 23 cm/s to 63 ± 29 cm/s and inflow velocities ranging from 61 ± 18 cm/s to 54 ± 17 cm/s both decreasing with age⁴. LAAs with peak velocities of <35 cm/s are considered to be at high risk of thrombus formation⁵. Our CFD analysis shows data consistent with the clinical profile of the study subjects. LAA 1 shows velocity levels with a low risk of thrombus formation (maximum >35 cm/s). This result is expected since no stagnation or thrombus was detected from the CT data and this patient did not have AF. LAA 2 shows velocity levels that are low normal and indicates less risk of thrombus formation. LAA 3 shows low velocities which agree with CT finding of soft filling defect/stasis. Finally, LAA 4 shows very low velocities which match with the detection of dense filling defect consistent with severe blood stasis/thrombus. These low flow velocities show how regressed blood velocities can become while a patient is experiencing AF. Furthermore, LAAs 3 and 4 also showed very low shear stresses. Nesbitt et al.⁶ has shown that platelet aggregates can form in locations with low shear, this coupled with low velocities could be why there was a detection of blood stasis/thrombus in these LAAs. It is important to note that although subject 2 and 3 have similar clinical profile (both has history of AF and both are in normal sinus rhythm during the CT scan), their CFD profiles are quite different with high risk of thrombosis in subject 3 and low in subject 2.

The use of CFD in this application allows for the non-invasive measuring of blood velocities while using only routine CT scans. It can be used as an alternative for predicting the potential of thromboembolism in patients intended for cardioversion. It also constitutes a first step towards integrating blood flow into the decision of anticoagulation pharmaceutical prescription in atrial fibrillation patients. The ability to analyze shear stresses is also beneficial since it can play a large role in platelet activation and the development of thrombi – which with the current clinical tools, is not possible. The use of CFD can be utilized to further study shear stress and its impact specifically within the LAA.

INTRODUCTION

Genetically manipulated murine models for atherosclerosis (e.g., apolipoprotein-E-null knock out; ApoE^{-/-}) have become valuable tools for understanding the disease pathogenesis [1]. As data have convincingly demonstrated the role of hemodynamics in atherosclerosis development [2], these animal models have been used to extensively investigate the relationship between wall shear stress (WSS) and mechanosensitive cellular mechanisms. As a result, image-based modeling techniques have been established to predict the *in vivo* hemodynamic environment and associate distinct flow patterns to changes in gene and protein expression [3]. Recent advancements in medical imaging [e.g., velocity phase-contrast magnetic resonance (PCMR) imaging] have become effective tools to advance these computational models. For example, PCMR imaging provides highly resolved, quantitative data on blood flow patterns that can serve as boundary conditions (BC) for subject-specific models to predict WSS distributions in complex geometries. However, the acquisition of 3D flow patterns at all inlet and outlets of interest can be tedious and costly, with no data having demonstrated the essential imaging data required to accurately predict the *in vivo* hemodynamics. Furthermore, application strategies for BC can greatly vary, leading to possible differences in the predicted hemodynamic environment and WSS distributions.

Thus, the aims of this study were to (i) examine the effects of variations in applied BC on predicted flow rates and (ii) quantitatively compare the effects of idealized, spatially reduced, and comprehensive subject-specific BC on predicted WSS distributions, both in the murine aorta.

METHODS

Animal Model Male ApoE^{-/-} mice (n = 3; C57BL6 background; 12, 14, and 16 weeks of age) on an atherogenic from 8 weeks of age

were utilized in this study. Animals were housed and cared for according to guidelines proposed by the NIH, and all experimental procedures were approved by the IACUC at the University of Utah prior to study execution.

Image Data Collection Under anesthesia (isoflurane in oxygen), animals were connected to physiologic monitoring system (ECG, temperature, respiration) and placed in 7T MR scanner (Bruker BioSpec). Velocity-encoded PCMR imaging data were acquired in planes perpendicular to the aorta at the root and the three major branches off the aortic arch. Three-dimensional (3D) PCMR imaging data were acquired at the aortic root (through-plane VENC = 50 cm/s, in-plane VENC = 25 cm/s), and only through-plane data were collected at the three major branches off the aortic arch (VENC=13 cm/s). All scans were ECG-gated with an in-plane resolution of 118 μ m.

Anatomic data were obtained by micro-computed tomography (μ CT) scanning of the vasculature following perfusion with an iodine-based contrast agent (BrightVu®, Scarlet Imaging). Briefly, animals were injected with 100 units of heparin immediately following MRI acquisition. After 30 minutes, the animals were euthanized via CO₂ inhalation, and a thoracotomy was performed to expose the heart. Animals were exsanguinated via cardiac puncture and a saline flush, followed by contrast agent perfusion. Upon completion of perfusion, specimens were placed in an ice bath to solidify the contrast agent and stored in a 10% neutral buffered formalin solution. Animals underwent μ CT imaging (Quantum GX μ CT, PerkinElmer) to acquire high-resolution data of the aorta at an isotropic voxel resolution of 78 μ m. Volumetric data were segmented (Seg3D), and the aortic region from the root to the suprarenal aorta, including 12 mm of the root branching vessels, were isolated (Geomagic; Geomagic, Inc.).

Computational Modeling Flow extensions were added to the outlets, and the isolated volumes were discretized with hexahedral

elements (ICEM, Ansys, Inc.), including an 8-element boundary layer. The mesh was imported into the FEBio software suite for computational fluid dynamics (CFD) analysis [4]. PCMR data were processed to map velocity information onto the computational mesh. Briefly, circular grids were assigned to corresponding PCMR- and μ CT-derived inlets. The deformation gradient to map the PCMR grid to the μ CT grid was calculated and applied to the PCMR velocity data. Finally, velocity values were interpolated at the mesh element centroids.

To assess sensitivity of predicted hemodynamics to the applied BC, five finite element models were created for each aortic geometry: A) temporal 3D velocity profile at inlet, temporal mass flow split at outlets (i.e., the % of inlet flow exiting each outlet varied over time); B) temporal 1D (through plane PCMR data) velocity profile at inlet, temporal mass flow split outlets; C) temporal 3D velocity profile at inlet, steady mass flow split outlets (i.e., a constant % of inlet flow exited each outlet); D) temporal 3D velocity profile at inlet, traction free outlets; E) steady plug profile (velocity was average of through plane pulsatile waveform) at inlet, traction free outlets. The descending aorta outlet was always assumed to be traction free. For all models, the fluid was assumed to be an incompressible Newtonian fluid ($\rho = 1060 \text{ kg/m}^3$, $\mu = 3.5 \text{ cP}$), the arterial walls were assumed rigid, and a no-slip BC was applied at the wall.

Following solution convergence, predicted outlet flow rates in the traction free models were determined. Furthermore, data were post-processed to generate time-averaged WSS (TAWSS) magnitude maps. TAWSS values were extracted from distinct regions (superior and inferior aortic arch; medial and lateral descending aorta) to evaluate anatomic differences in the predicted hemodynamics.

RESULTS

Significant differences were observed between PCMR-measured and predicted outlet flow rates for all three aortic arch branching vessels. For example, measured flow rates in the brachiocephalic (BCA), left common carotid (LCCA), and left subclavian (LSA) arteries of the 12 week old animal were 0.16 ± 0.006 , 0.0035 ± 0.001 , and $0.00042 \pm 0.0002 \text{ mL/s}$, respectively, while predicted values under temporal flow conditions (model D) were 0.018 ± 0.008 , 0.021 ± 0.009 , and $0.00042 \pm 0.0002 \text{ mL/s}$ ($p < 0.05$ across all). Furthermore, maximum measured flow rates were 12%, 83%, and 98% smaller than predicted values in the BCA, LCCA, and LSA, respectively. Similar trends were detected when comparing PCMR-derived flow rates to predicted flow rates under steady flow conditions (model E). For example, predicted flow rates in the BCA, LCCA, and LSA in model E were 0.022 ± 0.009 (41% lower than measured), 0.0055 ± 0.002 (38% lower), and 0.00061 ± 0.0003 (32% lower) mL/s ($p < 0.05$ for BCA and LCCA). Regardless of age, similar trends in flow rates were observed.

Variations in applied BC resulted in appreciable differences in predicted TAWSS distributions throughout the aortic territory, including the aortic arch, branching vessels, and descending aorta (Fig. 1). However, despite differences in TAWSS values across models,

Figure 1: Time-averaged wall shear stress (TAWSS) distributions across models for 12 week old animal.

relative trends were apparent in all models. Specifically, TAWSS values in the inferior aortic arch were lower than values on superior arch and values on the medial side of the descending aorta were similar to values on the lateral side. For example, in model A (pulsatile 3D velocity profile applied at the inlet, temporal mass flow split applied at the outlets), TAWSS values in the inferior and superior arch were 14.9 ± 1.5 and $40.9 \pm 7.6 \text{ dynes/cm}^2$, respectively (174% difference), and values were 34.2 ± 2.9 and $28.7 \pm 1.2 \text{ dynes/cm}^2$ in the medial and lateral descending aorta, respectively (16% difference).

Quantitative comparisons across the five models revealed significant differences in predicted TAWSS values at the evaluate anatomic regions as compared to model A, which was defined as the most comprehensive animal-specific model (Fig. 2). For example, application of temporal mass flow split at the outlets, but a temporal 1D profile at the inlet (model B) resulted in significantly higher TAWSS values in the inferior arch and descending aorta (16.6 ± 0.9 and $12.1 \pm 1.1 \text{ dynes/cm}^2$, respectively) as compared to model A ($p < 0.05$). Likewise, application of a temporal 3D profile at the inlet, but temporal mass flow split at the outlets (model C) led to significant differences in the inferior arch ($16.7 \pm 0.9 \text{ dynes/cm}^2$) when compared to model A ($p < 0.05$). Most notably, application of traction free BC at the outlets resulted in significant differences in TAWSS values in the superior arch and descending aorta even when a temporal 3D profile was applied at the inlet and significant differences in all anatomic regions if a steady plug inlet velocity profile was applied (model E). Regardless of age, similar trends in TAWSS anatomic differences were observed.

Figure 2: TAWSS values at anatomic regions of the murine aorta across models for the 12 week old animal; * $p < 0.05$.

DISCUSSION

The presented study highlights the effects that variations in BC have on the predicted hemodynamics in the murine aorta. We demonstrated that application of traction free or steady mass flow splits at model outlets resulted in significantly overestimated outlet flow rates when compared to PCMR-measured *in vivo* values. Furthermore, we identified that while all models had similar relative TAWSS distributions, variations in inlet and outlet BC significantly affected TAWSS magnitudes. While only murine aortic hemodynamics were examined, our findings agree with previously reported data in the human aorta [5]. These data further highlight the importance of judiciously identifying a BC strategy to ensure predictive accuracy in hemodynamic models across animal and patient-specific models.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a new and exciting approach to treat aortic valve stenosis in patients who are considered to be high-risk for open heart surgical aortic valve replacement (SAVR)[1]. Due to the minimally invasive approach of TAVR, it has a strong appeal to becoming the standard of care for low-risk patients as well [1]. However, TAVR also has complications associated with it such as coronary obstruction (CO) [2], paravalvular leakage (PVL), thrombosis among others. In particular, coronary obstruction is the cause of mortality of about 1.5% of the patients undergoing TAVR [3]. The current predictive models of CO involve measurement of coronary artery height (h) and the Sinus of Valsalva diameter (SOVd) to compare with criteria developed on the basis of clinical observations. Despite the efficiency of these models, there are about 1% of TAVR patients that still suffer from coronary obstruction [3]. Therefore it is necessary to accurately predict and determine the possibility of occurrence of such adverse effects as part of pre-procedural planning. The most commonly used and commercially available TAVs are the balloon expandable Edwards SAPIEN characterized by a short profile (height) and the self-expandable Medtronic Corevalve/Evolut valve characterized by a long profile. The selection parameters between SAPIEN and Evolut are not yet completely established for different coronary obstruction cases, however it is possible that valve selection can play an important role in mitigating the occurrence of coronary obstruction [4]. The objective of this study is to predict and compare the deployment behavior of Edwards SAPIEN and Medtronic Evolut transcatheter aortic valves in the context of coronary obstruction by using patient specific 3D computational modelling.

METHODS

This study utilized computational modelling of TAVR for a set of 5 patients considered to be at risk of coronary obstruction based on predictive guidelines of SOVd > 30mm and h < 12mm. Patient specific 3-D geometries of the aortic root, leaflets and calcification were reconstructed from pre-procedure 2-D computed tomography (CT) images. Using Mimics Research 21.0, (Materialise NV, Leuven, Belgium) a threshold mask was applied onto the CT images and by highlighting the corresponding regions of interest, the 3D models of the root, leaflets and the calcification were generated. The generated 3D models were exported to 3-Matic Research 13.0 where the models were meshed with triangular elements of size 1.0 mm. The number of elements generated in each model was of the order ~50000 triangle elements. Post-processing was done to ensure anatomical correctness of the models. The final geometry was then exported to ABAQUS Explicit 6.14 (SIMULIA, DS Corp., Providence, RI, USA) for finite element analysis to simulate the deployment of the Evolut and SAPIEN valves. To allow for positioning of the Evolut and SAPIEN stents during deployment, the leaflets were pre-expanded using a model cylinder expanding radially. The Evolut and SAPIEN stents were created using Solidworks (DS Corp., Waltham, MA, USA) and the bio-prosthetic leaflets were ignored in the making of the stent to cut down computational time. The stent is modelled as elasto plastic with $\rho = 8.2 \times 10^{-9}$ ton/mm³ and $E = 241316$ MPa with $\nu = 0.3$ and $\sigma_y = 585$ MPa and $\sigma_y = 1035$ MPa. The aortic root is modelled as a hyperelastic material with $\rho = 1.0$ Kg/m³ and Neo Hookean coefficients $C10 = 0.5$, $D1 = 5$; the calcium is modelled as an elastic material with $\rho = 1.2$ Kg/m³, $E = 2.5$ MPa and $\nu = 0.475$. A self-expanding stent deployment method was used to simulate the behavior of the Evolut valve. The stent

was crimped using a funnel and holder cylinders and the holder was then moved to the intra-annular position where the stent was released for self-expansion. The SAPIEN valve was deployed using a balloon. A crimped balloon and the SAPIEN stent were situated at the intra-annular position and fluid is injected to inflate the balloon with a fluid cavity pressure of 0.48MPa. The deployment of the Evolut and the SAPIEN valve were also simulated at the supra-annular and sub-annular positions.

Fig. 1: Visualization of the assembly to deploy Evolut(top) and SAPIEN(bottom) valves

RESULTS

Fig. 2 shows the cross-sectional view of the deployed valve and the left coronary artery comparing the Evolut and SAPIEN valve deployment behavior. It is observed that the deformation of the leaflets is different between the two valves. Fig. 3 compares the valve deployment of the Evolut and SAPIEN in supra-annular, intra-annular and sub-annular positions.

DISCUSSION

The difference in the stent geometry is the reason for the difference in the deformation seen in Fig.2 between the valves. Since the SAPIEN valve is balloon expanded, the valve deforms according to each patient's aortic geometry while Evolut maintains its shape across all deployments. Due to the shorter profile of the SAPIEN valve, the depth at which the valve is deployed affects the leaflet deformation caused by the valve whereas in the case of the Evolut, the leaflet deformation remains the same across all the 3 positions of deployment. The approach presented here can be used as a predictive procedural planning tool to achieve better clinical outcomes.

INTRODUCTION

Within the adult population, approximately 3.2% of individuals have an unruptured intracranial aneurysm (UIA) [1]. Advancements in medical imaging resulted in an increasing number of (UIAs) discovered incidentally. Current clinical procedures for risk-stratification of cerebral aneurysms have been shown to be unreliable [2]. This has resulted in the over-treatment of patients with UIAs through potentially risky surgical or endovascular procedures. Recent studies indicate that local hemodynamic factors, e.g. wall shear stress (WSS) and oscillatory shear index (OSI), relate to aneurysm progression [3]. Consequently, these hemodynamic factors may help predict the stability of UIAs and assist clinicians in decision-making and management of UIA patients. Intra-aneurysmal hemodynamics can be acquired in vivo with three-directional phase-contrast MRI (4D Flow MRI) or with patient-specific modeling techniques, which include in vitro measurements or Computational Fluid Dynamics (CFD). 4D Flow measurements in cerebral vasculature can be affected by limited spatiotemporal resolution and velocity dynamic range of the technique. The range of velocities that can be measured with 4D Flow depend on a “venc” (velocity encoding) parameter, typically set above the expected maximum velocity. In measuring complex flows with a large dynamic range, velocities exceeding the venc would cause image aliasing, while a venc set too high results in low velocity-to-noise ratio (VNR) for slow flow. Schnell et al. has introduced dual-venc 4D Flow MRI which has a higher dynamic range and lower noise in its measurements [4]. Dual-venc 4D Flow MRI combines two acquisitions with different venc values, a smaller venc tailored to slow flow regions and the larger one for high velocities observed in jets.

Compared to in vivo 4D Flow, in vitro techniques can provide higher resolution which can improve the accuracy of calculated hemodynamic metrics. Currently, almost all modeling studies rely on CFD for the

calculation of intra-aneurysmal velocity fields. While providing superior resolution, CFD results may be affected by image segmentation errors and the many modelling assumptions, such as flow boundary conditions, wall compliance, fluid material properties, etc. Experimental studies can serve as a separate modality providing validation to both in vivo and in silico approaches. This study aims to investigate the effects of increased resolution and dynamic range of 4D Flow MRI on resulting flow metrics, by conducting in vitro flow measurements in a scaled cerebral aneurysm model.

METHODS

Collaborators at Northwestern University provided 4D Flow MRI and time-of-flight (TOF) MR angiography data which was acquired for an internal carotid artery (ICA) aneurysm. TOF data of the aneurysm with the proximal and distal arteries were segmented and a flow phantom was fabricated through 3D printing. A 1-to-1 and a 2-to-1 scaled models were printed (Figure 1). Extensions were added to the inlet of the flow models to ensure

Figure 1: Cerebral aneurysm flow phantoms a) 1-to-1 model b) 2-to-1 model

fully developed flow. These aneurysm models were connected to a flow loop which pumped a gadolinium enhanced water-glycerine fluid through the models at a steady flow rate. The density and viscosity of this working fluid matched those of blood. The Reynolds number of the fluid flow in both models was 313, matching that calculated for the in vivo flow conditions at peak systole. The inlet flow rate for the 1-to-1 and 2-to-1 models was 4.45 and 8.90 mL/s, respectively, matching that of in vivo measurements. Velocity measurements in both models were acquired with both dual and single-venic 4D Flow MRI. This resulted in a total of four datasets. MRI studies were performed on a Siemens 3T PRISMA scanner at a spatial resolution of $0.8 \times 0.8 \times 0.8 \text{ mm}^3$. The low and high venics for the 1-to-1 model were 30 and 60 cm/s, while the low and high venics for the 2-to-1 model were 15 and 30 cm/s, respectively. The reported high venic values were the venics used for the standard single-venic 4D Flow MRI measurements. The acquired phase-contrast MRI images were post-processed using software developed at Northwestern and the flow fields were visualized using Paraview software. The resulting velocity distributions were used to compare 4D flow resolution in low velocity regions and to calculate the velocity divergence for each model.

RESULTS

Two 4D flow techniques used in two models of different scale resulted in a total of four cases representing the same flow conditions. Figure 2a displays the increased spatial resolution of 4D Flow as a result of scaling the model. Additionally, the observed velocities at the surface of the 2-to-1 model are noticeably lower than that of the 1-to-1 model. Flow streamlines obtained in all four cases were compared. Figure 2b demonstrates that the scaled model provided a better depiction of recirculating flow within the dome of the aneurysm and in the ICA bend. Regardless of scale, dual-venic results provided denser streamlines and a better flow visualization within the near-wall regions and areas of secondary flow (e.g. ICA bend). Figure 2c displays the divergence results comparing the unscaled and scaled models at a cross section of the aneurysm. These results show that mass conservation was not maintained with 4D Flow measurements, which leads to errors in other flow-derived metrics. Most notably, the divergence was observed to decrease by two orders of magnitude within the scaled model. In all four cases, divergence increased along the walls, where the velocities were comparable to image noise.

DISCUSSION

This study experimentally investigated the advantages of using dual-venic 4D Flow MRI technique along with increased relative resolution on measured intra-aneurysmal hemodynamics. Dual-venic measurements provided better assessment of low velocity regions due to its lower noise and increased dynamic range. In particular, these better represented flow features near the wall and within the ICA bend. Additionally, the measured velocity fields in the 2-to-1 scaled model were more consistent with the laws of physics. With a higher relative resolution, each voxel better captures local velocity profiles, thus increasing the accuracy of calculated velocity gradients. This results in a substantially lower local and global divergence, i.e. mass conservation. Additionally, Figure 2a shows that the 2-to-1 model provides an improved assessment of near-wall velocities. Due to the higher relative resolution, the low velocities in the voxels adjacent to the wall were not averaged with the higher velocities farther away.

The findings of this study demonstrate that dual-venic 4D Flow MRI and a scaled model improved the accuracy of the measured intra-aneurysmal hemodynamics. In particular, the scaled model measurements resolved the flow near the wall and reduced the divergence. Furthermore, this experiment suggests that the use of dual-venic 4D Flow MRI will provide a more accurate assessment of slow flow features. This suggests that the resolution of in vivo 4D Flow MRI in cerebral vessels should be substantially increased in order to accurately assess intra-aneurysmal hemodynamics. These improved measurements are crucial to providing reliable calculations of flow-derived metrics such as WSS and, therefore, predictions of aneurysm progression.

INTRODUCTION

Deciding on the course of treatment for pulmonary hypertension (PH) requires multiple sessions of a six-minute walk test, transthoracic echocardiography, and right heart catheterization (RHC). These invasive procedures, particularly RHC, substantially limits the clinicians' ability to safely diagnose and monitor disease progression. Multiple imaging and simulation-based studies have indicated that patient-specific pulmonary hemodynamics can potentially identify a developing PH condition [1-4]. Moreover, computational methods facilitate the assessment of complex multivariate interactions between the arterial wall, blood stream, and the right ventricle. Spatiotemporal localization can possibly identify individual contributions of the proximal and distal pulmonary vasculature (PPV and DPV) towards disease progression. Our research aims to identify the deviations from regular flow phenomenon and simulation-based metrics that can potentially contribute towards developing non-invasive diagnostic procedures.

METHODS

Following IRB approval, patient-specific geometries of the pulmonary vasculatures were reconstructed from chest computed tomography angiography images obtained from PH patients at Allegheny General Hospital (Pittsburgh, PA). The surface reconstruction procedure is described in detail by Kheyfets et al [5]. The computational model for each patient extends from the proximal main pulmonary artery (MPA) up to six generations of branching pulmonary arteries. Each geometry was discretized with 5 to 8 million tetrahedral mesh elements in ANSYS ICEM (Ansys Inc., Canonsburg, PA).

The CFD solver was developed using open source C++ libraries available in OpenFOAM v5.0 distribution. The governing equations were evaluated using the pressure-velocity coupling method which can

be described in three steps: (1) momentum predictor, (2) pressure solver, (3) momentum corrector.

Figure 1: Pressure and velocity waveforms obtained from averaging the data collected from eight PH patients via a Volcano catheter. The velocity profile possesses a systolic notch typical of PH patients [6].

Velocity and pressure data was recorded with a Volcano catheter in eight PH patients at Allegheny General Hospital. The data was normalized with respect to the mean of the distributions. Cardiac output derived peak inlet velocity and mean pulmonary arterial pressure (mPAP) were used as dimensional factors to generate quasi patient-specific waveforms, as seen in Fig. 1. A resistance structured-tree outflow boundary condition, proportional to the outlet radius, was applied at each outlet cross-section. The outlet resistances were dynamically adjusted to achieve the patient-specific pressure waveform at the inlet. This transient resistance boundary condition ensured the time lag between velocity and pressure waveforms typical of the human circulation in large arteries.

Following the simulations, multiple hemodynamic metrics were evaluated. For brevity, only the computation of wall shear stress (WSS)

is covered in this abstract. For the complete cardiac cycle, spatially averaged wall shear stress (SAWSS) was evaluated using Eq. (1).

$$SAWSS = \frac{1}{A} \int_A \mu \frac{\partial u}{\partial n} \partial A \quad (1)$$

Power regression correlations were evaluated between SAWSS and pulmonary vascular resistance (PVR), which is a clinically derived metric evaluated using Eq. (2),

$$PVR = \frac{mPAP - PCWP}{HR \times SV} \quad (2)$$

where PCWP is the pulmonary capillary wedge pressure, HR is the heart rate, and SV is the stroke volume. The correlations were reported at four time instants representing the pre-systole ($t/t_{cycle} = 0.06$), peak systole ($t/t_{cycle} = 0.11$), systolic notch ($t/t_{cycle} = 0.33$), and diastole ($t/t_{cycle} = 0.9$) phases of the cardiac cycle.

RESULTS

SAWSS increased tenfold, from approximately 1.5 dyn/cm^2 to 15 dyn/cm^2 from the beginning of the cardiac cycle to peak systole, as shown in Figure 2. Neglecting the high WSS values close to the outflow boundaries, spatially, a maximum WSS of 18 dyn/cm^2 was obtained for an exemplary patient-specific vasculature (see Figure 3 for patient P1). Figure 4 illustrates the power law correlations between SAWSS and PVR at the aforementioned four instants of the cardiac cycle. The lowest R^2 value was observed at peak systole (0.7686), while the highest R^2 value was obtained at diastole (0.8936). This is in close agreement with the steady-state analysis conducted at mid-systole by Kheyfets et al [5]. It must be noted that Kheyfets and colleagues reported on a 20-patient dataset compared to the five-patient dataset presented in this work. The pressure distribution obtained for patient P1 is in agreement with the prevalent velocity distribution of an incompressible fluid flow, as seen in Figure 5.

Figure 2: Spatially averages wall shear stress obtained for five PH patient-specific geometries for a complete cardiac cycle.

Figure 3: Wall shear stress (WSS) distributions at selected time instants during one cardiac cycle for patient P1.

Figure 4: Power law regression correlations between SAWSS and PVR at $t/t_{cycle} =$ a) 0.06, b) 0.11, c) 0.33, and d) 0.9.

Figure 5: Pressure distribution in patient P1 at selected time instants during the cardiac cycle. The temporal locations are the same as those identified in Figure 3.

DISCUSSION

Efforts to non-invasively identify PH markers have rendered substantial significance to computational flow analysis. The onset mechanisms of abnormal flow patterns can be linked to signs and symptoms of a developing PH condition. For example, in pulmonary arterial hypertension, the narrowing of arteries and low radius of curvature of the left/right pulmonary artery surfaces contribute to flow separation and shear layer instability. A major limitation of this study is the small pool of patient-specific data. In addition, we lack precise knowledge of the individual inlet velocity and pressure waveforms at the proximal MPA. Nevertheless, applying spatiotemporal localization on computationally derived indices is expected to gage the relative contributions of the PPV and DPV for diagnosis and progression of PH.

DEVELOPMENT OF AN EXPERIMENTAL SYSTEM EXPLORING THE EFFICACY OF CYCLIC ASPIRATION ON CLOT DISPLACEMENT IN A CEREBRAL THROMBECTOMY MODEL

INTRODUCTION

Emboloc occlusion of the cerebral artery causes an acute ischemic stroke (AIS) in an estimated 700,000 patients every year [1]. Removal of the thromboembolus requires surgical intervention involving a catheter-based thrombectomy. Advancements in clot removal techniques have led to recanalization rates of up to 85% in cases studied [2], but 17% of patients deemed successful will still die within 90 days after the procedure [1]. Successful recanalization rates in all patients cannot be achieved without more of an understanding to the mechanics of thromboemboli removal. Current methods of catheter-based thrombectomy involve the release of anticoagulant drugs at the clot site (catheter-directed thrombolysis) and mechanical intervention. Mechanical thrombectomy is based upon stent retrieval and static aspiration methods. Previous research done by Simon *et al.* on aspiration-based thrombectomy demonstrated the effectiveness of an alternative method, cyclic aspiration [3]. The study showed promise in potentially increasing recanalization rates based on the speed and clearance rates of the clots tested. However, further validation is needed for cyclic aspiration thrombectomy to be considered as an alternative surgical procedure. This study will look at the development of an experimental model to predict the deformation, adhesion and dislodgement of thromboemboli under induced cyclic loading. The goal of this study is to track the displacement of an embolus analog under controlled cyclic aspiration.

METHODS

The system was modeled to represent a thromboembolus lodged in a cerebral artery in which cyclic aspiration is introduced by a cerebral catheter. An optically clear, hollow chamber was designed and 3D printed to represent the inside of a cerebral artery (**Fig 1**). Neoprene rubber was inserted into the chamber to represent an embolus analog

and clear PVC tubing to represent a cerebral catheter. The parameters of this chamber were determined using physiological reasoning, and the chamber was scaled up 5x. Therefore, the embolus analog was determined to have a diameter of 0.7" (5x-enlargement of the middle cerebral artery diameter [4]) and the tubing was determined to have an inner diameter of 5/16" (5x-enlargement of the Penumbra Ace 68 Reperfusion Catheter).

Figure 1. Model of the chamber representing cerebral artery, catheter, and embolus analog.

An experimental flow-loop was designed and created to model the cyclic aspiration (**Fig 2**). A Roscoe Medical Cliq Aspirator was used to introduce a constant aspiration pressure to the system. In order to create cyclic aspiration rather than static aspiration, the model required the use of an ASCO 3-way solenoid valve that was controlled through a self-programmed Arduino microcontroller to open and close between ports 1 and 2 at a frequency of 1 Hz. Additional ports were added to the artery chamber to allow for monitoring of the locally applied pressure and connection to a fluid reservoir.

Figure 2. Schematic of the experimental flow loop.

Initial pressure waveforms contained maximum and minimum pressures of approximately 40 and -60 mmHg, respectively. This waveform contained unwanted sharp peaks and rebounding due to very rigid tubing (Durometer 95A) (**Fig 3A**). A second design iteration included softer tubing (Durometer 65A) and the addition of a compliance chamber to control the effect that the tubing had on the pressure signal. The newly obtained pressure waveform had maximum and minimum pressures of approximately 0 and -40 mmHg, respectively (**Fig 3B**). The newer design provided results that were more physiologically relevant compared to the first and were deemed to be ideal for the goal of gradually dislodging an embolus without causing clot fracture.

Figure 3. A) Pressure waveform measured experimentally with the first design iteration. B) Pressure waveform measured experimentally with the second design iteration.

The 2D motion and displacement of the embolus analog were tracked using a video camera with specifications of 1080p HD at 30 frames per second. Individual frames were extracted from the video using MATLAB, and the clot displacement in each frame was measured using ImageJ.

RESULTS

The 2D displacement of the embolus analog was measured in each image. By performing these measurements, the clot was able to be tracked as it displaced outward due to the applied negative aspiration pressure (**Fig 4**). The maximum displacement of this embolus analog was measured to be approximately 1.06 mm at the maximum aspiration pressure of -40 mmHg.

Figure 4. A) Image 1 at time=0 seconds. B) Image 10 at time=0.33 seconds. C) Image 20 at time=0.67 seconds. D) Image 30 at time=1 second. E) Tracking of the embolus analog's 2D displacement over 1 second.

DISCUSSION

This study developed an experimental model of embolic occlusion of the cerebral artery that can be used as a baseline for further testing of cyclic aspiration conditions. In comparison with previous tests [3], the similarities in the pressure waveforms collected add confidence in the data. Pressure and displacement data from this experiment will be used to validate future computational models of cyclic aspiration in cerebral arteries. Further testing on the effects of changing frequency, pressure magnitude, and clot material need to be conducted in order to design a more physiologically relevant model using synthetic clots and catheters in the future.

ASSESSING FEMORAL IMPLANT FAILURE RISK BY APPLYING CONTROLLABLE TORQUE WITH ROBOT MANIPULATOR AND 6 DOF SENSOR

INTRODUCTION

Assessment of femoral implant failure risk requires customizable testing and measurement systems, particularly for situations where the interactions between multiple orthopaedic implants are of interest. An increasing number of individuals are obtaining total knee arthroplasties, with a subset also requiring surgery for a subsequent fracture, months or years following the knee replacement procedure. By the American Joint Replacement Registry, AJRR, the incidence rates of periprosthetic fractures is 0.3–5.5% for over 600,000 primary Total Knee Arthroplasty not including revision.

Robotic systems are widely used in industry and research. Their advantages lie in the ability to apply precise moments and forces to the object(s) being tested.

This study focuses on risk of femoral shaft fracture using a dual approach; (i) computational modeling, and (ii) experimental validation using an industrial robot manipulator (KUKA KR 5 Six R650 CR2) coupled with a 6DOF sensor. The integration of these technologies is used to assess the response of surgically-repaired femurs to physiologically-appropriate external loads. The aims of this study are to evaluate/validate computational model results by means of the robot manipulator and 6 DOF sensor.

METHODS

A computational model of a femur implanted with a TKR and Introchanter Antegrade Nail (Smith and Nephew models Genesis II femoral component size 5 and Intertrochanter Antegrade nail sizes 5213 to 5227) was created in Abaqus and modeled using a volumetric tetrahedral mesh. Regions of interest (ROI's) were identified for each model, corresponding to the anatomical areas between the TKR that are considered at risk for fracture. Loading conditions included (i) axial forces of 1.7kN, and (ii) torques of 5 to 15 Nm that were applied to the

proximal end of the femur with the distal end being fixed. Material conditions for bone ranged from 17 GPa to 11.56 GPa, corresponding to Young's moduli for normal and osteoporotic bone, respectively.

Figure 1: Femur with ipsilateral implant model

A synthetic bone specimen from Sawbones (3403) was utilized for testing as an analogue representation of an actual bone. A set of rosette strain gauges (WA-06-060WR-120) were applied with each ROI, corresponding with peak strain results in the Abaqus simulation. The exact position was verified with a Microscribe G2 instrument.

In order to evaluate stresses within the ROI, a clamp was attached to the femoral head and connected to the distal end of the KUKA robot. All loading was applied by way of torsion from the KUKA linkage to the head of the femur. These loading conditions were applied with the distal femur being fixed in dental cement. The position of the femur was set at a 0° in abduction and 0° in flexion. The kinematics scheme of the testing system are shown in Figure 2.

A LabView program was designed to control the testing parameters. The software collects and saves force and torque sensor data and the robot's kinematics. In this case, the torque was set to 5 Nm and rotations about the robot axis (along the femoral neck) were incrementally increased by 0.1 degree. This was done because the LabView cannot control a KUKA robot directly, and can only execute the program which is stored in robot controller.

Figure 2: Kinematics scheme of testing system

Since the LabView software cannot control the robot's continuous motion, and can only execute the program in the controller, all testing was performed in a quasi-static manner. Sensor values were measured periodically until such time that the trial was concluded.

RESULTS

For each loading condition there were significant effects due to both bone quality and loading conditions. At 5 Nm torque (Figure 3), normal bone density, and an interprosthetic gap of 8 cm, fracture risk increased by 14% (compared to a situation with a TKR alone). With bone density reduced to 1.6 gm/cm³, the fracture risk increases 19%. The fracture increases dramatically when applying osteoporotic bone instead of non-osteoporotic bone.

Figure 3: Risk of Fracture for 5 Nm

After the controllable torque test, the results of sensors Z axis torque (Tz) exhibited a step-type incremental process. This graph is similar to the graph of strain gauge measured values of the bone torque (Figure 4). This figure shows the step increments of deformation in the synthetic femur along the anterior surface. These results can be correlated with the applied torque from axis 6 of KUKA robot. In case the software are made to run as an infinity loop, the test results shows three trials in which the robot created torques of 5 Nm.

Figure 4: Rosette Strain Results for 45 degrees

DISCUSSION

The results highlight the dependence of fracture risk on both interprosthetic distances as well as bone quality. A gap length corresponding to a 2-cortical diameter margin shows a limited stress-riser effect. The results highlight that the careful consideration in nail length is necessary for reducing stress risers by nearly 30% for both non- and osteoporotic femurs with ipsilateral implants.

The controllable torque with robot manipulator and 6DOF sensor test validates the approach of incrementally rotating the robot arm while measuring sensors data. In the future, different sawbone models will be assessed to further validate the results of placing both intramedullary and total knee implants in a femur.

DRILL PLUNGE IN ORTHOPEDIC SURGERY DEFINED

S. Baskerville (1), T. Conway (1), S. Schultz (1)

(1) Biomedical Engineering
Florida Institute of Technology
Melbourne, Florida, USA

INTRODUCTION

Although *drill plunge* is commonly mentioned within orthopedic surgical studies, there has been minimal effort to define the phrase. The clinical relevance of orthopedic *drill plunge* is undeniable, as plunging can damage neurovascular and connective tissues near the drilling site (3,6). Further complications may arise as a result of iatrogenic *drill plunge* injury, including enhanced post-operative pain and the possibility of additional corrective surgeries. One of the studies evaluated showed that even experienced orthopedic surgeons plunge past the opposite cortical boundary of the drilling site by 5.1mm on average (1). The objective of this research is to define *drill plunge* clearly and its detrimental effects.

METHODS

The major process involved in the development of a quantifiable definition for *drill plunge* required the compilation of as many references and attempted descriptions in the literature as possible. These definitions were pulled from patents and research papers as far back as the 1980s. Some authors provide a short, vague definition while others do not attempt to define it, and instead assume that references to *drill plunge* are common knowledge. Once all of the definitions of *drill plunge* were gathered, similarities and discrepancies were found and evaluated.

Additionally, the geometry and mechanics of a drill bit were studied. The goal was to determine how much of the drill bit needs to go completely through the bone for optimal

placement of the screw or pin in ideal cases. It is necessary to study the drill bit to define *drill plunge* properly. The proposed definition seeks to address the shortcomings of previous references to *drill plunge*, as well as provide a quantifiable metric, which can be normalized across all bit geometries.

RESULTS

Papers dating back to the early 1980s were reviewed. They mentioned *drill plunge* as a prevalent source of error in commonly implemented orthopedic surgical methods. Many of these papers provide unclear definitions, while others make poor attempts at describing *drill plunge* or providing a standardized measurement descriptor or methodology. The definitions provided are similar to each other, but none describes completely what qualifies as *drill plunge*. Additionally, *drill plunge* is mentioned in patents for devices that help to prevent plunging, but they do not provide any definition of plunging (8, 9). Various select definitions from the reviewed papers can be found in Table 1.

Research papers studying the average *drill plunge* in a variety of scenarios explain how the plunge was measured. There have been a number of methods used to measure *drill plunge*, most involving measurement of the indent in spongy material caused by the plunging of the drill bit (4). Another method involved placing a cover over the drill bit and measuring the amount of drill bit exposed after drilling (1).

Table 1: References to *drill plunge* and available definitions.

Date(s)	Definition
2004	“length of drill protruding after the bone has been drilled” (2)
2012, 2017	“soft tissue penetration” (1,7)
2009	“amount of drill bit penetration into the underlying soft tissues” (5)
2018	“distance a drill bit obtrudes the far cortex during the process of drilling through a bone” (4)

In order to understand the placement of the drill bit needed, figure 1 shows a diagram of a typical drill bit. This illustrates the key features of drill bit geometry. In order for the drilled pilot hole to have uniform diameter equivalent to the major diameter of the drill bit, the flutes of the drill bit must differentially approach the opposite cortical boundary of the drilled bone. Therefore, the drill bit does not fully drill through the bone until the leading edges of the bit are completely through the bone.

Figure 1: Drill bit diagram.

Through observation, discussion, and literature review, a new formal and quantitative definition of *drill plunge* is proposed. *Drill plunge* can be classified as the measured length of fully-fluted drill bit that travels beyond the opposite cortical boundary of the bone. This metric excludes any length of the drill bit which must theoretically move past the opposite cortical boundary in order for a full and complete pilot hole to be formed. This excluded length is typically referred to as the drill bit tip. Manipulating the geometry of the drill bit, the tip can be taken into consideration when measuring *drill plunge* by using the following equation:

$$T = \frac{D}{2 \tan(\frac{\phi}{2})} \quad (1)$$

Where T is the drill bit tip length that should be taken into account when measuring plunge depth. D is the diameter of the drill bit and ϕ is the point angle on the drill bit. The calculated drill bit tip length should be subtracted from the amount of measured plunge to provide the true plunge depth of the full functional geometry of the bit. As the drill bit becomes dull, the length of the drill bit tip will decrease. Therefore, there will be a small amount of error the longer the drill bit is in use. This

definition of *drill plunge* is not to be limited to cases exclusively involving soft tissue penetration.

DISCUSSION

Anytime a bone is drilled during surgery, the soft tissues on the opposing side of the bone are at risk for serious damage (3). Many surgeons do not want to address that they plunge when drilling, but it is almost inevitable with the tools currently available. Therefore, many studies have been completed on *drill plunge* and ways to minimize it. Even with the harmful effects, literature lacks a proper definition explaining what qualifies as *drill plunge*.

There is a real necessity for a thorough definition of *drill plunge*, as the definitions provided by the papers reviewed do not fully classify *drill plunge* with a universally useful level of detail. The studies that measured the *drill plunge* as the depth of the hole created in a spongy material past the bone is inaccurate because it does not account for the geometry of the tip of the drill bit. The tip of the drill bit needs to go completely through the entire bone so the implant can be properly anchored. Therefore, the end of the fluted length of the bit should be flush with the far side of the drilled bone. The exclusion of drill bit tip length in *drill plunge* measurements allows for normalization in experimental data across all drill bit geometries.

INTRODUCTION

Microarchitectural features have a direct effect on the mechanical behavior of trabecular bone. In the past, morphological parameters are usually used to characterize microarchitectural features of trabecular bones, which at best provide average measures of trabecular bone microarchitecture. Recent studies have shown that trabecular bone can be decomposed into individual trabecular plates and rods by using Individual Trabecula Segmentation (ITS) techniques [1,2,3]. This advanced technique allows for accurate characterization of microarchitectural features based on information of individual trabeculae, which could help improve patient-specific prediction and prevention of bone fragility fractures. Our previous study indicates that there exists a commonality in the underlying probabilistic distributions of individual microstructural features of trabecular bones [4,5]. However, it is still unknown regarding the correlations between the microarchitectural parameters obtained from the individual trabeculae, which may provide further details about the interplay of these microarchitectural parameters. In this study, the correlations between microarchitectural parameters were analyzed based on data from sixty-six trabecular bone specimens, which were obtained from donors of different age and sex and from different anatomic locations (femoral neck, vertebral body, proximal tibia, and greater trochanter) [6]. The results of this study showed that the correlations between trabecular microarchitectural parameters followed similar patterns irrespective of anatomic locations. This finding is important for understanding the natural design of trabecular microstructures.

METHODS

Trabecular bone specimens from twelve femoral neck ($N_{FN}=12$), eleven lumbar 1 vertebral body ($N_{VB}=11$), twenty-two proximal tibia ($N_{PT}=22$) and twenty-one greater trochanter ($N_{GT}=21$) trabecular

structures were analyzed to determine if the microarchitectural parameters of trabecular bone were correlated. The sixty-six trabecular bone samples were cored from the center of their respective anatomic locations and the longitudinal axis of each specimen was aligned with the principal axes of trabecular orientations. The specimens were imaged using μ CT at a resolution of $21\mu\text{m}$ voxels and digitally reconstructed. The digitized models were then decomposed using Individual Trabecula Segmentation (ITS) software to determine the size, orientation, and spatial arrangement of individual trabeculae. Eight microstructural parameters were defined from ITS data, including plate area (PA), plate thickness (PT), plate nearest neighbor distance (PS), plate orientation (PO), rod length (RL), rod diameter (RD), rod nearest neighbor distance (RS) and rod orientation (RO). Finally, pairwise quantile-quantile regression was performed to determine the correlations among the microstructural parameters.

RESULTS

The pairwise quantile-quantile regression analyses indicated that correlations might exist between the pairs of trabecular bone microarchitectural parameters (*i.e.* PA vs PT, PA vs PO, PA vs PS, PT vs PO, PT vs PS and RL vs RD, RL vs RO, RL vs RS, RD vs RO, RD vs RS) at different anatomic locations (**Fig. 1**). Due to the missing data, the results for the correlations between plate or rod spatial parameter and other microarchitectural parameters for greater trochanter were not available. The results indicated that the quantile-quantile regression patterns between the microstructural features of trabecular bone were similar irrespective of anatomic locations. In addition, some correlations were observable between the trabecular size, orientation, and spatial arrangements. For instance, it appeared that larger and thicker plates tended to orient parallel to the major principal axis of trabecular bone specimens. The plate area vs. plate thickness and rod

length vs. rod diameter were following a similar pattern at difference anatomic locations.

DISCUSSION

First, the results of this study indicate that the correlations between most microarchitectural parameters are similar irrespective of anatomic locations (*i.e.* femoral neck, vertebral body, proximal tibia and greater trochanter) and donor ages and sexes, except for trabecular sizes vs. trabecular orientations showing some different patterns at different

Figure 1: Correlations between microarchitecture parameters

Notes: The plate and rod orientations were expressed in terms of co-latitude (PO1, RO1) and Longitude (PO2, RO2).

anatomic locations. This implies that the size of trabeculae is correlated with their orientations differently at the different anatomic locations.

Secondly, the pairwise quantile-quantile regression between PA and PT, RL and RD exhibits a similar pattern of triangular shape, suggesting that the plate area has a weak correlation with plate thickness. In addition, the pairwise quantile-quantile regression between PA and PO2, PT and RO2 illustrates a peaked pattern around the major principal direction of the bone samples. This suggests that larger and thicker plate are preferentially oriented parallel to the principal direction of the bone specimens. Moreover, the pairwise quantile-quantile regression between PA and PS, PT and PS, RL and RS, RD and RS follows a similar pattern of semi-circular shape, indicating a weak correlation between the parameters.

Finally, no correlation between PA and PO1, PT and PO1, RL and RO1, RD and RO1, and RD and RO2 appears to exist since no distinguishable patterns could be observed (rectangle shape).

In summary, the results of this study indicate that some of the microstructural parameters may be correlated, thus giving rise to more insights into the underlying organization of individual trabeculae for trabecular bones.

INTRODUCTION

It is known that residual stresses have a strong effect on the homeostatic stress state in arteries and should be accounted for in biomechanical models. The conventional approach of modelling residual stresses is the opening angle method. In this method, the circumferential residual deformations are measured by simple ring cutting experiments, and the corresponding residual stresses are then mathematically derived. However, it has been demonstrated that the three-dimensional residual stress model, introduced in [1], is more accurate in capturing not only the circumferential residual deformations, but also the axial ones, which are found to be essential in preventing arterial buckling. Moreover, accounting for the individual layers' residual deformations as proposed in [1] is very important considering the non-homogeneous nature of arteries. In this work, we extend the model from [1] to the anisotropic case using the recently introduced material model from [2]. This allows us to study the influence of anisotropy and microstructure on the residual stresses.

METHODS

In this work, we focus on residual stresses of the abdominal aorta. The axial and circumferential residual deformations of individual layers of the healthy abdominal aorta are estimated from the experimental study conducted in [3] – see Figure 1. To describe the anisotropic response of an aortic layer and account for both in-plane and out-of-plane collagen fibre alignments, the material model from [2] is employed. The strain-energy function (SEF) Ψ can be split into an isotropic term Ψ_1 and an anisotropic term Ψ_2 , i.e.

$$\Psi = \underbrace{\frac{c}{2}(I_1 - 3)}_{\Psi_1} + \underbrace{\sum_{i=4,6} \frac{k_1}{2k_2} [\exp(k_2 E_i^2)) - 1]}_{\Psi_2}. \quad (1)$$

Here, I_1 is the first invariant of the right Cauchy-Green tensor, E_4 and E_6 are Green-Lagrange quantities, and c, k_1, k_2 are mechanical material parameters. In addition, E_4 and E_6 depend on the microstructural material parameters κ_{ip} and κ_{op} describing in-plane and out-of-plane fibre dispersions.

Figure 1: Dominant axial (for the medial layer) and circumferential (for intimal and adventitial layers) residual deformations, as measured for the healthy human abdominal aorta.

Material parameters for this model must be determined from both microstructural analysis and mechanical testing of individual layers - the corresponding data for the healthy abdominal aorta were taken from [4].

Kinematics of the residual deformations together with the anisotropic SEF (1) $\Psi = \Psi_1 + \Psi_2$, and its “isotropic” version $\Psi = \Psi_1$, were used to derive expressions for isotropic and anisotropic residual stresses in individual aortic layers. The equilibrium equations, boundary conditions of zero-stress on the surfaces of the aorta and interface conditions of continuous radial stresses across the layers form boundary-value problems that were solved to determine all the unknowns of the problem. This allows a comparison of isotropic and anisotropic residual stresses of a quantification and investigation of the contribution of the anisotropic term Ψ_2 in the SEF (1), which is associated with the fibrous structure of the aorta.

SELECTED RESULTS

Residual stresses for the healthy abdominal aorta are shown in Figure 2 for the isotropic ($\Psi = \Psi_1$) and the anisotropic ($\Psi = \Psi_1 + \Psi_2$) SEFs. As can be seen, that the intimal layer of the aorta behaves rather isotropically, while the effect of the anisotropic term Ψ_2 in the adventitia is minimal. In contrast, the anisotropy seems to have a significant contribution in the media.

Figure 2: Influence of the anisotropic term Ψ_2 , in the SEF (1) on the residual stresses: (a) radial; (b) circumferential; (c) axial.

DISCUSSION

The different layers of large arteries such as the aorta have been shown to exhibit residual deformations in both the axial and circumferential directions. Modeling this complex behaviour requires a consideration of the heterogeneous material properties of the different layers, as well as the micro-structural differences. We achieved this by using an anisotropic SEF. Because residual strains are present in the absence of loads the presence of anisotropy has often been neglected in the computation of stresses derived from such residual strains. Our results show that this is legitimate for the intimal layer, which is highly compressed when unloaded and therefore any fibers present can be assumed to be unloaded. However, this is not the case for the other two layers. The adventitia is a highly collagenous layer, and while many fibres are most likely in a “non-activated” state at low strains, some effects due to the anisotropy of the structure were noted (see Figure 2). On the other hand, the media has a large fraction of elastin fibres, which appear to play a role on the residual stresses, together with any medial collagen fibres, if present. The model developed captures the most relevant effects of residual deformation in all three layers of a healthy abdominal aorta considering their unique mechanical and structural properties.

INTRODUCTION

Type A Aortic Dissection (TAAD) is a life-threatening condition involving delamination of aortic media layers. Current clinical guidelines recommend prophylactic surgical replacement of the ascending aorta at an aneurysm diameter >5.5cm to mitigate the risk of TAAD. However, large retrospective series and data from the international registry of acute aortic dissection (IRAD) has shown that as high as 62% of patients with TAAD have aortic diameters distinctly less than 5.5 cm [1], indicating the need of improved evidence-based risk prediction metrics. From a mechanics perspective, dissection is the biomechanical failure of the aortic wall that occurs when ascending aortic aneurysm wall stress exceeds wall strength; thus, wall stress may serve as a reasonable predictor of dissection. Both maximum wall stress and stretch based risk prediction metrics have been recently suggested in the literature. However, the lack of the clinical knowledge of whether a dissection actually ever occurred restricts the accuracy and validity of these models. We hypothesized that patients sustaining TAAD exhibit abnormal aortic wall stress in the longitudinal direction prior to the development of dissection. Our objective in this work was to establish the dissection potential index (DPI), a metric for early adjudication of TAAD risk based on longitudinal component of the wall stress. Towards that end, we constructed pre-dissection aortic images of the dissected as well as non-dissected patients from our clinical database, and created wall stress maps for each patient utilizing patient-specific wall tissue biomechanical properties. These maps were used to create patient specific dissection potential index.

METHODS

Aortic dissection patients with pre-dissection CT imaging ($n = 10$) were chosen as the study group. A control set of patients without aortic

dissection ($n = 9$) was also chosen for comparison. A number of clinical data including age, gender, weight, height, body mass index, body surface area and blood pressure were matched for these two cohorts. Scans were collected with patient consent and IRB approval. Mimics (Materialize, Leuven, Belgium) and Geomagic (3D Systems, Rock Hill, SC) were used to 3D reconstruct a solid model of the thoracic aorta from the scans. Finite element meshing was performed using Trelis (csimsoft, American Fork, UT) resulting in meshes with 30,000-50,000 3-noded triangles. Systolic (AoS) and diastolic (AoD) aortic diameters for each patient was assessed using the parasternal long axis window of two-dimensional transthoracic echocardiography, measured 3 cm above the aortic valve. AoD was obtained at the peak of the R wave in the simultaneously recorded electrocardiogram, while AoS was measured at the initiation of the T wave. Patient specific aortic stiffness was estimated from these diameter measurements and knowledge of corresponding systolic and diastolic blood pressure [2]. A two-parameter isotropic constitutive model, previously developed for abdominal aortic tissue [3], was calibrated in a patient-specific manner to match imaging obtained aortic stiffness.

The aortic models were loaded to an internal pressure of 200 mmHg using a custom membrane dynamic finite element program. Displacements at all the boundaries of the resulting aortic model were restrained to zero to prevent rigid body motion during finite element simulation. Convergence of the computational results was ensured by decreasing the pressurization rate if the change in maximum stress exceeded 5% under a 2x increase in load steps. $DPI = \sigma_{LONG}/S_{LONG}$, relating the stress and the strength of the tissue in the longitudinal direction, was plotted over the entire aorta. Proposed dissection potential is based on longitudinal wall stress and strength inspired by our recent work on biomechanical pathways of TAAD [4]. Population-relevant longitudinal strength was measured from uniaxial tensile

experiments [5]. Locations of dissection origin were identified by direct evaluation of perioperative contrast CT scans by clinicians blinded to the dissection potential mapping, and compared to the regions of high dissection potential.

RESULTS

There was significant difference ($p < 0.005$, Student's t-test) in the peak dissection potential of the control set ($DPI = 0.30 \pm 0.04$, mean \pm std) and the dissection set ($DPI = 0.49 \pm 0.06$). Interestingly, longitudinal trend of the DPI (Figure 1), obtained from multiple CT scans taken over a period for each dissection patient, revealed a monotonic increase. Moreover, we found that DPI was >0.30 in regions of clinically observed dissection for 8 patients (Figure 2). In general, there was elevated dissection potential on the greater curvature of the ascending thoracic aorta compared to the rest of the aorta (red regions in Figure 2).

Figure 1: Evolution of DPI with time for dissected patients. Data for individual patients are denoted by different colored circles.

DISCUSSION

We found that peak longitudinal wall stress for the dissected patients is significantly different than the control patients. This finding corroborates previous investigations that identified aberrant imaging-based aortic wall biomechanics in patient populations with known increased dissection risk. Finite element simulation and associated biomechanical analysis as a means to assess aortic dissection risk have been previously posited. However, these prior studies focused on the maximum circumferential stress or stretch as the limiting factor, and the dissection-risk metrics discussed in these studies were devoid of clinical data validation. Our proposed dissection potential, based on longitudinal wall stress and strength, is consistent with the surgical observation of dissection initiation from primarily circumferentially oriented intimal tears, and appears to be capable of stratifying patients with aortic dissection from those without. The locations of dissection initiation fell within the regions of elevated risk ($DPI > 0.3$) for 8 of the 10 patients.

The presented study has the following limitations. The number of patients for whom we had multiple pre-dissection CTAs and echocardiograms among a consecutive series of TAADs was small ($n=10$), and consequently may not be representative of the entire TAAD population. Our future study will include more dissected patients as well as patients with stable aneurysms. For the

computational simulations, we assumed that the stiffness in the longitudinal direction was similar to that in the circumferential direction thus motivating our use of an isotropic material model. Our future work will include other methods of image based distensibility measurements so that both longitudinal and circumferential stiffness can be separately assessed.

Our findings support using a new, biomechanically-based approach to predicting aortic dissection potential using multiple patient-specific imaging data points. A biomechanically-based paradigm using patient-specific metrics will likely improve our ability to predict aortic dissection potential and thus better direct appropriate elective aortic intervention relative to the current guidelines that are based on maximal orthogonal aortic dimensions.

Figure 2: Regions indicating dissection potential, DPI, greater than 0.30 (red) and location of aortic dissection initiation as determined by surgical notes (black highlighted regions) for the dissected cohort ($n = 10$).

INTRODUCTION

Type A Aortic Dissection (TAAD), initiated from an intimal tear in the ascending thoracic aorta, is a major health concern. Current clinical practice for the prediction of patient-specific dissection risk, based on maximum orthogonal diameter of the aorta [1], is not adequate. However, as high as 62% of patients with TAAD have aortic diameters distinctly less than the clinical guideline of 5.5 cm [2], strongly suggesting the clinical need for improved evidence-based dissection risk prediction metrics. As dissection ultimately involves biomechanical failure of the vessel wall, construction of such metrics will require fundamental knowledge of the aortic wall tissue strength under physiologic loading conditions.

Uniaxial as well as equibiaxial tissue strength of healthy and aneurysmal human aortic tissue specimens have been reported in the literature. Under physiologic loading conditions, however, the ascending thoracic aortic wall is subjected to a wide range of stress biaxiality. To quantify the aortic tissue failure behavior under such physiologic loading conditions, the tissue strength under the entire plausible spectrum of physiologic stress biaxiality must be evaluated. In this work, we present an experimentally-informed structural model of the aortic wall media to estimate the physiologic tissue strength under general biaxial loading conditions. Extensive biaxial simulations were then performed on the experimentally validated model to estimate physiologic tissue strength for a feasible range of biaxiality ratio.

METHODS

We created a finite element-based representative volume element (RVE) of the lamellar structure of the aortic media for two clinically relevant patient populations: patients with normal (tricuspid) aortic valve with and without aortic aneurysm. The RVE was constructed of

two elastic lamellae (EL) separated by an interlamellar (IL) space, all modeled as isotropic neoHookean materials. For symmetry reasons, the thickness of the EL were taken as 0.75 μm (half their physiological thickness) and the thickness of the IL was taken as 11 μm . Two planar collagen networks were created within the IL space and adjacent to the EL. The networks were constructed of discrete collagen fibers 3 μm in diameter and were modeled as linear elastic rods active only in tension beyond their recruitment stretch. Previously determined network parameters: mean fiber diameter (γ), orientation index (OI), and areal density (AD) were used as inputs to a custom Matlab (R2016b, Mathworks, Natick, MA) script to construct the collagen networks. Mean fiber direction was $+\gamma$ for one of the networks and $-\gamma$ for the other. For the control (and aneurysmal) patient population, $\gamma = \pm 11^\circ$ ($\gamma = \pm 35^\circ$) and $OI = 0.67 \pm 0.01$ ($OI = 0.60 \pm 0.01$) [3]. Based on the literature, there are no significant difference in collagen content between aneurysmal and non-aneurysmal populations [4]; thus an areal fiber density of 0.48 for both patient populations was used. For each cohort, five different collagen fiber networks with the same target OI were constructed to minimize the effect of individual network artifacts on the final result for the aortic media.

Finite element simulations were performed using a custom non-linear embedded-fiber finite element method [5,6] in which the collagen fibers are explicitly modeled within the simulation. All RVEs were loaded biaxially with physiologically plausible tractions σ_{CIRC} and σ_{LONG} . Per convergence studies, the final RVE consisted of 15,000 8-noded hexahedral elements. The biaxiality of the stress state was quantified by biaxiality ratio $B = \sigma_{\text{LONG}} / \sigma_{\text{CIRC}}$, where $B=0$ and ∞ represents uniaxial CIRC and LONG loading, respectively, and $B=1$ is equibiaxial loading scenario. A drop in stress in either direction indicated tissue failure, and corresponding peak stress was recorded as the physiologic tissue strength. Visualization of the finite element

mesh and the simulated network were performed using Paraview (v5.6, Kitware, Clifton Park, NY).

RESULTS

Aortic tissue strength exhibited a dependence on the biaxiality ratio (Fig. 1, left column) for both non-aneurysmal and aneurysmal tissue. Both circumferential (CIRC, $B=0$) and longitudinal (LONG, $B=\infty$) uniaxial strength matched experimental data [7]. There was a transition from failure in the CIRC to LONG direction at $B_{trans}=0.68$ and 0.69 for non-aneurysmal and aneurysmal tissue, respectively. Below B_{trans} (blue shaded region), the overall tissue failure was governed by the failure of circumferentially oriented fibers. In contrast, tissue failure was caused by the failure of longitudinally oriented fibers beyond B_{trans} (pink shaded region). Evolution of fiber stress leading to aneurysmal tissue failure for two representative values of B from each regime are shown in Fig 2 (similar trend seen for non-aneurysmal tissue, not shown). Physiologic tissue strength, the maximum stress at which the tissue failed under biaxial loading condition, varied linearly with B in both regions remaining within 10% of the respective uniaxial strength. Fig. 1 (right column) presents the comparison of physiologic strength and corresponding experimentally observed uniaxial strength both above and below B_{trans} . For both populations, physiologic strength was statistically similar to uniaxial CIRC strength for biaxiality ratios below transition, and to uniaxial LONG strength above B_{trans} .

Figure 1: Physiologic strength under different biaxiality ratios for control and aneurysmal tissues (left column). Large open circles with error bars denote the mean and standard deviation for uniaxial tensile experiments in either the CIRC (blue) or LONG (red) directions. Comparisons of physiologic strength (blue bars) and experimentally derived uniaxial strength (yellow bars) are also shown for both populations (right column).

DISCUSSION

We found that physiologic tissue strength is dependent on the biaxiality ratio of the applied loading. Importantly, the critical physiologic strength, defined by its lowest magnitude over the entire range of stress biaxiality, is statistically similar to the uniaxial longitudinal strength of the tissue. This fact suggests that critical physiologic strength can be estimated from the uniaxial testing of the aortic tissue in LONG direction. A non-aneurysmal aorta ($B=0.5$ for

idealized cylindrical geometry) is expected to fail at a stress in excess of uniaxial circumferential strength, explaining why this event is extremely rare. B increases in aneurysmal aortas due to localized bulging, often noted in TAAD patients [8]. This geometric change in turn may cause a dramatic decrease in physiologic tissue strength at locations with $B > B_{trans}$, providing a potential rationale for higher susceptibility to dissection for aneurysmal patients.

Figure 2: Stress contours in the fibers (color, failed fibers white) and matrix (greyscale) for a representative aneurysmal aortic tissue RVE for $B=0.5$ (top row) and $B = 1.0$ (bottom row). The CIRC component of the matrix stress is shown in the upper panels and the LONG component of the matrix stress in the lower panels.

In conclusion, using a structural finite element model of the aortic media, we have estimated the physiologic aortic tissue strength under the entire range of plausible biaxial loading conditions. Our work extends the current experimental knowledge of uniaxial and equibiaxial tissue strength. The work presented herein is an important first step towards understanding the failure biomechanics of aortic dissection under physiologic loading conditions. An important future direction will be the non-invasive estimation of patient-specific tissue physiologic strength from the experimentally assessed population-specific uniaxial tissue strength.

INTRODUCTION

Inverse finite element method, which solves problems of which a deformed state is given at the onset, has demonstrated its utility in stress analysis of vascular systems structures [1]. However, the pure displacement formulation is known to suffer from volumetric locking in the incompressibility limit and shear locking in bending-dominated deformations. To overcome the issue, mixed and enhanced formulations have been developed for forward finite element analysis [2, 3]. These methods have been widely used and demonstrated the effectiveness in resolving the locking issues in forward analysis. Recently, we introduced inverse formulations of the mixed and enhanced strain methods for large deformation analysis of hyperelastic material. The methods draw on existing forward formulations [4] and are designed in such a way that the deformation predicted by forward elements can be exactly reverted. In this presentation, we discuss the importance of using the inverse mixed method for abdominal aortic aneurysm (AAA) stress analysis. It will be demonstrated that the mixed formulation can provide trustworthy stress solution in the limit of incompressibility. Moreover, the abdominal aortic aneurysms can be thought as statically determined structure in that the wall stress depends primarily on the deformed geometry. However, when using the pure displacement formulation, this feature may not be sharply captured because of the presence of numerical noise in the computed pressure field in the incompressibility limit. It will be shown that the inverse mixed method can effectively resolve this issue.

METHODS

In the pure displacement finite element approach, the discrete balance equations are developed from the weak form:

$$\int_{\Omega} \delta \mathbf{F} : \mathbf{F} \mathbf{S} dV + \delta \Pi_{ext}(\mathbf{u}) = 0 \quad (1)$$

The proposed inverse mixed method is based on $\bar{\mathbf{F}}$ projection. $\bar{\mathbf{F}}$ is defined as Equation (2):

$$\bar{\mathbf{F}} = \left(\frac{\theta}{J}\right)^{\frac{1}{3}} \mathbf{F} \quad (2)$$

$J = \det \mathbf{F}$, and θ is an additional field variable representing the volumetric strain, constructed as the least square projection of the volume ratio J on a lower dimensional space. Replacing \mathbf{F} with $\bar{\mathbf{F}}$, the weak form can be expressed as in the current configuration Ω :

$$\int_{\Omega} \delta \bar{\mathbf{F}} : \bar{\mathbf{F}} \bar{\mathbf{S}} j dv + \delta \Pi_{ext}(\mathbf{u}) = 0 \quad (3)$$

Here $j = 1/J$ is the inverse volume ratio. The equation is now understood as one solving the inverse deformation $\Phi : \Omega \rightarrow \Omega_0$. To obtain the finite element equation, the weak form is linearized with respect to the increment of the inverse displacement $\mathbf{U} = \mathbf{X} - \mathbf{x}$, where \mathbf{X} is reference configuration and \mathbf{x} is the current configuration.

RESULTS

Some illustrative results of the proposed mixed method are presented in this section. An abdominal aneurysm model is used to examine the stress solution as the material approaches the incompressibility limit and the sensitivity of stress to material parameters. The geometry of the abdominal aneurysm is shown in Figure 1. The aneurysm is meshed with a single layer of 8-node solid elements which has 4112 elements. The top and bottom edges of the mesh are fixed. A pressure of 120 Hgmm is applied to the inner surface of the aneurysm. The compressible neo-Hookean model in [5] is used.

For convenience, the Lamé parameters μ and λ are converted to Young's modulus E and Poisson ratio ν .

(1) Stress at the incompressibility limit

Six material sets: $\nu = 0.3, 0.4, 0.45, 0.49, 0.499, 0.4999$ with the same $E = 1.0E5$ MPa are used to investigate the performance of the method at the incompressibility limit in terms of the value of the peak stress. To compare, the same analyses are conducted using the pure displacement formulation. The peak stresses are presented in Figure 2. As can be seen from the figure, the stress values from the mixed formulation (in black) are insensitive to the value of the Poisson's ratio. For the pure displacement method (in blue), the von Mises stress reduces significantly when ν approaches 0.5. The magnitude of displacement becomes significantly smaller when ν approaches 0.5, indicating numerical locking.
