1 Podium Sessions

Tuesday, June 25		3:45PM - 5:15PM	
Thermal Damage Processes in Tissues		Sunburst	
Session Chair: Rupak Banerjee <i>University of Cincinnati</i>			
Session Co-Chair: Liang Zhu <i>University of Maryland Baltimore County</i>			
3:45PM	Adventures In Thermal Therapy: From Surgery To Cancer Treatment SB ³ C2019-001 John Pearce ¹ , ¹ <i>The University of Texas at Austin, United States</i>		
4:00PM	Microwave Thermal Therapy of Benign Adrenal Adenomas For Treatment of Primary Aldosteronism SB ³ C2019-002 Punit Prakash ¹ , Martin O'Halloran ² , Michael Dennedy ² , ¹ <i>Kansas State University, United States</i> , ² <i>National University of Ireland - Galway, Ireland</i>		
4:15PM	Metabolize Or Die: John Pearce'S Fascination With Bioenergetics In Cancer, and What We Know (and do Not Know) Now SB ³ C2019-003 Michael Graner ¹ , Petr Paucke ² , Natalie Serkova ³ , Anthony Fringuello ¹ , Steven Ojemann ¹ , Aviva Abosch ¹ , Julia Craft ¹ , Xiaoli Yu ¹ , ¹ <i>University of Colorado Denver, Anschutz Medical Campus, Department of Neurosurgery, United States</i> , ² <i>University of Colorado Denver, Anschutz Medical Campus, Department of Neurology, United States</i> , ³ <i>University of Colorado Denver, Anschutz Medical Campus, Department of Anesthesiology, United States</i>		
4:30PM	Examining Arrhenius Kinetics Over A Large Temperature Range SB ³ C2019-004 Daipayan Sarkar ¹ , Peiyuan Kang ¹ , Zhenpeng Qin ¹ , ¹ <i>University of Texas at Dallas, United States</i>		
4:45PM	Heating Protocol Design Affected By Thermal Damage Model In Magnetic Nanoparticle Hyperthermia For Cancer Treatment SB ³ C2019-005 Manpreet Singh ¹ , Qimei Gu ¹ , Ronghui Ma ¹ , Liang Zhu ¹ , ¹ <i>University of Maryland Baltimore County, United States</i>		
Tuesday, June 25		3:45PM - 5:15PM	

Heart Valve Mechanics and Cardiovascular Devices		Snowflake
Session Chair: Ankush Aggarwal <i>University of Glasgow</i>		
Session Co-Chair: Ali Akyildiz <i>Erasmus Medical Center</i>		
3:45PM	A Physiologically-Driven Biaxial Bioreactor System To Investigate Valve Interstitial Cell Phenotypic State After Surgical Repair SB ³ C2019-006 Salma Ayoub ¹ , Jordan Graves ¹ , Chung-Hao Lee ² , Michael Sacks ¹ , ¹ <i>The University of Texas at Austin, United States</i> , ² <i>The University of Oklahoma, United States</i>	
4:00PM	Restriction of Annulus Movement Alters The Dynamic Deformation and Strain Distribution of The Tricuspid Valve Leaflets: A Simulation Study SB ³ C2019-007 Keyvan Amini Khoiy ¹ , Rouzbeh Amini ¹ , ¹ <i>The University of Akron, United States</i>	
4:15PM	Tricuspid Valve Leaflet Strains In The Beating Ovine Heart SB ³ C2019-008 Manuel Rausch ¹ , Mrudang Mathur ¹ , William Meador ¹ , Marcin Malinowski ² , Tomasz Jazwiec ² , Tomasz Timek ² , ¹ <i>University of Texas at Austin, United States</i> , ² <i>Spectrum Health, United States</i>	
4:30PM	Materially Heterogeneous Annuloplasty Ring Reduces Loading On Posterior Annular Sutures SB ³ C2019-009 Beatrice Ncho ¹ , Eric Pierce ¹ , Ajit Yoganathan ¹ , ¹ <i>Georgia Institute Of Technology, United States</i>	

4:45PM 3d Reconstructions of Deployed Coronary Stents In The Clinical Setting: Investigation of Distortion Effects From Curvature On The Circumferential Orientation of Oct Images SB³C2019-010

Mark Elliott¹, David Molony², Brigham Smith³, Sarang Joshi¹, Habib Samady², Lucas Timmins¹, ¹University of Utah, United States, ²Emory University School of Medicine, United States, ³University of Utah School of Medicine, United States

5:00PM Effects of Right Ventricular Assist Device On Treating Pulmonary Arterial Hypertension: An In-Silico Study Using Image Based Biventricular Modeling Framework SB³C2019-011

Sheikh Mohammad Shavik¹, Lik Chuan Lee¹, ¹Michigan State University, United States

Tuesday, June 25

3:45PM - 5:15PM

Cardiovascular Biomechanics and Tissue Engineering

Wintergreen

Session Chair: Joao Soares *Virginia Commonwealth University*

Session Co-Chair: Zhijie Wang *Colorado State University*

3:45PM Controlling Compliance of Polycaprolactone/gelatin Tissue Engineered Vascular Graft In A Rat Model SB³C2019-012

Kenneth Furdella¹, Shinichi Higuchi¹, Kang Kim¹, William Wagner¹, Jonathan Vande Geest¹, ¹University of Pittsburgh, United States

4:00PM A Bio-Chemo-Mechanical Computational Model of Tissue Engineered Vascular Graft Development In Vivo SB³C2019-013

Ramak Khosravi¹, Abhay Ramachandra¹, Jason Szafron¹, Christopher Breuer², Jay Humphrey¹, ¹Yale University, United States, ²Nationwide Children's Hospital, United States

4:15PM Role of Hyaluronic Acid In Regulation of Contractile Forces In Heart Valve Tissue Constructs SB³C2019-014

Ying Lei¹, Luciano Bortolin¹, Frank Benesch-Lee¹, Teniola Oguntolu¹, Kristen Billiar¹, ¹Worcester Polytechnic Institute, United States

4:30PM Adipose Stromal Cell Secreted Factors Induce The Elastogenesis Cascade Within Aortic Smooth Muscle Cells SB³C2019-015

Aneesh Ramaswamy¹, Rachel Sides¹, Eoghan Cunnane², David Vorp¹, Justin Weinbaum¹, ¹University of Pittsburgh, United States, ²University of Pittsburgh; Royal College of Surgeons in Ireland, United States

4:45PM Quantifying and Modeling Spatial Heterogeneity In Valve Interstitial Cells SB³C2019-016

Emma Lejeune¹, Alex Khang¹, Michael Sacks¹, ¹University of Texas at Austin, United States

5:00PM Cyclic Stretch Causes Liberation of Caveolin-1 In Extracellular Vesicles From Vascular Smooth Muscle Cells SB³C2019-017

Mohammad Shaver¹, Jessica Molina¹, Joshua Daniel Hutcheson¹, ¹Biomedical Engineering Department of Florida International University, United States

Tuesday, June 25

3:45PM - 5:15PM

Mechanics of Cartilage in Health and Disease

Seasons 1-3

Session Chair: Corinne Henak *University of Wisconsin-Madison*

Session Co-Chair: Corey Neu *University of Colorado Boulder*

3:45PM Focal Chondral Defects In The Dysplastic Hip Cause Activity- and Size-Dependent Increases In Stress and Strain SB³C2019-018

Jocelyn Todd¹, Travis Maak¹, Jeffrey Weiss¹, ¹*University of Utah, United States*

4:00PM Mechanical Property Changes In The Tibial Plateau Cartilage Following Traumatic Injury and Repair Procedures To The Lapine Knee SB³C2019-019

Patrick Vaughan¹, Feng Wei¹, Albane Fauron¹, Loic DeJardin¹, Tammy Haut Donahue², Roger Haut¹, ¹*Michigan State University, United States*, ²*University of Massachusetts - Amherst, United States*

4:15PM Collagen-Derived Residual Stress Enhances The Biphasic Lubrication Property In Articular Cartilage SB³C2019-020

Hiromichi Fujie¹, Soh Morishita¹, Seido Yarimitsu¹, ¹*Tokyo Metropolitan University, Japan*

4:30PM Shorter More Regular Activity Improves Cartilage Function Compared To Longer Less Regular Activity SB³C2019-021

Brian Graham¹, Axel Moore², David Burris¹, Christopher Price¹, ¹*University of Delaware, United States*, ²*Imperial College London, United Kingdom*

4:45PM Impact of Decorin On Cartilage Pericellular Matrix Micromechanics and Chondrocyte Mechanotransduction SB³C2019-022

Daphney R. Chery¹, Prashant Chandrasekaran¹, Qing Li¹, Biao Han¹, Su Chin J. Heo², Renato V. Iozzo³, Motomi Enomoto-Iwamoto⁴, Robert L. Mauck², Lin Han¹, ¹*School of Biomedical Engineering, Science and Health Systems, Drexel University, United States*, ²*Department of Orthopaedic Surgery, University of Pennsylvania, United States*, ³*Department of Pathology, Anatomy and Cell Biology, Thomas Jefferson University, United States*, ⁴*Department of Orthopedics, University of Maryland, United States*

5:00PM Through-Thickness Patterns of Shear Strain Change With Early-Stage Progression of Osteoarthritis SB³C2019-023

Franz Maier¹, Courtland G. Lewis², David M. Pierce¹, ¹*University of Connecticut, United States*, ²*Hartford Health-care, United States*

Tuesday, June 25

3:45PM - 5:15PM

Reproductive and Abdominal Biomechanics

Seasons 4-5

Session Chair: Raffaella De Vita *Virginia Tech*

Session Co-Chair: Kristin Miller *Tulane University*

3:45PM Material Property Characterization of Human Cervical Tissue Based On Biphasical Viscoelastic Model SB³C2019-024

Lei Shi¹, Joy Vink², Ronald Wapner², Kristin Myers¹, ¹*Department of Mechanical Engineering, Columbia University, United States*, ²*Department of Obstetrics and Gynecology, Columbia University, United States*

4:00PM Effects of Pelvic Organ Prolapse On The Biaxial Biomechanical Behavior of Post-Menopausal Uterosacral Ligament SB³C2019-025

Elvis Danso¹, Jason Schuster¹, Isabella Johnson¹, Emily Harville¹, Laurephile Desrosiers², Leise Knoepp², Kristin Miller¹, ¹*Tulane University, United States*, ²*Ochsner Clinical School, United States*

4:15PM Rupture Mechanisms of The Vagina Under Inflation SB³C2019-026

Jeffrey McGuire¹, Woowon Lee², Kimani Toussaint², Caleb Stine¹, Jennifer Munson¹, Raffaella De Vita³, ¹*Virginia Tech, United States*, ²*University of Illinois at Urbana Champaign, United States*, ³*Virginia tech, United States*

4:30PM Remodeling of The Diabetic Urinary Bladder: A Comparison of An Obese and A Lean Animal Model of Type II Diabetes SB³C2019-027

Marissa Grobbel¹, Matthew Lewis¹, Anne Tonson¹, Robert Wiseman¹, Sara Roccabianca¹, ¹*Michigan State University, United States*

- 4:45PM Lactating Human Breast Response To Infant Oral Movements** SB³C2019-028
Diana Alatalo¹, Lin Jiang¹, Fatemeh Hassanipour¹, ¹*The University of Texas at Dallas, United States*
- 5:00PM Contribution To The Understanding of The Genese of The Ligamental System of The Pelvic System** SB³C2019-029
Olivier Mayeur¹, Mathias Brieu², Michel Cosson³, ¹*Centrale Lille, France*, ²*California State University, United States*, ³*CHR Lille - Jeanne de Flandres, France*

Tuesday, June 25**3:45PM - 5:15PM****Biomedical Engineering Education****Hemlock****Session Chair: Sara Wilson** *University of Kansas***Session Co-Chair: Choon Hwai Yap** *National University of Singapore*

- 3:45PM Broadening Research Exposure and Research Participation In Mechanical Engineering: Findings From The Umbric Me S-Stem Scholarship Program** SB³C2019-030
Liang Zhu¹, Ronghui Ma¹, Deepa Madan¹, Charles Eggleton¹, L. D. Timmie Topoleski¹, Shuyan Sun¹, ¹*University of Maryland Baltimore County, United States*
- 4:00PM Lessons Learned: Five Years of The Biomedical Engineering In Simulations, Imaging, and Modeling (bme-Sim) Reu Site** SB³C2019-031
Stephanie George¹, ¹*East Carolina University, United States*
- 4:15PM Incorporating Clinical Rotations, Online Lectures, and Business Concepts In Bme Senior Capstone Design: Are We There Yet?** SB³C2019-032
Alan Eberhardt¹, Joel Dobbs¹, ¹*University of Alabama at Birmingham, United States*
- 4:30PM Outcomes of Incorporating Clinical Simulation Laboratories In Biomedical Engineering Education** SB³C2019-033
Anita Singh¹, Dawn Ferry¹, ¹*Widener University, United States*
- 4:45PM Industrial Ergonomics Risk Assessment Meets Research In The Biomechanics Classroom** SB³C2019-034
Johannes Brombach¹, Megan DeRidder², Laurel Kuxhaus², ¹*University of Applied Sciences, Germany*, ²*Clarkson University, United States*
- 5:00PM On The Role of Project-Based Active Learning Techniques On Computer Programming Self-Efficacy of Undergraduate Biomedical Engineering Students and The Interactive Effects of Gender** SB³C2019-035
S. Cyrus Rezvanifar¹, Rouzbeh Amini¹, ¹*The University of Akron, United States*

Tuesday, June 25**3:45PM - 5:15PM****Respiratory, Lymphatic, Ocular and Other Organ System
Fluid Mechanics****Fox Den****Session Chair: Jessica Oakes** *Northeastern University*

- 3:45PM Numerical Modeling of Lamina Cribrosa Hemodynamics** SB³C2019-036
Yi Hua¹, Bryn L. Brazile¹, Ian A. Sigal¹, ¹*University of Pittsburgh, United States*
- 4:00PM Particle Deposition Correlates With Wall Shear Stress Divergence In Human Airways** SB³C2019-037
Ali Farghadan¹, Kamran Poorbahrani², Sahar Jalal³, Jessica Oakes², Filippo Coletti³, Amirhossein Arzani¹, ¹*Northern Arizona University, United States*, ²*Northeastern University, United States*, ³*University of Minnesota, United States*

- 4:15PM Computational Modeling of Pathogen Leakage Through N95 Respirators** SB³C2019-038
Prasanna Hariharan¹, Neha Sharma², Gavin D'Souza², Suvajyoti Guha¹, Rupak Banerjee², Matthew Myers¹, ¹US Food and Drug Administration, United States, ²University of Cincinnati, United States
- 4:30PM Regional Targeting of Therapeutic Particles In Healthy and Asthmatic Lungs** SB³C2019-039
Kamran Poorbahrami¹, Sean Fain², David Mummy², Jessica Oakes¹, ¹Northeastern University, United States, ²University of Wisconsin-Madison, United States
- 4:45PM Differential Effects of Bladder Outlet Obstruction Associated Pressure Cycling On Urothelial Cell Inflammation and Fibrosis In Vitro** SB³C2019-040
Cody Dunton¹, Todd Purves², Francis Hughes², Jiro Nagatomi¹, ¹Clemson University, United States, ²Duke University Medical Center, United States
- 5:00PM Effect of Airway Cilia Properties On Its Physiological Functioning** SB³C2019-041
Uduak George¹, ¹San Diego State University, United States

Wednesday, June 26	9:30AM -11:00AM
---------------------------	------------------------

Drug Delivery in Cancer, Ocular, and Central Nervous Systems

Sunburst

Session Chair: Ying Li *University of Connecticut*

Session Co-Chair: Bryn Martin *University of Idaho*

- 9:30AM In Vivo Measurement of Bevacizumab Diffusion Coefficient In The Rabbit Vitreous Humor Using Fluorescein Labeling** SB³C2019-042
Anita Penkova¹, Shuqi Zhang¹, Komsan Rattanakijsumton², Mark Humayun¹, Juan Carlos Martinez¹, Alejandra Gonzalez Calle¹, Ana Galesic¹, Abigail Tadde¹, Matthew Pratt¹, Mark Thompson¹, Satwindar Sadhal¹, ¹University of Southern California, United States, ²Ubon Ratchathani University, Thailand
- 9:45AM Precise Targeting of Polr2a As A Therapeutic Strategy For Human Triple Negative Breast Cancer** SB³C2019-043
Jiangsheng Xu¹, Xiaoming He¹, ¹University of Maryland, United States
- 10:00AM Characterization of Injection-Induced Tissue Swelling During Subcutaneous Injection of Biologics** SB³C2019-044
Yingnan Shen¹, Bumsoo Han¹, ¹Purdue University, United States
- 10:15AM Analysis of Convective and Diffusive Transport In The Brain Interstitium** SB³C2019-045
Lori Ray¹, Jeff Iliff², Jeff Heys¹, ¹Montana State University, Chemical & Biological Engineering, United States, ²Ohsu, United States
- 10:30AM Three-Dimensional Nonlinear Biphase Finite Element Model of Backflow During Flow-Controlled Infusions Into The Brain** SB³C2019-046
Gustavo Orozco¹, Joshua Smith², Jos Garca³, ¹University of Eastern Finland, Finland, ²Lafayette College, United States, ³Universidad del Valle, Colombia
- 10:45AM Relating Chemical and Physical Properties of Oligonucleotide Polyelectrolyte Complex Micelles** SB³C2019-047
Alexander Marras¹, Jeffrey Viereggs¹, Jeffrey Ting¹, Matthew Tirrell¹, ¹University of Chicago, United States

Wednesday, June 26	9:30AM -11:00AM
---------------------------	------------------------

Growth Remodeling and Repair I**Snowflake****Session Chair: Colleen Witzenburg** *University of Wisconsin***Session Co-Chair: Sara Roccabianca** *Michigan State University*

- 9:30AM Structural Remodeling and Volumetric Growth In The Right Ventricle Under Pulmonary Arterial Hypertension** SB³C2019-048
Reza Avaz¹, Emilio Mendiola¹, Michael Sacks², ¹*UT Austin, United States*, ²*University of Texas at Austin, United States*
- 9:45AM Mathematical Modeling of Regional Hypertensive Aortic Remodeling Reveals A Critical Role For Inflammation** SB³C2019-049
Marcos Latorre¹, Matthew Bersi², Jay Humphrey¹, ¹*Yale University, United States*, ²*Vanderbilt University, United States*
- 10:00AM Effect of Glucose On The Interlamellar Bonding of Arterial Elastin** SB³C2019-050
Ruizhi Wang¹, Xunjie Yu¹, Yanhang Zhang¹, ¹*Boston University, United States*
- 10:15AM Cortical Thickness Differences Emerge From Passive Physical Forces Generated By Growth** SB³C2019-051
Maria Holland¹, Ellen Kuhl², Alain Goriely³, ¹*University of Notre Dame, United States*, ²*Stanford University, United States*, ³*University of Oxford, United Kingdom*
- 10:30AM Targeting Cadherin-11 For Renal Fibrosis** SB³C2019-052
Tessa Huffstater¹, Leslie Gewin¹, W. David Merryman¹, ¹*Vanderbilt University, United States*
- 10:45AM Plastic Remodeling of Collagen Upon Tumor Growth Alters Fluid Transport Properties of The Extracellular Matrix** SB³C2019-053
Jacopo Ferruzzi¹, Meng Sun¹, Anastasia Gkousioudi¹, Anahita Pilvar¹, Darren Roblyer¹, Yanhang Zhang¹, Muhammad Zaman¹, ¹*Boston University, United States*

Wednesday, June 26	9:30AM -11:00AM
---------------------------	------------------------

Celebration of YC Fung's 100th Birthday**Wintergreen****Session Chair: Grace O'Connell** *UC Berkeley*

- 9:30AM Yc Fung Symposium Introduction** SB³C2019-054
Robert Nerem
- 9:45AM Pulmonary Arterial Mechanics: Something Old, Something New, Something Borrowed, Something Blue** SB³C2019-055
Naomi Chesler¹, ¹*University of Wisconsin - Madison, United States*
- 10:00AM Coronary Calcifications: From Vesicles To Plaque Rupture** SB³C2019-056
Natalia Maldonado¹, Luis Cardoso², Sheldon Weinbaum², ¹*New York City College of Technology, United States*, ²*The City College of New York, United States*
- 10:15AM The Impact of Hemodynamic Reflex Compensation Following Myocardial Infarction On Subsequent Ventricular Growth** SB³C2019-057
Colleen Witzenburg¹, Jeffrey Holmes², ¹*University of Wisconsin, United States*, ²*University of Virginia, United States*

10:30AM Effect of Ltbp-3 On The Circumferential and Axial Mechanics of The Aorta In A Mouse Model of Marfan Syndrome SB³C2019-058

Arina Korneva¹, Arunika Makam², Jay Humphrey¹, Chiara Bellini², ¹*Yale University, United States*, ²*Northeastern University, United States*

10:45AM Contribution of Matrix Remodeling To Biaxial Mechanics of Right-Ventricular Myocardium In Pulmonary Arterial Hypertension SB³C2019-059

Daniela Velez-Rendon¹, Justin Shieh², Daniela Valdez-Jasso², ¹*University of Illinois at Chicago, United States*, ²*University of California San Diego, United States*

Wednesday, June 26

9:30AM -11:00AM

Biomechanics of Lower and Upper Extremities

Seasons 1-3

Session Chair: Mariana Kersh *University of Illinois at Urbana-Champaign*

Session Co-Chair: Jennifer Wayne *Virginia Commonwealth University*

9:30AM Flexion Angle Dependent Differences In Joint Kinematics and Acl Force In Response To Applied Loads Are Conserved Throughout Skeletal Growth In The Porcine Stifle Joint SB³C2019-060

Stephanie Cone¹, Danielle Howe¹, Emily Lambeth¹, Jorge Piedrahita², Jeffrey Spang³, Matthew Fisher¹, ¹*North Carolina State University and the University of North Carolina – Chapel Hill, United States*, ²*North Carolina State University, United States*, ³*University of North Carolina – Chapel Hill, United States*

9:45AM A Novel Geometric Ratio To Predict The Flexion Gap In Total Knee Arthroplasty SB³C2019-061

Shady Elmasry¹, Peter Sculco¹, Timothy Wright¹, Andrew Pealre¹, Michael Cross¹, David Mayman¹, Cynthia Kahlenberg¹, Geoffrey Westrich¹, Carl Imhauser¹, ¹*Hospital for Special Surgery, United States*

10:00AM Micromotion In Tibial Components Recovered Post Mortem: A Pilot Study SB³C2019-062

Heath Baskin¹, Elie Ghanem¹, Jack Lemons¹, Alan Eberhardt¹, ¹*University of Alabama at Birmingham, United States*

10:15AM Computational Mechanics Demonstrate How A Transcondylar Screw Enhances Healing of Subchondral Bone Cysts SB³C2019-063

Lance Frazer¹, Elizabeth Santschi², Kenneth Fischer¹, ¹*University of Kansas, United States*, ²*Kansas State University, United States*

10:30AM A Generalized Framework For Objective Determination of Functional Musculoskeletal Joint Coordinate Systems SB³C2019-064

Tara Nagle¹, Ahmet Erdemir¹, Robb Colbrunn¹, ¹*Cleveland Clinic, United States*

10:45AM Cartilage Contact Stiffness Effects On Contact Pressure and Area At The Elbow Joint SB³C2019-065

Jonathan Parman¹, Cuneyd Gunay², Akin Cil¹, Antonis Stylianou¹, ¹*University of Missouri - Kansas City, United States*, ²*Eskisehir Osmangazi University, Turkey*

Wednesday, June 26	9:30AM -11:00AM
---------------------------	------------------------

Ocular Biomechanics**Seasons 4-5****Session Chair: Rouzbeh Amini** *The University of Akron***Session Co-Chair: Andrew Feola** *Atlanta VA and Georgia Institute of Technology*

- 9:30AM A Multiscale Finite Element Modeling Approach To Characterize Iris Deformation** SB³C2019-066
Vineet Thomas¹, Sam Salinas¹, Anup Pant¹, Syril Dorairaj², Rouzbeh Amini¹, ¹*The University of Akron, United States*, ²*Mayo Clinic, United States*
- 9:45AM Correlation of Human Lamina Cribrosa Strain Response To Axon Counts In The Optic Nerve Across Racioethnic Donor Eyes** SB³C2019-067
Hirut Kollech¹, Reza Behkam¹, Katelyn Axman¹, Jr-Jiun Liou¹, Jonathan Vande Geest¹, ¹*University of Pittsburgh, United States*
- 10:00AM Tensile Behavior of Anterior and Posterior Corneal Flaps Subjected To CxI Treatment Procedure** SB³C2019-068
Hamed Hatami-Marbini¹, ¹*University of Illinois at Chicago, United States*
- 10:15AM Genomic Loci Modulating Ocular Compliance In Mice** SB³C2019-069
Elizabeth Boazak¹, Cassandra Chu¹, Rebecca King², Joseph Sherwood³, Darryl Overby³, Eldon Geisert², C. Ross Ethier¹, ¹*The Georgia Institute of Technology, United States*, ²*Emory University, United States*, ³*Imperial College London, United Kingdom*
- 10:30AM Characterizing The Actin and Gfap Network Structure of The Astrocytic Lamina In Mouse Eyes** SB³C2019-070
Yik Tung Tracy Ling¹, Mary Pease², Harry Quigley², Thao (Vicky) Nguyen¹, ¹*Department of Mechanical Engineering, Johns Hopkins University, United States*, ²*Wilmer Eye Institute, Johns Hopkins University, United States*
- 10:45AM Snapshot Polarized Light Microscopy To Visualize and Quantify Collagenous Soft Tissue Microstructure At 156 Frames/second** SB³C2019-071
Bin Yang¹, Po-Yi Lee¹, Bryn Brazile¹, Ian Sigal¹, ¹*University of Pittsburgh, United States*

Wednesday, June 26	9:30AM -11:00AM
---------------------------	------------------------

Human Movement and Gait**Hemlock****Session Chair: Wu Pan Zagorski** *Lear Corporation***Session Co-Chair: Antonis Stylianou** *University of Missouri Kansas City*

- 9:30AM A Human Cadaveric Model For Quantifying Knee Joint Mechanics During Simulated Gait: Effect of Astm and Iso Derived Input Profiles** SB³C2019-072
Amanda Wach¹, Olufunmilayo Adebayo¹, Caroline Brial¹, Tony Chen¹, Russell Warren¹, Peter Torzilli¹, Suzanne Maher¹, ¹*Hospital for Special Surgery, United States*
- 9:45AM Predicted Gait Alterations Due To A Unilateral Reduction In Muscle Synergies** SB³C2019-073
Marleny Arones¹, Carolyn Patten², Benjamin J. Fregly¹, ¹*Rice University, United States*, ²*University of California, United States*
- 10:00AM System Identification of Pressure-Measuring Insoles For Determining Ground Reaction Force During Walking** SB³C2019-074
Jessica DeBerardinis¹, Janet S. Dufek¹, Mohamed B. Trabia¹, Yann Le Gall², Nicolas Da Silva Sacoto², ¹*University of Nevada Las Vegas, United States*, ²*Ecole Supérieure d'Electronique de l'Ouest, France*

- 10:15AM Utilizing Cross-Correlation To Determine Phase Shift In Gait Data For A Neural Prosthesis** SB³C2019-075
Martin L. Tanaka¹, David Hudson¹, ¹*Western Carolina University, United States*
- 10:30AM Movement Patterns In Dancers** SB³C2019-076
Rita Patterson¹, Nathan Hersberger¹, Elizabeth Balyakina¹, Sajid Surve¹, ¹*University of North Texas Health Science Center, United States*
- 10:45AM Can Superhydrophobic Slip Flow Improve Centrifugal Blood Pump Performance and Reduce Blood Damage?** SB³C2019-077
Wei Xuan Chan¹, Vivek Vasudevan¹, Jia Jun Low Adriel¹, Janani Venkatesan¹, Choon-Hwai Yap¹, ¹*National University of Singapore, Singapore*

Wednesday, June 26	9:30AM -11:00AM
---------------------------	------------------------

Data Driven Fluid Mechanics Modeling and Visualization

Fox Den

Session Chair: Alejandro Roldan-Alzate *University of Wisconsin-Madison*

- 9:30AM Non-Invasive Diagnostics of Coronary Artery Disease Using Machine Learning and Computational Fluid Dynamics** SB³C2019-078
Kritika Iyer¹, Christopher J. Arthurs², Cyrus P. Najarian¹, S.M. Reza Soroushmehr¹, Brahmajee K. Nallamothu¹, C. Alberto Figueroa¹, ¹*University of Michigan, United States*, ²*King's College London, United Kingdom*
- 9:45AM Statistical Modeling For Assessment of Aneurysm Rupture Status - Implications For Japanese and Finnish Populations** SB³C2019-079
Felicita Detmer¹, Sara Hadad¹, Sven Hirsch², Philippe Bijlenga³, Yuya Uchiyama⁴, Juhana Frsen⁵, Juan Cebra¹, ¹*George Mason University, United States*, ²*ZHAW University of Applied Sciences, Switzerland*, ³*University of Geneva, Switzerland*, ⁴*Tokyo University of Science, Japan*, ⁵*Kuopio University Hospital, Finland*
- 10:00AM Accelerating Cardiovascular Model Building With Convolutional Neural Networks** SB³C2019-080
Gabriel Maher¹, Nathan Wilson², Alison Marsden¹, ¹*Stanford University, United States*, ²*Open Source Medical Software Corporation, United States*
- 10:15AM Cardiac Motion Tracking From Noisy Ultrasound Images - Exploiting Cyclic Constraint Fitted To Non-Rigid Image Registration** SB³C2019-081
Hadi Wiputra¹, Wei Xuan Chan¹, Yoke Yin Foo¹, Yu Zheng¹, Sheldon Ho¹, Choon Hwai Yap¹, ¹*National University Of Singapore, Singapore*
- 10:30AM Deep Neural Networks For Hemodynamic Analysis of Human Thoracic Aorta** SB³C2019-082
Liang Liang¹, Wenbin Mao², Wei Sun², ¹*Department of Computer Science at University of Miami, United States*, ²*Georgia Institute of Technology and Emory University, United States*
- 10:45AM Effect of Nonlinear Elastic Properties of Arterial Walls On Pulse Wave Propagation** SB³C2019-083
Alberto Coccarelli¹, Sanjay Pant¹, Ankush Aggarwal², ¹*Swansea University, United Kingdom*, ²*University of Glasgow, United Kingdom*

Wednesday, June 26	11:15AM -12:45PM
---------------------------	-------------------------

Biotransport in a Tumor Microenvironment

Sunburst

Session Chair: Sihong Wang *The City College of New York*

Session Co-Chair: Rana Zakerzadeh *University of Texas at Austin*

- 11:15AM Fast Tumor Spheroid Growth In Microfluidic Device** SB³C2019-084
Yaling Liu¹, Chris Uhl¹, Yuyuan Zhou¹, ¹*Lehigh University, United States*
- 11:30AM A Microfluidic Tissue Array For Mid-Throughput Drug Screening Using Tumor Tissues For Personalized Medicine** SB³C2019-085
AH Rezwanuddin Ahmed¹, Xuejun Jiang², Sarat Chandarlapaty², Sihong Wang¹, ¹*The City College of New York, United States*, ²*Memorial Sloan Kettering Cancer Center, United States*
- 11:45AM Circulating Tumor Cell Transport and Adhesion In Microfluidic Devices** SB³C2019-086
Jifu Tan¹, Zhenya Ding², Wei Li², ¹*Northern Illinois University, United States*, ²*Texas Tech University, United States*
- 12:00PM An In Vitro Tumor Platform For Modeling Breast Tumor Stromal Interactions and Characterizing The Subsequent Response** SB³C2019-087
Manasa Gadde¹, Marissa Rylander¹, ¹*University of Texas at Austin, United States*
- 12:15PM Computational Fluid Dynamics Model of Pressurized Intraperitoneal Aerosol Chemotherapy: Gravity Matters!** SB³C2019-088
Mohammad Rahimi-Gorji¹, Leen Van de Sande¹, Charlotte Debbaut¹, Patrick Segers¹, Wouter Willaert¹, Wim Ceelen¹, ¹*Ghent University, Belgium*
- 12:30PM Microtissues For Biomechanical Investigations of Angiogenesis** SB³C2019-089
M.K. Sewell-Loftin¹, Priscilla Hwang¹, Joshua Katz¹, Steve George², Gregory Longmore¹, ¹*Washington University School of Medicine in St. Louis, United States*, ²*University of California, Davis, United States*

Wednesday, June 26	11:15AM -12:45PM
---------------------------	-------------------------

Cardiac Mechanics

Snowflake

Session Chair: Manuel Rausch *University of Texas at Austin*

Session Co-Chair: Colleen Witzenburg *University of Wisconsin*

- 11:15AM A Robust 3d Constitutive Model For The Passive Properties of Left Ventricular Myocardium** SB³C2019-090
David Li¹, Reza Avazmohammadi¹, Samer Merchant², Tomonori Kawamura³, Edward Hsu², Joseph Gorman³, Robert Gorman³, Michael Sacks¹, ¹*The University of Texas at Austin, United States*, ²*University of Utah, United States*, ³*University of Pennsylvania, United States*
- 11:30AM Fast Predictions of Cardiac Growth During Ventricular Dyssynchrony** SB³C2019-091
Pim Oomen¹, Colleen Witzenburg², Thien-Khoi Phung¹, Kenneth Bilchick¹, Jeffrey Holmes¹, ¹*University of Virginia, United States*, ²*University of Wisconsin, United States*
- 11:45AM Role of Talin1 In Cardiac Fibroblasts On Cardiac Hypertrophy** SB³C2019-092
Natalie Noll¹, Qinkun Zhang¹, Hind Lal¹, W. David Merryman¹, ¹*Vanderbilt University, United States*

- 12:00PM Modeling of Anisotropic Reverse Cardiac Growth In Response To Local Alteration of Electromechanics** SB³C2019-093
Jayavel Arumugam¹, Ghassan Kassab², Lik Chuan Lee¹, ¹*Michigan State University, United States*, ²*California Medical Innovations Institute, United States*
- 12:15PM The Effect of Collagen Heterogeneity On Rat Myocardial Infarct Mechanics In A Multiscale Fiber Network Model** SB³C2019-094
Christopher Korenczuk¹, William Richardson², Victor Barocas¹, ¹*University of Minnesota - Twin Cities, United States*, ²*Clemson University, United States*
- 12:30PM Analyzing The Biomechanical Response of Failing Right Ventricular Tissue To Sacubitril/valsartan Treatment** SB³C2019-095
Danial Sharifikia¹, Claire Tushak¹, Evan Benza², Kang Kim³, Marc Simon³, ¹*Department of Bioengineering, University of Pittsburgh, United States*, ²*Heart and Vascular Institute, University of Pittsburgh Medical Center (UPMC), United States*, ³*Department of Bioengineering, University of Pittsburgh; Division of Cardiology, School of Medicine, University of Pittsburgh; Heart and Vascular Institute, University of Pittsburgh Medical Center (UPMC); McGowan Institute for Regenerative Medicine, Univer, United States*

Wednesday, June 26**11:15AM -12:45PM****Celebration of YC Fung's 100th Birthday****Wintergreen****Session Chair: Spencer Lake** *Washington University in St. Louis*

- 11:15AM Osmotic Swelling Behavior of The Pregnant Mouse Cervix and The Contribution of Hyaluronic Acid** SB³C2019-096
Charles Jayyosi¹, Shanmugasundaram Nallasamy², Priya Madhukaran², Mala Mahendroo², Kristin Myers¹, ¹*Columbia University, United States*, ²*University of Texas Southwestern Medical Center, United States*
- 11:30AM From Biomechanics To T Cell Affinity To Systems Immunology My Path In Biomedical Engineering That Is Inspired By Dr. Yc Fung** SB³C2019-097
Ning Jiang¹, ¹*University of Texas at Austin, United States*
- 11:45AM A Mathematical Model For The Post-Implant Collagen Maturation Behavior of Engineered Tissues** SB³C2019-098
Michael Sacks¹, ¹*University of Texas at Austin, United States*
- 12:00PM Non-Invasive Brillouin Moduli and Membrane Fluctuation Measurements of Live Tumor Cell Nuclei** SB³C2019-099
Anya Roberts¹, Vijay Singh¹, Peter So¹, Roger Kamm¹, ¹*Mit, United States*
- 12:15PM A Micromechanical Model For Collagenous Tissues and Applications To Study Growth and Remodeling** SB³C2019-100
Thao Vicky¹, ¹*Johns Hopkins University, United States*
- 12:30PM Yc Fung Symposium Conclusion** SB³C2019-101
Savio Woo

Wednesday, June 26**11:15AM -12:45PM****Mechanics of Cartilage and Meniscus****Seasons 1-3****Session Chair: Deva Chan** *Rensselaer Polytechnic Institute***Session Co-Chair: David M Pierce** *University of Connecticut*

- 11:15AM Mechanical Property Changes In The Meniscus In A Novel Closed Joint Animal Impact and Surgical Model** SB³C2019-102

Gerardo Narez¹, Albane Fauron², Loic Dejardin², Feng Wei², Roger C. Haut², Tammy L. Haut Donahue¹,
¹University of Massachusetts, Amherst, United States, ²Michigan State University, United States

11:30AM Non-Invasive Mri Assessment of Meniscus and Cartilage Changes In A Large Animal Model of Meniscus Injury SB³C2019-103

Kyle Meadows¹, Sonia Bansal², John Peloquin¹, Liane Miller², Jay Patel², Kamel Saleh², Michael Hast², Miltiadis Zgonis², Robert Mauck², Dawn Elliott¹, ¹University of Delaware, United States, ²University of Pennsylvania, United States

11:45AM Maintaining Cartilage Hydration During Sliding Part 2: Modes and Competitive Recovery Rates SB³C2019-104

David Burris¹, Axel Moore², Brian Graham¹, Jamie Benson¹, Caroline Kook¹, Steven Voinier¹, Christopher Price¹,
¹University of Delaware, United States, ²Imperial College London, United Kingdom

12:00PM Collagen Fiber Orientation and Mechanical Properties Correlate Across Human Articular Cartilage Zones SB³C2019-105

Kristine Fischenich¹, Joseph Wahlquist¹, Virginia Ferguson¹, ¹University of Colorado at Boulder, United States

12:15PM Toward Quantifying Changes In The Collagen Network of Human Articular Cartilage During Early-Stage Osteoarthritis SB³C2019-106

Szarek E. Phoebe¹, Magnus B. Lilledahl², Courtland G. Lewis³, David M. Pierce¹, ¹University of Connecticut, United States, ²Norwegian University of Science and Technology, Norway, ³Hartford Healthcare, United States

12:30PM Type III Collagen Is A Key Regulator of Collagen Fibrillar Structure In Cartilage Pericellular Matrix SB³C2019-107

Chao Wang¹, Becky Brisson², Qing Li¹, Masahiko Terajima³, Motomi Enomoto-Iwamoto⁴, Mitsuo Yamauchi³, Susan Volk², Lin Han¹, ¹Drexel University, United States, ²University of Pennsylvania, United States, ³University of North Carolina, United States, ⁴University of Maryland, United States

Wednesday, June 26

11:15AM -12:45PM

Injury: Imaging

Seasons 4-5

Session Chair: Steve Rowson *Virginia Tech*

Session Co-Chair: Liming Voo *Johns Hopkins University Applied Physics Laboratory*

11:15AM A Comparison of The Deformation Response of The Brain To Mild Acceleration In The Axial and Sagittal Planes In A Healthy Volunteer SB³C2019-108

Andrew Knutsen¹, Arnold Gomez², Jerry Prince², Philip Bayly³, John Butman⁴, Dzung Pham¹, ¹The Henry M Jackson Foundation, United States, ²Johns Hopkins University, United States, ³Washington University in St. Louis, United States, ⁴National Institutes of Health, United States

11:30AM Longitudinal Head Impact Exposure and White Matter Integrity Analysis Among Returning Youth Football Players SB³C2019-109

Mireille Kelley¹, Jillian Urban², Derek Jones², Elizabeth Davenport³, Logan Miller², Beverly Snively⁴, Alexander Powers⁵, Christopher Whitlow⁶, Joseph Maldjian³, Joel Stitzel², ¹Virginia Tech-Wake Forest School of Biomedical Engineering and Sciences, United States, ²Virginia Tech-Wake Forest University School of Biomedical Engineering and Sciences, United States, ³Department of Radiology, University of Texas Southwestern, United States, ⁴Department of Biostatistical Sciences, Wake Forest School of Medicine, United States, ⁵Department of Neurosurgery, Wake Forest School of Medicine, United States, ⁶Department of Radiology (Neuroradiology), Wake Forest School of Medicine, United States

11:45AM Imaging and Mechanical Characterization of The Pia-Arachnoid Complex SB³C2019-110

Nikolaus Benko¹, Emma Luke², Yousef Alsanea¹, Brittany Coats¹, ¹University of Utah Mechanical Engineering, United States, ²University of Rochester Biomedical Engineering, United States

- 12:00PM Mechanical and Interfacial Characterization of Meningioma Through Mr Imaging** SB³C2019-111
Efe Ozkaya¹, Dominic Nistal², Zeynep Suar¹, Alexander Chartrain², Cassandra Gologorsky³, Priti Balchandani², Raj Shrivastava², Mehmet Kurt¹, ¹*Stevens Institute of Technology, United States*, ²*Icahn School of Medicine at Mount Sinai, United States*, ³*Cornell University, United States*
- 12:15PM A Network-Based Brain Injury Metric For Concussion Prediction** SB³C2019-112
Shaoju Wu¹, Wei Zhao¹, Bethany Rowson², Steve Rowson², Songbai Ji¹, ¹*Worcester Polytechnic Institute, United States*, ²*Virginia Tech, United States*
- 12:30PM Changes In Brain Tissue In Vivo Deformation Following Decompression Surgery In Chiari Patients** SB³C2019-113
Maggie Eppelheimer¹, Blaise Simplicie Talla Nwotchouang¹, Soroush Heidari Pahlavian², John Oshinski³, Daniel Barrow³, Rouzbeh Amini¹, Francis Loth¹, ¹*The University of Akron, United States*, ²*USC Stevens Neuroimaging and Informatics Institute University of Southern California, United States*, ³*Emory University, United States*

Wednesday, June 26**11:15AM -12:45PM****UG Design Competition****Hemlock**

Session Chair: Michael Moreno *Texas A&M University*
Session Co-Chair: Ted Conway *Florida Institute of Technology*

- 11:15AM Design and Optimization of A Finger-By-Finger Vibrational Therapy** SB³C2019-114
Joshua Posen¹, George Durrant¹, Samuel Langlois¹, Chirsteen Abdalla¹, Gary Drzewiecki¹, ¹*Rutgers University, United States*
- 11:30AM Jogging Stroller Attachment Device For Natural Arm Motion** SB³C2019-115
Tamara Chambers¹, Amy Ramos¹, Meghan Blanks¹, ¹*Embry-Riddle Aeronautical University, United States*
- 11:45AM Assistive Device For Stretching Exercise In Patients With Frozen Shoulder Syndrome** SB³C2019-116
Maria Owsiak¹, Monsour Al Awami¹, Ryan Daher¹, Scott Goeltz¹, Rebecca Gomezrueda¹, Russel Maurer¹, Andrew Saylor¹, Ria Mazumder¹, ¹*Widener University, United States*
- 12:00PM Wearable Robotic Wrist Orthosis For Stroke Rehabilitation** SB³C2019-117
Neshat Baset¹, Dona Antony¹, Mahdi Haghsheenas-Jaryani¹, Muthu Wijesundara¹, ¹*University of Texas at Arlington Research Institute, United States*
- 12:15PM Design of 3d Printed Robotic Glove Augmenting Manual Manipulation of Humans** SB³C2019-118
Mason Araujo¹, Immanuel Ponminissery¹, Seok Chang Ryu¹, ¹*Texas A&M University, United States*
- 12:30PM Assistive Device For Muscular Degeneration In The Upper Arm** SB³C2019-119
Alexandria Barber¹, Emily Eaton¹, Jillian Farmer¹, Samantha Gladd¹, Natalie Jagelski¹, Jenny Lin¹, ¹*Clarkson University, United States*

Wednesday, June 26**11:15AM -12:45PM****Translational Cardiovascular Diagnosis and Treatment****Fox Den**

Session Chair: John LaDisa *Marquette University*

- 11:15AM Analyses of Hemodialysis Arteriovenous Fistula Geometry Obtained By Serial Magnetic Resonance Imaging** SB³C2019-120
Yong He¹, Daniel Pike², Yan-Ting Shiu², Prabir Roy-Chaudhury³, Alfred Cheung², Scott Berceli¹, ¹*University of Florida, United States*, ²*University of Utah, United States*, ³*University of Arizona, United States*

- 11:30AM Effect of Gravity On Hemodynamics In Cerebral Aneurysms - An In Vitro Study** SB³C2019-121
Melissa Brindise¹, Sean Rothenberger¹, Susanne Schnell², Michael Markl², David Saloner³, Vitaliy Rayz¹, Pavlos Vlachos¹, ¹Purdue University, United States, ²Northwestern University, United States, ³University of California San Francisco, United States
- 11:45AM A Nonlinear Mechanics-Based Virtual Coiling Method For Intracranial Aneurysm** SB³C2019-122
Seyyed Mostafa Mousavi Janbeh Sarayi¹, Robert J. Damiano¹, Palak Patel¹, Gary Dargush¹, Adnan H. Siddiqui¹, Hui Meng¹, ¹University at Buffalo, The State University of New York, United States
- 12:00PM Computational Assessment of Left-Ventricular Outflow Tract Hemodynamic Alterations In Discrete Subaortic Stenosis** SB³C2019-123
Jason Shar¹, Sundeep Keswani², Jane Grande-Allen³, Philippe Sucosky¹, ¹Wright State University, United States, ²Texas Children's Hospital, United States, ³Rice University, United States
- 12:15PM Blood Flow Modeling of Cerebral Aneurysm Treated With Intracranial Flow Diverting Devices** SB³C2019-124
Fernando Mut¹, Bong Jae Chung², Juan Cebral¹, ¹George Mason University, United States, ²Montclair State University, United States
- 12:30PM Impact of Post-Tavr Patient-Specific Geometry On Neo-Sinus Flow: A Computational Fluid Dynamics Study** SB³C2019-125
Shelly Singh-Gryzbon¹, Sanchita Bhat¹, Vahid Sadri¹, Joseph Choi¹, Mandy Salmon¹, Zhenglun (Alan) Wei¹, Philipp Ruile², Franz-Joseph Neumann², Philipp Blanke³, Ajit Yoganathan¹, ¹Georgia Institute of Technology, United States, ²University Heart Center Freiburg-Bad Krozingen, Germany, ³St Paul's Hospital and University of British Columbia, Canada

Thursday, June 27

9:30AM -11:00AM

PhD Paper Competition: Cell & Tissue Engineering**Sunburst****Session Chair: Tamara Bush** *Michigan State University***Session Co-Chair: Zhenpeng Qin** *The University Of Texas At Dallas*

- 9:30AM Igf-1 Suppresses Trpv4 Osmosensation Through The Map7 Binding Domain In Chondrocytes** SB³C2019-126
Nicholas Trompeter¹, Lauren Hurd¹, Joseph Gardinier², Victor DeBarros II¹, Mary Boggs¹, Randall Duncan¹, ¹University of Delaware, United States, ²Henry Ford Health System, United States
- 9:45AM High-Velocity Stretching Causes Mechanically-Induced Tau Pathology In Neurons** SB³C2019-127
Nicholas Braun¹, Dezhi Liao¹, Patrick Alford¹, ¹University of Minnesota - Twin Cities, United States
- 10:00AM Introduction of Heterogeneous Cell Properties For Modeling Emergent Stress Fields In Multicellular Systems** SB³C2019-128
Zachary Goldblatt¹, Heather Cirka¹, Habibeh Ashouri Choshali¹, Nima Rahbar¹, Dannel McCollum², Kristen Billiar¹, ¹Worcester Polytechnic Institute, United States, ²UMASS Medical School, United States
- 10:15AM Concentration Dependent Tgf-Beta Internalization Rate In Engineered Musculoskeletal Tissues** SB³C2019-129
Sedat Dogru¹, Danial Sharifikia¹, Samuel Sze¹, Michael Albro¹, ¹Boston University, United States
- 10:30AM A Micropatterning Approach To Study Cellular Communication Via Mechanical Forces In Fibrous Microenvironments** SB³C2019-130
Christopher Davidson¹, Brendon Baker¹, ¹University of Michigan, United States
- 10:45AM Endothelial Nitric Oxide Synthase Glycosylation Is A Potential Target For Reducing Endothelial Dysfunction** SB³C2019-131
Sarah Basehore¹, Alisa Morss Clyne¹, ¹Drexel University, United States

Thursday, June 27	9:30AM -11:00AM
--------------------------	------------------------

PhD Paper Competition: Imaging, Injury, and Biomedical Engineering Education

Snowflake

Session Chair: Corinne Henak *University of Wisconsin-Madison*

Session Co-Chair: Victor Barocas *University of Minnesota*

9:30AM Developing A Stem+m Identity In Underrepresented Minority Groups Through Sports and Biomechanics SB³C2019-132

Brittany Marshall¹, Amy Loya², John Drazan³, Anthony Prato⁴, Nicole Conley⁵, Stavros Thomopoulos¹, Katherine Reuther¹, ¹*Columbia University, United States*, ²*Rensselaer Polytechnic Institute, United States*, ³*University of Pennsylvania, United States*, ⁴*SUNY Geneseo, United States*, ⁵*Union College, United States*

9:45AM 3d Strain Gradients Correlate With Murine Myocardial Infarct Severity SB³C2019-133

Arvin Soepriatna¹, John Boyle², Abigail Clifford¹, Alex Yeh¹, Semih Bezci³, Grace O'Connell³, Craig Goergen¹, ¹*Purdue University, United States*, ²*Washington University in Saint Louis, United States*, ³*University of California Berkeley, United States*

10:00AM Development of A Dual-Venc 4d Flow Mri Framework For The Generation of Patient Specific Aortic Finite Element Models SB³C2019-134

Jamie Concannon¹, Kevin Moerman¹, Peter Dockery¹, Peter McHugh¹, Christof Karmonik², Patrick McGarry¹, ¹*National University of Ireland Galway, Ireland*, ²*MRI Core, Debaquey Heart and Vascular Center, Houston Methodist, TX, USA, United States*

10:15AM 5-Ht2b Antagonism Controls Border Zone Mechanics To Improve Outcomes Following Myocardial Infarction SB³C2019-135

J. Caleb Snider¹, Qinkun Zhang¹, Hind Lal¹, W. David Merryman¹, ¹*Vanderbilt University, United States*

10:30AM An Integrated Machine Learning-Inverse Finite Element Approach For Identification of Patient-Specific Material Properties of The Aortic Wall From Clinical Ct Images SB³C2019-136

Minliang Liu¹, Liang Liang², Fatiesa Sulejmani¹, Xiaoying Lou³, Glen Iannucci³, Edward Chen³, Bradley Leshnowar³, Wei Sun¹, ¹*Georgia Institute of Technology, United States*, ²*University of Miami, United States*, ³*Emory University, United States*

10:45AM Comparative Analysis of Head Impact Kinematics In High School and Collegiate Football Using Mig2.0 Instrumented Mouthguard SB³C2019-137

Ileana Pirozzi¹, Michael Fanton¹, Chiara Giordano¹, Sohrab Sami¹, India Rangel¹, William Mehning¹, Pritha Roy¹, Brett Avery¹, Michael Zeineh¹, Gerald Grant¹, David Camarillo¹, ¹*Stanford University, United States*

Thursday, June 27	9:30AM -11:00AM
--------------------------	------------------------

PhD Paper Competition: Extracellular Matrix Biomechanics

Wintergreen

Session Chair: Alejandro Roldan-Alzate *University of Wisconsin-Madison*

Session Co-Chair: Bahareh Behkam *Virginia Tech*

9:30AM Plasticity and Elasto-Plastic Damage Mechanics Using Reactive Constrained Solid Mixtures: A Modeling Approach For Biomedical Materials SB³C2019-138

Brandon Zimmerman¹, Gerard Ateshian¹, ¹*Columbia University, United States*

9:45AM Inflammatory and Non-Inflammatory Synovial Fluids Exhibit Distinct Tribological Phenotypes SB³C2019-139

Elizabeth Feeney¹, Devis Galesso², Cynthia Secchieri², Roberta Ramonda³, Lawrence Bonassar¹, ¹*Cornell University, United States*, ²*Fidia Farmaceutici S.p.A., Italy*, ³*University of Padua, Italy*

- 10:00AM Failure Mechanisms In The Tendon Enthesis Under Quasistatic, Cyclical, and Pathological Loading** SB³C2019-140
Mikhail Golman¹, Adam Abraham², Iden Kurtaliaj², Brittany Marshall², Guy Genin³, Victor Birman⁴, Stavros Thomopoulos², ¹*Columbia University, United States*, ²*Columbia University, United States*, ³*Washington University in St. Louis, United States*, ⁴*Missouri Science & Technology, United States*
- 10:15AM Real-Time Measurement of Collagen Architecture and Deformations At Sub-Micron Resolution** SB³C2019-141
Po-Yi Lee¹, Bin Yang¹, Ian A Sigal¹, ¹*University of Pittsburgh, United States*
- 10:30AM Collagen Fatigue Damage Evolves With Creep Strain and Is Strain Rate Dependent** SB³C2019-142
Jared Zitnay¹, Gang Seob Jung², Allen Lin¹, Zhao Qin², Yang Li¹, Markus Buehler², S. Michael Yu¹, Jeffrey Weiss¹, ¹*University of Utah, United States*, ²*Massachusetts Institute of Technology, United States*
- 10:45AM Collagen Denaturation Occurs Upon Tissue Failure In Energy Storing Tendons** SB³C2019-143
Allen Lin¹, Jared Zitnay¹, Alexandra Allan¹, Jeffrey Weiss¹, ¹*University of Utah, United States*

Thursday, June 27

9:30AM -11:00AM

Bone Mechanics**Seasons 1-3****Session Chair: Daniel Nicoletta** *Southwest Research Institute*

- 9:30AM Metabolic Acidosis Causes Physio-Chemically Induced Mechanical and Compositional Changes To Murine Bones** SB³C2019-144
Kathryn Morozov¹, Brian Wingender¹, Anna Peterson¹, Alix Deymier¹, ¹*UConn Health, United States*
- 9:45AM Effect of Hydration On Mechanical Properties of Individual Collagen Fibrils and Extrafibrillar Matrix** SB³C2019-145
Heber Martinez Barron¹, Wei Gao¹, Xiaodu Wang¹, ¹*University of Texas at San Antonio, United States*
- 10:00AM Effects of Exercise and Posture On Subchondral Bone Density and Thickness of Sheep** SB³C2019-146
Hyunggwai Song¹, John Polk¹, Mariana Kersh¹, ¹*University of Illinois at Urbana-Champaign, United States*
- 10:15AM Statistical Shape Analysis For The Assessment of Proximal Femur Shape Features Meaningful To Osteoporotic Risk of Fracture** SB³C2019-147
Alessandra Aldieri¹, Mara Terzini¹, Cristina Bignardi¹, Alberto L. Audenino¹, Umberto Morbiducci¹, ¹*Politecnico di Torino, Italy*
- 10:30AM Nondestructive Mapping of 3d Bone-Implant Contact and 3d Peri-Implant Strain** SB³C2019-148
Yuxiao Zhou¹, Chujie Gong¹, Mehran Hossaini-Zadeh², Jing Du¹, ¹*The Pennsylvania State University, United States*, ²*Temple University, United States*

Thursday, June 27

9:30AM -11:00AM

**Frontiers in Experiments, Imaging, and Modeling in Tissue
Solid Mechanics****Seasons 4-5****Session Chair: Adrian Buganza Tepole** *Purdue University***Session Co-Chair: Mathias Brieu** *California State University - Los Angeles*

- 9:30AM Choroidal Swelling Is Predicted To Cause Significant Optic Nerve Head Deformation: Potential Relevance To Sans** SB³C2019-149

Andrew Feola¹, Brian Samuels², Brandon Macias³, Michael Stenger⁴, Nimesh Patel⁵, C. Ross Ethier⁶, ¹Atlanta VA and Georgia Institute of Technology, United States, ²University of Alabama at Birmingham, United States, ³KBRwyle, United States, ⁴Nasa-jsc, United States, ⁵University of Houston, United States, ⁶Georgia Tech, United States

- 9:45AM Biomechanical Characterization of Active and Passive Properties of Murine Branch Pulmonary Arteries** SB³C2019-150
Abhay B. Ramachandra¹, Jay Humphrey¹, ¹Yale University, United States
- 10:00AM Effects of Long Term Spinal Cord Injury On The Mechanical Behavior of The Urinary Bladder Extracellular Matrix** SB³C2019-151
Tyler Tuttle¹, Heidi Lujan¹, Stephen DiCarlo¹, Sara Roccabianca¹, ¹Michigan State University, United States
- 10:15AM Multi-Scale Model of Pressure-Driven Hypoxia In The Skin Resulting From Microvascular Collapse** SB³C2019-152
Vivek Sree¹, Manuel Rausch², Adrian Buganza Tepole¹, ¹Purdue University, United States, ²The University of Texas at Austin, United States
- 10:30AM A Comparative Classification Analysis of Abdominal Aortic Aneurysm By Machine Learning Algorithms** SB³C2019-153
Balaji Rengarajan¹, Wei Wu¹, Crystal Weidner², Satish Mukul³, Mark Eskandari⁴, Ender Finol¹, ¹Department of Mechanical Engineering University of Texas at San Antonio San Antonio, TX, U.S.A., United States, ²Department of Management Science and Statistics University of Texas at San Antonio San Antonio, TX, U.S.A., United States, ³Department of Thoracic & Cardiovascular Surgery, Allegheny General Hospital Allegheny Health Network Pittsburgh, PA, U.S.A., United States, ⁴Division of Vascular Surgery, Feinberg School of Medicine Northwestern University Chicago, IL, U.S.A., United States
- 10:45AM Design, Calibration, and Preliminary Testing of A System To Measure The Viscoelastic Properties of A Pacinian Corpuscle** SB³C2019-154
Tiffany Senkow¹, Emily Chandler¹, Amy Moeller², Victor Barocas¹, ¹University Of Minnesota, United States, ²Twin Cities Orthopedics, United States

Thursday, June 27	9:30AM -11:00AM
--------------------------	------------------------

Rehabilitation and Assistive Technologies

Hemlock

Session Chair: Sara Wilson *University of Kansas*

Session Co-Chair: Carrie Peterson *Virginia Commonwealth University*

- 9:30AM The Effect of Intermittent Theta Burst Stimulation On Biceps Corticomotor Excitability In Nonimpaired Individuals and Individuals With Tetraplegia** SB³C2019-155
Neil Mittal¹, Blaize Majdic¹, Carrie Peterson¹, ¹Virginia Commonwealth University, United States
- 9:45AM Inertial Measurement Units Used To Quantify Arm Elevation Angles of Manual Wheelchair Users and Able-Bodied Controls Throughout A Typical Day** SB³C2019-156
Brianna Goodwin¹, Stephen Cain², Meegan Van Straaten¹, Emma Fortune¹, Melissa Morrow¹, ¹Mayo Clinic, United States, ²University of Michigan, United States
- 10:00AM Exercise Therapy Affects Glenohumeral Kinematics In Patients With Isolated Supraspinatus Tears** SB³C2019-157
Luke Mattar¹, Camille Johnson¹, Tom Gale¹, Adam Popchak¹, James Irrgang¹, William Anderst¹, Volker Musahl¹, Richard Debski¹, ¹University of Pittsburgh, United States
- 10:15AM Changes In Hand Function Due To Basal Joint Suspensionplasty** SB³C2019-158
Joshua Drost¹, James Clarkson¹, Tamara Bush¹, ¹Michigan State University, United States

10:30AM Macroscopic Surface Deformation of Retrieved Glenoid Components For Total Shoulder Arthroplasty SB³C2019-159

Giuliana Davis¹, Noah Bonnheim¹, Louis Malito¹, Stephan Gunther², Tom Norris³, Lisa Pruitt¹, ¹*Department of Mechanical Engineering, University of California, Berkeley, United States*, ²*Martha Jefferson Hospital, United States*, ³*San Francisco Shoulder, Elbow & Hand Clinic, United States*

10:45AM Development of An Annular Flow Mechanism For Maintaining Intraocular Pressure With A Glaucoma Drainage Device SB³C2019-160

Sara Wilson¹, Anna Donovan¹, Hussain Alantari², Paul Munden³, Ronald Dougherty¹, ¹*University of Kansas, United States*, ²*University of Missouri - Kansas City, United States*, ³*Oklahoma City VA Health Care System, United States*

Thursday, June 27**9:30AM -11:00AM****Ventricular and Valvular Flow****Fox Den****Session Chair: Lakshmi Prasad Dasi** *Ohio State University***9:30AM Aortic Sinus Vortex Spatio-Temporal Variations With Leaflet Calcification SB³C2019-161**

Hoda Hatoum¹, Lakshmi Prasad Dasi¹, ¹*The Ohio State University, United States*

9:45AM An Initial Fluid Mechanics Study of Bioprosthetic Heart Valves In An Accelerated Dynamic Environment SB³C2019-162

Sailahari Ponnaluri¹, Ming-Chen Hsu², Michael Sacks³, Keefe Manning¹, ¹*The Pennsylvania State University, United States*, ²*Iowa State University, United States*, ³*University of Texas, United States*

10:00AM Experimental Testing of Polymeric Tavr Valve Performance In Patient-Specific Models SB³C2019-163

Brandon Kovarovic¹, Oren Rotman¹, Marvin Slepian², Danny Bluestein¹, ¹*Department of Biomedical Engineering, Stony Brook University, Stony Brook, NY, United States*, ²*Sarver Heart Center, University of Arizona, Tucson, AZ, United States*

10:15AM Comparative Quantification of Mitral Regurgitation By Computer Modeling and Simulated Echocardiography SB³C2019-164

Wenbin Mao¹, Andrs Caballero¹, Rebecca Hahn², Susheel Kodali², Wei Sun¹, ¹*Georgia Institute of Technology, United States*, ²*Columbia University Medical Center, United States*

10:30AM The Effects of Anterior Mitral Leaflet Laceration On Left Ventricular Flow With Transcatheter Mitral Valves: An In Vitro Study SB³C2019-165

Thomas Easley¹, Vahid Sadri¹, Pranav Dorbala¹, Norihiko Kamioka², Vasilis Babaliaros², Ajit Yoganathan¹, ¹*Georgia Institute of Technology, United States*, ²*Emory University, United States*

10:45AM Patient-Specific Modeling of The Left Ventricular Hemodynamics Using The Chimera Overset Mesh Technique SB³C2019-166

Federico Can¹, Matteo Selmi², Gianluca De Santis³, Alberto Redaelli⁴, Patrick Segers¹, Joris Degroote⁵, ¹*IBiTech bioMMeda, Department of Electronics and Information Systems, Ghent University, Belgium*, ²*Division of Cardiac Surgery, Department of Surgery, Universit di Verona, Italy*, ³*FEops NV, Belgium*, ⁴*Department of Electronics, Informatics and Bioengineering, Politecnico di Milano, Italy*, ⁵*Department of Flow, Heat and Combustion Mechanics, Ghent University, Belgium*

Thursday, June 27	11:15AM -12:45PM
--------------------------	-------------------------

PhD Paper Competition: Computational Biomechanics and Diagnostic Models

Sunburst

Session Chair: Chiara Bellini *Northeastern University*

Session Co-Chair: Craig Goergen *Purdue University*

- 11:15AM Designing Tissue Engineered Vascular Grafts For Young and Aged Hosts: In Vivo, Ex Vivo and In Silico Study** SB³C2019-167
Piyusha Gade¹, Keewon Lee¹, Yadong Wang², Anne Robertson¹, ¹*University of Pittsburgh, United States*, ²*Cornell University, United States*
- 11:30AM Computational Fluid Dynamics Modeling of Myocardial Bridging Using Coronary Angiography** SB³C2019-168
Mohammadali Sharzehee¹, Ran Gao², Yuan Chang², Jiangping Song², Hai-Chao Han³, ¹*University Of Texas At San Antonio, United States*, ²*Fuwai Hospital, China*, ³*Professor, United States*
- 11:45AM Axial Stretch Modulates Lymphatic Contractility: An Experimental-Computational Approach In A Novel Rat Tail Model** SB³C2019-169
Mohammad S. Razavi¹, Julie Leonard-Duke¹, Rebecca Hardie¹, Brandon Dixon¹, Rudolph Gleason¹, ¹*Georgia Institute of Technology, United States*
- 12:00PM Simulation of Cardiac Flow: Analysis of Geometry Simplification** SB³C2019-170
Fanwei Kong¹, Christoph Augustin², Kevin Sack³, Shawn Shadden¹, ¹*Department of Mechanical Engineering, University of California, Berkeley, United States*, ²*Institute of Biophysics, Medical University of Graz, Austria*, ³*Division of Biomedical Engineering Department of Human Biology, University of Cape Town, South Africa*
- 12:15PM A Combined Mri Arterial Spin Labeling and Computational Modeling Strategy To Quantify Patient-Specific Blood Flow and Perfusion In Cerebrovascular Occlusive Disease** SB³C2019-171
Jonas Schollenberger¹, Luis Hernandez-Garcia², C. Alberto Figueroa³, ¹*Department of Biomedical Engineering, University of Michigan, United States*, ²*fMRI Laboratory and Department of Biomedical Engineering, University of Michigan, United States*, ³*Departments of Surgery and Biomedical Engineering, University of Michigan, United States*
- 12:30PM Evaluation of Artificial Neural Networks As A Potential Rupture Discrimination Model** SB³C2019-172
Sricharan S Veeturi¹, Hamidreza Rajabzadeh-Oghaz¹, Jason M Davies¹, Hui Meng¹, ¹*University at Buffalo, United States*

Thursday, June 27	11:15AM -12:45PM
--------------------------	-------------------------

PhD Paper Competition: Morphogenesis, Development, Growth, and Remodeling

Snowflake

Session Chair: Kristin Miller *Tulane University*

Session Co-Chair: Jeffrey Weiss *University of Utah*

- 11:15AM Systematic Modulation of Cell-Cell Adhesion In Vivo Modulates Epithelial Tissue Mechanics and Remodeling** SB³C2019-173
Xun Wang¹, Karen Kasza¹, ¹*Columbia University, United States*
- 11:30AM Relating Bone Strain To Local Changes In Radius Microstructure Following 12 Months of Axial Forearm Loading In Women** SB³C2019-174
Megan Mancuso¹, Karen Troy¹, ¹*Department of Biomedical Engineering, Worcester Polytechnic Institute, United States*

- 11:45AM Effects of Reproduction and Lactation History On Rat Maternal Bone Mechano-Responsiveness and Osteocyte Microenvironment** SB³C2019-175
Yihan Li¹, Ashutosh Parajuli², Chantal de Bakker¹, Hongbo Zhao¹, Wei-Ju Tseng¹, Rebecca Chung¹, Liyun Wang², X. Sherry Liu¹, ¹*University of Pennsylvania, United States*, ²*University of Delaware, United States*
- 12:00PM Biphasic Network Model of Collagen and Elastin Remodelling Recapitulates Compositional and Organizational Changes During Aortic Growth and Development** SB³C2019-176
Ryan Mahutga¹, Victor Barocas¹, ¹*University of Minnesota, United States*
- 12:15PM Pregnancy and Lactation Impair Subchondral Bone Leading To Reduced Rat Supraspinatus Tendon Failure Properties** SB³C2019-177
Ashley Fung¹, Snehal Shetye¹, Yihan Li¹, X. Sherry Liu¹, Louis Soslowsky¹, ¹*University of Pennsylvania, United States*
- 12:30PM Modeling Adaptive Remodeling of The Bladder Wall During Aging** SB³C2019-178
Fangzhou Cheng¹, Lori Birder¹, Paul Watton², Anne Robertson¹, ¹*University of Pittsburgh, United States*, ²*University of Sheffield, United States*

Thursday, June 27

11:15AM -12:45PM

PhD Paper Competition: Cellular Mechanics, Drug Delivery, and Therapeutics

Wintergreen

Session Chair: Sarah Bentil *Iowa State University*Session Co-Chair: Brendon Baker *University of Michigan*

- 11:15AM Membrane Wrapping Efficiency of Elastic Nanoparticles During Endocytosis: Size and Shape Matter** SB³C2019-179
Zhiqiang Shen¹, Huilin Ye¹, Xin Yi², Ying Li¹, ¹*University of Connecticut, United States*, ²*Peking University, China*
- 11:30AM Neck Skin Thermal Features As A Measure of Stenosis In The Carotid Artery: Computational and In-Vivo Study** SB³C2019-180
Ashish Saxena¹, Eddie Yin Kwee Ng¹, Vignesh Raman¹, Soo Teik Lim², ¹*Nanyang Technological University, Singapore*, ²*National Heart Center Singapore, Singapore*
- 11:45AM A Cold-Responsive Nanoparticle Enables Intracellular Delivery and Rapid Release of Trehalose For Fast Freezing of Stem Cells** SB³C2019-181
Samantha Stewart¹, Xiaoming He², ¹*University of Maryland, College Park, United States*, ²*University of Maryland, College Park, United States*
- 12:00PM Engineering and Characterization of Collagenase-Expressing Salmonella Typhimurium For Enhanced Interstitial Transport In Tissue** SB³C2019-182
Eric Leaman¹, Bahareh Behkam¹, ¹*Virginia Tech, United States*
- 12:15PM A Systematic Approach To The Thermal Mitigation of Irreversible Electroporation Therapy** SB³C2019-183
Timothy O'Brien¹, Melvin Lorenzo¹, Yajun Zhao¹, Robert Neal, II², John Robertson¹, S. Nahum Goldberg³, Rafael Davalos¹, ¹*Department of Biomedical Engineering and Mechanics, Virginia Tech, United States*, ²*AngioDynamics, United States*, ³*Department of Radiology, Hadassah Hebrew University Hospital, Israel*
- 12:30PM Optical Opening of Blood-Brain Barrier For Macromolecules Penetration By Laser Excitation of Vasculature-Targeted Plasmonic Nanoparticles** SB³C2019-184
Xiaoqing Li¹, Hejian Xiong¹, Vamsidhara Vemireddy², Xiuying Li¹, Monica Giannotta³, Heather Hayenga¹, Edward Pan², Shashank Sirsi¹, Elisabetta Dejana³, Robert Bachoo², Zhenpeng Qin¹, ¹*University of Texas at Dallas, United States*, ²*University of Texas Southwestern Medical Center, United States*, ³*FIRC Institute of Molecular Oncology Foundation, Italy*

Thursday, June 27	11:15AM -12:45PM
--------------------------	-------------------------

Musculoskeletal Tissue Engineering**Seasons 1-3****Session Chair: Alix Deymier** *UConn Health***Session Co-Chair: Spencer Szczesny** *Pennsylvania State University*

11:15AM Recapitulating The Complex Biomechanical Properties of Intervertebral Disc Using Tunable 3d Printing SB³C2019-185

Samantha Marshall¹, Timothy Jacobsen¹, Kevin Anton¹, Archana Murali¹, Nadeen Chahine¹, ¹*Columbia University, United States*

11:30AM Orientation and Size of The Porcine Anterior Cruciate Ligament Vary Between Yorkshire and Yucatan Breeds At Early Adolescence SB³C2019-186

Stephanie Cone¹, Danielle Howe¹, Emily Lambeth¹, Jorge Piedrahita², Lynn Fordham³, Jeffrey Spang³, Matthew Fisher¹, ¹*North Carolina State University and the University of North Carolina – Chapel Hill, United States*, ²*North Carolina State University, United States*, ³*University of North Carolina – Chapel Hill, United States*

11:45AM For Ligaments, Material Stiffness Is Not What It Appears To Be: How To Build More Accurate Material Models and Implications On Acl Graft Selection SB³C2019-187

Callan Luetkemeyer¹, Ellen Arruda¹, ¹*University of Michigan, United States*

12:00PM An Engineered Biomaterial Microenvironment To Direct The Formation of A Living Barrier To Seal Cartilage Defects SB³C2019-188

Jay Patel¹, Claudia Loebel¹, Brian Wise¹, Kamiel Saleh¹, James Carey¹, Jason Burdick¹, Robert Mauck¹, ¹*University of Pennsylvania, United States*

12:15PM Sustained Release of Tgf-3 From Heparinized Collagen Biofabric Induces Chondrogenic Differentiation of Human Mesenchymal Stem Cell Macromass SB³C2019-189

Hyungjin Jung¹, Phillip McClellan¹, Ozan Akkus¹, ¹*Case Western Reserve University, United States*

Thursday, June 27	11:15AM -12:45PM
--------------------------	-------------------------

Nano to Micro Multiscale Mechanics**Seasons 4-5****Session Chair: Kristin Myers** *Columbia University***Session Co-Chair: Vicky Nguyen** *Johns Hopkins University*

11:15AM A Computational and Experimental Study of Short Bowel Syndrome Biomechanics SB³C2019-190

Hadi S. Hosseini¹, Jordan S. Taylor¹, James C. Y. Dunn¹, ¹*Stanford University, United States*

11:30AM A Discrete Fiber Network Model of Arterial Elastin Considering Inter-Fiber Crosslink SB³C2019-191

Xunjie Yu¹, Yanhang Zhang¹, ¹*Boston University, United States*

11:45AM In Vivo Lamin A/c Deficiency Maintains Bulk Nuclear Shape and Stiffness, But Leads To Abrogated Intranuclear Mechanics and Chromatin Organization SB³C2019-192

Soham Ghosh¹, Adrienne Scott¹, Jessica Kelly¹, Benjamin Seelbinder¹, Xin Xu¹, Stephanie Schneider¹, Corey Neu¹, ¹*University of Colorado Boulder, United States*

12:00PM Tunable Dna Nanocalipers Capable of Applying Forces To Biomolecules SB³C2019-193

Jenny Le¹, Kyle Crocker¹, Michael Darcy¹, Michael Poirier¹, Ralf Bundschuh¹, Carlos Castro¹, ¹*The Ohio State University, United States*

12:15PM Microstructure of Tendon Reveals Helically Wrapped Fibrils With The Potential To Mediate Mechanical Load Transfer By Friction SB³C2019-194
Babak N. Safa¹, John Peloquin¹, Jessica Natriello¹, Jeffrey Caplan¹, Dawn Elliott¹, ¹*University of Delaware, United States*

12:30PM Deformation Characteristics of The Rat Pia-Arachnoid Complex Through Multimodal Imaging SB³C2019-195
Zeynep M. Suar¹, Gloria Fabris¹, Luke Langner¹, Mehmet Kurt¹, ¹*Stevens Institute of Technology, United States*

Thursday, June 27

11:15AM -12:45PM

Vascular Biomechanics

Hemlock

Session Chair: Patrick Alford *University of Minnesota*

Session Co-Chair: Seungik Baek *Michigan State University*

11:15AM Uncertainty Analysis of Vascular Surrogate Models SB³C2019-196
Zhenxiang Jiang¹, Jongeun Choi², Seungik Baek¹, ¹*Michigan State University, United States*, ²*Yonsei University, South Korea*

11:30AM Effect of Calcification & Fibrous Tissue Features On Rupture Risk In Atherosclerotic Plaques SB³C2019-197
Bas Vis¹, Hilary Barrett¹, Astrid Moerman¹, Frank Gijzen¹, Ali Akyildiz¹, ¹*Erasmus Medical Center, Netherlands*

11:45AM Initiation of Dissection In The Aortic Arch SB³C2019-198
Brian FitzGibbon¹, Kevin Moerman¹, Peter McHugh¹, Patrick McGarry¹, ¹*National University of Ireland Galway, Ireland*

12:00PM Comparative Biomechanical Phenotyping of The Murine Central Vasculature SB³C2019-199
Jay Humphrey¹, ¹*Yale University, United States*

12:15PM Regional Anisotropic Mechanical Characterization of Porcine Pulmonary Arteries SB³C2019-200
Narasimha Rao Pillalamarri¹, Sourav Patnaik¹, Senol Piskin¹, Ender Finol¹, ¹*University of Texas at San Antonio, United States*

12:30PM Investigating The Effects of Extracellular Stiffness On Vascular Smooth Muscle Cell Stress and Mechanical Properties SB³C2019-201
Elizabeth Shih¹, Patrick Alford¹, ¹*Department of Biomedical Engineering at University of Minnesota Twin Cities, United States*

Thursday, June 27

11:15AM -12:45PM

Patient-Specific Flow and Physiology

Fox Den

Session Chair: Amirhossein Arzani *Northern Arizona University*

11:15AM Cardiac Flow Dynamics of Healthy Volunteers : Sex Differences SB³C2019-202
David Rutkowski¹, Gregory Barton¹, Christopher Francois¹, Alejandro Roldan-Alzate¹, ¹*University of Wisconsin-Madison, United States*

11:30AM Wall Shear Stress Topological Skeleton Identification In Cardiovascular Flows: A Practical Approach SB³C2019-203

Valentina Mazzi¹, Diego Gallo¹, Karol Cal¹, Muhammad O. Khan², David A. Steinman³, Umberto Morbiducci¹,
¹Polito BIOMed Lab, Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Turin, Italy,
²Cardiovascular Biomechanics Computation Lab, Department of Pediatrics Stanford University, Stanford, United States,
³Biomedical Simulation Laboratory, Department of Mechanical & Industrial Engineering University of Toronto, Toronto, Canada

- 11:45AM Patient-Specific Fluid-Structure Interaction Analysis of A Bicuspid Aortic Valve** SB³C2019-204
 Monica Emendi¹, Ram Ghosh², Matteo Bianchi², Francesco Sturla³, Filippo Piatti³, Alberto Redaelli¹, Danny Bluestein², ¹Politecnico di Milano, Italy, ²Stony Brook University, United States, ³IRCCS Policlinico San Donato, Italy
- 12:00PM Introduction of A Simple 2d Computational Model To Predict Risk of Coronary Obstruction During Transcatheter Aortic Valve Replacement** SB³C2019-205
 Megan Heitkemper¹, Hoda Hatoum¹, Amirsepher Azimian¹, Breandan Yeats¹, Jennifer Dollery¹, Bryan Whitson¹, Gregory Rushing¹, Juan Crestanello¹, Scott Lilly¹, Lakshmi Prasad Dasi¹, ¹The Ohio State University, United States
- 12:15PM Machine Learning For Discrimination of Posterior Communicating Artery Aneurysm Rupture Status** SB³C2019-206
 Felicitas Detmer¹, Daniel Lckehe², Fernando Mut¹, Martin Slawski¹, Sven Hirsch³, Philippe Bijlenga⁴, Gabriele von Voigt², Juan Cebal¹, ¹George Mason University, United States, ²Leibniz University Hannover, Germany, ³ZHAW University of Applied Sciences, Switzerland, ⁴University of Geneva, Switzerland
- 12:30PM A Reduced Order Modeling Method For Cardiovascular Flow** SB³C2019-207
 Mehran Mirramezani¹, Shawn Shadden¹, ¹University of California, Berkeley, United States

Friday, June 28

12:00PM - 1:30PM

Biotransport in Thermal Therapy and Cryopreservation

Sunburst

Session Chair: R. Lyle Hood *University of Texas at San Antonio*

Session Co-Chair: Nilay Chakraborty *University of Michigan Dearborn*

- 12:00PM Whole Body Hyperthermia Induced Interstitial Fluid Pressure Reduction and Enhanced Nanoparticle Delivery To Pc3 Tumors** SB³C2019-208
 Qimei Gu¹, Shuaishuai Liu¹, Arunendra Saha Ray¹, Lance Dockery¹, Marie-Christine Daniel¹, Charles Bieberich¹, Ronghui Ma¹, Liang Zhu¹, ¹University of Maryland Baltimore County, United States
- 12:15PM Quantification of Tissue Electrical and Thermal Response Due To High Frequency Irreversible Electroporation: A Pilot Study In Ex Vivo Perfused Livers** SB³C2019-209
 Melvin Lorenzo¹, Tim O'Brien², Kenneth Aycock¹, Navid Manuchehrabadi³, Rafael Davalos¹, ¹Department of Biomedical Engineering and Mechanics Virginia Polytechnic and State University, United States, ²Virginia Department of Biomedical Engineering and Mechanics Virginia Polytechnic and State University, United States, ³AngioDynamics, United States
- 12:30PM Magnetic Nanoparticle Hyperthermia For Pancreatic Cancer: A Computational Study** SB³C2019-210
 Anilchandra Attaluri¹, Sri Kamal Kandala², Robert Ivkov³, ¹The Pennsylvania State University - Harrisburg, United States, ²University of Texas MD Anderson Cancer Center, United States, ³Johns Hopkins University School of Medicine, United States
- 12:45PM In Situ Photo-Inactivation of Proteins By Molecular Hyperthermia** SB³C2019-211
 Peiyuan Kang¹, Xiaoqing Li¹, Stephanie Shiers¹, Hejian Xiong¹, Theodore Price¹, Zhenpeng Qin¹, ¹The university of texas at dallas, United States

- 1:00PM Diffusion Limited Cryopreservation of Arterial Tissue To 1.5 Mm With Radiofre-Quency Heated Metal Forms** SB³C2019-212
Zonghu Han¹, Zhe Gao¹, Anirudh Sharma², John Bischof², ¹University Of Minnesota, United States, ²University of Minnesota, United States
- 1:15PM Counterintuitive Scaling Effects In The Developing Thermomechanical Stress During Cryogenic Cooling of The Kidney With Implications To Electromagnetic Rewarming For Organ Banking** SB³C2019-213
Prem Solanki¹, Yoed Rabin¹, ¹Carnegie Mellon University, United States

Friday, June 28**12:00PM - 1:30PM****Aneurysm Mechanics****Snowflake****Session Chair: Spandan Maiti** *University of Pittsburgh***Session Co-Chair: Yanhang (Katherine) Zhang** *Boston University*

- 12:00PM Patient-Specific Estimation of Ascending Thoracic Aortic Aneurysm Growth and Remodeling: Fem Based Constrained Mixture Model** SB³C2019-214
S. Jamaledin Mousavi Mousavi¹, Stephane Avril¹, ¹Mines Saint-Etienne, Univ Lyon, Univ Jean Monnet, INSERM, U 1059 Sainbiose, Centre CIS, F - 42023 Saint-Etienne France, France
- 12:15PM Machine Learning Prediction of Rupture Strength of Ascending Aortic Aneurysm Tissue** SB³C2019-215
Xuehuan He¹, Anna Ferrara², Yuanming Luo¹, Ferdinando Auricchio², Jia Lu¹, ¹University Of Iowa, United States, ²Universit degli Studi di Pavia, Italy
- 12:30PM Wall Stress and Geometric Measures In Electively Repaired Abdominal Aortic Aneurysms** SB³C2019-216
Balaji Rengarajan¹, Wei Wu¹, Mirunalini Thirugnanasambandam², Shalin Parikh², Raymond Gomez¹, Ender Finol¹, ¹Department of Mechanical Engineering University of Texas at San Antonio San Antonio, TX, U.S.A., United States, ²UTHSA/UTHSA Joint Graduate Program in Biomedical Engineering University of Texas at San Antonio San Antonio, TX, U.S.A., United States
- 12:45PM A Particle-Based Model Reveals An Insidious Feed-Back Loop Between Aortic Lamellar Disruption and Cell Apoptosis** SB³C2019-217
Hossein Ahmadzadeh¹, Jay Humphrey¹, ¹Yale University, United States
- 1:00PM Alterations In Biomechanical Properties of Aortic Wall In A Mouse Model of Marfan Syndrome** SB³C2019-218
Nazli Gharraee¹, Rahul Raghavan¹, Yujian Sun¹, Susan Lessner¹, ¹University of South Carolina, United States
- 1:15PM Can The Elastase Induced Aneurysm Model Be Used To Study Remodeling In Saccular Aneurysms** SB³C2019-219
Chao Sang¹, David Kallmes², Watkins Simon¹, Anne Robertson¹, ¹University of Pittsburgh, United States, ²Mayo Clinic, United States

Friday, June 28**12:00PM - 1:30PM****Mechanobiology - a Symposium in Memory of Christopher R. Jacobs****Wintergreen****Session Chair: Eno Ebong** *Northeastern University***Session Co-Chair: Ed Guo** *Columbia University*

- 12:00PM Adhesion Models For Cell Migration Simulator On Continuous Substrate** SB³C2019-220
Jay Hou¹, Liam Tyler¹, Daniel Keefe¹, David Odde¹, Victor Barocas¹, ¹University of Minnesota, United States

- 12:15PM Red Blood Cell Biomechanics In Chronic Fatigue Syndrome** SB³C2019-221
Amit Saha¹, Brendan Schmidt², Arun Kumar², Amir Saadat¹, Vineeth Suja¹, Vy Nguyen², Justin Do², Wendy Ho², Mohsen Nemat-Gorgani¹, Eric Shafqeh¹, Anand Ramasubramanian², Ronald Davis¹, ¹*Stanford University, United States*, ²*San Jose State University, United States*
- 12:30PM Development of Recombinant Inner-Ear Motor Protein Prestin Equipped With Affinity Tag** SB³C2019-222
Michio Murakoshi¹, Hiroshi Wada², ¹*Kanazawa University, Japan*, ²*Tohoku Bunka Gakuen University, Japan*
- 12:45PM Inhibition of Gsk-3 By Licl Does Not Affect Msc Differentiation In Vitro Or Bone Formation In Situ** SB³C2019-223
Alyssa Oberman¹, Angela Patel¹, Glen Niebur¹, ¹*University of Notre Dame, United States*
- 1:00PM Mechanical Feedback and Cooperativity In A Theoretical Model of Airway Smooth Muscle Cell-Matrix Adhesion** SB³C2019-224
Linda Irons¹, Markus Owen², Reuben O'Dea², Bindi Brook², ¹*Yale University, United States*, ²*University of Nottingham, United Kingdom*
- 1:15PM Extracellular Matrix Stiffness Regulates Calcium Oscillations In Multicellular Ensembles, But Not In Isolated Cells** SB³C2019-225
Suzanne Stasiak¹, Ryan Jamieson¹, Hari Krishnan Parameswaran¹, ¹*Northeastern University, United States*

Friday, June 28

12:00PM - 1:30PM

Imaging and Mechanics of Ligament and Tendon**Seasons 1-3****Session Chair: Mona Eskandari** *University of California Riverside***Session Co-Chair: Mariana Kersh** *University of Illinois at Urbana-Champaign*

- 12:00PM Elastography Evaluation of The Elbow Ulnar Collateral Ligament In Overhead Throwing Athletes** SB³C2019-226
Seyedali Sadeghi¹, Dov Bader¹, Daniel Cortes¹, ¹*Penn State University, United States*
- 12:15PM Assessment of Tendon Hydraulic Permeability Using Osmotic Loading and Biphasic Finite Element Modeling** SB³C2019-227
Babak N. Safa¹, Ellen Bloom¹, Andrea Lee¹, Michael Santare¹, Dawn Elliott¹, ¹*University of Delaware, United States*
- 12:30PM Three Dimensional Morphological Changes In Carpal Tunnel Ligament Arch In Response To Wrist Compressive Forces** SB³C2019-228
Rakshit Shah¹, Zong-Ming Li¹, ¹*Hand Research Laboratory, Department of Biomedical Engineering, United States*
- 12:45PM Fibroblast-Like Synoviocytes Alter Matrix Mechanics & Neuronal Mmp-1 Expression Under Tensile Failure To Different Degrees Depending On Concentration** SB³C2019-229
Meagan Ita¹, Nicholas Stiansen¹, Sarah St Pierre², Beth Winkelstein¹, ¹*University of Pennsylvania, United States*, ²*Worcester Polytechnic Inst, United States*
- 1:00PM Aging Adversely Affects Different Rat Rotator Cuff Tendons Similarly** SB³C2019-230
Joseph Newton¹, George Fryhofer¹, Snehal Shetye¹, Ashley Rodriguez¹, Andrew Kuntz¹, Lou Soslowsky¹, ¹*University of Pennsylvania, United States*
- 1:15PM Comparison of The Deformation Behavior of The Anterior Cruciate Ligament In Response To Various External Knee Loadings** SB³C2019-231
Satoshi Yamakawa¹, Richard Debski¹, Hiromichi Fujie², ¹*University of Pittsburgh, United States*, ²*Tokyo Metropolitan University, Japan*

Friday, June 28	12:00PM - 1:30PM
------------------------	-------------------------

Injury: Models**Seasons 4-5**

Session Chair: Brittany Coats *University of Utah*

Session Co-Chair: Mehmet Kurt *Stevens Institute of Technology*

- 12:00PM Development of Finite Element Model of Subhuman Primate Brain and Investigation of Diffuse Axonal Injury Thresholds Induced By Head Rotation** SB³C2019-232
Tushar Arora¹, Priya Prasad², Liying Zhang¹, ¹Wayne State University, United States, ²Prasad Engineering, LLC, United States
- 12:15PM Development of A Computational Biomechanics Mouse Model For Traumatic Axonal Injury** SB³C2019-233
Connor Bradfield¹, Liming Voo¹, KT Ramesh², ¹Johns Hopkins Applied Physics Lab, United States, ²Johns Hopkins Department of Mechanical Engineering, United States
- 12:30PM A Study of The Brain-Skull Interface Conditions of The Worcester Rat Head Injury Model (wrhim)** SB³C2019-234
Wei Zhao¹, Brian Stemper², Songbai Ji¹, ¹Worcester Polytechnic Institute, United States, ²Marquette University & Medical College of Wisconsin, United States
- 12:45PM Probabilistic Analysis of Injury Risk Using Human Body Finite Element Models** SB³C2019-235
Travis Eliason¹, Matthew Davis², Derek Jones², Daniel Nicoletta¹, ¹Southwest Research Institute, United States, ²Elemance, United States
- 1:00PM Characterization of Injured Brain Tissue After Controlled Cortical Impact** SB³C2019-236
Suhao Qiu¹, Wenheng Jiang², Changxin Lai¹, Tianyao Wang³, Wei Chen², Luyang Tao², Mingyuan Gao², Jun Liu³, Jianfeng Zeng², Yuan Feng¹, ¹Shanghai Jiao Tong University, China, ²Soochow University, China, ³Fudan University, China
- 1:15PM A Model of Tension-Induced Organization of Subcortical Axons During Cortical Folding of The Brain** SB³C2019-237
Kara Garcia¹, Christopher Kroenke², Philip Bayly³, ¹Indiana University School of Medicine, United States, ²Oregon Health and Science University, United States, ³Washington University in St. Louis, United States

Friday, June 28	12:00PM - 1:30PM
------------------------	-------------------------

Cardiovascular and Musculoskeletal Device Design**Hemlock**

Session Chair: Amy Throckmorton *Drexel University*

Session Co-Chair: Lucas Timmins *University of Utah*

- 12:00PM Synthesis and Characterization of Porous Shape Memory Polymer Materials For Use In The Design of Implantable Medical Devices** SB³C2019-238
Robert Kunkel¹, Jingyu Wang¹, Jishan Luo¹, Bradley Bohnstedt², Yingtao Liu¹, Chung-Hao Lee¹, ¹University of Oklahoma, United States, ²University of Oklahoma Health Sciences Center, United States
- 12:15PM Dual-Support Mechanical Assistive Technology For Pediatric and Young Adult Patients** SB³C2019-239
Carson Fox¹, Randy Stevens², Joseph Rossano³, Francisco Arabia⁴, Amy Throckmorton¹, ¹Biomedical Engineering, Drexel University, United States, ²St. Christopher's Hospital for Children, United States, ³Cardiology, The Children's Hospital of Philadelphia, United States, ⁴Cardiothoracic Surgery, University of Arizona, United States
- 12:30PM Durable and Flexible Superhydrophobic and Blood-Repelling Surface With Shape-Customizable Features For Biomedical Applications** SB³C2019-240

Zhe Li¹, Ba Loc Nguyen², Junmin Xue³, Graeme MacLaren⁴, Choon Hwai Yap¹, ¹*Department of Biomedical Engineering, National University of Singapore, Singapore, Singapore*, ²*National University of Singapore Department of Biomedical Engineering, National University of Singapore, Singapore, Singapore*, ³*Department of Material Science and Engineering, National University of Singapore, Singapore, Singapore*, ⁴*Department of Surgery, Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore*

- 12:45PM Quantifying The Capacitance and Resistance of A Double-Walled Aortic Stent-Graft Prototype** SB³C2019-241
Shannen B Kizilski¹, Omid Amili¹, Filippo Coletti¹, Rumi Faizer¹, Victor H Barocas¹, ¹*University of Minnesota, United States*
- 1:00PM Development and Evaluation of An Intratracheal Aerosol Delivery Device For Avian Wildlife Conservation Efforts** SB³C2019-242
Carlos Ruvalcaba¹, Susana Ramirez-Perez¹, Stephanie Ortega¹, Lisa Tell¹, Jean-Pierre Delplanque¹, ¹*University of California Davis, United States*

Friday, June 28	12:00PM - 1:30PM
------------------------	-------------------------

Thrombosis Hemolysis and Mechanical Circulatory Support

Fox Den

Session Chair: Keefe Manning *The Pennsylvania State University*

- 12:00PM Superhydrophobicity and Vortex Generators Potential To Reduce Thrombogenicity After Prosthetic Valve Implantation** SB³C2019-243
Hoda Hatoum¹, David Bark², Hamed Vahabi², Sanli Movafaghi², Brandon Moore², Marcio Forleo², Arun Kota², Ketul Popat², Lakshmi Prasad Dasi¹, ¹*The Ohio State University, United States*, ²*Colorado State University, United States*
- 12:15PM A Multiscale Model For Simulating Platelet Aggregation: Correlating With In Vitro Results** SB³C2019-244
Peng Zhang¹, Prachi Gupta¹, Jawaad Sherif¹, Changnian Han¹, Marvin J. Slepian², Yuefan Deng¹, Danny Bluestein¹, ¹*Stony Brook University, United States*, ²*University of Arizona, United States*
- 12:30PM 3d Flexible Non-Newtonian Computational Framework To Study Thrombosis Initiation** SB³C2019-245
Sabrina R. Lynch¹, Christopher J. Arthurs², Zelu Xu³, Onkar Sahni³, Jose A. Diaz¹, C. Alberto Figueroa¹, ¹*University of Michigan, United States*, ²*King's College London, United Kingdom*, ³*Rensselaer Polytechnic Institute, United States*
- 12:45PM Refining A Numerical Model For Device-Induced Thrombosis** SB³C2019-246
Ling Yang¹, Steven Deutsch¹, Keefe Manning¹, ¹*Department of Biomedical Engineering, The Pennsylvania State University, United States*
- 1:00PM Investigation of The Interplay Between Blood and Thrombus Mechanical Properties: A 3d Fluid-Solid Interaction Model** SB³C2019-247
Fatama T. Huda¹, Tarek Abdel-Salam¹, Nathan E. Hudson¹, Ali Vahdati¹, ¹*East Carolina University, United States*
- 1:15PM Numerical Models of Valve-In-Valve Deployment To Evaluate The Risk of Leaflets Thrombosis** SB³C2019-248
Halit Yaakobovich¹, Dar Weiss¹, Uri Zaretsky¹, Shmuel Einav¹, Gil Marom¹, ¹*Tel Aviv University, Israel*

Friday, June 28	1:45PM - 3:15PM
------------------------	------------------------

Biotransport in Disease Detection and Therapy

Sunburst

Session Chair: Zhongping Huang *West Chester University*

Session Co-Chair: Rebecca Heise *Virginia Commonwealth University*

- 1:45PM Accurate Detection of Differential Interaction Strengths In Energy Landscapes Using Machine Learning** SB³C2019-249
Ahmad Haider¹, Alan Liu¹, Todd Sulchek¹, ¹*Georgia Institute of Technology, Atlanta, United States*
- 2:00PM Aerosolized Surfactant Replacement Therapy In An In Vivo Rodent Lung Injury Model** SB³C2019-250
Franck J Kamga Gninzeko¹, Michael Valentine¹, Sahil Chindal¹, Susan Boc², Sneha Dhapare¹, Michael Hindle¹, Dale Farkas¹, P. Worth Longest¹, Rebecca Heise¹, ¹*Virginia Commonwealth University, United States*, ²*Virginia Commonwealth University, United States*
- 2:15PM Numerical Analysis of Dense Suspension Rheology of Red Blood Cells In A Shear Flow** SB³C2019-251
Naoki Takeishi¹, Marco Rosti², Yohsuke Imai³, Shigeo Wada¹, Luca Brandt², ¹*Osaka University, Japan*, ²*Royal Institute of Technology (KTH), Sweden*, ³*Kobe University, Japan*
- 2:30PM Deep Learning Assisted Label-Free On-Chip Selective Extraction of Single-Cell-Laden Droplets From Oil Into Aqueous Solution With Dielectrophoresis** SB³C2019-252
Alisa White¹, Yuntian Zhang², Gang Zhao², Xiaoming He¹, ¹*University of Maryland College Park, United States*, ²*University of Science and Technology of China, China*
- 2:45PM Biotransport In The Glymphatic System: Measuring and Modeling Flow Through Perivascular Spaces** SB³C2019-253
Humberto Mestre¹, Jeffrey Tithof², Ting Du¹, Wei Song¹, Weiguo Peng¹, Amanda Sweeney¹, Genaro Olveda¹, John Thomas², Maiken Nedergaard¹, Douglas Kelley², ¹*University of Rochester Medical Center, United States*, ²*University of Rochester, United States*

Friday, June 28	1:45PM - 3:15PM
------------------------	------------------------

Vascular Pathology and Disease Progression

Snowflake

Session Chair: Umberto Morbiducci *Politecnico di Torino*

- 1:45PM Prediction of Carotid Restenosis Risk After Endarterectomy By Hemodynamic and Geometric Analysis: A 5-Years Follow-Up** SB³C2019-254
Diego Gallo¹, Maurizio Domanin², Christian Vergara³, Umberto Morbiducci¹, ¹*Politecnico di Torino, Italy*, ²*Universit di Milano, Italy*, ³*Politecnico di Milano, Italy*
- 2:00PM Comparison of Healthy and Pulmonary Hypertension Hemodynamics** SB³C2019-255
Senol Piskin¹, Ender A. Finol¹, ¹*University Of Texas At San Antonio, United States*
- 2:15PM Functional Characterization of Arteriovenous Fistula On Swine Models Using Mri** SB³C2019-256
Eleonora Tubaldi¹, Jose A. Rosado-Toro¹, Diego Celdran-Bonafonte¹, Prabir Roy-Chaudhury¹, ¹*University of Arizona, United States*
- 2:30PM Impact of Hemodynamics and Endothelial Glycocalyx On Cancer Cell Adhesion To Vascular Wall Endothelium** SB³C2019-257
Solomon Mensah¹, Alina Nersesyan¹, Ian Harding¹, Mark Niedre¹, Vladimir Torchilin¹, Eno Ebong¹, ¹*Northeastern University, United States*

- 2:45PM Pulmonary Artery Hemodynamic Changes In Pediatric Patients With Ventricular Septal Defects** SB³C2019-258
Melody Dong¹, Weiguang Yang¹, Marlene Rabinovitch¹, Jeffrey Feinstein¹, Alison Marsden¹, ¹*Stanford University, United States*
- 3:00PM Fluid-Solid Growth Modeling of Pulmonary Vascular Tree: Establishing A Homeostatic Baseline State** SB³C2019-259
Hamidreza Gharahi¹, Seungik Baek¹, Vasilina Filonova², C. Alberto Figueroa², ¹*Michigan State University, United States*, ²*University of Michigan, United States*

Friday, June 28**1:45PM - 3:15PM**

Mechanobiology - a Symposium in Memory of Christopher R. Jacobs

Wintergreen**Session Chair: Kara Garcia** *Indiana University School of Medicine***Session Co-Chair: Tammy Haut Donahue** *University of Massachusetts Amherst*

- 1:45PM An Active Chemo-Mechanical Model Predicts Adhesion and Microenvironmental Regulation of 3d Cell Shapes** SB³C2019-260
Xingyu Chen¹, Veronika te Boekhorst², Peter Friedl², Vivek Shenoy¹, ¹*University of Pennsylvania, United States*, ²*University of Texas MD Anderson Cancer Center, United States*
- 2:00PM Myosin-Independent Regulation of Cell and Nuclear Structures In Wavy Patterns** SB³C2019-261
Bor-Lin Huang¹, Chin-Hsun Huang¹, Richard Assoian², Pen-hsiu Grace Chao¹, ¹*National Taiwan University, Taiwan*, ²*University of Pennsylvania, United States*
- 2:15PM Mapping 3d Mechanical Strains During Tissue Formation With A Novel Fibronectin-Based Nanomechanical Biosensor** SB³C2019-262
Daniel Shiwarski¹, Joshua Tashman¹, Alkis Tsamis¹, Quintin Jallerat¹, Malichi Blundon¹, John Szymanski¹, Brooke McCartney¹, Lance Davidson², Adam Feinberg¹, ¹*Carnegie Mellon University, United States*, ²*University of Pittsburgh, United States*
- 2:30PM Tendon Enthesis Cilium Assembly Is Driven By Mechanical Loading and Hedgehog Signaling** SB³C2019-263
Fei Fang¹, Andrea Schwartz², Stavros Thomopoulos¹, ¹*Columbia University, United States*, ²*Washington University in St. Louis, United States*
- 2:45PM Sensing The Curvature: Protrusive Sensitivity of Invasive Breast Cancer Cells** SB³C2019-264
Apratim Mukherjee¹, Bahareh Behkam¹, Amrinder Nain¹, ¹*Virginia Tech, United States*
- 3:00PM Towards Fiber-Level Traction Force Microscopy In Collagen Gels** SB³C2019-265
Lauren Bersie-Larson¹, Jay Hou¹, Victor Barocas¹, Paolo Provenzano¹, ¹*University Of Minnesota, United States*

Friday, June 28**1:45PM - 3:15PM**

Spine Biomechanics

Seasons 1-3**Session Chair: Alicia Jackson** *University of Miami***Session Co-Chair: Daniel Cortes** *Penn State University*

- 1:45PM Inhibition of The Integrin Beta-1 Subunit Increases Strain Thresholds For Peripheral Neuron Dysfunction and Injury** SB³C2019-266
Sagar Singh¹, Beth Winkelstein¹, ¹*University of Pennsylvania, United States*

- 2:00PM Vertebral Endplate Remodeling Reduces Small Molecule Diffusion Into Degenerative Intervertebral Discs** SB³C2019-267
Beth Ashinsky¹, Edward Bonnevie¹, Sai Mandalapu¹, Stephen Pickup¹, Chao Wang², Lin Han², Robert Mauck¹, Harvey Smith¹, Sarah Gullbrand¹, ¹*University of Pennsylvania, United States*, ²*Drexel University, United States*
- 2:15PM In-Plane Shear Mechanical Characterization of The Lumbar Facet Capsular Ligament** SB³C2019-268
Emily Bermel¹, Arin Ellingson¹, Victor Barocas¹, ¹*University of Minnesota - Twin Cities, United States*
- 2:30PM Direct Quantification of Intervertebral Disc Water Content Using Magnetic Resonance Imaging** SB³C2019-269
Bo Yang¹, Michael Wendland¹, Yu Ma¹, Grace O'Connell¹, ¹*University Of California Berkeley, United States*
- 2:45PM Location-Wise Fatigue Damage Prediction For The Intervertebral Disc Annulus of The Cervical Spine** SB³C2019-270
Adhitya Vikraman Subramani¹, Phillip Whitley², Harsha Teja Garimella², Reuben Kraft¹, ¹*Pennsylvania State University, United States*, ²*CFD Research, United States*
- 3:00PM Bone Volume Fraction Vs. Bone Mass Density As A Predictor For Mechanical Properties of The Cancellous Bone of Human Lumbar Vertebral Bodies** SB³C2019-271
Francesco Travascio¹, Abeer Al-Barghouthi², Loren Latta¹, ¹*University of Miami, United States*, ²*Max Biedermann Institute for Biomechanics, Mount Sinai Medical Center, United States*

Friday, June 28

1:45PM - 3:15PM

Growth Remodeling and Repair II: Musculoskeletal System Seasons 4-5

Session Chair: Reuben Kraft *Penn State University*

Session Co-Chair: Johannes Weickenmeier *Stevens Institute of Technology*

- 1:45PM Murine Rotor Cuff Tendinopathy Models: The Role of Muscle Loading** SB³C2019-272
Adam Abraham¹, Fei Fang¹, Mikhail Golman¹, Panagiotis Oikonomou¹, Stavros Thomopoulos¹, ¹*Columbia University, United States*
- 2:00PM The Effect of Fatigue On The Impact Response of Rat Ulna** SB³C2019-273
Chenxi Yan¹, Mariana Kersh¹, ¹*University of Illinois Urbana Champaign, United States*
- 2:15PM Microindentation Maps Two Gradients In Mechanical Properties Across The Zones of The Growth Plate** SB³C2019-274
Kevin Eckstein¹, Karin Payne², Virginia Ferguson¹, ¹*University of Colorado at Boulder, United States*, ²*University of Colorado at Anschutz, United States*
- 2:30PM Fibrous Network Topography Regulates Fibrotic Phenotypes In Annulus Fibrosus Cells** SB³C2019-275
Edward Bonnevie¹, Sarah Gullbrand¹, Beth Ashinsky², Tonia Tsinman¹, Dawn Elliott³, Harvey Smith¹, Robert Mauck¹, ¹*University of Pennsylvania and CMC VA Medical Center, United States*, ²*University of Pennsylvania, CMC VA Medical Center, and Drexel University, United States*, ³*University of Delaware, United States*
- 2:45PM Mitochondria Function, Structural, and Mechanical Outcomes After Exposure To Near-Infrared Light During Tendon Maturation and Adult Healing** SB³C2019-276
Ryan Locke¹, Elisabeth Lemmon¹, Ellen Dudzinski¹, Sarah Kopa¹, Harrah Newman¹, Elahe Ganji¹, Megan Killian¹, ¹*University of Delaware, United States*
- 3:00PM Primary Synovial Fibroblast-Collagen Gels Exhibit Unique Tensile Failure Properties & Microstructure From 3T3-Collagen Gels** SB³C2019-277
Meagan Ita¹, Harrison Troche¹, Beth Winkelstein¹, ¹*University of Pennsylvania, United States*

Friday, June 28	1:45PM - 3:15PM
------------------------	------------------------

Soft Tissue Mechanics**Hemlock****Session Chair: Kristin Myers** *Columbia University***Session Co-Chair: Joao Soares** *Virginia Commonwealth University*

- 1:45PM Contact Experiments Reveal Pressure Evolution In Soft Hydrated Interfaces** SB³C2019-278
Christopher Johnson¹, Jiho Kim¹, Alison Dunn¹, ¹*University of Illinois at Urbana-Champaign, United States*
- 2:00PM Harmonic Shear Wave Imaging: A New Elastography Method To Evaluate Mechanical Properties of Soft Tissues** SB³C2019-279
Seyedali Sadeghi¹, Daniel Cortes¹, ¹*Penn State University, United States*
- 2:15PM Strong Triaxial Coupling and Anomalous Poisson Effect In Collagen Networks** SB³C2019-280
Ehsan Ban¹, Hailong Wang², J Matthew Franklin³, Jan Liphardt³, Paul Janmey¹, Vivek Shenoy¹, ¹*University of Pennsylvania, United States*, ²*University of Science and Technology of China, China*, ³*Stanford University, United States*
- 2:30PM Fiber Orientation and Structure Characterization of Pregnant and Nonpregnant Human Uterus** SB³C2019-281
Shuyang Fang¹, James McLean², Christine Hendon², Joy Vink³, Kristin Myers¹, ¹*Department of Mechanical Engineering Columbia University, United States*, ²*Department of Electrical Engineering Columbia University, United States*, ³*Department of Obstetrics and Gynecology Columbia University Medical Center, United States*
- 2:45PM Cadherin-11 Regulates Aortic Valve Interstitial Cell Force Generation and Mechanical Properties** SB³C2019-282
Matthew Bersi¹, Meghan Bowler¹, W. David Merryman¹, ¹*Vanderbilt University, United States*
- 3:00PM A Volumetric Growth Model For Healing Post-Infarction Scar** SB³C2019-283
Derek Bivona¹, Ana Estrada¹, Jeffrey Holmes¹, ¹*University of Virginia, United States*

Friday, June 28	1:45PM - 3:15PM
------------------------	------------------------

Emerging Computational and Experimental Methods in Fluid Mechanics**Fox Den****Session Chair: C. Alberto Figueroa** *University of Michigan*

- 1:45PM A Multiscale Flow-Mediated Platelet Adhesion Model and Its Experimental Validation** SB³C2019-284
Peng Zhang¹, Jawaad Sherif¹, Peineng Wang¹, Marvin J. Slepian², Yuefan Deng¹, Danny Bluestein¹, ¹*Stony Brook University, United States*, ²*University of Arizona, United States*
- 2:00PM Deep-Learning Based Region-of-Interest Selection In 3d Cerebrovascular Images** SB³C2019-285
Tatsat Rajendra Patel¹, Prakhar Jaiswal¹, Nikhil Paliwal¹, Adnan H Siddiqui¹, Rahul Rai¹, Hui Meng¹, ¹*University at Buffalo, United States*
- 2:15PM A Forward Incremental Prestressing Approach For Nonlinear Fluid-Structure Interaction Hemodynamics** SB³C2019-286
Nitesh Nama¹, Miquel Aguirre², Jay D. Humphrey³, C. Alberto Figueroa¹, ¹*University of Michigan, United States*, ²*Mines Saint-tienne, France*, ³*Yale University, United States*
- 2:30PM Fsi Modeling of Cyclic Aspiration For Acute Ischemic Stroke Patients** SB³C2019-287
Bryan Good¹, Francesco Costanzo¹, Scott Simon², Keefe Manning¹, ¹*The Pennsylvania State University, United States*, ²*Penn State Hershey Medical Center, United States*

- 2:45PM A Systematic Methodology For Correcting Pc-Mri and Cfd Incompatibilities** SB³C2019-288
Thomas Puiseux¹, Anou Sewonu², Franck Nicoud¹, Simon Mendez¹, Ramiro Moreno², ¹IMAG, Univ. Montpellier, CNRS, France, ²ALARA Expertise, France
- 3:00PM Reduced-Order Leaflet Models For Numerical Experiments On Transcatheter Aortic Valves** SB³C2019-289
Shantanu Bailoor¹, Jung-Hee Seo¹, Hoda Hatoum², Lakshmi Prasad Dasi², Rajat Mittal¹, ¹Johns Hopkins University, United States, ²Ohio State University, United States

Friday, June 28

3:30PM - 5:00PM

Multiscale Biotransport in Hemodynamics and Lymphatics**Sunburst****Session Chair: Brandon Dixon** *Georgia Institute of Technology***Session Co-Chair: Mona Eskandari** *University of California Riverside*

- 3:30PM Biotransport In The Glymphatic System: Pulsation, Peristalsis, and High Blood Pressure** SB³C2019-290
Humberto Mestre¹, Jeffrey Tithof¹, Ting Du¹, Wei Song¹, Weiguo Peng¹, Amanda M. Sweeney¹, Genaro Olveda¹, John H. Thomas¹, Maiken Nedergaard¹, Douglas H. Kelley¹, ¹University of Rochester, United States
- 3:45PM Micro Particle Image Velocimetry For In Vitro Assessment of Patient Specific Whole Blood Rheology** SB³C2019-291
Erdem Kucukal¹, Yuncheng Man¹, Ailis Hill¹, Shichen Liu¹, Jane Little¹, Umut Gurkan¹, ¹Case Western Reserve University, United States
- 4:00PM Patient-Specific Metrics From Quantitative Rheology of Whole Sickle Blood Using Microfluidics** SB³C2019-292
Jose Valdez¹, Yvonne Datta², John Higgins³, David Wood¹, ¹University of Minnesota-Department of Biomedical Engineering, United States, ²University of Minnesota-Department of Medicine, United States, ³Harvard University-Department of Systems Biology, United States
- 4:15PM Instability of Phospholipid Bilayer Under Shear Flow: Molecular Dynamics Simulation** SB³C2019-293
Taiki Shigematsu¹, Kenichiro Koshiyama², Shigeo Wada³, ¹Global Center for Medical Engineering and Informatics, Osaka University, Japan, ²Graduate School of Technology, Industrial and Social Sciences, Tokushima University, Japan, ³Graduate School of Engineering Science, Osaka University, Japan
- 4:30PM Computational Simulations of Thrombolytic Therapy In Acute Ischaemic Stroke** SB³C2019-294
Boram Gu¹, Andris Piebalgs¹, Yu Huang¹, Dylan Roi², Kyriakos Lobotesis², Rongjun Chen¹, Simon A. Thom³, Xiao Yun Xu¹, ¹Department of Chemical Engineering, Imperial College London, United Kingdom, ²Imaging Department, Charing Cross Hospital, Imperial College Healthcare NHS Trust, United Kingdom, ³National Heart & Lung Institute, Imperial College London, United Kingdom
- 4:45PM Combined Microfluidic-Computational Approach To Quantify The Effect of Sickle-Cell Disease On Blood Rheology** SB³C2019-295
Marisa Bazzi¹, Jose Valdez², David Wood², Victor Barocas², ¹Department of Chemical Engineering and Material Science University of Minnesota, United States, ²Department of Biomedical Engineering University of Minnesota, United States

Friday, June 28	3:30PM - 5:00PM
------------------------	------------------------

Cardiovascular Mechanics: Other**Snowflake**

Session Chair: Seungik Baek *Michigan State University*

Session Co-Chair: Sourav Patnaik *University of Texas at San Antonio*

- 3:30PM Mechanical Characterization of Atherosclerotic Coronary Arteries By Ex-Vivo Inflation Testing and Inverse Finite Element Modeling** SB³C2019-296
 Su Guvenir¹, Giulia Gandini¹, Irene Berselli², Veronica Codazzi², Francesco Migliavacca², Claudio Chiastra², Frank J.H. Gijzen¹, Ali C. Akyildiz¹, ¹*Erasmus Medical Center, Netherlands*, ²*Politecnico Di Milano, Italy*
- 3:45PM Histomechanical Analysis of Decellularized Porcine Internal Thoracic Arteries** SB³C2019-297
 Colton Kostelnik¹, Wayne Carver², John Eberth², ¹*University of South Carolina - Department of Biomedical Engineering, United States*, ²*University of South Carolina School of Medicine - Department of Cell Biology and Anatomy, United States*
- 4:00PM Understanding The Transmural Variation In Extracellular Matrix Fiber Orientation Using Multi-Photon Microscopy** SB³C2019-298
 Anastasia Gkousioudi¹, Jacopo Ferruzzi¹, Yanhang Zhang¹, ¹*Boston University, United States*
- 4:15PM Kinematic Analysis of Murine Cardiac Hypertrophy Using High-Frequency Four-Dimensional Ultrasound** SB³C2019-299
 Frederick Damen¹, Mauro Costa², Craig Goergen¹, ¹*Purdue University, United States*, ²*The Jackson Laboratory, United States*
- 4:30PM Selective Stiffening of A Myocardial Infarct Improves Predicted Systolic Function Without Impairing Filling** SB³C2019-300
 Kyoko Yoshida¹, Ana Estrada¹, Jeffrey Holmes¹, William Richardson², ¹*University of Virginia, United States*, ²*Clemson University, United States*
- 4:45PM Hypertension-Induced Changes In The Mechanical Behavior of The Left Ventricular Wall** SB³C2019-301
 Marissa Grobbel¹, Ari Hollander¹, Analeeza Dubay¹, Emma Darios Flood¹, Kibrom Alula¹, Gregory Fink¹, Stephanie Watts¹, Lik Chuan Lee¹, Sara Roccabianca¹, ¹*Michigan State University, United States*

Friday, June 28	3:30PM - 5:00PM
------------------------	------------------------

Biofabrication and 3D in Vitro Systems**Wintergreen**

Session Chair: Matthew Fisher *NC State University*

Session Co-Chair: Anna Grosberg *University of California, Irvine*

- 3:30PM Bioprinting 3d Breast Epithelial Spheroids To Study Vascular Interactions In Human Cancer** SB³C2019-302
 Swathi Swaminathan¹, Alisa Morss Clyne¹, ¹*Drexel University, United States*
- 3:45PM Fabricating 3d Cellular Aggregates Via Laser Direct-Write Bioprinting: Size- and Shape-Controlled Embryoid Bodies and Tumor Spheroids** SB³C2019-303
 David Kingsley¹, Cassandra Roberge¹, David Corr¹, ¹*Rensselaer Polytechnic Institute, United States*
- 4:00PM Fluid-Structure Interaction At Drop-Drop Interface During Drop-On-Demand Printing of Hydrogel-Based Soft Materials** SB³C2019-304
 Cih Cheng¹, George T. C. Chiu¹, Bumsoo Han¹, ¹*Purdue University, United States*

- 4:15PM Directed Self-Assembly of 3d In Vitro Tissue Models Using Droplet Microfluidics** SB³C2019-305
Jasmine Shirazi¹, Michael Donzanti¹, Jason Gleghorn¹, ¹*University of Delaware, United States*
- 4:30PM Engineering A 3d Model of Ductal Carcinoma In Situ Using Multimaterial Fresh 3d Bioprinting** SB³C2019-306
Joshua Tashman¹, Thomas Hinton¹, Daniel Brown², Daniel Shiowski³, Andrew Lee¹, Andrew Hudson¹, Adrian Lee², Adam Feinberg¹, ¹*Carnegie Mellon University, United States*, ²*University of Pittsburgh, United States*, ³*Carnegie Mellon University, United States*
- 4:45PM Integrating In Vitro and In Silico Technologies: Development of A Perfusion Bioreactor and Its Digital Twin** SB³C2019-307
Liesbet Geris¹, Mohammad Mehrian¹, Sebastien de Bournonville², Toon Lambrechts², Jean-Marie Aerts², Frank Luyten², Ioannis Papantoniou², ¹*University of Lige, Belgium*, ²*KU Leuven, Belgium*

Friday, June 28

3:30PM - 5:00PM

Mechanics and Modeling of Musculoskeletal Soft Tissues Seasons 1-3

Session Chair: Sara Roccabianca *Michigan State University*

Session Co-Chair: Adrian Buganza Tepole *Purdue University*

- 3:30PM Sex-Dependent Orientation and Size of The Anterior Cruciate Ligament Throughout Skeletal Growth In The Porcine Stifle Joint** SB³C2019-308
Danielle Howe¹, Stephanie Cone¹, Jorge Piedrahita², Lynn Fordham³, Jeffrey Spang³, Matthew Fisher¹, ¹*North Carolina State University and the University of North Carolina- Chapel Hill, United States*, ²*North Carolina State University, United States*, ³*University of North Carolina- Chapel Hill, United States*
- 3:45PM Decorin, Alone and In Tandem With Biglycan, Alters Viscoelasticity In Aged Tendons** SB³C2019-309
Ryan Leiphart¹, Snehal Shetye¹, Stephanie Weiss¹, Louis Soslowsky¹, ¹*University of Pennsylvania, United States*
- 4:00PM Bath Osmolarity Alters Multiscale Mechanics and Damage In Tendon** SB³C2019-310
Ellen Bloom¹, Andrea Lee¹, Dawn Elliott¹, ¹*University of Delaware, United States*
- 4:15PM Quantifying Differences In The Mechanical Properties of The Flexor and Extensor Muscles In The Human Forearm Using Mr Elastography** SB³C2019-311
Daniel Smith¹, Andrea Zonnino¹, Peyton Delgorio¹, Raymond Duda¹, Fabrizio Sergi¹, Curtis Johnson¹, ¹*University of Delaware, United States*
- 4:30PM Sex-Related Differences In Carpal Arch Morphology** SB³C2019-312
Kishor Lakshminarayanan¹, Rakshit Shah¹, Zong-Ming Li¹, ¹*Hand Research Laboratory, Department of Biomedical Engineering, United States*
- 4:45PM Utilizing Arfi Imaging To Predict Linear Region Modulus of Tendons From Toe Region Data** SB³C2019-313
Gerald A Ferrer¹, Waqas Khalid¹, Volker Musahl¹, Kang Kim¹, Richard E Debski¹, ¹*University of Pittsburgh, United States*

Friday, June 28	3:30PM - 5:00PM
------------------------	------------------------

Injury: Biomechanics**Seasons 4-5****Session Chair: Songbai Ji** *WPI***Session Co-Chair: Yuan Feng** *Shanghai Jiao Tong University*

- 3:30PM Shear Wave Propagation and Estimation of Material Parameters In A Nonlinear, Fibrous Material** SB³C2019-314
Zuoxian Hou¹, Ruth Okamoto¹, Philip Bayly¹, ¹*Washington University in St.Louis, United States*
- 3:45PM Shock Wave Propagation In Brain Tissue** SB³C2019-315
Donghoon Keum¹, Soroush Assari¹, Kurosh Darvish¹, ¹*Temple University, United States*
- 4:00PM Effect of Corpus Callosum Demyelination On Murine Brain Injury Mechanism** SB³C2019-316
Javid Abderezaei¹, Gloria Fabris¹, Zachary Lopez¹, Cassandra Gologorsky², Johannes Weickenmeier¹, Mehmet Kurt¹, ¹*Stevens Institute of Technology, United States*, ²*Cornell University, United States*
- 4:15PM High-Rate Anisotropic and Region-Dependent Properties In Human Infant Cranial Bone** SB³C2019-317
Robert Metcalf¹, Jessica Comstock², Brittany Coats¹, ¹*University of Utah, Mechanical Engineering, United States*, ²*University of Utah, Pediatric Pathology, United States*
- 4:30PM Bilateral Skull Fractures Due To Controlled Head Drops In Infant Porcine Specimens** SB³C2019-318
Patrick Vaughan¹, Alexis Goots¹, Todd Fenton¹, Roger Haut¹, Feng Wei¹, ¹*Michigan State University, United States*
- 4:45PM Estimates of High-Risk Single and Cumulative Head Impact Doses In American Football** SB³C2019-319
Adam Bartsch PhD¹, ¹*Prevent Biometrics, United States*

Friday, June 28	3:30PM - 5:00PM
------------------------	------------------------

Government Perspectives on Multiscale Biomechanics, Bioengineering, and Biotransport**Hemlock****Session Chair: Alisa Morss Clyne**, *University of Maryland***Grace Peng**, *NIH Program Director, Division of Discovery Science & Technology and Mathematical Modeling, Simulation, and Analysis***Michele Grimm**, *NSF Program Director, Biomedical Engineering***Laurel Kuxhaus**, *ASME Federal Fellow*

Friday, June 28	3:30PM - 5:00PM
------------------------	------------------------

Pediatric and Congenital Fluid Mechanics**Fox Den****Session Chair: Amy Throckmorton** *Drexel University*

- 3:30PM Stent Intervention Improves Flow Distribution and Vascular Growth In Porcine Pulmonary Artery Stenosis** SB³C2019-320
Ryan Pewowaruk¹, Klarka Mendrisova¹, Carolina Larrain¹, Christopher Francois¹, Luke Lamers¹, Alejandro Roldan-Alzate¹, ¹*University of Wisconsin - Madison, United States*

- 3:45PM Shear Stress Modulates Cardiomyocyte Proliferation Via Endothelial Cell-Cardiomyocyte Signaling** SB³C2019-321
Matthew Watson¹, Lauren Black², Erica Kemmerling³, ¹*Tufts University, Department of Mechanical Engineering and Department of Biomedical Engineering, United States*, ²*Tufts University, Department of Biomedical Engineering, United States*, ³*Tufts University, Department of Mechanical Engineering, United States*
- 4:00PM Computational Surgical Planning For Peripheral Pulmonary Artery Stenosis In Children With Alagille and Williams Syndromes** SB³C2019-322
Ingrid Lan¹, Weiguang Yang², Jeffrey Feinstein³, Alison Marsden³, ¹*Bioengineering, Stanford University, United States*, ²*Pediatric Cardiology, Stanford University, United States*, ³*Bioengineering and Pediatric Cardiology, Stanford University, United States*
- 4:15PM Fluid-Structure Analysis of A Collapsible Axial Impeller and Protective Cage For Dysfunctional Fontan Physiology** SB³C2019-323
Matthew Hirschhorn¹, Evan Bisirri¹, Randy Stevens², Joseph Rossano³, Amy Throckmorton¹, ¹*Drexel University, United States*, ²*St. Christopher's Hospital for Children, United States*, ³*Children's Hospital of Philadelphia, United States*
- 4:30PM Mechanics and Efficiency of The Zebrafish Embryonic Heart Tube** SB³C2019-324
Alireza Sharifi¹, Alex Gendernalik¹, Deborah Garrity¹, David Bark Jr.¹, ¹*Colorado State University, United States*
- 4:45PM Whole Embryonic Heart Ultrasound Imaging, Motion Tracking and Flow Simulations Reveal Hemodynamic Role of Embryonic Atria** SB³C2019-325
Sheldon Ho¹, Wei Xuan Chan², Nhan Phan-Thien², Choon Hwai Yap², ¹*Biomedical Engineering, National University of Singapore, Singapore*, ²*National University of Singapore, Singapore*

2 Poster Sessions

2.1 Poster Session I	Wednesday, June 26 12:45PM - 2:15PM
-----------------------------	--

Posters - BS Level Competition: Cardiovascular System

Assessment of Pulmonary Arterial Structure and Its Association With Right Ventricular Function SB³C2019-P001

Frankangel Servin¹, Rebecca R Vanderpool², Rajesh Janardhanan³, Jose Rosado⁴, Franz P Rischard⁵, Jason X.J Yuan⁶,
¹University of Arizona, Department of Biomedical Engineering, United States, ²University of Arizona, Department of
 Biomedical Engineering, Division of Translational and Regenerative Medicine, United States, ³University of Arizona,
 Department of Medical Imaging, United States, ⁴University of Arizona, Department of Medical Imaging, United States,
⁵University of Arizona, Division of Pulmonary, Allergy, Critical Care and Sleep Medicine, United States, ⁶University of
 Arizona, Division of Translational and Regenerative Medicine, United States

Quantitative Analysis of Flow Distribution Within The Fetal Heart Using In-Vitro 4d Flow Mri SB³C2019-P002

Lucille Anzia¹, Katrina Ruedinger¹, Shardha Srinivasan², Barbara Trampe¹, Timothy Heiser¹, J. Igor Iruretagoyena², Ale-
 jandro Roldan-Alzate¹, ¹University of Wisconsin Madison, United States, ²University of Wisconsin School of Medicine and
 Public Health, United States

On The Use of Pentagalloyl Glucose For Mechanistic Suppression of Abdominal Aortic Aneurysm SB³C2019-P003

Vangelina Osteguín¹, Sourav Patnaik¹, Alycia Berman², Craig Goergen², Ender Finol¹, ¹University of Texas at San Anto-
 nio, United States, ²Purdue University, United States

Novel Method of Detecting The Effect From Inhaled Anesthetics On Peripheral Venous Pressure Waveforms SB³C2019-P004

Kaylee Henry¹, Ali Al-Alawi¹, Md Abul Hayat¹, Patrick Bonasso², Hanna Jensen¹, Jingxian Wu¹, Kevin Sexton², Morten
 Jensen¹, ¹University of Arkansas, United States, ²University of Arkansas for Medical Sciences, United States

Fluvastatin Decreases Endothelial Nitric Oxide Synthase O-GlcNacylation SB³C2019-P005

Danika Meldrum¹, Sarah Basehore¹, Alisa Morss Clyne¹, ¹Drexel University, United States

Investigations of The Chordae Tendineae'S Mechanical Properties of Porcine Atrioventricular Heart Valves SB³C2019-P006

Colton Ross¹, Devin Laurence¹, Yan Zhao², Ming-Chen Hsu³, Ryan Baumwart⁴, Yi Wu¹, Chung-Hao Lee¹, ¹The University
 of Oklahoma, United States, ²The University of Oklahoma Health Sciences Center, United States, ³Iowa State University,
 United States, ⁴Oklahoma State University, United States

Relationship of Platelet Adhesion With Surface Topography In The Penn State Pvad SB³C2019-P007

Cecilia Richardsen¹, Ashlyn Mueser¹, Branka Lukic², Christopher Siedlecki², William Weiss², Keefe Manning¹,
¹Pennsylvania State University, United States, ²Penn State Hershey Medical Center, United States

Mouse Aortic Mechanical Properties From Finite Element Model Optimized To Match Ring-Pull Experiments SB³C2019-P008

Carl Schoepfoerster¹, Ryan Mahutga¹, Victor Barocas¹, ¹Department of Biomedical Engineering, University of Minnesota-
 Twin Cities, United States

A Computational Study of The Role of The Pericardium On Cardiac Function In Normal and Hypertensive Hearts SB³C2019-P009

Emilio A. Mendiola¹, Huan Nguyen¹, Reza Avaz¹, Michael S. Sacks¹, ¹The University of Texas at Austin, United States

Estimating The Contribution of The Endovascular Catheter On Cerebral Hypoperfusion During Mechanical Thrombectomy SB³C2019-P010

Christina Ngo¹, Jeffrey Pyne², Jaiyoung Ryu³, Shawn Shadden², ¹*Department of Bioengineering, UC Berkeley, United States*, ²*Department of Mechanical Engineering, UC Berkeley, United States*, ³*Department of Mechanical Engineering, Chung-Ang University, South Korea*

Alteration of The Mechanical Response of Porcine Tricuspid Valve Anterior Leaflets Following Exposure To De-ionized Water SB³C2019-P011

Margaret Clark¹, Samuel Salinas¹, Rouzbeh Amini¹, ¹*The University of Akron, United States*

On The Distribution of Aortic Valve Cusp Calcification SB³C2019-P012

Varshini Guhan¹, Megan Heitkemper¹, Lakshmi Prasad Dasi¹, ¹*The Ohio State University, United States*

An Investigation of Layer-Specific Tissue Biomechanics of Porcine Atrioventricular Valve Anterior Leaflets SB³C2019-P013

Cortland Johns¹, Katherine Kramer¹, Anju Babu¹, Chung-Hao Lee¹, ¹*Biomechanics and Biomaterials Design Lab, School of Aerospace and Mechanical Engineering, The University of Oklahoma Norman, OK, USA, United States*

A Study of Pressure Dynamics Across A Stenotic Orifice SB³C2019-P014

Tori Burton¹, Hoda Hatoum¹, Lakshmi Prasad Dasi¹, ¹*Department of Biomedical Engineering at The Ohio State University, United States*

A Study of The Effects of An Increased Beat Rate On The Penn State Pediatric Ventricular Assist Device SB³C2019-P015

Brady Houtz¹, Sailahari Ponnaluri¹, Maureen Gallagher¹, Charlee Dawson¹, Bryan Good¹, Steven Deutsch¹, Keefe Manning¹, ¹*Pennsylvania State University, United States*

Hemodynamics of Coronary Artery Aneurysms In Kawasaki Disease An Idealized Aneurysm Model SB³C2019-P016

Alex Lu¹, Noelia Grande Gutierrez¹, Alison Marsden¹, ¹*Stanford University, United States*

Fluid Dynamics Study of An Implantable Blood Pump For Patients With A Failed Fontan Circulation SB³C2019-P017

Cody Kubicki¹, Bryan Good¹, William Weiss², Keefe Manning¹, ¹*The Pennsylvania State University, United States*, ²*Penn State Hershey Medical Center, United States*

Posters - BS Level Competition: Musculoskeletal, Respiratory, Ocular and Other Systems

Heterogeneity and Anisotropy In The Microscale Energy Dissipating Properties of The Knee Meniscus SB³C2019-P018

Kev'ther Hoxha¹, Chao Wang¹, Biao Han¹, Robert Mauck², Lin Han¹, ¹*Drexel University, United States*, ²*University of Pennsylvania, United States*

2d Or Not 2d; Comparing 2d and 3d Measurements of Collagen Microstructure SB³C2019-P019

Gosia Fryc¹, Bin Yang¹, Alexandra Gogola¹, Bryn Brazile¹, Yi Hua¹, Tian Yong Foong¹, Ian A. Sigal¹, ¹*University of Pittsburgh, United States*

The Effect of A Cannabinoid Receptor 2 Agonist On Motor Function After Blast-Induced Neurotrauma SB³C2019-P020

Bayan Alturkestani¹, Soroush Assari¹, Ola M Sharaf¹, Ian Hendricks¹, Sara J. Ward¹, Ronald F. Tuma¹, Kurosh Darvish¹, ¹*Temple University, United States*

Drone Blade Induced Skin Laceration and Eye Injury Risk; An Investigation of Skin and Eye Surrogate Models SB³C2019-P021

Lauren Duma¹, Mark Begonia², Barry Miller¹, Stefan Duma¹, ¹*Virginia Tech, United States*, ²*Virginia Tech, United States*

Direct Measurement of Collagen Fiber Orientation Along The Surface of Ligaments and Tendons of The Knee In A Porcine Model SB³C2019-P022

Emily Lambeth¹, Stephanie Cone¹, Matthew Fisher¹, ¹North Carolina State University and the University of North Carolina - Chapel Hill, United States

Elastase Treatment Increases and Accelerates Stress Relaxation In Tendon. SB³C2019-P023

James Abraham¹, Jeremy Eekhoff², Spencer Lake³, ¹Department of Mechanical Engineering and Materials Science at Washington University in St. Louis, United States, ²Department of Biomedical Engineering at Washington University in St. Louis, United States, ³Department of Mechanical Engineering and Materials Science at Washington University in St. Louis, Department of Biomedical Engineering at Washington University in St. Louis, Department of Orthopaedic Surgery at Washington University in St. Louis, United States

Ultrasound Shear Wave Elastography of The Anterior Cruciate Ligament SB³C2019-P024

Gabi Schwartz¹, Rachel Heller¹, Seyedali Sadeghi¹, Daniel Cortes¹, ¹Penn State, United States

Extracellular Matrix Stiffness Alters Chondrocyte Phenotype Through Trpv4 Regulation SB³C2019-P025

Ryan Skinner¹, Mallory Griffin¹, Nicholas Trompeter¹, Cindy Farino¹, Omar Banda¹, John Slater¹, Randall Duncan¹, ¹University of Delaware, United States

Asthmatic and Healthy Airway Morphology Measured From Ct-Based Geometries SB³C2019-P026

Irina Pyataeva¹, Kamran Poorbahrami¹, Ellesse Cooper¹, Ben Piperno¹, David Mummy², Sean Fair², Jessica Oakes¹, ¹Northeastern University, United States, ²University of Wisconsin-Madison, United States

Contributions of Collagen Ii, Laminin, and Fibronectin To Vitreoretinal Adhesion In Human Eyes SB³C2019-P027

Joseph Phillips¹, Christopher Creveling¹, Brittany Coats¹, ¹University of Utah, United States

Rapid Quantitative Assessment of Postural Control Function For Mild Traumatic Brain Injury: Evaluation of A Portable Force Plate Device SB³C2019-P028

Jonathan VanPaepeghem¹, Kunal Dave¹, Liying Zhang¹, ¹Wayne State University, United States

Mechanical Influence of Graphitic Carbon Nitride Filler On Poly(vinyl Alcohol) Thin Film Hydrogels For Wound Healing SB³C2019-P029

Bradley Henderson¹, Katelyn Cudworth¹, Andrew Clifford², Dylan Quintana², John Thurston², Trevor Lujan¹, ¹Boise State University, United States, ²College of Idaho, United States

A Novel Workflow For Generation of Patient-Specific Asthmatic Airway Models From Ct Data SB³C2019-P030

Ellesse Cooper¹, Kamran Poorbahrami¹, Ben Piperno¹, David Mummy², Sean Fair², Jessica Oakes¹, ¹Northeastern University, United States, ²University of Wisconsin, United States

Water Sport Head Injuries; Ability of Helmets To Reduce Head Impact Accelerations SB³C2019-P031

Brock Duma¹, Mark Begonia¹, Casey Charron¹, Stefan Duma¹, ¹Virginia Tech, United States

The Influence of Radiographic Projection Angle On Visualization of The Subtalar Joint SB³C2019-P032

Kalebb Howell¹, Nicola Krahenbuhl², Rich Lisonbee¹, Beat Hintermann², Charles Saltzman¹, Andrew Anderson¹, Alexej Barg¹, Amy Lenz¹, ¹University of Utah, United States, ²Kantonsspital Baselland, Switzerland

Effects of Volumetric Boundary Conditions On The Compressive Mechanics and Modeling of Passive Skeletal Muscle SB³C2019-P033

Anurag Vaidya¹, Benjamin Wheatley¹, ¹Bucknell University, United States

Posters - MS Level Competition: Solid Mechanics

The Effect of In Vivo Ionizing Radiation On The Micromechanics of Mouse Vertebrae SB³C2019-P034

Tongge Wu¹, Megan Pendleton¹, Noah Bonenheim¹, Joshua Alwood², Tony Keaveny¹, ¹University of California, Berkeley, United States, ²NASA Ames Research Center, United States

Investigating Sex-Specific Accuracy of Proximal Femur Coordinate Systems Derived From Statistical Shape Models SB³C2019-P035

Carla Winsor¹, Xinshan Li², Ju Zhang³, Corinne Henak¹, Heidi-Lynn Ploeg⁴, ¹University of Wisconsin - Madison, United States, ²University of Sheffield, United Kingdom, ³Auckland Bioengineering Institute, New Zealand, ⁴Queen's University, Canada

Effects of Collagenase and Elastase On The Mechanical Properties of Porcine Abdominal Aorta SB³C2019-P036

Celeste Blum¹, Chris Korenczuk², Victor Barocas², ¹University of Minnesota - Twin Cities, United States, ²University of Minnesota- Twin Cities, United States

Finite Element Simulation Framework For Investigating Pathological Effects On Organ-Level Tricuspid Valve Biomechanical Function SB³C2019-P037

Devin Laurence¹, Emily Johnson², Ming-Chen Hsu², Arshid Mir³, Harold Burkhart³, Yi Wu¹, Chung-Hao Lee¹, ¹University of Oklahoma, United States, ²Iowa State University, United States, ³University of Oklahoma Health Sciences Center, United States

An Integrated Opto-Mechanical System For Quantification of Dynamic Microstructure and Mechanics of Heart Valve Tissues SB³C2019-P038

ADVENTURES IN THERMAL THERAPY: FROM SURGERY TO CANCER TREATMENT

John A. Pearce (1),

(1) Department of Electrical and Computer Engineering
The University of Texas at Austin
Austin, TX, USA

INTRODUCTION

While thermal treatment has been used therapeutically for millennia there are still many useful and interesting avenues of investigation open to study. In my view it will remain a vital clinical treatment for the foreseeable future. My goal today is to convince new investigators of the rich and fertile ground available to the perpetually curious in thermal therapy. The opportunities are virtually unbounded.

My own adventure was originally motivated by almost 5 years of clinical experience in the Department of Surgery at the Medical University of South Carolina. We worked closely with folks in the Burn Unit developing devices and strategies. We experienced some adverse outcomes related to electrosurgery burns; consequently my PhD dissertation research at Purdue University was on the topic of electrosurgical dispersive electrodes. Over the past 43 years of research the problems we encountered ran the gamut from very basic undergraduate engineering fundamentals to the most challenging advanced science and engineering principles.

METHODS

Here's how to get involved in thermal therapeutics: 1) Find an amenable pathologist colleague with whom to collaborate. The best work I have been able to complete has been with my long-term pathologist colleague, Dr. Sharon Thomsen. This collaboration opened so much in the way of other sciences and their far-reaching influences, for which I am eternally grateful. 2) Be ever alert for interesting avenues of investigation: if you see something cool, don't hesitate to go there, even if you have to learn a lot. Sitting in on courses on Cell Biology, Tumor Biology and 2 semesters of Biochemistry launched the last 5 years of my work in so many new directions its just not funny. All of the recent work stemmed from the chance purchase of a book The Systems Biology of Cancer. I highly

recommend all of those courses. Be curious, branch out. 3) Establish effective collaborative relationships with industrial colleagues and partners in the medical device industry. Our collaboration with Valleylab (now Medtronic Minimally Invasive Therapies), for example, resulted in "Ligasure", the first RF system capable of reliably sealing large arteries and veins. I believe that some of those colleagues are here today. The Ligasure system now has multiple competitors (i.e. imitators), illustrating its ubiquitous contributions in open and laparoscopic surgery. I assure you, I'm not selling these devices ... I have no financial interest in any vessel sealing entity (dang it).

As your work continues, never forget the basic engineering fundamentals. Quite by luck (rather than any grand strategy on my part) I have had strong educational backgrounds in both electrical and mechanical engineering and have used all of it most of the time. Perhaps this stems from my initial quandary as a newly admitted student to Clemson University in 1964. I couldn't decide between Mechanical and Electrical Engineering, so after long deliberations I finally pulled out a quarter and it came up Mechanical. My 43 years of research is a combination of heat transfer, thermodynamics and electromagnetic field theory, so I guess I never did decide. That's the fun of it, actually.

SOME EXAMPLE THEORY

The fundamental relation describing irreversible thermal alterations has been the Arrhenius model for first order irreversible reactions, which can be configured to predict the remaining concentration of undamaged tissue constituent, $C(\tau)$, relative to the initial concentration, $C(0)$:

$$\ln \left\{ \frac{C(0)}{C(\tau)} \right\} = \int_0^{\tau} A e^{\left\{ \frac{-E_a}{RT} \right\}} dt \quad (1)$$

where: A = the “frequency factor” (1/s), E_a = the activation energy (J/mole), R = the gas constant (J/mole/K), and T = temperature (K). The temperature history (from the bioheat equation) can be used with such a calculation to compare numerical model results with histology and other experimental assessment variables. This simple formulation works very well when applied to structural proteins, but fails for functional protein cascades at moderate (hyperthermic) temperatures, for which the sequences of reactions are higher order. [1] It can be successfully applied when coupled to a temperature-dependent time delay. [2] Direct comparison between histology and numerical creates a powerful combination of theory and experiment, the best kind of science in my view.

RESULTS

Analysis by this thermal damage model and the careful application of basic thermodynamics led directly to development of the Ligasure system, for example. Other models based on this formulation can predict thermally-induced collagen shrinkage, a prime component of almost all cosmetic surgery by RF and laser sources.

DISCUSSION

Results like Ligasure don’t come along very often in a career and must be thoroughly appreciated when they do. We had a very large number of failed vessel seals before the underlying physics were resolved to result in a practical system. However, thermal therapy is an excellent avenue by which significant advances in patient care can be realized. After all is said and done, that’s what we all hope for, I would say.

Happy research and please do seriously consider this arena of investigation. It’s fascinating.

MICROWAVE THERMAL THERAPY OF BENIGN ADRENAL ADENOMAS FOR TREATMENT OF PRIMARY ALDOSTERONISM

INTRODUCTION

Primary aldosteronism (PA) accounts for 5 - 12% of all hypertension and confers a higher risk for cardiovascular and cerebrovascular complications compared to age and blood pressure (BP) matched essential hypertension[1], [2]. Despite this, PA remains under-diagnosed and under-treated, largely due to the lack of definitive management options for the majority of affected individuals[1], [3]. PA is driven by unregulated aldosterone secretion from unilateral (40%) or bilateral (60%) aldosterone producing adenomas (APA) (0.5-2 cm³) or aldosterone producing cell clusters (APCC) (<0.5 cm³), and is characterized biochemically by raised aldosterone and suppressed renin[4], [5]. The current definitive approach to unilateral PA is surgical adrenalectomy. Bilateral disease is managed medically using mineralocorticoid receptor antagonists (MRA), and is often poorly tolerated due to off target anti-androgen effects of MRAs. Only ~30% of all individuals diagnosed with PA undergo surgery, and collateral resection of normal cortex limits the option of surgery to unilateral disease, given the inevitable risk for adrenocortical insufficiency with bilateral adrenalectomy[6], [7]. There exists a need for improved definitive options for treatment of unilateral and bilateral PA alike, not offered by currently available therapeutic modalities. An ideal approach would selectively eliminate or defunctionalize pathological aldosterone producing adenomas (APA), while simultaneously preserving normal adjacent adrenal cortex.

The standard approach for localizing APAs following diagnosis of PA is with adrenal venous sampling[8]. The recent development of ¹¹C metomidate PET/CT imaging has enabled, for the first time, localization of APAs within adrenal glands, paving the way for the development of localized treatment approaches for PA[8], [9]. Thermal ablation, which is in clinical use for minimally-invasive image-guided treatment of cancers in the liver and other sites, presents a plausible approach for

partial treatment of an adrenal gland[10]. Some clinical case series have used radiofrequency ablation (RFA) to treat unilateral functioning adrenocortical adenomas, with clinical and biochemical outcomes demonstrating resolution of PA-associated endocrinopathy[10], [11]. However, these studies did not spare normally-functioning adrenal cortex adjacent to the pathological lesions, and did not provide supporting histology or molecular data to demonstrate the cellular-level effects of heat on the adrenal gland. Compared to other energy modalities for thermal treatments, microwave energy offers the advantages of rapid treatment, and is minimally impacted by tissue heterogeneities[12]. However, (1) the relationship between biological effects of heating and applied thermal history (intensity and duration of heating) on adrenal cells is unknown; (2) currently available microwave heating technology is optimized for thermal ablation of large tissue volumes (diameter > 20 mm), and is ill-suited to minimizing thermal damage to tissue adjacent to offending APAs[11]; (3) inserting ablation probes into adrenal targets is technically challenging; and (4) there are no means to assess the functional status of adrenal tissue immediately following thermal therapy.

Our team is developing a minimally invasive solution for definitive management of APAs: image-guided, cortically-sparing, microwave thermal therapy (MWT) that targets APAs and areas of high autonomous aldosterone production, and preserves areas of ipsilateral normally functioning adrenocortical tissue. Here, we report on our preliminary *in vivo* studies assessing the effects of microwave heating on adrenal cell survival and function.

METHODS

Collaborative work between our labs has investigated the effects of ablative MWT on porcine adrenal gland *in vivo*. All *in vivo* studies were conducted at Kansas State University under approved Institutional

Animal Care and Use Committee protocol number #4019. We aimed to achieve targeted subtotal adrenocortical ablation (adrenal volumes $0.8 - 1.2\text{cm}^3$), with preservation of non-targeted tissue. We applied MWT under direct surgical visualization, using a lateralized, non-penetrative approach to normal swine adrenal cortex ($n=8$ animals). Ablation was performed with a 2.45 GHz directional microwave antenna, previously reported by our group [13]. We assessed tissue histologically, at 48 h post ablation for evidence of coagulative necrosis, heat-induced cellular damage, steroidogenic enzyme expression, and immune infiltration. These data were matched to biochemical measurement of serum concentrations of steroids pre- and post-ablation.

RESULTS

At 48 h post-MWT, coagulative necrosis was induced in the targeted adrenal cortex with disruption of steroidogenic enzyme expression, while the non-targeted cortex remained intact, without evidence of inflammation or upregulated heat-induced damage markers (see Fig. 1). Importantly, steroidogenic enzyme expression was preserved in non-targeted tissue and this was accompanied by normal post-procedural circulating steroid concentrations.

Figure 1: Hematoxylin and Eosin (H&E) staining of porcine adrenal cortex at 48 h following 70 W, 60 s ablative MWT illustrates an area of coagulative necrosis (ablation zone), with preserved normal histological appearance in non-targeted cortex.

DISCUSSION

We conclude from this work that our approach to subtotal adrenocortical ablation is technically feasible and that this merits development. However, further specific details of adrenocortical cellular response to heat are required. Specifically, further insight into the dose-dependent effects of heating on adrenocortical function may identify sub-ablative thermal doses that enable disruption of APAs, while maximally sparing adjacent normal adrenocortical and medullary tissue. Our ongoing *in vitro* studies are geared towards identifying the relationship between duration and intensity of heating on adrenocortical cell survival, cellular damage, and steroidogenesis (i.e. cell function).

INTRODUCTION

Dr Pearce had a scientific “dalliance” with cellular apoptosis, the rather organized and structured means of programmed cell death, and he enjoyed modeling such processes in the context of hyperthermia [1]. He was also intrigued by the relationships amongst the members of the apoptotic process and their roles in cellular metabolism (eg, cytochrome C as a critical player in mitochondrial electron transport, but also as an intermediary in apoptosis). The connections between metabolism and apoptosis become “altered states” in cancer, where the Warburg Effect (a shift towards glycolysis and away from oxidative phosphorylation despite adequate oxygen, ie, aerobic glycolysis) and a stunning avoidance of apoptosis are standard features. However, bioenergetic flexibility is also prevalent in tumors. The consequences of the Warburg Effect may have benefits for tumors, but there are questions as to the ultimate mechanistic relevancy, and numerous controversies surrounding the Warburg Effect impacts remain [2].

Our work has done little to clarify this situation. Here we will show that tumor stress responses induce elements of glycolysis that correlate with tumor growth (and recurrence) [3]. We also show that tumors release extracellular vesicles (EVs), virus-sized membrane-enclosed particles, that can promote stress responses and push a glycolytic phenotype in both tumor cells and in the “normal” cells of the tumor microenvironment. The tumors we work with are high-grade gliomas such as glioblastomas (GBMs), the worst of the brain tumors with universally fatal outcomes. We hope to show here that tumor stress tends to eventually benefit the tumor, and may be tied to the altered metabolic states that coincide with resistance to therapies. On the other hand, using canine lung cancer cells, we do suggest that such stresses may “set up” the tumor for therapeutic interventions aimed directly at the stress response itself.

METHODS

Cell lines include U87MG (GBM, from ATCC); F3-8 and E8-5 (GBMs, UCD Neurosurgery); STAR line (K9 lung tumor, UCD Neurosurgery) [3] [4] [5]. Human tumor tissues and human normal brain samples were acquired in UCD Neurosurgery (COMIRB, protocol no. 13-3007). Exosomes/extracellular vesicles were collected by concentration, filtration, and differential centrifugation and were characterized by standard means [4].

Drug treatments with temozolomide and PU-H571 were as described [3] [5]. Metabolic studies were performed as described [3]. Two-photon microscopy was utilized to measure changes in bound/free NADH. Cells were stressed by heat shock (42degC, 2hrs) and by induction of the unfolded protein response (UPR) by treatment with 1mM DTT for 4 hrs [3] [5]. Cells were allowed to recover for 24 hrs.

Phospho-signaling and apoptosis arrays were performed as described; cell survival was measured by MTS assay and by soft agar colony formation [3] [4] [5].

RESULTS

We have shown that inducing stress such as the UPR can promote metabolic shifts in U87GBM cells (Fig 1) along with profound resistance to temozolomide, the standard-of-care chemotherapy for GBMs (Fig 2). Thus, stress induction, mirrored by metabolic changes, coincided with resistance to drug-driven apoptosis. However, in a canine lung cancer model, UPR induction followed by treatment with an HSP90/GRP94 inhibitor did result in reduced proliferation (with prolonged treatment, Fig 3). The apoptotic phenomena under stress were mostly muted, with survival characteristics enhanced (Fig 4), but overcome in targeted drugs. We also show that tumor EVs (F3-8) incubated on a human brain slice can shift the ratio of bound/free NADH, indicative of glycolysis on tumor cells themselves (Fig 6).

Fig 1: NMR-based quantitative metabolomics of U87MG cells in unstressed (red bars) vs UPR-stressed cells (blue bars)

Fig 2: Soft-agar assay measuring U87 MG colony growth after drug treatment, without (red) or with (blue) UPR stress induction

Fig 3: Soft-agar assay measuring STAR cell growth following standard conditions, heat shock, or UPR induction in the presence or absence of PU-H571, an inhibitor of HSP90/GRP94

DISCUSSION

Our results show that tumor stress can alter the metabolic phenotype of brain tumor cells and can engender those cells with therapeutic resistance. However, tumor stress may also put the tumor in a vulnerable setting, where inhibiting proteins that enable stress survival (eg, heat shock/chaperone proteins such as HSP90 and GRP94) may result in tumor cell death amidst the stress. Exosomes/EVs released by

Fig 5: 2-photon microscopy of EV-tx human brain slices showing phasor plot shift towards free NADH

Fig 4: Apoptosis array with expression changes in key apoptotic and anti-apoptosis proteins following UPR and/or drug therapy

Fig 6: Incubation of GBM EVs on GBM cells induces glycolysis

tumors may also affect the metabolic phenotypes of recipient cells, including normal cells of the tumor microenvironment. This adds layers of complexity to an already disturbing outlook for targeting metabolism or its apoptotic counterparts. Certainly Dr Pearce would love to generate equations describing these events.

Celebrating Dr. John Pearce's 70th Birthday

ABSTRACT

Thermal denaturation of proteins has significant impact on cell injury in focal cancer thermal therapies as well as fundamental studies of protein folding and unfolding. For focal therapies, Arrhenius kinetics is a simple yet widely used model to predict cell injury¹⁻³ up to 70 °C or 343 K. We have previously examined the kinetics of protein denaturation and found that the kinetic parameters including activation energy E_a (kcal/mol) and frequency factor A (s^{-1}) are correlated with each other, thus providing a simple method to fit the kinetic parameters from experimental data. Furthermore, we found that the activation energy tends to decrease when extending to higher temperatures⁴. However, the validity of Arrhenius kinetics extending beyond this temperature range (>70 °C or 343 K) or over a wide temperature range remains a long-standing fundamental question for focal therapy and protein unfolding. Previous experimental investigations of protein unfolding have been predominately conducted by small temperature perturbations (e.g. temperature jump spectroscopy), while molecular simulations are limited to small timescales (microseconds) and high temperatures to observe unfolding. Thus, it remains unclear how fast a protein unfolds across a large temperature range.

To examine the temperature dependent protein denaturation at high temperatures, we have recently developed a technique called molecular hyperthermia⁵ that uses nanosecond pulsed heating of individual plasmonic nanoparticles to create precise localized heating. Molecular hyperthermia generates very high temperatures (~85 % of critical temperature of water or 550 K) in a very localized region (nanometers), without any global temperature rise of the bulk solvent. Connecting this with protein unfolding measurements at low temperatures using temperature-jump experiments (T-jump)⁶, we observe that the kinetics of protein unfolding is less sensitive to temperature change at the higher temperatures, which significantly

departs from the Arrhenius behavior extrapolated from low temperatures. To account for this effect, we propose the use of a reaction-diffusion model⁷ that modifies the temperature-dependence of protein unfolding by introducing a diffusion limit. Analysis of the reaction-diffusion model provides general guidelines in the behavior of protein unfolding (reaction-limited, transition, diffusion-limited) across a large temperature range from physiological temperature to extremely high temperatures. The experimentally validated reaction-diffusion kinetics of protein unfolding is an important step towards understanding protein-unfolding kinetics over a large temperature range. It also calls for future studies to examine this model for other protein molecules.

HEATING PROTOCOL DESIGN AFFECTED BY THERMAL DAMAGE MODEL IN MAGNETIC NANOPARTICLE HYPERTHERMIA FOR CANCER TREATMENT

Manpreet Singh, Qimei Gu, Ronghui Ma, Liang Zhu

Baltimore, Maryland, USA

INTRODUCTION

Advancement in computational resources in recent years has allowed accurate theoretical simulation based on scanned images of tumors and nanoparticle concentration distribution in magnetic nanoparticle hyperthermia. This leads to determination of heating protocols for individualized designs specific for targeted tumors and their nanoparticle distributions.

Although many cell survival models have been developed and tested, the original Arrhenius integral developed by Henriques, often coupled with simulated temperature elevations in tumors during transient heat transfer process, has been used extensively in hyperthermia treatment to quantify extent of thermal damage in tumor regions. Recently, Pearce¹ observed that the Arrhenius model does not capture the initial shoulder region representing no cell death initially after heating starts. The Arrhenius model was then modified by Pearce to include a time-delay accounting for the initial cellular activities before cell apoptosis can occur.¹

In this study, we implement both the traditional Arrhenius model and the Pearce model in designing heating protocols for magnetic nanoparticle hyperthermia. MicroCT scans of tumors implanted on mice by prostatic cancer (PC3) cells are used to generate a realistic tumor physical model and a 3-D distribution of volumetric heat generation rate when the tumor is subject to an alternating magnetic field. Coupled with the temperature elevations in tumors, both thermal damage models are implemented to determine the heating time needed to induce thermal damage to the entire tumor.

METHODS

MicroCT scans of five resected PC3 tumors are used for this study, obtained from a previous study.² The microCT scan of the tumor was then used to generate a tumor physical model of a uniform

material.³ The tumor was then attached to a previously generated mouse body to mimic the situation in the original animal experiments.³ The volumetric heat generation rate distribution Q'''_{MNH} in each tumor was obtained from that in Gu et al.² The Pennes bioheat equation⁴ is the governing equation for simulating the transient temperature field during magnetic nanoparticle hyperthermia:

$$\rho_t c_t \frac{\partial T_t}{\partial t} = k_t \nabla^2 T_t + \omega_t \rho_b c_b (T_b - T_t) + Q'''_{met,t} \quad (1)$$

$$\rho_c c_c \frac{\partial T_c}{\partial t} = k_c \nabla^2 T_c + \omega_c \rho_b c_b (T_b - T_c) + Q'''_{met,c} + Q'''_{MNH} \quad (2)$$

where subscripts t and c denote tissue and cancer, respectively. Magnetic nanoparticles are only deposited in the cancer region. All the thermal properties such as density ρ , specific heat c , thermal conductivity k , blood perfusion rate ω , boundary conditions, and initial condition are the same as that in Lebrun et al.³

The thermal damage at any tumor location is assessed by the following equation:

$$\Omega(x, y, z, \tau) = A \int_0^{\tau} \exp \left[-\frac{E_a}{R_u T_c(x, y, z, t)} \right] dt - A \int_0^{\tau_d} \exp \left[-\frac{E_a}{R_u T_c(x, y, z, t)} \right] dt \quad (3)$$

where the time delay τ_d either is zero for the traditional Arrhenius model, or is temperature-dependent in the Pearce model¹ as:

$$\tau_d = 2703 - 49.6 * T(x, y, z, t) \quad (4)$$

where the coefficients in Eq. 4 are specific to the PC3 cells. Note that the temperature in Eq. 4 is in Celsius. The designed heating time for causing permanent damage to the entire tumor is determined when Ω is larger than or equal to 4 in the tumor.

Implementing Eq.3 and Eq.4 in simulation is difficult since the time delay depends on local tumor temperature that keeps changing

with time. Examining Eq. 3, one finds that the heating time is determined by the tumor location with the lowest temperature. In this study, we first simulated the steady temperature to determine the tumor location with the lowest value. Then, we performed the simulation of the transient heat transfer process to determine the temperature rising curve verse time at this tumor location. The temperature rising was finally plotted with the curve of Eq. 4. It yields an intersection between those two curves, which gave the time delay τ_d . All the simulations were performed by COMSOL software.

RESULTS

Figure 1 gives the color contours of the generated volumetric heat generation rates on a cross-sectional plane, induced by the magnetic nanoparticles deposited inside the five tumors. The physical model of the mouse with an attached tumor is shown in Figure 2.

Figure 1: Generated volumetric heat generation rate (W/m^3) on a cross-sectional plane in the five tumor models in COMSOL.

Figure 2: A simplified mouse model with an attached tumor.

Color contours of the simulated steady state temperature fields are illustrated in Figure 3. Most of the elevations occur in the tumor region, however, there is some heat conduction from the tumor to the mouse body. The maximal temperature inside the five tumors varies from 68.77°C to 77.91°C . The location of the lowest temperature inside each tumor is also identified at the interface between the tumor and mouse body. Figure 4 shows how the time delay for this location is determined in one tumor. The time delay calculated as 494 seconds, from the intersection of the two curves in Figure 4. The time delay varies from 346 to 534 seconds in the tumor group.

The heating time required to damage the entire tumor is listed in Table 1 using both the traditional Arrhenius integral and Pearce modified model with a time delay. It is interesting to see that both thermal damage models give very similar results. The Pearce thermal damage model leads to a longer time than that predicted by the traditional Arrhenius model, with less than 6% increase in the designed heating time. This may be due to the relatively large temperature elevations in the tumor, and typically heating time required is dramatically reduced when the temperature is much higher than 43°C . Showing in Figure 4, during the initial heating period before the apoptosis occurs ($t < \tau_d$), tumor temperature is low, around 44.5°C ($45.6 \pm 1.7^\circ\text{C}$ in the tumor group). When one uses the traditional Arrhenius model, the accumulative thermal damage within the initial time delay duration, shown by the second term on the right of Eq. 3, is small, around 0.36 ± 0.08 . Later the tumor temperature increases significantly to $50.36 \pm 2.87^\circ\text{C}$. To compensate the unaccounted initial

thermal damage (2^{nd} term on the right of Eq. 3) in the Pearce model, a longer heating time is needed than that in the traditional Arrhenius model. For tumor 1, the steady state temperature at the lowest temperature location is around 47.3°C , the required heating duration is 104 s (1.73 min) longer than that predicted by the traditional Arrhenius model.

Figure 3: Steady state temperature field on a cross-sectional plane in both the tumor and its surrounding mouse body.

Figure 4: A typical temperature rising curve verse time at a tumor location, and the time delay relationship in Eq.4.

Table 1: Determined heating time (minutes) to damage the entire tumor using both thermal damage models.

	Tumor 1	Tumor 2	Tumor 3	Tumor 4	Tumor 5
Traditional	33.13	22.35	36.00	15.05	14.72
Pearce	34.87	23.24	37.44	15.82	15.34
	5.25%	3.98%	4%	5.12%	4.21%

SUMMARY

In this study, both the traditional Arrhenius model and Pearce model are implemented to quantify tumor thermal damage in magnetic nanoparticle hyperthermia. Theoretical simulations are performed to predict transient temperature elevations in five PC3 tumors implanted on the flank of a mouse model. Previously obtained volumetric heat generation rate distribution due to injected nanoparticles in the tumors is implemented to induce temperature rise. To damage the entire tumor, the traditional Arrhenius model predicts that the average heating time needed is 24.24 minutes, similar to that in our previous study. The modified damage model by Pearce excluding the thermal damage in an initial time delay leads to a minor increase in the required heating time as 25.34 minutes. The mild effect may be due to the relatively high tumor temperature achieved in the tumors. The effect of the modified damage model may be significant when the temperature elevation is modest from 37°C .

INTRODUCTION

Despite the phenomenal level of reliability of heart valves, more than five million people are diagnosed with valvular disease in the United States each year, with approximately 95,000 annular valve replacement surgeries and 20,000 mortalities per year [1]. Though ring annuloplasty for mitral regurgitation is beneficial in the short-term, it has been shown to be less promising in the long term, with repair failure as high as 60% [2-3]. Mechanical stress is a strong etiological factor: alterations in mechanical loading caused by surgical repair lead to stress-induced changes in mitral valve interstitial cell (MVIC) function that affect both tissue structure and composition, ultimately leading to repair failure. In this work, we develop a robust experimental-computational approach that allows us to answer specific questions on mitral valve (MV) mechanobiology and provides insight into the micromechanics of surgically repaired valves. This work is thus three-fold: the first part focuses on the design and development of a planar biaxial bioreactor system. The second part involves the use of an established finite element model of the mitral valve [4] to estimate *in vitro* pre-stresses and functional stresses before and after different surgical repair scenarios. We then use the biaxial bioreactor system to apply the estimated stresses to stimulate MV samples and follow-up with downstream biological assessments of the valves.

METHODS

Biaxial bioreactor design and development: In brief, a biaxial stretch device was developed to replicate the complex physiological biaxial strains of the MV. The design consists of four linear actuators and two load cells, one on each axis. A four-pillared stacking system in the middle of the system holds the specimen chamber, which is made of wear-resistant and temperature-stable polysulfone (**Fig. 2A-C**).

Figure 1. A model-driven experimental design: simulations of MVIC nuclear aspect ratio (NAR) using a macro-micro finite element model from [5] to drive experiments in the BBR.

Figure 2. (A) Biaxial bioreactor system. (B) Top view of specimen chamber, (C) Tissue attachment system (tissue phantom in blue).

Estimating *in-vivo* stresses: The estimated stresses from the finite element inverse modeling framework (**Fig. 2**) are reported in **Table 1**. To emulate the physiological environment, pre-stresses are applied to the samples. Samples are then cyclic stretched from pre-stress to normal

physiological stress. Two groups were used in the bioreactor studies: (1) Normal/Physiological and (2) Post-Ring Repair.

Tissue preparation and bioreactor treatment: Fresh ovine hearts were collected from lamb (6-10 months, 150-175 lbs.) from a local USDA approved abattoir (Mercantile Meat Processing Company, Utopia, Texas) within 30 minutes of slaughter. MV anterior leaflets (MVAL) were isolated on-site and submerged in ice-cold Hypothermosol FRS (Sigma-Aldrich, St. Louis, MO) for transport to the laboratory. Once in the laboratory, cruciform shaped samples (5-7 mm \times 3-4 mm, circumferential \times radial) were dissected from the clear zone of the anterior leaflet and mounted onto the specimen chambers. Control samples were acquired using the same approach. Samples were cut from the clear zone of the anterior leaflets, snap frozen with liquid nitrogen, and stored at -80°C. For each bioreactor treatment group, 3 (n = 3) MVs were used. Each specimen chamber was filled with 12 mL of media. The specimen chamber was then attached to the system base of each bioreactor housed within the incubator (37°C, 5% CO₂). Samples were then stretched for a total of 48 hours.

ECM Biosynthesis and Cell activation: Samples were fixed with formalin, embedded in paraffin, sectioned (5µm), and stained with Movat pentachrome to analyze layer-specific morphological changes. Staining for α -SMA was performed to quantify VIC activation. Collagen, elastin, and glycosaminoglycan content were quantified using the Sircol, Fastin, and Blyscan assays, respectively.

RESULTS

Mitral valve interstitial cell deformation under normal/physiological stress: In some of our more recent work, we identified MV interstitial cell deformation as a key player in leaflet tissue homeostatic regulation and as such, used it as the metric that makes the critical link between *in vitro* responses to simulated equivalent *in vivo* behavior [5]. Similarly, in this work, we use MVIC deformation to make the same link. We first quantified the nuclear aspect ratio (NAR) in the control ovine samples (juvenile) as well as the NAR in the pre-stress state and the normal/physiological state.

Figure 3. Extracellular matrix composition for the three groups: (1) Control, (2) Normal Stress, and (3) Post-Flat Ring Annuloplasty Stress. All bar graphs, mean \pm SEM, n = 3. ECM content (s-GAG, collagen, and elastin) quantified with colorimetric assays is presented in µg/mg dry weight. (a) collagen, (2) sGAG, (3) elastin.

Biosynthetic response: homeostasis and ring repair: The Sircol assay demonstrates that although there appears to be a decrease in acid-epsin soluble collagen after biaxial bioreactor treatment under post-annuloplasty ring stresses, from 34.31 ± 4.97 µg/mg DW (dry weight) for the control group to 27.47 ± 1.90 µg/mg DW, such a difference is not statistically significant ($p > 0.05$). The Sircol assay also demonstrates that the normal stress group has a relatively similar ($p > 0.05$) amount of collagen to the control group, 35.93 ± 4.96 µg/mg DW and 34.31 ± 4.97 µg/mg DW, respectively (**Fig. 3a**). Blyscan results indicate that the amount of sulfated glycosaminoglycans remains relatively the same after a 48-hr bioreactor treatment under normal physiological stress, whereby the sGAG content is 7.46 ± 0.51 µg/mg

DW and 7.80 ± 0.18 µg/mg DW for the control and normal stress groups, respectively. This said, there is a statistically significant drop in sGAG content after a bioreactor treatment under post-flat ring repair stresses ($p < 0.05$), whereby the sGAG content is 5.88 ± 0.04 µg/mg DW (**Fig. 3b**). The Fastin colorimetric assay indicates that the elastin content, though it changes, is not statistically different across the three groups: 19.10 ± 3.73 µg/mg DW, 22.10 ± 2.23 µg/mg DW, 18.91 ± 3.23 µg/mg DW for the control, normal stress, and ring stress groups, respectively (**Fig. 3c**).

Figure 4. Soluble collagen and sGAG synthesis related to MVIC nuclear aspect ratio. Results from our recent work on MVIC biosynthesis under stretch [5] compared to results from this study.

Mitral valve interstitial cell phenotypic activation after ring stress treatment: Phenotypic activation of VICs is characterized by an upregulation of α -SMA, whereby MVICs become myofibroblast-like and begin to actively remodel the ECM, highlighting the fact that VIC phenotypic state is linked to the remodeling demands of the tissue. The SMA stains shows that the level of phenotypic activation of valve interstitial cells in the control group is similar to the one in the normal stress group. The ring stress group stains, however, show a clear decrease in SMA, highlighting a decreased phenotypic activation after a lower stress level stimulation for 48 hours in the bioreactor.

DISCUSSION

The integrated experimental-computational approach presented in this work allowed us to truly emulate *in vivo* loading conditions and reproduce *in vivo* cellular deformations, quantified by the NAR, in our *in vitro* biaxial bioreactor system. We were able to bridge the crucial gap between the *in vivo* functional and *in vitro* experimental configurations by applying pre-stresses estimated from the inverse modeling framework [4], and also subsequently applied normal/physiological stresses. Most importantly, we were able to validate our hypothesis that cell deformation, more specifically, nuclear deformation is the main driver for VIC mechanobiological response. Our approach can, in the future, serve as a platform for identifying biomechanical treatments that optimize surgical repair and elucidate mechanisms of disease progression.

RESTRICTION OF ANNULUS MOVEMENT ALTERS THE DYNAMIC DEFORMATION AND STRAIN DISTRIBUTION OF THE TRICUSPID VALVE LEAFLETS: A SIMULATION STUDY

Keyvan Amini Khoiy, Rouzbeh Amini

Biomedical Engineering Department
The University of Akron
Akron, Ohio, USA

INTRODUCTION

In order to develop new surgical techniques for tricuspid valve (TV) repair and improve the available strategies, it is necessary to have an accurate FE model for the TV. Such a model can be used to simulate surgical procedures and predict the outcomes before the surgery is performed, helping the surgeon to preplan the procedure so as to maximize the quality of the result. This model could also be used in the development of new prosthetic heart valves that can more accurately mimic the behavior of a native valve. Such a development will facilitate in-silico examination of valve repair techniques and will aid in predicting alterations in the biomechanical behavior of TV following such surgeries. While a couple of finite element (FE) models of TV are presented in the literature [1, 2], no study has simulated the effects of TV environmental changes (due to surgeries or diseases) on its mechanical behavior.

In our previous studies [3, 4], a material model was developed to represent the mechanical behavior of the TV in response to estimated environmental strains due to the transvalvular pressures. Moreover, using sonomicrometry, we were able to measure TV annulus and septal leaflet deformations [5]. In the current study, we have utilized our previous studies to establish an FE model of TV to simulate the valve mechanical behavior. We then used this FE model to evaluate the effects of restricting the annulus movement (which normally happens during rigid ring annuloplasty) on TV deformations and strain distributions.

METHODS

The average sonocrystal positional data of the annulus obtained using sonomicrometry [5] were used to reconstruct the three-dimensional geometry of the annulus, and the valve apparatus were reconstructed on top of the annulus geometry using the measurements taken from excised porcine TVs (Figure 1). The number of chordae

connected to the free edge and on the ventricular surface of each leaflet were also counted and included in the model (Figure 2 a).

Figure 1: Dimensions used in TV geometry development, anterior segment length (ASL), posterior segment length (PSL), septal segment length (SSL), anterior leaflet height (ALH), posterior leaflet height (PLH), septal leaflet height (SLH), anteroposterior commissure height (ACH), posteroseptal commissure height (PCH), and anteroposterior commissure height (SCH).

The TV was assumed to have three papillary muscles, each considered as a single point in which all the chordae of that area merge. The positions of these points were chosen based on the observations made for porcine heart TVs. First-order chordae (chordae on the edges) were assumed to be distributed uniformly along the edge for each leaflet. Second-order chordae (chordae on the leaflets) were assumed to be uniformly distributed on the surface of each leaflet and positioned at a distance about one-third of the total leaflet length from the leaflet distal (free) edges.

The developed TV geometry (Figure 2a) was imported into Abaqus (Dassault Systèmes, Vélizy-Villacoublay, France) for FE modeling. A

structured technique was implemented to mesh the leaflets using standard linear quadratic-shape shell elements with an approximate global size of 0.5 mm while the thicknesses of the anterior, posterior, and septal leaflets were considered to be 0.313 mm, 0.346 mm, and 0.491 mm, respectively [3]. The chordae were meshed using standard linear truss elements with an approximate global size of 7 mm and a cross-sectional area of 0.171 mm² [1, 6] (Figure 2b).

Figure 2: (a) Developed TV geometry, (b) finite element mesh, (c) computerized model, including loading and boundary conditions.

A linear elastic model with parameters (modulus of elasticity = 0.4 MPa, Poisson's ratio = 0.45) obtained from the literature [7] was used to represent the mechanical responses of the leaflets. Chordae tendineae mechanical response was modeled using an isotropic hyperelastic Ogden material model [2]. The papillary muscles were considered to be fixed and the time dependent relative transvalvular pressures was applied on the surface of the leaflets (Figure 2 c).

In the first simulation, previously quantified dynamic deformation of the annulus was imposed as the boundary condition and the closure of the valve was simulated. Then, the annulus was kept fixed to mimic the ring annuloplasty and the simulation was repeated.

RESULTS

The developed model was used to simulate the closure of TV. In Figure 3 the deformation of the valve during the simulation is illustrated at different time points.

Figure 3: Maximum in-plane principal strain distribution illustrated over the anterior (A), posterior (P), and septal (S) valve leaflets during the valve closure simulation.

The color map in this figure shows the maximum in-plane principal strain distribution. The maximum principal strain was under 25% for most locations, and the strains appeared to be uniform at the belly areas over the surface of the leaflets. The strains in the belly area of the septal leaflet ranged from approximately 8 to 15%.

The simulation resulted in maximum in-plane principal stresses as high as 120 kPa. The distribution of the stresses shows that the anterior leaflet experiences the highest stress, while the septal leaflet experiences the lowest stress.

Figure 4 shows the comparison between the strain distribution of the septal leaflet for the simulation with a fixed annulus and the simulation with moving annulus boundary conditions.

Figure 4: Comparison of effects of changes in the annulus boundary conditions on the strain distribution and deformations of the septal leaflet.

DISCUSSION

We used a finite element model to examine the effect of annular restrictions on TV leaflet deformation. The septal leaflet maximum in-plane principal strain distribution from the simulation (~8 – 15%) was comparable to the values we measured experimentally (~11%) [5]. Moreover, the levels of the stresses in the FE model (120 kPa) were analogous to the estimated values for normal physiological stress levels on the leaflet surfaces [3] from the biaxial experiments (the values ranged roughly from 80 kPa for the septal leaflet to 130 kPa for the anterior leaflet).

As shown in Figure 4, there was a slight increase in the range of the strains in the belly area following annular restriction. However, for the areas in the proximity of the commissures, the strain distributions and the leaflet deformations were notably altered. This alteration in the strain distribution and leaflet deformation indicated that changes in the normal biomechanical environment of TV (due to valvular treatments or diseases) can affect the valve mechanical responses, leading to potential tissue degeneration and long-term valvular failure.

INTRODUCTION

The tricuspid leaflets are an integral part of the tricuspid valve apparatus that directs blood from the right atrium into the right ventricle and prevents regurgitant blood flow from the right ventricle to the right atrium. Between the open and closed states of the valve, the leaflets undergo very large deformations and experience large strains. However, exactly how large these strains are is currently unknown because they have never been directly measured *in vivo*. Knowledge of these strains is not only important to our basic understanding of tricuspid valve function, it could also be important for diagnostic purposes. Specifically, the leaflet strains are a result of the transvalvular pressure, contraction of the peri-valvular tissue and, indirectly via the chordae tendineae, of ventricular contractions. Thus, deviations from normal strains may be indicative of disease of any of these structures or could be predictive of future disease. The purpose of this current study is to establish a baseline measurement of the tricuspid valve leaflet strains.

Figure 1: Schematic of tricuspid valve leaflets with sonomicrometry crystals on annulus and leaflets. Blue delineates the leaflet belly region, while red delineates the leaflet free edge.

The black lines illustrate the full leaflet triangulation that will later be used in combination with a subdivision scheme to create smooth leaflet surfaces.

METHODS

To determine *in vivo* strains in the tricuspid valve leaflets, we implanted sonomicrometry crystals around the tricuspid valve annulus (6) and on each tricuspid valve leaflet (12, 4 per leaflet) of five sheep in an open heart surgery, see Figure 1. After weaning the animals off cardiopulmonary bypass, we recorded the crystal locations throughout the cardiac cycle alongside hemodynamic data in the beating hearts under open pericardium, open chest conditions.

We computed *in vivo* strains by first interpolating crystal locations in the reference configuration and the deformed configuration via linear shape functions, viz.,

$$\mathbf{X}(\theta^1, \theta^2) = \sum_{I=1}^n N_I(\theta^1, \theta^2) \mathbf{X}_I, \mathbf{x}(\theta^1, \theta^2) = \sum_{I=1}^n N_I(\theta^1, \theta^2) \mathbf{x}_I. \quad (1)$$

Here, $N_I(\theta^1, \theta^2)$ are aforementioned linear shape functions, and \mathbf{X}_I and \mathbf{x}_I are the crystal coordinates in the reference configuration (at end-diastole) and spatial configuration, respectively. Based on the partial derivatives of the shape functions, we next computed the covariant base vectors in both configurations,

$$\mathbf{G}_\alpha(\theta^1, \theta^2) = \sum_{I=1}^n \partial N_I / \partial \theta^\alpha \mathbf{X}_I, \mathbf{g}_\alpha(\theta^1, \theta^2) = \sum_{I=1}^n \partial N_I / \partial \theta^\alpha \mathbf{x}_I, \quad (2)$$

while we determined the contravariant counterparts to the above bases via the covariant surface metric in the reference configuration $G_{\alpha\beta} = \mathbf{G}_\alpha \cdot \mathbf{G}_\beta$, i.e.,

$$\mathbf{G}^\alpha = G^{\alpha\beta} \mathbf{G}_\beta, \text{ where } G^{\alpha\beta} = G_{\alpha\beta}^{-1}, \text{ with } \alpha, \beta = 1, 2 \quad (3)$$

and via the covariant surface metric in the current configuration $g_{\alpha\beta} = \mathbf{g}_\alpha \cdot \mathbf{g}_\beta$, i.e.,

$$\mathbf{g}^\alpha = g^{\alpha\beta} \mathbf{g}_\beta, \text{ where } g^{\alpha\beta} = g_{\alpha\beta}^{-1}. \quad (4)$$

Moreover, we computed the Green-Lagrange strain tensor as,

$$\mathbf{E} = E_{\alpha\beta} \mathbf{G}^\alpha \otimes \mathbf{G}^\beta, \text{ where } E_{\alpha\beta} = \frac{1}{2} [g_{\alpha\beta} - G_{\alpha\beta}]. \quad (5)$$

RESULTS

We included five animals in our study which all recovered well after coming off bypass, i.e., their hemodynamic data normalized before we record crystal coordinates. Based on our finite kinematic approach, we calculated area strain, radial strain, and circumferential strain in the bellies and the free edges of each leaflet and illustrated them throughout the normalized cardiac cycle. Because of space limitations, we are showing the results for the anterior leaflet only, see Figure 2A. These data demonstrate that strains varied throughout the cardiac cycle. They were largest during systole when the transvalvular pressure is highest, and were minimal during diastole. Also, the strain data demonstrates heterogeneity in radial and circumferential strains, between the belly region and the leaflet region, as well as anisotropy between the two strains. Specifically, strains were overall larger in the radial direction than in the circumferential direction.

Figure 2: A) Area strain, radial strain, and circumferential strain in the belly and free edge of the anterior leaflet throughout the cardiac cycle. B) Area strain, radial strain, and circumferential strain across the entire anterior leaflet surface between end-diastole and end-isovolumetric contraction. The surface reconstruction is based on the Loop triangular subdivision surface algorithm and an iterative optimization method to ensure that the surfaces interpolate the original crystal coordinates. C) Comparison of peak strains between leaflets, strain types, and leaflet regions.

Additionally, we illustrate all strain types across the entire anterior leaflet surface. The grey configuration in Figure 2B is end-diastole, while we show the strain contours on the leaflet state at end-isovolumetric contraction. All strains show significant heterogeneity with the largest strains either in the leaflet belly or at the free edge, see Figure 2B. Note, strains toward the annulus are likely negative due to annular contraction during systole.

Finally, in Figure 2C, we show a comparison between leaflets, types of strain, and leaflet regions in terms of peak strain, i.e., the largest strain throughout the cardiac cycle. Using a three-way ANOVA (which included “subject” as a random effect), we found that strains are significantly larger in the anterior leaflet ($p=0.003$) and that strains are larger in the radial direction than in the circumferential direction ($p=0.044$).

DISCUSSION

This is the first time direct measurements of *in vivo* tricuspid leaflet strains have been reported. All previous strain measurements have been performed in an *in vitro* right heart simulator [1], an *in vitro* beating heart model [2], or through computational simulations [3]. Interestingly, our measurements are not well-aligned with previous data. Specifically, our strains are larger than those reported in the *in vitro* beating heart model by Khoiy et al. (who only reported strains in the septal leaflet) [1]. Additionally, our findings contradict those made in the *in vitro* right heart simulator by Spinner et al. [2]. In detail, our strains in the anterior leaflet exceed Spinner et al.’s, while our measurements in the posterior leaflets are smaller. Although comparison to *in silico* findings by Kong et al. is challenging as they did not report quantitative data, analysis of their strain maps shows relatively good agreement with our data in that their strains are largest in the anterior leaflet (agreeing with us) and that peak strains are as large as ~50% [3]. However, in contrast to us, they found circumferential strains to be larger than radial strains. Note, a comparison between the three studies is difficult, among other reasons, as they used different methodologies. Additionally, all measurements have been made in different species. Hence, to gain more confidence in our findings and shed additional light on the strains in the tricuspid valve leaflets, more work is needed. Specifically, we are planning to include more animals in our study to improve confidence. Also, our methodology should be applied to other species to allow for better comparison to previous data.

In conclusion, for the first time, we report *in vivo* strains in the tricuspid valve leaflets. Combining sonomicrometry with a finite strain kinematic framework, we computed area, radial, and circumferential strains across the entire leaflet surfaces and throughout the full cardiac cycle. We found that strains were significantly larger in the anterior leaflet than in the posterior or septal leaflets and that radial strains were larger than circumferential strains. We believe our work is another important step toward a deepened understanding of the tricuspid valve leaflets, which will aid our basic scientific understanding of the valve itself and better inform future surgical and technological strategies toward tricuspid valve repair.

INTRODUCTION

Surgical repair by undersized ring annuloplasty remains one of the most common methods of treatment for ischemic mitral regurgitation (IMR) [1]. Although usually successful, reports indicate recurrence of moderate to severe MR in approximately one third of treated patients within 12 months of surgery [2]. A recognized cause of recurrent MR after annuloplasty is ring dehiscence, and is estimated to underlie 13-42% of reoperations for failed annuloplasty repairs [3]. This phenomenon challenges repair durability, and occurs when mechanical loading on sutures attaching the annuloplasty ring to the mitral annulus pull out from the tissue. Its consequences are often severe, and can include device migration, embolization, endocarditis and increased patient morbidity. Clinical reports have indicated dehiscence to be more common along the posterior annulus [4].

Previous studies establish that the forces experienced by the annuloplasty sutures are influenced by ring design (shape, stiffness), ring-annulus sizing, suture position and region. These studies suggest that suture retention could be improved by incorporating flexibility in novel ring designs. Despite these advantages of flexibility, rigidity is required to restore normal annular geometry in IMR patients who have undergone significant annular distortions. As such, in pursuit of an optimized ring design, we present a novel materially heterogeneous ring that could incorporate benefits of flexibility and rigidity. We hypothesize that the segmental flexibility of this ring will reduce loading on the posterior annulus like the flexible ring, while maintaining minimal loss to the repair efficacy of a rigid saddle-shaped ring.

METHODS

Creation of novel heterogeneous annuloplasty ring. Materially heterogeneous rings were created with rigid anterior and posterior, and flexible commissural segments. These rings were created to match the geometry of the Profile 3D ring (Medtronic, Dublin, Ireland). Profile 3D rings of three ring sizes (24, 26 and 28) were subjected to micro-computed tomography (μ CT) imaging in a Siemens Inveon scanner (Siemens Medical Solutions USA, Inc., Malvern, PA). These images were segmented, smoothed and reconstructed to obtain the ring

geometry. For each ring size, molds were designed in SolidWorks (Dassault Systemes, Waltham, MA) and 3D printed from Clear Resin material (Formlabs, Boston, MA) at 0.001" resolution (3D Printing Tech, Atlanta, GA). Rigid cores were designed in SolidWorks and 3D printed from titanium (Ti-6Al-4V) via direct metal laser sintering (resolution < 0.001"). Heterogeneous rings of each size were overmolded atop the titanium inserts with a fast-setting silicone (shore hardness: A40).

Suture force transducers and annuloplasty ring attachment.

Each ring was instrumented with 10 custom suture force transducers. These transducers are strain gage-based, designed to report tension on each individual suture as a positive force. The transducer positions around the ring circumference represented mitral annular positions with one transducer on each of the left and right trigones, one each on the antero-lateral (3 o'clock) and postero-medial (9 o'clock) commissures, two on the inter-trigonal positions (11 and 1 o'clock) of the anterior annulus, and four on the inter-commissural positions of the posterior annulus (4, 5, 7 and 8 o'clock).

In-vivo testing and surgical protocol. The instrumented rings were tested in 6 healthy Dorsett hybrid sheep.

Prior to cardiopulmonary bypass, epicardial 2-D, 3-D echocardiography and Doppler were collected to assess ventricular function, transmitral gradients and MR grade. After establishment of bypass, each animal's mitral annulus size was measured, and the ring was selected to undersize the animal's mitral valve by two sizes. Ten mattress sutures (2-0 Ticron with Y-31 needles, Covidien, Mansfield, MA) were placed around the mitral annulus, and through the mounting holes of the transducer. After left atrial closure, the animal was weaned from bypass, and Doppler, 2-D, and 3-D echocardiography were collected to assess ventricular function, transmitral gradients and mitral regurgitation (MR) grade. Cyclic suture forces (F_c) were then recorded during cardiac cycles with a maximum LVP (LVP_{max}) of 100, 125, and 150 mmHg. F_c was compared to previously reported values with the fully-rigid Profile 3D [5] and fully-flexible prototype [6] rings.

All animals received care according to protocols approved by the Institutional Animal Care and Use Committee at the University of Pennsylvania, and in compliance with the guidelines for humane care.

RESULTS

Fc was observed to increase with increasing levels of LVP_{max}. In healthy subjects mean Fc increased with LVP, from 1.38 ± 0.97 N (100 mmHg), to 1.61 ± 1.12 N (125 mmHg), and 1.80 ± 1.24 N (150 mmHg). Averaged over 6 subjects, the maximum and minimum Fc's were 3.09 ± 1.38 and 0.90 ± 0.60 N and again located at 1 and 9 o'clock, respectively.

Figure 1: Suture force (Fc) in healthy subjects for each LVP_{max} at all suture positions. Shown: Fc mean \pm standard deviation (N).

Grouped Fc are presented at the right, Left trigone – right trigone, ant (anterior); 3 and 9 o'clock, com (commissural); and 4-8 o'clock, pos (posterior).

In comparison to homogeneous fully-rigid Profile 3D and fully-flexible prototype rings in healthy subjects, use of the heterogeneous ring overall decreased mean Fc by 0.50N from the fully-rigid Profile 3D case (2.10 ± 1.08 N vs 1.60 ± 1.12 N), and Fc was overall similar to fully-flexible prototype ring (1.58 ± 1.25 N vs 1.60 ± 1.12 N). ANOVA indicated pair wise differences between the fully-rigid Profile 3D and heterogeneous ring ($p < 0.001$), but non-significance between the heterogeneous and fully-flexible prototype.

Figure 2: Comparison of heterogeneous ring suture force (Fc) data with that of previously measured rings fully-rigid Profile 3D, and fully-flexible prototype ANOVA results (A) Main effects of ring type, (B) Interaction effects of ring type and suture region. Plots indicate Fc means and 95% confidence intervals (N); pairs whose 95% confidence intervals do not overlap differ significantly ($p < 0.05$).

DISCUSSION

This ring design featured rigid anterior and posterior segments interspersed by flexible commissural segments. As a whole, its construction was more similar to the fully-rigid alternative than to the fully-flexible (with its rigid titanium cores occupying approximately 60% of its circumference). Yet, in terms of the observed Fc dynamics, its performance more closely matched that of the fully-flexible ring. Across all suture positions, mean Fc when using the heterogeneous ring was 24% ($p < 0.001$) lower than when using the fully-rigid ring, but only

1.27% ($p = 0.851$) higher when using the fully-flexible ring. Examining these same comparisons by region, we observe all three rings agreed within 8% in the anterior region. These suggests that suture loading in this region is primarily driven by the cardiac motion itself rather than by the ring construct. In the commissural region, the heterogeneous ring reduced Fc by 0.86 N ($p < 0.001$) vs. the fully-rigid but increased by 0.22 N ($p = 0.420$) vs. the fully-flexible. This significant reduction was likely a direct result of the heterogeneous ring's flexible commissural segments. Finally, in the posterior region, the heterogeneous ring reduced Fc by 32% ($p < 0.001$) vs. the fully-rigid but increased by 4.7 % ($p = 0.420$) vs. the fully flexible. This further reduction was likely an indirect result of the flexible commissural segments.

Ongoing experiments with the heterogeneous ring in diseased IMR subjects indicate Fc dynamics follow similar trends. Overall Fc is significantly less than those observed in healthy subjects (1.29 ± 0.63 N vs 1.60 ± 1.12 N, $p < 0.01$). These initial findings show that repair effectiveness of mitral regurgitation was 100% in all IMR subjects as their MR grade moved from 2+ or 3+ before ring implantation to none after surgical repair.

Successively, while the flexible commissural segments of the heterogeneous ring confer a benefit by reducing posterior suture loads relative to the fully-rigid case, the rigid posterior will simultaneously confer a benefit relative to the fully-flexible case, by enabling more effective downsizing of dilated mitral annuli. This is demonstrated by the elimination of MR in preliminary IMR subjects. Additionally, the rigid, saddle-shaped anterior segment is likely to benefit leaflet curvature and coaptation and decrease leaflet stress.

A few limitations specific to this novel ring and its comparisons with other rings should be noted. The rigid sensors likely caused stiffening across all positions for all rings. Particularly the case for flexible ring material, thus the benefits to Fc of ring flexibility may be even greater than we were able to detect. Nonetheless, manual manipulation of the instrumented rings revealed this effect to be relatively small. Furthermore, the fully-flexible prototype ring had a flat geometry based on the Physio ring (Edwards LifeSciences, Irvine, CA) and this could potentially confound the intended force comparisons between ring types. However, previous investigation comparing the saddle-shaped Profile 3D and flat Physio rings observed no differences in mean Fc between these geometries [5]. Additionally, given all subjects were terminal, long term repair efficacy with this ring type was not evaluated.

Overall this study demonstrates that a materially heterogeneous annuloplasty ring can reduce loading on the structurally weaker posterior annulus, without compromising repair efficacy suggesting a positive approach to reduce the potential of harm associated with suture dehiscence.

INTRODUCTION

The non-physiologic mechanical loads that vascular stents place on arterial tissue have been identified as contributing factors for the failure of these devices due to neointimal hyperplasia and stent thrombosis [1, 2]. Indeed, computational models evaluating the post-stent mechanical environments in generalized vascular geometries have provided insight on the role of mechanics in stent failure. However, current understanding of the impact of mechanics in device failure at the lesion-specific level, and the development of pre-interventional planning strategies, is limited in the clinical setting. This shortcoming is a direct result of the lack of understanding of the post-deployment stent and vessel geometry at the required resolution for modeling efforts. Towards the development of lesion-specific stenting strategies, we recently development and validated a framework to reconstruct the 3D post-deployed stent geometry through the fusion of optical coherence tomography (OCT) and micro-computed tomography (μ CT) image data in a well-controlled experimental setup [3].

To advance this research into the clinical setting, the aim of this investigation was to extend the established framework and reconstruct the *in vivo* 3D post-deployed stent geometry through the fusion of angiographic and OCT imaging data.

METHODS

Clinical Data Biplane coronary angiography and OCT image data from patients ($n = 2$) undergoing percutaneous coronary intervention for treatment of a flow limiting lesion were retrospectively analyzed. An Integrity[®] BMS (ID: 3.0 mm, length: 18 mm; Medtronic, Minneapolis, MN) was implanted in the mid-left anterior descending (LAD) coronary artery in one patient, and the other patient had a Xience Alpine[™] (ID: 3.0 mm, length: 42 mm; Abbott Vascular, Santa Clara, CA) also implanted in the mid-LAD.

OCT Stent Strut Detection and Angular Drift Correction Stent struts were automatically identified in the OCT image data utilizing a modified version of a previously described algorithm [3]. Briefly, raw 16-bit OCT image data were windowed to remove the catheter and perivascular image data and axial-lines (A-lines) were classified as containing a stent strut or the lumen boundary based on unique signal characteristics (e.g., peak prominence, intensity decay, width of signal). Strut centroids were determined by adjoining contiguous strut define A-lines and accounting for strut thickness. Application of the A-line classification scheme to all images in the OCT pullback resulted in a 3D point cloud of the deployed stent (OCT_{PC}).

Upon examination of the OCT_{PC}, an angular (circumferential) drift in the orientation of the OCT images was observed. As the stent reconstruction algorithm is dependent on an accurate orientation of OCT-derived stent struts, the relationship between curvature and angular drift, which has been noted previously in intravascular ultrasound image data [4], was investigated to establish a *correction factor* for fusion with angiography data. A torsion-free (i.e., planar) experimental test bed, consisting of four 2 mm-wide, 'U'-shaped channels of constant curvature ($\kappa = 0, 1/60, 1/30, 1/20 \text{ mm}^{-1}$) at least 54 mm long, was manufactured out of Delrin[®] using a CNC-machine (Fig. 1A). An OCT catheter (Dragonfly[™] OPTIS[™], Abbott Vascular) was guided into each channel, and OCT images were acquired in both "high-resolution" and "survey" mode (54 mm and 74 mm length scans, respectively, with images separated by 0.1 mm and 0.2 mm, respectively) via automatic pullback.

The circumferential orientation of each acquired image was determined by identifying the opening at the top of the channel, defining a line across the channel opening, and calculating the angle between the defined line and the first A-line of the image. The analysis resulted in angle versus image position (axial location) data. A *correction factor*

due to the drift was calculated by averaging the angular drift per mm for each curved channel evaluated and performing a linear regression to identify a relationship between curvature and angular drift per mm. Furthermore, image orientation angles versus position data were calculated across multiple pullbacks of the same channel to evaluate reproducibility.

Deformed Stent Geometry Reconstruction The angular drift *correction factor* was applied to the OCT_{PC} prior to fusion with angiography data. Segmented OCT images were fused with a catheter centerline derived from biplane angiography [4]. A wireframe model derived from μ CT image data (14.8 μ m isotropic voxels) of a stent identical to the one deployed *in vivo*, but rather deployed in a stress-free environment (i.e., open-air) was created. The wireframe was spatially co-registered to the OCT_{PC} through an initial bending along the catheter centerline. Subsequently, the wireframe was deformed to the geometry of the OCT_{PC} through an constrained iterative deformation process directed by diffeomorphic metric mapping [3]. Following convergence, a volume derived from the stent strut cross-sectional area was lofted about the deformed wireframe, resulting in a continuous, high-resolution 3D reconstruction of the *in vivo* stent geometry.

RESULTS

A positive correlation was observed between curvature and the magnitude of angular drift, such that the angular drift was greater with increasing channel curvature values (Fig. 1). For curvature values of 0, 1/60, 1/30, and 1/20 mm^{-1} , the average angular drift per mm of pullback was $0.10^\circ \pm 0.06^\circ$, $-0.05^\circ \pm 0.02^\circ$, $-0.24^\circ \pm 0.05^\circ$, $-1.0^\circ \pm 0.05^\circ$, respectively ($p < 0.05$ for all, Fig. 1B). Linear regression demonstrated the relationship between curvature (κ) and angular drift per mm (Δdeg) as $\Delta deg = -21\kappa + 0.23$. Finally, strong reproducibility in the calculated image orientation angle and position data was observed across the scanned data at either acquisition rate (i.e., “high-resolution” or “survey”). The cross correlation of the angle versus image position data from each pullback mode showed highest correlation near zero lag with correlation values of 0.84, 0.97, 0.85, and 0.87 for $\kappa = 0$, 1/60, 1/30, and 1/20 mm^{-1} , respectively.

Figure 1: Angular drift experimental test bed and results. (A) A schematic of the experimental setup with constant curvature channels. (B) Average angular drift versus channel curvature with fitted linear regression (dashed line).

Implementation of the angular drift *correction factor* into the stent reconstruction algorithm had an observable effect on the OCT_{PC}. The catheter path for the OCT scan of the Xience Alpine™ stent had an

average curvature of $0.04 \pm 0.02 \text{ mm}^{-1}$, resulting in an average angular drift of $-0.75^\circ \pm 0.41^\circ$ per mm, which accumulated to an angular drift of -29.6° at the proximal end of the stent. Catheter curvature, angular drift, and accumulated angular drift values were $0.05^\circ \pm 0.03^\circ$, $-0.95^\circ \pm 0.57^\circ$ per mm, and -18.2° , respectively, for the Integrity® BMS. A representative example of the automatic 3D stent reconstruction algorithm, which includes angular drift correction, for the *in vivo* deployed Xience Alpine™ is shown in Figure 2. Note the agreement in stent strut location and orientation between the OCT_{PC} and deformed wireframe around the catheter centerline. Most importantly, the deformed, high-resolution wireframe, derived from μ CT, provides a continuous stent geometry, which is not observed in sparse OCT-derived stent point-cloud.

Figure 2: Wireframe coregistration and deformation to catheter centerline and OCT_{PC}. From left to right, the wireframe model before coregistration, the OCT_{PC} fused with the angiographic defined catheter centerline (green), and the completed reconstructed stent that is bent along the catheter centerline and deformed to the OCT_{PC}.

DISCUSSION

Our investigation highlights the influence that vessel curvature has on OCT image angular (circumferential) drift, and the requirement for drift correction when reconstructing a deployed vascular stent from OCT image data. We identified a relationship between angular drift and vessel curvature and proposed a *correction factor* to account for this image distortion. Finally, we integrated the image correction into our established stent reconstruction framework [3], demonstrating the feasibility to reconstruct a high-resolution 3D geometry of a deployed coronary stent through the fusion of clinically relevant imaging modalities. Future studies to validate the *in vivo* stent reconstruction algorithm are warranted, as we have previously performed experimentally [3], to ensure accurate geometries prior to post-stent mechanical environment model predictions.

EFFECTS OF RIGHT VENTRICULAR ASSIST DEVICE ON TREATING PULMONARY ARTERIAL HYPERTENSION: AN IN-SILICO STUDY USING IMAGE BASED BIVENTRICULAR MODELING FRAMEWORK

Sheikh Mohammad Shavik, Lik Chuan Lee

Department of Mechanical Engineering
Michigan State University
East Lansing, Michigan, USA

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a debilitating disease that is characterized by an abnormally elevated pulmonary artery (PA) pressure (> 25 mmHg). Without treatment PAH progresses rapidly and adversely affects the right ventricle (RV) function, eventually leading to heart failure and death [1]. The elevated PA and RV pressure due to a high afterload in PAH can cause unusual ventricular deformation, such as a left ventricular septal bow (LVSB) in which the septum wall bulges towards the left ventricle (LV). Moreover, long-term functional, structural, and geometrical changes such as enlargement of the RV also occur as the disease progresses. Left ventricular assist devices (LVAD) have been successfully used in the past to treat patients who have left heart failure. Recently, right ventricular assist device (RVAD) has been proposed as a treatment for PAH patients to unload the RV. Because the RV is different from the LV in terms of its structure, geometry and operation, the effects of RVAD on RV may be different from that of LVAD on the LV. Few studies, however, have investigated the effects of RVAD and all computational studies have neglected the effect of RVAD on the ventricular mechanics. To address this limitation, we developed an image based biventricular computational modeling framework to investigate the effects of RVAD in PAH patients.

METHODS

Patient specific biventricular geometry was constructed from the cine magnetic resonance (MR) images of one normal human subject and two PAH patients who had different degree of remodeling. For the PAH patients, one of them had severe RV remodeling (PAHR) with a large RV end-diastolic volume (EDV) and the other had little remodeling (PAHN) and normal RV chamber size and volume (Fig. 1). Finite element (FE) meshes were generated using these geometries acquired at early diastole when the LV and RV pressures were at their lowest values in the cardiac cycle. Myofiber helix angle was varied linearly in the transmural direction across the ventricular wall from 60° at the endocardium to -60° at the epicardium [2] using a Laplace-Dirichlet Rule-Based algorithm. We assumed a homogeneous helix angle distribution due to the lack of experimental measurements in humans.

The biventricular FE models were coupled to a closed loop circulatory model (Fig. 1A) that describes both systemic and pulmonary circulations. The modeling framework consists of eight compartments with four components each (ventricle, atrium, artery and vein) in the systemic and pulmonary circulation. The systemic and pulmonary vessels (arteries and veins) were modeled using their electrical analogs and the contraction of left and right atriums (LA and RA) were modeled using a time varying elastance function. The RVAD flow was simulated using the pressure gradient – flow characteristics of the SynergyTM continuous flow miniature pump (CircuLite Inc, Saddle Brook, NJ) with operating speeds between 20 to 28krpm. Flow through the RVAD was sourced from the RV and ejected to PA.

An active stress formulation was used to describe the mechanical behavior of the myocardial tissue in the cardiac cycle. In this formulation, the first Piola stress tensor \mathbf{P} was decomposed additively into a passive (\mathbf{P}_p) and an active (\mathbf{P}_a) stress tensor. The active stress tensor has the form $\mathbf{P}_a = P_a \mathbf{e}_f \otimes \mathbf{e}_{f_0}$, where \mathbf{e}_f and \mathbf{e}_{f_0} denote the local myofiber direction in the current and reference configurations, respectively. The active stress P_a behavior was described by a previously developed active contraction model [3] in which the contractile force is dependent on the sarcomere length. The passive stress tensor was defined by $\mathbf{P}_p = dW/d\mathbf{F}$, where W is a strain energy function of a Fung-type transversely-isotropic hyperelastic material [4] and \mathbf{F} is the deformation gradient tensor.

The biventricular FE models were divided into 3 material regions, namely the LV free wall (LVFW), the septum and the RV free wall (RVFW) for the normal subject and the PAH patients. Contractility parameters associated with these 3 regions as well as circulatory model parameters (resistances and compliances) were adjusted to match the LV and RV pressure and volume waveforms. The simulations were run for several cardiac cycles until the steady-state pressure-volume loop was found. The cardiac cycle time for each case was also matched with the acquired heart rate of the normal subject and PAH patients.

RESULTS

The PV loops as well as both volume and pressure waveforms (not shown here) of the LV and RV predicted by the model were closely matched with the measured data for the normal subject as well as the PAH patients (Fig. 2A). In both PAH patients, RV peak pressure was higher compared to the normal subject while their LV peak pressure was only slightly higher than the normal subject. The LV end-diastolic volume (EDV), end-systolic volume (ESV) and ejection fraction (EF) (69% in normal vs. 64% in PAHR vs. 64% in PAHN) were similar in all 3 cases. On the other hand, RV EDV and RV ESV were both significantly larger in PAHR compared to normal, producing a substantially lower RV EF compared to the normal (37% vs. 59%).

Figure 1: (A) Schematic of the biventricular FE modeling framework, (B) Unloaded geometry of normal and PAH patients with three material regions.

By contrast, PAHN had slightly lower RV EDV, RV ESV compared to the normal. RV EF in PAHN was also lower compared to the normal (51% vs. 59%) but higher than PAHR.

Implantation of RVAD produced a triangular shaped RV PV loop without any isovolumic (contraction and relaxation) periods. In addition, PA diastolic and mean pressures increased significantly together with a slight increase in the PA systolic, LA systolic, and aortic pressures (Fig. 2B). With increasing RVAD speed, both the PA diastolic and mean pressures increased progressively together with an increase in LV EDV and aortic pressure for both PAH cases. The increase in LV EDV and aortic pressure were, however, more pronounced in PAHR than PAHN.

Average LVFW, septum and RVFW stress were higher in both PAH patients (cf. normal) (Fig. 2C). RVAD reduced the average LVFW, septum and RVFW stress in PAHR whereas the stress in PAHN was almost similar to the baseline (without RVAD). Compared to the normal subject, the septum curvature (Fig. 2D) in the PAH patients were substantially lower than that found in the LVFW (not shown here) and PAHR had the lowest septum curvature. RVAD increased the septum's curvature in both PAH patients as it shifted towards the RV.

DISCUSSION

Based on an image-based biventricular FE modeling framework that was calibrated and matched well with 1) PV loops, 2) LV and RV volume waveforms and 3) LV and RV pressure waveforms acquired from patients and normal subjects, we have shown that the implantation of RVAD is able to reduce average stress and improve the septum curvature. These positive effects are, however, compromised by an increase in the (mean and diastolic) PA pressure as well as LV EDV in PAH patients with severe RV remodeling. Thus, while RVAD can help reduce RV load, it may worsen LV function by increasing its preload.

Figure 2: (A) Comparison between measurements and model predictions of LV and RV PV loops, (B) LV and RV PV loops and pressure waveforms of PAH patients at different RVAD speeds, (C) Average LVFW, Septum and RVFW stress, and (D) Septum curvature for different cases.

These findings are consistent with the previous reports of an increase in PA pressure with RVAD that depends on the severity of the disease. Similarly, we found that the effects of RVAD on hemodynamics as well as mechanics were not same in two PAH patients with different degree of remodeling. These results suggest that the RVAD flow rate should be optimized individually for each patient to minimize the adverse effects.

INTRODUCTION

In the U.S., coronary artery bypass surgery occurs in over 400,000 patients with a one year patency rate ranging from 60%-95% [1, 2]. This lack of patency is attributed to graft thrombosis and/or intimal hyperplasia [3, 4]. While there are many factors that contribute to procedural failure, compliance mismatch between the implant and the native vessel is thought to be a prominent contributor and will be tested in this study [3, 5].

The current “goal standard” for a bypass procedure is an autologous vessel, but this graft is generally less compliant and usually limited due to widespread vascular disease. Hence, there is a need for a synthetic off the shelf vascular graft. The Soft Tissue and Biomechanics Laboratory has demonstrated that the compliance of a tissue engineered vascular graft (TEVG) can be modulated by using a computational and experimental approach [6]. Specifically, the user defines the material, thickness of the construct, and number of layers which will be computationally simulated to determine the formulation of a compliance specific construct.

For this study, Polycaprolactone (PCL) and gelatin were selected due to their mechanical strength and biocompatibility, respectively. The mechanical strength of PCL increases the burst strength and suturability of the construct while gelatin provides increased biocompatibility and a fast degrading scaffold.

In this study, the composition of a vascular graft will be modulated to illustrate the role compliance facilitates in vascular graft design using a rat model. The composition of a TEVG will be modulated to create a stiff and compliance matched to rat aorta implant. This graft will then be implanted into a rat model, in vivo flow measurements will be taken, explanted, and evaluated for cell content.

METHODS

The TEVG was manufactured by electrospinning varying ratios of gelatin and PCL to create a rat aorta compliance matched (CM) and hypocompliant (Hypo) graft with 6 alternating layers of higher and lower gelatin percentage (n=3). The Hypo group was defined as having a similar compliance to commercially available DACRON or ePTFE grafts and contained about 30% gelatin or half the amount of gelatin in the CM. For electrospinning, gelatin and PCL were each dissolved into 1,1,1,3,3,3-hexafluoro-2-propanol (HFP) to create a 10% (w/v) solution and electrospun using the IME electrospinning machine. The electrospinning parameters were as follows: 50 μ l/min flow rate, 15kV voltage, working distance of 10cm, and 22-gauge needle tip. These acellular grafts were then cross-linked in a genipin solution for 24 hours, implanted interpositionally into the aorta of a Sprague Dawley rat for 1 month. During implantation, Doppler ultrasound was used to measure in vivo relative area change before surgery, 1, 2, and 4 weeks post implantation. The relative area change was measured at 4 locations using a cross sectional b-mode image and was calculated as follows:

$$\frac{(\text{Maximum Aorta Area} - \text{Minimum Aorta Area})}{\text{Minimum Aorta Area}}$$

After one month, the rat was sacrificed and evaluated for cellular infiltration using fluorescent microscopy. A two-way ANOVA was used to determine differences between the groups. Scaffold degradation and cell count were calculated using ImageJ. Cell count was defined as any cell within the construct, lumen of the implant, or within a cell length away from the outside of the implant. For scaffold degradation, autofluorescence of the scaffold was used to define the construct area post implantation. The explanted construct area was divided by the original area of the construct to determine the percent degradation.

RESULTS

The compliance of rat aorta, CM, and Hypo graft were $5.6 \pm 3.1 \times 10^{-4}$, $4.8 \pm 0.09 \times 10^{-4}$, and $1.46 \pm 0.15 \times 10^{-4}$ mmHg⁻¹, respectively. The CM and Hypo inner diameter were $542 \pm 3 \mu\text{m}$ and $548 \pm 25 \mu\text{m}$, respectively. The Hypo group had a 100% survival rate, while the CM had 2 deaths, a graft tear and an unknown cause. The average implant length was between 5-7mm. In vivo relative area measurements showed that the CM group was similar to native aorta throughout the study. The Hypo graft had a significant increase in relative area change from 7 to 14 days, **figure 1**.

Figure 1. Relative area change of CM and Hypo at day 7, 14, and 28 (n=3). * p<0.01.

In vivo diameter measurements showed a slight increase in maximum diameter of the CM ($590 \pm 17 \mu\text{m}$) while Hypo showed a slight decrease ($520 \pm 70 \mu\text{m}$) from 14 to 28 days. The explanted diameters of the Hypo were larger than CM, $486 \pm 6 \mu\text{m}$ to $370 \pm 12 \mu\text{m}$, respectively. The 28-day cell count showed significantly more cellular infiltration in CM compared to Hypo 1908 ± 790 to 580 ± 181 , respectively. CM also showed significantly faster degradation with $56 \pm 4\%$ of the construct remaining compared to $77 \pm 15\%$. Representation images showing cellular infiltration and construct degradation are presented in **figure 2**.

Figure 2. Representative 10 μm cross sectional images of hypo (A) and CM (B) samples. Green is autofluorescence of the implant and blue is cell nuclei.

DISCUSSION

In this study, we were successfully able to create a Hypo and CM graft to rat aorta. Our data showed that our Hypo graft became more compliance throughout the study while the CM graft remained similar to native aorta. Cellular infiltration and graft degradation were significantly higher in the CM compared to the Hypo graft.

For Hypo, this group showed an in vivo relative area shift from a Hypo/stiff to compliance matched graft from 7 to 14 days. Although there is only explant data at 28, we believe this shift in area change/compliance is from the degradation of gelatin. PCL degradation

in vivo can last over two years while gelatin degrades at a much quicker rate [7]. Thus, the Hypo grafts contain around 30% gelatin with the explant showing on average a 23% loss of scaffold, thus suggesting the gain in area change/compliance is related to gelatin degradation. Even though these results are encouraging, the limited cellular infiltration, **figure 2A**, may limit the usefulness of this graft. The lack of cells could prevent vasoactivity and the incorporation of a protective endothelium that could lead to thrombosis or graft failure. Longer time points will be needed to determine if cellular infiltration is delayed.

For CM, our results show there is some difficulty implanting the CM grafts but the in vivo and explant results show great promise. Specifically, our data demonstrates that our CM graft will maintain the area change/compliance throughout implantation while promoting a high cellular infiltration. The shrinking of the in vivo to explant diameter may also demonstrate that the cells are functioning properly and depositing an extracellular matrix (ECM). With a higher cellular content and ECM deposition, this suggests that the relative area/compliance is a more beneficial scaffold than a stiff/Hypo graft.

While the results from this study are encouraging, there are some limitations. As described above, we chose to adjust the compliance of the graft by modulating gelatin content. Even though we were successful, gelatin and PCL degrade at different rates. The Hypo had about half as much gelatin as the CM and this may be a source for the differences in the groups. In the future, we would recommend evaluating similar gelatin content grafts, but with different crosslinking time to achieve a compliance match.

As we continue to evaluate this work, we will further examine the types of cells in our grafts. Specifically, we will determine the percent of endothelium, smooth muscles cells, and macrophages M1 and M2. Finally, we will evaluate collagen and elastin content using multiphoton microscopy.

INTRODUCTION

Treatment strategies for many cardiovascular diseases often rely on replacement conduits, but the lack of suitable autologous vessels and high failure rates of synthetic materials significantly limit surgical intervention [1]. Tissue-engineered vascular grafts (TEVGs) are a promising alternative that have recently been used in clinical trials as extracardiac cavopulmonary conduits in congenital heart patients with single ventricle physiology [2, 3]. These biodegradable scaffolds are composed of a woven fabric poly(glycolic acid), or PGA, felt sealed with a 50:50 copolymer solution composed of poly(caprolactone and L-lactide), or P(CL/LA). Although safe, the primary graft-related complication is stenosis: at 5.8 years, 16% of recipients had developed critical graft stenosis (>75% decrease in luminal diameter), and the prevalence increased to 28% at the most recent follow up (11.1 years). Clearly, before routine clinical use of TEVGs can be recommended, an understanding of cellular, molecular, and biomechanical mechanisms underlying neovessel formation and their effective manipulation is required to optimize long-term conduit patency.

To investigate such mechanisms in an animal model, we implanted similar scaffolds as venous interposition grafts in the abdominal inferior vena cava (IVC) of mice for up to two years [4]. We showed that the transformation of our scaffolds into functional neovessels involves polymer degradation and immune cell infiltration, which occurs concurrently with vascular cell recruitment and extracellular matrix deposition and remodeling; moreover, the degree of macrophage infiltration is directly proportional to the incidence of TEVG stenosis. Given the myriad possible design modifications and potential pharmacological therapies that can be explored to increase graft patency, an empirical trial-and-error search for an optimal scaffold design and specific clinical interventions quickly becomes impractical.

Hence, we present a mechanistic bio-chemo-mechanical model that explicitly models interactions between the polymeric scaffold, multiple cell types, key cytokines and growth factors, matrix constituents, and mechanical stimuli, and captures graft properties that emerge from this complex interplay [5]. By combining identifiability analysis with Bayesian estimation techniques and simplex optimization, we determine non-identifiable parameter combinations, and estimate optimal model parameters that match experimental measurements in the presence of uncertainty. We then illustrate the model's clinical utility by hypothesis-driven simulations that examine the effect of altering scaffold design and administering targeted pharmacological interventions with the potential to improve graft performance.

METHODS

A dynamic system of coupled, nonlinear, constant rate ordinary differential equations governs the number of inflammatory and vascular cells, molecular concentration of cytokines and proteases, and mass density of matrix constituents in the system. The normalized mass density and evolving pore size of the degrading polymeric scaffold, along with computationally predicted intramural and wall shear stresses throughout neovessel development, serve as model inputs [6]. The model consists of 43 parameters tuned against 18 measurements from *in vivo* and *in vitro* experimental studies. Parameter bounds were chosen to be consistent with the literature or simply to be biologically reasonable when data were lacking. The administration of clodronate liposomes [7] or the TGF- β R1 kinase inhibitor SB431542 [8, 9], two pharmacological interventions employed in our murine model for the first two weeks following graft implantation to reduce the incidence of stenosis, was modeled using modified gamma distribution functions.

We use a previously published Bayesian-based estimation framework [10] to address the issue of parameter estimation in a data-

poor system in the presence of uncertainty. This framework employs adaptive Markov Chain Monte Carlo (MCMC) methods to sample from the joint posterior distribution of the unknown parameters, which are treated as random variables [11]. The estimation process is complemented with an identifiability analysis to determine unidentifiable parameters. The maximum *a posteriori* estimate is then determined on the identifiable parameters using simplex optimization [12], with the best posteriori estimate from MCMC as the initial guess to the optimization. Using a combination of Fisher information matrix (FIM) analysis and learnability metrics from MCMC simulations, we reduce the set of 43 parameters to a set of 22 identifiable parameters that can completely recover the synthetic targets. These 22 parameters were further estimated to match the desired targets. Following parameter estimation, local parameter sensitivity is determined by calculating the local sensitivity index (LSI), defined as the percentage change in the targets for a percentage change in each parameter [13]. The LSI is averaged over multiple perturbations (<10%) local to the maximum *a posteriori* estimate.

RESULTS

We began with an implanted scaffold having an initial pore radius of 20 μm (similar to those implanted in our murine model) and calibrated model parameters that yielded outputs consistent with experimental observations. Experimental targets were reproduced well, with the percent deviation between experimental targets and simulation outputs ranging from 0.16% to 6.5%. LSI analysis revealed that our model has a dominant downwind behavior, suggesting that the process of neovessel development from an implanted biodegradable scaffold may be an open-loop formulation governed less by positive and negative bio-chemo-mechanical feedback and more by the inherent immunogenicity of the scaffold. For these baseline simulations, the model predicts marked monocyte infiltration, a large number of classically activated macrophages known to contribute to graft stenosis, and a substantial number of inflammatory smooth muscle cells (SMCs) responsible for an early burst in production of stiff inflammatory collagen that adversely affects neovessel distensibility [4, 9].

Reducing the pore radius to 2 μm in our bio-chemo-mechanical model to emulate our clinically used scaffolds decreases the number of infiltrating monocytes and macrophages that enter the scaffold, and therefore reduces the number of recruited vascular cells that eventually populate the graft. Although this reduction in pore size could improve distensibility by reducing the early peak in inflammatory collagen, the inability of immune cells to enter the scaffold directly after implantation drastically compromises graft patency and reduces long-term cellularity, suggesting the need to explore alternative solutions.

When simulating clodronate administration, we observed a significant decrease in monocytes and macrophages secondary to apoptosis, markedly reduced vascular cell recruitment, and a reduction in extracellular matrix production, all consistent with empirical observations [7]. Thus, although clodronate treatment may ameliorate compliance mismatch by diminishing the peak in inflammatory collagen deposition and decrease the incidence of stenosis by inhibiting immune cell infiltration, it compromises graft cellularity and matrix production, which can have catastrophic consequences once the polymer loses load-bearing integrity.

Finally, the model revealed that administration of the TGF- β R1 inhibitor not only improves initial graft patency by inhibiting endothelial-to-mesenchymal transition and preventing the TGF- β -induced classic activation of infiltrating monocytes [9], it may also improve distensibility by significantly reducing inflammatory collagen production during early scaffold remodeling. Treatment with this

inhibitor was the only simulated intervention that minimizes compliance mismatch between the implanted polymeric scaffold and the adjacent native vessel while still maintaining graft cellularity.

DISCUSSION

Our model's dominant downwind behavior suggests that variations in graft physical properties and immunogenicity may have far-reaching effects on the elicited inflammatory response, which then strongly influences the eventual patency and functionality of the remodeling graft. This may explain why early intervention with immunomodulatory therapies has proven to be so effective in reducing the incidence of stenosis (7, 8, 9). Our study also has a few limitations: first, the uncertainty in input parameters is not accounted for in the simulations or parameter estimation; second, the targets against which the parameters are estimated are from different sources that encompass varying methods, scales, and systems; third, the proposed system is mostly at a cellular scale and lacks spatial fidelity.

We emphasize the need for focused data collection and carefully designed experiments in our murine model that are explicitly intended to increase the number and diversity of experimental targets. System-specific data remain sorely lacking on the temporal and spatial profiles of immunomodulatory cytokines and the relationship between scaffold physical parameters and the elicited immune response. Increasing the number of experimental targets considered may in turn expand the number of identifiable parameters.

This mechanistic model will be integrated into a pre-existing constrained mixture theory of growth and remodeling to create a fully coupled multiscale bio-chemo-mechanical model of neotissue formation informed and validated by experimental observations. Such a model can aid in rational design by enabling us to perform an extensive series of time- and cost-efficient parametric studies that determine ideal clinical interventions and optimal scaffold parameters for achieving favorable long-term graft outcomes, which can then be evaluated experimentally in animal models and eventually be validated in clinical trials.

ROLE OF HYALURONIC ACID IN REGULATION OF CONTRACTILE FORCES IN HEART VALVE TISSUE CONSTRUCTS

Ying Lei, Luciano Bortolin, Frank Benesch-Lee, Teniola Oguntolu, Kristen Billiar

Biomedical Engineering Department
Worcester Polytechnic Institute
Worcester, Massachusetts, USA

INTRODUCTION

The main treatment option for heart valve disease is replacement. However, mechanical prosthetic valves require lifelong anticoagulants therapy, while bioprosthetic valves tend to undergo degeneration and calcification, and both types often require follow-up surgeries. Tissue engineered heart valves (TEHVs) are a promising alternative since they have the potential to self-repair and grow. While numerous TEHVs have been developed, retraction of the leaflets often occurs involving excessive contraction of the resident cells and buildup of residual stress rather than regeneration of normal tissue. Retraction is especially detrimental since it has been shown that even a slight shortening of the leaflets can lead to regurgitation.

Hyaluronic acid (HA) has been investigated for TEHV design in the hopes that it could contribute to maintaining a healthy quiescent valvular interstitial cell (VIC) phenotype. While studies suggest addition of exogenous HA is a promising strategy to reduce retraction in TEHVs,^{1,2} the effects of HA on the active contractile forces of the cells and the passive residual stress build up in the matrix remain unclear. To optimize the design of TEHVs, a better understanding of how HA interacts with the resident cells is necessary.

The goal of this work is to investigate the role of HA in regulating valvular tissue retraction. We developed a 3D tissue construct culturing and monitoring system, and created VIC-populated fibrin-based tissue models with/without HA. The active contractile and residual forces, compressive stiffness, cell alignment, and extracellular matrix (ECM) components and structures were analyzed for each group.

METHODS

Engineered tissue constructs were cultured between polydimethylsiloxane (PDMS) posts. Plugs with posts were cast using stainless steel molds. The stiffness of each post was tested using a

custom bending device. Given the bending stiffness of the posts, the contractile forces of the engineered tissues could be calculated based on the deflections of the posts tracked by a monitoring system with a CMOS camera. The deflection was calculated as the difference between the original distance without tissue and the distance with tissue, divided by a factor of 2, assuming that both posts bend equally.

VICs were isolated from pig hearts obtained from a local slaughter house. They were pre-treated with 1 ng/ml TGF- β 1 for 3 days before tissue casting, in which two solutions were mixed in wells and incubated for 1 h allowing gelation. In one solution, 6.6 mg/ml soluble fibrinogen was diluted in sterile Dulbecco's phosphate buffered saline with 6 mg/ml HA when applicable, while in the other one cells were suspended with 2 U/ml thrombin in media.

To separate the active cell and passive matrix contributions to tissue contractile forces, two groups of microtissues with or without HA respectively were first cultured for four days, and then incubated with 10 μ M cytochalasin D (cyto-D) for 2 h to disrupt the actin network of the cells. Forces before and after cyto-D treatment were quantified. The compressive stiffness of tissues were calculated based on loading curves generated by an Instron EP1000 tensile tester with a loading rate of 0.05 mm/s and a maximum elongation of 150%. To investigate the influences of HA on the mechanical properties provided to cells at the initial stage of tissue formation, an Anton-Parr rheometer was used to perform strain sweep tests on acellular gels. The storage modulus and loss modulus were tested with strain ranging from 0.001% to 10% at 1 Hz with a cone plate of 40 mm in diameter.

The collected tissues were fixed with 4% paraformaldehyde, and H & E staining was performed to observe the general structure of the tissues using hematoxylin and eosin. Cell numbers on the sections were counted using the cell counter in ImageJ. To visualize α SMA, tissue sections were stained with primary monoclonal anti-actin α SMA, and

images were obtained through a Leica SP5 scanning confocal/DMI6000 inverted microscope. Alignment of α SMA was analyzed by OrientationJ plugin in ImageJ.

Data represents mean and standard error. Statistical significance was determined using two-way analysis of variance (ANOVA), where $p < 0.05$ was considered significant.

RESULTS

We first tested the influence of varying initial cell density on tissue-generated forces and compressive stiffness in samples with/without HA. Results of groups with 1 M cells/ml and 2 M cells/ml initial cell densities suggest that incorporating HA in the scaffold could significantly reduce the contractile forces, and result in tissues with significantly higher compressive stiffness regardless of the different cell densities, as shown in Figure 1. In addition, tissues with HA have significantly reduced total and residual forces, and trend to have lower active cell contractile forces, as shown in Figure 2.

Figure 1: Effect of cell density and presence of HA on (a) contractile force and (b) compressive stiffness.

Figure 2: Total, active cell generated and passive residual forces in tissues with/without HA. (Initial cell density: 2 M cells/ml)

Histology results show that while having the same initial cell density of 2 M cells/ml, tissues with HA have denser ECM structures, more evenly distributed cells, significantly larger amount of cells and more collagen fibers secreted by the cells, as shown in Figure 3 and 4.

Figure 3: Collagen concentration normalized to total protein contents (a) and cell density of tissues (b) with/without HA.

Figure 4: H&E staining of 6 micron tissue sections without (a) and with (b) HA.

For tissues with or without HA, the amounts of α SMA shown in staining images are not significantly different. (Figure 5) However, vector field map analysis suggests that α SMA fibers are well aligned along one direction in tissues with HA, while fibers have two major directions in tissues without HA (analysis not shown).

Figure 5: α SMA expression in tissues without (a) and with (b) HA.

DISCUSSION

Our results suggest that incorporating HA in the scaffold significantly reduces the passive residual forces within the ECM, and also trend to reduce active cell-generated forces, thus lessen the contraction overall. The reduction of residual forces could result from the higher initial stiffness of the scaffolds with HA. As shown in Figure 6, acellular fibrin gels with HA have 89% higher storage and loss moduli than gels without HA. In line with previous studies^{3,4}, the positive influence of HA on cell proliferation, migration, alignment, and secretion of collagen could also contribute to decreasing in both active and passive contractile forces. Since our current results indicate the potential of further decreasing tissue contraction by reducing the active forces, in the future we will explore the effects of growth factors on cell in these fibrin and HA based tissue models.

INTRODUCTION

Aortic aneurysms (AA) are balloon-like enlargements of the aorta that possess a life-threatening risk of rupture, representing the 15th leading cause of death in the United States [1]. AA are most prominent in both aging populations (primarily smokers), and pediatric or young adult patients with genetic connective tissue disorders [2]. Approximately 5 million Americans over the age of 50 are living with abdominal/thoracic AA [3, 4], with over 200,000 new AAs diagnosed annually [5]. If left untreated, AA can weaken and ultimately rupture or dissect, with over 15,000 high-mortality events annually [6].

Currently, surgical intervention is governed by aortic diameter measurements. Adults are diagnosed with AA once aortic diameter exceeds 1.5-times normal value, with surgical intervention recommended after crossing a "critical diameter" of 5.5cm. Pediatric patients with 'rapid aortic expansion' exceeding 0.5cm/year undergo surgical intervention, often with several repeated surgeries with broad-targeted therapies prescribed (beta blockers, ACE inhibitors). Recent work from our group has shown that periadventitial adipose-derived stromal stem cell (ASC) delivery to a growing elastase-induced mouse aneurysm slows dilation and preserves elastic lamellae [7]. A targeted treatment to regenerate functional elastic fibers could offer a non-surgical therapeutic for adults with sub-critical AA, or an aortic maintenance therapy for children with connective tissue disorders.

While multiple mechanisms can potentially explain this ASC effect, this study tested if paracrine signaling through ASC secreted factors (ASC-SF) induced deposition of elastin by aortic smooth muscle cells (SMCs) within three-dimensional *in vitro* fibrin gel constructs. We evaluated ASC-SF effects on elastin regeneration using three different cohorts of SMCs: (1) purchased healthy adult SMCs (hSMCs); (2) adult patient-isolated SMCs from bicuspid aortic valve (BAV) non-aneurysmal aortas (BAV-NA) and thoracic AA (BAV-TAA); and (3) pediatric SMCs following aortic dilation (pSMC). Elastin analysis included several points in the elastogenesis cascade: elastin organizational protein transcription, elastic fiber organization, elastin cross-linking, and mechanical functionality.

METHODS

hSMCs were purchased from ATCC. Adult BAV SMCs were generously provided by Dr. Thomas Gleason at UPMC Presbyterian Hospital, and pediatric SMCs were isolated from ascending thoracic aorta and aortic root tissue of a two-year old patient following a Ross procedure by Dr. Victor Morell at the Children's Hospital at UPMC (genetic screening ongoing). The tissue was enzymatically digested using a solution ratio of 10mg type IV collagenase to 5mg elastase in serum-free SMC growth medium.

Fibrin gel constructs were fabricated as described [8] using a volume of 200 μ L and a SMC seeding density of 5x10⁵ cells/mL (**Figure 1**). A fibrinolysis inhibitor (12mM aminocaproic acid) was used to halt construct breakdown. Culture media was changed every 48-72 hours, for either 20 or 30 days in culture.

Treatment groups included: (1) No Treatment (NT), consisting of SMC growth-supplemented media; (2) ASC-SF, a 1:1 combination of SMC growth-supplemented media and ASC conditioned media, collected after 24-48 hour ASC incubations within preadipocyte growth supplemented media; and (3) Non-Conditioned Media (NCM), a 1:1 combination of SMC growth-supplemented media and fresh ASC culture media.

qPCR was used to analyze protein transcription. Human aortic elastin immunofluorescence staining was performed using an Olympus FluoView FV1000 confocal microscope (20x oil, NA=0.85 objective). Ninhydrin (insoluble elastin) and hydroxyproline (collagen) protein assays were used to quantify deposition as a percentage of total protein within the construct [9]. Uniaxial tensile testing was performed using an Instron #5543A mechanical system.

Figure 1: 3D SMC-seeded fibrin gel constructs.

RESULTS

qPCR analysis on hSMCs (**Figure 2**) revealed that both ASC-SF (4.94±0.71-fold increase vs NT control) and NCM (3.09±0.29-fold increase) induced a significant increase in SMC tropoelastin. Microfibril protein fibrillin-1 (4.22±1.10-fold increase), elastin organizational protein fibulin-5 (5.42±0.53-fold increase), and cross-linking proteins LOX (2.31±0.44-fold increase) and LOXL-1 (2.22±0.53-fold increase) were also increased with ASC-SF stimulation. LTBP-4 was significantly downregulated with both ASC-SF stimulation and NCM. NCM did not induce significant differences in fibrillin-1, fibulin-4, fibulin-5, LOX, or LOXL-1.

Figure 2: qPCR of hSMC elastin chaperone protein transcription.

ASC-SF stimulation of hSMC induced a 136% increase versus NT control in insoluble elastin percentage of total protein after 20 days (0.15±0.023% NT control and 0.15±0.03% NCM control, vs 0.37±0.1337% ASC-SF), and a 94% increase after 30 days (0.12±0.04% NT control & 0.098±0.038% NCM control, vs 0.25±0.07% ASC-SF) (**Figure 3**). Elastic matrix imaging revealed ASC-SF-induced continuous, thick elastic fibers. Image quantification revealed increased intersection density with ASC-SF (data not shown).

Figure 3: Insoluble elastin within stimulated hSMC constructs.

Tensile testing of hSMC constructs following 30 days of stimulation revealed an ASC-SF induced 151% increase in high elastic modulus (12.48±2.21kPa NT control vs 31.30±13.56kPa ASC-SF), while low elastic modulus remained statistically unchanged.

Figure 4: Tensile testing of hSMC constructs.

When cells within the construct were changed to pSMCs (**Figure 5A**), ASC-SF-stimulation resulted in a 226% increase in insoluble elastin deposition when compared to no treatment control (0.05±0.005% control, 0.19±0.05% ASC-SF).

Constructs loaded with BAV-NA cells (**Figure 5B**) saw a 102% increase with ASC-SF stimulation (0.078±0.013% NT, vs 0.16±0.06%

ASC-SF). Interestingly, NCM stimulation saw a similar increase (0.22±0.028%). This trend held with BAV-TAA cells, as ASC-SF induced a 183% increase in insoluble elastin (0.058±0.010% NT, 0.16±0.042% ASC-SF), while NCM induced a 195% increase (0.17±0.069% control).

Figure 5: Insoluble elastin from patient-derived SMC constructs.

DISCUSSION

Our multi-level hSMC elastogenesis analysis shows that while NCM induces tropoelastin deposition, the accompanying milieu of elastin chaperone proteins induced by ASC-SF stimulation results in greater insoluble elastin, and increased fibril interconnectivity and mechanical functionality. We also found collagen fraction after 30 days of ASC-SF stimulation saw a 233% increase (0.045%±0.028% NT vs 0.15±0.063% ASC-SF), showing the potentially wide-ranging vascular extracellular matrix regenerative capabilities of ASC-SF.

pSMCs displayed a similar pattern of insoluble elastin stimulation to hSMCs, showing ASC-SF therapy as a potential post-surgical therapeutic mechanism to help local cells fortify vasculature after initial surgery. BAV-NA and BAV-TAA SMCs showed an increase in elastin deposition with both ASC-SF and NCM, necessitating further study as to the elastogenic components both have in common.

We conclude that ASC-SF can stimulate elastic fiber assembly by healthy adult SMCs, and both explanted pediatric and adults SMCs, possibly mediated through the increased activity of SMC-secreted elastin accessory proteins. This could potentially lead to an effective non-surgical regenerative therapy for treatment of AA.

INTRODUCTION

Valve interstitial cells (VICs) play a critical role in maintaining normal valve function. Therefore, changes to the valve mechanical environment induced by both disease and surgical intervention can lead to adverse changes in VIC behavior and negative clinical outcomes. While much has been learned from tissue scale modeling of heart valves, many critical aspects of VIC regulated tissue response are only recently being investigated [1]. And, while much has been learned about VICs in isolation, the direct impact of these observations on tissue scale behavior is far from fully understood [2]. To address this gap, new strategies for bridging the cellular and tissue scales are vital. Here we present a combined experimental/computational framework to quantify and model the contractile behavior of VICs in a tunable experimental environment. We introduce statistical methods to quantify spatial heterogeneity in individual VICs, and introduce a computational framework to understand the implications of this heterogeneity across scales. The knowledge gained from this work is a step towards a better understanding and ability to potentially control how VICs remodel tissue in the native valve environment.

METHODS

Measuring spatial heterogeneity. For measurements taken within the bounds of a single cell, there is often substantial spatial variation. To understand the nature of this spatial variation, we first introduce a strategy for measuring spatial autocorrelation (similarity of spatially near points) of given properties in each cell. To do this we use the Global Moran's I statistic and compare the results to the null hypothesis that there is no spatial autocorrelation [3]. When spatial autocorrelation is high, values of I approach 1. In addition, we plot experimental semivariograms that show variance in a given property with respect to the distance between measurement points (lag) for bins of data. Here we

demonstrate this method by analyzing data from a set of experiments that use atomic force microscopy (AFM) to measure the Young's Modulus of VICs derived from the Aortic Valve (AV) and Pulmonary Valve (PV). In these experiments, the cells are adhered to a two-dimensional substrate with indentation measurements taken at 40-60 discrete points per cell [3].

Experimental data:

Computational model:

Figure 1: Multiple imaging modalities are used to quantify the spatially heterogeneous properties and irregular geometries of VICs (a-c). A suite of computational models is used to understand the implications of this heterogeneity across scales (d-e).

Gaussian process regression for interpolating experimental data. For each experimental modality, data is only available at discrete points in space. As an improvement on traditional interpolation methods, we utilize gaussian process regression (GPR), to predict properties between measurement points. Gaussian process regression is a non-parametric approach that finds a distribution over all possible functions f that are consistent with the observed data [5]. Through using GPR tuned to optimize fit on unseen data, we are better able to infer and ultimately model properties at each point in space. For example, Fig. 1c shows a GPR based interpolation of cell height acquired through AFM. This approach becomes particularly meaningful in regions where experimental data is present but sparse.

Computational analysis framework. Given experimental data describing VICs, we are able to construct a suite of computational cell models with realistic cell geometry and spatially heterogeneous cell properties. As a toy example to demonstrate the flow of the computational framework, consider a two dimensional finite element model of a cell embedded in a substrate and loaded uniaxially. We can describe the boundaries of the toy cell with a rose function:

$$\mathbf{x} = [\mathbf{R} + \mathbf{a} \sin(n(\theta + \Phi))] \cos \theta + \mathbf{x}_c \quad (1)$$

$$\mathbf{y} = [\mathbf{R} + \mathbf{a} \sin(n(\theta + \Phi))] \sin \theta + \mathbf{y}_c \quad (2)$$

where \mathbf{x} and \mathbf{y} are the coordinates of cell boundary, $(\mathbf{x}_c, \mathbf{y}_c)$ is the cell center, \mathbf{R} is the inner radius, \mathbf{a} is the petal amplitude, \mathbf{n} is the number of petals, and Φ is the initial rotation. This shape is illustrated in Fig. 1d. In addition to geometry, we vary cell shrinkage α and average modulus E . We then choose some Quantity of Interest (QoI), such as the predicted maximum stress under a given loading condition, where the goal is to determine which simulation input parameters are most critical to that QoI. Even with this simple example, many simulations are required. To make this a tractable problem, we use a global sensitivity analysis procedure for random models [6]. This pipeline is illustrated in Fig. 1e. With this framework, we can analyze a suite of computational models that represent the variations observed in the experimental data.

Table 1. Moran's I and Z-score for each cell. Cells marked with (★) show statistically significant spatial autocorrelation.

Cell No.	I	z_i	Cell No.	I	z_i
AV-1	0.095	1.15	PV-1★	0.42	6.33
AV-2★	0.27	2.39	PV-2★	0.30	3.63
AV-3	-0.012	0.092	PV-3★	0.57	9.25
AV-4	-0.082	-0.31	PV-4★	0.70	10.29
AV-5	-0.023	-0.11	PV-5★	0.39	6.24
			PV-6★	0.50	7.68

RESULTS

The first result shown here is a comparison of spatial autocorrelation of stiffness in AV and PV VICs. This comparison is shown in Table 1. Critically, only one out of five AV cells shows statistically significant spatial autocorrelation in stiffness while six out of six PV cells show statistically significant spatial autocorrelation. This is also reflected in the shape of the experimental semivariogram shown in Fig. 3. For the PV cells, the spatial autocorrelation indicates that GPR is suitable for modeling spatial variation in cell modulus. For the AV cells, an alternative approach is required to generate synthetic representative models of spatial variation.

The plots in Fig. 4 show the results of running the toy problem through the computational analysis framework. First, we run a global sensitivity analysis to determine which of the varied model input parameters are the most critical. Then, we conduct a parameter sweep.

Within the assumptions of this simplified model, we see that the maximum stress experienced by the cell under identical external loading conditions varies widely. In particular, we highlight the importance of cell shrinkage α and relative petal amplitude a/R .

Figure 3: Experimental semivariograms for AV and PV cells.

Figure 4: Left: a global sensitivity analysis on the rose model shows that cell shrinkage (α) and petal amplitude variation (a/R) are the most crucial parameters for predicting the max von Mises stress within the cell. Right: a corresponding parameter sweep.

DISCUSSION

This work on quantifying and modeling spatial heterogeneity in VICs primarily serves as a platform for future investigation into how the effects of altered cell behavior traverse scales from a bottom-up perspective. For the first time, we quantitatively show that AV and PV VICs have fundamentally different levels of spatial autocorrelation in stiffness. We also outline and demonstrate the functionality of a computational modeling framework to identify and explore mechanical mechanisms that increase our understanding of VICs and their interactions with their surroundings. Rather than simulating a single average cell with fixed parameters, our framework is set up to simulate hundreds to thousands of different cells with variable geometries and properties and interpret the results. Next, we will use our statistical techniques to generate a library of representative heterogeneous cells from experimental data and use computational modeling to test the mechanistic connection between altered cell properties and changes to experimentally observed bulk mechanical properties. Moving forward, this combined experimental/computational approach will help pave the way for understanding the impact of modified cell behavior on the tissue scale manifestation of valve disease.

CYCLIC STRETCH CAUSES LIBERATION OF CAVEOLIN-1 IN EXTRACELLULAR VESICLES FROM VASCULAR SMOOTH MUSCLE CELLS

Mohammad Shaver (1), Jessica Molina (1), Joshua D.Hutcheson (1)

INTRODUCTION

Caveolin-1 (Cav-1), an integral structural component of caveolae plasma membrane invaginations, has been reported to play important functions in atherogenesis and vascular calcification. Caveolae buffer the membrane to sudden changes in tension and mediate intracellular trafficking [2,3]. When plasma membrane tension increases caveolae flattening prevents membrane rupture. In vascular calcification, endocytosis of caveolae domains on the plasma membrane of vascular smooth muscle cells (SMCs) initiates the formation of calcifying extracellular vesicles (EVs). However, the role of plasma membrane tension in Cav-1 trafficking and EV formation in SMCs remains unknown. As pressures change over the cardiac cycle, SMCs experience cyclic mechanical stretch, causing elevated plasma membrane tension [4]. The aim of this study is to investigate the changes in Cav-1 trafficking and EV formation through application of mechanical stretch to SMCs *in vitro*.

METHODS

Porcine left coronary artery SMCs were harvested from hearts obtained from a local abattoir. The cells were expanded for no more than 7 passages and cultured on Bioflex culture plates. Cyclic stretch (5, 10 and 15%, 0.5 Hz) was applied to the SMCs for 72h using a Flexcell FX-5000T. Non-stretched SMCs were used as controls. Following mechanical stimulation, Cav-1 in SMCs and EVs collected from the culture media was assessed via western blotting. Equal protein loading was confirmed using Ponceau S staining. Immunofluorescence imaging was

performed to assess changes in Cav-1 distribution within SMCs. Tunable resistive pulse sensing (TRPS) was used to quantify the number and size of EVs.

RESULTS

Western blotting showed elevated Cav-1 in non-stretched control SMCs compared to SMCs exposed to 5,10 and 15% cyclic stretches (**Figure 1A**); where 10% is considered as a physiological cyclic stretch while 5% is sub-physiological and 15% is pathological cyclic stretch [5]. However, western blotting of EVs isolated from conditioned media from these samples revealed increased of Cav-1 in EVs collected from the stretched SMCs compared to the non-stretched controls (**Figure 1B**).

Figure1. Western blotting of intracellular (A) and EV (B) caveolin-1.

Densitometry-based quantification of n=3 independent replicates indicated a dose-dependent inverse relationship between stretch and intracellular Cav-1 (**Figure 2**). EV Cav-1 was higher in all stretched samples compared to control and exhibited a maximum in the SMCs exposed to 10% stretch.

Figure 2. Values of caveolin-1 within the SMCs in comparison with the extracellular.

Immunofluorescence showed Cav-1 clustering (red fluorescence) within the cytoplasm of stretched SMCs (**Figure 3A**) compared to the non-stretch samples (**Figure 3B**), indicative of caveolae flattening and Cav-1 liberation from the plasma membrane. Actin fibers within the SMCs were identified using a green fluorescent phalloidin stain (**Figure 3A-B**).

Figure 3. (A) Immunofluorescent images of SMC exposed to cyclic stretch (B) and non-stretched control SMCs.

TRPS can determine absolute concentration and size of EVs in media samples. The application of cyclic stretch led to increased EV release (**Figure 4A**). The concentration of EVs in the conditioned media from non-stretched VSMCs was 1.1×10^{12} EVs/mL. Exposing SMCs to 15% strain increased EV concentration to 2.0×10^{12} EV/mL. Mechanical stretch also led to a more uniform EV size and charge distribution (**Figure 4B & 4C**).

Figure 4. (A) Relative concentration of samples based on final particle count (B) EV size distribution for non-stretched control and 15% strain samples (C) EV charge distribution for non-stretched control and 15% strain samples.

DISCUSSION

The results indicate that cyclic mechanical stretch induces intracellular trafficking and subsequent release of Cav-1 in EVs of SMCs. Cav-1 has been noted to play an important role in cardiovascular diseases such as hypertension, atherosclerosis, and vascular calcification. EVs help mediate paracrine signalling and extracellular remodelling responses. Therefore, changes in Cav-1 trafficking and EV release in response to mechanical stimulation might play an important role in intercellular communication and matrix remodeling. Future studies may lead to the identification of therapeutic strategies for a number of cardiovascular diseases by modulating Cav-1 trafficking.

FOCAL CHONDRAL DEFECTS IN THE DYSPLASTIC HIP CAUSE ACTIVITY- AND SIZE-DEPENDENT INCREASES IN STRESS AND STRAIN

INTRODUCTION

Osteoarthritis (OA) is a highly prevalent joint disease characterized by the degradation of articular cartilage and the underlying bone. The hip is one of the most common joints in the body that is affected by OA. In the hip, bony pathomorphology such as dysplasia produces abnormal loading of the cartilage. This abnormal loading on the articular cartilage can overload the tissue, resulting in focal chondral defects and subsequently the development of OA¹. Focal chondral defects present as partial- or full-thickness voids in the articular cartilage, on the articular surface or at the osteochondral interface.

Although mechanical factors are understood to influence the initiation and progression of OA², the alterations in mechanics due to bony pathomorphology, the development of chondral defects, and the progression to OA are not well-understood. Due to the paucity of research on these mechanical effects, surgical treatment of chondral defects in the hip is rarely attempted. A clear understanding of the mechanical effects of these conditions would help to separate stable defects that will not expand and can potentially be treated conservatively (non-surgically) from defects that are likely to expand and thus should be treated more aggressively (i.e., with arthroscopic or even open surgical intervention). Finite element (FE) analysis can be used to understand the mechanics of cartilage in the hip and the various effects of different sizes and locations of focal chondral defects³. The method allows incorporation of highly nonlinear factors, such as geometry, material properties, and loading conditions, for analysis of mechanical environments which would otherwise be nearly impossible to test *in vivo*. The objective of this study was to assess the effects of the presence and size of focal chondral defects on the time-dependent response of articular cartilage in a patient-specific, dysplastic hip during activities of daily living.

METHODS

A validated patient-specific FE model of a dysplastic hip was selected from a cohort of ten models⁴ (Fig. 1A). Acetabular and femoral cartilage were represented as anisotropic biphasic materials. The solid phase consisted of a continuous ellipsoidal distribution of tension-only collagen fibrils embedded in an isotropic matrix to capture tension-compression nonlinearity, initial anisotropy, and strain-induced anisotropy^{5, 6}. A physiologically realistic distribution of fibril orientation was applied through the thickness of the cartilage layers, where fibrils were aligned tangent to articular surface in the superficial zone, spherical in the middle zone, and perpendicular to the osteochondral interface in the deep zone. A continuous variation of fibril reinforcement through the thickness was achieved with a custom FEBio plugin that allows scaling of the contribution from a local element axis as a function of surface depth (<https://febio.org/plugins/>). Permeability was represented as strain-dependent and anisotropic to align fluid flow with the direction of the fibrils. The labrum was modeled with a biphasic transversely-isotropic material with an isotropic ground matrix and fibers aligned circumferentially. Material coefficients and parameters were determined experimentally and guided by previously published sensitivity studies^{6, 7}.

An intact case was compared to cases with chondral defects of 3, 7 and 15 mm in diameter at a clinically relevant location on the chondrolabral boundary⁸ (Fig. 1A). Single-leg stance (SLS), gait, and squatting were simulated using three-dimensional loading and kinematics from Bergmann et al⁹. SLS was simulated by ramping to the maximum load and analyzing the response under creep for 600 s, as pilot simulations indicated that the variation of dependent variables was minimal after this time. A full cycle of gait and squatting were simulated to assess the effect of the presence and size of chondral defects on the same variables during dynamic scenarios. All models

were analyzed with FEBio (www.febio.org). The osteochondral interfaces were represented as impermeable and they were tied to rigid bodies representing the femur and pelvis. All other surfaces of the articular cartilage layers were free-draining.

For each kinematic scenario, the region around the defect (Fig 1B) was analyzed throughout the motion. The peak value over time in this region was selected for comparison between the different defect cases and activities. Maximum tensile strain on the articular surface (E_1) and

maximum shear stress at the osteochondral interface (τ_{\max}) were examined within the acetabular cartilage as the major dependent variables, due to the potential for collagen fibril fissuring and delamination of the cartilage from the bone, respectively. Fluid flux around the defect region was analyzed qualitatively.

RESULTS

Regardless of the activity performed, the presence of a chondral defect increased solid phase stress and strain (E_1 and τ_{\max}) in the defect region compared to the intact case (Fig. 1B-C). The 15 mm defect model experienced the highest magnitude for E_1 and τ_{\max} : 23.5% during SLS and 2.53 MPa during gait, respectively. For SLS and gait, E_1 and τ_{\max} increased with increasing defect size. During squatting, E_1 and τ_{\max} were highest for the 3 mm case and decreased slightly for the 7 mm and 15 mm defect cases. Fluid flux around the defect was much higher and concentrated in the defect region during gait and SLS compared to squatting (Fig. 1D).

DISCUSSION

Elevated solid phase stress and strain in the defect region may put the cartilage at risk of further damage progression. However, the magnitude and trends of these variables differed based on the applied motion.

During SLS and gait, the 15 mm case experienced tensile strain within the reported range of collagen fibril failure in articular cartilage¹⁰. Therefore, depending on the applied loading, larger defects may have greater potential for damage progression. This may indicate a threshold defect size, beyond which more aggressive treatment strategies should be recommended; however, more cases must be tested to verify this trend, as well as to determine the threshold size.

Increasing the defect size increased the stress and strain near the defect region during gait and SLS. In these scenarios, the loading vector is more directly applied toward the defect region. Loading applied more directly to the defect will induce a higher rate of fluid loss from the defect and could elevate stresses and strains due to edge loading. This was demonstrated by increased fluid flux around the defect and indicates that loss of fluid pressurization due to different loading patterns is closely linked to increased damage in the regions. During squatting, the load was not directed towards the defect region. Interestingly, while all defect cases exhibited a localized region of elevated E_1 and τ_{\max} during squatting, increasing the size of the defect from 3 mm to 7 mm and further to 15 mm decreased the stress and strain around the defect. This discrepancy in stress and strain magnitudes for increasing defect sizes indicates that the type of loading greatly affects the potential for damage progression.

INTRODUCTION

Acute, traumatic injuries to the anterior cruciate ligament (ACL) and meniscus significantly increase the risk of a long-term, chronic disease known as post-traumatic osteoarthritis (PTOA) [1], whether or not the patient has an early surgical reconstruction of the traumatized knee [2]. Using a previously developed closed-joint knee injury lapine model, our group demonstrated that 12 weeks after traumatic ACL and meniscal injury, untreated lesions result in intraarticular soft tissue changes consistent with clinical mid to late stage PTOA [3]. While post-traumatic ACL reconstruction and meniscal debridement represent the standard of care in clinical cases, surgical treatment of the traumatized knee was not performed in our previous studies.

Osteoarthritis (OA) is a degenerative joint disease, with which the articular cartilage begins to break down and wear away over time. In order to determine the changes that occur in the mechanical properties of articular cartilage in a traumatized knee, in situ indentation relaxation tests have been the experiment of choice to extract the material characteristics of cartilage, as the method preserves the structural integrity of the tissue on the joint surface [4].

The purpose of the current study is to develop a new lapine model that combines traumatic injury and subsequent surgical repair of the knee, and perform indentation relaxation tests on the tibial plateau cartilage to document changes in mechanical properties of the cartilage over time. It was hypothesized that acute damage to the articular cartilage resulting from a controlled, traumatic impact to the lapine knee would develop chronic changes in material properties of the cartilage, consistent with the previous description of mid to late stage PTOA in the lapine model, despite the subsequent application of repair procedures to the traumatized joint.

METHODS

Traumatic ACL and meniscal tears were induced on 12 skeletally mature, anesthetized Flemish Giant rabbits. With the animal in sternal recumbency, the right knee and paw were secured into a custom fixture that allowed unrestricted anterior tibial subluxation while constraining lateromedial motion. Controlled impact was delivered by a servo-hydraulic actuator (Instron, Norwood, MA) which thrust the tibia proximally at a rate of 0.5 Hz until ACL failure. Following debridement of the torn ACL and medial meniscus, reconstructive surgery was performed 2-3 weeks post-impact. The semitendinosus (ST) tendon's musculotendinous junction was transected while its tibial insertion was preserved. The tendon's free end was rerouted through tibial and femoral tunnels, of which intraarticular locations overlapped the ACL footprints. The ST tendon was tensioned and then secured into the femoral tunnel using an interference fit screw and periosteal sutures. A drawer test was performed to assess postoperative joint stability prior to routine closure. An IACUC approval was obtained for the study.

Animals were euthanized 1 (n=4), 3 (n=4), and 6 (n=4) months post-impact. Tissue was harvested immediately after euthanasia and refrigerated until mechanical tests were performed (within 12 h). Indentation relaxation testing was performed in a room temperature saline bath on the tibial plateau cartilage at four sites to account for both meniscus-covered and -uncovered cartilage surface (Figure 1). The cartilage thickness of each indentation site was measured by inserting a needle at a location adjacent to each site and observing when the reaction force increased due to contact with subchondral bone. A 1.59 mm diameter, spherical nonporous steel indenter was then pressed into the cartilage 30% of its thickness for 180 s, while the relaxation force-time data were collected. The mechanical tests were simulated with a previously described fibril-reinforced biphasic model

and implemented in a finite element package (Abaqus, Pawtucket, RI) [5]. The fiber modulus (E_f), matrix modulus (E_m), and tissue permeability (k) of cartilage were determined from this model. These property data were then compared with those from a previous study that uses a similar knee injury lapine model but without the surgical repair of the traumatized knee [3].

Unpaired t tests were used to compare differences in cartilage mechanical properties between impacted and contralateral control limb, and between results in the 3-month group of the current study and those from 12-week post-impact in Fischenich et al. [3], with $p < 0.05$ considered as significant.

Figure 1: Experimental setup for the indentation relaxation tests with the four indentation sites on the tibial plateau (a).

RESULTS

Mid-substance ACL tears were documented in 10/12 animals, while damage to the caudal horn of the medial meniscus occurred in 8/12 animals. Mean (\pm SD) failure force was 859.5 ± 117.6 N, correlating with approximately 12-13 times body weight of the animal.

Cartilage thickness was significantly greater in the impacted limbs than that in the control limbs at 3 and 6 months post-impact (Table 1). Mechanical properties of the tibial plateau cartilage showed remarkable degradations of the tissue, with a significant decrease in fiber modulus at 3 and 6 months post-impact, a significant decrease in matrix modulus at all three time-points post-impact, and a significant increase in tissue permeability at all three time-points.

Table 1: Average tibial plateau cartilage thickness and mechanical properties at three different time-points. * Denotes significant difference with $p < 0.05$ between control and tested limb.

Group	Cartilage Thickness t (mm \pm SD)	Fiber Modulus E_f (MPa \pm SD)	Matrix Modulus E_m (MPa \pm SD)	Tissue Permeability k (10^{-14} m ⁴ /Ns)
Left Tibial Plateau (control, average of covered and uncovered sites)				
1-month	0.29 ± 0.08	48.9 ± 15.0	1.52 ± 0.52	6.39 ± 4.11
3-month	0.42 ± 0.09	51.2 ± 13.4	1.49 ± 0.21	6.58 ± 3.01
6-month	0.26 ± 0.05	45.2 ± 10.8	0.99 ± 0.24	7.73 ± 5.99
Right Tibial Plateau (tested, average of covered and uncovered sites)				
1-month	0.38 ± 0.06	35.5 ± 19.1	$0.85 \pm 0.14^*$	$20.6 \pm 5.22^*$
3-month	$0.64 \pm 0.12^*$	$15.7 \pm 11.2^*$	$0.50 \pm 0.11^*$	$21.9 \pm 7.45^*$
6-month	$0.47 \pm 0.09^*$	$4.78 \pm 6.67^*$	$0.41 \pm 0.13^*$	$47.7 \pm 11.5^*$

In addition, a comparison of the current results with those from a previous study [3] under the same time-point (12 weeks post-impact) showed that no statistically significant difference was observed in the

mechanical properties of the impacted tibial plateau cartilage between studies (Figure 2).

Figure 2: Comparisons of mechanical properties in tibial plateau cartilage between the current study and Fischenich et al. [3]. Means that do not share a letter are significantly different.

DISCUSSION

This closed-joint knee injury model successfully and reliably generated traumatic mid-substance ACL tears and in most cases, meniscal damage. Repair procedures were then successfully performed for surgical treatment of the traumatized knee. ACL reconstruction and meniscal debridement replicated current surgical management of these injuries. Thus, this study provides a combined *injury* and *repair* model that can be used to study clinically relevant damages to the menisci, articular cartilage and subchondral bone associated with traumatic ACL rupture. Additionally, the fibril-reinforced biphasic model used in the current study accurately fitted the experimental curve, extracting both the instantaneous (fiber modulus) and equilibrium (matrix modulus) responses and tissue permeability.

The mechanical property results suggested significant degenerative changes of articular cartilage due to a traumatic knee impact, despite surgical repair of the traumatized joint. In addition to mechanical properties, as the ongoing project also uses morphological, functional, histological and imaging analyses, soft tissue lesions due to traumatic knee injury could be correlated to clinical progress of PTOA using this new animal model. This new model will therefore allow evaluations of the efficacy of an early intraarticular pharmacological intervention (P188) post-trauma.

COLLAGEN-DERIVED RESIDUAL STRESS ENHANCES THE BIPHASIC LUBRICATION PROPERTY IN ARTICULAR CARTILAGE

INTRODUCTION

Articular cartilage is heterogeneous and consists of three zones: superficial, middle, and deep zones. Previous studies indicated that articular cartilage surface could be split along collagen fiber direction in response to insertion of a dissecting needle [1]. This phenomenon is known as “split-line” that would suggest a collagen-derived residual stress is contained in articular cartilage. In fact, sliced cartilage specimens from mature animals tend to curve due to residual stress (Figure 1). In the present study, the effect of residual stress on the biphasic lubrication property in articular cartilage was analyzed [2].

Figure 1 Natural curvature of articular cartilage after sliced from a porcine femur (surface faces up)

METHODS

A fiber-reinforced 2-dimensional poroelastic cartilage model was developed on Abaqus 6.14 (Dassault Systemes, US), while referring to our previous study [3]. Cartilage of 3 x 1.5 mm was assumed to consist of fiber-reinforced poroelastic elements. Each element consisted of a pore pressure, plane strain element (CPE4RP) as a model of

proteoglycan, and laterally oriented spring elements (SPRING A) as a model of collagen fibers. While the permeability, Poisson' ratio, and coefficient of friction for solid-to-solid contact of proteoglycan were obtained from previous studies [4-6], the elastic moduli of proteoglycan and collagen fibers were determined through a curve fitting procedure to a confined compression test (Table 1). Note that the modulus of the collagen fibers was set to be dependent on compressive strain. This model was termed as standard model (SD model). Then, residual stress was contained in the collagen fibers in the surface layer of 0.3 mm in thickness by applying 1%-5% of tensile strain to collagen fibers. These models were termed as residual stress models (RS1-RS5 models). A rigid cylinder of 1 mm in diameter was translated on the cartilage model with a contact force of 0.1 N at a friction speed of 0.05-10.0 mm/s. The coefficients of start-up and dynamic friction were calculated from the integral of shear stress divided by the integral of contact pressure.

RESULTS

At 1 mm/s of friction speed, the coefficient of start-up friction at the first cycle was approximately 0.21 in SD model while it was slightly higher in RS models (Figure 3). However, at the second cycle of friction, the coefficient was approximately 0.16 in SD model while it was much lower in RS models; approximately 0.11 in RS1 model and 0.13 in other RS models. The coefficient of dynamic friction in the 1st and 2nd friction cycles was also lower in RS models than in SD model. This trend of decreasing coefficients of start-up and dynamic friction in RS models was also observed at other friction speeds.

Figure 3 Coefficients of start-up friction at the 1st and 2nd cycles of friction and averaged coefficient of dynamic friction at a speed of 1 mm/s in SD and RS models of articular cartilage

DISCUSSION

It was found that the residual stress in arterial wall played a role in decreasing its pressure gradient in a previous study [7]. To our knowledge, the present study is the first one that clarified the effect of residual stress on the lubrication property of articular cartilage. The coefficients of start-up and dynamic friction were decreased in RS models as compared with SD model, with the largest decrease observed at 1% of strain remained in collagen fibers (RS1 model) at friction speed of 1 mm/s. The modulus of collagen fibers in RS models was higher than that in SD model due to the contained residual stress. Thus, negative pressure behind the contact area was higher in RS model, shown in black in Figure 4, than in SD model, which caused a rapid rehydration in the region and higher fluid load support at the second and further friction cycles (Figures 4 & 5). Note that the coefficient of start-up friction was lower at a friction speed of 1 mm/s (cycle of 2s) as compared with 10 mm/s (cycle of 0.2s). Therefore, it

is suggested that collagen-derived residual stress enhances the biphasic lubrication property in articular cartilage, with the most significant effect appeared around walking speeds.

INTRODUCTION

Our sedentary lifestyle has been associated with increased risk of cardiovascular disease, metabolic disorders, cancers, and all-cause mortality.^{1,2} On this basis, the CDC has recommended a minimum of 30 minutes of daily exercise in order to maintain health.¹ Nonetheless, a pervasive impression exists among the lay public, and among many practitioners, that osteoarthroses result from ‘wear and tear’; leading to concerns that even moderate activity can promote cartilage wear. However, innumerable studies refute this relationship, instead, epidemiological studies indicate that moderate physical activity can decrease risk of joint disease.^{3,4}

The link between exercise and cartilage health is at least partially understood. Static loading (during sitting and standing) pressures the interstitial fluid of cartilage, which preferentially supports loads, minimizes tissue strains and shear, and reduces frictions.^{5,6} However, because cartilage is porous, load-driven exudation drives fluid losses and defeats this interstitial lubrication.⁶ Consequently, loss of interstitial fluid due to compressive loading represents a serious impediment to cartilage’s mechanical, tribological, and biological function. However, during articulation, cartilage recovers interstitial fluid and pressure, as evidenced by *in vivo* observations of activity-induced joint-space (cartilage) thickening.^{7,8}

Links between joint movement and cartilage hydration, hydration and mechanical function, and mechanical function and chondrocyte function suggest that activity promotes cartilage health by preventing the detrimental mechanical, tribological, and biological effects of cartilage dehydration. However, direct insight into practical matters such as how activity should be prescribed to support and optimize joint health outcomes (how much and how often) has been sorely lacking. This is in part due to the fact that the gold standard platform for conducting ‘controlled’ studies of cartilage tribology and

mechanobiology, the stationary contact area, induces rapid fluid exudation without providing any mechanism for competitive recovery, leading to functional compromise of the tissue and an inability to realistically study the link between cartilage tribology and health.

Recently, we have shown that by enlarging cartilage explant samples to allow for the creation of a convergent wedge at the leading edge of the stationary contact area (cSCA), one can drive sliding-induced fluid and deformation recoveries (which we term ‘tribological rehydration’) similar to that observed *in vivo*.⁹ Follow-up studies have suggested that sliding-induced hydrodynamic pressures restore cartilage hydration by competing directly against the load-induced exudation process, and this restoration of hydration and interstitial pressurization facilitates both surface lubrication and solute transport.^{10,11} Here, we leverage the cSCA testing configuration to determine if and how one distributes a fixed volume of activity (i.e. 30 min. of sliding) affects cartilage strain, which we use as a real-time predictor of cartilage health, within a simulated day of joint activity.

METHODS

19 mm diameter osteochondral cylinders (n = 5) were harvested from the femoral condyles of mature bovine stifles and tested on a uni-directional pin-on-disc materials tester (a.k.a. tribometer). When compressed against the glass disc, the curvature of the cartilage explants creates a convergence zone at the contact periphery that permits hydrodynamic effects during sliding that are necessary for tribological rehydration.⁹ Since the contact area is kept stationary relative to the cartilage, this geometry is referred to as a convergent stationary contact area (cSCA).⁹ Explants were subject to a 150-min ‘equivalent day’ (based on area-exudation scaling of time); which consisted of 90-min ‘awake’ period in which a constant 5N load (~0.25MPa) was applied, and a 60-min ‘sleep’ periods in which the load was reduced to 0.1N load

and held (**Figure 1A**). The awake period was further divided into a 30 min ‘active’ (100mm/s sliding) and 60 min inactive ‘sedentary’ period. Each specimen ($n = 5$ explants) was subjected to five different equivalent daily activity regimens in a random order, consisting of 1 (1x30-min), 3 (3x10), 6 (6x5), 15 (15x2), or 30 (30x1) equally spaced bouts (see **Figure 1B**). Direct measurements of normal force, friction force, compression, and thickness were used to quantify a number of biomechanical outcomes including compressive strain, friction coefficient, contact radius, contact pressure, shear stress, effective modulus, interstitial pressure, and fluid load fraction (**Figure 1C**).

Figure 1: Figure caption centered below the graphic.

RESULTS

The data in **Figure 1C** illustrates the effects of loading, sliding, and resting on the deformation and strain recovery responses, and friction response of cSCA articular cartilage (data for 3x10-min activity paradigm shown). When loaded statically, the deformation jumps more or less immediately to 100 μm , which represents the elastic response of cartilage. Over time under static load, deformations increase due to load-induced fluid exudation. Subsequent high-speed sliding restores thickness via tribological rehydration to nearly the original ‘elastic’ limit of 100 μm ; this rehydration process also restores interstitial pressure (not shown) and lubrication (friction coefficient).

Increasing the regularity of activity bouts (decreasing sedentary interval length) within our fixed 30-min of ‘daily’ activity substantially reduced the total loss of interstitial fluid as illustrated by **Figure 2A**. Increasing the number of bouts from 1 (‘daily’) to 30 (‘half-hourly’) decreased max strain accumulation and the loss of interstitial fluid by 80%, while also decreasing the extent of sliding friction at the start-of-sliding (**Figure 2B**). However, for a fixed volume of ‘daily’ sliding activity (30-min), strain at the end of each sliding bout, at the end of the loaded portion of the day, and at the end of the overnight unloading period were insensitive to the regularity of activity (or the length of contiguous time spent sedentary).

DISCUSSION

Our results demonstrate that the tribomechanical functions of cartilage are significantly affected by the length of sedentary bouts they are exposed to when controlling for total sedentary (60-min) and active

(30-min) time in the cSCA. The results provide new insights into both cartilage biomechanics and cartilage function. The application of static load causes cartilage to lose interstitial fluid and pressure, and lubricity when sliding/activity is initiated.^{6,9} Without any change in load, sliding-induced tribological rehydration reverses this exudation, restoring numerous biomechanical functions.⁹ Because exudation increased over time, the detrimental biomechanical effects of inactivity increased with sedentary bout length. From a cartilage biomechanics standpoint, the results demonstrate that shorter and more regular bouts of intermittent activity are preferred to longer and less regular bouts.

Figure 2: A) Deformation/strain and B) Friction traces for a representative sample subjected to the 5 different activity regimens tested in the present study.

The cSCA, and the discovery of tribological rehydration, offers us an opportunity to speculate about mechanistic connections between exercise, inactivity, joint health, and cartilage degradation. While it is intuitive that exercise might promote physical ‘wear and tear’ of joints, which are bearings after all, our results suggest the counterintuitive possibility that activity-induced mechanical damage is actually least likely to occur under conditions of sliding and joint activity that co-opt tribological rehydration to prevent the excessive loss of interstitial hydration and lubrication.

In conclusion, the result of this work demonstrates that the regularity of the ex vivo activity regimen, specifically the duration of each sedentary bout, has a significant effect on the biomechanical functions of cartilage. In more practical terms, the results suggest that brief but regular movement patterns (e.g. every hour) may be biomechanically preferred to long and infrequent movement patterns (e.g. a long walk after a sedentary work day) when controlling for daily activity volume (e.g. 30 minutes).

INTRODUCTION

In articular cartilage, the pericellular matrix (PCM) is a structurally distinct, 3-5 μm thick region surrounding chondrocytes that occupies the space between the further-removed territorial/interterritorial matrix (T/IT-ECM) and the cell [1]. Cartilage PCM is defined by the exclusive presence of type VI collagen [2]. In comparison to the further-removed T/IT-ECM, the PCM has a higher concentration of aggrecan, perlecan, type IX collagen and fibronectin, and has mechanical and structural properties that are distinct from the T/IT-ECM [3]. Serving as the immediate microenvironment of each cell, it has been hypothesized that the PCM serves as a transducer for biomechanical, biophysical and biochemical signals between the cell and the ECM [3]. For example, studies have found that the PCM is critical to many mechanosensitive cell activities such as cell adhesion, migration, solute transport and mechanotransduction [4-6]. However, the contribution of each molecular constituent to the PCM properties is not fully understood [1]. This study investigated the role of decorin, a small leucine rich proteoglycan, in the mechanical properties of cartilage PCM. In normal cartilage, decorin can bind to many different molecules [7] including: collagens II [8] and VI [9], aggrecan [10] and transforming growth factor- β (TGF- β) [11]. In chondrocyte culture, decorin is one of the first molecules that accumulates in the newly formed PCM [12]. In addition, we recently showed that decorin-null murine cartilage develops with a much reduced proteoglycan content and impaired mechanical properties [13]. Based on these findings, this study tests the hypothesis that decorin is crucial for establishing PCM micromechanical properties and chondrocyte mechanotransduction.

METHODS

Sample preparation. Tibial condyles were harvested from 3-day (newborn), 2-week (juvenile) and 3-month old (adult) wild-type (WT) and decorin-null (*Dcn*^{-/-}) mice [14]. Following our established procedure, the Kawamoto's film-assisted method [15] was used to obtain unfixed 5 μm -thick cryo-sections for AFM testing.

Immunofluorescence-guided AFM-nanomechanical mapping. Cryo-sections were labeled by immunofluorescent antibodies specific

for collagen VI, the biomarker of cartilage PCM [2]. Guided by the IF-images, AFM-nanomechanical mapping was performed using a Total Internal Reflection Fluorescence (TIRF) 3D-Molecular Force Probe (MFP-3D) in PBS ($R = 2.25 \mu\text{m}$, $k = 1 \text{ N/m}$, $10 \mu\text{m/s}$ indentation rate), following established procedures [16]. Using a custom Matlab code and IF-images, the moduli of PCM and T/IT-ECM moduli were analyzed separately.

Collagen fibril structural analysis. For both genotypes, additional 20- μm thick cryo-sections were prepared at all ages. Samples were treated with Karnovsky's fixative, dehydrated in hexamethyldisilazane and imaged under a scanning electron microscope (Zeiss Supra 50VP SEM) to visualize collagen fibrils [17]. Diameter of the fibrils were quantified in ImageJ.

Intracellular $[\text{Ca}^{2+}]_i$ signaling under osmotic stimuli. Intact tibial articular cartilage of both genotypes at all three ages was labeled with Ca-520TM AM in DMEM at 37° C for 1-hour. Time-series confocal images were taken to track the intracellular calcium signal of cells, $[\text{Ca}^{2+}]_i$ every 2 seconds for up to 15 min [18]. Osmotic stimuli were applied by varying ionic strength (IS) of DMEM in hypotonic (165 mOsm, IS = 0.075 M), isotonic (330 mOsm, IS = 0.15M) and hypertonic (550 mOsm, IS = 0.23M) conditions for all three ages [19]. To test the role of sGAGs in chondrocyte $[\text{Ca}^{2+}]_i$ signaling, additional juvenile cartilage was treated with chondroitinase-ABC (ChABC) in DMEM for 12 hours to remove CS-GAG [20]. Time series images were taken in the same conditions as above. The responsive rate, $\%R_{\text{cells}}$, for each sample was calculated as the fraction of responsive cells over total cell counts within a region of interest.

RESULTS

Guided by collagen VI IF-imaging, we separately analyzed the moduli of the T/IT-ECM and the PCM (Fig 1a). For juveniles and adults, *Dcn*^{-/-} cartilage PCM showed significantly lower modulus than that of WT. However, this difference was absent in newborns. Under SEM, we also found a mild, but significant increase in collagen fibril diameter in the PCM in adults, but not in newborns or juveniles (Fig. 2). Spontaneous intracellular $[\text{Ca}^{2+}]_i$ oscillations were observed for

both genotypes under all three osmotic conditions. In isotonic DMEM, adult $Dcn^{-/-}$ chondrocytes had significantly lower $\%R_{cell}$ than WT, while juvenile and newborn chondrocytes were not different than WT. This trend was consistent in hypotonic and hypertonic conditions as well, with $\%R_{cell}$ decreasing with increases IS for both genotypes (Fig. 3a). Upon depletion of sGAGs, there was a significant decrease in $\%R_{cell}$, reaching levels similar to that of a loss of decorin (Fig. 3b).

DISCUSSION

This study showed that decorin is a crucial component of the cartilage PCM, impacting micromechanics and chondrocyte mechanotransduction. Previously, we showed that decorin plays an indispensable role in mediating the assembly and stability of the aggrecan network in cartilage [13]. As a result, decorin null cartilage develops much lower aggrecan content and shows impaired biomechanical properties during post-natal growth. In cartilage, aggrecan is more concentrated [2], and undergoes faster turnover in the PCM [21]. Here, using our newly established method integrating Kawamoto's film-assisted cryo-sectioning [15] with IF-guided AFM [16], we further show that decorin directly mediates the structural integrity and micromechanics of the PCM (Figs. 1,2). On one hand, given that the PCM is where newly synthesized aggrecan is localized [22], decorin possibly mediates the integration of newly synthesized aggrecan. On the other hand, as chondrocytes are highly sensitive to their PCM micromechanical environment, decorin may also affect chondrocyte activities via mediating the integrity of PCM.

Indeed, we noted that the loss of decorin significantly reduces chondrocyte intracellular $[Ca^{2+}]_i$ signaling in adults. $[Ca^{2+}]_i$ signaling is one of the earliest cell mechanoresponses to its micromechanical environment [23]. We found a reduction in $\%R_{cell}$ that correlates well with the changes in PCM modulus, where the effect is absent in newborn and juvenile tissue, but becomes significant in adult tissues (Fig. 3a). In the PCM, the localization of proteoglycans, primarily aggrecan, provides a specialized, highly negatively charged microenvironment for residing chondrocytes. When hypotonic stimuli were applied to enhance the electrical double layer repulsion in the matrix, $\%R_{cell}$ increased accordingly. In $Dcn^{-/-}$ cartilage, we attribute the reduction of $\%R_{cell}$ to the decreased aggrecan content in the PCM. Indeed, when CS-GAGs were removed in WT cartilage, a similar trend of decreased $\%R_{cell}$ was observed (Fig. 3b). Therefore, we hypothesize that, during post-natal cartilage growth, decorin regulates chondrocyte mechanosensitive activities by mediating aggrecan content and assembly and the micromechanical properties of the PCM.

INTRODUCTION

In osteoarthritis (OA), degenerated cartilage eventually becomes unable to withstand normal (daily) intra-tissue mechanical loads, and begins a sustained degradation of the extracellular matrix (ECM) [1]. Currently no treatment exists to fully restore damaged or degenerated cartilage [2]. Tools to detect/monitor preclinical degeneration of cartilage may facilitate the development and validation of earlier treatments, allowing intervention before cartilage degenerates beyond repair [3]. Methods to track OA progression based on histological images, e.g. OARSI scoring [4] or adapted Mankin grading [5], are sensitive to early-stage OA but require tissue explants generally unavailable in a clinical setting. Methods used in clinical practice to quantify degeneration of cartilage rely on arthroscopic evaluation, e.g. Outerbridge [6], or magnetic resonance imaging (MRI), e.g. protocol by International Cartilage Repair Society (ICRS) [7], but are currently not sensitive enough to detect the onset of degeneration (i.e. early stage). Improved imaging techniques based on MRI have the potential for accurate, non-invasive assessment of cartilage health, particularly beyond the articular surface. However, a challenge remains to identify sensitive and reliable MRI markers associated with early OA.

OA-induced degeneration also affects collagen fiber orientation across the cartilage surface, as well as through the thickness. Desrochers et al. [8] found that minute changes in the collagen structure precede other changes (e.g. PG loss in particular) and cause alterations in the mechanical responses of cartilage at the onset of OA. Intra-tissue mechanics may thus provide more sensitive image-based biomarkers for quantifying the degeneration of cartilage. For example, Griebel et al. [9] found that changes in shear strain magnitude, measured by dualMRI, showed a stronger correlation with OA severity than T1ρ relaxometry. Such imaging methods highlight the potential of detecting the onset of OA by leveraging changes in local mechanics caused by OA.

Given the structural changes associated with the progression of OA, we hypothesized that patterns of through-thickness, large-strain shear evolve with early-stage OA. We therefore aimed to characterize changes in patterns of shear strain during early-stage OA to gauge the potential of patterns in shear strain to serve as image-based biomarkers of early-stage, preclinical OA, and to provide high-fidelity, through-thickness data for proposing, fitting, and validating constitutive models.

METHODS

Preparation of Specimens: We harvested nine lateral femoral condyles ($n = 9$, 67.0 ± 11.9 years old) undergoing total knee arthroplasty (TKA) at Hartford Healthcare Bone & Joint Institute. After determining the local split-line directions (SLDs), we extracted pairs of adjacent test specimens from load-bearing regions within the joint cartilages. From each pair, we used one specimen for mechanical testing (cuboid, $3 \times 3 \text{ mm}^2$ footprint, full thickness), with one through-thickness plane parallel to the local SLD, and the other specimen for histological evaluation. We immediately fixed the specimens for histology in 10% neutral buffered formalin while we stored the specimens undergoing mechanical testing in PBS at -80°C prior to testing. On the day of a mechanical test, we thawed and glued the articular surface and the subchondral bone (i.e. top and bottom) of a specimen to a loading platen, ensuring a flat surface perpendicular to the stereo camera setup (front surface). We then air brushed (CM-C Plus, IWATA) a speckle pattern on the front surface using a tissue marking dye (Cancer Diagnostics, Durham, USA) diluted with deionized water ($\sim 1:1$).

Histological Assessments: After decalcification in 0.5M EDTA, we embedded specimens for histology in paraffin and sectioned them at $6 \mu\text{m}$. To determine overall cartilage health, we stained sections with Safranin-O fast green (NovaUltra Safranin O stain kit, IHC World,) and examined the slides using a light microscope. Two trained observers (FM, DMP) quantified the progression of OA using the OARSI grading

method [5]. We considered only tissues up to grade 3.5 (moderate disease, presence of vertical fissures). We binned specimens into three groups based on their OARSI grades: normal cartilage (grade < 2, group OA-1), mild OA ($2 \leq \text{grade} < 3$, group OA-2), and moderate OA (grade ≥ 3 , group OA-3). To assess the integrity of the through-thickness zonal architecture, we stained sections with Picosirius red (NovaUltra Sirius red stain kit, IHC World) and examined the slides under polarized light. Two trained observers (FM, LM) quantified the integrity of the zonal architecture using the PLM-CO score [10]. We binned specimens into three groups based on PLM-CO scores: normal collagen structure (score ≥ 4), mild disruption (score 3), and moderate disruption (score ≤ 2).

Digital Image Correlation During Applied Shear Strains: Using a triaxial shear-testing device (Messphysik) we performed quasi-static (75 $\mu\text{m}/\text{min}$) cyclic simple shear tests and recorded images of the deformation in the SLD. We applied 1% precompression and applied displacements corresponding to ± 5 , ± 10 , and $\pm 15\%$ simple shear strain. Our cyclic tests included three preconditioning cycles, and we recorded images of the fourth loading cycle to calculate patterns of displacement and strain. We completed all tests in a bath of PBS at 37°C ($\pm 1^\circ\text{C}$) including antibiotics (100U/ml penicillin and 100mg/ml streptomycin) and protease inhibitors (P2714, Sigma Aldrich) to avoid degeneration. To record images for subsequent DIC, we used a stereo camera system with two five-megapixel cameras (Manta G-505, Allied Vision).

Data Analyses: We used the commercial software Istra4D (V4.4.3.414, Dantec Dynamics) for image processing and strain calculations. We approximated the displacement field by an analytic function (bi-cubic splines) to obtain 2-D deformation gradients for subsequent strain calculations. We exported the full field of 2-D Green-Lagrange tangential shear strain and we performed further processing and analyses using MATLAB (R2017b, The MathWorks). First, we averaged ($M \pm \text{SD}$) the shear strain values along horizontal lines at each height through the specimen's thickness to generate a through-thickness strain curve. We then grouped those curves by either OARSI grade or PLM-CO score and averaged them to obtain master curves representing normal, mildly degenerated, and moderately degenerated cartilage.

RESULTS

We successfully imaged the distribution of deformation at three applied strain levels (5, 10, and 15%) on most of the 44 specimens. Seven of our specimens showed signs of mechanical failure during testing and we excluded these data from subsequent analyses.

Histological Assessments: Our OARSI grading resulted in $n_{\text{OA-1}} = 17$, $n_{\text{OA-2}} = 16$, and $n_{\text{OA-3}} = 11$ specimens per binned group. Inter-observer agreement for the unbinned OARSI grades was 0.925 and for the binned OARSI-graded groups was 1.0. Our PLM-CO scoring resulted in $n_{\text{PLM-2}} = 18$, $n_{\text{PLM-3}} = 12$, $n_{\text{PLM-4-5}} = 14$ specimens per binned group. Inter-observer agreement for the unbinned PLM score was 0.735 and for the binned PLM score was 0.766.

Through-Thickness Patterns of Shear Strain: We observed three general shapes for the curves of averaged through-thickness Green-Lagrange shear strains consistent over all applied strain magnitudes (Fig. 1). We found the largest shear strains (by magnitude) at or near the articular surface. Normal tissue (OA-1) also showed a distinct relative peak in shear strain near the transition from the MZ to the DZ, near or at the advancing cartilage-bone interface. With advancing OA (mild degeneration, OA-2) the through-thickness shear strain became more homogeneous. Finally, with further advancing OA (moderate degeneration, OA-3) the shear strain became more heterogeneous with the deformation focused near the articular surface.

DISCUSSION

Histological Assessments: Semi-quantitative, histology-based methods for assessing cartilage degeneration have inherent drawbacks: e.g. these discrete categories likely cannot fully capture the dynamic,

Figure 1: Green-Lagrange shear strains by OARSI grades (a-c) and PLM scores (d-f) at bulk shear strains = 5%, 10%, and 15%.

years-long progression of disease in its full complexity. Despite the good-to-excellent inter-observer agreement reported here, application of OARSI grading and PLM scoring is still subjective and automated tools may reduce potential bias.

Through-Thickness Patterns of Shear Strain: We found three general qualitative through-thickness patterns of shear strain depending on the stage of degeneration of the specimens (Fig. 1). We are the first to report a region of increased shear strains in normal cartilage in the transition from MZ to DZ, i.e. near the cartilage-bone interface.

Limitations and Conclusion: Despite predominately-external compression to cartilage *in vivo*, shear strains within cartilage tend to exceed compressive strains [11]. We found that early-stage OA presents characteristic through-thickness patterns of shear strain for normal cartilage, and mild and moderately degenerated cartilage. We propose that changes in through-thickness patterns of shear strain could provide sensitive biomarkers for early clinical detection of OA, changes that can be quantified *in-vivo* using advanced MRI protocols [9,11]. Reliable early detection will aid the development and validation of treatments.

INTRODUCTION

The human cervix is essential to pregnancy for protecting the fetus before delivery, acting as a mechanical barrier. It is believed preterm birth (PTB) - defined as birth before 37 weeks of gestation - is related to a mechanically weak cervix. Therefore, the mechanical property characterization of the cervical tissue may contribute to our understanding of the causes of preterm birth.

The cervix is a soft tissue that behaves as a strong nonlinear poroviscoelastic material. It is composed of cross-linked collagen fibers embedded in a ground substance formed by the negatively charged proteoglycans and glycosaminoglycans [1, 2]. These components provide the anisotropic and time-dependent material response to mechanical loading. In our earlier studies, the time-dependent force response under indentation was modeled using a simple viscoelastic model [3], ignoring possible contributions of preferred collagen fibers and poroelastic mechanisms [4].

In this study, load-relaxation indentation experiments on human cervical tissue samples were conducted. This indentation test was coupled with a video extensometer to capture tissue deformation in addition to load-time data. Inverse finite element analysis (IFEA) of the indentation experiment is utilized to fit a poroviscoelastic material model to the indentation response and tissue strain. The model is informed by previous measurements of collagen fiber directionality and dispersion of each sample [5] and permeability measured from a separate set of human samples [4]. At last, statistical analysis was performed to investigate the differences in material properties between samples of different obstetric backgrounds and between different anatomical locations within each sample.

METHODS

Sample Preparation 13 non-pregnant cervical tissue slices were sectioned from 7 different consented hysterectomy patients. The thickness of the cervical slices ranged from 1.8 to 7.1 mm, with the majority being between 2.5 and 6 mm. The radii of the samples were 10 – 15 mm. The slices were stored flat in a -80°C freezer immediately after sectioning until testing.

Indentation Experiments Before scheduled indentation tests, each sample was microtomed and equilibrated in phosphate-buffered saline (PBS) at 4°C for 12 hours. The bottom surface of the cervical slices was speckled using india ink and then the edges of the bottom surface were glued to a petri dish. The cervical slice was immersed in PBS solution. Samples were put onto a glass, as shown in Fig. 1 (A). A camera was placed in front of the setup and captured the deformation of the bottom surface using a right-angle prism. Four locations (anterior, posterior, left, right) of each sample were indented (Fig. 1 (C)). A displacement-controlled, ramp-hold indentation test was conducted at each location using a 6 mm stainless steel indenter, with a ramp rate = 0.2% thickness/s and a holding time = 495 s. (Fig. 1 (B))

Figure 1: (A) The indentation experiment setup. (B) Testing profile of the load – relaxation experiment. (C) Four indentation locations.

FEA Model The FEA model was created in FeBio (V2.6.2, url: febio.org) to simulate the indentation experiments. As shown in Fig. 2

(B), the cervical sample was modeled as a flat half-cylinder hollow in the center, and the indenter was modeled as a hollow quarter-sphere with rigid body material. The critical points of the FEA model corresponded with those in the DIC (digital image correlation) strain map of the bottom surface generated using Vic-2D (V6, Correlated Solutions Inc.) system (Fig. 2 (A)). Points A and B were the two ends of the diameter of the canal, and C was the center of the canal. D was the indenter spot. E and F were the glued boundary and the edges of the sample, respectively. R_f^c , R_f^r , and R_f^l were the refined domain in the radial, circumferential, and axial direction to guarantee the accuracy. The z – displacement between B and E was fixed to represent the bottom surface. The symmetric boundary condition was set on the middle plane. All displacements between E and F were fixed to represent the glued boundary.

Figure 2: FEA model of the sample under indentation experiments. (A) DIC strain map of the bottom surface of the cervical tissue sample under the experiments. (B) the corresponding FEA model of the indenter and the cervical sample. The points A-F in the FEA model (B) are determined based on the points in DIC strain map (A).

Constitutive Equations The cervix was modeled as a poroviscoelastic material, where the solid component of the material is a continuously distributed fiber composite with a von Mises fiber network. The details of this kind of material are found in the FeBio user manual [5]. The material parameters of the elastic part are E , ν , ξ , b , β , and α , which were the Young's modulus, the Poisson's ratio, the fiber stiffness, the distribution coefficient, the fiber polynomial index, and the fiber exponential coefficient, respectively. The parameters of the time-dependent part are g_1 , g_2 , τ_1 , and τ_2 , where g_i 's are the stiffness coefficients for each level and τ_i 's are the time-decay coefficient for each level. k is the hydraulic permeability.

IFEA Process The goal of IFEA was to fit the FEA model predictions to the force-relaxation response to find the material parameters listed in Table 2 (previous IFEA was conducted using the strain maps to find anisotropic material parameters – see Table 1). The known material parameters are listed in Table 1, where ξ , b , ν , and α were obtained from previous studies and varied from slice to slice. Therefore, the range of each parameter was listed. β was fixed as 2 for exponential form of free energy density. k was chosen as $2.1 \times 10^{-14} \text{ m}^4/\text{N}\cdot\text{s}$ according to our previous measurement. [4] The objective function of the IFEA optimization process was defined in Eq. (1).

$$\chi = \frac{1}{n} \sum_i^n \frac{|F_i^{\text{EXP}} - F_i^{\text{FEA}}|}{F_i^{\text{EXP}}} \quad (1)$$

where F_i^{EXP} is the experimental force response data at time series i , F_i^{FEA} is the corresponding FEA force response data. n is the total time series used to fit. The range of the parameters to be fitted and the optimized values are listed in Table 2.

Table 1: The material parameters obtained from previous study.

ξ	b	ν	α	β	k
$[10^{-2}, 10^3] \text{ kPa}$	$[0, 5]$	$[0, 0.499]$	$[0, 10]$	2	$2.1 \times 10^{-14} \text{ m}^4/\text{N}\cdot\text{s}$

RESULTS

The representative fitting results of the force – relaxation responses are shown in Fig. 3 (A). The final value of the objective function is 0.045 for this case, which is very small and proves to be a good fitting.

Table 2: The range and the optimized results of parameters.

Parameter	Range	Optimized Results (n=41)
E	$[10^{-2} \text{ kPa}, 10^2 \text{ kPa}]$	$1.65 \pm 1.48 \text{ kPa}$
g_1	$[0, 2]$	0.93 ± 0.32
g_2	$[0, 2]$	0.45 ± 0.30
τ_1	$[1, 100] \text{ s}$	$25.73 \pm 23.79 \text{ s}$
τ_2	$[1, 500] \text{ s}$	$69.76 \pm 20.09 \text{ s}$

The one-way ANOVA statistical analysis of the parameters were conducted by dividing the samples into different groups, such as different parities (parity < 2 & > 2), different locations (anterior, posterior & left, right), and different parts of the cervix (external os & internal os). Only τ_2 was found significantly different ($p < 0.05$) at anterior and posterior compared to left and right. (Fig. 3 (B))

Figure 3: (A) Representative force – relaxation response to indentation and the corresponding IFEA fit for the experimental data. The final value of the objective function is 0.045. (B) Statistic analysis of the IFEA results using one-way ANOVA. Only τ_2 among different groups of quadrants (anterior and posterior vs. left and right) were found significantly different ($p < 0.05$).

DISCUSSION

The FEA model represents a good approximation of the real force – relaxation experiment appropriately. g_1 and g_2 are not far away from our previous study. τ_1 and τ_2 are very different from our previous study. [3] This is due to the additional consideration of permeability in this study compared to the previous one. It also contributes to the time – dependent response.

The main limitations of this study are that the constitutive model of the groundsubstance is a kind of general viscoelastic model with internal variables, whose physical meanings are not clear. We are studying the viscoelastic model based on reactive mixture theory, in which all variables are observable and have physical meaning. The strain maps of the bottom surface have not been fitted. The strains should also be considered in the fitting process in the future.

INTRODUCTION

Pelvic organ prolapse (POP) is a prevalent condition characterized by the abnormal descent of female pelvic organs due to the loss of structural support. Ten percent of women in the United States undergo surgical intervention related to POP [1], and 4 out of 10 women experience reoccurrence of prolapse symptoms 2 years after surgery [3]. In the United States alone, direct cost of over a billion dollars is incurred annually for POP associated interventions [2]. Despite the epidemiologic importance of this disorder, our knowledge of its pathophysiology is limited. Although the etiology of POP has not been fully elucidated, some risk factors include mechanical injury, vaginal delivery, obesity, age, race, family history, higher parity and constipation [3, 4].

The uterosacral ligament (USL) provides structural support (Level 1) to the female pelvic floor [5]. The loss of the structural integrity of USL may induce POP. The USL is primarily composed of smooth muscle and collagen fibers, with a limited quantity of elastin [3, 5]. To assess the physiologically-relevant biomechanical properties of USL and tissue anisotropy, biaxial testing permits acquisition of biomechanical data from two axes simultaneously, thus providing a more physiologic assessment compared to standard uniaxial testing [3]. Despite this importance, biaxial USL properties have only been reported for swine [7, 8] and women without POP to date [3]. To the best of our knowledge, biaxial USL properties have not been determined for women with POP. Therefore, the objective of this study was to quantify and compare the biaxial biomechanical properties of USL from post-menopausal women with and without POP.

METHODS

USL samples were obtained (Ochsner Clinical School IRB approved: 2017.016A) from post-menopausal women with either POP ($n=15$, 64 ± 7 years old, 31 ± 8 kg/m² BMI) or non-POP ($n=11$, 62 ± 5 years

old, 33 ± 5 kg/m² BMI) condition following transvaginal hysterectomy surgeries (Figure 1A). Samples were snap-frozen following surgery and stored at -80°C until the day of biomechanical assessment. All the samples were from Europeans/White women, except 4 that were from African-Americans/Black women (non-POP controls). **Biaxial testing.** Samples were thawed at room temperature, cut into squares and then speckle coated with alcohol ink for strain tracking. Using a non-contacting laser micrometer, tissue thickness was measured across multiple locations and averaged. Four fish hooks were used to mount each sample side into a custom planar biaxial test device equipped with load cells (22 N) in both axes (Figure 1B). The samples were fully submerged in Hank's balance saline solution throughout the experiment. A tare load of 0.1N was applied in the X- and Y-directions, followed by 10 equibiaxial preconditioning cycles to 0.1MPa, after which the samples were allowed to equilibrate for 10 minutes. Next, samples were loaded in the X- and Y-directions to different X:Y loading ratios of 1:0.5, 1:0.75, 1:1, 0.75:1 and 0.5:1 at 0.2%/sec. For each of the loading ratios, 5 preconditioning cycles were applied. Using a custom Matlab code and a built-in minimization algorithm (*lsqnonlin*), Fung type constitutive model was fitted to the averaged experimental data for the POP and non-POP groups by minimizing the mean square error between the experimental data and model curves. The strain energy is given by

$$W = \frac{1}{2}K(e^Q - 1) \quad (1)$$

$$\text{where } Q = c_1 E_{xx}^2 + c_2 E_{yy}^2 + 2c_3 E_{xx} E_{yy}.$$

The parameter K has a unit of MPa. Parameters c_1 , c_2 , c_3 are dimensionless, and E_{xx} , E_{yy} are Green strains. **Statistical Analysis.** All

data are presented as Mean±SD. Independent samples t-tests were used to assess differences in age, body mass index (BMI), parity, gravidity, nulliparous, nulligravid, average stress and stretch between POP and non-POP patients. Statistical significance was set to $p<0.05$. All statistical analyses were performed using SPSS software.

RESULTS

The measured thickness were 3.27 ± 1.15 mm and 3.51 ± 0.96 mm for the non-POP and POP specimens respectively. No statistically significant differences ($p<0.42$ (age), $p<0.439$ (BMI), $p<0.264$ (parity), $p<0.073$ (gravidity)) were identified with respect to age, BMI, parity and gravidity, between the POP and non-POP patients. USL from POP patients exhibited statistically significantly ($p<0.00001$) larger stretches when subjected to either 1:1 or 0.75:1 loading ratios in both the X- and Y-directions (Figure 2B&D), as compared to the non-POP USL (Figure 2A&C). This indicates that the tissue from POP patients is more extensible compared to tissue from non-POP controls. Additionally, tissues demonstrated anisotropic behavior. In particular, the Y-direction in the non-POP group demonstrated higher extensibility compared to the X-direction for the 0.75:1 and 0.5:1 loading ratios ($p<0.00005$). The constitutive model described the data reasonably well ($R^2 = 0.99$, for both non-POP and POP). Table 1 shows the parameters from the averaged data obtained from the Fung constitutive model for each group. Noting that the c_1 and c_2 parameters were larger in the POP group, while c_3 was smaller in comparison to the non-POP group (Table 1).

Group	K [MPa]	c_1 [-]	c_2 [-]	c_3 [-]
Non-Prolapsed	1.27E-3	41.27	42.59	147.36
Prolapsed	8.48E-4	93.48	119.49	96.16

Figure 1: (A) USL specimens were obtained at the distal right and left insertions. (B) Samples were speckle-coated and mounted in a planar biaxial testing device via fishhooks.

DISCUSSION

POP tissues demonstrated increased extensibility, in particular, in the 1:1 loading ratio compared to the non-POP control USL. USLs from women with POP demonstrate significantly higher collagen type III expression than their non-POP counterparts [6]. No significant differences in collagen I expression and smooth muscle cell content, however, were identified between these two groups [6]. The significantly higher collagen III expression for the POP USL may be a contributing factor for its higher extensibility. Future work, however, is needed to identify potential statistical correlations between type III collagen content and tissue extensibility. Further, elastin may significantly contribute to tissue extensibility. Loss of elastin has been highly implicated in POP development and progression in other tissues

Figure 2: Representative stress-stretch plots in the X direction for non-POP (A) and POP (B) USL. Representative stress-stretch plots in the Y direction for non-POP (C) and POP (D) USL. Figure shows that POP USL exhibits more extensibility than non-POP.

within the pelvic floor [9]. The elastin composition of the USL with and without POP, however, has not been identified to date. This study also identified that the non-POP and POP USL demonstrate an anisotropic mechanical response. Generally, the USL was more extensible in the Y-direction compared to the X-direction (Figure 2). The Fung-type model was able to reasonably describe the biomechanical behavior of the non-POP and POP USL ($R^2 = 0.99$). The Fung parameters indicated that there was minimal biomechanical contribution from the ground substance (Table 1). Further, the model suggests potential remodeling of the fiber component during POP, as an increase was observed in the c_1 and c_2 compared to the controls. This may be explained by altered collagen fiber alignment, undulation, or possible alterations in the type I:III ratio. Further work is needed to identify correlations between model parameters and tissue composition, as well as to examine possible microstructural models to improve clinical relevance.

This study was not without limitations. One such limitation is the lack of racial diversity in the patient population. Current patient recruitment seeks to improve diversity. Noting, however, that the rate of POP in the African Americans/Blacks population is much lower than other racioethnic [10]

INTRODUCTION

During childbirth the female pelvic floor endures substantial stretching, frequently resulting in tearing of the vaginal wall and major surrounding tissues and organs. Childbirth-related maternal trauma is the primary etiological factor of pelvic floor disorders (PFDs) such as urinary incontinence, fecal incontinence, and prolapse. These disorders affect one out of three adult women, representing a major healthcare concern in the U.S. Although the prevalence of PFDs increases with childbirth, there are currently no quantitative methods that can predict maternal trauma and the development of PFDs. In this study, we conduct inflation tests together with the digital image correlation (DIC) method to determine the tear behavior of the vaginal wall using the rat as an animal model. Inflation tests are preferred over planar biaxial tests since they are physiologically more relevant and prevent tearing at the hooks that are used in planar biaxial testing [1]. We also analyze the collagen fiber organization in the regions where the tears form using second harmonic generation (SHG) imaging. This micro-mechanical analysis reveals the possible mechanisms of vaginal tears.

METHODS

This study was approved by the Institutional Animal Care and Use Committee (IACUC) at Virginia Tech. Eight (n = 8) vaginal tracts were isolated from eight virgin Sprague-Dawley rats (~3 months old). Initial axial, radial, and thickness measurements were taken using a CMOS camera (Thorlabs Inc.)

on a dissecting microscope. Each specimen was then mounted onto two dispensing needles which allowed one end of the vaginal tube to freely move while being inflated. After mounting, specimens were dyed blue with an aqueous methylene blue solution (1% w/v) and speckled with an aerosol fast dry gloss white paint. This created a high contrast speckle pattern on the surface of the specimen for non-contact strain measurements. Throughout the preparation process, the specimens were hydrated with phosphate buffered saline (PBS). Specimens were housed in an acrylic water bath filled with PBS and inflated with PBS via a computer-controlled syringe pump (New Era Pump Systems Inc.) to a pre-load of 0.2 psi as measured by a 50 psi pressure transducer (Omega Engineering Inc.). This point was established as the reference configuration. Specimens were pre-conditioned for 20 cycles at 4.7 mL/min up to a 100% increase in volume and back to the reference configuration. Following a 10 minute long period of rest, specimens were inflated at 4.7 mL/min until rupture. High-resolution images of the specimens were taken during inflation via two CMOS cameras (Basler Inc.) equipped with c-mount lenses (Schneider Optics Inc.). Non-contact strain measurements were performed with a DIC system (Correlated Solutions Inc.). Once testing was completed, specimens were removed from the setup, kept hydrated, and the rupture site was imaged using the SHG imaging. Specimens were placed on a motorized stage of a Zeiss LSM 880 upright confocal microscope (Zeiss). Backward-SHG imaging was performed with a 140 fs Ti:Sapphire laser (Coherent Inc.) centered at 780 nm at 80 MHz repetition rate. The beam was

deflected into the back port of the microscope and scanned across the vaginal specimens by a galvanometric x-y scanner. The beam was passed through a 690 nm dichroic mirror and focused onto the specimen. A 20X non-immersion microscope objective and a 40X oil-immersion microscope objective were used for imaging. The average excitation power illuminating the specimen was approximately 30 mW as measured by a power meter (Newport Corp.). The backscattered SHG signal from the specimen traveled through the objective and was collected by reflected to a detector after going through a 690 nm long-pass dichroic beam splitter. The SHG signal was isolated by a secondary beam splitter followed by a 390 nm bandpass filter (Semrock). Two-dimensional images were acquired from various depths into the specimen.

Figure 1: Lagrangian strains in the longitudinal direction (LD) and circumferential direction (CD) for a representative vaginal specimen at a 118 kPa pressure. For this specimen failure occurred at 119 kPa pressure. Note that the z-axis is oriented along the longitudinal axis of the vagina.

RESULTS

Rupture of the vaginal wall consistently occurred in the central region away from the clamps. The main axis of the tear was oriented along the longitudinal direction (LD) of the vagina. The tissue was observed to strain far more in the circumferential direction (CD) than in the LD (Figure 1(a)-(b)). Larger strains in the CD were expected, but in the LD the strain was surprisingly near zero. The average axial Lagrangian strain at failure was 0.41 ± 0.38 in the CD compared to 0.05 ± 0.03 in the LD. The average pressure at rupture was 106.8 ± 26.2 kPa, which corresponded to an average maximum stress of 1035 ± 254 kPa and 487 ± 123 kPa in the CD and LD, respectively. Paired t-tests confirmed a statistically significant difference between the average failure stresses ($p < 0.001$) and strains ($p = 0.032$) in the two directions.

Images collected using the SHG imaging after mechanical testing showed that the collagen fiber orientation changes through the thickness of the specimens (Figure 2 (a)-(b)). However, fibers seemed to be preferentially aligned along the LD of the vagina. In regions that were close to the tear, the fibers appeared to be oriented along the edges of the tears (Figure 2 (c)-(d)). Moreover, post-failure analysis of the vaginal specimens via SHG imaging revealed three primary failure mechanisms: delamination, collagen fiber failure, and collagen fiber re-orientation.

Figure 2: (a)-(b): Collagen fibers in the dorsal region of the rat vagina, near the rectum, at 20X and 40X magnifications. (c)-(d): Collagen fibers in the ventral region of the rat vagina, near the urethra, where tearing occurred. The orange arrow indicates the LD of the vagina. Scale bar=50 μ m.

DISCUSSION

This study presents the first mechanical characterization of the rat vagina up to under inflation. Our results demonstrated that the vagina is highly anisotropic and undergoes large deformations (Figure 1). The strain in the LD was significantly lower than in the CD due to the preferred orientation of the collagen fibers in the LD (Figure 2(a)-(b)). Our results indicated a nearly zero and sometimes negative strain in the LD. It is possible that the complex strain behavior may be determined by the magnitude of the applied strain relative to the in-vivo strain as shown in a previous study performing inflation of murine vaginas [3].

Under inflation, we observed that the vaginal specimens successfully failed in regions away from the clamped ends. Our SHG analysis of these regions showed that the primary mechanisms of tear formation are delamination, collagen fiber failure, and collagen fiber re-orientation. Future studies will be conducted to determine the tear propagation mechanisms under inflation. Knowledge about the tear behavior of the vagina can guide the development of new prevention and treatment strategies for maternal birth trauma.

INTRODUCTION

Diabetic cystopathy is a form of neurogenic bladder dysfunction that occurs in diabetic patients experiencing peripheral neuropathy. Loss of connection between the urinary bladder and the nervous system dulls the sensation of fullness in the bladder. This causes delays in voiding, leading to chronic over-filling of the bladder. This type of volume overload has been shown to cause changes in extracellular matrix (ECM) content, wall thickness, tissue compliance, and inflammation in the bladder [1, 2, 3]. Furthermore, obesity — often associated with type II diabetes, specifically — also has been shown to increase systemic inflammation, which could induce even further remodeling to the bladder wall (e.g., high level of inflammation are often associated with fibrosis in the remodeling of the lungs, liver, and heart). Finally, stiffening of the bladder wall associated with fibrosis can diminish the bladder distensibility, which in turn could increase the urine storage pressure, posing a threat to kidney function of these patients. For these reasons, it is crucial to understand what specific changes are taking place in the ECM within the bladder. In this study, we have measured experimentally the mechanical behavior of the ECM of urinary bladders from a lean and an obese rat model of type II diabetes. We then employed a Fung-type exponential isotropic strain energy function to model the experimental data, and quantify material parameters for each model of type II diabetes.

METHODS

Uniaxial ring tests were conducted using transversely sliced, decellularized rings of urinary bladder tissue from: **Goto-Kakizaki** rats (**lean diabetic**, GK-D, $n = 5$), **Zucker diabetic fatty** rats (**obese diabetic**, ZDF-D, $n = 4$), Wistar as a control for GK-D animals (GK-C, $n = 6$), and lean ZDF littermate as a control for ZDF-D animals (ZDF-C, $n = 4$) [4]. Before the ring tests were conducted, each ring was

decellularized through a 48 hour soak in a 1% sodium-dodecyl sulfate solution to isolate the ECM. Following this procedure, the rings were mounted on a uniaxial testing machine using suture and submerged in a modified, calcium-free Krebs buffer. Each ring was subjected to a pre-load of 2-3g. Finally, the ring test consisted of: 10 cycles at 5% stretch (preconditioning), 5 cycles at 10% stretch, 5 cycles at 20% stretch, and 5 cycles at 30% stretch.

Assuming incompressibility and isotropic behavior of the tissue, the final loading curves of the stress-strain data from these tests were then fitted to a Fung-type material model, Eq. 1.

$$W = c(e^{k(I_1(C)-3)} - 1) \quad (1)$$

Two parameters, c and k , have been reported for each test group, see **Table 1**. Additionally, the product $2ck$ was also used in the comparison of different groups, as this term serves as an important parameter in the equation for theoretical stress, Eq. 2.

$$t_{11} = 2ck\left(\lambda^2 - 1/\lambda\right)e^{k(\lambda^2 - 2/\lambda - 3)} \quad (2)$$

While k has an effect on the entire curve, $2ck$ is specific to the toe-region, which will provide crucial information about compliance at low stresses.

Additionally, histological analyses were performed to assess changes in the extracellular matrix due to remodeling—namely elastin and collagen fibers—and mast cell activation, which is indicative of inflammation. To measure elastin fiber, collagen fiber, and mast cell content, the slices were stained with Verhoeff-Van Gieson (VVG), Picrosirius Red (PSR), and a modified toluidine blue (t-blue),

respectively. Because mast cells are present regardless of inflammation, simply counting the number of mast cells present in the tissue samples or estimating an area fraction would not provide sufficient information about inflammation in the urinary bladder. Instead, mast cell activation was estimated through a ranking system: 1-completely inactive (no granulation), 2-beginning activation, and 3-completely inactive (high granulation). Mast cells were counted and ranked to provide an overall score of activation for each sample.

RESULTS

Our experimental results showed that the ECM of bladders collected from both GK-D and ZDF-D diabetic animals presented an increase in compliance when compared to their respective controls, namely Wistar (GK-C) and ZDF lean littermates (ZDF-C), **Figure 1**. Furthermore, we observed that the ECM of bladders from ZDF animals, both the ZDF-C and ZDF-D, show a higher compliance when compared to GK animals, GK-C and GK-D, respectively. The only two groups that showed no difference were GK-D and ZDF-C.

Figure 1. Stress-strain data from uniaxial ring test. Each point represents average (error bars showing standard deviation) strain from all samples in each group. Data shown is from final loading curve.

The model proved useful in identifying where differences between the groups are present in regards to the mechanical parameters. Specifically, a decrease in *c* and *k* when comparing controls to diabetic, using a student t-test, is present in both the GK and ZDF models (*p* < 0.05), **Table 1**. The differences in *2ck* were significant across all test groups except for ZDF-C v. GK-D and ZDF-C v. GK-C (the comparison ZDF-C v. GK-C was close to significance, *p* = 0.061).

Table 1. Optimized material parameters for each test group.

Group	<i>c</i> (avg ± stdev)	<i>k</i> (avg ± stdev)	<i>2ck</i> (avg ± stdev)
ZDF-C	0.466 ± 0.113	36.067 ± 13.428	32.039 ± 7.374
ZDF-D	0.271 ± 0.090	25.983 ± 4.370	14.055 ± 5.496
GK-C	0.725 ± 0.342	79.625 ± 26.131	121.931 ± 79.230
GK-D	0.433 ± 0.193	31.839 ± 6.986	25.72 ± 8.417

Histological analyses are ongoing but have shown thus far a potential increase in elastin fiber content and mast cell activation in ZDF-D compared to ZDF-C, **Figure 2**. Additionally, ZDF-D appears to have thinner collagen fibers than ZDF-C.

Figure 2. Histological stains from ZDF-C and ZDF-D groups. Arrows show elastin fibers and mast cells.

DISCUSSION

While GK and ZDF rat models are both useful models of type II diabetes, they result in significantly different remodeling of the urinary bladder ECM. Though in both models the ECM was more compliant in diabetic bladders than controls, ZDF diabetic bladders are significantly more compliant than GK diabetic. Differences in compliance were especially significant in the toe-region of the stress-strain curves, suggesting that the diabetic bladders are especially compliant at low physiological stresses. Because the bladder fills at low-pressure, this decrease in compliance at low stress could have a large impact on urinary bladder function in vivo.

Changes in the mechanical behavior of the bladder ECM are the result of remodeling of the bladder tissue, which we have observed through histology. It is also known that tissue remodeling could be exacerbated by systemic or localized inflammation, which is evident in soft tissues such as lungs, liver, and the heart. Hence, the increase in mast cells recruitment and activation in the wall of ZDF-D bladders could suggest that inflammation is triggering a more dramatic remodeling in this model when compared to the GK. An increase in elastin fibers, as well as thinning of collagen fibers could also contribute to the increase in compliance of the tissue.

These results strongly suggest that there is remodeling of the ECM within the bladder wall in both of the models studied. The response however seems to be more prominent in the bladder of obese animals. We suggest that inflammation could play a key role in this difference, since a higher level of systemic inflammation is generally associated with obesity. However, in order to draw a conclusion such as this, further histological analyses will need to be performed on the GK groups. Results of this study help us to understand the differences in mechanical behavior of the urinary bladder affected by obese and non-obese diabetic cystopathy.

ACKNOWLEDGEMENTS

We kindly thank the MSU investigative histopathology lab for help with staining our samples.

LACTATING HUMAN BREAST RESPONSE TO INFANT ORAL MOVEMENTS

D. Alatalo* (1), L. Jiang* (1), F. Hassanipour (1)

(1) Department of Mechanical Engineering
The University of Texas at Dallas
Richardson, Texas, USA

INTRODUCTION

Breastfeeding provides nourishment and other responses in both infants and mothers that promote survival. The biomechanics of breastfeeding have been studied for over half a century, primarily by clinicians. Four primary stages of latch-on have been identified (see Fig. 1). Latch-on and suckling involves positive pressures applied by the lips, mandible, maxilla, tongue, and palate. The movement of the tongue creates a negative intra-oral vacuum. The vacuum pressure created during breastfeeding has been investigated for decades. Studies show that infants who are unable to maintain a negative vacuum frequently have difficulty extracting sufficient milk and mothers suffer from sore and damaged nipples. Additionally, a healthy suckling pattern creates a sinusoidal intra-oral vacuum [1]. Previous works have modeled the effect of vacuum pressure on milk flow within the breast. However, the effects of positive pressure on milk flow have been largely ignored, either because they are deemed negligible or simply because clinical recordings of these pressures do not exist. Recent experimental work captured the positive peripheral oral pressure exerted on the areola during breastfeeding in conjunction with intra-oral cavity ultrasound imaging and vacuum. The objective of this study is to understand the relationship between positive compression and negative vacuum pressures on the geometry of the nipple during suckling with milk expression.

METHODS

Collection of pressure data, ultrasound images, and 3D scans of the breast before and after feed was obtained as outlined by Alatalo et al. [2] for six breastfeeding infants ranging in age from 6 days to 4.5 months. Arbitrary white noise and unpredictable outliers in raw sen-

sor data for both vacuum and compression were filtered in MATLAB using a polynomial de-noising algorithm known as BUTTERWORTH.

Figure 1: Latch-on is when the infant attaches to the nipple and begins to suckle. The four stages of successful latch-on are (a) infant's lips clamp, (b) tongue pulls the nipple into oral cavity, (c) tongue pushes the nipple to the hard palate, and (d) infant's gums compress the nipple [1].

Periods of milk transfer were visually identified in ultrasound videos. For each mother-infant dyad, 1-2 suck cycles with milk transfer were chosen for measurements of nipple dimension changes based on clarity of imaging. Calibration used a self-decided base-line in images. A self-programmed measurement system was achieved in MATLAB to measure average dimension changes of the nipple width and length with tongue moving up and tongue moving down (see Fig. 2).

Prefeed and postfeed 3D scans of the breast were captured using Polhemus FASTSCAN and the .dxf files were imported into SolidWorks for measurements of nipple. The nipple was assumed to be cylindrical in shape and two orthogonal cross-sectional areas were used to calculate an average value for nipple width (NW) and nipple length (NL). Since no clinical signs of tissue damage were noted after feeding, the nipple was assumed to experience total elastic compression/torsion. The prefeed measurements and ultrasound measurements were used to calculate the apparent strain ratio using Equation (1), where L_i and W_i are the initial length and width and L_f

*Shared first authorship

and W_f are the length and width at different times during milk transfer or nutritive suck cycle.

$$v = \frac{\frac{L_f}{L_i} - 1}{1 - \frac{W_f}{W_i}} \quad (1)$$

Figure 2: Nipple dimension measurement in ultrasound images. (a) Vacuum peaks when tongue moves down. (b) Tongue moving up (lowest vacuum). (c) Tongue moving down (strongest vacuum)

RESULTS

All infants applied sinusoidal compression patterns on the areola during suckling for both maxilla and mandible, which has not been previously reported particularly for the maxilla (see Fig. 3). The change in compression (3.63 kPa) is considerably smaller than the change in vacuum (-13.77 kPa) during nutritive suckling. Correlation between compression and vacuum pressures was moderate for only the 2 youngest infants with correlations coefficients of 0.57 and 0.72.

Figure 3: Sinusoidal patterns are evident in (a) vacuum pressure, (b) compression pressures, and (c) nipple dimensions.

The nipple dimensional changes in response to compression and vacuum pressures showed that compression dominates nipple deformation. Ultrasound images show that when the tongue is down, milk is expressed from the nipple and milk continues to be expressed as the tongue rises up toward the palate. When the tongue is down, the vacuum pressure is at its lowest but the nipple is at its shortest length. Whereas when the tongue is up, the vacuum is higher but the nipple is longer. Thus, the dominate pressure that impacts the deformation of the nipple appears to be the positive pressure applied by the tongue and palate, not the vacuum.

Strain ratio calculations showed large variation between dyads over time (see Fig. 4.) with mean values ranging from 0.13 to 0.65. Postfeed nipple measurements showed volume changes when compared to prefeed dimensions ranging from -315 mm³ to 1166 mm³.

Correlations between strain ratio and vacuum pressure were strong for 3 dyads (>0.7) but weak for the other 3 dyads (<0.3). A summary of findings is presented in Table 1.

Table 1: Mean values plus standard deviations for all dyads.

Nipple Height Changes	1.56±0.24 mm
Nipple Length Changes	3.00±0.37 mm
Intra-oral Vacuum Changes (min-max)	-13.77±4.86 kPa
Peripheral Oral Pressure Changes (min-max)	3.63±3.53 kPa
Strain Ratio	0.39±0.19

Figure 4: Strain ratio of the nipple during nutritive suckling varies greatly between dyads but in a sinusoidal.

DISCUSSION

The dynamics of breastfeeding are extremely complex and require novel methods to capture data. The oscillatory compression of the areola by the maxilla has not been previously reported and would not be obvious to external observers since the maxilla does not appear to move after forming a teat. Rather movement of the mandible is generally evaluated for correct suckling patterns. The small variations in compression pressure under maxilla and mandible are sufficient to occlude milk ducts under the areola. The lack of correlation in older infants between compression and vacuum suggests that as infants mature they develop two methods of controlling milk flow.

Compression dominates the nipple deformation, however the dominate pressure over milk flow remains unsolved [1]. The variations in strain ratio during nutritive suckling are likely related to volume changes within the nipple. These results challenge the current practice of assuming a Poisson's ratio near or at 0.5 for breast tissue during lactation. Further study is planned.

INTRODUCTION

The physiology and pathology of the pelvic organs remains a key question in terms of mechanical modelling to reach a better understanding of pelvic trauma. The pelvic system, and its suspension elements, presents a complex equilibrium related to the mechanical properties of tissues involved and their geometries [1]. Disturbance of such an equilibrium may induce pathophysiology mobility such as genital prolapse, which is a major health problem concerning 30% of the women population [2]. Different anatomical structures seem to play a key role in that balance and the authors have remained on the role of the pelvic muscles. Recently it has been demonstrated that the uterosacral ligaments also play an important role in supporting organs [3, 4]. This complex equilibrium might be impacted by the life events such as aging, pregnancy or delivery.

During pregnancy, a modification of the pelvic floor appears [5]. During life time and aging evolution of the anatomy is also reported [6, 7]. The evolution of the pelvic floor and the ligaments that sustain the pelvic organs seems to be one of the key factors of pathology such as prolapse [8]. However, while study are reporting some observance of the evolution of the pelvic suspension with age and/or physio-pathology no understanding of the mechanism of evolution is proposed.

The objective of this work is to propose a mechanical approach to explain the evolution of the pelvic suspension. In a first part, a generic model of the pelvic anatomy will be introduced to model the pelvic suspensions. In a second part, an optimization process will be proposed to minimize and homogenized the stress-strain equilibrium within the suspension device modeled. The analysis of the obtained result will propose an explanation of the pelvic suspension element whose appearance will be interpreted as a remodeling process aiming at uniformly distributing the strain within the suspension elements.

METHODS

The approach used in this study is purely numerical. It is based on one side on a refined model of the pelvic cavity, fully reconstructed with medical imaging technics [9] and on the other side on Finite Element method under large strain [10]. The images data provided from a healthy patient with no medical history and in agreement with ethical approval. MRI was performed thanks to classical parameters used for clinical gynecologic examination. Segmentation and contouring of all the organs allowed us to obtain the bone structures and main organs of the pelvis such as the vagina, the rectum, the uterus and the bladder. This geometrical information makes it possible to know precisely the position of the organs on the pelvic cavity. CAD tools are used to generate a representative surface of the level I support. This anatomical area is characteristic for our study because the constitutive structures (uterosacral and cardinal ligaments) provide a support of the vagina cervix [11]. The limits of this surface correspond to precise anatomical zones (fig.1a), following an anteroposterior trajectory, posterior face of the pubis (z1), arcus tendinous (z2), sacrospinous ligaments (z3) and the sacrum (z4). This surface is also in interaction with the positions of reconstructed organs such as the bladder, the cervix and the rectum (fig.1b).

Parameterization of this surface was performed to apply pressure levels on different areas (fig1a). The pressures may be oriented normal to the surface or oriented at a specific inclination. A study was conducted to select the most appropriate configuration, in accordance with the dynamic MRI analysis performed in previous team work [11].

Figure 1: Geometrical representation of the Level 1 support with location. a) Anatomical areas near the bone structures and b) integration of the 3D organs.

The study aims to analyze the deformations that undergoes on this anatomical area. We chose a “generic” material with mechanical properties ($E_0 = 0.3\text{MPa}$, Poisson ratio = 0.45) closed to the analyze carried out on the ligamentous tissues [13, 14]. We assume that the material is linear elastic, undergo small strain and stress, homogeneous and thickness of the surface is constant. Numerical simulations is performed on Abaqus CAE. The convergence of the calculation, as well as a mesh sensitivity study, was carried out in order to guarantee the validity of the results. Considering that the remodeling process aims at reaching a stress-strain equilibrium for cells, and since where considering only applied stress problems, we have introduced an optimization procedure aiming at reaching a strain equilibrium by minimizing the difference between the maximum and the minimum of strain. The variable optimized is the effective local stiffness, assumed as homogeneous at the initial stage.

RESULTS

A first simulation (fig 2a) allows us to provide an analysis of the principal strain levels, by considering a surface with a homogeneous stiffness E_0 value. The strain is observed to be highly heterogeneous. Based on those results, we have implemented an optimization process on the FE method to minimize the gap between the maximum and minimum deformations making varying the local stiffness. With this optimization process, we are able to homogenize the deformations by modifying, for each element of the mesh, the mechanical properties by a ratio of E_0 . Taking into account the strain level in our analysis is in accordance with literature review which reveals that the damage of the pelvic tissues is dependent to the deformation [15].

Figure 2: Comparison between initial simulation (with homogenous material) and optimization process results (with un-homogenous material) - a) Strain level and b) material properties map.

At the end of the optimization loop, a map of the floor can be plotted (fig2b). On fig. 2 representation, we can observe on the left hand side the homogeneity of the strain, and on the right hand side the areas where the material properties must be rigidified to normalize the strain level. Homogeneous mechanical property on the considered surface leads highly heterogeneous strain fields. However, the introduction of the optimization process proposed, leads to homogenize the strain field by densify locally the material and increasing its stiffness. It leads to make uterosacral ligaments appearing with module stiffness 3 times higher than E_0 to reduce the strain level. In the same way, the areas corresponding to the cardinal ligaments are also more densify with a ratio of $4 \times E_0$.

DISCUSSION

The literature reveals that quadruped animals have no utero-sacral ligaments. It also reveals that in the childhood and even at the foetal stage, women have neither utero sacral ligaments nor cardinal ligaments [6, 7] while old women have very stiff and thick uterosacral and Cardinale ligaments [8].

The optimization process we have developed is initially considering a suspension surface with homogeneous mechanical properties. It is a model of a connective tissues which function aims at providing a suspension to pelvic organs. Since the stiffness is homogeneous in this initial surface of suspension, no specific sub-domain can be highlighted. The optimization process introduce aims at homogenizing the strains answering to a stress-strain equilibrium expectation. The results of this optimization process highlights to zone with densified mechanical properties which are corresponding to the location of uterosacral and cardinal ligaments.

CONCLUSION

The genese of pelvic ligaments is not well understood. The approach we are proposing tends to show that pelvic ligaments, and more specifically, are appearing with age to reach stress-strain homogenized equilibrium within the pelvic system.

Further study, using this approach, may lead to propose some remodeling models of the pelvic system with respect to the loadin history of patients.

INTRODUCTION

Since 2008, many public universities have undergone continuous and substantial budget cuts, while the number of students enrolling in Mechanical Engineering (ME) programs continues to grow. Financial difficulty has forced some community college students to forego pursuing a 4-year BS degree. Many of our students pursuing a BS degree in the ME program have to seek employment outside of engineering to pay for their education. This limits their time available to focus on their course work. For the 2010 cohort of our ME freshmen, the 4 year retention rate was around 50% and the 4 year graduation rate was 23%. The retention and graduation rates were even worse in underrepresented minority (URM) students and transfer students.

Studies¹⁻³ have demonstrated that integrating a research experience into a student's education program improves retention rates, and plays a role in increasing the percentage of students pursuing graduate degrees. Despite efforts at the university level, very few undergraduate students on our campus attend regular research seminars in the STEM departments and less than 10% of the undergraduate students actively participate in research. This may be due to lack of information, conflict of schedules, as well as the depth of the research topics. We believe that providing students with research opportunities and actively exposing them to STEM advancements would lead not only to more students applying and/or transferring to our ME undergraduate program, but also retaining them through graduation. Extra effort is needed to inspire students' interest in research, especially interdisciplinary research.

Starting in 2010, the ME department at UMBC has been awarded three NSF S-STEM grants to increase student diversity, improve retention, and provide successful paths toward job placement and graduate study in our department. In addition to scholarships and faculty mentoring, we implemented approaches to integrate research

into various aspects of our curriculum, including visiting community colleges, giving research seminars to community college students and UMBC students, organizing lab visits for undergraduate students, and providing undergraduate research opportunities. In this study, we asked students to complete a survey after specific research related educational activities. Data analyses were conducted to evaluate whether the perceived experiences from exposure to research differed by ethnic group, family educational background, whether they are community college transfers, and whether the students are part of a scholarship program. The survey results were also used to measure the satisfaction of the participants from the research related activities, and to collect feedback for future improvements.

METHODS

Two short surveys were designed, one for community college visits, and the other for ME lab tours. An ME faculty member visited a community college and gave a seminar typically consisting of three parts: a description of the ME S-STEM Scholarship Program at UMBC, the transfer process to the ME program, and ongoing research projects in the faculty's lab at UMBC. The lab tour at UMBC was scheduled during a University "free-hour" so that all ME undergraduate students could attend. During the lab visit, the faculty gave a Powerpoint presentation, and then a show and tell session, followed by a Q&A session to answer their questions. The surveys were given to all participants after the events and were collected on the site. Both surveys were similar, with only 15 questions covering information about their demographic background, their previous exposure to research and research experience, and their satisfaction to the event. All survey results were entered into EXCEL for data analyses. Not all participants answered every question in the survey. Percentages of participations were calculated based on the sample size of individual groups stated by the participants.

RESULTS

We received 27 surveys after the community college visit and 58 surveys after the ME lab tour. Figure 1 gives the demographic data of the participants. The percentages of any specific group were higher than 19%, and thus provided good sample sizes for analyses. In both surveys, more than 30% of the participants were female or URMs defined as African Americans, Hispanics, and Native Americans.

Figure 1: Percentages of participants' demographic data.

We wanted to know whether the students had any exposure to research by attending any research seminar before the event. Overall, 37% (community college students) and 21% (UMBC participants) of the participants attended at least one research seminar. The percentages of participants in specific groups are shown in Figure 2. Exposure to research in the URM group and the group of the 1st generation of college students is better in the community college students; however, in the UMBC ME participants, those two groups' exposure to research is much lower than the White group. Contrary to stereotype, exposure to research for Asian students in community colleges and in the ME department also trailed that for the White group.

Figure 2: Percentages of attending at least one research seminar before the event in individual groups

The ME undergraduate students can apply for scholarships at UMBC. Three scholarship programs identified by the participants are the ME S-STEM Scholarship Program that our team is managing, the Meyerhoff Scholarship Program at UMBC, and the CWIT Program by the College of Engineering and Information System at UMBC. All three scholarship programs not only provide financial assistance, but also engage their scholars in research. Our program also promotes community college transfer students to pursue research.

Overall, among the 58 participants in the UMBC survey, 21% attended a seminar, and 19% did research in a lab. The positive impacts of those scholarship programs on the research participations of students in the ME department at UMBC are illustrated in Figure 3. Note that the solid bars represent participation percentage of their previous attendance of a research seminar, while the pattern bars

represent participation percentage of the students who actually did research in a research lab before the event. As shown in the bars on the left, for all the 34 participants in at least one scholarship program, 29% of the 34 participants attended a seminar and had at least one research experience in a lab, both exceed the overall averages of 21% and 19%, respectively. However, among the 23 participants who were not in any scholarship program, only 9% attended a research seminar and 0% worked in a research lab. The data from the 15 participants who originally transferred from a local community college illustrate similar trends. Among the 11 community college transfer students who are in at least one scholarship program, 9 of them (or 82%) attended a research seminar and 3 of them (27%) had an opportunity working in a lab. However, for the 4 community college transfer students not in any scholarship program, only 1 of them (25%) attended research seminars, and none of them worked in a research lab.

Figure 3: Different participation rates between students in a scholarship program or students not in any scholarship program in the ME department at UMBC.

More than 88% of the participants after the community college visit and 100% of the participants after the lab tour stated that they understood more of the technical content of ongoing research projects. More than 70% (community college) and 88% (UMBC lab tour) were satisfied with the overall event. 71% of the community college students would like to attend future seminars offered by ME faculty. For the UMBC ME students, 86% stated that the experience made them more interested in pursuing undergraduate research, and 97% of them are interested in attending another lab tour in the future.

SUMMARY

Survey data were collected after several research related events sponsored by the ME S-STEM Scholarship Program at UMBC. Exposure to research measured by attending a research seminar was low for the participants, around 37% in community college students and 21% in ME students at UMBC. There is little correlation between students' demographic background and their research exposure and their opportunity of working in a research lab. The results show the positive impact of the scholarship programs at UMBC on the research exposure and research experience, while the impact is more evident in students originally transferred from a community college. The overall satisfaction rates to the events were high, suggesting rationale to continue to offer those research related events to students.

ACKNOWLEDGEMENTS

This research was supported by an NSF S-STEM grant (DUE-1742170).

LESSONS LEARNED: FIVE YEARS OF THE BIOMEDICAL ENGINEERING IN SIMULATIONS, IMAGING, AND MODELING (BME-SIM) REU SITE

Stephanie M. George (1)

(1) Department of Engineering
College of Engineering and Technology
East Carolina University
Greenville, NC, USA

INTRODUCTION

Quality undergraduate research opportunities (URO) increase understanding of how to conduct a research project, confidence in skills, and awareness of graduate school [1]. In addition, such programs can clarify, refine, and reinforce STEM career path goals [2] and increase the likelihood of pursuing a graduate degree in a STEM field [3]. Research shows UROs have the same affect or greater on under-represented minorities (URM) [2]. Thus, engaging URM in URO may increase the retention rate and matriculation into STEM graduate programs. This is critical because while African-Americans and Hispanics make up 7% and 8.8% of the STEM BS degrees awarded, they only make up 1.8% and 2.3% of PhDs awarded (white students make up 77% of PhDs awarded) [4,5].

Research Experiences for Undergraduates (REU) Sites funded by the National Science Foundation have provided numerous students with UROs. The REU Site in Biomedical Engineering in Simulations, Imaging, and Modeling (BME-SIM) was initially funded in 2014 (EEC-1359183) and renewed in 2017 (EEC-1659796). The goals of the BME-SIM REU program are to provide quality research experiences increasing awareness of and application to graduate school. The purpose of this study is to provide an example program framework, report outcomes for the past five years, and share lessons learned.

METHODS

The BME-SIM program provides research experiences for 10 students (initially 8 students) for 10 weeks each summer. Each student has an individual research project and faculty mentor. The projects are bound by a methodological theme, simulations, imaging, and modeling, instead of an application or disease pathology [6]. Because of this, students learn techniques that are relevant to a wide variety of

applications, and not traditionally taught in an undergraduate curriculum. The faculty mentors span six departments (Engineering, Kinesiology, Health Education and Promotion, Physical Therapy, Communication Sciences and Disorders, and Physics) and four colleges providing a culture of multidisciplinary research. Running an REU site consists of four tasks; recruitment, assessment, follow-up, and summer program.

Recruitment. The BME-SIM recruitment campaign includes a national component (program website, social media, email, professional organizations, webinars, and NSF website) and a targeted regional component (partner institutions and site visits). During the planning process partner institutions and faculty liaisons were identified within a 3-hour radius of campus. The institutions (8) include minority serving institutions, community colleges, and predominantly undergraduate/MS serving institutions.

Program Assessment. Program assessment is conducted by an external evaluator and includes a pre/post survey (in-house), and pre/post writing sample assessment. Feedback on program components, mentoring, and environment is solicited.

Follow-Up. Follow-up involves an online survey 3 and 9 months following the program and annually thereafter. The first survey focuses on national conference attendance. All students are funded by the grant to attend the Biomedical Engineering Society (BMES) annual meeting which provides an opportunity to share research with a larger audience and reconnect after the summer. The latter surveys track career (graduate school, job), academic (major, GPA, honors), and research (abstracts, publications, experiences) outcomes.

Summer Program. Delivery of the summer program is the largest task and can be subdivided into structured program elements, professional development, mentoring, and research projects. Here the focus will be on the first three. The program schedule can be found in

Table 1. The BME-SIM program includes several **structured program elements** designed to build camaraderie and facilitate research dissemination. The summer begins with a campus tour, team building program, and informal cookout with the mentors. Formal training begins with a 2-day research bootcamp to help prepare the students for their research project and get them acclimated to ECU. Key deliverables for the students include research plan (Week 3), oral presentation (Week 9), poster presentation (Week 10), personal statement (Week 10) and BMES abstract submission (Week 10).

Our **professional development series** is designed to provide information on graduate school (application, funding, fellowships), career paths (program panel, graduate school student panel), and soft skills (communication, social media, networking). Based on feedback, special communication workshops have been developed and implemented in years 4 and 5. These workshops are offered by the University Writing Center and Speech Communication Center. Quality **mentoring** is a top priority for the BME-SIM program. To extend the reach of our program, we have developed a home institution mentor model [7]. Each student is matched to a faculty member from their home institution who they meet with before and after the program. The hope is to not only provide quality mentoring while on campus, but also when they return to their home institution. Summer faculty mentors are chosen based on their mentoring experience; with informal training provided prior to the program.

Table 1: REU Summer Program Schedule (S: Social, PE: Program Element, CW: Communications Workshop, PD: Professional Development)

Week	Activities
1	S: Campus tour, team building challenge, cookout, team trivia, ice cream social; PE: 2-day Research Bootcamp
2	CW: Literature Reviews: Making Synthesis Happen; PD: Graduate School Application; S: Bowling
3	CW: Professional Communication Skills; PD: Graduate Program Presentation; S: Board Game Night
4	CW: Personal Statements: Packing a Punch in 1-2 pages; PD: NSF Graduate Research Fellowship
5	S: Baseball game; PD: Building a Professional Social Media Presence
6	CW: Mock Interview and Elevator Speech; PD: How to Compose a Scientific Poster
7	PD: Graduate Student Panel; CW: Scientific Writing
8	CW: Practice Presentation; PD: Speed-Networking Event
9	PE: Oral Presentations; S: Women in STEM
10	PD: Research Conferences: What to Expect; PE: Poster Presentations; S: Celebration Lunch

RESULTS

To-date 45 students have participated in the BME-SIM program. Twenty-five (55.5%) participants were women and 20 (44.4%) were underrepresented minority students of which 12 were women. The majority of students were from R2 institutions or lower (86.7%) with 42.2% of students from masters level institutions or lower. All learning outcomes significantly increased (p value < 0.05) following the summer program. Outcomes include understanding the research process, confidence in research skills, understanding how scientists work on problems, understanding how to design and implement a research project, development of identify as a scientist/engineer, understanding the role of modeling in biomedical engineering, increase knowledge of graduate school and career opportunities, and developing a meaningful mentoring relationship. Of the students who have graduated, 75% (21) have gone on to graduate programs with 16 pursuing STEM degrees.

DISCUSSION

Based on our five years of experience, we report on some of our lessons learned and current challenges.

Recruitment. A concerted effort is required to recruit our target students (female, URM, low socioeconomic status, and veteran students along with students with disabilities and those from institutions with limited research opportunities). Reliance on the NSF directory and website presence is generally not enough. We have found targeted recruiting through partner institutions, and programs that recruit or target similar students (NIH MARC, McNair Scholars, and NSF LSAMP) to be successful. In-person recruiting through site visits and conferences have also been extremely successful. We have experimented with live webinars, hosting our second one this year.

Mentoring. It is important to have clear expectations for the faculty mentors. Our faculty mentors are actively participating in the research process and often meet daily with students. Because our graduate program is relatively new, graduate students are part of the mentoring program, but primary mentoring (both research and career) is accomplished by our faculty mentors. To complement our current mentoring plan, we are investigating cultural competence training programs to help create a more inclusive environment. It is important that all students feel like they belong.

Administrative Burden. Organizing program logistics (housing, dining, stipend, hiring, travel, programming) can be time consuming, especially if there is not a central office to coordinate. As PI, I am primarily responsible for the above duties. As the second REU site on campus, many protocols were not in place so we had to write them. While this is a summer program, work is required all year long.

Follow-up. In order to evaluate the long term success of the program, all participants must be tracked through their undergraduate careers and post-graduation. In order for tracking to be successful, a strong sense of community must be established during the program. Further, alternate contact information should be collected including permanent address, non-school email, and phone numbers. Follow-up surveys are sent by email, LinkedIn, then text, and finally a phone call. Based on feedback from students, we recommend sharing research updates and achievements so that students can see how their work has contributed to the bigger picture. Another option for sustaining long term follow-up is to offer incentives for survey completion, such as a drawing for a gift card.

Appropriately Scoped Projects. Finally it is important to provide students with appropriately scoped projects to be completed in 10 weeks. This has involved some trial and error and reflecting on what has worked in the past. Faculty mentors must also be willing to adapt projects to fit the skills and interests of their students.

In conclusion, an REU program takes careful planning and a dedication to training the next generation of students.

INCORPORATING CLINICAL ROTATIONS, ONLINE LECTURES AND BUSINESS CONCEPTS IN BME CAPSTONE DESIGN: ARE WE THERE YET?

Alan W. Eberhardt (1), Joel H. Dobbs (2)

(1) Dept. of Biomedical Engineering
University of Alabama at Birmingham
Birmingham, Alabama, USA

(2) Collat School of Business
University of Alabama at Birmingham
Birmingham, Alabama, USA

INTRODUCTION

Since 2001, with the support from the National Science Foundation (RAPD and GARDE programs), the lead author has run the senior capstone experience in which biomedical engineering (BME) student teams design and prototype assistive technologies for people with disabilities. In 2013, with the receipt of an NIH R25 award, a working partnership was formed with the UAB Collat School of Business to bring engineering and business students together to develop functional prototypes and commercialization strategies around new medical device designs. The co-author joined as a team instructor, and the Biodesign text [1] was adopted as a resource for students to gain an appreciation for clinical needs finding and screening, establishing the market for their product, and in developing an operating plan for development of a commercial product. In the past two years, UAB Solution Studios™ was piloted as a source for clinical matchmaking between engineering/business students and clinical mentors.

By bringing engineering and business students together, the capstone design course has focused on team-based learning with students of truly multidisciplinary backgrounds. In the past 5 years, we have incorporated a number of experiences in order to promote commercialization of devices developed during the two-semester sequence. The following article provides our current approach and the steps that led to this point.

METHODS

BME 498 Product Development and BME 499 Capstone Design represent the two-semester capstone course sequence required by all BME seniors at our institution. We have coordinated class times to allow BME students to be joined by business students enrolled in a senior entrepreneurship elective series (ENT 424 New Product Development/ENT 426 Practicum in Commercialization). The fall

semester begins with clinical shadowing to determine device needs and ideate potential solutions. Using an approach modeled after Stanford Biodesign [1], students work to “identify, invent and implement” medical and assistive devices for local clients. Teams form around clinical needs of their choosing. Market analyses are performed as a preliminary vetting of the needs. Need specifications are turned into engineering design constraints and the students are coached through the process of brainstorming and evaluation using the Pugh Method [2]. Concurrently, the students begin their investigation into business development for their medical devices, including IP and patent landscapes, and business models using the “Business Model Canvas” [3]. On-line modules were created where Biodesign readings and quizzes were assigned as homework, prior to in-class instruction. Regulatory topics include medical device classes and FDA approval processes. As part of the original R25, we expanded our instructional efforts around how to work effectively in teams. Lectures include project management, the classic “five dysfunctions” of a team [4], and how to have “crucial conversations” [5] to help students resolve team issues that arise during the year. In BME 498, a series of writing assignments culminate in a formal Design Proposal that includes concepts for a functional prototype as well as a marketable design. The teams are required to have signature approvals from their client, as well as that of a lab manager, who has mentored the team throughout the ideation and design process. The fall semester ends with an oral presentation to a “Shark Tank” that includes faculty from the Harbert Institute for Innovation and Entrepreneurship (HIIE).

Spring semester emphasizes building of functional prototypes and formulation of a commercialization strategy. BME students take part in manufacturing rotations where they gain hands-on experiences with state-of-the-art methods for machining metals and forming plastics and composites. In this manner, we ensure that students have adequate

access to equipment and expertise to help fabricate their prototype devices. Business topics are continued, including project management and the use of Gantt charts. Students are required to present Gantt charts for the 14-week development of their working device as well as a one-year Operating Plan that includes research and development and financial planning of their “marketable device,” including plans for verification and validation, and a complete Risk Analysis.

Over the past five years, we have experimented with different approaches where the business students “split off” from the BME students at various times during the second semester. In the current iteration, the business students left the BME teams at the start of the second semester in order to pursue development of commercialization strategies for three projects. These projects were selected by the Shark Team in the first semester based on their commercial potential.

Additional engineering lectures are provided on an as-needed basis, including finite element analysis, motor/bearing selection, and/or structural frame design. As projects take final shape, teams with patentable ideas submit IP disclosures to our tech transfer office in the HIIE. The students perform verification testing (as is feasible) and demonstrate some form of customer validation of the final working product. The Final Design Presentation includes a 3-minute video investor pitch, a scientific poster, and demonstration of their working device, held during the final BME seminar for the term. This seminar is attended by BME faculty, students, clients and members of the HIIE.

In recent years we have begun offering extra credit for submission and/or participation in student design competitions, such as the Design of Medical Device Conference in Minneapolis, MN, as well as the annual RESNA Conference and the SB3C, among others.

Various surveys were used to assess the effects of changes made to the course. In BME 498, students were asked to provide their input regarding the length of time and quantity of clinical rotations, which served as the source for their year-long project activities. In addition, the students who participated in the UAB Solution Studios™ web platform were asked specifically if it enhanced their experience. Later on, students in BME 499 were asked if they preferred the on-line learning module approach piloted in BME 498, as compared to the traditional PowerPoint style lectures given in class during BME 499. IDEA surveys were examined for student comments regarding the inclusion of business students, problems with team dynamics, etc.

RESULTS

IDEA survey results have consistently indicated student satisfaction levels exceeding 4.5/5 with respect to “Progress on Relevant Objectives,” as well as “Excellent Course” and “Excellent Instructor.” The results of the student surveys (Fig. 1) indicated that 92% (36/39) preferred the online approach, with a consensus that “doing the lectures on-line freed up valuable class time for working on our design projects.” 69% (27/39) responded favorably, indicating that “more time for rotations would allow us the opportunity to better vet the project opportunities.” In this case 80% (16/20) students who participated in UAB Solution Studios™ indicated that their overall experience was enhanced.

Other results indicated that the majority of teams functioned well together – for example, in fall 2018, only two teams experienced problems with teammates, which seemed to center around two scenarios: i. a BME student who was overly committed to honors research and/or medical school preparation that prevented them from spending adequate time on their capstone project or ii. a business student who took the course less seriously than their BME counterparts, resulting in a “takeover” by BME students where they simply did all the business work themselves. In the past three years, we have had multiple student teams take part in student design competitions, and three teams

that took 2nd or 3rd place (e.g., Fig. 2). Feedback from these experiences has been extremely positive.

Figure 1: Survey results from BME capstone experience.

Figure 2: A BME team taking second place at the 2017 Design of Medical Device Conference

DISCUSSION

Senior capstone design continues to be a success story for the Department of Biomedical Engineering at UAB. The involvement of business and engineering is viewed extremely favorably by the upper administration and is often cited as a shining example of interdisciplinary education at our institution. The establishment of the online modules, the use of UAB Solution Studios™ for clinical matchmaking, the use of sharks to evaluate commercial potential, and the encouragement of teams to apply to student design competitions, all have worked to enhance the success of our program.

OUTCOMES OF INCORPORATING CLINICAL SIMULATION LABORATORIES IN BIOMEDICAL ENGINEERING EDUCATION

Anita Singh (1), Dawn Ferry (2)

(1) Department of Biomedical Engineering
Widener University
Chester, PA, USA

(2) School of Nursing
Widener University
Chester, PA, USA

INTRODUCTION

Simulation laboratories are primarily used in nursing education to simulate real world scenarios through the inclusion of role-play, standardized patients, virtual simulation, and computerized mannequins. While the primary goal of biomedical engineering education is to train the next generation of engineers who can tackle the problems at forefront of healthcare and related fields, their preparedness requires a different approach than other basic engineering disciplines. Biomedical engineers should be trained to work in real-world health care settings where most medical device industry emerges. Inability to perform and translate their knowledge in these setting can prove to be the biggest setback in today's biomedical engineering education. To overcome this problem, we investigated utilizing teaching approaches currently employed in the training of health care providers and assess their use in better preparedness of biomedical engineers who perform in similar environments.

METHODS

A total of 20 BME seniors were matched with 20 Nursing Juniors in a semester long (BME448: Medical Device and NURS338: Evidence-based practice) course. The BME and Nursing faculty worked collaboratively to create an interdisciplinary environment by bringing the engineering and nursing students together in one classroom setting. To further their collaborations and enhance their communication skills, the teams were exposed to two different simulation labs.

Simulation Labs

The two simulation classes (75 minutes long and accounting for 7% of the total course contact hours), included three scenarios that prompted collaboration and communication among students from

these two disciplines. Student learning was further fostered by orienting them to the environment, debriefing them about the scenarios, and making them aware of their roles in troubleshooting the problem they were to observe in these settings. During the first simulation class, in teams of two comprising of one engineering and one nursing student, students attended two scenarios (10 minutes each). Both scenarios were device/equipment based. In the first scenario, an actor was positioned in the observation room while waiting to be diagnosed with a beeping intravenous (IV) device. In the second scenario, a mannequin was showing signs of distress while being hooked up to the gas (Figure 1).

Figure 1: Engineering Students embedded in simulation based clinical scenarios to trouble shoot gas-line related problem

These scenarios were specifically created so that the team could successfully fix the problem through effective communication and coordinated actions. A 15-minute debriefing was conducted immediately following each simulation where students assessed their

performance and were provided with feedback from instructors, who were observing them throughout the process from the outside through a camera placed in the room. During the second simulation class, students were again teamed up in pairs consisting of one engineering and one nursing student and introduced to a scenario that was more clinically oriented. Also, another such student team observed their performance from outside the room through the camera placed in the room to offer student-oriented feedback during debriefing (Figure 2).

Figure 2: Student observing from outside the room

The scenario consisted of a mannequin who was admitted to the emergency room with blurred vision. The goals for the team were to make a diagnosis of his condition, administer the required medication, and offer the correct treatment option. The overall goal of this simulation was to better prepare engineering students for real-world clinical scenarios. Knowing clinical settings, understanding roles played by all individuals in providing care to the patients and family, knowing procedures involved during the care process, and feeling comfortable in these environments to ask relevant questions are all critical to the training of biomedical engineers.

Survey

With Institutional Review Board approval, voluntary anonymous student surveys were obtained to evaluate the impact of the clinical immersions through simulation labs (Table 1). These items were measured on a yes/no and Likert-type scale ranging from 1 (strongly disagree) to 5 (strongly agree).

RESULTS

As shown in Figure 1, the three simulation scenarios promoted better learning than slides explaining these scenarios. These simulation scenarios allowed them to demonstrate their ability to communicate with the other providers of the healthcare team, to use critical thinking skills learned through the engineering program, and an active hands-on learning environment. Students agreed that having a nursing partner in the room during these individual simulation scenarios made the experience more realistic. Students felt confident in providing specific rationales for their actions during the simulation scenarios. Overall, the simulation scenarios helped students better understand their role in the healthcare industry as an engineer. Students agreed that the experience was novel to engineering education and should be part of future offerings.

Table 1: Survey Questions

Q1: The knowledge gained through the simulation experience can be transferred to the clinical setting
Q2: The offered simulation scenarios promote better learning than slides explaining these scenarios
Q3: The individual simulation scenario allowed you to demonstrate your ability to communicate with the other providers of the health care team
Q4: The individual scenario allowed you to use the critical thinking skills learned through the engineering program during the simulation
Q5: The faculty provided constructive feedback and discussion after the simulation scenarios
Q6: You can provide specific rationales for your actions during the simulation scenarios
Q7: The nursing partner in the room during the individual simulation scenario made the experience more realistic
Q8: Simulation lab provided an active hands-on learning environment
Q9: The simulation lab experience is novel to engineering education and should be offered in future offerings
Q10: Simulation lab helps you better understand your role in health-care industry as an engineer

Figure 3: Survey Results

CONCLUSION

Simulation labs can successfully be used in biomedical engineering education due to its proven efficacy in offering a safe, controlled environment in which problem-based learning can be fostered to achieve better preparedness of future biomedical professionals.

INTRODUCTION

Students crave real-world applications of their studies and such examples increase student engagement, improve learning, and better prepare students for their careers. Context-rich projects, especially those for which the ‘answer’ remains unknown, foster an entrepreneurial mindset [1]. Opportunities for students to engage in the inquiry-based process of being a researcher and translating the results to the real world are limited in the traditional curriculum. For example, students often engage with the research process in a prescribed manner (traditional laboratory exercises with a detailed instruction manual), or by reading published work. To engage students in an open-ended way, it is helpful to direct students to a well-defined topic such as the risk of spinal injury.

Musculoskeletal disorders (MSD), especially injuries of the spine, are a burden for the individual and an economic problem for society. In Germany 22.1 % of the sick leave days as well as production losses of 13 Billion Euro are connected to MSD [2]. According to the Bureau of Labor Statistics (BLS) in the US, 33% of all worker injury and illness cases are attributed to MSD. In the United States the annual prevalence of lower back pain ranges from 15 to 20% of the working population [3]. Workplace design requires a constant improvement of knowledge about the interaction of the human being in the work system [4, 5], and is therefore well-suited for open-ended industry-focused class projects.

Here, we present an example of a context-rich research-based class project that requires students to use their classroom knowledge to link a research experiment to a real-world ergonomics application.

METHODS

This undergraduate class project merged practical risk assessment tools used in industry with ongoing fundamental biomechanics research topics in a highly interactive undergraduate course. Briefly, students worked together to critically analyze experimental results from ongoing

laboratory research at Clarkson University, with the goals of explaining the experimental results using basic biomechanics principles and translating the results to workplace ergonomic recommendations.

Prior to beginning the project, students learned basic ergonomics and biomechanics concepts in the classroom, with a typical week shown in Table 1. In a term paper, completed individually near the start of the project, each student examined a specific topic in relation to risk assessment (e.g. in sport or industry). Journal articles were analyzed weekly [6] and specific homework assignments fostered technical skills (Table 1). For the project, the class of 32 undergraduate students was then divided into 8 teams. The overall task was to critically analyze a research study performed at Clarkson University [7,8] and translate the results to an ergonomic risk assessment. The project was coached on a weekly basis for 10 weeks. Students were encouraged to explore both German and US content for their term paper topic of choice. Methods used to establish connections include literature searches, experiments and ergonomic risk assessments. Assessment included a short presentation near the beginning of the project, and a longer presentation by each team at the end of the semester. Instructor evaluation of the logic of the student presentations was based on classic scientific quality criteria (e.g. objectivity, reliability, validity).

Table 1: Typical class schedule and content

Monday <i>50 min</i>	Wednesday <i>50 min</i>	Friday <i>50 min morning + 90 min afternoon</i>
Ergonomics and biomechanics lecture: anthropotechnics, occupational physiology, risk identification.		Project related Journal Club (morning); Coaching activity for term paper and project work (afternoon)

The published work was introduced to the students by one of the study's authors. In brief, ex-vivo cervine lumbar spinal motion segments were subject to low-angle low-load cyclic loading, up to 40,000 cycles. Some specimens showed evidence of ring apophysis fractures, and the load displacement data and hysteresis loops (in the force displacement plots) during cyclic loading indicate that the damage occurred gradually, i.e. without trauma [7]. Students were tasked with explaining the results using basic biomechanics principles and translate the results to the workplace using current risk assessment tools.

Figure 1: Schematic of experiments in [7].

Students had learned through classroom instruction and individual problem solving that workplace risk assessment is based on models of degradative effects of repeated motion on the musculoskeletal system over long-term data plots. Spinal injury risk assessment is based on the analysis of the human spine and the physical pressure that occurs due to the working situation. Generally, the consensus is that higher loads and a higher frequency will lead to a higher risk of injury.

The resulting damage from low-load high-repetition loads is contrary to the current consensus. Students were tasked to explore how traditional ergonomics risk assessment tools could be used in situations where these low-load high-repetition loads exist. Each team was given a unique question to focus on, as presented below.

- How certain are the results of the new study?
- Which situation in industry could yield to a stress level “low-load high-repetition loads”? Are there other studies that support these results? (2 Teams: different approaches and statistical analysis)
- How would that be assessed (with usual or advanced ergonomics methodologies)?
- How does the age-and-gender-related limits based on the load-bearing capacity of spinal elements compare?
- How does the flexibility of the spine influence the risk (in general)?
- Which different “dose-response models” exist and how would a revised “dose-response model” look like? (2 teams: research and new ideas)

Instructor feedback steered students towards appropriate aspects of the risk assessment and suggestions for further investigations were made. Students compared different “Dose Models” from ergonomics literature [9] and biomechanics literature. At the conclusion of the project, each group presented a 15-minute presentation, with one of the authors of the original study in attendance.

RESULTS

The presentations exceeded the instructor's expectations. In general, the students were highly involved in the research and found many interesting published studies, and explored related research areas. For example, they questioned if an increase in flexibility might not be a positive indicator like it has been discussed in sports biomechanics. That widened the scope of the project and lead to engaging discussions.

Students appeared engaged with the topic throughout and asked detailed questions. The instructor observed that student questions

tended to be critical towards characteristics of the experimental design such as: limited sample selection, the difference between the cervine model and a human cadaver, the freezing of disc and potentially altered kinematic properties, temperature and moisture considerations, and the realism of the number of cycles and frequency. Students also found other published studies to support their ideas. For example, after finding a study that showed recovery after 10000 cycles and a rest period of 18h, [10] students suggested studying this with future laboratory experiments.

While students readily found fault with the published work and could eagerly suggest improvements, they remained challenged to provide suggestions that could be feasibly implemented given the realities of research funding and available resources. Thus, this project provided opportunity for students to confront some of the harsh realities of performing research in the real world.

Students also struggled to come up with an explanation the unexpected findings of the research study using basic biomechanics principles. They were challenged to question the widely-accepted paradigm that only high-load high-repetition loads cause injury. Despite encouragement, they did not consider that the mechanical characteristics of soft tissues change with the speed of the motion and become increasingly hard and less flexible, even though they recognized that the specimens lost liquid during loading. As described in [7] the spinal flexion-extension movement was controlled and the forces measured. With reduced forces over the course of the experiment, tensile forces were necessary to fully extend the spine. Students did not recognize this as a different mechanical loading scenario, or consider that the micro fractures may have occurred due to this. Future scientific work might investigate how intermittent rest and recovery periods would alter the results, and future iterations of this project might include additional emphasis in lessons on the importance of recognizing when a loading scenario changes.

DISCUSSION

This project offered students opportunities to link their classroom knowledge by translating contemporary experimental results into real-world implementation, e.g. by recommending study of the effect of rest breaks during low-load high-frequency tasks. The instructor benefited from this discussion process, and the researchers benefited from hearing the students' ideas to further the work. Students also considered a global perspective, merging recommendations from Germany with those from the US. Students discovered differences between available public datasets between the two countries. As a result of this style of project, the students develop an entrepreneurial mindset, and the instructor benefits widely. In this specific case, the utility of this research comes from the translation of the laboratory results into actionable recommendations for workers. Other educators may consider using a similar approach to engage students with both the research process and an industrial application in the classroom.

ON THE ROLE OF PROJECT-BASED ACTIVE LEARNING TECHNIQUES ON COMPUTER PROGRAMMING SELF-EFFICACY OF UNDERGRADUATE BIOMEDICAL ENGINEERING STUDENTS AND THE INTERACTIVE EFFECTS OF GENDER

S. Cyrus Rezvanifar, Rouzbeh Amini

Department of Biomedical Engineering
The University of Akron
Akron, Ohio, USA

INTRODUCTION

Active learning significantly improves students' educational achievements as compared to passive learning [1, 2]. In Biomedical Engineering (BME), active learning can be incorporated through various techniques such as problem- and project-based learning [3]. Such approaches lead to students' deeper and more efficient retention of new concepts. During the past two decades, perceived self-efficacy has been increasingly considered as a highly effective predictor of students' motivation and learning, as well as an important contributor to their academic development [4, 5].

Over the past two years, we investigated how project-based active learning techniques used in a biomedical computing class affected the self-efficacy of undergraduate BME students, while also examining the main and interactive effects of gender. We hypothesized that project-based active learning techniques enhance computer programming self-efficacy and expectation of success in undergraduate biomedical engineering students.

METHODS

This study was carried out under an official exemption by the Institutional Research Board at the University of Akron. In our project-based learning approach, three-member student groups were instructed to build a heart rate monitor/activity tracker using Arduino UNO microprocessors interfacing with MATLAB and MATLAB Mobile (Fig.1), as described in our previous publication [6].

Seven-point Likert-scale anonymous surveys with 14 questions were collected prior to and following the project within all three sections. Due to the anonymous nature of the surveys,

two-way ANOVA with significance level set at $\alpha=0.05$, along with post-hoc Tukey's tests were used to statistically compare the pre- and post-activity self-efficacy scores across genders.

Figure 1. Hands-on experience through project-based learning. All of the groups were required to build a heart rate monitor/activity tracker using Arduino UNO microprocessors interfacing with MATLAB and MATLAB Mobile.

RESULTS

For the entire cohort of participants, the overall average score for *clearer vision of programming application in engineering* (Question 1) and *BME careers* (Question 3) significantly improved upon the completion of the hands-on project. Similarly, for the entire cohort, *the expectation of success in a future BME career that involves developing medical devices* (Question 14) significantly increased after they completed their project (Fig.2).

Figure 1. Average scores (\pm SD) of Questions 1, 3, and 14 which indicated significant differences between pre- and post-activity. “*” indicates statistically significant difference.

Given the combined pre- and post-activity scores, a significant difference was observed between female and male students’ *self-confidence about understanding the most complex course material* (Question 6): the combined average score of the female group was 4.81 ± 1.37 ($N = 58$), as opposed to a combined average score of 5.33 ± 1.23 for the male group ($N = 63$). In addition, female students were significantly less willing to *have a future career in BME that involves intensive computer programming* (Question 11) (females combined average score = 3.23 ± 1.90 and males combined average score = 3.99 ± 1.60).

Comparing pre- and post-activity scores, only among the male students, we observed a statistically significant improvement in one’s *clear vision of the application of programming concepts in engineering and BME careers* (Questions 1 and 3). In pre-activity results, the average scores for these measures were rather higher in female students compared to male students; however, they only slightly increased to post-activity average scores below those of male students (Fig.3).

Figure 3. Average scores (\pm SD) of female and male students in pre- and post-activity results of Questions 1 (top) and 3 (bottom). “*” indicates statistically significant difference.

DISCUSSION

The results of this study agree well with the existing literature on the positive impacts of active learning techniques on students’ learning experience [1, 7, 8]. Hands-on projects provide students with an opportunity to apply their theoretical knowledge into

solving a real-life problem, which enhances their perspective on the practical applications of course material and boosts their self-efficacy in relatively complicated topics such as computer programming.

The significantly lower *self-confidence about understanding the most complex course material* and *expectation of success in BME careers with intensive programming* observed in our female students can be attributed to multiple factors, including but not limited to lesser previous experience in computer programming and sociocultural barriers for women entering STEM fields [9]. On the other hand, the higher pre-activity average score of female students’ *in clear vision of the application of programming in engineering and BME careers* can be interpreted as the relatively more informed decision of female students upon entering engineering fields, supposedly due to the foregoing sociocultural factors.

We observed a significant improvement in students’ *expectation of success in a career that involves developing medical devices*, without a significant increase in their “willingness” for such career—according to another question within the survey. This finding implies that students were already aware of the nature of such careers, and that the enhancement in their expectation of success is a sheer indicator of improved self-efficacy, and not due to obtaining “new information”.

In summary, the results of this study confirm our hypothesis that project-based active learning techniques enhance computer programming self-efficacy and expectation of success in BME careers in undergraduate biomedical engineering students. The lower average scores of the female students, measured in a number of self-efficacy and expectation of success questions, further justifies the need for the continual efforts of “Women in Engineering” societies and K-12 outreach programs in order to raise public awareness toward aforementioned sociocultural factors. These earnest efforts will help eliminate barriers for women entering STEM fields and will enhance their corresponding self-efficacy and expectation of success. For both female and male students, we strongly believe that the foregoing improvements achieved through the completion of hands-on projects have direct influence on students’ motivation and performance, and would maximize the accomplishment of learning objectives.

INTRODUCTION

Glaucoma is a potentially blinding disease characterized by irreversible damage to the retinal ganglion cell axons within the optic nerve head, where the axons pass through the lamina cribrosa (LC) and exit the eye. [1] The mechanisms underlying the development and progression of glaucoma remain unclear. It is hypothesized that deformations of the optic nerve head, for example due to increased intraocular pressure, may in turn compress capillaries and compromise perfusion to LC astrocytes and axons, contributing to neural tissue distress and eventually retinal ganglion cell axon death. [2] To understand the potential contribution of perfusion on glaucomatous neuropathy, we must therefore understand how LC hemodynamics are altered by capillary occlusion. The LC capillaries form a complex interconnected network, in which blood can take a number of routes. Hence, the effects of occlusion are much more difficult to predict and understand than in a relatively simple arterial tree.

Our goal in this project was to understand the changes in LC hemodynamics caused by capillary occlusion. Specifically, we used a specimen-specific map of LC vasculature to develop a numerical model of LC hemodynamics. We then evaluated the effects of occluding some capillaries or arterial inlets. To understand potential differences in regional sensitivity to occlusion we repeat the virtual experiments with occlusions in different LC quadrants.

METHODS

Serial histological sections (thickness: 16 μm) were obtained from a monkey optic nerve head, in which the blood vessels had been labeled with a fluorescent dye. [3] The sections were imaged with fluorescence microscopy at a resolution of 0.73 μm per pixel and registered to one another. A 3D stack was created of the registered images to obtain a Z-projection of maximum intensity of three sections through the LC. The result was then skeletonized, and any isolated branches were removed to ensure that all vessels were connected except at the periphery for blood inflow and the center for outflow (Figure 1). [4, 5] The skeleton was converted into a mesh of the LC vasculature suitable for solving flow numerically.

We assumed blood as an incompressible Newtonian fluid. [6] The hemodynamics boundary conditions are illustrated in Figure 1. A fluid mechanics approach was used to predict the blood pressure and blood

flow velocity within the vessels. As a first approximation, we assumed the flow is one-dimensional, such that only the average flow velocity was solved for each cross-section of a vessel.

The LC vasculature was divided into four quadrants: nasal (N), temporal (T), superior (S) and inferior (I). The blood flow in the model as reconstructed was considered the baseline. To evaluate the impact on LC hemodynamics of capillary occlusion we considered two tests: First, to test minor occlusions, we gradually removed from the model 1, 2 and then 3 vessels in each quadrant. Second, to test the effect of a major occlusion in one of the feeder vessels of the circle of Zinn-Haller, we eliminated blood inflow in all but one of the inlets in a quadrant.

Figure 1. A specimen-specific model of LC vasculature generated from monkey optic nerve head. An inlet velocity (v) of 1 mm/s was applied at the periphery to simulate the blood flow originated from the Circle of Zinn-Haller, a variably complete anastomotic ring of arteries around the LC. An outlet pressure (p) of zero was applied at the center to simulate the blood drainage via the central retinal vein. The dashed square indicates the region where we removed the vessels in the nasal quadrant.

RESULTS

Due to space limitations, we only present the results related to the changes made to the nasal quadrant. The results observed for other quadrants were similar. The effects of removing a few capillaries on

LC blood pressure and velocity are shown in Figure 2. The effects of reducing blood inlets from 9 to 1 are shown in Figure 3.

Figure 2. Color map of the blood pressure (second column) and blood flow velocity (third column; arrows indicate the direction of the velocity) predicted by the models with and without removing the blood vessels (first column). The flow was highly resilient to removing the vessels. Interestingly, flow reversal was observed in a vessel adjacent to the ones removed (an example is highlighted by the dotted red ellipse in the third column).

Figure 3. Color map of the blood pressure (left column) and blood flow velocity (right column) predicted by the models with 9 (baseline, top row) and 1 (constrained, bottom row) arterial inlets in the nasal quadrant, respectively. The small black circle in the bottom row indicates the single arterial inlet left. Reducing the number of arterial inlets decreased the blood pressure and blood flow velocity inside the vessels.

DISCUSSION

We studied LC hemodynamics using a numerical model based on specimen-specific LC vasculature of a monkey. To test the robustness of LC hemodynamics to artery occlusions, we reduced virtually the number of arterial inlets and removed a couple of vessels in each LC quadrant. Our models predicted that: (1) removing a few vessels within the LC had a very small effect on the overall blood flow behavior in the LC, though the effects were larger locally; (2) an occlusion of a feeder artery resulting in no blood inflow in most of the inlets substantially decreased the blood pressure and blood flow velocity, with effects throughout the LC.

The minor effects of removing a few vessels suggest that LC defects, for instance such as could occur from a hemorrhage, may also have a limited impact on the LC. [7, 8] Even though the magnitude of blood flow velocity did not change substantially with the removal of the vessels, we observed flow reversal in a few adjacent vessels. This is consistent with the observation by Fu et al. that modeling the retinal blood flow with the loss of several retinal capillaries. [9] It is unclear if this reversal behavior is physiologically realistic. Improvements in imaging and in vivo measurement of LC blood flow are needed to confirm model predictions.

We found that LC hemodynamics was highly influenced by the number of arterial inlets to the LC. LCs with fewer arterial inlets exhibited lower blood pressure and blood flow velocity inside the vessels. A decreased blood velocity inside can reduce oxygen transport to the surrounding neural tissues. [10] Our findings suggest that occlusion of the circle of Zinn Haller could have a substantial impact on LC hemodynamics. In vivo evaluation of the sensitivity of the feeder arteries to compression when under elevated IOP is necessary to confirm our predictions.

In summary, we developed a model of LC hemodynamics based on specimen-specific data. Our findings suggest that the interconnected network of capillaries in the LC increases its robustness by decreasing sensitivity to occlusion of some capillaries. The interconnectivity is, however, insufficient to completely compensate for the compromised blood flow resulting from an occluded feeder vessel. All four sectors had similar sensitivities. Ongoing efforts are directed toward developing more advanced 3D models of LC vasculature and to quantify oxygen and nutrient diffusion.

PARTICLE DEPOSITION CORRELATES WITH WALL SHEAR STRESS DIVERGENCE IN HUMAN AIRWAYS

Ali Farghadan (1), Kamran Poorbahrami (2), Sahar Jalal (3), Jessica M. Oakes (2), Filippo Coletti (3), Amirhossein Arzani (1)

INTRODUCTION

Lungs are directly exposed to harmful aerosols, which increases the vulnerability of the respiratory and cardiovascular systems. On the other hand, recent developments in inhalation treatment for various lung diseases highlight the need to understand deposition processes. Wall shear stress (WSS) is a substantial parameter in biological flows. We have recently used WSS vectors to study near-wall transport in cardiovascular flows [1, 2]. WSS divergence (WSSdiv) represents near-wall normal velocity and could be used to study transport towards or away from the wall [1]. In this study, we test our hypothesis that particle deposition in lung airways correlates with WSSdiv. Specifically, we hypothesize that particle deposition mainly occurs in regions of positive WSSdiv (near-wall velocity towards the wall) and that there is a correlation between deposition concentrations and positive WSSdiv magnitudes. Computational fluid dynamics (CFD) simulations were performed to quantify the airflow in the upper tracheobronchial tree. A comprehensive comparison between the numerical simulation and magnetic resonance velocimetry (MRV) measurements were made to validate the CFD simulation. We performed global and regional statistical analyses on a case-control and six patient-specific models (2 healthy and 4 asthmatic)

METHODS

Velocity and WSS data were obtained from CFD simulations. In the case-control, a mesh with a total of 5.3M linear tetrahedral elements with five layers of boundary layer meshing was created via the open source SimVascular software (simvascular.org). The open-source finite element solver Oasis (github.com/mikaem/Oasis), which is a CFD solver with minimal numerical dissipation, was used to solve the fluid flow. The same lung model was 3D printed and MRV measurements were performed to quantify time-resolved 3D velocity. The outlet resistances in CFD simulations were tuned such that each lobe outflow had less than 1% relative error with respect to the corresponding experimental outflow measurements. The case-control simulations and experiment were done assuming steady flow with Reynolds number of 1500 at the trachea. WSS and velocity field along with particle deposition locations for six patient-specific models with unsteady inhalation were obtained from a recent study [3].

WSSdiv scalar field is derived from time-averaged WSS vector field at the surface. The near-wall normal velocity can be written as a scale of WSSdiv ($\nabla \cdot \tau$) [1]:

$$u_n = -\frac{1}{2\mu} \nabla \cdot \tau \delta n^2 + O(\delta n^3), \quad (1)$$

where δn is the distance normal to the wall and μ is dynamic viscosity. Hence, positive and negative WSSdiv could exemplify flow

impingement and separation, respectively.

Lagrangian particle tracking throughout inhalation is performed for all models (by solving the Maxey-Riley equation). We released particles at the inlet of case-control (steady flow) with two conditions. First, it was made sure that the entire surface is covered with 250K particles and the interactions between the particles were ignored. Second, particles were released in a staggered fashion in accordance to parabolic inlet profile such that in total around 1M particles were integrated. Also, on average 3.5M particles were released for the other six patient-specific models (unsteady flow) and tracked throughout inhalation.

To quantify the density of particles, we defined the normalized deposition concentration as:

$$DC = \frac{N_e}{A_e} \times \frac{A}{N_d} \quad (2)$$

Where N_e is the number of particles at the surface element, A_e is the area of that element, A is the entire lung surface area, and N_d is the total number of deposited particles during inhalation. The second fraction in Eq. 2 is the normalization coefficient. Deposition percentage (DP) is defined as the ratio of particles deposited in the upper tracheobronchial tree (N_d) to the total number of released particles at the inlet (N_t). Also, negative DC is the ratio of cumulative DC in negative WSSdiv region to the sum of all DCs.

RESULTS

Representative results are presented in this section. Figure 1 shows the experimental and numerical models. We performed a comparison between MRV [4] and CFD secondary flow patterns and velocity magnitude on the locations shown in Fig. 1. A very good agreement between CFD and MRV methods can be seen in Fig. 2.

FIGURE 1: The experimental and CFD models. The slices on the models show the locations where the comparison is made.

The scattered DC vs. WSSdiv results are shown in Fig. 3. The majority of particle deposition occurs in positive WSSdiv regions. Technical Presentation #037 Copyright 2019 SB³C Foundation, Inc.

FIGURE 2: MRV (voxel-based) velocity field (top row) and CFD velocity field at the same location (bottom row). The secondary flow motion is shown with black vectors on the top of velocity magnitude (cm/s).

FIGURE 3: Deposition concentration vs. WSS divergence plots for 1, 3, 5, 7, and 10 microns diameter particles (case-control model). Colors represent various regions in the lungs as shown in Fig. 4.

Pearson's correlation coefficients (for the data in positive WSSdiv region) are shown in Table 1. A strong correlation is seen between positive WSSdiv and DC. Correlation values drop as larger particles are considered. This is expected as larger particles tend to deviate more from the fluid pathlines. The same investigation on

Table 1: The DP and negative DC are shown for each particle diameter. Pearson's correlation coefficients are calculated for positive WSSdiv data with respect to DC.

Diameter	Stokes number	DP	negative DC	Pearson's values
1 μm	2.8×10^{-4}	3.5%	11%	0.83
3 μm	2.5×10^{-3}	4.6%	10%	0.84
5 μm	7.0×10^{-3}	7.5%	9.7%	0.83
7 μm	1.4×10^{-2}	15%	10%	0.79
10 μm	2.8×10^{-2}	41%	15%	0.67

six patient models (unsteady flow) shows that our conclusions are extensible (results not shown). One notable observation is negative DC, which shows that the majority of deposition occurs at positive WSSdiv as expected. We also performed a regional analysis in each specific division shown in Fig. 4 (results not shown), and the spatial integral of positive WSSdiv (over each region) was strongly correlated to the spatial integral of DC.

FIGURE 4: Case-control and patient-specific models are divided into localized regions for a regional analysis. Healthy subjects (HS) and asthmatic subjects (AS) were studied.

DISCUSSION

Numerical simulation of particle transport in the lung airways has been widely studied in recent years and has provided insight into detrimental airborne aerosol deposition and optimal particle transport for therapeutic developments. However, no previous studies have shown a strong relationship between particle deposition quantifications and fluid flow characteristics. In this study, we compared and validated our highly resolved CFD simulations with MRV measurements of the same upper tracheobronchial tree model. Lagrangian particle tracking was performed over a range of Stokes numbers. Deposition concentration (DC) was defined to quantify the deposition patterns and enable statistical analysis. As only a small fraction of DC occurs in the negative WSSdiv regions (Table 1 and Fig. 3), we directed our analysis to the positive WSSdiv side. Positive WSSdiv has a strong linear correlation with DC indicating higher deposition concentrations in regions with greater positive WSSdiv. Additionally, our conclusions were verified in six diseased and healthy patient-specific models with physiologic unsteady flows.

Our study introduces WSSdiv as a parameter that is quantified on the airway wall and provides a strong correlation with particle deposition. Our group has previously demonstrated the important role that topological features in WSS play in determining near-wall biochemical localization patterns in cardiovascular flows [1, 2]. Such transport processes are often considered passive where biochemicals follow fluid flow. However, aerosols in lung airways may have their own inertia, causing them to deviate from fluid pathlines. Nevertheless, our results showed that WSS could still be used to predict particle deposition patterns in the range of particle diameters that are of interest in the conducting airways.

INTRODUCTION

During an airborne pandemic or bio-terror attack, N95 respirators could form the first line of defense against hazardous bio-aerosols. The effectiveness of PPEs is strongly dependent on preventing aerosol leakage through gaps between the human face and PPE in addition to the intrinsic penetration through the respirator's porous layers [1, 2]. The leakage through gaps can be significantly reduced by performing fit testing and selecting the appropriately sized respirator. However, during a public health emergency, fit-testing of respirators may not be possible and leakage of aerosol through the gaps could compromise the effectiveness of the PPE. Hence, it is important to locate the leakage sites (gaps) and quantify the gap surface area and aerosol leakage for different face and masks combinations.

This paper presents a computational fluid dynamics (CFD) approach for quantifying the aerosol leakage through respirators for multiple human face-respirator combinations under realistic flow conditions. The gap surface area for different face-respirator combinations has been recently quantified by our group [3]. This study takes the CFD model further and establishes a relationship between the amount of aerosol leakage and the gap surface area for each of the face-respirator combinations. The leakage results from this study will be combined with our recently published comprehensive risk assessment models [4] to quantify the infection risk to pediatric and adult populations when exposed to various types of bio-pathogens such as *Bacillus anthracis* or Influenza virus.

METHODS

Four adult headforms and two brands of respirators, shown in Fig. 1, were selected for evaluating the gaps between the face and respirator. The geometric data of the headforms were obtained from an

anthropomorphic survey of 3,997 US workers, conducted at the National Personal Protective Technology Laboratory at the Center for Disease Control [5], and categorized based on shape and size as: small, medium, large, and short/wide. Subsequently, mannequins resembling realistic solid models of each of the headforms were obtained using 3D printing (Materialise, Inc.). The two respirator brands, labeled as Model A and Model B, belonged to the class of N95 surgical respirators, which are certified by the National Institute for Occupational Safety and Health (NIOSH) and regulated by the US Food and Drug Administration (FDA). Therefore, eight unique headform-respirator combinations were obtained by donning each of the two respirators on all four headforms.

Figure 1: An image of headforms and N95 respirators

Computed Tomography (CT) was used to capture the gap between the face and the mask for different mask-face combinations. Before the CT scans, the inside layer of the mask was coated with a thin layer of

gold to enhance the pixel intensity of the mask layer relative to the face. The CT slices were reconstructed using Mimics and 3-matics software and converted to 3D CAD geometry. A computational domain of size 150x150x200 mm³ which includes the face, respirator and the surrounding enclosure are shown in Fig 2. An inlet tube of diameter, 6 mm, was attached to the front side of the enclosure (opposite the face and respirator), while the outlet was modeled as a circular region (diameter = 6 mm) on the mouth (Fig. 2). The domain was then meshed into finite volumes consisting of tetrahedral elements using commercial meshing software (3-matic, Materialise Inc.). The mesh around the face and respirator region was refined to accurately solve the leakage flow through the gaps. Subsequently, the meshed computational domain was exported to a commercial CFD solver, CFX (Ansys, Inc.).

Figure 2: A computational domain of the face-respirator model surrounded by a bounding box

A 3-step numerical methodology was adopted for simulating the airflow and aerosol transport around and through the face-respirator geometry.

In the first step, the porous media properties (porosity and linear resistance coefficient) of the masks were obtained by performing a no-leakage CFD simulation of the masks attached to the flat plate. For this simulation, all the aerosol penetration was assumed to happen through the porous layers of the mask. The pressure drop required across the mask to attain the necessary flow was measured experimentally for all two masks. Subsequently, the mask porosity and the linear resistance coefficient were adjusted in the CFD simulations until the pressure drop matched with the experimental data. After completion of first stage, for mask Model A, the simulation with 10LPM intake flow rate resulted in porosity value of 0.5 and linear resistance coefficient value of 93700 kg m⁻³s⁻¹, while the simulation with 70LPM intake flow rate resulted in porosity value of 0.5 and linear resistance coefficient value of 89800 kg m⁻³s⁻¹.

In the second step, fluid flow simulation through the face-respirator geometry was performed using the mask properties obtained from the first stage. An inlet boundary condition of zero static pressure was specified at the inlet and mass flow rate was specified at the mouth outlet. This combination of boundary conditions simulates a suction flow through the inlet. Subsequently, the amount of fluid flow through

the leakage sites and through the porous layers of the mask was determined.

In the third step, a particle tracking algorithm was used to track the leakage of aerosols through the leakage sites between face and the respirators. The flow split between the leakage sites and the mask (obtained from the second step) was provided as the input for this stage. The input parameters for aerosol transport including the density (2250 kg/m³) and aerosol size (100 nm) were obtained from the experimental studies. Finally, the amount of aerosol leakage was obtained as a function of flow rate to understand the relationship between the gap surface area and the leakage percentage for different face-respirator combinations.

RESULTS

The variation of flow leakage as a function of gap surface area for two different intake flow rates of 10 LPM and 70 LPM is shown in Fig. 3. The gap surface area for the eight human face-respirator combinations were obtained from image based modeling and ranged from 29.45mm² to 409.43mm² [3], while the flow leakage varied from 20% to 95%. The rate of increase of flow leakage is observed to be high up to a gap surface area of 200 mm² beyond which it stabilizes to a value of ~90%. As expected, flow leakage is observed to increase with gap surface area.

Figure 4. Variation of CFD simulations based flow leakage with gap surface area for intake flow rates of 10LPM and 70LPM

DISCUSSION

Future studies will provide the relation between gap surface area and aerosol leakage (instead of the flow leakage reported here). The aerosol leakage % obtained from the CFD will also be validated with the experimental results. Subsequently, the leakage results will be input to our comprehensive risk assessment model [4] to quantify the infection risk to pediatric and adult populations when exposed to various types of bio-pathogens.

INTRODUCTION

Targeting drug particles to specific regions in the lungs in asthmatic subjects may improve therapeutic response while reducing side effects, benefiting the 10-15 percent of patients with uncontrolled asthma [1]. Contributing factors of ventilation heterogeneity, airway remodeling, and mucus plugging make it challenging to deliver therapeutics to obstructed airways, resulting in inadequate dose concentrations. Identifying the variables that most influence regional deposition is the first step towards targeting inhaled medications. Previously, we developed a framework that combines imaging data (e.g. MRI and CT) with computational fluid dynamic simulations to study the structural-functional abnormalities in healthy and asthmatic lungs [2]. Here, we extend this framework to include particles and apply it to predict airway dose concentrations and test delivery conditions on particle fate in the lungs.

METHODS

We perform unsteady computational fluid dynamics and particle transport (CFD-PT) simulations in six human airways: 2 healthy subjects (HS1 and HS2) and 4 asthmatic subjects (AS1-2 mild/moderate, and AS3-4 severe), all of whom underwent CT and MRI. Airway models were created based on each subject's CT images at FRC [2]. We registered and integrated hyperpolarized (HP) ³He MRI and CT data to model the regional ventilation defects [2] as resistance boundary conditions.

An open-source finite element solver (SimVascular [4]) is used to solve the unsteady three-dimensional Navier-Stokes equations for an incompressible Newtonian fluid (density = 1.2E-6 g/mm³ and viscosity = 1.81E-5 g/mm-s). We prescribe a parabolic velocity profile on the trachea entrance based on the waveform presented by Longest et. al., which models generic use of a dry powder inhaler:

$$\begin{cases} Q(t) = \frac{Q_{max}}{T_{Qmax}} t & 0 \leq t \leq T_{Qmax} \end{cases} \quad (1a)$$

$$\begin{cases} Q(t) = Q_{max} \cos\left(\frac{\pi(t-T_{Qmax})}{2(1-T_{Qmax}/T_f)} t\right) & T_{Qmax} < t \leq T_f \end{cases} \quad (1b)$$

where Q_{max} is the peak flowrate set to 61.4 L/min, T_{Qmax} is the time when the flowrate reaches its peak, and T_f is the inhalation time (set to 1.22 s and 4.86 s, respectively).

The airway resistances within the conducting airways (R_{3D}) are calculated by dividing the time averaged pressure gradients by the trachea flowrates. In addition, we calculate wall shear stress (WSS):

$$WSS = \int_S \mu \frac{du}{dn} dS \quad (2)$$

where μ is viscosity, \mathbf{u} is the velocity vector, and \mathbf{n} is the normal vector to the wall.

Following the airflow simulations, 3 μ m diameter particles are released and tracked throughout inhalation by solving a force balance equation that incorporates gravity and drag. Particles are marked as deposited once they intersect with airway wall, and the remaining particles are assumed to be delivered to the lung periphery. We compute total and regional deposition for each subject, and to visualize deposition hotspots, we calculate the area-normalized number of deposited particles in each surface element with respect to the total deposited particles:

$$NP = \frac{N_e \sum T}{N_T \sum e} \quad (3)$$

where N_e is the number of deposited particles within a surface element, $\sum e$ and $\sum T$ is the element and total surface area, respectively, and N_T is the total number of deposited particles.

We hypothesize that the time and injection locations that particles are released are important variables linked to the particle's fate within the lung. To test this hypothesis, time frames corresponding with enhanced deposition efficiency are identified by recording particle deposition over inhalation time and are correlated with the particle injection time. We then alter particle release time frames to enhance the fraction of particles delivered to the central or peripheral airways.

In addition, we study the correlation between particle initial locations (at the start of the inhalation) and the lobe that they are delivered to. We choose a severe asthmatic subject (AS3) for this analysis. Our aim here is to improve delivery to the Right Middle lobe, which has the highest segmental ventilation defect percentages (SVDP indicates inability to deliver inhaled gas).

RESULTS

Time averaged wall shear stress (TAWSS) is calculated by averaging the WSS over inhalation time (Figure 1A). In Table 1 we present the TAWSS normalized by $\sum T$. AS3 has the lowest R_{3D} in comparison to the other subjects due to its larger distal airways [2]; airway resistances are reversely correlated to the fourth power of airway diameter. High regions of TAWSS are located at the distal airways of AS4 (Fig. 1A), likely because this subject's airways are smaller and less circular than the other subjects [2], leading to higher velocity magnitudes and near-wall gradients. The velocity streamlines show helical-type patterns, likely because this subject has asymmetric airways, including curved and irregularly shaped airways (Fig. 1B).

While total deposition within the conducting airways are similar among the healthy subjects (which agrees with our previous study [4]), we see larger variations among the asthmatic subjects (Table 1). Despite similar asthma severity, the percentages of

deposited particles is almost 10 times less in AS3 than in AS4, suggesting that far more particles are delivered to the lung periphery in AS3.

Table 1. Simulated total deposition for the three particle sizes, resistances within the 3D airways (R_{3D}), and area normalized time averaged wall shear stress for the six subjects

Subjects	Deposition (Percent)			R_{3D} cmH ₂ O-s/ml	$TAWSS$ g/mm-s2
	1 μ m	3 μ m	5 μ m		
HS1	4.4	26.6	68.7	6.9E-3	1106
HS2	4.4	26.6	73.5	7.9 E-3	1800
AS1	5.6	33.4	79.1	4.8 E-3	2034
AS2	7.8	40.3	81.7	13.8 E-3	1023
AS3	2.6	5.9	21.6	0.1 E-3	602
AS4	8.7	56.3	90.6	31.9 E-3	1542

We choose to either enhance or reduce central airways deposition based on an arbitrary threshold of 30% central airway deposition (Fig. 1C). To enhance conducting airway deposition in HS1, HS2, and AS3, we release particles only during the times of peak flowrates (between 1.2 to 2.5s). To enhance peripheral delivery in subjects AS1, AS2, and AS4, which have relatively higher central deposition fractions, we release particles only during the slower flowrate times (3.2 to 4.5s). Fig. 1C shows the results of these alterations, total dosimetry in subject AS4 is reduced from 56% to 32% (Fig. 1D and 1E).

Figure 1. Time averaged wall shear stress (A), velocity colored streamlines (B), variations of central/peripheral deposition due to altering the particle release time (C, left/right), and AS4 number concentration before and after modification (D-E)

We correlate lobar deposition with the release locations of particles on the trachea face for subject AS3, in order to investigate the influence of the particles' initial locations on regional deposition. Subpanel of Fig. 2A shows the trachea inlet, where the colors represent the concentration of deposited particles in the Right Middle lobe (highest SVDP). Leveraging these results, we change the initial location of the 3 μ m particles in order to deliver them to the lobe with the highest ventilation defects. Fig. 2A shows the percentage of particles that deposited on the walls of the airways that leads to a specific lobe and Fig. 2B shows the particles delivered to that lobe's periphery. By altering the seeding location of particles, we are successful in increasing regional deposition within the Right Middle lobe (RM) from 6 to 11 % and the delivery percentage from 10 to 43%.

Figure 2. Lobar deposition percentages and the initial location of the Right Middle Lobe (RM) deposited concentrations (panel A) and lobar delivery percentages (panel B) for subject AS3, before and after seeding modifications. LS=Left Superior, LI=Left Inferior, RI=Right Inferior, and RS=Right Superior.

DISCUSSION

Asthma is typically controlled by direct delivery of therapeutics to the lung. Optimization of drug delivery may lead to a reduction in the total dosage, potentially reducing adverse side effects while preventing future exacerbations. We performed a patient-specific airflow and aerosol simulation in healthy and asthmatic airways and found that (1) total and regional tissue dosimetry varies between asthmatic subjects, (2) central vs. peripheral deposition can be adjusted by altering the aerosol bolus injection time, and (3) lobar targeting can be achieved by altering the seeding locations of particles. This knowledge brings us one step closer to our ultimate goal of optimizing drug delivery based on each patient's needs. Here, we focus on the link between the initial location of the particles on the trachea inlet and their destination lobe, however therapeutics are inhaled through the mouth and the particles will likely re-distributed by the time they pass the trachea. Therefore, we plan to add the extra-thoracic airways in our future studies.

DIFFERENTIAL EFFECTS OF BLADDER OUTLET OBSTRUCTION ASSOCIATED PRESSURE CYCLING ON UROTHELIAL CELL INFLAMMATION AND FIBROSIS IN VITRO

INTRODUCTION

Partial bladder outlet obstruction (pBOO) is a condition that affects one-sixth of the worldwide population¹ and is typically diagnosed by the presence of lower urinary tract symptoms (LUTS) such as hesitancy, weak stream, and incomplete bladder emptying. In addition, pBOO is frequently accompanied by inflammation leading to fibrosis of the bladder wall tissue and reduced tissue compliance². Early evidence of pBOO is generally determined by a voiding pressure increase as the bladder contracts against the obstruction. As pBOO progresses, the storage pressure within the bladder also increases due to changes in bladder tissue compliance. Thus, it was hypothesized that changes in voiding and/or storage pressure associated with pBOO disease progression may induce activation of pro-inflammatory and pro-fibrotic mechanosensitive pathways in the urothelium.

Our previous *in vitro* study demonstrated that exposure of bladder urothelial cells to simulated elevated voiding pressures (40 cm H₂O for 1 minute) as well simulated elevated storage pressures (15 cm H₂O for 60 minutes) both induced an increase in extracellular ATP release³. Moreover, exposure of these cells to elevated hydrostatic pressure led to an increase in activation of intracellular caspase-1, part of inflammasome cascade. We concluded that the pressure-induced ATP release led to additional ATP-induced ATP release via activation of P2X7 receptor, which then resulted in caspase-1 activation via activation of P2X4 receptor³. These results provided a potential mechanism at the cellular-level for a previous *in vivo* study that demonstrated elevated levels of caspase-1 present in the urothelium of pBOO rats⁴. In the present study, we exposed urothelial cells to simulated pressure cycling profiles in order to elucidate the mechanisms for increased collagen content found in the bladders of pBOO rats⁵. Specifically, we compared the effects of early stage pBOO (elevated voiding pressure), and late stage pBOO (elevated

voiding and storage pressures) on caspase-1 activation and pro-fibrotic gene expression *in vitro*.

METHODS

For experiments investigating the role of hydrostatic pressure magnitude during storage/voiding cycles on inflammation and fibrosis, a custom apparatus⁶ was used to expose rat urothelial cell line MYP3 cells to sustained pressure over designated time intervals. Briefly, the system consisted of a computer that ran a custom LabView program (National Instruments) with a pump and pressure transducer to monitor and regulate the pressurized environment within a closed chamber. Cells were plated at 1.2×10^6 cells/well in sterile 6 well cell culture plates and incubated for 48 hours until the cells reached 90% confluence. The complete F-12K media was then replaced with complete media containing 25 mM MOPES buffer immediately prior to exposure to hydrostatic pressure in order to minimize the effects of basal extracellular ATP levels on the results after exposure to pressure. Cells were subjected to pressure cycles for 24 or 72 hours of either 0 cmH₂O for 175 minutes followed by 30 cmH₂O for 5 minutes to simulate unobstructed bladder cycling, 0 cmH₂O for 175 minutes followed by 75 cmH₂O for 5 minutes to simulate early stage (ES) pBOO, or 15 cmH₂O for 175 minutes followed by 75 cmH₂O for 5 minutes to simulate late stage (LS) pBOO. Following exposure, RNA was isolated using a commercially available RNA isolation kit (Qiagen) and purified with DNase (Thermo Scientific). RT-PCR was conducted on the purified RNA following the established protocol of a commercially available qRT-PCR kit (Invitrogen) with primers designed to amplify a region of mRNA corresponding to regions of target genes that lack homology with other subtypes. Separate cells exposed to the same cyclic pressure regime for 24 hours were lysed

and intracellular caspase-1 activity was measured using an established method^{4,7}.

Each experiment was performed in triplicate, with a minimum of three repetitions (n=3). The mean values of the data from the repetitions were calculated using SAS software (SAS Institute) and compared using single-factor analysis of variance (ANOVA). When a statistically significant difference was displayed, a *post hoc* pairwise analysis was conducted using the Tukey-test. P-values less than 0.05 were considered statistically significant.

RESULTS

MYP3 cells exposed to simulated early stage (ES pBOO) and late stage (LS pBOO) pressure cycling for 24 hours exhibited similar gene expression for collagen type I (Col I), collagen type III (Col III), lysyl oxidase (LOX), or prolyl 4-hydroxylase (P4H) (Figure 1A). However, cells exposed to these pressure cycling conditions resulted in increased level of intracellular caspase-1 activity in both ES pBOO (1.15-fold) and LS pBOO (1.21-fold) when compared to the non-pressure treated control. Unlike the 24 hour experiments, MYP3 cells exposed to ES pBOO pressure cycling for 72 hours demonstrated decreased levels of collagen type III expression and increased levels of prolyl 4-hydroxylase expression compared to cells exposed to unobstructed pressure conditions. In addition, MYP3 cells exposed to LS pBOO pressure cycling for 72 hours demonstrated decreased levels of collagen type III expression, but also demonstrated increased levels of both prolyl 4-hydroxylase and collagen type I expression compared to cells exposed to unobstructed cycling conditions (Figure 1B). The data also indicates a trend of increasing expression of collagen type I and prolyl 4-hydroxylase and decreases expression of collagen type III and lysyl oxidase as pBOO progresses.

Figure 1: Gene expression of cells exposed to simulated early and late stage pBOO pressure cycles of unobstructed, early stage (ES), and late stage (LS) pBOO for 24 (A) and 72 (B) hours *in vitro*. Results are mean \pm SEM; *P<0.05, n=3.

DISCUSSION

Although changes in the mechanical environment have long been correlated with the progression of pBOO associated disorders, the role of specific mechanical cues in disease progression has yet to be elucidated. In the present study, we hypothesized that changes in pressure cycling associated with different stages of pBOO resulted in progression of associated disorders. Using a custom set-up, we exposed urothelial cells to simulated early stage and late stage pressure cycling and determined the effect of pressure variation on precursors of inflammation and genes associated with fibrosis. Results indicate that increased voiding pressure and storage pressure associated with early stage and late stage pBOO resulted in increased activation of intracellular caspase-1, indicating activation of the NLRP3 inflammasome within 24 hours of pressure exposure. Simulated early stage pBOO and late stage pBOO pressure cycling also resulted in increased collagen type I and prolyl 4-hydroxylase as well as decreased collagen type III after 72 hours. Increased collagen type I and prolyl 4-hydroxylase content indicates fibrosis of the tissue and is consistent with previous findings that demonstrated BOO rats exhibited increased levels of collagen in urothelial cells⁵. The collagen type I/III ratio also increases with progression of the simulated pressure cycles. It has been reported that the ratio of collagen type I/III is an important indicator of fibrosis as increased collagen type I/III ratio is correlated with changes in tissue compliance⁸ and that there is an increase in collagen type I/III ratio in rabbit ventricles in response to pressure overload⁹. Further research, however, is needed to elucidate the underlying mechanisms by which elevated pressure and distention trigger ATP release and intracellular caspase-1 activation in order to improve understanding of mechanically induced bladder pathologies such as pBOO.

EFFECT OF AIRWAY CILIA PROPERTIES ON ITS PHYSIOLOGICAL FUNCTIONING

Uduak Z. George

Department of Mathematics and Statistics
San Diego State University
San Diego, CA, United States

INTRODUCTION

Mucus clearance in the airway is regulated by carpets of cilia on the epithelial layer of the lungs. Each cell of the epithelium contains about 200-500 cilia that beat synchronously with each performing about 20-30 beating cycle per second [1]. Bordering the epithelial layer and surrounding the cilia is the periciliary liquid (PCL) that lubricates the epithelial layer. The mucus layer is sandwiched between the PCL and the air in the core airways. The PCL and mucus layer are also referred to as the airway surface liquid (ASL) [2]. PCL is known to facilitate mucus clearance by providing a favorable environment for the beating cilia [3]. The impairment of mucus clearance is often devastating and may result in inflammation [4] and infection [5] in the airways. It has also been observed that people born with certain abnormal ciliary structure may have reduced mucociliary transport efficiency. Permanent changes in ciliary structure and function results in mucus retention [6]. We seek to understand the mechanism by which changes in ciliary structure affect its functional role and causing mucus clearance to fail. We speculate that changes in ciliary structure would affect its biomechanical properties and structural integrity and impede the proper functioning of mucociliary transport.

METHODS

A computational model describes the lung airways. The cilia are represented as an elastic solid. The PCL and mucus layer are modeled as fluids with different density and viscosity. We consider three different cases:

- I. PCL occupy the whole region of ASL (i.e. no mucus is present).
- II. Physiologically healthy mucus occupies the whole region of ASL (i.e. PCL is absent).

- III. Highly viscous mucus occupies the whole region of ASL (i.e. no PCL is present).

We choose the geometry of the model to correspond to a cross-section of a bronchi (Figure 1A). Model geometry and parameter values are chosen to correspond to experimental observations [7]. The radius of a cilium is approximately 0.1 μ m and its height is 8 μ m long [8]. The lung is continuously undergoing cyclic changes in pressure gradient, a necessity for gaseous exchange. The model investigates the resilience of cilia to deformation during exposure to normal cyclic pressure gradient in the airways.

Navier-Stokes equation for airway surface liquid

Let $\Omega = \Omega_A \cup \Omega_c$ denote the lung airways in \mathcal{R}^2 with Ω_A the region resided by the airway surface liquid and Ω_c the cilia. Let $\mathbf{v} = \mathbf{v}(\mathbf{x}, t)$ denote the velocity of the airway surface liquid (ASL), $p = p(\mathbf{x}, t)$ the pressure at the ASL, ρ_F and μ_F the density and dynamic viscosity of the ASL respectively. The airway mucus and PCL are assumed to be incompressible viscous fluids. The motion of the mucus and PCL is governed by the incompressible Navier-Stokes equation defined in a bounded domain $\Omega_A \subset \mathcal{R}^2$. The equation of motion is:

$$\rho_F(\partial_t \mathbf{v} + (\mathbf{v} \cdot \nabla) \mathbf{v}) = \nabla \cdot \boldsymbol{\sigma}, \quad \text{in } \Omega_A, \quad t \in (0, T) \quad (1)$$

$$\nabla \cdot \mathbf{v} = 0, \quad \text{in } \Omega_A, \quad t \in (0, T) \quad (2)$$

where $\boldsymbol{\sigma} = -p\mathbf{I} + 2\mu_F \mathbf{D}(\mathbf{v})$ is the fluid Cauchy stress tensor and $\mathbf{D}(\mathbf{v}) = \frac{1}{2}((\nabla \mathbf{v} + (\nabla \mathbf{v})^T))$ is the symmetrized gradient of \mathbf{v} . \mathbf{I} is the identity tensor in \mathcal{R}^2 . Values of ρ_F and μ_F for ASL are $1 \times 10^3 \text{ kg/m}^3$ and 0.001 Pa·s respectively (for case I, no mucus is present).

Elastic model for cilia

We denote by $\mathbf{u} = \mathbf{u}(\mathbf{x}, t)$, $\mathbf{x} \in \Omega_c$, $t \in (0, T)$, the displacement of the cilia. We assume that cilia is a homogeneous isotropic material and the displacement gradient for cilia is small (i.e. $\nabla \mathbf{u} \ll 1$) and the equilibrium equation is [9]:

$$\rho_s \partial_{tt} \mathbf{u} = \nabla \cdot \mathbf{S}, \quad \text{in } \Omega_c, \quad t \in (0, T) \quad (3)$$

where \mathbf{S} is the linearized Saint Venant-Kirchhoff model that describes the mechanical property of cilia.

$$\mathbf{S} = \mu(\nabla \mathbf{u} + (\nabla \mathbf{u})^T) + \lambda(\nabla \cdot \mathbf{u})\mathbf{I}, \quad \text{in } \Omega_c, \quad t \in (0, T)$$

Here, μ and λ are the Lamé constants, describing the compression and distortion of the cilia. The constants μ and λ can be expressed as [10]:

$\mu = \frac{E}{1+v}$, $\lambda = \frac{Ev}{(1+v)(1-2v)}$, where E is the modulus of elasticity (Young modulus) of a cilium, v the contraction ratio (Poisson ratio) of cilium and ρ_s is the density of cilium. Value of ρ_s and v used in the model is $1.11 \times 10^3 \text{ kg/m}^3$ and 0.49 respectively.

Young modulus for motile cilia Let a denote the radius of a cilium, E its Young modulus and I its area moment of inertia then $EI = 6 \times 10^{-22} \text{ Nm}^2$ [11]:

$$\text{where } I = \frac{\pi a^4}{4} = \frac{\pi(0.1 \times 10^{-6})^4}{4} = 0.78546 \times 10^{-28} \text{ m}^4.$$

Given that $EI = 6 \times 10^{-22} \text{ Nm}^2$, we can write that

$$E = \frac{6 \times 10^{-22} \text{ Nm}^2}{0.7859 \times 10^{-28} \text{ m}^4} = 7.639 \times 10^6 \text{ N/m}^2$$

Coupling condition for the elastic model and Navier-Stokes equation

We apply a linear coupling at the ASL-cilia interface by imposing continuity of stresses at the interface. That is at the interface the normal stress experienced by the cilia is equal to the normal fluid stress.

Let \mathbf{n} denote the outward pointing unit normal at the ASL-cilia interface, the coupling condition at the ASL-cilia interface is expressed as follows: $\boldsymbol{\sigma} \cdot \mathbf{n} = -\mathbf{S} \cdot \mathbf{n}$ on the ASL-cilia interface.

Pressure gradient in the airways

The maximum local pressure drop in the airways is higher before forced inhalation (about 120 Pa) compared to before quiet inhalation (about 8 Pa) [12]. We note that local pressure gradient is higher compared to the linear pressure gradient because of local bifurcations of the airways at different generations.

RESULTS

The pressure boundary condition at the inlet and outlet of the domain mimics the pressure gradient in the airways and the model is simulated for $T = 1$ sec. Simulation results (for case I) is presented in Figure 1B. The von Mises stress is higher at the stalk than at the tip of the cilia. Increase in pressure drop leads to an increase in the deformation of cilia. The deformation of cilia decreases for increasing Young's modulus. The values of the Young's modulus are chosen to correspond to typical values for normal and abnormal cilia.

DISCUSSION

The pressure gradient in the airways during inhalation and exhalation causes a displacement of the peri-cilia liquid and this in turn deforms the cilia. Deformation of the cilia would decrease the effective stroke of cilia. The model shows that changes in ciliary structure may influence cilia dynamics and in turn the transport of mucus. Most models seek to understand the active transport of mucus in the airway, a contribution of this work is in showing that changes in ciliary structure would affect its biomechanical properties and structural integrity and impede the proper functioning of mucociliary transport.

Figure 1: A. Model domain in \mathcal{R}^2 representing a cross-section of a bronchi. B. Stress distribution in cilia for different values of Young modulus and pressure P_{\max} at $t=1\text{sec}$. Top row, $P_{\max} = 5\text{ Pa}$. Bottom row, $P_{\max} = 20\text{ Pa}$. Top row from left to right: Young modulus increases by an order of 10. Same for bottom row. Color scale shows the distribution of von Mises stress. Red is high and green is low. Deformed geometry at $t = 1\text{sec}$ is superimposed on the undeformed initial geometry ($t=0$).

INTRODUCTION

In making progress towards ocular drug delivery, predictive modeling along with corresponding experimentation has taken an important role. While sophisticated computational models for drug transport are being developed, it is fundamentally important to obtain the relevant biophysical parameters for the ocular tissues. One of the important parameters in this regard is the mass diffusion coefficient of the vitreous humor. A large body of literature exists on the measurement techniques in the vitreous humor, and a concise review of these works has been provided by Penkova et al. [1]. They discuss the advantages of the visualization techniques such as MRI and fluorescence that provide a snapshot of drug distribution profile provided, of course, the drug can be labeled with a contrast agent. Penkova and coworkers [2, 3] have developed the 'contour method' for measuring the diffusion coefficient for various drugs and contrast agents.

METHODS

The procedure consists of injecting a drug labeled with a contrast agent into the vitreous humor and tracking its spread therein by MRI. The image intensity distribution upon calibration provides the concentration snapshot at the various time points when the image is taken. At the same time the concentration distribution can be theoretically predicted on the basis of the diffusion equation solution for a given initial deposition of a bolus of a drug/contrast agent. A comparison of the theoretical and the experimental distributions and minimizing the difference (least-squares best fit) while floating the unknown diffusion coefficient D returns the value of D . For real drugs, this technique relies on successful labeling of the drug with a contrast agent. Our goal for the current work has been to establish the diffusion coefficient for bevacizumab. With this drug,

labeling it with gadolinium for MR imaging has not been very successful. Therefore, we have resorted to applying the contour method with fluorescence imaging. We have in fact been able to label bevacizumab with fluorescein.

Labeling Bevacizumab

We labeled bevacizumab with Alexa Flour 488 dye. A 20 μ l bolus of the labeled drug with concentration of 6.74 μ M was injected into the vitreous of a with a 30G hypodermic needle via pars plana (1.5mm away from the limbus) of an anesthetized dutch-belted rabbit at a slow rate of 2 μ l/min over a period of 10 minutes using a syringe pump. The slow rate gave a nearly spherically symmetric bolus. In order to not disturb the imaging process, the needle was not removed after the completion of the injection.

Imaging

Using the HRA+OCT Spectralis (Heidelberg Engineering, Inc; Heidelberg, Germany) and its fluorescein angiography software (Figure 1), a series of images of the diffusion labeled bevacizumab had been acquired every 30 second during the injection period (10 minutes) and every 15 minutes thereafter for a total period of three hours. Images were acquired using a wide field 55° lens focused on the needle inserted into the mid-vitreous (Figure 1). To analyze the intensity of the images and their labeled-bevacizumab distribution, MatLabR 2016a software (MathWorks, Inc; MA, USA), was used. The images show that the drug initially distributes around the needle but with time a more spherical bolus shape emerges.

Figure 1: In vivo set up acquisition.

Analysis

From the raw intensity data, color maps of the drug distribution were constructed. These contours were compared with the theoretical intensity distribution. We approximated the initial bolus to be spherical in shape and used the distribution (see [1, 4]) for an infinite medium around the bolus,

$$c(r, t) = c_0 \left\{ \frac{1}{2} \left[\operatorname{erf} \left(\frac{a-r}{\sqrt{4Dt}} \right) - \operatorname{erf} \left(\frac{a+r}{\sqrt{4Dt}} \right) \right] - \frac{1}{r} \sqrt{\frac{Dt}{\pi}} \left[e^{-\frac{(a-r)^2}{4Dt}} - e^{-\frac{(a+r)^2}{4Dt}} \right] \right\}, \quad (1)$$

where $c(r, t)$ is the labeled bevacizumab intensity distribution, c_0 is the initial signal intensity of the bolus, a is the bolus radius, r is the spherical distance from the bolus center, t is the time. For the timescale involved, the infinite-medium approximation is quite good [2]. It should be noted that since the relationship between signal intensity and bevacizumab concentration is linear, we do not need a calibration curve. Additionally, since the diffusion equation is linear, inverse problem for obtaining the diffusion coefficient from the data is invariant with the intensity to concentration conversion (and hence no need for a calibration curve). A comparison of the theoretical distribution in Equation (1) with the signal intensity data returns the value of D .

RESULTS AND DISCUSSION

A large set of signal intensity data has been acquired, and a colormap example is given in Figure 2. A theoretical model based on a spherical bolus of the drug and its quantitative comparison with experimental data provided the value of the unknown diffusion coefficient, giving approximately $D = 4 \times 10^{-7} \text{ cm}^2/\text{s}$ for bevacizumab (149 kDa). This value is somewhat higher than that for Gd-Immunoglobulin (160 kDa) for the ex vivo bovine vitreous but about the same order of magnitude ($2.1 \times 10^{-7} \text{ cm}^2/\text{s}$). As discussed by Penkova et al. [1], the contour method using MRI has provided very accurate measurements of the diffusion coefficients for various Gd-labeled molecules. However, when such labeling presents challenges, fluorescein labeling provides an alternative. With bevacizumab, the fluorescein labeling alternative worked out very successfully, and led to in vivo through-the-lens imaging with a dutch-belted rabbit. The analysis of the imaging data gave for

Figure 2: Colormapped images of the fluorescein-labeled bevacizumab signal intensity distribution at 15, 90, 150 and 210 minutes. The indentation is the needle mark.

Colormap key for intensity data:

the rabbit vitreous the fluorescence intensity distribution which is proportional to the labeled bevacizumab concentration. The current results provide information towards developing a comprehensive model for fluid flow and transport in the eye. However, experimental and analytical refinements in the approach are being explored to provide a higher degree of experimental accuracy.

PRECISE TARGETING OF POLR2A AS A THERAPEUTIC STRATEGY FOR HUMAN TRIPLE NEGATIVE BREAST CANCER

INTRODUCTION

Triple negative breast cancer (TNBC) is negative for the expression of oestrogen and progesterone receptors, and absent of human epidermal growth factor receptor 2 (HER2) overexpression¹. These receptors are molecular targets for treating breast cancer. As a result, other than olaparib, a poly(ADP-ribose) polymerase inhibitor that can benefit a small subset of TNBC patients with *BRCA* mutation, no approved targeted therapies are available for most TNBC patients. Standard chemotherapy is the only approved option, but it is ineffective with undesired side effects^{2,3}. Therefore, new targeted therapies are critically needed for TNBC.

TP53 is the most frequently mutated or deleted gene in triple negative breast cancer (TNBC). Both the loss of *TP53* and the lack of targeted therapy are significantly correlated with poor clinical outcomes, making TNBC the only type of breast cancer that has no approved targeted therapies. Through in silico analysis, we identified *POLR2A* in the *TP53*-neighboring region as a collateral vulnerability target in TNBC tumours, suggesting that its inhibition via small interfering RNA (siRNA) may be an amenable approach for TNBC targeted treatment. To enhance bioavailability and improve endo/lysosomal escape of siRNA, we designed pH-activated nanoparticles for augmented cytosolic delivery of *POLR2A* siRNA (siPol2). Suppression of *POLR2A* expression with the siPol2-laden nanoparticles (siPol2@NPs) leads to enhanced growth reduction of tumours characterised by hemizygous *POLR2A* loss. These results demonstrate the potential of the pH-responsive nanoparticle and the precise *POLR2A* targeted therapy in TNBC harbouring the common *TP53* genomic alteration.

METHODS

The Cancer Genome Atlas analysis. The Cancer Genome Atlas primary (origin: METABRIC Nature 2012 & Nat Commun 2016, and Cell 2015) and metastatic (origin: France 2016) breast cancer data were

downloaded from cBioPortal, which included copy number variation at segment levels in log-ratio, copy number variation at gene levels estimated by using the GISTIC2 algorithm, RNA-seq for gene expression in base-2 log scale, and patient information on oestrogen receptor, progesterone receptor, and HER-2/neu status. We analysed the correlation between gene copy number and the corresponding gene expression as previously described⁴. The triple-negative breast cancer (TNBC) subtypes, defined by PAM50 profiling test, included all the basal-like and claudin-low groups.

Synthesis of nanoparticles. The nanoparticles were synthesized using the double-emulsion method⁴⁵, with slight modification. First, chitosan was modified with a guanidine group according to the literature to form chitosan-guanidinate (CG). The guanidine group is a common functional group in many natural products including the naturally occurring amino acid *L*-arginine.

RESULTS

TP53 is frequently inactivated by mutation or deletion in a majority of human tumours. The Cancer Genome Atlas analysis shows that 53% (202 out 380) of TNBC cases bear the hemizygous loss of *TP53* (**Fig. 1a**). More severe stages of TNBC are associated with higher frequencies of patients with hemizygous *TP53* loss (**Fig. 1b**). This indicates one copy of *POLR2A* is enough to maintain cell survival. This positive correlation is also validated in a panel of TNBC cell lines (**Fig. 1c**). In immunohistochemical analysis using a tumour tissue microarray containing 100 TNBC samples, the expression of *POLR2A* was scored according to the staining intensity and proportion of signals in each sample (**Fig. 1d**). The *TP53* deletion is included in a large fragment deletion of Chr17p that spans over ~19.8 megabases of DNA in TNBC and other human breast cancers (**Fig. 1e**). The *POLR2A* gene is almost always co-deleted with *TP53* in the Chr17p deletion region (**Fig. 1f**). Although one allele deletion of the Chr17p fragment significantly

decreases mRNA expression of *POLR2A*. Accordingly, the copy numbers of *POLR2A* in the tumour tissue samples were determined and shown that a tight correlation was validated between *POLR2A* copy numbers and protein expression levels (Fig 1g). Collectively, these data suggest inhibition of *POLR2A* is an amenable approach for targeted treatment of TNBC.

Figure 1: *POLR2A* is almost always deleted together with *TP53* in triple negative breast cancers

We developed a core-shell nanoplatform for delivering siPol2 to target *POLR2A*. The core contains siRNA and chitosan modified with guanidine. The guanidine group can react reversibly with CO₂ to form chitosan-guanidinate-CO₂ (CG-CO₂) in a pH dependent manner, which is utilized to capture/store CO₂ at neutral pH for release at reduced pH such as that (~5) inside endo/lysosomes. Typical transmission electron microscopy images of the siPol2-laden nanoparticles (siPol2@NPs) are shown in Fig. 2a. The siPol2@NPs have a spherical morphology and core-shell structure. The size of the nanoparticles synthesized using CG without CO₂ is not significantly affected by either pH 6.0 or pH 5.0. These results indicate that the CO₂ generation from CG-CO₂ encapsulated in the nanoparticles under low pH (particularly pH 5.0) conditions could expand and/or break open the nanoparticles, to give the “nano-bomb” effect. The migration of siPol2 into electrophoretic agarose gel is almost completely inhibited by nanoparticle encapsulation with negligible release at pH 7.4 (Fig. 2b). Moreover, the strong signal observed under pH 5.0 closely resembles the free siPol2 band. Under pH 6.0, smaller bands indicating slower release of the siRNA could be seen. These data demonstrate the low pH activated “nano-bomb” effect of the nanoparticles could trigger the release of the encapsulated siPol2. Furthermore, the siPol2@NPs were observable for at least 24 h in serum while most of the free siPol2 degraded shortly and no siPol2 was discernible after 3 h (Fig. 2c). These data indicate the nanoparticles could enhance the stability of the siPol2 in blood and allow for pH triggered release of the siRNA.

To exclude potential genetic differences across cell lines, we generated two isogenic HCC1937 cell lines with hemizygous loss of *POLR2A* using CRISPR (clustered regularly interspaced short palindromic repeat)/Cas9. The wild type HCC1937 is *TP53*^{+/mut}, *POLR2A*^{+/+} (*POLR2A*^{neutral}). The parent and two isogenic *POLR2A*^{loss} HCC1937 cells exhibited similar cell growth rates, confirming hemizygous deletion of *POLR2A* does not affect cell survival. siPol2@NPs

decreases *POLR2A* expression in all the cells. (Fig. 2d). However, hemizygous loss of *POLR2A* (HCC1937^{loss-1} and HCC1937^{loss-2}) markedly sensitizes the HCC1937 cells to siPol2@NPs (Fig. 2e). As expected, siNT@NPs or free siPol2 had no substantial effect on the cell proliferation. *POLR2A* expression is reduced in isogenic HCC1937 cell lines (Fig. 2d, e, control groups). Collectively, these data show the materials in the nanoparticles (other than siPol2) do not have an effect on *POLR2A* expression in cells or their proliferation, and siPol2@NPs effectively kill *POLR2A*^{loss} isogenic TNBC cells.

Figure 2: Synthesis and characterization of nanoparticles for stabilizing and delivery *POLR2A* targeting siRNA.

DISCUSSION

In this study, by analysing TNBC databases, we reveal that *POLR2A* gene is almost always co-deleted with *TP53* in the Chr17p deletion region, and 53% of TNBC harbours this heterozygous deletion. Moreover, the *POLR2A* expression levels are highly correlated with the copy number of *POLR2A*, rendering cancer cells with heterozygous loss of *TP53* vulnerable to *POLR2A* inhibition. This collateral loss of *POLR2A* with *TP53* prompted us to use RNAi to precisely target *POLR2A* for TNBC treatment. To overcome the hurdles to cytosolic delivery of siRNA for RNAi, we developed a unique nanoplatform with a low pH-activated “bomb-like” effect for endo/lysosomal escape. This improves cytosolic delivery of siPol2 to inhibit *POLR2A* in *TP53*^{loss} cells.

CHARACTERIZATION OF INJECTION-INDUCED TISSUE SWELLING DURING SUBCUTANEOUS INJECTION OF BIOLOGICS

Yingnan Shen, and Bumsoo Han

School of Mechanical Engineering
Purdue University
West Lafayette, IN, USA

INTRODUCTION

Recent emergence in biologics provides effective solutions to treat a variety of diseases that presently have no other treatment options available. These biopharmaceuticals include vaccines, blood and blood components, somatic cells, and recombinant therapeutic proteins. Major limitations of the biologic drugs are attributed to difficulties in effective delivery, which significantly increases the treatment cost and the burden on the health care sector [1]. Subcutaneous (SQ) injection of biologics has been thought as a promising delivery route to address this problem. However, due to large molecular weights of biologic drugs, pain and discomfort are induced during SQ injection. This poses significant challenges for broader use of biologic drugs, design and development of injection and infusion devices, and quality of patient's life [2, 3]. Thus, it is critically important to be able to assess and quantify the extent of the injection-induced pain and discomfort (IPD). However, current available methods are mostly very subjective and inadequate to quantify the extent of IPD.

In this study, we developed a biomimetic platform to quantify spatiotemporal tissue swelling during SQ injection of biologics, and to predict associated increase in mechanical stress and interstitial fluid pressure (IFP) of tissues. Our overarching hypothesis is that the IPD is caused by tissue swelling and subsequent increase in mechanical stress and IFP of tissues near injection sites. This mechanical stress and fluid pressure stimulate nociceptors, which are primarily present at the dermis of the skin. Accurate measurement of tissue swelling, thus, can be a quantitative and predictive indicator of the IPD. We constructed and tested an experimental setup capable of measuring injection-induced swelling of engineered tissue constructs, dermal equivalents.

METHODS

A schematic of the testing platform is shown in Figure 1. The platform consists of injection system, imaging system and engineered tissue constructs (ETCs). The injection system infuses or injects biologic drugs and macromolecules into the ETCs at various injection rates to simulate a wide range of injection conditions. The ETCs are prepared by seeding quantum dot (QD)-labeled fibroblasts in collagen matrices whose mechanical and chemical properties are designed to mimic the dermal layer of skin. The imaging system includes a

fluorescence macro/microscope (MVX10, Olympus, PA, USA) and a CCD camera (Aqua, QImaging, Canada), and images QD-labeled fibroblasts during injection of biologics drugs, and determine the spatiotemporal deformation of ETCs.

Figure 1. Schematic of experimental setup.

The detailed description of the construction of engineered tissues can be found in our prior publications [4, 5]. Briefly, the early human foreskin fibroblasts were cultured up to 17th passage and consistently harvested at 80 ~ 90 % confluency. The collected cells were labeled with quantum dots (Qtracker 655, Invitrogen, OR, USA) by being mixed with the labeling solution and incubated for 45 min. After incubation, the cells were washed twice to remove the excess quantum dots. To construct the engineered tissue mimicking the dermal layer of skin, the labeled fibroblasts were suspended in 1.5 mL of type I collagen solution (Corning, MA, USA) containing 3 mg/mL collagen, and the cell concentration was 2×10^5 cells/mL.

The collagen solution containing labeled fibroblasts was placed in a cylindrical hole punched through a PDMS layer filling a petri dish. The dimension of the hole is $11 \text{ cm}^2 \times 1 \text{ cm}$. The engineered tissue was generated when the fibroblasts-contained collagen solution polymerized at 37°C for 1.5 hours. After being incubated with complete culture

medium for 24 hours, as shown in Figure 2, the fibroblasts embedded in collagen matrix developed a dendritic morphology and were still labeled with QDs. Figure 2(b) shows that the QDs accumulate in the cytoplasm of dendritic fibroblasts.

Figure 2. (a) Labeled fibroblasts, embedded in collagen matrix. (b) Quantum dots accumulate in the cytoplasm of dendritic fibroblasts.

As shown in Figure 3(a), a conventional 27-gauge needle was manipulated to penetrate into the engineered tissue. The injection rate ranged within 0.3 ~ 3 mL/min, and distilled water was injected as a preliminary experiment which aims to validate the platform and estimate the range of the injection-induced tissue swelling. During the injection, the tissue was continuously imaged with a 0.2 s interval. As shown in Figure 3(b), the QD-labeled cells were visualized with a TRITC filter, and the fluorescence image showed the entire tissue was labeled by fluorescence particles.

The acquired sequential images were cross-correlated to estimate the local deformation rates throughout the tissue during the injection. Briefly, a pair of consecutive images was put into the DaVis software (LaVision, MI, USA), and each of the images was divided into a grid of 32×32 pixels (1 pixel equals 4 μm) interrogation windows. The density of the fluorescence particle pairs was large enough to guarantee that there were typically no less than 4 fluorescence particles in each window. The interrogation windows in the consecutive images were cross-correlated to generate correlation peaks, the location of which provided the deformation rate vector in the corresponding window. For example, the vector marked in Figure 4 was generated in a 32×32 pixels interrogation window containing 7 fluorescence particles which were used to perform cross-correlation. Multi-pass processing was used with decreasing interrogation window size (2 iterations of 64×64 pixels followed by 3 iterations of 32×32 pixels) and 50% overlap, and finally the deformation vector field throughout the tissue was generated.

Figure 3. Brightfield and fluorescence (TRITC filter) images of the engineered tissue during the injection.

RESULTS AND DISCUSSION

A representative spatiotemporal deformation rate of the dermal equivalent at the initiation of the injection (2 mL/min) is shown in Figure 4. The deformation rate vector field of the tissue was determined in terms of μm/s. The tissue swelling during the injection is clearly

shown by the vector field, and the vectors indicating the largest local deformation rates locate close to the needle injection site. The largest deformation rate is up to 28 μm/s, and the deformation rate gradually decreases below 6 μm/s when it reaches the outskirts of the tissue. The region without vectors is due to that the needle blocks the view of the tissue, as well as that the deformation of the tissue due to the penetration of the needle causes the area near the injection site to be out of focus.

Figure 4. Deformation rate vector field indicating the tissue swelling at the initiation of the injection (2 mL/min).

In the present study, we demonstrated the feasibility of measuring injection-induced deformation, which is expected to cause IPD using dermal equivalents and digital image correlation. The underlying rationale is that most nociceptors are present at the dermal layer, even though injection occurs at the SQ layer. However, we plan to further develop the ETCs by adding adipocytes, hyaluronic acids and fibronectins to create more realistic dermal and subcutaneous tissue models. The platform can also measure transport of biologic drugs at various injection conditions. Ultimately the platform will provide a reliable test bed to systematically design and optimize biologic drugs, their injection devices and schemes.

INTRODUCTION

Transport of interstitial molecules is an essential link in many physiological processes of the brain: communication, nutrient delivery, waste clearance. For example, transport governs the dynamics of pathological molecules that transit the extracellular space (ECS); impairment of the clearance of mis-aggregating proteins is believed to underlie the vulnerability of the aging and injured brain neurodegeneration. Despite advances in imaging and experimental techniques, the nature of transport mechanisms at the smallest scales remain elusive. Mathematical modelling validated using available experimental data offers a powerful tool for investigating hypotheses regarding extracellular transport of molecules in brain tissue. Here we use a finite-element model to investigate interstitial transport mechanisms, especially the potential for convection and its relevance to interstitial solute transport, for which there is conflicting evidence.

Brain tissue is comprised of cells along with the extracellular space (ECS) between cells. The ECS is a continuously-connected network filled with interstitial fluid (ISF), where interstitial transport occurs. Researchers have established the presence of a perivascular space (PVS) surrounding penetrating vasculature that is connected to cerebrospinal fluid (CSF), providing a potential source of interstitial fluid and efflux route for interstitial solutes and fluid (Figure 1). The PVS is surrounded by a sheath of astrocytic endfoot processes. To enter or exit the ECS via the PVS, molecules must pass through small gaps between endfeet.

There is strong evidence that transport in the PVS is more rapid than can be explained by diffusion, possibly transport by convective flow or dispersion [1-3]. Mestre et. al. used particle tracking of fluorescent microspheres to measure velocity in the PVS *in vivo*, reporting a mean speed around $19 \mu\text{m s}^{-1}$ in the same direction as blood

flow [4]. There is conflicting evidence whether interstitial transport is dominated by diffusion, or convection plays a role [1,2,5].

Figure 1. Illustration of proposed interstitial transport in brain tissue where fluid (green arrows) moves from the CSF along the periarterial space following penetrating vasculature deep into the brain. The fluid enters the interstitium, where interstitial solutes (purple) and fluid are transported to and out the perivenous space [6].

Real-time Iontophoresis (RTI) experiments offer a well-established data set for brain transport, where analysis assumes diffusion-only transport in a homogenous material. RTI experimental data displays a consistent level of variability among data sets [7-9], which leads one to question whether some physical phenomena has

been overlooked that may be uncovered by applying different transport models. We hypothesize the inclusion of convection and heterogeneous perivascular efflux may account for the observed experimental range.

METHODS

Despite the incredible complexity of brain tissue, transport of molecules has been successfully described using relatively simple porous media models [6]. A 3D finite-element model of transport in a small volume of brain tissue ($< 0.5 \text{ mm}^3$) was developed using Darcy's Law and the mass-transport equation adjusted for porous media[6]:

$$\mathbf{v} = -k'(\nabla P) \quad (1)$$

$$\nabla \cdot \mathbf{v} = 0 \quad (2)$$

$$\frac{\partial c}{\partial t} = D^* \nabla^2 c + \frac{s}{\alpha} - \mathbf{v} \cdot \nabla c \quad (3)$$

where: c = concentration in the ISF, D^* = apparent diffusivity = D/λ^2 , λ = tortuosity, s = source term, and α = void volume = $V_{\text{ECS}}/V_{\text{total}}$. The mass-transfer resistance at the endfeet is modelled using a small percentage of the interstitial diffusivity for a narrow region surrounding vessels. Communication between the PVS and the interstitium is applied through boundary conditions at the vessel walls. The resulting system of partial differential equations is solved using FEniCS [10].

RESULTS

Figure 2 shows agreement between the range in Cserr's RTI data (grey) [9] and the range of concentration curves for simulations performed with an average superficial bulk velocity of $v=50 \text{ } \mu\text{m min}^{-1}$ (blue) combined with diffusion and perivascular efflux. Similar results are observed for other data sets [7,8]. Contributions from tissue variability were found to account for less than a third of the data range.

Figure 2. Range in TMA concentration curves for experimental data in rats (Cserr et al., n=33 [9]) compared with simulations of diffusion and convection ($v=50 \text{ } \mu\text{m min}^{-1}$) with perivascular efflux (blue, n=112). RTI uses tetramethylammonium (TMA) as its molecular probe.

TMA is a small molecule (114Da) with a relatively fast diffusivity. Molecules of interest in brain transport, such as beta amyloid (4.5kDa) and tau (45kDa), thought to play a significant role in neurodegenerative pathologies, are larger and have slower diffusivities. The Péclet number (Pe) is a ratio of convective to diffusive transport rates, allowing comparison of the relative importance of the two mechanisms.

$$Pe = \frac{\text{rate of convection}}{\text{rate of diffusion}} = \frac{Lv}{D} \quad (4)$$

Dextran-3kDa (Dex3), of similar in size to beta amyloid, has a Péclet number of 4 (Figure 3), meaning convection will have an effect similar in magnitude to, or potentially greater than, diffusion within the brain. Many molecules of interest to brain pathologies are larger than Dex3, therefore, the magnitude of convective transport due to bulk flow is likely to be of similar or greater magnitude than diffusive transport.

Figure 3. Péclet number versus apparent diffusivity for molecules of interest in brain transport. $L=250 \text{ } \mu\text{m}$, $v=15 \text{ } \mu\text{m min}^{-1}$, and D^* specific to each molecule. For $Pe \approx 1$, diffusive and convective rates are balanced; for $Pe > 1$, convection exceeds diffusion.

DISCUSSION

This work compares the range in simulated RTI concentration curves inherent to different transport mechanisms to experimental range. There are other possible contributions to experimental range not included in the present analysis: tissue damage, physiologic variations, and experimental variations. Therefore, the range attributable to perivascular efflux and convection may be less, suggesting less vascular heterogeneity and/or lower convective velocities.

Even at lower convective velocities, the analysis supports that molecular transport in the ISF may occur by both diffusion and convection, with both mechanisms potentially relevant and the apparent diffusivity, related to molecular size, determining which is dominant. There is limited experimental data on transport specifically in the brain interstitium. Iliff et. al. interpret tracer-study results as being caused by convective flow [2]. Smith et. al. interpret results of similar experiments in favor of diffusion only [1]. Mestre et. al. demonstrate the methods used by Smith result in hindered tracer transport [5].

In conclusion, simulations show that published RTI experimental ranges allow for bulk flow superficial velocities up to $v=50 \text{ } \mu\text{m min}^{-1}$; corresponding to intrinsic ISF velocities on the order of $100 \text{ } \mu\text{m min}^{-1}$ ($v_i = v/0.2$). A quantitative finding useful to scientists developing approaches for evaluating slow interstitial bulk flow over long distances. Results also support the hypothesis of perivascular routes of influx and efflux allowing exchange between the brain interstitium, the CSF, and perivenous drainage out of the brain.

INTRODUCTION

Convection-enhanced delivery (CED) is a technique to deliver controlled therapeutic agents for the treatment of tumors and brain diseases such as Parkinson's [1]. Despite CED studies in animals having shown encouraging results [2,3], clinical trials [4,5] have reported low effectiveness of CED, primarily due to the poor drug distribution. This lack of efficacy has been, in some cases, related to backflow, a phenomenon in which the infused medication flows toward the surface of the brain through the annular gap created outside of the cannula surface during the insertion.

Some clinical investigations have reported the influence of anatomical structures, such as the ventricles, the convolutions of the tissue, and the longitudinal fissure, on the loss of volume infused and on backflow [6,7]. Based on these effects, researchers have suggested recommendations for improving CED protocols, e.g., locate the cannula at a depth of no less than 2 mm in the cerebral cortex, place the cannula at a distance of no less than 10 mm from the ventricles and interhemispheric fissure, and perform the infusion in the peritumoral zone [8,9].

Analytical and numerical models have complemented the clinical and experimental CED studies to establish the variables that reduce backflow [10,11]. We developed a finite element model of infusion that incorporates backflow and includes material and geometrical nonlinearities to predict fluid distributions and mass transport under flow-controlled infusions [12,13]. Nevertheless, this computational model does not include the effect of anatomical structures of the brain. While a recent 3D transport model within a tumor has been developed to elucidate drugs delivery during CED [14], that study did not consider backflow or infusion-induced deformation of the brain tissue.

Hence, the aim of this study was to develop a 3D human brain nonlinear biphasic finite element model of backflow to investigate the influence of anatomical structures during flow-controlled infusions.

Backflow length predictions were compared under the influence of ventricular pressure and the position of the cannula relative to the ventricles.

METHODS

A healthy subject was imaged using an MRI scanner (3.0T scanner, General Electric). This MR imaging was conducted according to the ethical guidelines of Universidad del Valle, Colombia, and written informed consent was obtained from the volunteer. The acquired 3D MRI data was used to segment the brain, including the ventricles, corpus callosum, and longitudinal fissure, in 3DSlicer (Harvard University, USA) and then the geometry was imported into Abaqus (v6.14, Dassault Systèmes) where a finite element (FE) model was developed (Fig. 1).

The 3D FE infusion model was defined by two parts: (1) a cylindrical domain that includes two special layers of elements to represent backflow, based on our previous studies [11-13], and (2) the 3D brain geometry with a hole into which the cylindrical backflow domain assembles. This strategy allows for easily modifying the location of the cannula (Fig. 1).

The brain tissue was represented as a poro-hyperelastic medium composed of solid and fluid phases. The solid phase was represented with the Ogden-type compressible energy function W , described as

$$W(\bar{\lambda}_1, \bar{\lambda}_2, \bar{\lambda}_3) = \sum_{i=1}^N \frac{2\mu_i}{\alpha_i^2} (\bar{\lambda}_1^{\alpha_i} + \bar{\lambda}_2^{\alpha_i} + \bar{\lambda}_3^{\alpha_i} - 3) + \sum_{i=1}^N \frac{1}{D_1} (J - 1)^{2i}, \quad (1)$$

where $\bar{\lambda}_1, \bar{\lambda}_2, \bar{\lambda}_3$ are the principal deviatoric stretch ratios, α_i, μ_i , and D_1 are material parameters, and J is the determinant of the deformation gradient tensor. The hydraulic conductivity κ , which relates the flow

rate to the gradient of fluid pressure via Darcy's law, was allowed to vary with strain as

$$\kappa = \kappa_0 \exp(M e), \quad (2)$$

where κ_0 is the initial hydraulic conductivity, e is the volumetric dilatation, and M is a dimensionless coefficient. The material parameters were taken from values reported in the literature and used in previous infusion simulations [11-13] (Table 1).

The external surface of the brain was fixed to simulate the restraint caused by the skull. Likewise, a null fluid pressure was implemented on the external surface and adjacent faces of the longitudinal fissure.

To understand the impact of brain structures and the distance CD between the cannula and the ventricles, simulations were performed with three CDs (4, 20, and 36 mm), two ventricle pressures (VP, 0 and 100 Pa), and two infusion flow rates (1 and 4 $\mu\text{L}/\text{min}$), for a total of 12 simulations.

Figure 1: MRI images used to construct a brain geometry. The FE model includes the ventricles and longitudinal fissure. The model can evaluate different catheter positions (sectional view).

Table 1: Material parameters used in the FE simulations.

Parameter	Value
Energy function exponent, α_1	-4.7
Shear modulus, μ_1	2000 Pa
Poisson's ratio, ν	0.35
Initial hydraulic conductivity k_0	$2 \text{ mm}^4 \text{ N}^{-1} \text{ s}^{-1}$
Nonlinear conductivity, M	1
Radius catheter, r_c	0.98 mm
Flow rate, Q	1 and 4 $\mu\text{L min}^{-1}$

RESULTS

Numerical infusions with zero ventricle pressure displayed similar predictions of backflow length for the CDs of 20 and 36 mm and each flow rate (Fig. 2a). Compared to these results, the backflow lengths for a CD of 4 mm was smaller for both flow rates, and the fluid was observed to escape to the ventricle (Fig. 2b).

Models with a VP equal to 100 Pa showed an increase of fluid flow through the tissue and away from the ventricles, and a backflow length rather independent of the CD. For a CD of 4 mm the backflow length increased 167% and 80%, for the flow rates of 1 $\mu\text{L}/\text{min}$ and 4 $\mu\text{L}/\text{min}$, respectively, when compared to the results obtained with a VP of 0 Pa (Fig. 2a). For the two larger CDs, similar values of backflow length were obtained for both VPs studied, particularly, fluid flow reached the external brain surface ($\sim 45 \text{ mm}$) for the higher flow rate.

DISCUSSION

This study presents a novel 3D biphasic finite element model of backflow during flow-controlled infusions into a realistic human brain geometry that considers material and geometrical nonlinearities. Anatomical details such as the ventricles, the corpus callosum, and the longitudinal fissure were included in the model.

Figure 2: (a) Backflow length predictions for each flow rate (1 and 4 $\mu\text{L}/\text{min}$) with three catheter distances (4, 20, and 36 mm) and two ventricular pressures (0 and 100 Pa). (b) Fluid velocity distribution for a catheter distance of 4mm and zero ventricle pressure. The model predicts the leakage of fluid to the ventricles.

Increase in backflow length with CD might be associated with the increment of hydraulic resistance through the tissue relative to that through the annular gap that forms around the catheter. When VP is nonzero, this hydraulic resistance causes the infused fluid to flow away from the ventricles and either toward the longitudinal fissure or to the external brain surface. In contrast, the smaller backflow length when the VP was zero and the CD was 4 mm can be attributed to the smaller hydraulic resistance that allows leakage into the ventricles.

This model enables researchers to more accurately predict backflow lengths when accounting for both anatomical structures and deformation of the brain tissue.

INTRODUCTION

Developing effective non-viral methods for delivery of nucleic acids and other macromolecular therapeutics is one of the most pressing challenges for nanomedicine and polymer science [1,2]. The potential power of engineered nucleic acids as therapeutic agents is severely limited by the difficulty of overcoming the physical and biological barriers to using them as practical drugs. Polyelectrolyte complex micelles (PCMs, core-shell nanoparticles formed by complexation of a polyelectrolyte with a hydrophilic charged-neutral block copolymer) offer a solution to this critical problem. Still, few systematic studies have been conducted on how parameters such as polymer charge density, hydrophobicity, and choice of charged group influence PCM properties, despite evidence that these strongly influence the complexation behavior of polyelectrolyte homopolymers. Using small angle X-ray scattering (SAXS) and electron microscopy we investigate the relationship between the physical properties of oligonucleotide PCMs and chemical properties of the nucleic acids and block copolymers that form them. For instance, differences in charge density and hydrophobicity have been individually suggested to provide increased complex stability, but we find that other factors may disrupt this trend. These observations narrow the design space for optimizing therapeutic PCMs and provide new insights into the rich polymer physics of polyelectrolyte self-assembly.

METHODS

Poly((vinylbenzyl) trimethylammonium) (pVBTMA) homopolymers and pVBTMA-PEG block copolymers were synthesized by aqueous reversible addition-fragmentation chain transfer (RAFT) polymerization as described by Ting et al. [3]. Poly(lysine) (pLys), pLys-PEG, and oligonucleotides were purchased. PCMs were prepared using a salt-annealing method [4]. Briefly, the polyelectrolytes were mixed in PBS buffer, then

concentrated NaCl solution was added to obtain 1M final concentration to dissolve the complexes. The salt concentration was then slowly reduced over 36 h by step dialysis to a final working concentration of 1x PBS. SAXS measurements were made at the Advanced Photon Source at Argonne National Laboratory. Background subtraction and fitting were performed using multi-level modeling macros in the Irena software package for Igor Pro. PCMs were also imaged using cryo transmission electron microscopy (TEM) and traditional negative-stained TEM. Phase and morphology of homopolymer complexes were observed by bright field optical microscopy. To assess the stability of micelles vs. salt, micelle samples were titrated with 5M NaCl and light scattering intensity was measured.

RESULTS

In order to evaluate pVBTMA as a cationic polymer for nucleic acid delivery, we first prepared PCMs using pVBTMA-PEG block copolymers and single-stranded DNA oligonucleotides and compared them to PCMs assembled from pLys-PEG block copolymers of similar lengths. Both cationic polymers readily formed spheroidal PCMs when mixed with DNA, with low polydispersity in radius, and we observe a marked increase in PCM radius with charged block length.

For double-stranded DNA, we observe long, wormlike micelles with the pLys-PEG block copolymers, consistent with our previous report [4], but in this case we see a qualitative difference for PCMs prepared with pVBTMA-PEG. These micelles exhibit low polydispersity in radius, with fitted values very similar to those found for pLys-PEG PCMs, but the lengths are shorter and highly variable between and within samples [5]. Figure 1 depicts the distinct shapes and phases we obtain by adjusting parameters of our starting materials. These include spherical micelles, flexible cylindrical micelles, liquid coacervate droplets, and solid-like precipitates.

The critical ionic strength required for dissolution provides a measure of the stability of a given complex. To compare the stability of our PCMs, we titrated concentrated NaCl and observed changes in light scattering intensity. We found that pVBtMA-PEG PCMs are considerably less stable than those containing pLys-PEG, and observe a similar trend for homopolymer complexes. Likewise, we see phase transitions occurring at lower salt concentrations in pVBtMA-DNA complexes compared to pLys-DNA complexes.

Figure 1: Complexation between nucleic acids (polyanion) and hydrophilic cation-neutral block copolymers forms phase separated structures. This study explores the effect of chemical parameters determining the physical properties of polyelectrolyte complexes.

DISCUSSION

Investigations of polycations for nucleic acid delivery have focused on hydrophilic polymers such as pLys, poly(ethyleneimine), poly(amidoamine), and cationic polysaccharides, many of which are analogs of natural products. This may represent a missed opportunity, as synthetic polymers provide access to diverse bio-orthogonal structural motifs and allow tuning of intermolecular interactions (hydrophobicity, hydrogen bonding, cation- π , etc.) over a wider range than is possible with naturally-inspired polycations. This study was designed to provide a test of these tunable characteristics. Namely, pVBtMA has a larger linear charge density than pLys, has an aliphatic backbone and aromatic side chains, is largely unable to form hydrogen bonds, and contains a permanent positive charge rather than the ionizable primary amine.

We show many similarities and some marked differences when comparing PCMs formed by the two polycations. Oligonucleotide PCMs formed with pLys-PEG and pVBtMA-PEG show that micelle radius is controlled by the length of the charged block but largely insensitive to oligonucleotide length, suggesting this may be a universal property for PCMs. We find the hybridization state of the nucleic acid is a key parameter in determining the shape of the micelles, where, for both polycations, single-stranded oligonucleotides produce spheroidal PCMs, while double-stranded oligonucleotides generate elongated PCMs. We observe major discrepancies for PCMs with double-stranded oligonucleotides, where pLys-PEG forms micron-scale worm-like micelles, but pVBtMA-PEG forms much shorter cylindrical micelles that are highly polydisperse, implying some mechanical instability in this system. pVBtMA-PEG PCMs also proved to be less stable in high NaCl conditions, suggesting the interactions between

nucleic acids and pVBtMA are weaker than those with pLys, despite higher charge density, increased hydrophobicity, and non-susceptibility to neutralization. The large structural differences between pLys and pVBtMA suggest that the similarities in PCM properties we observe may be universal, while the differences provide useful leads for further investigation into the physics of polyelectrolyte self-assembly as well as possible solutions to the pressing problem of nucleic acid delivery.

INTRODUCTION

Pulmonary arterial hypertension (PAH) imposes pressure overload on the right ventricle (RV), leading to a substantial RV enlargement via simultaneous growth of cardiac myocytes and remodeling of the collagen fiber architecture [1, 2]. The effects of these alterations on the functional behavior of the RV free wall (RVFW) and global cardiac function remain largely unexplored. Computational rodent heart models (RHM) of the normal and hypertensive states [3-4] can be quite valuable in gaining insights into the pathophysiology of myocardium remodeling.

Recently, we developed high-fidelity biventricular finite-element RHMs using extensive data collected from rat hearts at normal and post-PAH time points [3]. In the current study, we extended our model to predict the *time-course* adaptations of RV under PAH from normal state to post-PAH state. Our model accounted for growth processes driven by sarcomerogenesis and collagen fibrosis, coupled with myo- and collagen fiber reorientation events. We used our model to investigate the correlations between the alterations in the wall stress, the remodeling of the RVFW microstructure, and the shape changes in the RV during the development of PAH. To the best of our knowledge, this is the first work to investigate the interaction between fiber remodeling and volumetric growth in the heart. Ultimately, the detailed description of organ-level remodeling patterns predicted by in-silico models such as ours could replace the traditional measures of RV dimensions and volume that often lead to gross and limited information on cardiac performance.

METHODS

Time-course measurements. The time-course variation of RV pressure was measured in PAH animal models during 30 days after monocrotaline (MCT) injection (Fig. 1). The pressure remained in an

approximately plateaued constant for a large part of the post-injection period. A key assumption in our model was that the volumetric growth and fiber remodeling were limited to this phase (Fig. 1).

Figure 1: (Top) Time-course pressure data during the development of MCT-induced PAH. (Bottom) Limitation of G&R processes to the plateau phase of pressure development.

Growth model. Our volumetric growth model to induce RV dilation is based on multiplicative decomposition of deformation gradient expressed as

$$\mathbf{F} = \mathbf{F}^e \mathbf{F}^g \quad (1),$$

where \mathbf{F}^e and \mathbf{F}^g denote the elastic and growth parts of the deformation, respectively. To generate an eccentric hypertrophy in the RV, we adopted the following form for \mathbf{F}^g

$$\mathbf{F}^g = \mathbf{I} + (\mathcal{G}^g - 1)\mathbf{N} \otimes \mathbf{N} \quad (2),$$

where \mathbf{N} is the fiber direction. A specific strain-driven evolution law for the growth multiplier \mathcal{G}^g is given by [4]

$$\dot{\mathcal{G}}^g = k^g(\mathcal{G}^g)(\lambda^e - \lambda^h) \quad (3),$$

where $k^g(\mathcal{G}^g)$ is a limiting function [4], and λ^e and λ^h denote elastic and homeostatic stretches, respectively.

Fiber remodeling model. In this work, the fiber remodeling is driven by the adaptation of fibers orientation towards the axis with the largest stretch. Through this mechanism, the fibers adapt their orientation following a change in the direction of the largest stretch (denoted by \mathbf{E}^{\max}) and/or in the value of the largest stretch. Accordingly, the angular velocity stimulus is expressed as

$$\boldsymbol{\omega} = \mathcal{G}^r \mathbf{N} \times \mathbf{E}^{\max} \quad (4),$$

where \mathcal{G}^r is the remodeling multiplier governing the speed at which the fiber direction reorientation takes place. Its evolution is given by

$$\dot{\mathcal{G}}^r = k^r(\mathcal{G}^r)(1 - \mathbf{E}^{\max} \cdot \mathbf{E}_h^{\max}) \quad (5),$$

where the subscript 'h' denotes to the homeostatic state. The evolution of the fiber direction is then calculated by [5]

$$\dot{\mathbf{N}} = \boldsymbol{\omega} \times \mathbf{N} \quad (6),$$

RESULTS

Significant dilation of the RV was observed while the left ventricle underwent little notable change. The RV end-diastolic volume increased by approximately 200%, from 40.1 to 78.3 uL (Fig 2). The stroke volume of the RV was nearly preserved. A small amount of hypertrophy of the RVFW was also noted (Fig 2). Evolution of the growth multiplier throughout the cycles identified locations of the RVFW that experienced the greatest amount of growth. Although the growth multiplier increased rather uniformly throughout the RVFW, the posterior corner was an area of growth concentration.

Figure 2: Short-axis views of the evolution of the FE RHM from the control to post-PAH state simulated by 30 growth cycles.

A large part of the dilation occurred at later cardiac growth cycles (Figs. 2 and 3) that significantly reduced the ejection fraction. This indicates that the dilation advances once the heart has exhausted other adaptations available to maintain the cardiac output. A nearly uniform

fiber reorientation across the RVFW thickness ($\sim 22^\circ$ from the circumferential direction) was consistent with previous histological studies [1]. In contrast to RV dilation and fiber reorientation that took place rapidly at later stages, myocardial contractility and stiffness seemed to increase early on during the maturation of the PAH (Fig. 3).

Figure 3. Adaptation of anatomical and structural properties of the RV from the asymptomatic to decompensatory states.

DISCUSSION

In this work, we took an essential step towards the modeling and predicting the multiscale growth and remodeling events in the RV during PAH with a focus on integrating remodeling events at the fiber level (such as fiber reorientation) with the volumetric growth of the RVFW and RV at the tissue and organ levels.

Our model results suggest that augmentation of the intrinsic contractility of myofibers is among the first remodeling events through which the RV strives to maintain the cardiac output against the pressure overload. In fact, the RV first exhausts its capacity to increase the contractility of RVFW myofilaments, which could go up to five fold (Fig. 3), before it succumbs to a rapid dilation to maintain the output. The changes in the contractility is accompanied by an increase in passive stiffness of RVFW which, based on our previous studies [1,2], we suspect to stem from the deposition of new collagen fibers and changes in the existing collagen structure. On the other hand, our model suggests that the reorientation of the fibers towards the longitudinal (apex-to-base) direction is rather a *maladaptive* mechanism that does not improve the overall contractility and ejection fraction of the RV and advances together with RV dilation at the later stages of PAH development. In this connection, we inferred from our simulations that although the fibers remodeling is assisting with the restoration of the wall stress in the circumferential direction, it undermines the contractility of the RV by shifting the circumferential contraction mode (seen in a normal heart) toward a more isotropic contraction. To fully understand the multiscale nature of these events, our next step is to separate the remodeling effects of myofibers and its contractile machinery from alterations in collagen content and structure.

INTRODUCTION

Uncontrolled hypertension is a major risk factor for myriad cardiovascular diseases. Among its many effects on the body, hypertension increases central artery stiffness, which in turn is now known to be both an initiator and indicator of disease and disease propensity. Despite extensive clinical, animal, and basic science studies, the biomechanical mechanisms by which hypertension drives aortic stiffening remain unknown. In this work, we show that a new computational model of aortic remodeling can capture salient effects of induced hypertension on the thoracic and abdominal aorta in a common mouse model of disease characterized primarily by regional adventitial fibrosis in the presence of marked inflammation. Because the model treats the aortic wall as a constrained mixture of different constituents having different material properties and rates of turnover, one can gain increased insight into underlying biomechanical mechanisms of aortic remodeling.

METHODS

We model the infrarenal abdominal aorta (IAA) and descending thoracic aorta (DTA), of 19-week old male *Apoe*^{-/-} mice rendered hypertensive via a continuous infusion of AngII at 1000 ng/kg/min for up to 28 days [1], using a constrained mixture framework for growth (changes in mass) and remodeling (changes in microstructure) that includes mechanical stress and inflammatory cell density as drivers of matrix turnover [2]. Comparisons with other recent constrained mixture formulations suggest that the artery is immuno-

mechano-biologically equilibrated after two-to-four weeks of hypertensive development. This finding allowed us to obtain best-fit values of constituent-specific material parameters from available biaxial data collected from pressure-diameter and axial force-length tests after predetermined durations of AngII infusion (0, 4, 7, 14, 21, and 28 days) for both regions [1]; in particular, we used a single model that allows many quantities to evolve over time, with gain-type parameters for constituent production and rate parameters for constituent removal, including an additional dependence on inflammatory cell density, estimated based on equilibrium relations [2].

RESULTS

Model results suggest that the aorta can mechano-adapt to blood pressure elevation in the absence of inflammation, but marked increases in inflammation drive a maladaptive response. Numerical simulations predict well the observed results, including differences in medial versus adventitial growth and remodeling and bulk biaxial mechanical measurements in both normotensive and hypertensive states, with the IAA and DTA mechano-adapted by 14 days, but the DTA markedly maladapted after 14 days of AngII infusion, when significant inflammation and adventitial fibrosis manifested most dramatically (Figure 1).

Model results also suggest that this fibrosis occurs via a marked increase in the rate of deposition of collagen having different material properties in the absence of a compensatory increase in the rate of matrix degradation, and moreover that

effects of inflammation appear to persist for long periods after removing the exogenous stimulus.

Figure 1: Model predictions (black lines) of medial (c) and adventitial (d) thickening for the DTA following a rapid 1.68-fold increase in systolic pressure (grey lines, model inputs) that persists up to 28 days (a) and an associated, retarded increase in inflammatory cell density (b). The model predicts well the experimentally measured (open squares with error bars [1]) adventitial versus medial thickening consistent with an exuberant production of inflammatory collagen in the adventitia.

DISCUSSION

Computational models of vascular adaptation and maladaptation can provide increased insight in progressive changes in geometry, structure, and properties in hypertension, including those due to mechano-adaptation and those due to immuno-maladaptation. Indeed, our simulations support the concept that controlling inflammation appears to be key to reducing fibrosis. Such therapeutic strategies, however, should not compromise the proteolytic activity of the wall that is essential for mechanical homeostasis. Whereas such homeostasis is promoted by negative feedback loops, as captured by the stress-difference term in our stimulus function, fibrosis appears to be driven either by positive feedback or no feedback, as modeled presently.

EFFECT OF GLUCOSE ON THE INTERLAMELLAR BONDING OF ARTERIAL ELASTIN

INTRODUCTION

Aortic dissection is a clinically challenging disease with a high rate of mortality [1]. It starts with a tear in the intima and propagates in the media [2]. Failure of various microstructural constituents can occur simultaneously during this process. As one of the major load-bearing proteins in the artery, elastin forms a 3D cross-linked fiber network of which ~29% are oriented in the transmural direction [3]. Thus, arterial elastin not only provides the tissue with in-plane stiffness and strength, but also plays an important role in maintaining the integrity and resisting damage propagation in the aorta.

Diabetes has been found to be closely associated with cardiovascular disease progression and vascular remodeling. Earlier stiffening of the arterial wall among diabetic patients has been attributed to glycation crosslinks of elastin and collagen [4]. Our previous studies have shown that arterial elastin exhibits larger stiffness and hysteresis in both the circumferential and longitudinal directions with glucose exposure [5]. Interestingly, in a nationwide case-control study, reduced risk of thoracic aortic dissection was found in patients with diabetes [6]. This study aims to investigate the change of interlamellar bonding properties of arterial elastin with glucose treatment. Peeling tests were carried out on glucose treated porcine elastin. Peeling force as well as dissection energy were quantified and compared for samples with different duration of glucose treatment.

METHODS

Porcine thoracic aortas were cut into circumferential and longitudinal rectangular strips of about 40 mm × 10 mm. Purified elastin network was obtained using a cyanogen bromide treatment method [7]. Samples were then incubated in 2 M glucose solution and were allowed to equilibrate at 37°C for 7, 14, 21 or 28 days. Elastin samples without any further treatment were also tested and served as a

control. Apart from the glucose-treated and control samples, one group of elastin samples were incubated in 1× phosphate buffered saline (PBS) solution at 37°C for 21 days for comparison.

A 10 mm incision was introduced at one end of each sample to initiate dissection. Steady-state mode-I peeling tests were conducted using a uniaxial tensile tester (Instron, Norwood, MA). A schematic of the experimental setup is shown in Figure 1a. Briefly, one side of the sample was fixed while the other side was pulled away at an extension rate of 0.2 mm/s. Peeling force and displacement were recorded until complete separation. To keep chemical balance, samples were submerged in glucose (glucose-treated groups) or PBS (PBS-treated and control groups) solution during experiments.

Figure 1: (a) Schematic of the experimental setup; (b) a representative force/width-displacement curve obtained from peeling tests; (c) and (d) zoom-in graphs of the force/width-displacement curve showing high-frequency oscillation of the peeling force; (e) finite element model.

The energy release rate, G_c , i.e., the energy required to split a unit area of interface, can be calculated as [8]

$$G_c = (W_{ext} - W_{elastic})/L \quad (1)$$

where $W_{ext} = 2Fl$ is the external work done by the peeling force, and $W_{elastic} = F(l - L)$ is the elastic energy stored in the tissue. F is the mean peeling force per unit width of the sample strip. L and l are length of the sample strip in the original and stretched states, respectively. Experimental data are summarized and plotted with mean \pm standard deviation. Two-tailed unpaired t-tests were used for analysis with $p < 0.05$ considered as statistically significant.

RESULTS

A representative curve of peeling force per unit tissue width versus displacement is shown in Figure 1b. Averaged peeling force/width (F/W) and energy release rate (G_c) of elastin before and after glucose treatment are plotted in Figure 2. Compared with untreated samples, glucose treatment increased both F/W and G_c significantly in the circumferential direction (Figure 2a). However, compared with the untreated group, significant increase in F/W and G_c in the longitudinal direction did not occur until 21 and 28 days of treatment time, respectively (Figure 2b). No drastic change can be observed for F/W and G_c with longer glucose treatment beyond day 7.

Figure 2: Change of (a) peeling force/width and (b) energy release rate before and after glucose treatment for 7, 14, 21, and 28 days in the circumferential (Circ) and longitudinal (Long) directions. (n=6-9, *p<0.05).

Averaged G_c of samples treated with PBS was plotted in Figure 3. Compared with the untreated group, G_c of samples treated with PBS exhibited a slight decrease in both circumferential and longitudinal directions, though no significant statistical difference was found. G_c of samples treated with glucose increased significantly compared to samples treated with PBS for the same amount of time. Also, glucose or PBS treatment has little influence on the direction-dependent phenomena of steady-state peeling of arterial elastin, as peeling tests along the longitudinal direction require larger values of F/W and G_c than the circumferential direction in all sample groups.

Figure 3: Comparison of energy release rate of elastin in the circumferential and longitudinal directions for untreated, and after treated with PBS or glucose for 21 days. (n=6-9, #p=0.11, ##p=0.47, *p<0.05).

DISCUSSION

Our study shows that glucose has a prominent effect on the interlamellar bonding of arterial elastin. Results of peeling tests demonstrate that larger force and energy are needed to delaminate glucose treated elastin. The most notable change seems to happen within the first week of glucose treatment, however there is a rising tendency of the mean peeling force/width and energy release rate over the incubation time (Figure 2). This suggests that the contribution of arterial elastin to interlamellar bonding is enhanced by longer glucose exposure. This effect can be further confirmed by comparative studies made in Figure 3. Submerging elastin samples in PBS alone for the same amount of time did not lead to a stronger interlamellar adhesion.

Results from the current study are consistent with the inverse relationship reported by Prakash et al. [6], that diabetic patients are better protected from aortic dissection. Higher glucose concentration can accelerate non-enzymatic glycation which may induce intermolecular and interfibrillar crosslinks. This provides a possible mechanism for the higher G_c obtained here. However, influences of glucose on the dissection properties of other interlamellar components, and on the stiffening and failure behavior of the intimal layer of arteries are not clear. Therefore, more studies are needed before we can form a thorough understanding on the relationship between diabetes and the occurrence of aortic dissection. It is worth noting that the peeling force oscillates at a high frequency (Figures 1c and 1d) which is a result of microstructural failure events. The slope of a ramp up of peeling force can be related to local interlamellar stiffness. Finite element models employing the cohesive theory of fracture (Figure 1e) will be developed based on tissue-level mechanical properties and microstructural failure evidence to better understand glycation and interlamellar bonding in aortas.

INTRODUCTION

Genetic, biochemical, geometric, and physical factors interact during morphogenesis, the biological development of shape. The roles and relationships of these factors in the developing human brain is of great interest. Recently, in addition to findings of genetic influence on folding, the biomechanics research community has found increasing evidence that the folding pattern in mammalian brains is correlated with physical forces and instabilities.

Cortical thickness, a characteristic biomarker for a wide variety of neurological disorders, is known to vary widely within individual healthy adult human brains, between 1.5 and 4.5mm in different regions. This variation is observed consistently between individuals, with gyri, or outer folds, consistently thicker than sulci, or inner folds (Fig. 1). Previous studies have suggested a genetic influence [1,2], but it remains unclear whether these thickness variations are a cause or consequence of cortical development.

Here we model cortical development in a computational simulation, a non-biological physical experiment, and an analytical solution, and show that this bifurcation occurs naturally as a result of the passive physical forces generated by growth [3]. Additionally, we investigate thickness patterns in a large dataset of typically-developing adult humans.

METHODS

Nonlinear numerical simulations were performed in a custom MATLAB code, modeling finite growth to represent isotropic, morphogenetic growth in the “cortex” (i.e., a thin stiffer layer adhered to a thicker, softer substrate). The stiffness ratio between the two materials was chosen to be ~ 3 .

Fig. 1: Histograms of regional cortical thickness in N=564 adults from age 7-64 (from [3])

Polymer experiments were performed using a prestretched silicon substrate and adhering a thinner, stiffer silicon film before slowly releasing the prestretch. The stiffness ratio between the two polymers was about 4.6.

The analytical solution was based on a model of morphoelastic instability caused by the homogeneous growth of an elastic film on an

elastic half space. Using a variational method, the folding mode with the lowest elastic energy was selected. Close to the instability point, the solution also details the shape of the folds, which were used to compare gyral and sulcal thicknesses.

To assess gyral and sulcal thicknesses in healthy adults, $N=564$ MRI scans were obtained from the public Autism Brain Imaging Data Exchange database [4], which contains anatomical, functional, behavioral, and phenotypic data. Preprocessing had previously been performed using Freesurfer [5], and the Destrieux atlas [6] was used to distinguish gyral and sulcal regions.

RESULTS

Our numerical simulations show that, after instability, gyri are consistently thicker than sulci, even when subject only to the passive forces generated by growth-induced instability (Fig. 2). Eventually, gyri can attain up to 1.8 times the thickness of sulci.

Fig. 2: Cortical development in numerical simulations (top) and polymer experiments (bottom) (both from [3])

When considering the results of the polymer experiments, as well as the lobe-specific thickness in adult humans, we find that they follow similar patterns (Fig. 3). After bifurcation, gyri continue to thicken nonlinearly, while sulci begin to thin. In each of these systems, even those without genetic or biochemical influence, gyri consistently become significantly thicker than sulci, and at similar rates.

DISCUSSION

Cortical thickness is a characteristic biomarker for a wide variety of neurological disorders. While recent studies suggest that thickness variations are primarily the result of genetic events, our work demonstrates that geometric and physical events alone could be sufficient to induce cortical patterning. Together, this suggests that genetic, geometric, and physical factors interact in human brain development.

Fig. 3: Evolution of cortical thickness difference as thickness increases (from [3]).

Importantly, understanding the causes and consequences of cortical thickness variations can provide insight into the development, diagnostics, and treatment of neurological disorders.

TARGETING CADHERIN-11 FOR RENAL FIBROSIS

Tessa M. Huffstater (1), Leslie S. Gewin (2), W. David Merryman (1)

(1) Biomedical Engineering
Vanderbilt University
Nashville, Tennessee, USA

(2) Nephrology & Hypertension

INTRODUCTION

Chronic kidney disease (CKD) is a fibrosis-mediated disease caused by severe or prolonged injury to the kidneys. Currently, there are very few pharmacological treatment options for CKD, while dialysis and kidney transplants are still considered the primary treatment options. Cadherin-11 (CDH11) is a transmembrane protein involved in cell-cell adhesion that has been implicated in rheumatoid arthritis, and calcific aortic valve, and whose inhibition has been shown to significantly improve outcomes in these diseases.¹⁻⁴ CDH11 has also been recently identified as a biomarker for renal fibrosis.⁵ The current study investigates the effects of CDH11 knockdown and inhibition in CKD to test CDH11 as a novel drug target for renal fibrosis.

METHODS

CKD was induced using two models of renal fibrosis: aristolochic acid nephropathy and unilateral ureteric obstruction (UUO). The first is a toxin-induced injury, whereby 10-week-old mice were injected with 2-4 mg/kg of aristolochic acid (AA) daily for one week. Mice were sacrificed at 6 weeks, at which point blood and kidneys were collected for analysis. The second model is a classic surgically-induced model of tubulointerstitial fibrosis, UUO, wherein one kidney is externalized and the ureter is ligated with a suture. Mice were sacrificed a week following the surgery, at which point kidneys were collected for analysis.

In both injury models, transgenic mice of wild-type (*Cdh11*^{+/+}), heterozygous (*Cdh11*^{+/-}), and null (*Cdh11*^{-/-})

genotypes were used to evaluate the effects of genetically inhibiting CDH11. To study CDH11 functional inhibition, C57BL/6J mice were injured and simultaneously injected with a CDH11 blocking antibody (SYN0012) or isotype control (IgG2a). To evaluate changes in function, morphology, and gene expression, several interrogative techniques were employed, including histological analysis, qPCR, and atomic force microscopy (AFM).

RESULTS

In preliminary studies, CDH11 expression was found to be elevated as much as 20-fold in injured kidneys relative to healthy controls (data not shown). In both injury models used, genetic inhibition of CDH11 results in improved outcomes and amelioration of disease (**Figure 1**). CDH11-heterozygous and null mice had significantly higher survival rates and diminished expression of renal injury markers compared to wild type littermates. Genetic inhibition of CDH11 also improved morphology (by Masson's trichrome stain) evident in the reduced incidence of tubule dilation, nephron damage, and immune infiltrate seen with CDH11 knockdown when compared to wild type. Tissue stiffness – measured using AFM in areas of fibrosis (α SMA-positive) – was reduced in mice with CDH11 knockout compared to wild type. Flow cytometry identified a reduction in lymphocyte invasion among CDH11 knockdown and knockout mice compared to wild type.

Similar results were obtained with pharmacological inhibition of CDH11 using SYN0012 (**Figure 2**). In these

Figure 1. *Cdh11*^{-/-} and *Cdh11*^{+/-} mice have lower mortality rates (A), diminished expression of tubular injury and inflammatory markers (B), reduced tissue stiffness (C), decreased infiltration of inflammatory cells (D), and preserved morphology (E-G) following kidney injury compared to *Cdh11*^{+/+} littermates. Images taken at 10X. † indicates trend of $p < 0.05$; * indicates $p < 0.05$ compared to *Cdh11*^{+/+}.

studies, injured mice that received the CDH11-blocking antibody had significantly improved morphology and significant reduction of renal injury, fibrotic, and inflammatory markers compared to mice that received the isotype control.

DISCUSSION

The results of this study clearly identify targeting CDH11 as an effective means of improving outcomes in murine renal fibrosis models. These studies demonstrated drastic differences in renal morphology, with both overall tissue health and immune infiltrate significantly improved with CDH11 inhibition, which was supported by reduction in the expression of renal injury and fibrotic markers. The reduction in fibrotic tissue stiffness is a particularly novel and impactful find, as previous studies have shown that stiffer tissues can alter extracellular matrix production and induce fibrosis.^{6,7} Based upon these data, CDH11 is a compelling target for therapeutic intervention in patients with CKD and its mechanism should be more fully investigated.

INTRODUCTION

The tumor microenvironment represents a complex and highly dynamic biological system which includes a remodeled extracellular matrix (ECM). A malignant phenotype is established not only due to genetic mutations, but also because of altered biochemical and biomechanical interactions between a tumor and its microenvironment. In particular, tumors generate both compressive and tensile forces [1], and typical biomechanical alterations observed in tumors include ECM stiffening and interstitial fluid pressurization. The established view is that ECM stiffening is caused by collagen deposition, reorganization and cross-linking, while fluid pressurization is due to leaky and disorganized blood vessels [2]. However, ECM remodeling by tumors typically involves collagen densification, which can also affect fluid transport properties and lead to interstitial fluid pressurization. Thus, there is a need for improved characterization of ECM mechanics, remodeling and how evolving ECM properties affect tumor progression.

Type I collagen is the predominant fibrous constituent of the ECM and reconstituted collagen gels are commonly used as substrates for 3D cell cultures. The mechanical properties of collagen gels are commonly assessed using rheometry and uniaxial tension, while their compressive properties are still poorly understood [3]. Here, we used a reductionist system – the tumor spheroid embedded in 3D collagen I – to quantify the extent of compressive matrix remodeling upon spheroid growth. We characterize the structural and mechanical properties of collagen networks at various concentrations (1-4 mg/mL), before (control) and after chemical cross-linking. Confined compression testing, continuum biphasic modeling, and discrete network dynamics were employed to provide a detailed understanding of the mechanisms underlying compressive matrix remodeling upon tumor growth. Overall, we show that tumor growth induces localized compression of the ECM via plastic remodeling, which in turn impacts convective fluid transport.

METHODS

Multicellular spheroids were generated using $\sim 10^3$ MCF-10A cells (ATCC) and were fully embedded in collagen gels of various densities, which were prepared as described below. Spheroid growth and matrix remodeling were examined by means of time-lapse imaging (Leica DMI 6000B) and multiphoton microscopy (Bruker Ultima Investigator). Collagen gels for biomechanical testing were prepared using rat tail type I collagen (BD Biosciences) at concentrations of 1, 2, 3, 4 mg/mL using established protocols [4]. For each concentration, half of the gels (controls) were exposed to regular deionized water (dH₂O), while the other half was cross-linked chemically by adding glutaraldehyde (GA) diluted in dH₂O on top of the self-assembled gels. Microstructural characterization of collagen networks was allowed via second harmonic generation (SHG) imaging both before and after biomechanical testing. Confined compression tests were carried out by preparing collagen gels within cylindrical PDMS wells and by using a DHR-2 rheometer (TA Instruments) equipped with a porous indenter to compress the samples. Stress relaxation tests with steps of 3-5% were applied at a constant rate of 1%/s and followed by a holding period of 180 s, during which the deformation remained constant while the force decreased to a plateau.

In virtue of the elevated content of water, collagen gels were modeled as biphasic mixtures consisting of a solid phase (collagen fiber network) and a fluid phase (interstitial liquid). From a constitutive standpoint, the hydraulic permeability was assumed to be isotropic and strain-independent, while the solid phase was modeled using a Yeoh strain energy function [5]. The material parameters and the hydraulic permeability were determined via nonlinear least squares by means of a two-step fitting procedure [6]. A mechanistic network model was also developed to gain further insights into the mechanisms of compressive remodeling. A 3D random network was generated and cross-linked within a volume of 50 μm^3 . Stretching and bending potentials govern

collagen fiber mechanics [7], while cross-linked nodes exchange forces until they exceed a breaking force. The mechanical behavior of the simulated network depends on the Young's modulus of individual fibers and by the cross-link breaking force. Therefore, these two quantities were varied parametrically to reproduce qualitatively the different behaviors observed experimentally

RESULTS

MCF-10A spheroid growth over 48 hours was found to be nearly independent from collagen concentration. Cell proliferation induced collagen deformations that were radially compressive and tangentially tensile (Figure 1a). Furthermore, SHG imaging of collagen revealed that collagen densified around the spheroid boundary instead of propagating its deformation in the bulk of the collagen matrix (Figure 1b). Motivated by these findings, we investigated collagen gel mechanics under confined compression and found that control gels develop modest reaction forces at each step of compression. After chemical cross-linking with GA, collagen gels displayed a distinct stiffening, lower energy dissipation, and frank rupture at large deformations. Microstructural features of the networks were found to be controlled by collagen concentration, not by cross-linking. However, cross-linked networks exhibited significantly higher autofluorescence with respect to controls, which indicates that the intrinsic fiber properties were altered by treatment with GA. Biphasic modeling showed that control gels display lower shear moduli but also lower hydraulic permeabilities, with respect to their cross-linked counterparts. The lower permeabilities, which cause higher peaks and slower decays in interstitial fluid pressure upon compression, were associated with the presence of plastic deformations in correspondence of the gel surface (Figure 2). The densification of collagen on the surface of the gel after compression was reminiscent of the densification observed around the spheroid boundary after 48 hours of proliferation. Additional insights into the mechanisms of compressive remodeling were gained from the network model. In fact, baseline simulations reproduced behaviors that were qualitatively similar to those observed in control networks. We found that both fiber stiffening (i.e., increase in Young's modulus) and cross-link strengthening (i.e., increase in breaking force) were required to reproduce behaviors similar to those observed after GA treatment. Conversely, these results suggest that cross-link rupture and fiber buckling under compressive loads underlie collagen densification and compressive matrix remodeling.

DISCUSSION

Altered cell-matrix interactions are implicated in the initiation and progression of multiple pathologies. In particular, malignant tumors are characterized by increased collagen deposition and stiffness, and such fibrotic features have been shown to play a causative role in cancer invasion [8]. A better understanding of tumor-driven ECM remodeling using realistic *in vitro* models, such as the multicellular spheroid embedded in a 3D collagen gel, will lead to a better understanding of the metastatic feedback loop existing between ECM densification and tumor invasion / metastasis. Our approach combined 3D cell culture models, microstructural characterization, biomechanical testing, and modeling at multiple length scales. We investigated the structure-function relationship in control and cross-linked gels, and found that the latter behave elastically, while the former display plastic behaviors even at small strains. Localized densification upon compression reduces the hydraulic permeability of control gels, which suggests that the fluid transport properties of the tumor ECM are altered by tumor growth. This finding implies that interstitial fluid pressurization can arise also from ECM remodeling, and not only from a leaky tumor vasculature. Furthermore, a remodeled ECM can act as a transport barrier that is responsible for the development of hypoxia and poor drug delivery.

Figure 1: (a) Radial (λ_r) and tangential ($\lambda_\theta = \lambda_\phi$) deformations imposed at the matrix boundary by MCF-10A spheroid growth in collagen for 48 hours. (b) Localized deformation of collagen around the spheroid boundary shown as a dense collagen layer from SHG.

Figure 2: (a) The biphasic model captures well the stress relaxation response of collagen gels. (b) The resulting hydraulic permeabilities decrease with increasing collagen concentration and are consistently lower in control gels. (c) After compression, plastic deformations and localized densification of collagen at the gel surface are present in control, but not in cross-linked, gels.

PULMONARY ARTERIAL MECHANICS: SOMETHING OLD, SOMETHING NEW, SOMETHING BORROWED, SOMETHING BLUE

Naomi C. Chesler

Department of Biomedical Engineering
 University of Wisconsin-Madison
 Madison, WI USA

INTRODUCTION

As early as 1966, YC Fung was advancing understanding of blood flow in the lungs [1]. According to an oral history [2], he first studied the lung in order to solve a problem posed by Dr. Benjamin Zweifach, a famous microcirculatory physiologist, which led to an even more exciting, long-lasting, and productive collaboration with Sidney Sobin, a pulmonary physiologist. According to the oral history, because so little was known about tissue mechanics when he entered the field, he had to measure it all: “From geometry, anatomy, histology, mechanical properties, to physiology and pathology.”

So the study of arterial mechanics, even pulmonary arterial mechanics, is quite old. That said, since the 1960s there have been many advances that have facilitated the study of pulmonary arterial mechanics, including imaging technologies (i.e., echocardiography, MRI, optical coherence tomography, second harmonic imaging, and others), instrumentation (e.g., 1.2F pressure catheters, ultrasound-based flow sensors), biological innovations (e.g., microRNA, CRISPR/Cas9), and computational modeling approaches. As a result, there is much knowledge of pulmonary arterial mechanics to be gained that is new.

While YC Fung initially focused his attention on the pulmonary vasculature and developed techniques to study the “lesser” circulation specifically, the field of vascular mechanics is dominated by attention to the systemic circulation. As a consequence, many approaches to investigating pulmonary arterial mechanics are borrowed ones designed for measuring systemic arterial mechanics. Significant differences in mean and pulse pressure, relative wall thickness, branching pattern and even luminal oxygen concentration call the appropriateness of these into question. The common illustrations in which pulmonary arteries are blue and systemic arteries are red belie a host of other differences in structure and function that have physiological and pathological consequences.

REPRESENTATIVE METHODS & RESULTS

Direct measurements of large pulmonary artery mechanics can be obtained ex vivo in static [3] or dynamic conditions [4] by controlling transmural pressure in cannulated arteries while diameter is measured by standard, dynamic light microscopy since the pulmonary artery wall is so thin relative. As shown in Figure 1, chronic pulmonary hypertension alters both static and dynamic properties of pulmonary arteries as a nonlinear function of frequency [4].

Figure 1: Frequency-dependent (A) structural stiffness κ normalized to κ of control at 0.01 Hz and (B) and damping capacity of pulmonary arteries from control animals and those exposed to 21 days of pulmonary hypertension (21d HySu). N = 5 per group. * p<0.05 vs. control. See [4] for methodological details.

If arteries cannot be cannulated, which is often the case for the short segments in the highly branching pulmonary vascular network, mechanics can be measured in contrast-perfused lungs [5] or in vivo [6] by quantifying diameters at known pressures using computed tomography, as shown in Figure 2, ultrasound, or magnetic resonance imaging.

Figure 2: (A) Planar computed tomography images of lung arteries reconstructed into 3D volumes. A 3D surface mask used to isolate (B) the right principal pathway. Then, the centerline coordinates and best fit diameters can be found for the principal pathway. (Bottom panel) Representative measurements of the mid-branch diameter for the first segment (mid 1) and the 10th segment (mid 10) as well as the pulmonary artery cannula (Cannula) at two different pressures. From [5].

Alternatively, large pulmonary arterial mechanics can be estimated from area-flow relationships non-invasively [7] (Figure 3) or pulmonary vascular impedance invasively [8, 9] (Figure 4). Distal pulmonary arterial mechanics can be estimated from pressure-flow relationships assuming all small arteries have the same stiffness [10].

Figure 3: (A) Time-lapse of magnetic resonance images of main pulmonary artery (PA) cross-section during early systole. (B) and (C) Flow rates and cross-sectional area (CSA) of the main PA were assessed based on the contours shown in the images (red). (D) Flow and CSA are measured from the MRI phase contrast-derived velocity maps integrated over the MRI magnitude-derived area. PWV velocity is calculated as the slope of QA plot at early systole. From [7].

Figure 4: Characteristic impedance (Z_c) as a function of mean pulmonary artery pressure (mean PAP) for control (CTL) and chronically hypoxic (HPH) lungs untreated, treated with serotonin (5HT, white) or sodium nitroprusside (SNP, gray). From [8].

DISCUSSION

Pulmonary arterial mechanics are critical to the ability to exercise, the progression of disease, and right ventricular function. Building on the foundational insights of Professor YC Fung, our knowledge of pulmonary arterial mechanics has grown exponentially since his first forays in this field over 50 years ago. But some things haven't changed; we still begin with geometry and anatomy to assess mechanical properties and use mechanics to understand physiology and pathology.

CORONARY CALCIFICATIONS: FROM VESICLES TO PLAQUE RUPTURE

INTRODUCTION

Approximately half of all cardiovascular deaths associated with acute coronary syndrome occur with the rupture of a vulnerable plaque, when a thin fibrous cap overlying a lipid rich core is ripped or fissured under the action of high blood pressure [1]

Clinical studies show that calcium score is an excellent predictor of cardiovascular morbidity and mortality, and coronary calcification is the most widely used marker of the advancement of atherosclerosis [2]; However, the identification of atheromas prone to rupture and the cause of subsequent acute cardiovascular events, such as myocardial infarction and stroke, is still challenging. Criteria based on morphology and tissue composition such as fibrous cap thickness, vasa-vasorum, necrotic core size, and macrophage infiltration [3] have been found to be relevant, but insufficient, to identify vulnerable plaques and assess the risk of rupture. Moreover, the link between calcification and plaque rupture is still controversial.

Formerly, the prevailing view was that the presence of calcification within atherosclerotic plaques acted as a biomechanical stabilizer. Indeed, large calcifications easily detected with coronary computed tomography (CT) do not seem to increase plaque vulnerability [4]. However, recent studies indicate an inverse relationship between cardiovascular risk and calcification density [5], and spotty or speckled areas of calcification, observed from intravascular ultrasound (IVUS) or optical coherence tomography (OCT) are a good indicator of susceptibility of rupture [6]. These observations provide insights into the role calcification may play in the stability of the atherosclerotic plaque and suggest that it is not only the amount of vascular calcification, but the morphology, size and location that affect plaque vulnerability.

A biomechanical explanation for the contribution of low density, spotty calcifications to plaque rupture is centered on subcellular

microcalcifications that exist within the thin fibrous cap of atherosclerotic plaques [7]. Finite-element modelling of the stress distribution within plaques indicates that these microcalcifications promote material failure of the fibrous cap [8,9]. Their presence within it greatly increases the stress in the intimal tissue, leading to rupture and the subsequent thrombus formation and vessel occlusion. Microcalcifications (μCalcs) $> 5\mu\text{m}$ within the cap have been shown to produce a 200–700% increase in peak circumferential stress, which transforms a stable plaque into a vulnerable one [10].

The origin of these dangerous microcalcifications remains largely unknown; In-vitro studies suggest that vascular calcifications form as part of an active, cell-mediated process involving the differentiation of multipotent cells and VSMCs into osteoblast-like cells. The osteochondrogenic transformation of SMCs in the vasculature initiate the formation and release of specialized phospholipidic membrane-bound bilayer structures with sub-micron diameter size named matrix vesicles (MVs) [11]. Calcium phosphate accumulates inside these matrix vesicles, forming hydroxyapatite crystals similar to bone formation. Once the mineral inside the MVs grows and penetrates the membrane, it can mineralize in the interstitial space [12] and grow, possibly following a passive crystal growth mechanism.

In this study, we examine individual human atheroma considering gross morphological features and the presence of calcified particles of sizes ranging from the subcellular level, to large calcifications a few mm in diameter. The quantitative analysis of the detailed axial progression of calcification within the necrotic core and fibrous cap of the atheroma, provides novel insights into the coronary calcification process.

METHODS

Specimens: Ninety-six human coronary arteries were harvested from 32 atherosclerotic whole human hearts obtained from the National

Disease Research Interchange. All procedures were approved by Institutional Animal Care and Use Committees of the City College of New York, NY.

High Resolution Micro Computed Tomography Scanning: Coronary specimens were scanned using a high resolution micro computed tomography (HR- μ CT) system (1172, SkyScan, Belgium) at 2.1- μ m resolution. **Histology:** Atheromas were processed for high-fidelity histological analysis of non-decalcified coronary arteries [12], using Alizarin Red S, von Kossa and Trichrome staining.

μ Calcs quantification: HR- μ CT images of the atheromas were binarized to segment the calcified particles from the soft tissues in the atheroma using a global thresholding method [12]. The volume, position and equivalent spherical diameter was calculated for each calcified particle. The size of the necrotic core was measured as the maximum area in the intima beneath the fibrous cap. Then, the region of the plaque of minimum cap thickness was identified and measured as the shortest distance between the necrotic core and the lumen

RESULTS

The quantitative analysis of calcifications within the atheroma reveals distinct patterns: microcalcifications at the core boundary, microcalcifications within the core, large calcifications within the core and advanced calcifications. The first pattern, microcalcifications at the core boundary, describes what seems to be the initial stage of calcification development, submicron and micron-size calcified particles that are aligned at the interface between the soft tissue and the necrotic core, possibly constrained by the internal elastic lamina in Figure 1A. The atheroma looks like a soft plaque, characterized by a mixed lipid/necrotic core, containing a few isolated μ Calcs within the core, and 0.5 - 5 μ m size μ Calcs appearing as a fuzzy/dotted border at the core boundary. The second pattern includes microcalcifications within the core, in which small calcified particles < 100 μ m diameter are dispersed within the necrotic core. As shown in Figure 1B, μ Calcs > 5 μ m visible at 2.1- μ m resolution cluster to form more abundant and larger μ Calcs within the core. The third pattern is characterized by large calcifications within the core, where calcifications > 100 μ m diameter either fuse together or grow through a crystallization process forming a calcification front and large calcifications in the core (Figure 1C). Large calcifications within the core may form large shells, which may fracture radially. The last pattern comprises advanced calcifications, which can grow until they completely fill the entire core area forming an advanced calcified plaque (Figure 1D), in some cases growing beyond the core and extending into the tunica media. Advanced calcifications may also undergo fracture and form calcified nodules with fibrin deposition. These calcified nodules are sometimes seen protruding into the lumen, where they have been associated with a thrombogenic response and cardiovascular events.

Most atheroma (75.4%) exhibit a combination of 2 or more of the patterns described above. As shown in Figure 1, all four calcification patterns are found at contiguous locations in this single atheroma along its axial length.

DISCUSSION

One of the key contributions of this study using HR- μ CT is to gain a better understanding of the calcification process that fibroatheromas undergo. Large calcifications > 50 μ m in diameter, that were often thought to be external to lipid/necrotic core are actually a part of a process in which microcalcifications agglomerate and form a crystallization front that advances from one boundary of the core and then spreads inward. We observed four distinct calcification patterns in the lipid/necrotic core that suggest different stages of calcification progression.

Figure 1. Sequence of images from a human atheroma taken approximately 250 μ m apart from each other displaying the spatial progression of calcification process in atheroma. (A, E) a soft plaque, characterized by a mixed lipid/necrotic core, containing few isolated μ Calcs within the core, (B, F) submicron μ Calcs cluster to form more abundant and larger μ Calcs within the core of the lesion, (C, G) microcalcifications further agglomerate to create a larger macrocalcification within the core, (D, H) the calcification fills the entire core area.

The frequency of each of these four patterns is quantified and it is shown that $\frac{3}{4}$ of all atheromas exhibit two or more of the patterns. Small μ Calcs accumulating at the borders of the core are the most commonly found pattern in this sample of 72 atheromas. Consistent with our findings, previous studies had described the presence of submicron size calcifications in the early stages of plaque progression; However, the use of high-resolution 3D images of the entire plaque, allows a unique description of the calcification process, that links the findings of calcified matrix vesicles with the large calcifications routinely seen in the clinic.

Elucidating the active process wherein cellular-derived vesicles serve as nucleating foci for the formation microcalcifications within the plaque provides hope that therapeutic strategies may be developed to target dangerous microcalcifications. As future studies progress our understanding of the nucleating events of mineralization, the development of preventive strategies for calcification or therapeutic interventions that may reduce calcification or shift it to a more favorable phenotype may be within reach

THE IMPACT OF HEMODYNAMIC REFLEX COMPENSATION FOLLOWING MYOCARDIAL INFARCTION ON SUBSEQUENT VENTRICULAR GROWTH

INTRODUCTION

Post-infarction heart failure is an important problem because it is common, with an incidence of 16 to 30% [1], and it is difficult to treat, with a 1-year mortality of 31 to 45% [1,2]. The development of heart failure following myocardial infarction (MI) is driven by a number of processes, however changes in regional mechanics play a central role by triggering myocyte elongation and left ventricular (LV) dilation.

Although the extent of post-infarction hypertrophy and dilation correlates with infarct size, there is striking variability in individual patients, particularly among those with moderately sized infarcts (15-25%) [3]. We hypothesized that compensatory reflexes that act to preserve mean arterial pressure following MI might be an important source of this variability. These reflexes trigger a suite of responses through the sympathetic nervous system, including an increase in heart rate, an increase in contractility of the surviving myocardium, arterial vasoconstriction, and venous vasoconstriction. Sympathetic activation not only directly promotes myocyte hypertrophy through intracellular signaling pathways, but also indirectly modulates hypertrophy by affecting the load placed on the myocardium. Thus, variability in post-infarction sympathetic activation could represent both a source of individual variability in the extent of LV remodeling and a target for therapies aimed at reducing that remodeling.

Studying post-infarction reflex compensation is complicated by the fact that some of the responses listed above cannot be directly determined from routinely available hemodynamic data. Thus, we used a computational model to reinterpret published hemodynamic measurements to better understand the contributions and variability of the individual compensatory mechanisms following MI. We then employed a published growth model to predict how variability in compensation might translate to variability in global LV remodeling.

METHODS

Modeling the Compensatory Response Post-Infarction

Compensatory responses post-infarction were modeled using our recently published compartmental model of the LV coupled to a circuit model of the circulation to simulate hemodynamics throughout the cardiac cycle [4]. Four model parameters reflect the primary hemodynamic compensations that occur in response to myocardial infarction: heart rate (HR), systemic vascular resistance (SVR , changes with arterial vasoconstriction), end-systolic elastance of the non-infarcted compartment (E_n , changes with myocardial inotropic state), and stressed blood volume (SBV , changes with venous vasoconstriction). Heart rate was prescribed directly in the model. We estimated SVR using the measured ratio of mean arterial pressure to cardiac output. The contractility of an intact ventricle is typically quantified by the slope of its end-systolic pressure-volume behavior [5,6]. In an infarcted heart, however, this slope depends not only on the behavior of the surviving contractile myocardium but also on the behavior of the non-contractile infarct region. Thus E_n could not be measured directly. Furthermore, SBV is rarely reported because measuring it typically involves circulatory arrest [7,8]. Therefore, we used the model to fit E_n and SBV simultaneously by minimizing the sum squared error in other experimentally reported hemodynamic values: LV end-diastolic pressure, the maximum derivative of LV pressure, and mean arterial pressure.

Simulating Left Ventricular Growth

To capture how differences in hemodynamic compensation can lead to differences in subsequent ventricular hypertrophy, we used our previously published model of post-infarction growth [4]. Briefly, an increase in the maximum circumferential strain drives dilation and an increase in the maximum radial strain drives thickening. No changes to

Fig. 1 A) Computed compensatory reflex profiles and B) predicted change in LV end-diastolic volume 6 weeks post-infarction for each infarct dog from [8].

the previously published growth parameters were made for this study.

RESULTS

Variability in Post-Infarction Compensation and LV Dilation

We fitted individual data from 4 sham and 12 acutely infarcted dogs originally published by [9] to assess the variability in compensatory responses post-infarction. Our optimization procedure matched the reported hemodynamics well (sum squared error < 9% in all cases), and optimized values were insensitive to initial guesses. There was a high degree of individual variability in the reported (HR and SVR) and fitted (E_n and SBV) responses to MI (Fig 1A). Overall, there was no clear relationship between infarct size and the compensatory mechanisms employed.

We tested whether the variability in hemodynamic compensation observed for [9] would lead to variability in predicted ventricular hypertrophy by simulating 6 weeks of ventricular growth for each infarct animal. We assumed hemodynamic parameters remained stable at their acute post-infarction values. Although the predicted change in end-diastolic volume (EDV) generally increased with infarct size (Fig. 1B), there was considerable variability, due in part to the mix of compensatory mechanisms employed. Animals with little dilation are labeled in green in Fig. 1. Interestingly, those with the least predicted dilation all exhibited increases in the contractility of the surviving myocardium with little change in heart rate or venoconstriction.

Effects of Therapeutic Intervention on Compensation and LV Dilation

We also simulated data from [10] in which nitroglycerin was administered following coronary occlusion to test the model's ability to assess changes in post-infarction hemodynamic compensation due to drug treatment. On average, dogs in that study compensated primarily by increasing heart rate. Simulated treatment with the vasodilator nitroglycerin reduced systemic vascular resistance and to a lesser degree stressed blood volume. Heart rate and myocardial contractility both increased, suggesting that animals relied more on these mechanisms.

Next, we tested whether the hemodynamic change induced by nitroglycerin would lead to different growth predictions by simulating 6 weeks of ventricular growth utilizing the acute hemodynamic parameters fitted above. We compared the predictions to data on the effect of nitroglycerin on post-infarction remodeling reported by [11]. In the absence of nitroglycerin treatment, the model correctly predicted the observed post-infarction increases in LV volume (Fig. 2). With infarction plus nitroglycerin treatment, the model predicted an acute

Fig. 2 The change in end-diastolic volume over 6 weeks with and without nitroglycerin.

drop in LV volume (Fig. 2) but no subsequent dilation, consistent with the results reported by [11]. Data show mean \pm SE.

DISCUSSION

The model simulations presented here suggest that post-infarction reflex compensation could be both a source of individual variability in the extent of LV remodeling and a target for therapies aimed at reducing that remodeling. We found a strikingly wide range of compensatory reflex profiles in response to MI. Most animals employed one or two mechanisms, but in some cases heart rate, systemic vascular resistance, or myocardial elastance actually reduced in individual dogs even as they compensated with other mechanisms. This variability in compensation translated to variability in the degree of predicted LV dilation consistent with variability reported in the literature. Treatment with a vasodilator had the expected result of shifting the compensatory response away from arterial and venous vasoconstriction and towards increased heart rate and myocardial contractility. Importantly, this shift reduced predicted LV dilation, a prediction that matched prior experimental studies well.

Heart failure is one of the most difficult to treat and deadly complications of MI. We propose that there may be opportunities to intervene early after infarction to prevent or reduce LV dilation that leads to failure, and that computational models can play an important role in customizing therapies to account for variability among individuals.

INTRODUCTION

Marfan syndrome (MFS) is an autosomal dominant disorder of connective tissues that results from mutations to the gene coding for the extracellular matrix glycoprotein fibrillin 1. Alongside other glycoproteins, fibrillin 1 associates with elastin to form the elastic fibers that endow the aortic wall with sufficient compliance to accommodate changes in blood flow throughout the cardiac cycle. Although MFS patients also manifest skeletal and ocular disorders, it is their predisposition to develop aneurysms of the ascending aorta (TAA) that often threatens their life.

Reduced fibrillin 1 content accelerates elastic fiber degradation due to mechanical fatigue [1] and increased MMP activity mediated by TGF β [2]. TGF β is secreted by the cell as a large latent complex, where the small latent complex consisting of TGF β and a TGF β propeptide is covalently linked to a latent TGF β binding protein (LTBP). It has been shown that the interaction between fibrillin 1 and LTBP-3 mediates the sequestration of TGF β in the matrix in vitro [3]. Furthermore, absence of LTBP-3 renormalizes signaling downstream of TGF β and improves the survival rate in the *Fbn1*^{mgR/mgR} mouse model of MFS [3]. Here we report a mechanical characterization of the ascending (ATA) and proximal descending (DTA) thoracic aorta from *Fbn1*^{mgR/mgR};*Ltbp3*^{-/-} mice compared to MFS and control vessels.

METHODS

Mechanical testing. Aortic specimens between the aortic root and the diaphragm were excised from 8-9 week-old mice. Following removal of perivascular tissue and ligation of lateral branches, specimens were secured to glass cannulae and coupled to a computer-controlled biaxial device in preparation for mechanical testing. Arteries were acclimated and preconditioned with cyclic pressurization to in

vivo pressures, while maintained at their preferred in vivo axial stretch (λ_z^{iv}). Biaxial protocols consisted of cyclic pressurization between 10 and 140mmHg, with the specimens held at constant axial length (λ_z^{iv} and $\lambda_z^{iv} \pm 5\%$), and cyclic axial extension up to an axial force of 40-60mN, with constant luminal pressure (10, 60, 100, and 140 mmHg). Outer diameter, luminal pressure, axial force, and axial stretch were measured online during testing. Tested specimens were fixed in formalin overnight and sent for histological analysis.

Constitutive modeling. Aortic tissue was modeled as a (pseudo)hyperelastic material, i.e. we postulated the existence of a strain energy potential W , from which stress and stiffness were obtained by first and second order differentiation with respect to an appropriate measure of deformation. We assumed a four-fiber-family form of W to capture the isotropic contribution of the amorphous matrix and transversely isotropic behavior of ECM fibrillar proteins,

$$W(\mathbf{C}, \mathbf{M}^j) = \frac{c}{2}(I_C - 3) + \sum_{i=1}^4 \frac{c_1^i}{4c_2^i} \left\{ \exp \left[c_2^i (IV_C^i - 1)^2 \right] - 1 \right\},$$

where c , c_1^i , and c_2^i are material parameters, $\mathbf{C} = \mathbf{F}^T \mathbf{F}$ is the right Cauchy-Green deformation tensor, \mathbf{F} is the deformation gradient tensor, I_C and IV_C^i are the first and fourth invariants of \mathbf{C} , \mathbf{M}^j is a vector in the fiber direction, and $\det \mathbf{F} = 1$ for assumed incompressibility. Experimental values of stress were inferred as radial averages. Material parameters were estimated with a nonlinear least-square regression and used to simulate the mechanical response of the aorta under loading conditions of interest.

Assessment of the skeletal manifestations of MFS. An InveonTM micro-PET/CT scanner with an 80-W, 35- to 80-kVp tungsten-anode X-ray source (Siemens) was used to acquire whole-body CT scans of mice placed in a prone position following euthanasia. Cross sectional images

were segmented in Mimics (Materialize) to create a 3D model of the skeleton. The kyphotic curve of the thoracic spine was characterized using dorsal-ventral asymmetries in the length of the vertebrae between T4 and L6 [4].

RESULTS

Gross anatomy. Although *Fbn1^{mgR/mgR}·Ltbp3^{-/-}* mice have lower body mass (21.9 ± 1.5 g) compared to controls (29.2 ± 0.4 g), the ratio between the systolic diameter of the ATA and their body mass falls within the confidence intervals for normal allometric scaling (Figure 1). This suggests that absence of LTBP-3 prevents or retards aneurysm formation in MFS mice, at least to 9 weeks of age.

Figure 1: Normal allometric scaling for the ATA diameter

Circumferential mechanics. Figure 2 displays the mechanical behavior of the ATA in the circumferential direction as estimated from biaxial tests. While the Pressure vs. Outer diameter (A) and the Cauchy stress vs. stretch (B) response of aneurysmal MFS mice clearly reflects the effects of fragmentation of elastic fibers within the media [2], the curve for *Fbn1^{mgR/mgR}·Ltbp3^{-/-}* mice overlaps that for controls. Consistently, absence of LTBP-3 restores normal values of circumferential stiffness (C), a parameter that was shown to strongly correlate with the propensity for and the development of thoracic aortic aneurysms [5]. Results for the DTA (not shown) mirror those for the ATA.

Figure 2: Circumferential mechanics of the ATA

Axial mechanics. Despite the reduced elastic fiber fragmentation in the *Fbn1^{mgR/mgR}·Ltbp3^{-/-}* aorta, both the DTA and the ATA of double mutant mice have limited axial extensibility. The in vivo axial stretch (λ_z^{iv}) in the ATA of *Fbn1^{mgR/mgR}·Ltbp3^{-/-}* mice (1.41 ± 0.02) is comparable to that of MFS mice (1.42 ± 0.06) and significantly reduced from WT mice (1.70 ± 0.04). Similarly, the in vivo axial stretch of the DTA is 1.44 ± 0.03 and 1.45 ± 0.03 in *Fbn1^{mgR/mgR}·Ltbp3^{-/-}* and MFS

mice, respectively, compared to 1.60 ± 0.05 in controls (Figure 3, A). Furthermore, the DTA from both *Fbn1^{mgR/mgR}·Ltbp3^{-/-}* and MFS mice maintained a significant curvature upon excision, while the control DTA remained fairly straight (B). Given that the basis of this behavior was not microstructurally-related, we shifted our focus on surrounding organs and tissues that impose structural constraints to the aorta. Amongst those, the spine provides support to the DTA, which is tethered to the vertebrae by the intercostal arteries.

Figure 3: Axial stretch and curvature of the DTA

Thoracic kyphosis. The kyphotic curve of the thoracic spine was exacerbated in MFS mice, as indicated by the pronounced wedging of the vertebrae in the dorsal-ventral plane (Figure 3, B). Furthermore, a strong correlation existed between the curvature of the unloaded aorta and the degree of spinal kyphosis, suggesting that the spine may play a role in the axial development of the aorta throughout somatic growth.

DISCUSSION

Increased TGF β activity often characterizes syndromic or familial connective tissue disorders that predispose affected individuals to the development of thoracic aortic aneurysms, including MFS. Consistent with this observation, the mechanical analysis of the *Fbn1^{mgR/mgR}·Ltbp3^{-/-}* aorta is consistent with the thought that renormalization of TGF β signaling through removal of LTBP-3 [3] protects MFS mice from thoracic aneurysms up to 9 weeks. First, double mutant aortas exhibited normal diameter compared to weight-matched controls. Second, absence of LTBP-3 reduced the predisposition towards aortic dilatation by contributing to the decrease in circumferential stiffness [5].

Despite normalizing circumferential properties, absence of LTBP-3 did not restore the axial mechanics of the thoracic aorta in MFS mice. While the progressive fragmentation of the elastic fibers is responsible for the decreased in vivo stretch of the MFS aorta, other mechanisms may influence the axial mechanics of the *Fbn1^{mgR/mgR}·Ltbp3^{-/-}* aorta, where elastic fibers are intact. The correlation between the curvatures of the aorta and the spine that emerged from our analysis hints to a possible coupling between the development of the vascular and skeletal systems that could influence the axial behavior of the aorta. Although the connection between the spine and the thoracic curvature necessitates further investigation, our results suggest that the skeletal phenotype might influence the vascular phenotypes in MFS.

ACKNOWLEDGEMENTS

We thank the Rifkin lab at NYU for providing the mice.

CONTRIBUTION OF MATRIX REMODELING TO BIAXIAL MECHANICS OF RIGHT-VENTRICULAR MYOCARDIUM IN PULMONARY ARTERIAL HYPERTENSION

INTRODUCTION

Right-ventricular (RV) function is a good prognostic indicator in pulmonary arterial hypertension (PAH), a progressive vasculopathy that commonly results in intractable RV failure and premature death. It has been shown in humans and animal models of PAH that the RV hypertrophies in response to increased RV systolic pressure, which can be associated with tissue fibrosis and altered end-diastolic stiffness. However, the extent to which altered RV chamber stiffness is due to increased RV wall stiffness, altered extracellular matrix (ECM) content or altered intrinsic ECM material properties remains unclear. Our recent (unpublished) measurement and model analysis of changes in RV geometry and hemodynamics suggest that by 6 weeks of PAH in a sugen-hypoxia animal model, RV end-diastolic chamber stiffness is significantly greater than baseline and that increase cannot be explained by the increased RV wall thickness alone. Hence, we sought to determine the extent to which increased resting myocardial material stiffness in this model could be attributed to changes in myocardial ECM content or changes in biaxial stress-strain properties of decellularized RV myocardium. We also found that the biaxial stress-strain tests in ionic and decellularized RV myocardium are well approximated by exponential strain energy functions first proposed by Y-C Fung, and we propose a new mixture based constitutive theory that allows these experimental measurements to be used in a novel strain energy formulation that accounts for matrix pre-stress in the myocardium and allows the contributions of ECM, myocytes and their interactions to the total strain energy to be separately identified.

METHODS

Male Sprague-Dawley rats were injected with a single dose of 20mg/kg of Sugan (SU5416, Sigma-Aldrich), a VEGF receptor inhibitor, and were placed in a hypoxia (10% oxygen) chamber for 3

weeks to induce PAH. Three weeks post returning to normoxia, *in-vivo* hemodynamic measurements were taken to assess ventricular function. The control group was untreated and maintained in normoxia.

Immediately after the hemodynamic measurements, the heart was harvested and the RV isolated and dissected. A square sample of the free wall was excised and oriented with one primary axis from the apex to the RV outflow-tract. Thickness, weight and surface dimension measurements were made. Four custom-made hooks were placed on each side of the sample and attached to the pulley-system of the Bose Electro Force planar biaxial testing device. While kept in an oxygenated and temperature-controlled bath of PBS, 4 material markers placed on the surface of the specimen were brought into the visual field of the optical tracking system to compute the deformation gradient tensor. The mechanical testing consisted of stretch-controlled biaxial tests with biaxial ratios of 1:0.5, 1:0.25, 1:1, 0.5:1, and 0.25:1, all recorded after 15 cycles of preconditioning. After obtaining the mechanical properties of the RV myocardium, the sample underwent a decellularization protocol to isolate the RV ECM. The decellularization protocol consisted of sequential exposure of specimens to Tris-buffered solution with 0.1% phenylmethylsulfonyl fluoride (PMSF), 1% Triton X-100, and 0.1% SDS for 48 h each. To prevent loss of the graphite markers, the specimens were placed securely in cell strainers, while on a stirring plate at room temperature as done previously [1]. At the conclusion of the decellularization protocol, the ECM-only specimens were kept in a -4 C refrigerator for 24 hours. In room-temperature PBS, the RV ECM specimens underwent the same biaxial testing protocol as the RV myocardium after the matrix sample dimensions were measured.

From the marker positions, the deformation gradient tensor \mathbf{F} was calculated for each loading cycle. From \mathbf{F} , the components of the in-plane Green strain tensor \mathbf{E} were calculated using $\mathbf{E} = \frac{1}{2}(\mathbf{F}^T \mathbf{F} - \mathbf{I})$. The shear components of \mathbf{E} were negligible in all test specimens, so only the

normal apex-outflow tract and circumferential component E_{11} and E_{22} were analyzed. The 1st Piola–Kirchhoff (PK) stress tensor \mathbf{P} was calculated from the measured loads in grams and the specimen dimensions. The 2nd PK stress tensor \mathbf{S} was determined using $\mathbf{S} = \mathbf{P}\mathbf{F}^{-T}$ [1]. Assuming a pseudoelastic, hyperelastic material response, the tissue-level 2nd PK stress \mathbf{S} is derived from the strain energy as [2]

$$\mathbf{S}(\mathbf{E}) = \frac{\partial \Psi(\mathbf{E})}{\partial \mathbf{E}} - p\mathbf{C}^{-1} \quad (1)$$

where the Lagrange multiplier p accounts for the incompressible nature associated with non-fibrillar tissue components [3]. In our case, p was eliminated as a result of the configuration of planar biaxial testing. Using the experimentally obtained \mathbf{S} - \mathbf{E} data, we fitted a Fung-type model (Equation 2) to first obtain the Ψ for each specimen. A set of model parameter that described the strain-energy of the RV myocardium and ECM in normo- and hypertension was achieved through gradient-based nonlinear optimization *fminsearch* function in Matlab (2018b).

$$\Psi(E_{11}, E_{22}) = c(e^{a_1 E_{11}^2 + a_2 E_{22}^2 + a_3 E_{11} E_{22}} - 1) \quad (2)$$

RESULTS

RV ECM samples significantly thinned (0.13 mm in control to 0.38 mm in PAH) and shorten in the normal directions (by 3 mm in control and 1mm in PAH) from their intact state. The decellularized to intact volume-ratio or hydrated volume-fraction went from 0.144 in control to 0.119 in PAH. The shortening or change in dimensions can be visualized in the pixel position of the markers (Figure 1A). Nevertheless, the intact and decellularized samples' Green strain space closely overlaps (Figure 1B).

Figure 1: A. Camera field of view of the material markers at the center of the intact (blue) and decellularized (red) RV samples. B. Green strain space of an intact and decellularized RV sample.

Figure 2: Equi-biaxial stress-strain relations of RV myocardium and ECM of a normotensive animal. As previously shown [1], the

RV display an anisotropic tissue response, with the apex to outflow tract being the stiffer direction in intact and decellularized states.

Figure 3: Strain-energy surfaces of the ECM of normo (CTL)- and hypertensive (PAH) rat.

Equi-biaxial stress-strain relationships of the control and PAH samples show both the myocardium and ECM being anisotropic materials, with the apex to outflow-tract direction being the stiffer direction (Figure 2). When comparing the strain-energy surfaces of the ECM of a normo- and hypertensive animal, the PAH sample is significantly stiffer even after accounting for the smaller hydration volume fraction.

DISCUSSION

Results show that while the amount of matrix increased, the volume fraction did not due to the significant hypertrophy. However, the PAH matrix was significantly stiffer and this contributed a greater amount to myocardium stiffness. This suggests that alterations to the fiber and/or molecular structure of the ECM such as increased diameter or decreased tortuosity of coiled perimysial fibers and/or increased collagen crosslinking may have played an important role in increased RV end-diastolic stiffness in PAH before any systolic decompensation. Classical Fung-type exponential strain energy functions do an excellent job of fitting the biaxial responses of both the intact and decellularized tissue. However, the fact that the matrix significantly shrinks from the reference state suggests the existence of prestresses in the matrix and collagen that are in equilibrium in the unloaded state. A mixture theory that properly represents the contributions of matrix and cells to the intact tissue properties in this experiment may account for these pre-stresses and may require the inclusion of additional terms in the constitutive equations to reflect interactions between myocytes, matrix and water.

INTRODUCTION

The incidence of anterior cruciate ligament (ACL) injuries has been increasing significantly in skeletally immature populations over the past decade [1]. ACL injuries are most commonly treated through surgical reconstruction procedures which are designed to restore function and stability to the knee joint under both translational and rotational loading conditions. Interestingly, in the mature knee joint, less translation (~3-5 mm) and axial plane rotation (~5-7°) occurs under applied tibial loads when the joint is extended compared to when the joint is flexed [2,3]. Joint flexion has implications in surgery. For example, the flexion angle of the knee can influence the force carried in the native ACL [3]. Likewise, flexion angle at the time of ACL graft fixation can have a substantial effect on the force carried by the reconstruction graft [3]. Additionally, joint laxity, which varies by knee flexion, can be used as an intraoperative measure of ACL graft function [2]. These flexion-dependent behaviors of different tissues under anterior tibial translation at full extension versus flexed positions depend on tissue engagement. Previous work in our lab has shown that the resulting kinematics from applied tibial loads is age-dependent with greater normalized translation in younger joints [4,5]. It is important to determine if the impact of flexion angle on joint laxity and ACL function is conserved throughout skeletal growth, potentially helping to inform optimal joint flexion during ACL reconstruction of pediatric patients. Here, we hypothesized that joint laxity under applied anterior-posterior and varus-valgus loads would be decreased and the percentage of applied anterior tibial force carried by the ACL would be decreased at full extension (40° in the pig) versus 60° of flexion across juvenile and adolescent stages in the porcine knee model.

METHODS

Hind limbs were collected from female Yorkshire cross-breed pigs representing four age groups ranging from juvenile to late adolescent stages (3-18 months, n=22 total). All soft tissue was dissected away from the femur and tibia in order to expose the surface of the bones, and a fiberglass epoxy was fixed to the bones inside of molds that were designed to fit custom-built clamps. Joints were mechanically tested using a 6 degree-of-freedom universal force sensing robotic system (KUKA/SimVitro) which is capable of operating under both kinematic and kinetic control.

The following biomechanical tests were performed using the robotic system. A passive path was established for each limb by moving the tibia from full extension (40° in the pig) to 90° of flexion and finding the kinematic positions with minimized loads in the remaining 5 degrees of freedom. The kinematics for passive path positions at 40° and 60° of flexion were recorded. Scaled anterior-posterior tibial loads and varus-valgus moments were applied to the joints at both 40° and 60° of flexion while loads in the remaining degrees of freedom were minimized. The kinematic paths were recorded and repeated in intact, AM bundle deficient, and ACL deficient (AM and PL bundle deficient) states and the resulting loads were recorded. The kinematic paths were exported for further processing. Parameters of interest included anterior-posterior tibial translation (APTT) and varus-valgus rotation (VVR) under applied loads. The principle of superposition was applied to determine the *in situ* forces carried by the ACL and its bundles at maximum anterior translation and varus and valgus rotation [5]. Normality of data sets was confirmed. Statistical analysis consisted of repeated measures ANOVA testing with Tukey's post hoc analysis where age and flexion angle were the main effects, and flexion angle as a repeated measure ($p < 0.05$).

RESULTS

Under the application of anterior-posterior tibial loads, APTT of the joint varied significantly as an effect of flexion angle ($p < 0.05$) with no significant effect due to age ($p > 0.05$) or the interaction of age and angle ($p > 0.05$). Specifically, increasing knee flexion resulted in mean APTT increases from extension (40° of flexion) to 60° of flexion of 1.6 mm at 4.5 months (19%), 1.4 mm at 6 months (21%), and 1.3 mm at 18 months (18%) (Fig. 1). These increases were statistically significant in all but the 3 month age group.

Figure 1: Anterior-posterior tibial translation (APTT) is greater at 60° of flexion relative to full extension during growth. Connected points show data from individual specimens, bar shows $p < 0.05$ between angles.

Joint rotation under applied varus-valgus moments were also measured. We found a significant effect due to age, flexion angle, and the interaction term ($p < 0.05$). Unlike APTT, we found that increasing flexion angle resulted in greater VVR in the 3, 4.5, and 6 month age groups ($p < 0.05$), but not in the 18 month age group ($p > 0.05$). The increase in flexion angle resulted in mean increases of 1.8° (3 months), 2.8° (4.5 months), and 2.2° (6 months) in the separate age groups. These effects due to flexion angle were coupled with an overall decrease with age of $\sim 11^\circ$ from 16.9° (full extension) and 18.7° (60° of flexion) in the 3 month group to 6.2° (full extension) and 7.4° (60° of flexion) at 18 months. Significant decreases occurred between 3 months and all older groups, and from 4.5 months to the remaining older groups ($p < 0.05$) (Fig. 2).

Figure 2: Varus-valgus rotation (VVR) decreased with increasing age in growth, and increased with joint flexion. Connected points show individual specimens, bar indicates $p < 0.05$ between angles, * $p < 0.05$ vs. 3 months, ** $p < 0.05$ vs. 3 and 4.5 months.

In addition to changes in joint kinematics, knee flexion had a significant effect on the forces carried in the soft tissues ($p < 0.05$) while

there was no significant effect due to age or the interaction term ($p > 0.05$). Specifically, the ACL carried an average of 72% of the total applied anterior force in the joint at full extension which was significantly less than the mean 87% carried at 60° of flexion ($p < 0.05$, Fig. 3). Furthermore, flexion angle had a significant effect ($p < 0.05$) on the relative contributions of the AM and PL bundles of the ACL to resisting anterior force. The AM bundle of the ACL carried significantly more force at 60° of flexion compared to 40° of flexion ($p < 0.05$, data not shown).

Figure 3: The ACL carried significantly less of the applied anterior tibial load ($p < 0.05$) at full extension compared to 60° of flexion. Connected points show data from individual specimens, bar shows $p < 0.05$ between angles.

DISCUSSION

In this study, we report significant increases in both translational and rotational joint laxity as a result of increasing knee flexion in skeletally immature pigs. Interestingly, these results were statistically significant in early through late adolescent groups for APTT while they were statistically significant in juvenile through mid-adolescent groups for VVR. Both translational and rotational laxity decreased as an effect of increasing age. Additionally, we found that the ACL carried a greater portion of applied anterior forces in flexed positions across juvenile and early adolescent porcine groups. These results are similar to previous studies focusing on the kinematic [2,3] and kinetic [6] properties of mature joints, while expanding our knowledge of the biomechanics of skeletally immature knees. While this study focused on a female model, future work will focus on expanding the data set to include male specimens and a greater range of ages. Additionally, the information gathered here may be used to motivate a non-invasive human study in pediatric and adolescent populations to investigate knee laxity at different flexion angles. Given that flexion angle is an important consideration for ACL graft function in adults, these findings may be important in developing age-specific clinical practices for a rapidly growing population of young patients with ACL injuries.

A Novel Geometric Ratio To Predict The Flexion Gap In Total Knee Arthroplasty

INTRODUCTION

Total knee arthroplasty (TKA), despite high rates of long-term implant survival, still suffers from elevated incidence of patient dissatisfaction of up to 15% [1]. These high rates of dissatisfaction are, in part, attributed to improper ligament tensioning during TKA implantation, which may lead to joint instability [2]. Ligament tensioning is clinically evaluated by assessing the gaps between the femur and the tibia in response to varus and valgus moments applied with the knee flexed and extended. Achieving equal (i.e. balanced) medial and lateral gaps is a common surgical target for successful TKA. Measured resection (MR) and gap balancing (GB) are commonly used techniques for gap balancing. In MR, femoral component placement relies solely on bony landmarks. This technique ignores the role of the restraining collateral ligaments in driving knee mechanics, which may lead to inconsistent knee function following TKA implantation [3]. In contrast, in GB, collateral ligament geometries and tensions dictate the rotation of the femoral component. This technique, however, may cause excessive internal or external rotations if the medial or lateral collateral ligaments (MCL & LCL) are deficient [3]. Therefore, we developed a new geometric measurement, “the MCL ratio”, which accounts for the geometry of both the femur and the insertions of the medial collateral ligament (MCL) when placing the femoral component. Our objective was to determine whether the MCL ratio can predict the flexion gaps produced from MR and GB techniques to help define the rotation of the femoral component to achieve balanced gaps.

METHODS

Six computational knee models were virtually implanted with both MR and GB techniques based on our previously-developed framework (all males; age 33 ± 15 years) [4]. A posteriorly stabilized implant system was utilized. In both MR and GB models, the distal femoral cut and the proximal tibial cut were perpendicular to the femoral and tibial mechanical axis, respectively. The only difference between MR and GB was the amount of external rotation of the femoral component. Specifically, in the MR models, the femoral component was aligned parallel to the transepicondylar axis (TEA). In contrast, in the GB models, the femoral component was externally rotated at 90° of flexion until equal gaps are achieved (within 2 mm), which reflects equal tension in MCL & LCL (Figure 1).

Figure 1: Posterior bony cuts for the placement of the femoral component for (a) measured resection where the component is externally rotated until it is parallel to the TEA, and (b) gap balancing, where the component is externally rotated until achieving equal tensions in the MCL and LCL

The collateral and capsular ligaments in each model were represented with twenty ligament fibers. Standardized ligament properties, including slack length and linear stiffness, were

controlled for the structural properties of the ligaments across all models [5]. Knee flexion from full extension to 90° under 500 N of compression was applied to simulate a common intraoperative examination. Then, to assess the lateral and medial gaps, varus and valgus moments of ± 20 Nm were applied at full extension and 90° of flexion, which reflect common intraoperative assessments [6]. The difference in the medial and lateral gaps at full extension and at 90° of flexion was measured for both MR and GB. Next, the MCL ratio, which is a ratio between the distances of the femoral insertions of the anterior fiber of the MCL to the posterior and distal cuts, was calculated (Figure 2). Finally, this ratio and the difference between the medial and lateral gaps at 90° of flexion for both the MR and GB knee models were compared for each knee model.

Figure 2: The MCL ratio is a ratio between the distances of the femoral insertions of the anterior fiber of the MCL to the posterior and distal cuts

RESULTS

The medial and lateral gaps at full extension were balanced (difference < 1.0 mm) for both MR and GB models. The external rotation that is required to achieve balanced gaps at 90° of flexion was the same for both MR and GB models of knees one, two, and six (Table 1). These three knee models yielded difference in flexion gaps of <1.0 mm and an MCL ratio <1.1 for both MR and GB (Figure 3). In contrast, knee models three, four, and five produced different external rotation between MR and GB (Table 1). Specifically, in MR, knee models three, four, and five were unbalanced and produced a gap difference and MCL ratio ranging from 3.6 to 10 mm and from 1.2 to 1.5, respectively (Figure 3). In contrast, in GB, knee models three, four, and five required more external rotation than in MR (Table 1). Moreover, the MCL ratio was lower in GB than in MR for knee models three, four, and five decreasing from 1.5 to 1.3, from 1.2 to 1.1, and from 1.4 to 1.2, respectively (Figure 3).

Table 1: External rotation of the femoral component for the six knee models using measured resection (MR) and gap balancing (GB) models in degrees

	Knee 1	Knee 2	Knee 3	Knee 4	Knee 5	Knee 6
MR	2.5°	0.6°	1.3°	1.6°	4°	2.5°
GB	2.5°	0.6°	6.3°	2.6°	7°	2.5°

Figure 3: The MCL ratio closely followed variations in the difference of the medial and lateral gaps at 90° of flexion for both MR and GB

DISCUSSION

Despite aligning the femoral component parallel to the TEA and having balanced gaps at full extension, three out of six knees were unbalanced in the MR models and produced a difference between the medial and lateral gaps >2 mm in flexion. Our findings challenge current clinical thinking that alignment of the femoral component with the TEA yields consistent gaps from knee to knee [7]; rather, our findings indicate that this variability in gaps is likely due to high interpersonal geometric variation in the femoral condyles as well as the MCL insertion. Interestingly, even though ligament properties and component placement were standardized across each knee model, the external rotation required to achieve balanced flexion gaps (i.e. < 2 mm) ranged from 0.6° to 7° (Table 1). The MCL ratio, however, may provide a useful reference for femoral component rotation in TKA; specifically, the less was the MCL ratio, the less was the difference between the medial and lateral gaps (Figure 3). The relationship between the MCL ratio and the gap difference at 90° of flexion can be explained by the ability of this ratio to capture the isometry of the MCL between extension and flexion. In conclusion, the MCL ratio could be a useful measure to guide femoral component placement to achieve more predictable knee function following TKA.

INTRODUCTION

Total knee arthroplasty (TKA) is among the most successful medical procedures, providing patients long term function, reduced pain and improved quality of life. By 2030, the demand for primary TKA is projected to exceed 3 million [1]. Despite the success, some device revision rates remain as high as 12.9% after ten years [2], translating into significant numbers of revision surgeries annually. A leading cause for revision TKA is aseptic loosening following stable fixation at the time of implantation, with mechanical loss of fixation over time and/or particle induced osteolysis. In the present study, we quantified radiolucency and micromotion in tibial components in TKA devices retrieved post mortem, which were still attached to host bone. We hypothesized that radiographic lucency would be indicative of high rates of micromotion and associated with visual evidence of wear and corrosion.

METHODS

Six (6) specimens recovered post mortem (“en bloc”) were obtained from RTI Biologics (Alchua, FL) that we presume were still functioning at the time of patient death. Device manufacturer and patient information including height, weight, age, and time in service were noted for analysis (Table 1). The tibial components were radiographed and scored for lucency according to the Knee Society TKA Radiographic Evaluation and Scoring System [3] using ImageJ software (Research Service Branch). In doing so, scores were given by the thickness (mm) of radiolucent lines in seven different zones in the anterior/posterior views of the tibial components. If lucency occurred in more than one zone the scores were added giving a single total score for each device. Clinically, a score of less than 4 is considered insignificant, 5 - 9 signifies follow-up needed, and greater than 10 predicts the device is approaching failure.

Micromotion was measured using an approach modified from Peters et al., [4]. Each en bloc tibial specimen was thawed at room temperature for 24 hours and equipped with four rods extending from the anterior, medial, posterior, and lateral tibial tray, affixed to the device by cyanoacrylate (Fig. 1). The tibial component was potted using Custom Tray Material (GC America Inc.) and fastened to the baseplate of an 858 Mini Bionix (MTS Systems Corporation) uniaxial testing station. A custom fixture was fabricated and attached to the actuator of the MTS to allow in vitro loading of the polyethylene of the tibial component using a femoral ball. Four linear variable differential transducers (LVDT, Stellar Technology Inc. Amherst, NY) were affixed to the tibia using a custom halo. The LVDTs were positioned so that each rod was fastened to the peg of the tibial construct, measuring lift-off and compression of the medial, lateral, anterior, and posterior tray, accounting for the distance of each LVDT from the edge of the tibial construct. Loads equal to 1.8 times the body weight were applied to the medial and lateral articulating surfaces of each component [4]. A cumulative micromotion value was determined by adding the absolute values of compression and lift-off for each specimen.

Four MyDAQ drivers (National Instruments, Austin, TX) were coupled with LabVIEW (National Instruments, Austin, TX) and a program was developed in which voltages were captured from the LVDTs, plotted against time into a user interface while simultaneously output into an Excel spreadsheet. Each LVDT was carefully calibrated by measuring the physical distance correlating to the full range of voltage (2.792 mm). This program allowed the correlation between micromotion and load supplied by the 858 Mini Bionix.

RESULTS

All tibial radiographic scores were below 4, which indicates that the lucencies present were not clinically significant [3]. All lucencies

found occurred around the tibial tray; none were found around tibial keels. The radiographs were further analyzed by an orthopedic surgeon (Ghanem) who concluded that all implants were cemented with no signs of scalloping due to osteolysis.

As expected, loading of the medial/lateral bearing surfaces of tibial components resulted in the largest compressive displacements of the medial/lateral tibial tray, respectively. Three components (170R, 170L and 395L) displayed liftoff of the opposing side and compressive displacements larger than 150 μm – a value associated with fibrous tissue formation at porous implant surfaces [5]. The cumulative magnitude of micromotion from each implant significantly correlated to time in service ($p = 0.0378$, Fig. 2). Furthermore, radiographic scores showed a strong correlation to levels of micromotion ($p = 0.0206$). Devices exhibiting radiolucency (170R, 170L and 395L) had the highest rates of micromotion among those tested.

DISCUSSION

The aim of this study was to establish the testing methodologies necessary to quantify radiolucency and micromotion for retrieved tibial components that were still affixed to the host bone. The methods were then applied to six devices for which we had patient data including time in service. The results suggested that micromotion was positively correlated with time in service. To our disappointment, radiographic images revealed little evidence of osteolysis or scalloping that might be correlated with the measured micromotion. The largest values of medial compression (-515.24 μm , -444.06 μm) occurred for two specimens with a small lucency under each medial plateau; however, a small lucency was also observed under the medial plateau of one other device that yielded only 8.8 μm of displacement under medial compression. In general, specimens exhibiting any amount of tibial lucency, even clinically insignificant levels (score < 4), experienced more micromotion on average when compared to specimen that did not (p -value = 0.0206). It should be noted that during testing, deformation of the cancellous bone may have affected the measurements [6]. No bone mineral density measurements or structural assessments were performed.

The secondary aim of this study was to investigate whether micromotion of en bloc specimens correlated to wear and corrosion. The results showed that micromotion of these en bloc devices did not correlate with the area of inflammatory cell induced corrosion (ICIC, $p = 0.7872$) or polyethylene wear scores ($p = 0.1481$, data not shown).

The study was limited by the small number of en bloc specimens obtained from our collection for which we had patient data. All tibial components were cemented and were designs marketed in the late 1990's to early 2000's. In the future, we hope to continue these efforts and include more contemporary design features, including highly crosslinked polyethylene.

INTRODUCTION

Subchondral bone cysts (SBCs) occur in young horses bred for racing, most often in the medial femoral condyle (MFC). These SBCs result in lameness and secondary pathologies such as meniscal tears and cartilage damage. Traditional treatments attempt to reduce local inflammation and promote bone healing by anti-inflammatory agents and debridement, but rates of radiographic healing are less than 20% [1].

While a horse may become “sound” after traditional treatments, the risk for re-injury and lameness exists if the void remains in the MFC. In a study by Frazer et al., high shear stresses (above yield) were found in the boundary of a SBC at high load, and increased stresses were reported in the medial meniscus with a femoral SBC [2]. In order to reduce the risk of re-injury and secondary meniscal injury, treatment strategies should focus on bone growth in the void.

A recently developed treatment which places a transcondylar lag screw across the void has shown high success rates in both lameness resolution and radiographic healing [3], but the mechanism of healing remains unclear. Understanding how a screw promotes bone formation would provide information to both improve the surgery and possibly develop more treatments in the future. As such, a previously developed finite element model of an equine stifle joint was used to test and predict the transcondylar screw’s primary mechanism of promoting healing [2].

Bone apposition will occur on free surfaces of bone with appropriate mechanical stimulus [4]. Lag screws create compression along their long axis and this mechanical change may promote bone formation in the void. We hypothesize that the lag screw treatment strategy stimulates bone growth on the inner lining of the SBC by increasing the mechanical stimulus the bone experiences. Furthermore, we hypothesize that the lag screw alters the direction of the principal

stresses surrounding the MFC to be transverse to the normal trabecular orientation.

In this study, finite element analysis was utilized to quantify the bone remodeling stimulus with and without a transcondylar lag screw through an equine MFC with a 2 cm³ void. Screw placement method, compression across the screw, steps allowed per day, and joint load were all varied to determine characteristics of the surgery and rehabilitation strategy most conducive to bone apposition.

METHODS

Previous work by our lab developed a finite element model of an equine stifle joint in extension with a 2 cm³ void in the MFC under gallop ground reaction force loading [2]. The present study used this model with an added sclerotic region of bone of thickness 5 mm (as seen clinically) outside of the SBC. The sclerotic density was assumed to be 1.0 g/cm³ and given a corresponding modulus of 3770 MPa using

$$E = 3770 \rho^3 \quad (1)$$

for the density-modulus relationship [5]. The remaining bone tissue was assigned properties using the same relationship. Cartilage material properties were lowered from our previous study to better represent the tissue response at lower loads and strain rates experienced in a post-operative environment ($E = 8$ MPa, $\nu = 0.45$).

Criteria for Effectiveness: To evaluate the efficacy of various surgical treatment strategies, Beaupre, Carter, and Orr’s theory of bone remodeling was adopted [4, 6]. The standard tissue stimulus (Ψ) was calculated to predict bone resorption, apposition, or no net change,

$$\Psi = \left(\sum_{day} n_i \sigma_{b_i}^m \right)^{\frac{1}{m}} \quad (2)$$

where n_i is the number of cycles per day (for a given load), σ_{b_i} is a bone tissue-level effective stress based on strain energy density, and m is an

empirical constant assumed to be 6 for the horse [7]. We assumed the standard attractor state (ideal reference stimulus) of 50 MPa and a “dead zone” of $\pm 20\%$ (i.e. 40-60 MPa). Thus, values of $\Psi > 60$ MPa predict bone apposition, and values of $\Psi < 40$ MPa predict bone resorption.

We also calculated third principal stress (compression), σ_{III} , directions, to indicate the preferred direction of trabecular alignment.

General Boundary Conditions and Analysis Procedures: Depending on the analysis, a varying magnitude of uniform pressure was applied to the proximal femur. The quadriceps tensile force on the superior aspect of the patella to prevent unrealistic femoral anterior translation was scaled down from our previous study to 100 N [2]. The proximal aspect of the femur was constrained in varus-valgus (0°) and flexion/extension rotations (155°). The tibia was fully constrained, and all femoral translations and internal rotation were allowed. Frictionless contact was defined between all articulating surfaces using general contact in ABAQUS. Stimulus, Ψ , was calculated on the interior surface elements of the SCL, and a percentage of the available surface area exceeding 60 MPa (predicting bone formation) was calculated. Peak strain values were also calculated.

Effect of Screw Compression: For all models with a transcondylar lag screw, a simplified screw (40 mm length and 4.5 mm diameter cylinder, $E = 200$ GPa) was constructed with a 6 mm head and tapered at the axial end. The head was constrained by contact with the outside of the bone and the tip was tied to the bone. Screw compression of 0 N, 75 N, 150 N, and 300 N was applied axially to simulate tightening.

Effect of Daily Cycles (steps during rehabilitation): This study also investigated the effects of increasing the number of steps, cycles per day (cpd), by adjusting n_i in Equation 2. Three n_i values were chosen as 750, 3000, and 6000 cycles per day.

Effect of Joint Load: Three different magnitudes of load were placed on the proximal femur to simulate joint load during different activities. Pure stall confinement was estimated to be 900 N, 1800 N corresponded to hand-walking loads, and 3000 N was used for light exercise. These three joint loads capture post-surgery activity for the first few weeks to months.

Effect of Screw Placement: Screws were placed from abaxial to axial in the MFC (i.e. from medial surface toward central femur). Three screw placements were tested: a proximodistal oblique transcondylar (PDO) screw that passed through the central void, a proximal horizontal screw that intersected the proximal aspect of the void (PH), and a distal horizontal screw through the central cavity of the void (DH).

RESULTS

As expected, increasing joint load, screw compression or steps per day all increased the predicted bone formation area (BFA, Table 1). Under no conditions did strains approach yield. More interesting were the results for screw placement, which indicate that the proximal horizontal screw is less effective in developing BFA and does not substantially change the principal stress directions (Figure 1).

Table 1: Predicted bone formation area (BFA) as a percent of void surface area at 3000 N joint load with increasing levels of screw compression and daily cycles (steps).

3000 N load			
Model	BFA% 750 cycles	BFA% 3000 cycles	BFA% 6000 cycles
Void only	5	19	31
Void/PDO hole	20	53	66
Void/SSS 0 N	24	59	72
Void/SSS 75 N	30	63	75
Void/SSS 150 N	37	68	78
Void/SSS 300 N	50	76	84

Figure 1. Top: Surface stimulus with an 1800 N joint load, 300 N stainless lag screw compression, and 3000 cpd for three screw placements. Bottom: Corresponding third principal stress vectors for bone immediately around the void. L=lateral, M=medial.

DISCUSSION

The transcondylar screw treatment of MFC SBC focuses on altering the biomechanical environment of the SBC to promote bone healing. The changes in bone stress stimulus and the reorientation of principle stresses caused by the transcondylar screw in this model suggests that the screw alters the mechanical environment to promote healing. As expected, increasing the lag screw compression, the loading cycles per day, and the joint loading all increase the stress stimulus, but only the lag screw compression reorients the principal stresses. The results of the screw placement comparison are consistent with clinical observations of poor bone healing after placement of a proximal horizontal lag screw.

There are a number of limitations to this study. All configurations tested were variations of a single finite element model based on a single healthy stifle joint. The SBC shape and the sclerotic region were idealized to match what is commonly seen clinically. The joint loading was estimated, as there are no kinetic data for the equine stifle. Also, the bone remodeling theory framework is based on limited samples that do not include equine data. While absolute values may be questioned, the relative values of stress stimulus and the reorientation of compressive principal stress clearly indicate the relative effectiveness of the lag screw treatment versus conservative treatment.

The results from this computational study support the use of a proximodistal oblique transcondylar lag screw to treat SBCs in the equine MFC and indicate the mechanisms that promote bone formation.

A GENERALIZED FRAMEWORK FOR OBJECTIVE DETERMINATION OF FUNCTIONAL MUSCULOSKELETAL JOINT COORDINATE SYSTEMS

Tara F. Nagle (1), Ahmet Erdemir (2), Robb W. Colbrunn (1)

INTRODUCTION

In biomechanics research, local coordinate systems (CS) of bones are typically defined based on anatomical landmarks. While using anatomical landmarks is a convenient approach for defining local CSs, it is sensitive to the variability in properly locating the landmarks. This variability is caused by excess soft tissue, the existence of osteophytes and other abnormalities, and the characterization of landmarks as contoured surfaces; not discrete points. Variability in collecting anatomical landmarks can result in vastly different CS definitions, and different kinematic representations of joint motion [1]. Even if landmarks are properly identified, it is not guaranteed that the CSs would be optimally aligned with the mechanical axes of the joint.

The aim of this study was to establish a generalized linear least squares (LLS) optimization approach to calculate the functional CSs of bones belonging to any joint utilizing a three-cylindrical joint kinematic chain decomposition method, from motion data.

METHODS

Optimization Method

a. Data Collection

The generalized framework for calculating functional CSs requires the collection of two low-resistance motion profiles; 1A) rotation about the axis fixed on the Base Reference Frame (BRF) and 2A) rotation about the axis fixed on the Relative Reference Frame (RRF).

b. Optimizing Coordinate System Origins

Kinematic data collected from motion profiles 1A and 2A can be used to redefine origins using the LLS optimization approach for calculating the hip origin established by Piazza et.al [2]. Collected kinematics should be recalculated using the redefined CS origins resulting in motion profiles 1B and 2B, respectively.

c. Optimizing Base Reference Frame Orientation

Transformed kinematic data from the first motion profile (1B) can be used in a LLS optimization for calculating respective axes on the two bones that are best aligned throughout the motion.

The change in orientation for the BRF and RRF can be reduced to orientation changes to the fixed Base axis (θ_1, θ_2) and its respective axis on the RRF (φ_1, φ_2), which are the metrics to be calculated.

The orientation of the axis of interest in the BRF ($B_{r_{xa}}, B_{r_{ya}}, B_{r_{za}}$) and RRF ($R_{r_{xa}}, R_{r_{ya}}, R_{r_{za}}$) can be determined using a LLS optimization, where a is the axis of interest (x, y , or z). The square of the difference between the a axes belonging to the BRF and RRF for each samples shall be calculated and the total error differentiated with respect to components of x , ($B_{r_{xa}}, B_{r_{ya}}, B_{r_{za}}, R_{r_{xa}}, R_{r_{ya}}$ and $R_{r_{za}}$), yielding Equation 1 when set to zero, where A is a symmetric 6 x 6 matrix.

$$Ax = 0 \quad (1)$$

Because Equation 1 is not solvable for $x \neq 0$, the following can be used where x is an eigenvector of A corresponding with the smallest eigenvalue, λ .

$$Ax = \lambda x \Rightarrow 0 \quad (2)$$

Once x is solved, it must be scaled so that the vectors $[B_{r_{xa}} \ B_{r_{ya}} \ B_{r_{za}}]$ and $[R_{r_{xa}} \ R_{r_{ya}} \ R_{r_{za}}]$ are unit vectors. The change in orientation for the BRF and RRF can be described using rotation matrices, R_B and R_R , as a function of $(\theta_x, \theta_y, \theta_z)$ and $(\varphi_x, \varphi_y, \varphi_z)$, respectively. Depending on the axis of interest, (θ_1, θ_2) and (φ_1, φ_2) can be calculated as Euler angles from the R_B and R_R definitions.

Collected kinematics should be recalculated using the redefined CS orientations resulting in motion profiles 1C and 2C, respectively.

d. Optimizing Relative Reference Frame Orientation

The LLS optimization method used for optimizing the BRF orientation can also be used for redefining the orientation of the RRF. Transformed kinematic data from the second motion profile (2c) should be used and the methods should be followed in the same manner, but with the axis of interest being that of the fixed RRF. Collected kinematics should be recalculated using the redefined Relative CS orientation resulting in motion profiles 1D and 2D, respectively.

Experimental Methods

Twelve fresh-frozen, cadaveric leg specimens, femoral head to foot were procured (6 female, 6 male, age: 40-79, BMI: 20-30). Optotrak motion Tracking sensors (Northern Digital Inc., Waterloo, Canada) were secured to the tibia and femur. Five trained observers digitized anatomical landmarks on the leg. For testing purposes, two sets of anatomical CSs were established using the Grood & Suntay definition [3] for the tibia and femur from the collection of digitized points; average anatomical (AA) and median variance anatomical (MVA) CSs. The specimens were prepared for biomechanical testing on a simVITRO® Universal Musculoskeletal Simulator (Cleveland Clinic, Cleveland, OH).

Testing was performed using AA-CSs and MVA-CSs. The knee underwent a flexion/extension (FE) profile and internal/external rotation (IR/ER) profiles at 0°, 30°, 60° and 90° flexion.

The optimization method for redefining functional CSs was performed. Kinematic data collected from the FE and IR/ER profiles were used in the optimization as motion profiles 1A and 2A, respectively. Because the IR/ER profile was performed four times, at four different flexion angles, the unit vector redefining the tibia IR axis ($[R_{r_{xa}} \ R_{r_{ya}} \ R_{r_{za}}]$) was calculated at each flexion angle, averaged, and scaled back to a unit vector.

Analysis Methods

The convergence of the two functional (AF and MVF) CS sets to a common solution was measured in the form of reproducibility, where the resultant differences between the tibia origins and femur origins, and the angles between the femur FE axes and the tibia IR/ER axes were measured between the two sets. Reproducibility of the anatomical (AA and MVA) CSs were calculated as well for comparison. Paired, equal variance, 2-tailed *t* tests were performed to evaluate the reproducibility of anatomical CSs compared to functional CSs.

RESULTS

The CS reproducibility was significantly improved between the functional CS definitions compared to the anatomical (Figure 1).

Figure 1: Average CS reproducibility error between anatomical CSs (AA and MVA) and between functional CSs (AF and MVF).
* represents significant difference ($p < 0.05$)

The off-axis range of motion during discrete flexion decreased significantly for all degrees of freedom except superior when comparing kinematics calculated from the AF-CS and AA-CS sets (Figure 2).

Figure 2: Average off-axis range of motion for FE profiles measured using the AA and recalculated using the AF CS sets. Shaded region represents one standard deviation amongst the twelve specimens.

DISCUSSION

In this study, a generalized framework was presented for objectively calculating functional CS definitions and the methodology was shown to be robust over 12 knee joints. Since the reproducibility in functional CSs is greater than in anatomical CSs, the use of functional CSs provides a more objective way for representing kinematic data so that it can be better compared amongst a population. Additionally, functional CSs could likely change as the joint is surgically altered, and these deviations might provide an important metric for evaluating surgical conditions.

This method was developed to be used on any joint utilizing the three-cylindrical joint kinematic chain decomposition method, and utilizes kinematic data of the joint moving through low resistance motion paths. This method is limited with joints like the hip or spine, where there are many possible low resistance motion paths, preventing this method from finding a singular solution.

INTRODUCTION

Upper extremity use depends largely on the elbow joint. The elbow serves as a link in the lever arm system that positions the hand, as a fulcrum of the forearm lever, and as a load-carrying joint. Because of the centrality of the elbow joint to the upper extremity, loss or diminished function of the elbow results in significant deficits in upper extremity function and loss of independence. Articular cartilage defects of the capitellum are typically seen in overhead athletes. These cartilage defects eventually cause pain, inability to compete at the desired level, functional impairment, and lead to osteoarthritis [1,2]. Treatment of osteochondritis dissecans (OCD) of the capitellum is often guided by the size, stability, and containment of the defect. The effects of altered cartilage stiffness at a typical OCD location has not been investigated. The objective of this study is to identify the influence of altered cartilage stiffness at a defect location on the magnitude and distribution of contact pressure in the elbow.

METHODS

A previously developed computational multibody model created from a cadaver specimen (61 years, male, right arm) was used in this study [3,4]. The model was created in ADAMS (MSC Software Corporation, Santa Ana, CA) using three-dimensional bone and cartilage geometries segmented from CT and MRI images using 3D Slicer (www.slicer.org). The model included three bundles for the lateral ulnar collateral ligament (LUCL), three bundles for the radial collateral ligament (RCL), three bundles for the anterior band of the medial collateral ligament (MCL), three bundles for the posterior band of the MCL, and two bundles for the annular ligament. All ligaments were modeled as non-linear force elements that included the “toe” region [3,4,5]. The humeral cartilage was divided into discrete hexahedral rigid bodies with a 3 x 3 mm cross-sectional area. Each

discrete cartilage body was rigidly fixed to the humerus and a contact constraint was defined between each humerus cartilage body and the radius and ulna cartilage geometries (equation 1).

$$F_c = k_c \delta^n + B_c(\delta) \dot{\delta} \quad (1)$$

Where F_c is the contact force, k_c is the contact stiffness, δ is the interpenetration of the geometries, n is a power exponent, $\dot{\delta}$ is the velocity of the interpenetration, and B_c is a damping coefficient. The model is shown in figure 1.

Figure 1: Elbow model with discrete cartilage.

Contact parameters were determined by optimization to a validated finite element model [6]. The initial contact stiffness was set at 40 N/mm. A humerus cartilage defect of 10mm diameter was created at the center of the capitellum at a 45 deg angle from the humeral axis. Three cartilage conditions were studied, no defect (ND), defect contact

stiffness 10 times higher than normal (HD) simulating a treated OCD lesion with microfracture resulting in fibrocartilage formation, and contact stiffness 10 times lower than normal (SD) simulating an untreated OCD lesion. For each cartilage scenario two conditions were simulated; a static simulation with the elbow in full pronation and fixed at 20 deg flexion with a compressive load of 377N on the humerus and a dynamic simulation of full flexion-extension of the elbow joint.

RESULTS

Under static loading, the SD condition resulted in an increase in contact area from 675 mm² to 702 mm² with no change in the maximum contact pressure. The HD condition increased the maximum contact pressure from 3.7MPa to 11.4MPa but did not result in any change of the contact area (figure 2). Both the SD and HD conditions increased the contact area on the medial humerus cartilage (trochlea) side with the HD condition causing a decrease in the maximum contact pressure on the trochlea from 3.7MPa to 2.1MPa (figure 3).

Figure 2: Contact pressure under static load. ND condition (a), SD condition (b), HD condition (c).

Figure 3: Ulno-humeral contact pressure under static load. ND condition (a), SD condition (b), HD condition (c).

Figure 4: Contact pressure during dynamic simulation (90 deg flexion shown). ND condition (a), SD condition (b), HD condition (c). For all the figures, the top of the figure corresponds to the posterior side of the humeral cartilage, bottom of the figure corresponds to the anterior side. Left is lateral (radius contact) and right is medial (ulna contact).

During flexion/extension the lower cartilage stiffness condition at the defect side, (SD) resulted in an increase in the contact area on the capitellum whereas the higher cartilage condition, (HD) caused a decrease. In terms of contact pressure on the capitellum, both altered stiffness conditions resulted in an increase of contact pressure (figure 4). Table 1 shows these results at a flexion angle of 90 deg.

Table 1: Contact pressure and contact area on the radial side at 90 flexion.

Contact Area (mm ²)			Contact Pressure (MPa)		
ND	SD	HD	ND	SD	HD
117	189	108	5.3	7.0	8.9

DISCUSSION

The purpose of this study was to investigate the influence of changes in the contact stiffness of humeral cartilage at the capitellum on the humero-ulna and humero-radial joint under static and dynamic conditions.

A decrease in the contact stiffness resulted in an increase of the contact area under all conditions without an increase in contact pressure. A higher contact stiffness at the defect side did not alter the contact area over the whole elbow joint but caused an increase on the trochlea. This in turn caused a decrease in contact pressure in the medial humerus cartilage with an accompanied large increase of contact pressure on the capitellum. Under dynamic conditions both softening and hardening of the cartilage at the defect side caused an increase in the contact pressure at the capitellum.

These results suggest that changes in the contact stiffness affect the pressure distribution both on the ulno-humerus and radio-humerus articulations. These changes may alter the mechanical response of the joint and predispose the elbow to degenerative changes ultimately leading to osteoarthritis.

The results of the current study are very limited because all simulations were done on one cadaver-derived model and only under full pronation conditions. Further studies on the effects of cartilage mechanical properties and defect locations throughout the whole envelope of elbow motion are needed.

ACKNOWLEDGEMENTS

INTRODUCTION

Insight into iris biomechanics plays an important role in understanding the pathophysiology of primary angle-closure glaucoma (PACG). Since abnormality in the iris and its interference with aqueous humor flow are established contributing factors in the closure or narrowing of the anterior chamber angle (e.g. via pupillary block), the iris has been studied extensively in the context of PACG [1].

Major component of the iris stroma are the striated collagen fibrils which provides support while undergoing continuous large mechanical deformation [2]. It is, however, unclear how regulation of these collagen fiber synthesis in an iris stroma relate to the iris stiffness. In general, cells sense and respond to changes in their surroundings by relaying signals to the nucleus. When stromal cells are subjected to mechanical stimuli in the micro-environment, the cytoskeleton of the cell exerts mechanical stresses on the nucleus. As a result, the shape of the nucleus is altered. This nuclear alteration results in the functional and morphological alteration of the cells [3].

We are able to predict changes in the microenvironment under different macro-scale loading for other soft tissues using our multiscale computational framework [4]. This approach links the volume-averaged stress in micrometer-scale representative volume elements (RVEs) to a macro-scale (millimeter-scale) FE continuum. In this study, for the first time, we characterize porcine iris tissue using our multiscale model and further investigate the stromal cell deformation in association with the collagen fiber reorientation, which is currently unknown.

METHODS

Whitcomb et al. (2009) [5] published uniaxial test data for both intact iris and excised iris sections in radial and azimuthal directions. We employed the uniaxial tension test data from the excised iris in the radial direction as a reference in order to fit the multiscale model

response and obtain its parameters. A three-dimensional finite element model of the sample was generated and meshed with 330 elements using Abaqus (Dassault Systèmes, Vélizy-Villacoublay, France). For the current study, we assumed isotropic fiber networks with anisotropy index $\alpha = 10\%$ and preferred fiber direction $\mu = 0^\circ$, throughout the sample. The mathematical definitions of the anisotropy index and preferred fiber direction are provided in our previous publications [6]. Strain of $\sim 15\%$ was applied to the model by simulating displacement boundary conditions uniaxially on the boundary nodes of the sample.

Figure 1: An ellipsoidal geometry was assumed for the cell nucleus [7]. The nuclear aspect ratio (NAR) was defined as the ratio of the largest to the smallest length of semi axes.

For our study, we considered the nuclear aspect ratio (NAR) as a measure to quantify cellular deformation (Fig. 1). To obtain NAR, DAPI-stained image stacks were used to reconstruct surfaces of the nuclei using a voxel-based 3-D image processor. Images were then segmented using ImageJ and the average NAR of the 3D reconstructed nuclei was measured. Based on the obtained images, an average initial NAR of 2.0 was considered for this study. An ellipsoidal geometry was assumed for the cell nucleus based on other studies in the literature [7]. The equation $(\mathbf{x}-\mathbf{x}_0)^T \mathbf{A} (\mathbf{x}-\mathbf{x}_0)$, where \mathbf{x}_0 is the coordinate of the center, \mathbf{A} can be written as \mathbf{QDQ}^T , where \mathbf{Q} is a symmetric matrix whose columns represent the principal axes of the ellipsoid and \mathbf{D} is the diagonal matrix with squared inverses of the length of the semi-axes along the diagonal elements, was used to construct the nucleus geometry. The NAR was defined as the ratio of the largest to the smallest eigenvalue of \mathbf{A} .

RESULTS

Figure 2a shows the deformed profile of the FE model in the final step of the uniaxial stretch simulation. The multiscale model fitted the uniaxial test data with R^2 value of 82 %. The model fitting parameters for the iris are as follows: shear modulus $-G = 3.5$ kPa, threshold fiber stretch ratio $-\lambda_c = 1.01$, fiber modulus $-E_f = 4.5$ kPa and parameter that governs the nonlinearity of the response $-\beta = 1.0$ (Fig. 2b).

Figure 2: (a) Deformed Configuration of the FE model under uniaxial stretch. (b) Multiscale model response after fitting the model parameters to the experimental data for the uniaxial extension of a porcine iris specimen ($R^2 = 82\%$).

The nucleus was initially assumed to be along the main fiber direction. Figure 3 shows the deformed configuration of the fiber

network chosen from the boundary element plotted with the deformed configuration of the nucleus. The NAR of the deformed nucleus was 1.9.

Figure 3: RVE with a 3D ellipsoidal geometry of the nucleus (in red) in the deformed state with the surrounding ECM collagen fiber network (in green)

DISCUSSION

Cellular configuration linked with ECM fiber architecture vary nonlinearly in response to tissue level stresses. From Fig. 3, it can be observed that nucleus deforms and realigns in association with the surrounding ECM fiber network in response to the mechanical loading. Cell level deformations are influenced through complex micro-mechanical interactions that occur within physiological conditions, imparting altered stress levels on the nucleus due to changes in the cell cytoskeleton, which affects an array of cell functions. Gene expression and protein synthesis has been associated directly to certain optimal change in nuclear shape [8].

We investigate nuclear deformation in stromal cells, which is an important factor in mechanical regulation of genome and gene expression. While recent studies show that ECM collagen I content increases in PACG irides, it is unclear how regulation of collagen synthesis in iris stroma relates to the iris stiffness. Although there is considerable understanding of relationship between mechanical stimulation on cellular processes, identifying specific mechanisms responsible for vital physiological phenomenon remains poorly understood. Our multi-scale modelling approach can provide insight into complex cell-matrix interactions which can aid in identifying such specific mechanisms.

INTRODUCTION

Glaucoma refers to a group of neuronal degenerative disease that damage the retinal ganglion cells (RGCs) at the optic nerve and leads to irreversible vision loss. The most common type, primary open angle glaucoma (POAG), is the second leading cause of blindness, and it is expected to affect 110 million people worldwide by 2040 [1-3]. In the US, the disease is more prevalent in African descent (AD) and Hispanic ethnicity (HE) when compared to European descent (ED) [4-6]. While the risk factors include ocular hypertension, age, elevated intraocular pressure (IOP) and ethnicity, there is sufficient evidence to suggest that differences in the biomechanical properties of the optic nerve head between these racial and ethnic groups contribute to this increased risk [7-8].

The optic nerve head (ONH) contains the lamina cribrosa (LC) which is a porous collagenous disc that undergoes significant remodeling in the presence of POAG [9-10]. The LC and the posterior sclera play a critical mechanical role in protecting RGC axons as they exit the eye through the ONH. Although there are several studies showing that eyes of AD and HE donors exhibit LC microstructure and biomechanical response that are significantly different than ED [11- 13], the correlation between the LC biomechanical response and RGC axonal health across racioethnic groups has not been studied. Therefore, the purpose of this study is to investigate correlation between the axon count and the LC strain response in non-glaucomatous samples across the racioethnic groups.

METHODS

Nine non-glaucomatous human donor samples (n=3 from the racioethnic groups: AD, ED and HE) were used for this study. Pressure inflation experiments were conducted on each donor LC at 5, 15, 30 and 45 mmHg while simultaneously collecting 3D images using a multiphoton microscope. A maximum intensity projection from second harmonic generation (SHG) is shown in Figure 1. Digital volume correlation (DVC) algorithm was used to generate 3D displacement fields [14]. These DVC results were used to calculate the Green strain components.

Figure 1: Representative mean intensity projection of the collagen (SHG) in a human LC

In addition, embedded optic nerve cross sections of the same nine samples were visualized on a Nikon Eclipse 90i microscope using a montage method with Nikon NIS-Elements software. The method used individually imaged 60X magnifications with autofocus capabilities and a 15% overlap. A montage of an axon cross section of one of the samples is shown in Figure 2. Axon counts were quantified using an established and validated semi-automated axon counting software [15]. Statistical analysis was done using Pearson correlation to study the relationship between LC strain and axon counts.

Figure 2: Microscope image of full optic nerve cross section. Dark sections indicate bundles of axons separated by lighter connective tissue. Scale bar denotes 500 microns.

RESULTS

Figure 3 shows the axons counts in the racioethnic groups. There were no significant differences in axon counts across race ($p=0.54$). The mean axon counts were $2.71 \times 10^5 + 8.9 \times 10^4$ for AD ($n=3$), $4.73 \times 10^5 + 3.2 \times 10^5$ for ED ($n=3$) and $2.96 \times 10^5 + 2.2 \times 10^5$ for HE ($n=3$).

Figure 3: Axon counts across the racioethnic groups.

In addition, in the first and second pressure levels, the LC strain showed correlation to the axon count. Pearson's correlation coefficient between Peak of XY strain and axon counts were $\rho=0.72$ ($p=0.03$) and $\rho=0.67$ ($p=0.051$) at 15mmHg and 30 mmHg, respectively. The p-value tested the hypothesis of no correlation against the alternative hypothesis of a nonzero correlation. Figure 4 shows this correlation at 15mmHg.

Figure 4: Correlation of axon counts to peak of XY strain at 15 mmHg ($\rho = 0.72$, $p=0.03$)

DISCUSSION

The ED group showed the biggest number of axons as compared to the other two groups. Although, axon counts across races were not significantly different in our study, the AD and HE groups showed lower count of axons. As the death of RGCs is associated with progression of glaucoma, with AD and HE groups (which are at a higher risk for POAG) showing lower axon counts may be related to the development and progression of the disease.

In addition, the correlation between the shear strain XY peak and axons may contribute to mechanisms of glaucoma. Previous work done in our laboratory showed that AD had a higher strain in XY peak than ED. Higher number of axons may assist the LC from straining significantly.

On the other hand, it should be noted that only 9 samples were studied in this work. Since the number of samples is small, future study will include additional samples (both glaucomatous and non-glaucomatous) in each racioethnic group to get a better understanding of the subject. In conclusion, the results of this study showed significant correlation between the shear strain in the LC with the axons present in the optic nerve.

TENSILE BEHAVIOR OF ANTERIOR AND POSTERIOR CORNEAL FLAPS SUBJECTED TO CXL TREATMENT PROCEDURE

Hamed Hatami-Marbini

Email: hatami@uic.edu

INTRODUCTION

Keratoconus is an eye disease that causes the cornea to become conical in shape. One of the treatment option to prevent the progression of this disease is corneal collagen cross-linking (CXL). In CXL, the photosensitizer riboflavin solution and ultraviolet A light (UVA) are used to create additional crosslinks in the corneal stroma [1]. These crosslinks have been shown to result in significant improvement of corneal mechanical properties.

The mechanical properties of the cornea are mainly from its extracellular matrix. The corneal extracellular matrix is composed of collagen fibers embedded in a proteoglycan matrix. The collagen fibers form sheet like structures, which are called lamellae. The composition of the collagen lamellae through the thickness of the cornea shows significant variation. In particular, anterior layers are composed of interwoven collagen lamellae while the posterior part of the cornea is composed of parallel collagen lamellae [2].

The CXL treatment has an effective crosslinking depth of a little more than about half of the thickness of the cornea. This depth has been recommended to avoid the toxic effects of UV light on the endothelium layer and other internal components of the ocular globe. There has been previous efforts in the literature in order to increase the depth of crosslinking with the hope of enhancing the stiffening effect of CXL procedure in patients. The primary objective of the present study is to determine the effects of the inhomogeneous microstructure of the cornea on the outcome of the crosslinking procedure. In other words, the present work assesses whether crosslinking the posterior part of the cornea has the same efficacy as crosslinking its anterior portion.

METHODS

Porcine eyes were obtained from a local abattoir. The corneal disks of about 800 μm were divided into anterior and posterior flaps of almost

equal thickness using a DSEAK system, Figure 1. From the flaps, corneal strips were prepared and soaked in the riboflavin solution for 30 minutes. The samples were then crosslinked following the Dresden protocol, i.e. they were subjected to a UVA irradiance of $3 \text{ mW}/\text{cm}^2$ for 30 minutes with continuous application of riboflavin solution to the strips during the crosslinking time [1]. Crosslinked specimens were tested in tension using a DMA machine (TA instruments, Maryland) at displacement rate of $2 \text{ mm}/\text{min}$. The same experiments were done on similar samples (control group), which were not crosslinked. The specimens in control group were subjected to similar treatment procedure with the difference that the UV light was turned off during the CXL treatment. The stress-strain curves for the samples in the control and treatment groups were compared together in order to determine the relation of CXL and microstructure of collagen fibers on improving the corneal biomechanical behavior.

Figure 1: From corneal samples, an anterior and posterior flaps were dissected using a DSEAK system.

RESULTS

Figures 2-4 show the tensile stress-strain behavior of anterior and posterior samples from the control and treated groups. It is observed that the flaps from the anterior part of the cornea had a much stronger tensile properties compared to those of the samples from the posterior part, Figure 2. Furthermore, it is seen that the CXL treatment significantly improved the mechanical response of anterior flaps, Figure 3. However, it had an insignificant effect on the tensile response of the posterior samples, Figure 4.

Figure 2: The tensile stress-strain response of the posterior and anterior flaps excised from the porcine cornea.

Figure 3: The effect of corneal crosslinking procedure on the tensile stress-strain response of the anterior flaps excised from the porcine cornea.

DISCUSSION

The present study compared the effects of CXL treatment on improving the tensile behavior of corneal flaps obtained from the posterior and anterior part of the cornea. The anterior flaps from the control group showed a stronger tensile properties compared to the posterior flaps, Figure 2. This finding is in agreement with previous studies [3] and is because the collagen lamellae in anterior part of the cornea are interweaved while they lie in parallel arrays in the posterior part. The interweaving of the collagen lamellae in anterior flaps induces stronger resistance to tensile force. The CXL procedure enhanced significantly

the tensile behavior of anterior flaps, Figure 3. This result is also in line with general consensus in the field, i.e. the CXL treatment causes enhancement of the mechanical properties of the cornea [1,4-6]. The unexpected result is that the CXL procedure did not significantly affect the mechanical response of the posterior flaps, Figure 4. This confirms that the architecture of collagen lamellae plays an important role in the efficacy of the corneal crosslinking treatment [6]. It is noted that the depth of crosslinking in normal corneas is often limited to the top portion of the corneal thickness in order to limit the toxic effects of UV radiations on the endothelial cells. Nevertheless, the normal architecture of the corneal lamellae are expected to be disturbed because of the keratoconus disease. Thus, it is important that clinicians pay extra attention to the important role of the collagen architecture whenever they decide to use the CXL procedure for arresting the progression of this disease.

INTRODUCTION

Glaucoma is the leading cause of irreversible blindness worldwide, and is characterized by progressive damage and loss of retinal ganglion cells (RGCs), resulting in visual field loss. While glaucoma can occur at any level of intraocular pressure (IOP), elevated IOP is a known risk factor¹. All current glaucoma treatments seek to reduce IOP, which reduces the progression of vision loss. However, a significant fraction of glaucoma patients present with normal IOPs^{2,3}, and it is thus widely recognized that additional risk factors remain.

The mechanisms by which elevated IOP result in RGC death are not well understood. Under elevated IOP, the optic nerve head (ONH) tissues experience abnormally high deformations, which are thought to play a major role in RGC damage. Modeling has shown that scleral stiffness plays a major role in modulating ONH deformation⁴. Recent animal and clinical data have also indicated that scleral stiffening may reduce susceptibility to glaucomatous damage^{5,6}. *Therefore, we hypothesize that low scleral stiffness is a risk factor for glaucoma.* We aim to identify the genes that control scleral stiffness.

Ocular compliance (OC), ϕ , is defined as $\phi = dV/dP$, where V is ocular volume and P is IOP, and reflects corneoscleral mechanical properties. Thus, OC can be used as an indicator of scleral stiffness. We expect the genomic loci associated with OC and scleral stiffness to significantly overlap. The BXD mouse set, comprising over 100 fully mapped, inbred substrains and fully sequenced parent strains, is a powerful tool for quantitative trait locus (QTL) analysis, and specifically for the identification of candidate genes modulating OC.

Here we identify a genomic locus modulating OC using the BXD mouse set. Our initial data indicates that differences in OC can be detected between BXD mouse strains and a significant QTL was identified on chromosome 11 (chr11). Within this locus we have identified 5 candidate genes: 3 genes with nonsynonymous single

nucleotide polymorphisms (SNPs) expected to disrupt protein function (Gm11939, Keratin 40, and Keratin 33b) and 2 genes that are cis-eQTLs (Smarce1 and Tensin 4).

METHODS

We measured OC using iPerfusion⁷. Following cannulation of enucleated mouse eyes, an adjustable pressure reservoir was used to apply a series of pressure steps (6.5 to 23 mmHg, range of reported IOP in BXD mice) to the eye, and the resulting flow rate into the eye was recorded. Pressure and flow data were analyzed by a Discrete Volume method, in which integration of flow traces, with adjustment for outflow, gives the change in volume of the eye following each pressure step, from which compliance was calculated. Pressure vs. compliance data were fit with the semi-empirical relationship:

$$\phi(P) = \phi_r \left(\frac{P_r \phi_r + \gamma}{P + \gamma} \right) \quad (1)$$

where ϕ_r is the reference compliance at reference pressure P_r , and γ is a nonlinearity parameter. ϕ_r was calculated at a reference pressure of 13 mmHg, the normal IOP of C57BL/6J mice.

Currently, we have evaluated OC in C57BL/6J (B6), DBA/2J (D2), and 14 BXD strains (n = 147, 4-16 mice per strain, male & female, ages 77-100 days). Mean OC values, normalized by eye volume, and standard errors for each strain were entered into GeneNetwork, a group of open access databases and software available for the study of gene and molecular networks, along with phenotypes. Detailed statistical and analytical methods employed by these tools are available at genenetwork.org. Candidate genes were identified within the significant QTL by assessing for SNPs, high whole-eye mRNA expression, and potential linkage to matrix or cytoskeletal mechanics as supported by the literature.

RESULTS

Compliance was successfully measured for 147 pairs of eyes using iPerfusion. From each pair, the eye with the lower uncertainty on ϕ_r was included in the strain data set. As OC is dependent on the initial volume of the eye, ϕ_r was normalized by the eye volume (Fig. 1). Eyes were weighed prior to cannulation and eye density⁸ was used to estimate volume. Error bars indicate the 95% confidence interval on the mean. After normalization, we observed significant differences in OC between some strains (ANOVA, $p < 0.0001$). However, we note that significant differences between all strains are not required to effectively identify a QTL.

Figure 1: Mean, normalized compliance for BXD strains

The genome-wide map (Fig. 2) generated from the data shown in Fig. 1 shows a significant peak on chromosome 11. The blue line indicates the total likelihood ratio statistic, a measure of the linkage between differences in traits and genotype markers. The pink and grey horizontal lines mark the threshold for significant and “suggestive” peaks, respectively. The red and green lines reflect the contributions of the B6 and D2 alleles, respectively.

Figure 2: Interval map of volume-normalized compliance across all chromosomes

The significant peak on chr11 (Fig. 3) was bounded by the genomic markers rs29445436 (98.9 Mb) and rs27058443 (99.8 Mb). The positive additive coefficient for the D2 alleles (green line in LRS plot) indicates that D2 alleles increase normalized OC values. In the haplotype map shown in the upper portion of Fig. 3, it can also be seen that D2 (green) and B6 (red) alleles segregate around this genetic locus and that B6 alleles correspond to lower normalized OC.

Figure 3: Haplotype map for the 16 evaluated BXD strains and map of gene locations across a subsection of chr 11.

Considering that the BXD genotyping density allows for mapping with a precision of approximately ± 1 Mb, we searched the 97.9 to 100.8 Mb region of chr11 for candidate genes involved in the regulation of OC. Tns4 and Smarce1 were identified as cis-eQTLs (i.e. their expression segregates with the parental alleles, and the genes driving the mRNA expression are located within the same region as the compliance QTL). Within this region there were also three genes with disruptive nonsynonymous SNPs (Gm11939, Krt40, and Krt33b).

DISCUSSION

We have developed methods to measure OC in mice with sufficient resolution to record significant differences between many genetic strains of mice. Our present data set has enabled the identification of five genes: Gm11939, Krt40, Krt33b, Tns4 and Smarce1, which may be involved in the modulation of corneoscleral mechanical properties. Keratins (Krt) are cytoskeletal and/or extracellular matrix proteins expressed in the eye. Tensins (Tns) are known to interact with actin filaments and β integrins in focal adhesions. In turn, how cells interact with and sense their matrix can influence gene expression and subsequently the regulation of the extracellular matrix composition. Meanwhile, Smarce1 (SWI/SNF Related, Matrix Associated, Actin Dependent Regulator of Chromatin) produces a subunit of SWI/SNF complexes, which are involved in chromatin remodeling. Future work will look for correlations between Smarce1 and extracellular matrix gene expression. The role of candidate genes in regulating corneoscleral mechanical properties remains to be evaluated.

A limitation of the current preliminary analysis is the small number of BXD strains used. Typically, robust QTL analysis is carried out with trait values from a minimum of 20 strains. Additional measurements may add and/or change the location of current significant peaks. We are continuing to evaluate additional BXD strains. Furthermore, we have been investigating alternate data analysis techniques and anticipate that better fitting of our current data will improve the precision of our OC measurements, and hence the power in the QTL analysis.

A challenge in the interpretation of our measurements is that OC reflects the mechanical behavior of the corneoscleral shell as a whole, and not the sclera alone. Direct tensile testing of mouse sclera mechanical properties is limited by tissue sample size. Additional studies relating corneal and scleral deformations using digital image correlation, as well as follow-up work to identify localization and tissue-specific changes in expression of candidate genes, are expected to yield complementary findings which will aid in data interpretation.

Thorough interrogation of the role of candidate genes in ocular mechanics, and/or successful identification of additional modulatory genes, will aid in the understanding of glaucoma pathogenesis, the identification of novel therapeutic targets, the identification of at-risk patients, and the possible development of a new mouse model for glaucoma research.

INTRODUCTION

Glaucoma is a blinding disease characterized by the progressive degeneration of retinal ganglion cell (RGC) axons at the optic nerve head (ONH), where axons exit the intraocular space, and remodeling of the ONH tissues [1]. In human, a connective tissue lamina cribrosa (LC) serves to structurally support the axons. The LC consists of a stack of cribriform plates that when viewed en face appears as a network of connective tissue beams and pores. The pores are spanned by astrocytes that guide the RGC axons as they pass through the ONH [2]. In rodent models, the lamina consists entirely of astrocytes with long processes that wrap around the axonal bundles [3] (Fig 1a). Wang et al. [4] showed that ONH astrocytes become reactive with increased intraocular pressure (IOP); and Nguyen et al. reported that ex vivo inflation response of the mouse astrocytic lamina was stiffer in eyes subjected to 3 days of IOP elevation *in vivo* [5]. Increase IOP is also associated with axonal degeneration and blockage of axonal transport in both human and in animal models [6]. Characterizing changes in astrocytic network that precedes the degeneration of axons is important for investigation of the mechanosensitive linkages.

Morphological changes in the astrocytes caused by changes in the mechanical environment have been investigated primarily through immunostaining of their intermediate filament, GFAP [7]. However, Tehrani et al. [8] showed in longitudinal mouse optic nerve sections that actin labeling revealed fine astrocytic processes that were not visible by GFAP immunostaining. The objective of this study is to quantitatively measure and compare the spatial distribution of GFAP and actin fiber networks in the astrocytic lamina of normal mouse eyes and those subjected to 3-day IOP elevation *in vivo*. Characterization of the actin cytoskeletal network will enhance understanding of the mechanobiological response of ONH astrocytes to sustained IOP elevation.

METHODS

Specimen Preparation: Four ONH segments were obtained from two 6-month old green fluorescent protein (GFP)-glutamate transporter-GLT1 transgenic mice, which express both GFP and glutamate transporter protein, GLT1 [9]. Elevated IOP were induced in the left eyes by injecting microspheres consisting of 2 μ L of 6- μ m diameter beads, 2 μ L of 1- μ m diameter beads and 1 μ L of viscoelastic compound (10 mg/mL sodium hyaluronate, Healon; Advanced Medical Optics, Inc.). The respective right eyes served as contralateral controls. The IOP was measured with a TonoLab rebound tonometer (TioLat Inc) before bead injection and before sacrificing. All mice were anesthetized after 72 hours of IOP elevation with 75/10/2 mg/kg of ketamine, xylazine and acepromazine respectively. The mice were perfused with 4% paraformaldehyde in Sorenson's phosphate buffer before enucleation. The globes were then immersed in the same fixative for an hour and were transferred into 0.1M PO₄ buffer, where the extraocular tissues were removed. ONH of 1mm length were separated from the posterior eye wall using a sharp razor blade. The optic nerve segments were cryopreserved and embedded in a mixture of 20% sucrose-buffer and OCT using a modified protocol from Barthel and Raymond [10]. The 1mm ONH segments were cryo-sectioned serially into 10 μ m slices using Cryostat CM3050S (Leica Biosystems) at -25 °C.

Immunostaining: Primary antibodies from rabbit against GFAP (1:1000, Abcam AB7260) and secondary antibodies from goat against rabbit (1:500, Invitrogen A11008) were used for GFAP labeling. ONH sections were also incubated with phalloidin (1:60, Invitrogen A1280) and DAPI (1:1000, Roche 10-236-276-001) for staining of actin filaments and nuclei respectively. All sections were mounted with Dako mounting media and covered with glass slide.

Image Acquisition: Confocal fluorescent images were obtained with a Zeiss LSM 710 confocal microscope using a Plan-Apochromat 40x objective. Three channels of images at excitation wavelength of 458nm for GFAP (Fig 1c), 561nm for actin (Fig 1e), and 405nm for nuclei were captured for each ONH section. Each channel consisted of 3 by 3 tiled images that were stitched with a 12% overlap (Fig 1a). The resulting images were exported as TIFF files for spatial characterization.

Characterizing GFAP and actin networks: Images were pre-processed with 2-D median filter and contrast-limited adaptive histogram equalization (CLAHE) to reduce noise and enhance contrast (Fig 1b). All three channels were individually binarized using Otsu thresholding method [11] followed by morphological dilation and erosion to segment the actin, GFAP and nucleus fluorescent regions. A lamina boundary was detected by tracing the outer boundary of the largest connected region in the binarized GFAP image. The boundary pixels were recorded and overlaid onto the contrast enhanced GFAP image to visually verify the accuracy of the segmentation (Fig 1b). The boundary segmentation was used to measure for each slice the (1) area of the astrocytic lamina, (2) the aspect ratio of the lamina, the (3) GFAP and (4) actin area fraction, and (5) the number of nuclei in the lamina. The aspect ratio was determined by fitting an ellipse to the boundary of lamina and calculating the ratio of the major to minor axes. The GFAP and actin area fraction were calculated as the total area of the GFAP (Fig 1d) and actin (Fig 1f) regions over the lamina area. The number of nuclei was determined by counting the number of regions with DAPI signal within the lamina. All image analyses were conducted in *Matlab R2017a*.

RESULTS AND DISCUSSION

The average area of the lamina of eyes subjected to 3-day IOP elevation in vivo was $0.057 \pm 0.007 \text{ mm}^2$, and the area of the lamina in the contralateral control eyes $0.053 \pm 0.001 \text{ mm}^2$. The lamina area for both groups increased with distance up to 400um from the retina. Previous measurements of the area of the astrocytic lamina ranged from $0.028\text{-}0.072 \text{ mm}^2$ in black Swiss mice [12].

The average GFAP area fraction across 4 eyes was $0.59 \pm 0.01 \mu\text{m}^2/\mu\text{m}^2$, whereas the average actin area fraction was $0.67 \pm 0.004 \mu\text{m}^2/\mu\text{m}^2$. The combined GFAP and actin area resulted in an average areal fraction of $0.82 \mu\text{m}^2/\mu\text{m}^2$. The area fraction of actin was on average 13.6% larger than the GFAP area fraction in all normal and contralateral hypertension eyes. The nucleus density was on average 2.86 ± 0.12 per $1000 \mu\text{m}^2$, which also falls in the range 0.9-12 per $1000 \mu\text{m}^2$ reported by Mabuchi et al. [12].

As a glial cell that expresses mechanosensitive channels, its actin coverage in transverse sections may provide insights to the astrocytic reactivity that have not been previously reported. The robust image processing program allowed for further analysis of actin rearrangements and investigation of non-actin labelled regions where axonal bundles reside. Further, the spatial arrangement of cytoskeletal network within the astrocytes and overall morphology of lamina may aid the development of computational model for the investigation of mechanical properties at the ONH. It is however important to note that while GFAP labeling is specific for optic nerve astrocytes, actin and DAPI labeling can include contributions from other cell types in the lamina, such as endothelial cells.

INTRODUCTION

Collagen fiber microstructure and orientation are important in soft tissue dynamics and are therefore of great interest to biomechanics [1]. Hence, several techniques have been developed to measure these collagen properties, such as polarized light microscopy (PLM) [2] and second harmonic generation (SHG) [3]. These techniques, while helpful for static and quasi-static conditions, lack the temporal and/or spatial resolution necessary to study soft tissue dynamics.

To facilitate the study of the role of collagen on the dynamic properties of soft tissues and their biomechanics, we developed a technique termed snapshot PLM. Snapshot PLM captures high resolution collagen fiber microstructure and orientation in a single full-field color-image. Requiring only a single image means that snapshot PLM imaging speed is limited only by the camera frame rate. Similarly, a single image also preserves optical resolution and ability to detect small details of the microstructure, not affected by the multi-frame post-processing. Our goal in this study was to introduce snapshot PLM, and to demonstrate its high spatial and temporal resolution when applied to both static and dynamic collagenous tissues.

METHODS

Snapshot PLM imaging system – The snapshot PLM imaging system was developed by retrofitting 2 sets of polarization components into a commercial upright microscope (Olympus IX-83) [4]. A broadband white LED light source was used for illumination and a 4X strain-free air objectives were used for imaging. The image/video acquisition was automated with cellSens, a commercial software from Olympus.

Color-based collagen analysis – We conducted numerical simulations to evaluate the imaging characteristics of snapshot PLM, and to establish the algorithm to extract collagen fiber orientation from the acquired image. The color was simulated over a range of fiber orientations (0-90 degrees) and tissue retardances (0.1-1.2 radians). The RGB color was converted to HSV color (Hue, Saturation, and Value) for analysis. We established the relationship of the hue and the fiber orientation. This relationship was verified experimentally using sections of chicken tendon imaged at various known orientation angles.

Ex-vivo tissue preparation, imaging and quantification – We stretched and imaged a chicken tendon section and a whole pig chordae tendineae to demonstrate the high spatial resolution (~1μm/pixel) and high temporal resolution (~10ms/frame), respectively, of snapshot PLM. Tendons are important force transmitting materials. Fresh chicken tendon was sectioned along the longitudinal fiber direction at a thickness of 30μm, and then stretched with a custom uniaxial stretcher. Chordae tendineae were chosen because they are highly dynamic during cardiac cycle, and therefore it is important to understand their dynamics and microstructure. Fresh porcine chordae tendineae (~400μm thick) was stretched by pulling manually with a tweezer during the imaging. Collagen fiber orientation during stretching was analyzed using circular statistics.

RESULTS

Color-based collagen analysis – The simulations showed a direct relationship between simulated color and collagen fiber orientation (Fig. 1a). At a given retardance, the hue and fiber orientation exhibited a unique and monotonic correlation (Fig. 1b). At a given fiber orientation, the hue is independent on the retardance. The experimental

chicken tendon verification also showed a monotonic relationship between the hue and fiber orientation, similar to that shown in Fig. 1b. Based on this curve, we developed an empirical color/angle conversion algorithm to retrieve the collagen fiber orientation.

Figure 1 (a) Simulated RGB colors over a wide range of collagen fiber orientation and retardance; (b) a monotonic relationship between the hue and the fiber orientation means that there is a unique orientation at each retardance value.

Ex-vivo tissue imaging and quantification –The chicken tendon section was directly imaged with a 4X objective and the only post-processing applied to the images shown in Fig. 2 was cropping. The high resolution of snapshot PLM revealed sub-bundle details of the tendon section (Fig. 2c). Fig. 2b shows highly complex fiber deformation traces computed using DIC. Fig. 2c shows the time sequence of the uncrimping process of a crimped region (white box in Fig. 2a). After applying 16.7% stretching along the longitudinal fiber direction, collagen fibers became highly aligned with preferred fiber orientation around 5 degrees, and the standard deviation decreased from 21.3 degrees to 4.1 degrees.

Figure 2 A 30μm-thick chicken tendon section stretched and imaged at 60 frames/second under 16.7% stretch. (a) Collagen fibers show clear crimp before stretching; (b) fiber deformation traces from DIC; (c) time-resolved uncrimping process.

The pig heart chordae tendineae uniaxial stretching was imaged at a frame rate of 156 frames/second with a 4X objective, resulting in an imaging speed of 6.5ms/frame. Snapshot PLM image revealed complex structure of the chordae tendineae, which appeared to have highly crimped collagenous structure in the core surrounded by less crimped structures as the cladding. This observation is consistent with previously reported structure of the chordae tendineae of pig mitral valves [5]. Upon applying 8.7% stretching, the fast imaging revealed

the uncrimping process (Fig. 3a-d). The uniform color in the close-up images shown in Fig.3e indicates that the central collagen core lost crimp quickly and became straight. Plotting the orientation along the chordae core (dashed-line in Fig. 3e) further demonstrated the uncrimping process (Fig. 3f). The quantitative angle analysis showed that the standard deviation of collagen fiber orientation decreased from 29.2 degrees to 5.1 degrees during the stretching, primarily from fiber uncrimping, and perhaps some reorientation. The outer layer did not show significant color change, which suggests that stretching imposed minimal structural changes in this region's collagen.

Figure 3 The pig heart chordae stretching imaged at 156 frames/second under 8.7% stretch. (a-d) Four stretching stages of the collagen core uncrimping indicated by color changes. White arrows in (a) indicate the stretching directions; (e) close-up images of the collagen core showing uncrimping; (f) plot of local orientation before and after stretching along the dashed line in (e).

DISCUSSION

We demonstrated that snapshot PLM is a fast and high-resolution imaging method, which is well-suited for real-time imaging collagenous tissues in both static and dynamic conditions. The high temporal resolution provides the opportunity to study the transient tissue deformations as well as deformations with complex trajectories that would have been missed with traditional slower imaging methods.

INTRODUCTION

While cadaveric models have been used to quantify the effect of injury and repair on knee mechanics, few models have captured the dynamics and contact mechanics of daily living activities. Previous cadaveric models could not dynamically control sufficient degrees of freedom [2-3] or simultaneously characterize knee kinematics and contact mechanics [4] and were most often run on complex customized machines. Confusion over the inputs required to best mimic human gait also exists and further complicated by the acceptance of two standardized sets of inputs – the ISO [5] and ASTM standards [6]. The ISO standard is an implant wear testing standard calculated from inverse dynamics gait studies of human subjects [7]. The newer ASTM standard, also intended for implant wear testing, is developed from direct load measurements from instrumented knee implants [8].

Our objectives were to: (i) develop a testing protocol to mimic walking using a commercially available six degree of freedom simulator and (ii) compare the contact mechanics and kinematics of human cadaveric knees subjected to ISO and ASTM inputs. We hypothesized that the inputs would have a significant effect on the distribution of contact forces across the knee joint.

METHODS

Following IRB approval, five intact, freshly frozen human cadaveric knees were stripped of bulk soft tissue and patella, leaving only the joint capsule. A Kirshner wire was drilled through the epicondylar axis of the femur under fluoroscopic guidance to assist with positioning during potting. Each knee was potted in full extension, such that the superior and epicondylar axes were aligned with the compression and flexion axes, respectively, of a six degree of freedom VIVO joint simulator (AMTI) and the tibial anterior axis was aligned with the anteroposterior axis of the simulator (Fig. 1). The knee was

compressed with a 1kN axial load within the simulator to imitate a static standing position. Each knee was subjected with both ASTM and ISO standard gait input waveforms for 60 cycles at 0.5Hz (Fig. 2).

Figure 1: A) A cadaveric knee fixed in a VIVO knee simulator (AMTI) with six degrees of freedom. B) ASTM (red) and ISO (blue) inputs for simulated gait. ASTM inputs were calculated assuming a 76kg bodyweight.

Femur and tibia motions were tracked using a motion capture analysis system (Motion Analysis Corporation, CA) with retroreflective markers attached to the fixtures. Knee joint kinematics were computed using bone-fixed coordinate systems, as defined by Grood and Suntay [9]. The femoral epicondyles and most medial and lateral points of the tibial plateau were manually digitized to define the femoral flexion axis and tibial mediolateral axis; the origins of both coordinate systems were defined as the midpoints of these axes. The femoral anteroposterior axis and tibial superior axis were defined as aligned with the simulator axes. *Tibia relative to femur rotations and translations were calculated*, using the 1kN standing position as the reference position.

Contact mechanics were directly measured using a Tekscan 4011 pressure sensor placed beneath the meniscus on the medial and lateral tibial plateau and sutured to the ACL and posterior joint capsule.

Data were averaged from cycles 55-59, then averaged across specimens. Results are shown for the stance phase of gait from heel strike to toe off (0-60% of the gait cycle). Differences between the resulting kinematics and contact mechanics from ASTM and ISO standard inputs were evaluated using a paired t-test at 0%, 4%, 8%, 14%, 20%, 45% and 60% of the gait cycle ($p < 0.05$).

RESULTS

Kinematics: Five knees were successfully tested with both ASTM and ISO gait input waveforms. Resulting joint kinematics were significantly different in early stance: ISO inputs resulted in higher tibial external rotation from 0-20% and a peak in tibial posterior translation at 8% of gait (Fig. 2). Knee joint kinematics were similar between the two standards from 20-60% of gait; while at 45% of gait ISO inputs resulted in higher external rotation. No differences were found between the resultant valgus rotations or medial and superior tibial translations of the ASTM and ISO standards. However, a higher variability in kinematics between specimens were measured with ISO inputs, particularly in anterior tibial translation.

Figure 2: ASTM (red) and ISO (blue) resulting kinematics (tibia relative to femur). * $p < 0.05$ between standard inputs

Contact Mechanics: Peak contact stresses were significantly higher at 4%, 14%, and 45% of gait with ISO standards compared to ASTM (Fig. 3A), corresponding to the compressive force inputs (Fig. 2B). No differences were found between the resultant total contact areas throughout stance. Qualitative changes in the location of contact across the tibial plateau reflect the differences in kinematics from the two standards. Specifically, the posterior tibial translation observed at 8% of gait shows a simultaneous anterior shift of weighted center of contact on the tibial plateau with ISO inputs compared to ASTM (Fig. 3B).

Figure 3: A) ASTM (red) and ISO (blue) resulting peak stress. * $p < 0.05$ between standard inputs B) Example contact maps at 8% gait cycle. Weighted centers of contact are marked with stars.

DISCUSSION

We successfully developed a protocol for the application of both ISO and ASTM gait standards to cadaveric knees, using a commercially available six degree of freedom test machine. Subtle differences in kinematics and contact mechanics were evident between ISO and ASTM inputs, predominantly in translation and rotation in the early phase of stance. The ASTM standard resulted in less knee-to-knee variability in joint motion and contact mechanics. Furthermore, the peak contact stresses were higher for ISO inputs, reflecting the higher input axial forces with the ISO standard. These changes in kinematics were reflected in differences in force distribution across the tibial plateau.

Our study suggests that while it is feasible to apply both input profiles to cadaveric knees, ISO inputs, as derived from human knees, may more accurately capture the nuances of knee motion in early stance. We suggest that this model is suitable for quantification of the effects of soft tissue injury and repair on contact mechanics and kinematics.

PREDICTED GAIT ALTERATIONS DUE TO PARETIC LEG REDUCTION IN NUMBER OF MUSCLE SYNERGIES POST-STROKE

INTRODUCTION

Muscle synergies may provide a helpful avenue for predicting patient function following clinical interventions, such as those arising from neurorehabilitation or orthopedic surgery. Theoretically, muscle synergies reduce the achievable control space making predicted muscle forces and consequently predicted motions more unique. In individual's post stroke, a reduced number of muscle synergies has been associated with a deterioration in walking function [1]. However, whether the degeneration in walking function is a direct result of reduced muscle synergies remains unknown.

Computational walking models coupled with optimal control provide an opportunity to test hypotheses that would otherwise be difficult or impossible to evaluate experimentally. This study aims to study the effect of reducing the complexity of locomotor control of one leg on a subject's walking function. Therefore, we predicted that differences in the number of muscle synergies assigned to one leg would be associated with differences in neuromusculoskeletal quantities.

METHODS

This study analyzed data from previously collected walking trials from one male subject suffering from chronic stroke walking dysfunctions (right-sided hemiparesis). All experimental procedures were approved by the University of Florida Health Science Center Institutional Review Board (IRB-01), and the subject provided written informed consent prior to participation. Motion capture (Vicon Corp), ground reaction (Bertec Corp), and electromyography (EMG) data (Motion Lab Systems) were collected simultaneously from the subject as he walked on a split-belt instrumented treadmill (Bertec Corp) at his self-selected speed.

The subject's neurophysiological and musculoskeletal components were taken into account using OpenSim (v3.3; [2]) and Matlab to develop four different modeling elements: a kinematic model, an EMG-driven calibration model, a foot-ground contact model, and a motion prediction model using the concept of muscle synergies. More specifically, the synergy-driven control model was calibrated using the subject's self-selected speed of 0.5 m/s using five-synergy activations per leg to track the following quantities: ground reaction forces, joint moments, joint angles, and muscle activations; see [3] for details.

The subject-specific neuromusculoskeletal model was used to develop two predictions for how the subject would walk following a reduction in the number of synergies controlling the paretic leg from the calibrated case (with five synergies) to two. Both predictions were generated using direct collocation optimal control [4], with the main difference between the two predictions being whether or not constraints were imposed in the formation of the two paretic leg synergies. In the first optimization, the two paretic leg synergy activations and synergy vectors were allowed to vary freely during the optimal control solution process. In the second optimization, the two paretic leg synergy vectors were constrained to be a linear combination of the original five paretic leg synergy vectors. Additionally, deviation of changes in the two paretic leg synergy activations from a linear combination of the original five paretic leg synergy activations were minimized in the cost function. During both predictions, the five-synergy vectors for the healthy leg were fixed to the values found during the calibration. The five-synergy activations controlling the healthy leg were allowed to change but the cost function was set to minimize the difference between the predicted and original synergy activation curves.

Figure 1| Comparison of joint angles produced between the different control strategies: five synergies (black line), two synergies (blue line), and two constrained synergies (red line)

The following parameters were analyzed after each prediction optimization: joint angles, joint moments, ground reaction forces and muscle activations. The NRMSE (Normalized Root Mean Square Error) values between the calibration and prediction results were calculated by normalizing each quantity by its range to identify what differences, if any, were observed and where.

RESULTS

When predicting a walking motion using two non-constrained synergies to control the paretic leg, it can be seen that there are minimal differences when compared to a walking motion produced using a five-synergy control (Figure 1). On closer inspection, there was no significant difference between the five- and two-synergy solutions when looking at the joint moments and ground reaction forces for both legs. Similarly, the muscle activations produced between the two optimizations did not significantly vary for the healthy leg, but it did vary significantly for the paretic leg (Table 1). Additionally, the stride length did not significantly vary between the five- and two-synergy walking motions (6.93% error) (Table 2).

Table 1| The average NRMSE of the muscle activations, joint moments, and ground reaction forces predicted by the model in comparison to the calibration quantities

	Muscle Activations	Joint Moments	Ground Reaction Forces
Two-synergy prediction unconstrained			
Paretic Leg	0.330	0.135	0.154
Healthy Leg	0.118	0.109	0.118
Two-synergy prediction constrained			
Paretic Leg	3.256	0.394	0.235
Healthy Leg	0.292	0.161	0.197

When predicting a walking motion using two constrained synergies to control the paretic leg, a significant difference was observed when comparing the joint angles to those generated using five synergies (Figure 1). Furthermore, a significant difference was discovered for the muscle activations, joint moments, and ground reaction forces produced by the paretic leg when comparing the five-synergy and two constrained synergy results (Table 1). Lastly, the stride length varied significantly between the five and two constrained synergy walking motions (35.3% error) (Table 2).

Table 2| Comparison of stride length between the calibration and predicted walking motions

	Stride Length (m)
Five-synergy calibration	0.701
Two-synergy prediction unconstrained	0.653
Two-synergy prediction constrained	0.453

DISCUSSION

This study evaluated the effect of reducing the number of synergies controlling the paretic leg of a stroke subject. We investigated whether reducing the control space directly resulted in the degeneration of walking function. We found that walking predictions generated using a two-synergy control over the paretic leg did not result in deterioration in walking function. Nevertheless, when the synergy activations and vectors were constrained to be a linear combination of the original five-synergy solution, deterioration in walking function was observed. The optimization predicted minor hip hiking of the paretic leg (pelvis tilt, Figure 1), which may be a direct effect of the decreased range of motion observed both at the hip and knee joints. Additionally, the joint angles of the healthy leg are forced to vary to compensate for the decrease of range of motion experienced by the paretic leg. Furthermore, the significant decrease in stride length can be directly associated with a degradation of walking performance (Table 2).

Our results support the findings from Clark et al. (2010) [1] who hypothesized that the impairment of locomotor coordination may correspond to the reduction in complexity of locomotor control. Our findings clarify that the reduction in synergies alone does not result in significant deterioration of walking performance. However, a reduction in synergies when constrained to be a linear combination of the original synergies does result in poorer walking performance.

Although our synergy-driven model predicts realistic walking motions, an important limitation of our simulation framework is that there is no enforcement of smoothness when generating muscle activations, which may be the reason why the two-synergy prediction is able to closely reproduce the walking gait generated by that of the five-synergy solution. Since the two constrained synergy model must be created from a linear combination, it doesn't have the same level of freedom to instantaneously vary the muscle activations resulting in the smaller NRMSE of the muscle activations for the two-synergy paretic leg compared to the two constrained synergy error (Table 1).

In conclusion, our findings support the idea that less complex neural control building blocks may not be the reason for degeneration of walking function; in fact, it may be that the less complex building blocks are constrained in a certain manner. Therefore, correctly identifying these building blocks may provide a channel for which neurorehabilitation interventions can be designed and locomotor impairments can be monitored.

INTRODUCTION

Pressure measuring insoles have relatively large number of pressure sensors. These insoles present an alternative for traditional instruments for measuring ground reaction force (GRF) as they can measure multiple, consecutive steps in addition to their portability. However, research validating the GRF measurements from pressure-measuring insoles has shown that they have some inaccuracies [1-2], which may be attributed to mechanical characteristics such as hysteresis of the sensors [3-5], or sensor drift [3-4]. Several researchers have attempted to address these issues through incorporating linear regression [6], load-unload calibration curves [7], polynomial adjustment of sensor drift [8], and artificial neural networks [9-10]. However, these studies were limited by their relatively small sample size. None included insole size-based analysis. The purpose of this project was to use system identification techniques to develop transfer function models that best described each of six different sizes of Medilogic® pressure-measuring insoles.

METHODS

GRF data from 29 participants was collected using pressure-measuring insoles (60 Hz) and force platforms (Kistler®, 1000 Hz). Previously published, standard biomechanical methods (IRB #724468) were used [1]. The participant demographics with respect to insole size are displayed in Table 1. The total number of data sets was 174 (29 participants x 3 trials x 2 limbs). Participants were asked to walk over two consecutive force platforms while wearing the insoles inside a pair of thin socks to allow a direct comparison between the two instruments. The GRF data from this experiment was zeroed and isolated to the steps that occurred on the force platforms.

The GRF data from each instrument were preprocessed. First, the two GRF curves of the two instruments were aligned to start at the same

time instant. Equally-sized data sets were required to perform system identification, which allowed a point-by-point comparison between the results of the two instruments. Therefore, the insole data were interpolated to match the sampling frequency of the force platform. Additionally, the signal duration of the insole was adjusted to match that of force platform if the insole had a shorter stance time. If the insole had a longer stance time, the GRF from the force platform was reflected across the x-axis until the time the two signals matched. The GRF from both instruments were normalized to the participant's body weight.

Table 1: Participant demographics separated by insole size.

Insole Size (EUR)	Total #	Male /Female	Age (yr)	Body Mass (kg)	Height (cm)
35-36	5	0/5	24.4(0.8)	48.9(6.0)	156(7.3)
37-38	9	0/9	22.0(2.5)	55.1(5.3)	158(5.4)
39-40	5	0/5	24.2(2.5)	75.3(18.6)	164(2.8)
41-42	3	0/3	21.7(1.7)	84.8(7.1)	181(8.7)
43-44	4	1/4	32.3(13.9)	91.6(26.4)	173(6.3)
45-46	3	3/0	28.3(2.1)	101.2(23.5)	182(2.9)

After preprocessing, the data were separated by insole sizes. System identification was performed through the following steps:

1. One-third of the total number of data sets for each insole size were randomly selected as training data. To avoid bias, this set had an equal number of left and right trials.
2. System identification (Matlab 2018b) was used for each experimental data set to create six transfer functions of the following forms: 3 poles, 3 zeros; 4 poles, 3 zeros; 5 poles, 3 zeros; 4 poles, 4 zeros; 5 poles, 4 zeros; 5 poles, 5 zeros).

- These estimated models were each validated on all data of an insole size. The root mean square error (RMSE) between the results of the estimated model and the force platform results was calculated and compared to the RSME between the original insole and force platform results to determine if the system identifications led to an improvement (Fig. 1).
- The number of data sets where an estimated model improved was recorded for each model and insole size and labeled a summed improvement score, SIS. Similarly, RMSE of all cases were summed and were labeled SRMSE
- For each estimated model, one trial that led to the most improvement were identified.

These steps were repeated for *one-sixth* the total number of trials for an insole size. The poles and zeroes of the repetitions were compared to assess the robustness of the model selection process.

Figure 1: Exemplar set of data curves showing the improvement of the 4p 3z model (red) over the original 37-38 insole data (blue) as it better fitted the force platform data (black).

The best estimated models from the six transfer functions for each insole size were compared across all data sets of an insole size using SIS and the SRSME, respectively.

RESULTS

As shown, in Fig. 1, using system identification resulted in GRF values that were closer to those of the force platform than the original insole data. Overall, the estimated model duplicated the two peaks of the force platform curve while missing the heel strike with some noise at the end of the curve. Table 2 presented the results for all insole sizes in terms of the SRSME and SIS with best model in bold for each insole size. To help assess the robustness of the proposed approach, the locations of the poles and zeros for all repetitions of the 3p 3z model of Size 35-36 are presented in Table 3.

DISCUSSION

Despite the variability associate with different participants wearing the same insole size, it was found that the proposed approach was somewhat robust. Different repetitions during the training phase of an insole size led to the same transfer functions, as shown in Table 3. It was also found that each insole size had a distinctive transfer function that best described it, which could be due to the difference of the number and placements of sensors in each insole size. These results were similar to what was reported in [1], [5] who identified unique results of each insole size.

The results of this research show that system identification can improve the accuracy of the insoles in measuring the vertical component of the GRF. Since assessment of specific events during the gait cycle is important, future work will focus on improving specific gait variables

(e.g., peak amplitudes and time to peak amplitudes) in comparison to the force platform results.

Table 2: The summed RSME and SIS for all insole sizes, combining all repetitions and the original insole RSME. The best performing model is shown in bold.

Transfer Function		Insole Size					
		35-36	37-38	39-40	41-42	43-44	45-46
3p 3z	SRMSE	3.94	9.00	4.47	2.26	2.88	1.58

INTRODUCTION

According to the PEW Research Center, nearly 40 million people in the US live with a disability. This number represents approximately 1/8 of the population. There are many reasons that people have disabilities and some people may be helped by innovative medical devices.

To address this need, our research group is developing a neural prosthesis to assist people with muscle weakness caused by injury or disease. The device is designed to monitor movement during gait and artificially stimulate the gastrocnemius muscle at the appropriate time in the gait cycle to enhance plantar flexion to improve gait. Because people change their gait during normal movement activities, the task of determining the current position in the gait cycle is not trivial. Our third-generation neural prosthesis utilizes inertial measurement units (IMUs) attached to the foot, shank, thigh, and pelvis. Each IMU has a triaxial accelerometer and a triaxial gyroscope to monitor the direction of the gravitational force vector and the angular velocity, respectively. These sensors are used to determine the segment angles with respect to the global reference frame and through calculation, the joint angles can be determined. The neural prosthesis also utilizes foot pressure sensors to provide additional information about the gait of the user. These sensors are accessed by an integrated computer within the neural prosthesis for real-time analysis of gait. However, it is not known how accurately the IMUs and foot pressure sensors can detect actual gait characteristics.

The gold standard for measuring human movement are multi-camera systems that utilize body markers to detect movement. These camera systems have proven to be accurate and will be used as a reference for measuring the accuracy of the IMUs in the neural prosthesis. The low cost IMUs (about \$5.00 US) are expected to be less accurate than the camera system (about \$500k US). However, the accuracy may still be sufficient to accurately determine the phase of the

gait cycle. This study was designed to determine the sensitivity of the system to measurement error. Mathematical analysis of human movement patterns were performed to determine the sensitivity of using the cross-correlation function to accurately detect phase shift in the presence of different levels of noise.

METHODS

An able-bodied individual was recruited to participate in the gait study. After being explained the nature of the study and signing the informed consent form approved by the IRB, reflective markers were placed on the lower body. The participant walked in a straight line over level ground while a camera system captured her movement.

These data were processed to determine joint angles and ground force reactions. These data sets were imported into a custom MATLAB code for data analysis. Gaussian random noise was added to the signal to simulate errors in the IMU's ability to accurately detect the exact joint angles. The probability density function is given by,

$$y(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}} \quad (1)$$

where, μ is the mean, and σ is the standard deviation. In our case μ was zero, and σ was one, so the equation simplified to,

$$y(x) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}x^2} \quad (2)$$

A random number generator within MATLAB was used to generate Gaussian random values with a root mean squared (rms) magnitude of one. These random values were multiplied by a noise level between 0.01 and 10 to scale the noise added to the original signal so that the effect of different levels of noise could be evaluated.

In order to comparing the data collected by the IMUs with camera system data, the data collected by the two separate systems would need

to be synchronized. Asynchronous data was simulated by randomly phase shifting two noisy gait cycle data sets between a range of 0 to 300. These data sets were analyzed using a cross correlation function to determine the phase shift between the two data sets,

$$(f \star g)(\tau) \stackrel{\text{def}}{=} \int_{-\infty}^{\infty} f^*(t)g(t + \tau)dt \quad (3)$$

where, f and g are the two randomly shifted signals, τ is the time shift and t is time. The cross-correlation function is maximized when the two signals are best aligned and the values of τ can be determined.

Finally, the effect of noise levels ranging from 0.01 to 10 degrees rms at 0.01 degree intervals was evaluated. Each of the 1000 different noise levels was evaluated 200 times and the ability of the cross-correlation function to accurately determine the actual phase shift was determined as a function of noise level.

RESULTS

Joint angles collected using the camera system from a single gait cycle of a typical able-bodied individual are shown below (Figure 1). The results also show that a low noise level generally follows the original gait shape.

Figure 1: Natural joint angles during gait (solid lines) and gait perturbed by Gaussian random noise at one degree rms (dashed lines). †The normalized force has units of Newtons/20.

Evaluation of two randomly shifted knee joint angles, with one degree rms of noise are shown before and after synchronization (Figure 2a). The method is also able to synchronize the signals the high noise levels, ten degree rms (Figure 2b).

Figure 2: Synchronization of signals using the cross-correlation function at two noise levels, (a) one and (b) ten degrees rms.

The sensitivity to noise is shown in Figure 3. The results show that at a noise levels below a rms of one degree the cross-correlation function is able to determine the exact phase shift 100% of the time. By a noise level of two, the accuracy of determining exact phase shift reduces to approximately 75%. By a noise level of ten, the accuracy reduces to about 20%.

Figure 3: Percent of time shifts accurately determined using the cross-correlation function at different levels of Gaussian random noise. Data was smoothed using in a moving average of 5 points.

DISCUSSION

The results show that if the noise levels can be kept below one degree rms, they have no impact on the ability of the cross-correlation function to synchronize the data sets. However, at higher levels of noise or measurement error, the ability to exactly determine the phase shift reduces. One notable point is that even though the cross-correlation function was able to only determine accurately the phase shift only 20% of the time at the maximum noise level, the magnitude of the error was typically only 1-2% of the gait cycle (see Figure 2). This implies that even if the neural prosthesis is not able to exactly time the stimulation, it may still be close.

INTRODUCTION

Ballet dancers have short-lived careers due to the demands placed upon their bodies throughout years of training, study, and performance. The average age a dancer retires is 34, according to the multi-country aDvANCE Project [1]. Their bodies are placed under significant stress during their professional years and injuries are common. Lower limb joint injuries have been found to be the most frequent, and length of time dancing was correlated with greatest risk for injury [2]. Faulty technique, or improper movement, has also been correlated with injury risk [3]. Early recognition of pathologic movement patterns could help prevent injuries, which could reduce injury and lengthen dancer's careers.

Of all the dance specialties, ballet is the most specific in terms of body position and movement. Ballet dancers are taught to keep the hips level and not to pronate the foot whenever the leg is lifted off the ground. It is not uncommon for amateurs to lift the left side of the hip up or pronate the foot to help lift the leg. These movements require significant flexibility and quickly adjusting the center of gravity over the standing leg. Additionally the standing leg must be constantly adjusted and ankle strength and stability are required as the entire body is balanced over one foot.

Previous research has determined that training and fatigue are important risk factors for injury during these difficult movements. Not only do dancers self-identify fatigue as a leading risk for injury [4], one study specifically showed "neuromuscular activation of the knee extensors and flexors in dancers changed in response to the dance-specific fatiguing protocol" [5]. Quadriceps and Hamstring fatigue has been shown to alter knee mechanics [6], altered mechanics of the knee have been tied to altered mechanics in the ankle [7] and alterations in the

ankle have been shown to affect the knee [8]. Essentially, in the lower extremity, the motion of one joint affects motion in all the others.

This fatigue, training level, and alterations in practice versus performance tempo puts dancers at risk for injury. Specifically, abnormal kinematics at the hip or ankle can cause musculoskeletal pain or significant joint injury. For example, inversion sprains of the ankle are common in ballet dancers and lead to alterations of the intrinsic motions of that joint. An inversion sprain happens when an ankle is taken to the furthest supinated position and the ankle is rolled over the outside, injuring the ligaments within the joint. A leading risk for ankle inversion sprain is having a previous inversion sprain (Milgrom, 1991). Identifying factors that lead to changes in biomechanics of the lower extremity is important in the search for modifiable risk factors that lead to pain and injury.

The goal of this study was to evaluate proper kinematics during dance movements in an attempt to identify motions and conditions that put them at risk for injury. Additional goals are to help dancers maintain musculoskeletal health and to provide valuable information to dance teachers to prevent injuries in all levels of dancers.

METHODS

Ten professional ballerinas currently employed by the Texas Ballet Theater (<https://www.texasballettheater.org/about>) were studied throughout their performance season. Five men and 5 female dancers ages 20-28 (average 24 years) with an average of 16 years of training (range 7-22 years) were studied.

Reflective markers were placed on bony landmarks of the body so that Infrared cameras in the Motion analysis system (Motion Analysis Corp, Rohnert Park, CA) could register a stick-based Skelton that was used to calculate kinematics of the body parts and joint range of motion during movements (Figure 1).

Figure 1 beginning & end motion of a Grand Plié in 2nd position.

Dancers were asked to perform 3 warm up exercises to music which included:

- Plié in 1st and 2nd position, Demi and Grand motions (Fig 1)
- Battement avant, seconde, derrière (front, side and back)
- Développé avant, seconde, derrière (front, side and back)

Data was collected over the performance season:

- August - Beginning of the season
- November - Height of the season (busiest, most tired)
- April - End of the season

Clinical data regarding prior injuries and past and current therapies/strategies to maintain health were recorded.

Ankle Pronation/supination (sprain risk) was calculated using vector mathematics using markers between the Heel – Toe (vector u) and navicular – base of the 2nd metatarsal (vector v) using the following equation (1).

$$\cos \theta = \frac{u \cdot v}{||u|| \cdot ||v||} \quad (1)$$

RESULTS

Clinical Data

Most common previous injuries

- Lower limb injury (7/10 dancers)
- Ankle sprain (4/10 dancers)
- Metatarsal fracture (2/10 dancers)
- Hamstring strain (2/10 dancers)

Most common therapy/strategy to keep healthy

- Massage (6/10 dancers).
- Physical Therapy (4/8 dancers)

Ankle Pronation/Supination variance is shown in figure 2

Figure 2

DISCUSSION

Professional ballet dancers are at risk for lower extremity injury. Specifically, ankle injury due to the repetitive and intense nature of the performance season. any dancers utilize alternative therapies to maintain their musculoskeletal health the most common being massage and Physical therapy.

3D kinematic data of dancer's movements during the performance season were evaluated for changes in ankle Pronation/supination motion and revealed that dancers with less experience exhibit more variation in ankle motion during basic warm up exercises. While there was very little variation in this population of professional (elite) dancers more variation would be expected in younger less experienced dancers and a potential indication of increased risk for ankle injury.

Knowledge of body kinematics could facilitate better understanding of the mechanism of injury, help identify fatigue, help dance instructors teach proper technique, and help focus clinical treatments to help prevent and identify injuries.

ACKNOWLEDGEMENTS

Special thanks to the Texas Ballet Theater for their cooperation in collecting the data. Thank you to the UNTHSC students and Human Performance Staff that helped with the data collection.

CAN SUPERHYDROPHOBIC SLIP FLOW IMPROVE CENTRIFUGAL BLOOD PUMP PERFORMANCE AND REDUCE BLOOD DAMAGE?

Chan Wei Xuan, Vivek Vasudevan, Adriel Jia Jun Low, Janani Venkatesan, Choon-Hwai Yap

INTRODUCTION

Centrifugal blood pumps save countless lives daily, being used in Extracorporeal Membrane Oxygenation (ECMO) circuit in the ICU, during heart surgeries, and being implanted as Left Ventricular Assist Devices (LVAD). High stresses imposed on blood by the rapidly rotating impeller [1] cause significant number of patients to suffer from severe hemolysis (in 7% of ECMO [2] and in 18% of LVAD cases [3]), which drastically reduces survival (by 6 times for ECMO [2]).

We recently proposed using superhydrophobic (SHP) coatings to enable slip-flow, so as to reduce blood stresses and blood damage, and demonstrated preliminary feasibility in a simple in-vitro pipe flow setup [4]. SHP material is a hydrophobic surface with micro-/nano-scale surface-structures which gives it enhanced fluid repellency and partial slip-flow characteristics. In the current study, we perform flow simulations to understand the potential advantages if SHP surfaces are coated on an ECMO centrifugal blood pump.

METHODS

A commercial blood pump (Maquet Rotaflow, Fig. 1a) was scanned by computed tomography, the pump features as well as measurements were extracted from the scanned DICOM images (Fig. 1b), and 3D reconstruction was done using SolidWorks® (Fig. 1c).

The model was discretized with more than 5 million tetrahedral cells and CFD simulations were performed at three flow rates: 2 LPM, 3 LPM and 5 LPM with RNG k- ϵ formulation to model turbulent flow in the centrifugal pump. A sliding mesh was used to rotate the impeller for at least 3.5 rotations at more than 1200 time steps per rotation. Blood was modelled as an incompressible fluid (1060 kg/m³) with a Newtonian viscosity of 3.5 cP. Boundary conditions imposed were velocity inlet, zero pressure outlet, no slip at impeller, and partial slip / no slip at pump housing wall.

Figure 1: (a) The Maquet Rotaflow centrifugal blood pump (b) CT scan of pump head (c) Digitally reconstructed CAD model

The SHP coatings were *applied* only on the inner surface of the pump housing, and two levels of slip lengths were investigated: 0 μm (No slip) and 100 μm . The partial slip boundary conditions were imposed as,

$$\mathbf{u} = \beta \frac{\delta \mathbf{u}}{\delta \mathbf{n}} \quad (1)$$

where \mathbf{u} is the velocity at the wall, β is the slip length and \mathbf{n} is the normal vector to the wall. A stress-based measure to estimate free-plasma hemoglobin (H_E), as indicator of blood damage severity [5] was used.

$$H_E = \frac{\int_{\text{outlet}} H \mathbf{u} \cdot \mathbf{n} \, ds}{\int_{\text{outlet}} \mathbf{u} \cdot \mathbf{n} \, ds} \quad (2)$$

$$\frac{\delta H^{\frac{1}{\beta}}}{\delta t} = -u \nabla H^{\frac{1}{\beta}} + C s^{\frac{\alpha}{\beta}} (1 - H^{\frac{1}{\beta}}) \quad (3)$$

$$s = 10^{\frac{1}{T}} \int_t^{t+T} \log_{10} \left(\sqrt{\frac{1}{2} \tau : \tau} \right) dt \quad (4)$$

where C (3.62×10^{-7}), α (3.416), and β (0.785) were taken from literature [5]. s is the log average fluid scalar stress, τ is the viscous stress tensor and T is the period of rotation.

RESULTS

Figure 2: Ratio of free-plasma hemoglobin (H_E) at outlet for flow rates of 2 LPM, 3 LPM and 5 LPM, at slip lengths of 0 μ m (No slip) and 100 μ m

Figure 3: Streamlines of blood flow in x-y plane: Path 1 – upper gap between rotating impeller and stationary casing. Path 2 – gap between rotating impeller blades. Path 3 - lower gap between rotating impeller and stationary casing.

Simulation results (Fig. 2) showed that at lower flow rates, SHP coating did not significantly alter the blood damage. However, at a higher flow rate of 5 LPM, a significant reduction in blood damage could be achieved on the 100 μ m slip surface.

The pump design allowed flow to occur in 3 paths from the inlet through the pump body (Fig. 3). Investigation of the flow fields revealed that there were reversed flows in Paths 1 and 3 (Fig. 4), which were most likely induced by high flow volumes through Path 2 that generated adverse pressure conditions for the other 2 paths. There was significant reverse flow in the No slip case, but this reduced significantly for the 100 μ m slip case. Reversed flow also increased proportionately with increasing flow rate.

A higher reverse flow recirculates blood within pump, resulting in higher chances of blood damage, indicating that reduction in reverse flow is one of the factors responsible for lower blood damage with the application of SHP coatings on the inner surface of the pump housing.

Fig. 5 shows that having SHP surfaces with slip flow decreases wall shear stress (WSS) on the pump housing. Fewer surfaces have a

high WSS (> 10 Pa and > 50 Pa) with increasing slip length, indicating lower chances of blood damage. Regions with high WSS are mainly distributed along Paths 1 and 3. The combined effects of reduced WSS and decreased reversed flow contributed to a lower blood damage for cases with higher slip length.

Figure 4: Reversed radial velocity contour in x-y plane in centrifugal pump (flow towards inlet) along Paths 1 and 3

Figure 5: Contours of time- & surface-averaged WSS at 5 LPM on stationary casing for different slip lengths. WSS contours were thresholded at 10 Pa and 50 Pa, displaying regions with high WSS

DISCUSSION

Based on the results of our CFD simulations, superhydrophobic (SHP) surfaces applied on a centrifugal ECMO blood pump offered reduced WSS and, at certain flow rates (5 LPM), also reduced blood damage. However, this was observed only at slip lengths of 100 μ m. With the introduction of SHP surfaces, characteristics of the flow field such as intensity of reversed flow between the impeller and housing (Paths 1 and 3) could change, which will have implications on extent of blood damage, and hence, a redesign of the pump should be conducted so as to minimize adverse flow patterns. Reversed flow in the gap between the impeller and housing have been previously acknowledged to be problematic in studies of other pump designs [6].

INTRODUCTION

Coronary Artery Disease (CAD) is one of the leading causes of adult mortality in the US^{1,2}. CAD is characterized by plaque buildup, or stenosis, in the arteries that feed the heart, which can lead to further complications such as myocardial infarction^{1,3}. The severity of the disease is typically quantified via an invasive, catheter-based diagnostic procedure that measures Fractional Flow Reserve (FFR): the ratio of pressures on either side of the stenosis under conditions of maximum flow^{4,5}. Due to its invasive nature, risks, and cost, clinicians often choose not to perform FFR and rely on visual inspection of angiograms to determine whether the severity of the stenosis is high enough to warrant coronary revascularization. However, this visual inspection of the angiograms often leads to an over-estimation of the disease severity⁶. Therefore, a noninvasive, computational method to calculate FFR would greatly improve CAD diagnostics while eliminating the risks associated with the catheter-based FFR procedure. To this end, this study aims to develop a method that uses machine learning and computational fluid dynamics to compute FFR from biplane angiography image data.

METHODS

A convolutional neural network (CNN) was used for automatic vessel segmentation of synthetic and clinical biplane angiograms. The synthetic dataset was created by imaging 3D printed phantom models of a coronary tree, while clinical data was obtained from the University of Michigan hospital. Both datasets were normalized to have uniform pixel intensity and augmented to include vertical and horizontal flips. Clinical data was further pre-processed using unsharp mask filters to improve local contrast and boundary sharpness. The CNN had a Deeplab v3+ architecture⁷ and was trained for 580 epochs using a batch size of 4, momentum gradient descent, cross-entropy loss, and L2

regularization (Figure 1). The network was trained separately on clinical and synthetic datasets.

Figure 1: The Deeplab v3+ network encoder uses convolutions to identify features corresponding to blood vessels. The decoder spatially maps features to classify pixels in the input image.

Once vessels were segmented, a skeletonization algorithm based on the work of Telea *et al.* was employed to find the centerline of the vessels in the coronary tree⁸. The branchpoints of the vessel centerline were used as reference points for a back-projection algorithm. The back-projection algorithm maps the reference points from each 2D plane into 3D space using information about the position of the sources when those images were taken. Once the 3D centerline is constructed, the vessel geometry can be filled in using the local radius at each point of the centerline. Local radii are computed and stored by the skeletonization algorithm referenced above. A diagram of the back-projection algorithm is given in Figure 2.

Figure 2: Back-projection algorithm. Skeletonized auto-segmented images are used to create the 3D geometry using spatial information from DICOM metadata.

Validation of the above segmentation and back-projection algorithm will be performed using the synthetic dataset. The computational hemodynamic open-source modeling software, CRIMSON, will be used to perform steady-flow simulations in the original 3D-printed geometry of the coronary tree. The simulation will yield a pressure field for the entire coronary tree, which can be used to compute FFR along the centerline of the vessels of interest. The pressure field in the original geometry will be used as a benchmark for the pressure field computed from simulations in the geometry reconstructed using the CNN and back-projection algorithms. FFR will again be calculated along the centerline of the vessels of interest, and the error between the two sets of FFR values will be calculated.

RESULTS

The accuracy of the automatic segmentation algorithm on the synthetic and clinical validation datasets is given in Table 1. The accuracy was quantified using MIOU (mean intersection over union of pixels) and the Dice score in the prediction and ground truth images. Sensitivity and specificity are also reported. Sample segmented images

from the synthetic and clinical datasets are shown in Figure 3.

Table 1: Segmentation Accuracy. Accuracy in clinical data is lower as the images contain more noise and artifacts

	Synthetic Data	Clinical Data
Training set size	1230	927
Validation set size	152	103
MIOU	0.975	0.917
Dice	0.980	0.916
Sensitivity	0.980	0.952
Specificity	0.994	0.995

Figure 3: Segmentation Results. The top row corresponds to synthetic data, while the bottom row is clinical data. The ground truth was manually labeled by hand, and the prediction was automatically generated by the neural network.

DISCUSSION

Visual inspection of the segmentation results shows a close alignment between the true vessel in the image and the neural network's prediction of the vessel. Further improvements can be obtained by increasing the size of the clinical dataset, allowing the network to learn from a wider pool of coronary tree geometries. Image post-processing techniques can also be utilized to refine the neural network segmentation and enhance accuracy. Once the network has achieved sufficient accuracy (MIOU score of 0.95), the output images will be used to create the 3D vessel geometry using the back-projection algorithm; CRIMSON simulations will then be performed to validate the accuracy of reconstruction and compute FFR.

INTRODUCTION

Cerebral aneurysms affect up to 5% of the total population [1]. Aneurysm rupture resulting in subarachnoid hemorrhage (SAH) is associated with high mortality and morbidity [2]. At the same time, the natural aneurysm rupture risk of less than 1% per year is low compared to the risk associated with aneurysm treatment to prevent a future rupture making the decision of whether to treat an aneurysm challenging [3]. A statistical prediction model could be helpful to compare a patient's natural rupture risk against the risk of treatment.

We recently developed an aneurysm rupture probability model based on hemodynamic and geometric parameters, aneurysm location, patient gender and age using patient data obtained mainly from hospitals in the US [4]. When externally validating the model in two European cohorts, it showed a good predictive performance [5]. Different studies have shown that Finnish and Japanese populations have a higher rate of SAH compared to other populations [6, 7].

Our purpose was the evaluation of the model in Finnish and Japanese data as well as the comparison of its performance with a new model trained on data including aneurysms from Finnish and Japanese patients.

METHODS

Patient and Image Data

For model evaluation, 255 aneurysms were studied, 147 Japanese aneurysms in 138 patients and 108 Finnish aneurysms in 73 patients. In the Japanese cohort, there were 81 (58.7%) female and 57 (41.3%) male patients, 17 (11.6%) of the aneurysms were ruptured and 130 (88.4%) unruptured. Of the Finnish patients, 40 (54.8%) were female and 33 (45.2%) male, 41 (38%) of the aneurysms were ruptured, 61 (56.5%)

were unruptured and 6 (5.5%) had an unknown rupture status and were excluded from the dataset resulting in a total number of 102 Finnish aneurysms.

For model development, an additional 1,631 aneurysms from US cohorts and 249 aneurysms obtained from two European (other than Finnish) hospitals were used (see [4] and [5] for a detailed description of the data).

Hemodynamic Modeling

To characterize each aneurysm's hemodynamic environment, computational fluid dynamics (CFD) simulations were performed based on the segmented angiographic images and following the same protocol as described in [4]. Briefly, unstructured grids with a maximum element size 0.2 mm were used to model the aneurysm and its surrounding arteries. Based on the aneurysm location, inflow boundary conditions were applied at the internal carotid artery (ICA) for aneurysms in the anterior circulation, at the vertebral artery (VA) for aneurysms at the posterior circulation, or the parent vessel of the aneurysm if the segmented images did not include more parts of the vascular tree. Depending on the location where the inflow boundary condition was imposed, the inflow was adjusted taking the area of the vessel into account [8]. Pressure and flow outlets were imposed as outlet boundary conditions. Numerical solutions of the unsteady Navier-Stokes equations were obtained from an in-house finite element solver [9]. To characterize the aneurysm and its hemodynamic environment, 22 hemodynamic and 25 morphological parameters were calculated based on the computed flow field as well as the 3D model. A detailed description of all parameters can be found in [4] and the references therein.

Statistical model development and evaluation

First, the previously developed model (Model-US [4]) was evaluated using all Finnish, Japanese, and combination of Japanese and Finnish datasets in terms of area under the receiver operating characteristic (ROC) curve (AUC).

Next, data from all four cohorts was divided into two parts, training and testing. To do so, from each of the four datasets (US, Europe, Japan, Finland), 10% of them were randomly excluded for testing the model while the remaining 90% were used for model training. The model was trained as described in [4] using logistic group lasso regression [10]. In a second step, interaction terms between patient population and the other continuous variables were included in the regression model. Such a model interpolates between separate models for each patient population and a global model.

The process of splitting the data into training and test sets and subsequent training of the respective models was repeated 100 times and for evaluation, the mean AUCs and their standard deviations were reported.

RESULTS

Figure 1 shows boxplots of the AUCs when evaluating the trained models in the left-out Japanese, Finnish, Finnish + Japanese combined, and all left-out data. When evaluating the US-Model in all Japanese (not only left-out data), all Finnish, and Finnish and Japanese data combined, the AUCs were 0.70, 0.72, and 0.74, respectively (shown by the black squares in Figure 1). For the models trained on the data from all four cohorts without interactions (Model_ALL_no_ints, white bars), the mean \pm standard deviation AUCs were 0.65 ± 0.33 for the left-out Japanese data, 0.75 ± 0.16 for the Finnish, 0.75 ± 0.14 for Finnish and Japanese combined, and 0.83 ± 0.03 for all left-out data. The same metrics for the models including interaction terms (Model_ALL_ints, gray bars), were 0.68 ± 0.30 (Japanese), 0.79 ± 0.13 (Finnish), 0.83 ± 0.10 (Finnish + Japanese), and 0.83 ± 0.03 (all left-out data).

Figure 1: Boxplots of AUCs when evaluating the models in the left-out test data

DISCUSSION

When evaluating the US-model in the Japanese and Finnish data, its predictive performance in terms of AUC was largely reduced compared to the AUC when evaluated in the European data. It has previously been suggested that Japanese and Finnish populations have

a higher aneurysm rupture risk [11]. The underlying mechanisms that lead to a higher rupture rate in those two populations are not clear. Our observation of the relatively poor performance of the US-model indicates that different aneurysm characteristics might be associated with rupture for these populations. This hypothesis is further supported by the fact that the model performance in the left-out Japanese and Finnish data improved significantly ($p < 0.0001$) when including interaction terms in the model.

The comparatively poor performance of all the models in only the Japanese left-out data could be explained by several aspects. First, in contrast to all other cohorts, the aneurysms from the Japanese population were obtained as longitudinal data resulting in a low number of ruptured aneurysms especially in the left-out data for model evaluation. Consequently, the AUC strongly depended on the specific left-out data set (large standard deviation) and a larger dataset might be needed to get a more robust estimation of the models' performance. Second, unlike for the other data, the computational 3D models used for the CFD simulations of the Japanese aneurysms were cut at the parent vessel of the artery which might have led to differences in the computed hemodynamics and needs to be investigated further.

The developed models were trained mainly on cross-sectional data (all but the Japanese data). They provide the predicted probability that an aneurysm is ruptured rather than assessing its risk for a future rupture. The idea that these models could still be used for aneurysm risk assessment is based on the assumption that high-risk aneurysms resemble those that have already ruptured. To assess this assumption, an evaluation of the model with more longitudinal data is planned for future work.

In conclusion, our results indicate that for development of an aneurysm rupture prediction model that accurately assesses Japanese and Finnish aneurysms, the inclusion of data from these two cohorts for model training as well as interaction terms in the statistical model is necessary. When including this information, the predictive performance of such a model in Japanese and Finnish data is close to the performance in US or European data.

ACKNOWLEDGEMENTS

The European (other than Finnish) data included the publicly available AneuRisk dataset and the AneuX dataset collected and processed in the context of the @neurIST project funded by the EU commission (IST-2004-027703) and AneuX project evaluated by the Swiss National Science Foundation and funded by the SystemsX.ch initiative (MRD 2014/261).

INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of death worldwide [1]. With recent advances in cardiac and vascular imaging, patient-specific simulations of cardiovascular hemodynamics are gaining increased clinical utility in relation to CVD [2]. Applications include development of novel surgical approaches for congenital heart disease [3], and coronary artery disease assessment [4].

In the clinic, the available time to produce simulation results is typically limited. For cardiovascular simulation in particular, high quality three-dimensional patient-specific models must be constructed for each patient, a process that delays simulation turnaround time. A common approach to build the models vessel by vessel. Specialized cardiovascular simulation software tools such as SimVascular [5], Cardiovascular Integrated Modeling and Simulation (CRIMSON) [6] and the Vascular Modeling Toolkit (VMTK) [7] can be used. The model building workflow typically begins by loading 3D medical image volume data, identifying vessels of interest, and annotating pathlines along vessel centerlines. Vessel lumen are then segmented, using 2D cross-sectional slices and interpolated to form vessel surfaces. Multiple vessels are merged, through Boolean and smoothing operations [8], producing a final 3D model.

A large and diverse body of existing work has been dedicated to the acceleration of cardiovascular segmentation [9]. However, the visual appearance of blood vessels in medical image data is subject to substantial variation making it challenging to develop general purpose algorithms that work well for the majority of cases. Recently, for image segmentation tasks, so-called Fully Convolutional Networks (FCNN) [10], have shown particular promise. However, to our knowledge, no studies have shown the utility of neural networks for

modality-independent cardiovascular model building on general vascular anatomy. The closest works are the I2I network [11], which did not consider downstream applications and DeepLumen [12] which is closed-source and restricted to CT coronary artery segmentation.

We aim to use FCNNs trained for cardiovascular segmentation to accelerate the existing cardiovascular model building workflow in SimVascular by building an automated segmentation pipeline, based on Fully Convolutional Neural Networks.

METHODS

With our proposed FCNN segmentation pipeline, the first few steps of model building remain the same as is currently implemented in SimVascular [5]: users first load medical image volume data and indicate points along the pathline of the vessel of interest (Fig. 1) and 2D images are extracted along pathline at discrete intervals. However, then the extracted 2D images are automatically preprocessed and input to a FCNN that has been trained to output vessel segmentation images. Vessel lumen points are then automatically computed by applying the Marching-Squares algorithm to each FCNN output image. Using the pathline, the produced contours are reoriented in 3D space and interpolated to form the final vessel surface.

Optimal values for the neural network's parameters are found by minimizing a loss-function using example input and output images. However, in our dataset, not all blood vessels in every image volume have been segmented. To resolve this issue we introduce a new loss function that ignores regions of images that were not labeled during the labeling process. Let y be a partially labeled image, where a pixel value of 1 indicates that the labeler designated that pixel as the structure of interest and a pixel value of 0 indicates a pixel that was

not labeled. Let \tilde{y} be a binary dilation of y by K pixels. Given a predicted image \hat{y} , our new loss function is then

$$L(\hat{y}, y) = \frac{-1}{\Sigma \tilde{y}} \Sigma \tilde{y} (y \log(\hat{y}) + (1 - y) \log(1 - \hat{y}))$$

Conceptually, \tilde{y} indicates the area of the image that the labeler focused on and only this region is considered in our loss function.

RESULTS

We compare a distance regularized level set (DRLS), threshold and each FCNN architecture via the average DICE scores on the test set (Tab. 1). FCNN indicates our neural network trained with standard loss functions and FCNN-M indicates training with our proposed masked loss function. We also measure results on small and large vessels separately by splitting the test dataset on vessel radius.

I2I-M produced better scores than I2I for all metrics when measured on small vessels ($r < 0.55$ cm, $p < 0.001$). Compared to reference methods, I2I-M produced better average DICE scores than DRLS and Threshold ($p < 0.001$).

As a final test, users were allowed to edit segmentations and add segmentations to construct final cardiovascular models in SimVascular. The ground-truth models and those built using the proposed FCNN-M method are visually similar (Fig. 2). Inspecting the kawasaki disease case, we see that essential features of the model such as aneurysms in the coronary arteries are preserved. Using the FCNN method resulted in reductions of manual segmentations required of 73%, 57% and 71% for each case respectively.

DISCUSSION

Comparisons of the FCNN segmentation methods and the reference Threshold and DRLS algorithms shows demonstrated that neural networks improved overall performances. Both FCNN methods significantly improved average DICE scores over the reference methods, illustrating that standard algorithms such as thresholding and level sets need to be recalibrated for each image, whereas neural networks provide more automated approaches. Our results further showed that the proposed masked loss function did indeed improve the performance of both neural networks, in particular the improvement was larger for small vessels than for large vessels, achieving more precise vessel delineation in regions that are difficult to segment.

INTRODUCTION

Accurate tracking of cardiac tissues from clinical scans is an important task to aid the evaluation of organ function, detect disease, and aid downstream biomechanics analysis of the heart. A good method for cardiac motion tracking is non-rigid image registration, where two images are matched by deforming one to fit the other. This has worked very well for clean MRI images, but in noisy images such as ultrasound (US), its accuracy is limited [1]. US has lower cost than MRI, is more readily available, and in clinical fetal heart scans, US is most feasible.

Tracking difficulties are, firstly, since pairwise image registration is typically performed on consecutive time points, accumulation of tracking errors over time points will lead to tracked objects drifting away. Secondly, due to constraints in the algorithm designed to obtain smoother registration displacement calculations, tracked cardiac boundaries often underestimates the stroke volume.

In this study, we proposed a novel method for cardiac motion tracking on US images, using a mathematical model for cyclic motion of myocardial points to avoid drift, which was curve-fitted to results of a series of non-rigid image registrations. Our algorithm had the added robustness of allowing image registration of non-consecutive time points. By placing emphasis on time points when the heart was largest and smallest, we could preserve stroke volume much better. Compared to techniques reported in a recent Cardiac Motion Analysis Challenge (CMAC) [1], our technique achieved better accuracy. We successfully applied the method to cardiac scans from multiple modalities, but will focus on human fetal right ventricle (RV) US and CMAC here.

METHODS

3D Non-rigid pairwise image registration was performed with an open source module, Elastix [2]. We described a cyclic mathematical model for image coordinates motion as spatially distributed B-splines

of temporal Fourier expressions (BSF). The Fourier coefficients could be calculated at location \vec{X}^0 by the formula:

$$\vec{F}_f(\vec{X}^0) = \sum_{l=0}^3 \sum_{m=0}^3 \sum_{n=0}^3 B_l(X_1) B_m(X_2) B_n(X_3) \vec{C}_{i+l,j+m,k+n,f} \quad (1)$$

The vector \vec{F}_o denoted the Fourier coefficients in the 3 Cartesian axes at frequency f . B was the cubic B-spline basis function, and \vec{C} was the 4D matrix of the coefficients of BSF. i, j, k were the 3D spatial index of the B-spline control points grid, and X_1, X_2 and X_3 were the Cartesian distance from the nearest B-spline control point. Next, \vec{C} was optimized using Levenberg-Marquardt algorithm with objective function:

$$\vec{C}^* = \underset{\vec{C}}{\operatorname{argmin}} \left(\frac{\sum_t \sum_{d\vec{X} \in R} \left\| (\vec{X}^{t+1} - \vec{X}^t) - d\vec{X} \right\|_2}{2} \right) \quad (2)$$

Where \vec{C}^* is the optimum \vec{C} , t is time point, T is the period of cardiac cycle, N is the maximum Fourier frequency, $d\vec{X}$ are the displacement vectors from one set of image registration results (R). \vec{X}^t is described as summation of \vec{F}_f in Fourier series. The initial descent value of \vec{C} , were calculated by Fourier decomposition and multi-level B-spline fit [3] to the displacement fields from pairwise-registration. In essence, the algorithm search for the BSF coefficients that best match the pairwise image registration results.

RESULTS

CMAC provides 15 volunteers cardiac US data with 12 tagged landmarks ground truth provided from tagged MRI. The Euclidean (Eu) distance error between tracked landmarks and the truth location of the landmarks, averaged across time, are shown in Figure 1, for the image tracking based on initialization (Init) BSF coefficients, and optimized

(Optim) BSF coefficients. Compared to the other three research groups participating in the challenge (Fraunhofer MEVIS, the INRIA-Asclepios Project, and Universitat Pompeu Fabra or UPF), our algorithm had lower errors. Without the iterative optimization step, our initialization BSF was found to be already comparable to the results of other groups with average Eu of 3.57mm. Iterative optimization reduced it further to 3.31mm, which was approximately 10% lower than the other groups (INRIA=3.76mm, MAVIS=3.72mm, UPF=3.63mm).

Figure 2. Comparison between the fetal RV obtained from manual segmentation and the proposed method for: a) ventricular volume and b) its gradient. Additional end diastole to end systole registration improves the stroke volume fit.

Figure 3. Tracked surface of the fetal RV, overlaid on the ultrasound images at various time points for (top) proposed algorithm and (bottom) manual segmentation.

The method was further applied to 4D human fetal cardiac US data. The volume of right ventricle (RV) across time obtained from tracking was compared against volume data from manual segmentations at all time points (Figure 2a), and a good fit was observed. The Euclidean distance error were was found to be similar to that from CMAC data, with $Eu=0.45\text{mm}$ averaged over all landmarks, which was approximately 3% of the width of the RV. Our tracking method was also able to track E- and A-wave volume gradients (Figure 2b).

Since our image tracking technique utilized BSF, it naturally imposed a smoothness constraint on the curve-fitting, resulting in retardation of tracked motion. In figure 2, we could observe that the optimized BSF tracking resulted in a slight reduction of the tracked

stroke volume compared to the manual segmentation truth. However, we could robustly include more pair-wise image registration displacement fields into the set of image registration results R (equation 2). By including displacement fields from end diastolic to end systolic time points, we could improve the tracked volume waveform fit, as shown the Figure 2.

To demonstrate utility in biomechanics simulation, the obtained cardiac wall displacements were used as boundary condition for computational fluid dynamics (CFD) of the fetal RV (data from a previous study [4]). Consistent E and A-wave vortex rings (Figure 4) were observed as expected [4] and CFD velocities and stroke volumes matched clinically obtained data (Table 1).

Figure 4. wall shear stress contour overlaid on top of vortex core during peak A and E waves.

Parameters	Clinic	CFD
EDV (mm^3)	675	629
ESV (mm^3)	272	285
E-wave velocity (m/s)	0.4	0.44
A-wave velocity(m/s)	0.7	0.62
Maximum pulmonary velocity(m/s)	0.6	0.68

Table 1. Cardiac physiological Parameters from clinic measurements matched CFD results.

DISCUSSION

We have implemented a novel cardiac motion tracking algorithm that could work well in noisy 4D US images, by incorporating a cyclic motion model for cardiac nodes, and curve-fitting the model to a series of non-rigid pair-wise image registration displacement fields.

BSF modelled a global motion with curve fitting across images of all time points. Other than preventing tracked nodes from drifting due to tracking error accumulation, it also enabled tracked nodes to cross over locations and time points where there were loss of signals, US shadowing by bone structure, or high noise.

The use of the B-spline spatial function also provided support to counter these localized loss of signals and high noise, as motion data from spatially-neighboring nodes can be used to bridge over areas with high noise and signal losses.

The choice of Fourier and B-spline functions are advantageous as they are continuous and easily differentiable. Further, these functions imposed a smoothness constraint naturally, which is akin to an inbuilt regularization term to the motion tracking. This simplified the form of the equation for optimisation. Further, by allowing any manner of image-pairing during image-registration, our motion tracking was robust to achieve the required stroke volume.

The performance of our proposed technique was highly encouraging, as it performed better than contemporary techniques included in the CMAC. Qualitative tracked images and quantitative tracking error computations demonstrated good performance. The algorithm should be useful for analyzing cardiac function and assist in image-based biomechanics simulations.

INTRODUCTION

Numerical analysis methods, including finite element analysis (FEA), computational fluid dynamics (CFD), and fluid-structure interaction (FSI) analysis, have been used to study the biomechanics of human tissues and organs, as well as tissue-medical device interactions, and treatment strategies. However, for patient-specific computational analysis, complex procedures are usually required to set-up the models, and long computing time is needed to perform the simulation, preventing fast feedback to clinicians in time-sensitive clinical applications.

In this study (Fig.1), by using deep machine learning (ML) techniques, we developed deep neural networks (DNNs) to directly estimate the steady-state distributions of pressure and flow velocity inside the thoracic aorta. After training on hemodynamic data from CFD simulations, the DNNs take as input a shape of the aorta and directly output the hemodynamic distributions in one second.

Figure 1. The proposed machine learning approach

The trained DNNs are capable of predicting the velocity magnitude field with an average error of 1.9608% and the pressure field with an average error of 1.4269%. This study demonstrates the feasibility and great potential of using DNNs as a fast and accurate surrogate model for hemodynamic analysis of large blood vessels.

METHODS

Dataset of Aorta Geometries and CFD Simulations. The DNNs were trained and tested using a dataset of 729 thoracic aorta shapes of virtual patients from our previous study¹ and corresponding CFD simulation results. As shown in Figure 2, the the aorta shape of a virtual patient (Fig.2-a1&a2, a shell mesh) is converted to a volume mesh suitable for CFD simulation (Fig.2-b1&b2). The CFD mesh is then converted to a mesh for machine learning (Fig.2-c1&c2), which has mesh correspondence¹ between patients (the same number of nodes/elements and the same nodal connectivity). The CFD simulations were performed using STAR-CCM+ (CD-adapco, Melville, NY) CFD software,

Figure 2. Three types of meshes for a virtual patient

Deep Neural Networks. In total, three DNNs with similar structures were designed to output pressure field, velocity magnitude field, and velocity vector field given an input aorta shape. The overall structure and data flow of the DNNs is shown in Figure 3. Given an input shape, a DNN will output a scalar/vector field in three steps: 1) encode the input shape as a set of scalar values, i.e. shape code; 2) conduct a nonlinear mapping of the shape code to the field code represented by a set of scalar values; and 3) decode the field code into the field values at

every node of the mesh. Autoencoders² are used to obtain the shape encoding modules and field decoding modules, which are three-layer fully connected neural networks using Softplus units.

Figure 3. The structure of the DNNs

RESULTS

The performance of the DNNs was evaluated using Monte Carlo cross validation. In each round of the cross validation, 90% of the shapes and corresponding pressure/velocity field data from CFD were randomly selected as the training data to determine the parameters of the DNNs; and the remaining 10% of the CFD data were used as the testing data to obtain performance measures. The process was repeated 100 times to obtain the mean and standard deviation of each performance measure. Four performance measures were used: mean absolute error (MAE), normalized mean absolute error (NMAE), root mean square error (RMSE), normalized root mean square error (NRMSE), absolute error of the peak value (AE_{peak}), and normalized absolute error of the peak value (NAE_{peak}). The results are shown in Table 1&2&3 and Fig 4.

Table 1: Accuracy of the velocity field from the 1st DNN

RMSE (m/s)	NRMSE (%)	MAE (m/s)	NMAE (%)
0.0804 ± 0.0435	4.3699 ± 2.3456%	0.1110 ± 0.0690	6.2140 ± 4.1691 %

Table 2: Accuracy of the velocity magnitude field from the 2nd DNN

MAE (m/s)	NMAE (%)	AE _{peak} (m/s)	NAE _{peak} (%)
0.0363 ± 0.0162	1.9608 ± 0.8367 %	0.0260 ± 0.0417	1.2913 ± 1.5258 %

Table3: Accuracy of the pressure field from the 3rd DNN

MAE (KPa)	NMAE (%)	AE _{peak} (KPa)	NAE _{peak} (%)

Figure 4. A representative example

DISCUSSION

Recently, ML-techniques have gained much attention in the field of biomechanics³⁻⁶. As an extension to our previous work on stress analysis⁶, in this study, we proposed to use DNNs as an ML-surrogate to directly estimate the steady-state distributions of pressure and velocity given the aorta geometry. The trained DNNs output pressure and velocity fields within one second, and the flow characteristics predicted by the DNNs are highly consistent with those from CFD. The success of this study holds promise for the use of Machine Learning techniques to expedite the patient-specific hemodynamic analysis of human blood vessels by bypassing the time-consuming model construction and simulation processes.

In our approach, CFD is treated as a black-box and the nonlinear relationship between CFD input and output is learned by the DNNs, which decouples ML-models from hemodynamic analysis methods. On average, it took about 15 min to run a CFD simulation for each shape, which seems to be fast enough for clinical applications. However, such CFD analysis is not accurate enough compared to FSI analysis which considers the interaction between tissue and blood flow and thus takes significantly longer computation time (hours ~ days)⁷. No matter what hemodynamic analysis method is used to generate the training data, the DNNs can still have the same structures and the same processing speed for steady state hemodynamic analysis.

Since the goal of this study was to evaluate the feasibility of using ML techniques to estimate the steady-state hemodynamics of the thoracic aorta, the following simplifications in the CFD models were made to facilitate the study: (1) the aortic wall was assumed to be rigid; (2) the field data in the branching vessels were not consider as a part of the DNN output, to ease the process of establishing mesh correspondence; and (3) the same boundary conditions and properties were used because we don't have patient-specific data. These limitations will be improved in our future work.

EFFECT OF NONLINEAR ELASTIC PROPERTIES OF ARTERIAL WALLS ON PULSE WAVE PROPAGATION

INTRODUCTION

The beating heart creates pulsating blood flow that travels through our vasculature as waves. The propagation of these pulse waves carries an immense amount of information about our cardiovascular health and has been a topic of research for many decades [1]. Our arterial network is extremely long and geometrically highly complex. Thus, the blood flow simulations for arterial networks approximate it as one-dimensional [2]. The governing equations incorporate the elasticity of the arterial wall via a constitutive relationship between pressure and cross-sectional area of the lumen. This constitutive relationship is commonly referred to as the “tube law”, which is usually approximated to be linear and sometimes as other functional forms [3].

In the last decade biomechanical researchers have assembled a large dataset on the elastic properties of various arteries, which characteristically show a high nonlinearity. Several three-dimensional constitutive models have been proposed to describe the arterial elastic properties, with the so-called “GOH model” [4] being one of them most widely used. In this study, we aimed to incorporate the detailed three-dimensional constitutive relationships of arteries into the one-dimensional blood flow simulations and thereby study the effect of material nonlinearity on pulse wave propagation.

METHODS

We assume that the arteries remain perfectly cylindrical at all stages of deformation and use axisymmetric cylindrical coordinates to describe three configurations: stress-free with a known opening angle, closed at a reference pressure, and loaded at a given pressure. The arterial wall is modeled to be fully incompressible and longitudinal stretch is assumed to be fixed throughout deformation. These assumptions allow us to describe the kinematics in a single variable: the radial deformation.

After integrating the radial equilibrium condition, we get the pressure difference between inside and outside of the artery is

$$\Delta p = \int_{r_i}^{r_o} (\sigma_{\theta\theta} - \sigma_{rr}) \frac{dr}{r}, \quad (1)$$

where $\sigma_{\theta\theta}$ and σ_{rr} are circumferential and radial Cauchy stresses. These are derived from a hyperelastic strain energy function ψ which is taken to be a combination of the fibrous and matrix components:

$$\psi(\mathbf{F}) = \frac{c}{2} (I_1 - 3) + \frac{k_1}{2k_2} (e^Q - 1), \quad (2)$$

where $Q = k_2[(1 - \alpha)(I_1 - 3)^2 + \alpha(I_4 - 1)^2]$. For the blood flow, the one-dimensional equations of mass and momentum balance, under Newtonian flow assumption, can be written as

$$\frac{\partial A}{\partial t} + \frac{\partial(Au)}{\partial x} = 0 \quad (3)$$

and

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + \frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{8\pi\mu u}{\rho A} = 0, \quad (4)$$

where A is the cross-sectional area of the lumen, u is the blood velocity, and p is the blood pressure. In order to close these equations, a tube law is required that defines the relationship between pressure and lumen area. Several different laws have been used in the literature, with the following most widely used

$$\Delta p = p_0 + \beta(\sqrt{A} - \sqrt{A_0}). \quad (4)$$

We apply our formulation to five specific artery properties reported in the literature, and also perform a parametric study by varying the various elastic parameters. We also look at the limit cases when the arterial wall is infinitely thick and infinitely thin. To match the results from linear tube law and our nonlinear one, we fit β such that the pulse wave velocity matches between the two cases.

ARTERY	Internal radius (cm)	Thickness of media (cm)	Thickness of adventitia (cm)
Rabbit carotid [5]	0.37	0.13	0.067
Human iliac adventitia [4]	0.4745	-	0.043
Human aortic arch [6]	0.9996	-	0.12
Human carotid [7]	0.37	0.13	0.067
Common iliac [8]	0.465	0.035	0.035

Table 1: Geometric details of five different arteries reported in literature (elastic properties are skipped in interest of space).

Under the approximation of no residual stresses and zero dispersion, we determined an analytical expression for the tube law (in interest of space, the final expression is skipped here). For other cases, we use numerical integration to evaluate Eq. (1).

RESULTS

The first question we explore is whether the detailed constitutive model which is nonlinear in three-dimensions can lead to a linear pressure-area relationship in one-dimension.

Using the properties for a rabbit carotid artery, we find that the stiffness of the matrix part decreases with pressure whereas that of the fibrous part increases (Fig. 1). Interestingly, the net result comes out to be approximately linear. However, for all other arteries this was not found to be the case (results not shown).

Figure 1: The pressure-area relationship for a rabbit carotid artery derived from its three-dimensional constitutive model

Next, we find the combination of elastic parameters that give a net linear response. Using the analytical expression, we noticed that the effective pressure-area relationship depends only on reduced parameters $\log(k_1 \cos^4(\beta)/c)$ and $\sqrt{k_2} \cos^2(\beta)$. Thus, we look at the range of inflation $\lambda = r/R$ up to which a linear approximation is more than 95% accurate (Fig. 2). We find that only for a small range of elastic parameters this is expected to be the case.

Figure 2: A contour plot of the combination of elastic parameters that lead to a net linear response

DISCUSSION

Models of pulse propagation through our arterial network have a potential of providing new ways to diagnose cardiovascular diseases. In spite of a wealth of information related to the elastic properties of different arteries, only generic tube laws are used for the pulse propagation. In this study, we present a first attempt in incorporating detailed three-dimensional information about arterial elasticity, including different layers and their specific properties. Results suggest that although for some specific arteries, a linear approximation might be appropriate, such cases are rare. Thus, we are currently investigating how this nonlinearity affects the pulse wave propagation.

FAST TUMOR SPHEROID GROWTH IN MICROFLUIDIC DEVICE

Yaling Liu^{1,2*}, Chris Uhl², Yuyuan Zhou²

¹Department of Mechanical Engineering and Mechanics

²Department of Bioengineering
Lehigh University, Bethlehem, PA

INTRODUCTION

Patient derived organoids have emerged as robust preclinical models for screening anti-cancer therapeutics. Current 2D culturing methods do not provide physiological responses to therapeutics, therefore 3D models are being developed to better reproduce physiological responses. 3D culturing however often requires large initial cell populations and one week to one month to grow tumors ready for therapeutic testing. As a solution a 3D culturing system has been developed capable of producing physiologically relevant tumors in an expedited fashion while only requiring a small number of initial cancer cells.

METHODS

Device Fabrication

Bi-layer microfluidic platforms were produced following similar techniques outlined in previous microfluidic works from the Liu group^{45–49}. The devices produced for expedited tumor spheroid growth contained a semi-permeable polycarbonate membrane which functioned to separate the apical and basal halves of the microfluidics. The circular chamber where the cancer cells were grown measured 3mm in diameter and 1.5mm in height. The straight sections of channel in the microfluidic devices measured 600µm in height and width. The use of the semi-permeable membrane within the system functioned to prevent the cancer cells introduced into the system from being washed downstream and out of the channel, which had an average pore diameter of 800nm. A depiction of the microfluidic setup can be viewed in Fig. 1.

HCT116 Spheroid Growth

Tumors were grown using HCT116 human colorectal cancer cells. The HCT116 cells used for testing were purchased from ATCC and all tests were carried out with cells within 5 passages from the initial frozen stock provided by ATCC. All spheroids utilized in this work were grown from an initial suspensions of 30 cells which were pre-formed into loose tumor spheroids via an 8 hour incubation in a low adhesion round bottom well plate under static conditions. The Ultra-Low Attachment Multiple Well Plates were manufactured by Corning that feature a covalently bound hydrogel layer that effectively inhibits cellular attachment. No additional coatings were required to facilitate spheroid formation in the round bottom wells. A hemocytometer was used to verify the concentration of cells in a stock suspension from which appropriate volumes of the suspension were separated to ensure that exactly 30 cells were introduced into each well. Due to the

small number of cells used in each test, visual confirmation was performed for each well to ensure that 30 cells were present. Well containing greater or fewer than 30 cells were discarded and not used for growth testing. The pre-formed spheroids were then collected and flown into their respective microfluidic devices. Once inside the microfluidic devices, the semi-permeable membrane functioned to capture the pre-spheroids and hold them in place over the duration of the experimentation. The same process of an 8 hour incubation in a low adhesion well plate to pre-form spheroids was utilized for the static based tests. After pre-forming the initial static test case spheroids, Matrigel was added to the well plate in order to further facilitate spheroid growth over the course of 120 hours. Tumor spheroids grown under flow conditions were established as noted in the leukemia growth section at specific flow rates of $3.4 \times 10^3 \mu\text{L/hr}$ and $3.4 \times 10^4 \mu\text{L/hr}$. Nutrient consumption for the HCT116 cells was also visualized and estimated as described for the leukemia cancer cells. Likewise, the HCT116 cells were maintained and grown under the same standard culturing conditions of 37°C and 5% CO₂ in an incubator as the leukemia cells.

Cancer Growth Measurements

Cancer growth was monitored daily over the course of five days with brightfield and fluorescence imaging. Data collection for spheroid growth was accomplished utilizing CellTracker™ Stain (10µM red, Thermo Fisher Scientific) and confocal microscopy (Nikon C2+, Apo 4X). Images of each cancer growth set-up were captured every 12 hours over the course of 5 days. All images were processed with FIGI (ImageJ) in order to measure HCT116 tumor sizes and cell counts for leukemia tests.

Statistical Analysis

Statistical analysis of all obtained results were run utilizing IBM's SPSS statistical software package (IBM Corp.). All of the figures have significant differences indicated above elements within the plots. One way ANOVA tests were run for each data set with confidence levels of 95% held throughout all plots. All analyses were carried out under conditions of Tukey equal variances assumed, along with tests of homogeneity of variance further verified by both Brown-Forsythe and Welch analyses.

RESULTS

On-chip cell culture and Imaging

Adherent cancer cells (HCT116) grown within the devices were first aggregated together under static culturing conditions within low adhesion well-plates. The cells were added to the wells and given 8 hours to adhere into loose spheroids before being introduced into the microfluidic devices. HCT116 cancer cells were successfully cultured within the microfluidic devices. Fig. 3b depicts representative images of HCT116 cells grown when subjected to a flow rate of $3.4 \times 10^4 \mu\text{L/hr}$ over the course of 120 hours. Both representative figures show overall increases in cell counts as time progresses as is indicated by the presented growth data in Fig. 2a.

Figure 1. Microfluidic device schema depicting device structure and cancer cell capture function utilizing semi-permeable membrane. Flow direction indicated by red arrows. (a), Device schema cross-section. (b), Device schema overview. (c), Image of sample microfluidic device utilized in experimental testing (white scale bar is 3mm long).

Cancer Growth Measurements and Nutrient Availability

Successful culturing of cancer cell lines was accomplished, as demonstrated by the growth of human colorectal (HCT116) in Fig. 2a. Growth of the cancer populations within the devices was measured directly through confocal imaging with CellTracker™ red stain. Through the application of various flow rates within the microfluidic devices, the rate of growth for the cancer cell populations was controlled. The use of convective flow allowed for a maximum of 4.76 times faster cancer cell growth when compared to the static growth cases. When compared to the static test cases, introducing $3.4 \times 10^3 \mu\text{L/hr}$ nutrient flow into the systems containing HCT116 results in an overall increase in the cell population by a factor of 2.47 at the end of 120 hours. Even more impressive was the observed increase in HCT116 growth when supplied with a nutrient flow of $3.4 \times 10^4 \mu\text{L/hr}$, which resulted in a 4.76 factor increase in the cell population.

Figure 2. HCT116 cell growth over time based on flow conditions (30 cell initial count). a, Normalized HCT116 cell count over time for various flow conditions and theoretical model predictions. b, Normalized nutrient availability within microfluidic system over time for various flow conditions. Equilibrium point indicates when nutrient availability within the system can no longer satisfy the requirements of the entire cancer cell population. c, Representative fluorescence images of HCT116 tumor spheroid growth over the course of 120 hours under a flow rate of $3.4 \times 10^4 \mu\text{L/hr}$ (scale bars are $60 \mu\text{m}$). Statistical significance indicated by *** between flow based tests and static conditions and *** between flow based tests at $p \leq 0.05$.

INTRODUCTION

Cancer is recognized as a complex disease driven by genetic and epigenetic factors in individual patients. The last few decades have seen an emergence of various treatments against the disease, including chemotherapy, radiotherapy, and immunotherapy. Previous clinical studies have shown that similar genetic makeup of patients and cancer expression does not guarantee the efficacy of same treatment within these patients. A more personalized drug selection that serves the patient individually would account for the epigenetic variations presented in each patient [1]. The high expenses of the drug development process of selecting a few drugs from thousands of potential agents may inadvertently reject potentially effective drugs, which could not obtain the approval by FDA due to their adverse or undesirable effects on the majority of the population but may be effective for a small subset of the population [2]. On the other hand, there is a clinical need and merit to screen drugs for personalized treatment that minimizes adverse effects on patients and expedites selection of accurate treatment. Current methods of personalized screening involve disaggregating the cells from the original biopsy sample, and culturing them in 2D or reconstructed 3D matrices. However, under current health insurance policies, these methods are not accepted as being substantially more informative than available traditional clinical approaches [3]. Isolated cells in 2D culture lack full microenvironment, and an artificial 3D structure provides an altered non-native physical and biochemical microenvironment. Towards this end, we have developed a microfluidic tissue array (μ FTA) as a platform for live culturing of tumor tissue samples directly under pathologically/physiologically relevant flow conditions. The tumor microarchitecture and microenvironment are preserved in our μ FTA by virtue of never being disaggregated. Currently it has been developed as 2x4, 4x4, 6x4, or 8x4 platform for performing drug

screening with mid-throughput and expected scalability up to 16x4 (16 conditions with 4 replicates per chip). The μ FTA is expected to be a clinically more relevant tool for precision medicine selection over current techniques using isolated cells or reconstituted matrices.

METHODS

The μ FTA is manufactured through standard soft lithography using a 3-layered construct of PDMS (polydimethylsiloxane). The 3 layers comprise of: (1) a bottom layer arrayed with traps to capture tissue pieces within a size of 0.5mmx1mmx1mm, (2) a top layer for media or drug perfusion located above the trap regions, and (3) a thin middle layer with a network of pores that provide a fluidic pathway between the top perfusion layer and the trap regions. The layers are bonded together as one complete device using oxygen plasma treatment. The tissue trap regions are situated within desired culture chambers which are hemispherical structures of 3-6mm diameter. The top perfusion layer spans to completely cover the trap region so to provide nutrients and optical clarity with a depth of at least 400 μ m. The pore-laden middle layer is about 40-60 μ m thick with each pore having a 150-250 μ m diameter. The design of the μ FTA is continuously being optimized through CFD simulation (ANSYS and COMSOL) to provide flow velocities that are physiologically prevalent. The CFD results are verified through particle tracing velocimetry using fluorescent 2 μ m latex beads.

Xenograft tumors were generated by subcutaneously injecting MB-MDA 231 and BT 474 breast cancer cells with GFP in NOD-SCID mice. Patient-derived xenografts of HER2+ breast tumor (M-37) and triple negative BRCA1 mutant breast cancer (M156) were kindly provided by the Chandarlapaty lab at MSKCC. Harvested tumors were manually cut into small pieces less than 1mm³, and then seeded into the μ FTA by flow. Tumor tissues in the μ FTA were cultured using

continuous flow at 1ml/day via a syringe pump in a 5% CO₂/37°C incubator. Following a 1-2 week culture, the xenografts were profiled with live-dead staining as well as EdU staining for proliferation. Doxorubicin was administered to the MB-MDA 231 samples after 2 weeks of culture, and to the M-156 samples after 1 week of culture, at a concentration of 2µg/ml, for 1 week, following which live-dead and proliferation assays were done. Histology stains for selected surface markers (HER2, EpCAM, CD44, and CD24) were performed on the M37 samples at day 0 and after day 10 of culture in the µFTA. Tissue images were captured with epi-fluorescent microscopy (AxioObserver Z1) or confocal microscopy (Zeiss LSM 700).

RESULTS

The CFD model results indicate that a 1ml/day supply of media is sufficient to maintain a flow on the order of 0.1µm/sec (Fig. 1) in accordance with its relevance to physiological flow, and has been verified using bead velocimetry. Under these culture conditions, the µFTA maintains the xenograft samples within culture for 1-3 weeks, allowing slight morphological changes or outgrowth (Fig. 2A-B), while maintaining the biopsy vitality and proliferation as noted from live-dead and EdU assays. There is no appreciable fluctuation in the expression of surface markers in the histology samples, with the exception of increased EpCAM expression. Treatment of the tissue samples to doxorubicin show a distinct clearance of the tissue as observed under phase-contrast imaging (Fig. 2 C-D).

Figure 1: ANSYS CFD simulation of flow in the µFTA. The elliptical regions in the traps are modeled as porous regions to simulate tissue. Note that the velocity around this simulated tissue area reaches the order of 0.1 µm/sec.

Figure 2: Culture of RFP-tagged MB-MDA 231 xenograft in the µFTA and following drug treatment. The tissue piece shown here corresponds to the tissue piece maintained in the µFTA on (A) day 1 after seeding, (B) day 5, (C) day 8, which is when doxorubicin was administered continuously at 2 µg/ml, and (D) day 6 of dox treatment, (day 14 of culture). Notable from (A) to (B) is the morphological reshaping and expansion of the tissue piece, from (C) to (D) is the visible reduction in tissue density (optical clearance of tissue) and significant removal of surface-adhered cells after the course of drug treatment. Scale bars: 200 µm.

DISCUSSION

The µFTA developed here has the potential to be a clinically relevant tool in the process of personalized medicine. In its current format, it provides a platform for conveniently seeding and culturing whole tissue samples under physiologically relevant flow conditions, with or without drugs. Depending on the format of the µFTA, different reagents can be administered onto a single chip such that varying drug treatments of assays can be performed on-chip on the whole tissue with biological replicates. The µFTA can be cascaded with different tissue types to study interorgan interaction. The versatility in the use of the µFTA is a promising technology to permit direct screening of effective drugs on patient biopsy samples to assist in a selection that would be beneficial to patients tailored to their individual cancerous tissue.

INTRODUCTION

Circulating tumor cells (CTCs) can lead to metastasis that accounts for 90% of the death for cancer patients[1], [2]. Thus, detecting CTCs at an earlier stage is important for diagnostics. However, detecting CTCs is very challenging, as CTCs are rare, e.g., there are only a few CTCs in 1 mL blood sample that contains billions of blood cells. Recently, microfluidic devices with micropost features have been shown in detecting CTCs successfully[3]. Different micropost sizes, separation distance, and layout has been proposed to separate CTCs from blood sample. Meanwhile, theoretical analysis and numerical simulations were performed to improve the design of the devices, e.g., a unified theoretical framework was proposed to infer the trajectories of particles in the whole device on the basis of trajectories in the unit cell[4]. The effect of post shift distance and deformability of blood cells on cell trajectories were also studied in[5], showing that it is possible to separate cells through label free method. Numerical simulations suggest better designs though combining a diffuser and a semi-cylindrical obstacles[6]. Despite these efforts, a general design principle for CTC detection considering the hydrodynamics, fluid cell interaction, cell transport and adhesion is currently not available. In the current work several numerical CTC detection simulations were performed to evaluate the binding behavior of CTCs and its diffusivity under the influence of blood cells. The numerical results on cell adhesion pattern and cellular trajectory agreed well with microfluidic experiments using human prostate cancer cells (PC-3).

METHODS

The fluid flow was solved by the lattice Boltzmann method because of its efficiency in modeling complex geometries and parallel computing. The cell membrane was modeled using a coarse grained molecular dynamics method where membrane stretching and bending

were considered. The adhesion between cells and microposts was modeled as pair wise interactive Morse potential. The immersed boundary method (IBM) was used to couple the fluid motion with the solid deformation. Briefly, the solid velocity at each particle position is obtained through velocity interpolation from local fluid nodes, while the fluid feels the existence of the solid through body force terms. Details of the immersed boundary method formulation can be found in Refs[7]. The blood cell model and numerical implementation was verified in our previous publications[8], [9].

Two different microfluidic designs were considered in the study: regular layout and shifted layout. The microposts in the regular one were separated by 50 μm . The shifted one was based on the regular design but the center position of the microposts were shifted 50 μm every other three row in vertical direction. A characteristic unit of the two designs device was created and periodic boundary conditions were applied to model the fluid flow. Experimentally diluted blood with PC-3 mixture (about 5000 cells/mL) was injected into the PDMS micro-fluidic device at the constant flow rate 0.12 mL/hr for 1hr to study the PC-3 cell adhesion and trajectory in the microfluidic devices.

RESULTS

The fluid flow was driven by body force with periodic boundary conditions in x and z directions. Cancer cells showed preferred adhesion locations on the surface of posts. The simulation results showed that the cells tend to settle down on the micropost surface where the shear stress is low, as indicated in the blue region in Fig. 1a. Microfluidic based experiments also confirmed that the cells do prefer adhered to those low shear stress regions, see Fig. 1b.

Figure 1. Cells showed preferred adhesion region on the microposts in the microfluidic device with regular design. (a) Simulation: three cells were adhered to the microposts, the background color shows the fluid velocity distribution. (b) Microfluidic experiments showing one cancer cell adhered on the front stagnant point.

Figure 2. (a) A snapshot of the blood cells (red) and cancer cells (green) mixture in a microfluidic device with shifted design. (b) the shift distance for cells after one cycle.

Blood cell mixture with cancer cells transport in microfluidic device with shifted design was also performed, as shown in Fig.2a. The cell drifting Δx in the direction perpendicular to the fluid flow was selected to quantify the cell motion in microfluidic device. Since periodic boundary conditions were applied in the simulation, the cell drifting in one cycle for micropost with a radius $R=50 \mu\text{m}$ was plotted in Fig.2b. It showed that drift for most of the cells is small, with a gauss like distribution with a mean of zeros and variance of $5.6 \mu\text{m}$. However, there are some cells showed significant drift in x direction, e.g. $\Delta x > 20 \mu\text{m}$, in particular in the negative x direction. The reason is due to the layout of the micropost where the resistance is smaller in the negative x direction. Simulation with micropost of different sizes showed similar pattern for the shifted distance in x direction (results not shown here).

DISCUSSION

The cell preferred adhesion location is consistent with the low shear stress region. It is expected as the ligand receptor bond is not stable at high shear stress. Thus, low shear is favorable for cell adhesion. The current model did not consider the stochastic nature of the bond formation and breaking. Another limitation is that the bond formation is instantaneous without considering the adhesion rate. Adhesion model following bell's model will be considered in the future study.

Cancer cell showed stochastic dispersion in the blood flow, as characterized by the shift distance in x direction. Cells are subjected to collisions from nearby cells, which results in a random walker like behavior. The deformability induced cell diffusion under shear flow also contribute to the cell diffusivity. If the cell trajectories can be approximated as a superposition of stream line trajectory and dispersion, then the cell micropost collision frequency can be estimated based on the device size in the flow direction and gap size perpendicular

to flow direction, as cells cover device size through convection, while converting gap size by dispersion. Then, the design problem for microfluidic device optimization can be formulated as an inverse problem such that the capture efficiency is given, based on the design layout, what size of the microfluidic device should be? The hypothesis will be studied in details in the future work.

INTRODUCTION

Inflammatory breast cancer (IBC) is an aggressive disease with poor prognosis, accounting for 10% of breast cancer mortality [1]. It is characterized by redness and swelling of the breast and spreads rapidly and diffusely within the primary site and surrounding tissue instead of developing a lump. Contrary to its inflammatory namesake, symptoms are manifested by blockage of lymph channels and skin invasion rather than inflammation [1,2,3]. A primary factor contributing to the bleak prognosis is the difficulty of early IBC diagnosis. Approximately 50% of IBC cases lack a tumor mass and present no radiographic IBC evidence. Also, at diagnosis, the tumor has advanced to stage III or IV, most patients have lymph node metastases, and 30% of IBC patients exhibit distant metastases compared to 5% for non IBC [2,3,4]. Despite advancements in diagnostic and therapeutic approaches have improved the bleak prognosis associated with IBC but the 5 year survival rate of IBC compared to locally advanced breast cancer is still inferior.

There are currently no IBC specific therapies due to rarity of the disease combined with the lack of IBC specific diagnostic and targeting markers. Most efforts have focused on identifying driver mutations and tumor targets. While numerous comparative genomic studies of IBC and non-IBC have been undertaken, none have implicated a compelling tumor cell autonomous driver to be targeted to improve outcomes. Interestingly, most of the genes in the IBC-like signature are predicted to represent stromal cells rather than tumor cells [5]. Studies have emphasized the significance stromal cells in mediating IBC-like symptoms in animal models. This highlights the significance of understanding the interactions of tumor cells with the microenvironment in greater detail and the knowledge would enable determination of targetable biology from these interactions which would facilitate identification of patients who would benefit from such approaches. What is critically needed is a validated model to capture

this complexity, identify critical spatial hetero-cellular interactions, and target them successfully in a more nuanced/physiologically relevant and high-throughput manner

To better study IBC, we have developed a novel *in vitro* breast tumor platform that possesses a matrix supportive of IBC cell representative growth incorporated with fully functional lymphatic and blood vessels for modeling critical invasion into these structures in a dynamic and spatial manner. The platform will be used to study 2 key critical features of IBC: (i) vascular sprouting and (ii) formation of IBC emboli surrounded by vascular sprouts. We will investigate the influence of macrophages, a key stromal cell in influencing IBC aggressiveness, and test the effect of various therapies such as trastuzumab on the aforementioned critical features of IBC.

METHODS

***In vitro* breast tumor platform:** 14 mg/ml collagen stock solution was mixed with 10x DMEM, 1N NaOH to and supplemented with DMEM containing HER2+ breast cancer cells and THP-1 macrophages. Cancer cells used were breast HER2+ IBC cancer cell line MDA-IBC3, and non IBC HER2+ cancer cell line BT474. The collagen mixture was then injected into a PDMS mold with a needle inserted through the center and allowed to polymerize around the needle. After polymerization and removal of the needle, a cylindrical hollow void was created in the collagen which was then seeded with either telomerase immortalized microvascular (TIME) cells labeled with red fluorescence or human derived lymphatic endothelial cells (hdLECs). Lymphatic vessels were confirmed through immunofluorescent staining for lymphatic markers LYVE and Prox-1. Vessel permeability was quantified by flowing the channel with 10 μ g/ml fluorescently labeled 70 kDa to investigate the barrier function of the endothelium. Vessel sprouting and emboli formation were analyzed using Leica TCS SP8

confocal microscope to observe vessel sprout formation and growth followed by analysis for number of tumor emboli and sprouts, size of emboli, sprout length, thickness, and branching. Lumen formation was analyzed by perfusing the vessels with one micron green fluorescent microspheres which aggregate at the vessel walls outlining the endothelial barrier.

Trastuzumab effect: Trastuzumab treatment has shown to improve survival rates of HER2+ breast cancers. To test the influence of trastuzumab on both IBC and non IBC HER2+ tumors, Herceptin was perfused through the platforms for 24 hours followed by perfusion of fresh media for 48 hours. Next, platforms were broken down using collagenase, cells collected and lysed. Luminex bead-based multiplex assay for total and phosphorylated HER2, ERK, AKT, p38MAPK was performed.

RESULTS

We created a HER2+ *in vitro* breast tumor platform as shown in Figure 1 capable of chemotherapeutic and cytokine perfusion. This unique platform, which will serve as the baseline platform, provides long-term, spatiotemporal characterization of multi-cellular interactions and tumor response to tissue microenvironmental conditions (matrix mechanics, cell composition, and biotransport) with high-resolution quantitative velocimetry, transport and imaging for target discovery.

The platforms were followed for a 3 week period and imaged using confocal microscopy to analyze vessel sprouting as illustrated in Figure 2 in MDA-IBC3 platform. The sprout lengths were measured over time and we observed a significant increase in sprout lengths at later time points (Figure 2A). Additionally, at later time points we see the formation of tumor emboli

Figure 1. *In Vitro* Breast Tumor Platform:
Perfusable blood (red) and lymphatic (green) vessels surrounded by collagen matrix seeded with HER2+ tumor (green) and stromal cells; scale 500 μ m.

Figure 2. Established Measurable Tumor – Stromal Cell Interactions. A) Vascular sprouting dynamically observed over a three week period in the MDA-IBC3/TIME *in vitro* platform. Longitudinal cross section images of the vessel showing vessel sprouting, branching, as well formation of tumor emboli (white arrows) scale bar: 200 μ m; B) Close up images of emboli (green) surrounded by vascular vessel sprouts (red); scale bar 300 μ m

surrounded by vascular nests replicating *in vivo* IBC characteristics seen in MARYX xenograft models. To test for lumen formation, vessels were perfused with 1 micron green fluorescent microsphere and as demonstrated in Figure 3, we saw the green fluorescent microspheres travel to the tips of the sprouts revealing the newly formed sprouts are patent and capable of handling flow. Additionally, we perfused trastuzumab, a HER2+ specific therapy and saw a greater sensitivity of the endothelium in the IBC *in vitro* breast tumor platform compared to non IBC breast tumor but saw a greater resistance in the IBC MDA-IBC3 tumor cells compares to non IBC BT474 cells.

Figure 3. Patent and Functioning Sprouts. Green microspheres travel to the periphery of the newly formed sprouts as indicated by the white arrows.

DISCUSSION

IBC is an aggressive and invasive breast cancer with a poor prognosis linked to tumor-stroma interactions. Current preclinical to study IBC consist primarily of xenograft animal models which are cost prohibitive due to large number of animal required. Additionally, determining the influence of specific signaling pathways and microenvironmental stimuli on tumor progression is challenging. Here we present a novel *in vitro* breast tumor platform to model two HER2+ breast tumors and saw a difference in their behavior. The MDA-IBC3 breast tumor platform demonstrated both vascular sprouting and emboli formation, 2 key features of IBC tumors seen in *in vivo* mice models. This behavior was observed specifically in the IBC platform and was absent in the non-IBC BT474 tumor platform. Furthermore, there was a difference in the response of the tumor platforms to trastuzumab therapy. BT474 cells were more sensitive to trastuzumab but the endothelium in the MDA-IBC3 platform which presented vascular sprouting was more affected by the trastuzumab therapy. The differences in the behavior in the two platforms highlight possible molecular targets that can differentiate between IBC and non IBC tumors and lead to development of effective IBC specific therapies.

COMPUTATIONAL FLUID DYNAMICS MODEL OF PRESSURIZED INTRAPERITONEAL AEROSOL CHEMOTHERAPY: GRAVITY MATTERS!

INTRODUCTION

Pressurized IntraPeritoneal Aerosol Chemotherapy (PIPAC) is a recent and innovative drug delivery strategy developed to treat peritoneal cancer using laparoscopy [1,2]. During PIPAC, a CO₂ pneumoperitoneum is established (12-15 mmHg) and chemotherapy is nebulized to obtain a homogeneous aerosol distribution within the peritoneal cavity (Figure 1). The aerosol is generated by injecting chemotherapy-containing liquid under high pressure through a single fluid nozzle (micro-injection pump) [3]. The increased intraperitoneal pressure may overcome the elevated interstitial fluid pressure (IFP) in tumor tissue and lead to enhanced tissue penetration of chemotherapy [1].

Figure 1: schematic overview of a PIPAC procedure [4].

Since tumor nodules tend to occur anywhere on the peritoneal surfaces, a *homogeneous distribution* of the aerosolized chemotherapy is of

paramount importance. Preclinical experiments suggest that aerosol distribution is not uniform, probably due to the effects of gravity [5]. The use of a Computational Fluid Dynamics (CFD) model may generate important insights in how treatment parameters affect aerosol distribution during PIPAC. Here, we developed a numerical PIPAC model to investigate the effect of gravity on the distribution and deposition of aerosol particles in the peritoneal cavity in a rat model.

METHODS

A micro-computed tomography (μ CT) multislice scan of the peritoneal cavity of a healthy rat (Infinity Lab, UGent) was used as input to generate the 3D simulation geometry. As we need the abdominal geometry of the rat during PIPAC, the abdomen of the rat was insufflated with CO₂ up to 8 mmHg (1066 Pa) and kept constant throughout the scan. The μ CT images (DICOM files) were imported into Mimics Research software (Materialise, Belgium) (Figure 2a-b) and segmented.

Figure 2: 3D reconstruction of the pressurized rat abdominal cavity: (a) 2D single slice of the CT dataset, (b) 3D reconstruction of the rat abdominal cavity and (c) the generated mesh with division of the volume in 8 subvolumes.

Figure 3. Geometry subdomains and illustration of the achieved homogeneous inflow (CO₂) pressure distribution.

The resulting STL-file was imported in COMSOL Multiphysics (Inc., Burlington, VT) to set up the CFD simulation. Next, a good quality mesh grid was generated resulting in 135000 tetrahedral elements. The geometry was divided into 8 subvolumes to compare different zones (Figure 2c and 3).

The first part of the CFD simulation focused on filling the abdominal cavity with CO₂ gas until its pressure equals 8 mmHg. The governing continuity and momentum equations of the CO₂ flow phase were considered under time-dependent, weakly compressible and Newtonian fluid (density of 1.98 kg/m³ and dynamic viscosity of 1.4*10⁻⁵ Pa·s) assumptions. The inflow boundary condition was set to a pressure of 8 mmHg. No-slip conditions were used for the walls.

Subsequently, particle flow was simulated using Comsol's Particle Tracing Module. Similar to experimental conditions, a volume of 20 mL of the chemotherapy solution (in this study AbraxaneTM) was used with a volumetric flow rate of 0.8 mL/s at a fixed injector position [6]. By using the values of flow, flow rate, inlet surface area and injection time, particle inlet velocity could be calculated. The initial position (random), velocity (15.92 m/s), diameter (30 μm), density (1004.6 kg/m³) and viscosity (1.0182 mPa·s) of individual particles were determined [6]. The time of injection was 25 s which resulted in 125000 particles being injected for each simulation. It was assumed that impacted particles do not bounce from the cavity wall, but adhere to it once the distance between particle center and the wall is less than the particle diameter. The trajectory and mass transfer calculations are based on the force balance on the particle, using the local continuous phase conditions as the particles move through the flow. Simulations were done with and without adding the gravity force in the force balance equations.

RESULTS AND DISCUSSION

The first results demonstrate that the first part of the simulation leads to a uniform pressure distribution of 8 mmHg in the peritoneal cavity filled with CO₂ (Figure 3). Figure 4 (a-b) illustrates that the aerosol distribution is not homogeneous, as is also confirmed by Khosrawipour et al. [5]. Furthermore, aerosol distribution and concentration vary considerably when taking into account gravity force. In some regions, the particle concentration was high, while it was very low for other regions. When neglecting the gravity force, the particle distribution in abdominal cavity is more homogeneous. Figure 5 displays the number of deposited particles on the abdominal wall divided in the different subvolumes (as defined in Figure 3). When considering the gravity force, most particles directly deposit in domain 6 (80% of particles). By removing the gravity force, the particle deposition in domain 6 decreases (36% of particles) and increases in other regions. Hence, these preliminary results indicate that the influence of the gravity force on aerosol distribution is significant in PIPAC and should be confirmed in validation experiments and other animal/patient- specific geometries. By considering additional forces, such as the electrostatic force [7], it may be possible to overcome the

gravity force effect and improve the distribution in the abdominal cavity.

In conclusion, aerosol distribution during PIPAC therapy is significantly affected by gravity. Use of a CFD model may allow to understand particle behavior during PIPAC therapy and inform improved treatment methods.

INTRODUCTION

Improving our understanding of the biomechanical factors that regulate tumor progression, including angiogenesis and metastasis, will permit the development of novel treatment strategies. Currently, the gold standard for cancer studies are murine models, which provide 3D physiological complexity but lack precise control over biomechanical parameters. On the other hand, many *in vitro* models permit high levels of control over mechanical inputs, however fail to exhibit the same level of complexity as *in vivo* systems. Microfluidic devices allow for a complex, 3D microenvironment that mimics *in vivo* systems while permitting improved control over multiple biomechanical parameters. The objective of this project was the development and optimization of microtissue system with independent inputs for multiple mechanical factors including spatiotemporal loading of cells and ECM-based gels, interstitial flow, and the transfer of mechanical strains between microtissues.

Cancer-associated fibroblasts (CAFs) have been shown to be key regulators of the tumor microenvironment, both in terms of secreted paracrine factors and reorganization of the ECM. Recent work in our group suggests that the mechanical behavior of CAFs is also an important factor in the growth of blood vessels, and that mechanically-inhibited CAFs cannot support vascularization in an *in vitro* model. As angiogenesis is necessary for tumor progression, an *in vitro* model allowing investigation of mechanobiological regulation of cancer-associated angiogenesis would elucidate how biomechanical factors promote tumor progression.

METHODS

Microfluidic devices were designed in AUTOCAD and generated using previously established techniques in our lab. To determine parameters for experiments, COMSOL modeling was employed to

predict fluid flow patterns; experimental parameters were established to control interstitial flow between chambers. For validation, 70kDa dextran, tagged with either FITC or RhodamineB, was loaded into devices containing fibrin gels.

Angiogenesis studies were carried out by loading fibrin gels containing cells into the separate tissue chambers. On Day 0 – Normal Human Lung Fibroblasts (NHLFs) and umbilical cord blood-derived endothelial cells (ECs) were loaded into the central chamber only. On Day 4 – CAFs or normal breast fibroblasts (NBFs) were loaded separately into the side chambers in fibrin gels. The fibrin gel concentrations were maintained across the device at 10mg/mL. Several devices were loaded with NBFs or CAFs in one side chamber, with a blank fibrin gel (no cells) loaded in the opposing chamber as a control. On Day 8, the devices were fixed with 10% formalin and stained for CD31.

RESULTS

A multi-tissue chamber microfluidic device was designed to allow for control over multiple biomechanical inputs including interstitial flow, ECM and cell loading (Figure 1A). The devices I comprised of three tissue chambers connected via communication ports (4 per interface, ~20µm each), with each chamber having its own set of fluidic lines. Using COMSOL, two flow regimes were generated including a Top-to-Bottom Flow (Figure 1B) that prevented interstitial flow between chambers and an Outward Flow (Figure 1C) that permitted flow only from the center chamber to the two side chambers, with the goal of limiting diffusion of soluble factors from the side chamber to the center. Line tracings of fluid velocities in the models indicate that for the Outward Flow regime, interstitial flow levels peak ~ 0.1µm/s, which is considered a normal physiological rate.

To validate our flow models, fluorescently-tagged dextran was loaded into the chambers in the Top-to-Bottom regime and allowed to equilibrate for 24h (Figure 1D). Results indicate significantly higher FITC-dextran in the side chambers compared to the center chamber (Figure 1E, * $p < 0.01$) and significantly higher rhodamine B-dextran in the center compared to the outer chambers (Figure 1F, ^ $p < 0.01$). Following this quantification, the dextran solutions were removed and replaced with DPBS in the Outward Flow regime, demonstrating a “washout” effect of dextran. Importantly, there was almost no detectable FITC signal in the center chamber, indicating that FITC-dextran from the side chambers did not diffuse into the central chamber during the “washout” studies.

Figure 1: (A) Schematic of multi-chambered device, with tissue chambers shown in blue; fluidic lines shown in pink. (B,C) Predicted interstitial flow velocities through communication ports. Grey arrows point to interfaces between tissue chambers for Top-to-Bottom Flow (B) or Outward Flow (C). (D) Fluorescent image of FITC- or RhodamineB-tagged dextran in multi-chamber device after 24h with Top-to-Bottom Flow. (E) Quantification of average fluorescent intensities in individual chambers of (D). * $p < 0.01$ and ^ $p < 0.01$ vs. center chamber. (F) Fluorescent intensities in individual chambers after 24h of Outward Flow with DPBS.

For angiogenesis studies, the NHLF and ECs in the central chamber supported self-assembled growth of a blood vessel network by Day4, when the side chambers were loaded. After 8 days, significant blood vessel occurred towards side chambers loaded with CAFs compared to NBFs (Figure 2A,B).

DISCUSSION

The microtissue design described in this project will allow for improved investigations of biomechanics in the tumor microenvironment. Our modeling and experimental flow studies demonstrate the ability to control flow across each tissue chamber and communication between chambers. With the Outward Flow regime, we suppressed diffusion from the side chambers toward the center chamber, thus limiting diffusion of paracrine factors secreted by CAF or NBFs into the center chamber for the angiogenesis studies. Even in the absence of these factors, the CAFs demonstrated higher levels of angiogenic potential compared to NBFs or blank control gels. The enhanced angiogenesis that occurred into the side chamber containing CAFs could be due to increased mechanical activity of CAFs compared to NBFs, supported by previous work in our group that demonstrates mechanical forces generated in the ECM can promote vascularization of a fibrin gel in the absence of secreted factors. Future studies will utilize fiducial markers in a bead tracking algorithm to determine the levels of cell-induced mechanical activity transmitted between tissue chambers. To eliminate soluble factors altogether, a series of studies utilizing magnetic beads to generate mechanical perturbations between chambers will also be completed.

INTRODUCTION

The myocardium is a complex biocomposite of myocytes, extracellular matrix, and blood vessels, possessing an intricate structural hierarchy and exhibiting complex behavior at multiple length scales. It has been the focus of mathematical modeling for several decades. Myocardium's highly anisotropic nature demands a comprehensive 3D constitutive formulation in order for its mechanical properties to be fully captured in a model, and the tissue is commonly thought of as a locally orthotropic material at the tissue-level scale. Current modeling efforts have shown success in developing forms to fit mechanical testing datasets acquired from samples of left ventricular myocardium. However, the datasets used for fitting these models have been limited to narrowly defined deformation types that may not fully reflect the 3D variation present in the tissue or may not be appropriate for obtaining the most robust estimates of material parameters. Moreover, assessment of fitted models' ability to accurately predict behavior in non-physical states associated with disease has not been substantially explored.

To this end, we have previously implemented a theoretically-driven numerical-experimental methodology, based on optimal design of experiments, to obtain structural-mechanical measurements from ovine myocardium in full 3D. Using this optimal dataset and a well-established constitutive model for myocardium, we demonstrate the effects of incorporating multiaxial deformation modes and 3D material structure into our inverse modeling framework for parameter estimation, and we uncover possible kinematic mechanisms for the observed behavior of myocardial tissue.

METHODS

Experimental Approach

Specimens of healthy myocardium were harvested from a cohort of adult Dorset sheep (n=5), with euthanasia performed via rapid injection of potassium chloride. 1x1x1-cm cuboidal sections (Figure 1a)

were cut out from the left ventricles and immediately placed in cardioplegic solution to relax into an unloaded state.

Each of the specimens was subjected to a comprehensive set of tensile, compressive, and shear deformations within our triaxial mechanical testing device (Figure 1b), specifically one-axis Simple Shear (SS) and two-axis Pure Shear (PS) deformation modes (Figure 1c), which were selected through optimal experimental design [1]. All tests were conducted immersed in cardioplegic solution maintained at 37°C, with multiple cycles in order to precondition the specimens.

Following testing, each specimen underwent diffusion tensor imaging (DTI) to determine their internal fiber structures, as measuring the diffusion of water molecules in tissue in response to magnetic fields

Figure 1: (a) Tissue specimen harvest. (b) Triaxial mechanical testing device. (c) 3D deformations. (d) Fiber structure of specimens (S1-S5). Abbreviations: left ventricle (LV), longitudinal (L), circumferential (C), radial (R), fiber (f), sheet (s), normal (n).

indicates the general orientation of myofibers within the sample. Each cuboid was scanned with magnetic field gradients of 600 mT/m. Encoding was performed along 48 directions with 500/19 TR/TE and a B-value of 800 s/mm, yielding a 40x33x38 matrix with a voxel resolution of 400 μm [2]. The fiber architecture of the specimens (Figure 1d) was determined through computing the eigenvectors in each voxel of the image using a custom MATLAB analysis routine.

Constitutive Modeling

The initial 3D constitutive model we used was introduced by Holzapfel and Ogden [3], in which the tissue features three mutually orthogonal material directions: \mathbf{f} , (myo)fiber; \mathbf{s} , sheet or cross-fiber; and \mathbf{n} , normal to the fiber-sheet plane (Figure 1a). Formulated as a function of invariants of the right Cauchy-Green deformation tensor \mathbf{C} , the strain energy ψ of the myocardium is described as

$$\psi = \frac{a}{2b} \exp\{[b(I_1 - 3)] - 1\} + \sum_{i=f,s} \frac{a_i}{2b_i} \{\exp[b_i(I_{4i} - 1)^2] - 1\} + \frac{a_{fs}}{2b_{fs}} [\exp(b_{fs}I_{8fs}^2) - 1], \quad (1)$$

where $I_1 = \text{tr}(\mathbf{C})$, $I_{4f} = \mathbf{f} \cdot \mathbf{C} \mathbf{f}$, $I_{4s} = \mathbf{s} \cdot \mathbf{C} \mathbf{s}$, and $I_{8fs} = \mathbf{f} \cdot \mathbf{C} \mathbf{s}$ are invariants of \mathbf{C} , and $\{a, b, \dots, a_{fs}, b_{fs}\}$ are fitted coefficients.

Parameter Estimation via Inverse Modeling

Our inverse modeling pipeline determines the optimal parameters needed to reproduce the experimental deformations with finite element simulations. Briefly, the optimal loading paths were prescribed onto a tetrahedral mesh whose elements were assigned material directions mapped from the DTI. The parameters for ψ were computed with nonlinear least-squares regression in order to match the model-computed stresses to experimentally measured stresses, with one set of parameters used to fit all protocols simultaneously. We first fit the model to a set of six SS protocols akin to the experiments performed by Dokos et al. [4]. The model was then fit to the optimal paths: three SS and three PS modes [1].

RESULTS

The maximum stress measured in triaxial testing bracketed a large range among specimens, especially in the PS modes. The fiber angle decreased from the endocardial to epicardial sides of the specimens. Interestingly, the fiber directions all showed a persistent “out of plane” component when projected onto the CL plane.

While the Holzapfel-Ogden model (Eq. 1) fit the six SS protocols, it was unable to capture the anisotropy in the optimal paths (Figure 2). Hypothesizing that the myocardium exhibits further modes of coupling, we incorporated additional 3D kinematics discussed in [3], extending the model to include all coupling invariant terms (I_{8ij}), given by

$$I_{8fn} = \mathbf{f} \cdot \mathbf{C} \mathbf{n} \quad I_{8sn} = \mathbf{s} \cdot \mathbf{C} \mathbf{n}, \quad (2)$$

to give the final form

$$\psi_{\text{ext}} = \frac{a}{2b} \exp\{[b(I_1 - 3)] - 1\} + \sum_{i=f,s} \frac{a_i}{2b_i} \{\exp[b_i(I_{4i} - 1)^2] - 1\} + \sum_{i,j=f,s,n} \frac{a_{ij}}{2b_{ij}} [\exp(b_{ij}I_{8ij}^2) - 1], \quad (3)$$

which successfully fit all optimal paths ($r^2=0.99$) (Figure 2).

Using the identity $I_{8ij} = \lambda_i \lambda_j \cos \theta_{ij}$, we determined that the optimal loading paths cause both relative stretching (quantified by $\lambda_i \lambda_j$) and shearing (quantified by $\cos \theta_{ij}$) of fiber families in the \mathbf{f} , \mathbf{s} , and \mathbf{n} directions, contributing to the stresses in the tissue. When examining the transmural distribution, we observed a considerable change in angle θ_{ij} throughout the specimen at maximum deformation (Figure 3).

Figure 2: Fit of the Holzapfel-Ogden model (Eq. 1) and extended model (Eq. 3) to the optimal triaxial data (black dots) of S4.

Figure 3: Distribution over transmural depth of relative stretches ($\lambda_i \lambda_j$), shearing ($\cos \theta_{ij}$), and change in angle ($\Delta \theta_{ij}$), at maximum deformation for fitted ψ_{ext} in PSCR. Subscripts: $i, j = f, s, n$.

DISCUSSION

We applied an integrated method to determine material parameters for left ventricular myocardium using a full 3D kinematic approach incorporating transmurally varying 3D structure, leading to the first determination of material parameters for myocardium for a cohort of multiple ovine specimens. Investigation of the extended model (Eq. 3) suggested that the coupling between \mathbf{f} , \mathbf{s} , and \mathbf{n} contained in the I_{8ij} invariants — namely, the shearing as quantified by $\cos \theta_{ij}$ — drives the need for these additional terms in order to capture the behavior of myocardium in multiaxial deformation modes. Interactions between myofibers and the surrounding collagen matrix could be a possible mechanism for these observations. Additionally, the behavior of myocardium in compression could become relevant for treatment interventions in which the heart wall is placed under non-physiological conditions, such as injection of biomaterials into the heart wall following heart attack. Ultimately, developing of more robust models in this manner will make them better suited for clinical evaluation.

INTRODUCTION

In the US alone, over 5 million patients suffer from heart failure, a number that is projected to exceed 8 million by 2030 [1]. Heart failure increases the likelihood of conduction abnormalities such as left bundle branch block (LBBB), which causes uncoordinated contraction and dilation of the left ventricle, leading to reduced pump efficiency [2,3].

In the last two decades, cardiac resynchronization therapy (CRT) has emerged as a revolutionary therapy for patients with heart failure and LBBB. A CRT pacing device can restore coordinated contraction of the heart by electrically stimulating multiple locations at appropriate times. When it works, CRT can stop and even reverse the progression of heart failure, reducing the ventricle size and improving pump function. However, over 35% of patients still fail to respond to CRT [4]. One of the greatest strengths of CRT is that it can be customized to individual patients, offering the potential to improve patient response rates [3]. Yet this also presents a dilemma: there are far too many possible lead locations and pacing settings to test directly during the implantation surgery.

Computational models can address this challenge by rapidly screening many pacing options before the CRT device implantation takes place. These models could in theory be used to pre-identify pacing locations which lead not only to the best electrical and mechanical synchrony but also to the greatest long-term reduction in ventricular volume. Several finite element models have been published that are capable of predicting cardiac growth, even in response to LBBB [5]. However, these models are computationally expensive, making them impractical for routine clinical use.

In this study, we propose a computational framework that can provide fast, patient-specific predictions of cardiac growth after the onset of LBBB. Furthermore, we demonstrate that our model's initial growth predictions agree with previously published experimental data.

METHODS

Model of the heart and circulation

Mechanics of the left ventricle (LV) were modeled using a recently published compartmental model that was coupled to a circuit model of the circulation to simulate hemodynamics throughout the cardiac cycle [6]. A previously published active contraction model [7] was adapted for use in the compartmental model, while the passive material behavior was governed by an exponential relationship between LV pressure and volumetric strain. The parameters of the active and passive LV mechanical behavior were fitted to the average pressure-volume relationship of canine hearts studied previously by our laboratory [8].

Simulation of LBBB

The healthy LV wall contracts almost simultaneously, however LBBB is characterized by dyssynchronous mechanical activation of the LV wall [3,9]. Therefore, the LV was functionally split into 10 compartments [10]. All compartments shared the same pressure at any time throughout the cardiac cycle, while the compartment volumes summed to the total LV volume. This approach allowed us to set the time of onset of mechanical activation in each compartment, thus simulating LBBB. To determine the activation times for the simulations reported here, we used DENSE MRI [9] to measure the local time of onset for circumferential shortening throughout the LV wall in a dog one week after inducing LBBB using radiofrequency ablation. Baseline activation times were obtained from [9].

Strain-driven cardiac growth law

Cardiac growth was modeled by a published strain-based kinematic growth relation that allows for independent growth in the circumferential and radial direction [11]. This growth law was previously adapted for use in the compartmental model and calibrated

Figure 1: The pressure-volume relationship of the LV remained similar to baseline acutely after the onset of LBBB, but shifted to the right following growth.

based on experimental canine pressure and volume overload studies [6]. In brief, in each LV compartment, circumferential and radial strains were estimated from volumes for each compartment by assuming a thin-walled spherical geometry, and used to drive growth of the respective compartments. Dilation was driven by a change relative to baseline of the maximum circumferential strain during the cardiac cycle, whereas thickening was driven by a change of the maximum radial strain. No changes to the published growth parameters were made for this study.

Experimental data comparison

To validate our model, we compared our results to experimental data published by Vernooij et al. [2], who used radio frequency ablation to induce LBBB in dogs, and performed echocardiography measurements at baseline and every two weeks for 16 weeks after LBBB onset. These measurements were used to obtain changes in LV end-diastolic volumes (EDV) and wall volume at end-diastole. For comparison, we simulated 16 weeks of cardiac growth after the onset of LBBB in our fast computational model and predicted changes in LV EDV and wall volume, as well as pressure-volume loops.

RESULTS

16 weeks of strain-driven cardiac growth after the onset of LBBB were simulated in just under two minutes on a laptop computer. Our model results showed that, immediately after simulating LBBB, the pressure-volume loop of the total LV was similar to baseline (Figure 1). However, the changes in strain caused by LBBB led to increases in peak circumferential strain in many of the compartments and consequently caused cardiac growth (not shown). After 16 weeks of cardiac growth the pressure-volume loop shifted to the right.

Dilation was most pronounced in the latest activated compartments and was not accompanied by thickening. Without calibrating any of the growth parameters, the model-predicted evolution of EDV closely matched the experimental results (Figure 2a). The change in LV wall volume at end diastole fell well within the standard deviation of the experimental results (Figure 2b).

DISCUSSION

The goal of this study was to develop and test a fast computational framework to predict cardiac growth during ventricular dyssynchrony. The initial results of this model matched previously reported experimental results. Strikingly, this was achieved without calibrating any of the growth parameters, instead using parameters that were

Figure 2: Predicted increases (green lines) in LV EDV (a) and wall volume (b)

previously fitted to pressure and volume overload data [6]. In contrast, a previously published anatomically realistic finite-element model was only able to correctly capture growth during LBBB after changing hemodynamic parameters [5]. Moreover, the finite-element model was required to run for 3 weeks on a cluster with 12 6-core processors to simulate 4 weeks of growth [5,6], whereas our model simulated 16 weeks of cardiac growth in just under two minutes on a laptop computer, making it suitable for routine clinical use.

The current model still includes several limitations. First, wall thickening was not observed in our model, but is known to occur in late-activated regions of the LV wall during LBBB. This probably caused the underestimation of the wall volume increase shown in Figure 2b. Second, parameter sensitivity studies suggest that the choice of activation pattern and passive material properties of the myocardium strongly affect strain and therefore growth, which in our model is driven by strain. Third, for the present study the activation pattern of a single dog was obtained and simulated and compared to mean results from a separate study. Additional subject-specific, matched activation patterns and growth outcomes should be used to further test the model.

In conclusion, in the present study we demonstrated that cardiac growth, in particular LV dilation, during dyssynchrony can be predicted using a fast computational model. While this work represents just the first step towards predicting patient-specific CRT responses, we believe both the results and the time frame required to customize and run this model suggest promise for this approach in a clinical setting.

INTRODUCTION

Cardiovascular disease is the underlying cause of 30.8% of all deaths in the United States annually, and continues to be the leading cause of mortality worldwide [1], [2]. Over 5.6 million adults in the United States live with congestive heart failure (HF), and nearly half will die within five years of diagnosis [3], [4]. HF patients often experience chronic left ventricular (LV) pressure overload leading to concentric hypertrophy of the LV. This persistent wall thickening leads to a reduction in LV volume, increased ventricle stiffening, and reduced elasticity resulting in diastolic dysfunction. Following injury, tissue-resident cardiac fibroblast (CF) activation occurs through a combination of mechanical strain, ventricle wall stress, and various pro-fibrotic signals such as transforming growth factor, fibroblast growth factor, and Wnt resulting in CF proliferation and switching toward a myofibroblast (MyoFB) phenotype [5], [6]. MyoFBs maintain a contractile, hyper-secretory phenotype characterized by increased α -smooth muscle actin (α SMA) and SM22 α expression with excessive deposition of extracellular matrix proteins, such as collagens and fibronectin. Altogether, MyoFB activity can result in increased ECM deposition resulting in increased interstitial fibrosis in the context of HF.

Talin is a focal adhesion protein that activates integrins by binding to the cytoplasmic β 1 domain, resulting in increased integrin affinity for ECM ligands. CFs express two forms of Talin, with Talin1 (Tln1) being the most highly expressed. Tln1 undergoes force-induced mechanical unfolding, wherein conformational changes expose binding sites for additional focal adhesion proteins, such as vinculin, paxillin, and α -actinin [7]. This is critical for the mechanotransduction of force from the ECM to the cell's cytoskeleton and vice versa. Tln1 has been implicated in disease through modulation of integrin activation and mechanotransduction resulting in altered fundamental processes such as focal adhesion assembly, cell spreading, migration, and survival [8].

Vinculin, a binding partner of Tln1, has been shown to promote ECM fiber formation and alignment in collagen matrices. We hypothesize that MyoFB-specific deletion of Tln1 will reduce ECM matrix deposition, resulting in a decrease in interstitial fibrosis, LV hypertrophy, and preserved cardiac function in the context of HF.

METHODS

CFs were isolated from WT mice for *in vitro* experiments. XtremeGene was used to knock down Tln1 in CFs (Tln1^{-/-}), resulting in a 40% KD of Tln1 transcription after 48h. Control cells were treated with scramble siRNA. Cells were plated on Fibronectin treated BioFlex® culture plates after 24 hours of XtremeGene treatment and incubated for 24 hours to allow a monolayer of cells to form. Cells were placed in the FX-4000™ Tension System at 10% equibiaxial strain for 24 hours.

A tamoxifen-inducible periostin Cre mouse was bred with a Tln1^{fl/fl} mouse for MyoFB specific deletion of Tln1 following injury (denoted CKO for condition knockout). Transverse aortic constriction (TAC), a model of pressure overload induced HF, was induced in WT and Tln1 CKO mice by permanent transverse aortic constriction with a 25-gauge needle. Hearts were extracted 42 days post-TAC and mRNA was extracted from the flash frozen LV using TRIzol. qPCR was performed to detect transcriptional differences in tissue amongst the sham and different genotypes.

RESULTS

Tln1^{-/-} and WT CFs were exposed to 10% equibiaxial strain for 24 hours. qPCR analysis after 24 hours indicated a statistically significant decrease in the relative expression of *Tln1* (schematic shown in **Fig. 1A**). This decrease coincides with a decrease in *Fln1*, with no change in *α SMA* relative expression (**Fig. 1B**). Due to a decrease in *Fln1* mRNA

expressional in *Tln1*^{-/-} CFs, *Tln1* deletion was investigated in mice in the context of the HF model TAC.

42-days following TAC, pictures taken after sacrifice showed WT mice have a significant increase in heart size as compared to *Tln1* CKO mice and sham animals (Fig. 2). This data demonstrates that *Tln1* deletion alters CF morphology in response to pressure overload induced injury.

Fig. 1: A) Biaxial Strain Device B) Transcription of proteins by WT and *Tln1*^{-/-} CFs under 10% biaxial strain. *p < 0.05.

qPCR analysis of the LV revealed an approximant 7-fold increase in transcription of the HF marker atrial natriuretic peptide (*Anp*) in the LV of WT mice as compared to sham controls (Fig. 3A). Furthermore, a significant reduction of *Anp* transcription back to the level of sham animals was observed in *Tln1* CKO mice (Fig. 3A). Preliminary data show collagen1a2 (*Col1a2*), collagen3a1 (*Col3a1*), insulin-like growth factor (*Igf1*) and α SMA transcription levels in WT mice correlated with *Anp* transcription 42-days post TAC (Fig. 3B) suggesting that during HF in WT animals, there is an increase in transcription of ECM related proteins.

Fig. 2: Hearts and carotid arteries imaged at 1.36 times real size 42-days post TAC or Sham procedures. Ventricles are outlined in yellow.

DISCUSSION

Our initial *in vitro* findings implicate that reduction of *Tln1* expression in CFs can change MyoFB phenotype under strained conditions. The reduction of *Fln1* mRNA expression in *Tln1*^{-/-} points to *Tln1* as a potential target to reduce fibrosis in the heart. As interstitial fibrosis during heart failure causes increased ventricular wall stiffening resulting in diastolic dysfunction, we believe modulating fibrosis through *Tln1* is a viable approach to limit damage during pressure induced HF.

We have found that 42-days following TAC WT mice have increased ventricular size as compared to sham animals indicating

hypertrophy of the ventricles occurred. Furthermore, WT TAC mice have a significant increase in the HF marker *Anp*. Both ventricular hypertrophy, and expression of *Anp* were reduced in *Tln1* CKO TAC mice demonstrating that *Tln1* deletion in CFs alters the heart at a tissue and cellular level in response to injury. We expect upon further analysis to see a decrease in cardiomyocyte (CM) size in the *Tln1* CKO TAC mice as compared to WT TAC mice, as an increase in CM size is the main cause of ventricular hypertrophy during disease.

Fig. 3: mRNA transcription in the LV of mice 42-days post-TAC A) *Anp* transcription in the LV B) WT mice correlation of ANP with *Col1a1*, *Col3a1*, *Igf1*, and α SMA. ** p < 0.01, * p < 0.001.**

Finally, we have identified that mRNA expression of *Col1a2*, *Col3a1*, *Igf1*, and α SMA correlate with the mRNA expression of *Anp*. The correlation of ECM related proteins to *Anp* in WT TAC mice proposes that there is also an increase in deposition of these ECM proteins during HF. This data suggests that with a decrease in mRNA expression of *Anp*, as seen in the *Tln1* CKO TAC mice, a decrease in the mRNA expression and deposition of ECM proteins may occur, resulting in a decrease in the interstitial fibrosis seen in HF.

Further exploration into the mechanical effects of *Tln1* genetic deletion in CFs following TAC will provide insight into the utility of targeting *Tln1* as a therapeutic approach for improve the outcomes of HF.

INTRODUCTION

We recently developed a cardiac growth and remodeling (G&R) constitutive model capable of describing both cellular hypertrophy and atrophy¹ that are driven by deviation from a homeostatic fiber stretch value. This model is able to predict reverse remodeling in the left ventricle (LV) when the mechanical loading is decreased. Often viewed as a favorable clinical course after heart failure (HF) treatments², reverse remodeling, in the form of a reduction in LV volume after CRT implantation, has been shown to be a strong predictor of lower long-term mortality and HF events³. While the G&R constitutive model takes into account all the mechanical states during the entire cardiac cycle, it does not describe anisotropic G&R that is necessary to reproduce asymmetric changes associated with local remodeling and reverse remodeling in the myocardium under various pacing conditions⁴. Here, we overcome this limitation by extending the reverse constitutive model to account for anisotropic growth. Specifically, we apply the model to investigate asymmetric G&R in a biventricular geometry due to alterations in electromechanics. We show that the long-term predictions of the coupled electromechanics-growth model are consistent with previous experimental studies and clinical observations^{5,6} suggesting that it is possible to capture G&R features using only myofiber stretch as a stimulant.

METHODS

We let $\chi_{\kappa_0}(\mathbf{X}, t)$ describe the mapping from an unloaded (stress-free) reference configuration κ_0 with material point position \mathbf{X} to a current configuration κ with the corresponding material point position $\mathbf{x} = \chi_{\kappa_0}(\mathbf{X}, t)$. The deformation gradient tensor, corresponding to a displacement field $\mathbf{u}(\mathbf{X})$, can be defined as $\mathbf{F} = \frac{\partial \chi_{\kappa_0}}{\partial \mathbf{X}}$. Under the

Figure 1: Schematic of anisotropic growth evolution.

volumetric growth framework⁷, we considered a multiplicative decomposition of the deformation gradient tensor into an elastic component \mathbf{F}_e and an incompatible growth component \mathbf{F}_g i.e.,

$$\mathbf{F} = \mathbf{F}_e \mathbf{F}_g. \quad (1)$$

The growth deformation gradient \mathbf{F}_g was parametrized by the growth multipliers θ_f , θ_s , and θ_n , i.e.,

$$\mathbf{F}_g = \theta_f \mathbf{f}_0 \otimes \mathbf{f}_0 + \theta_s \mathbf{s}_0 \otimes \mathbf{s}_0 + \theta_n \mathbf{n}_0 \otimes \mathbf{n}_0, \quad (2)$$

where \mathbf{f}_0 , \mathbf{s}_0 , and \mathbf{n}_0 are local myofiber, sheet, and normal directions in the reference configuration.

Figure 2. (Left) Evolution of left ventricular hemodynamics. (Middle) Evolution of regional volume and thickness. (Right) Geometry changes in mid short-axis and long-axis views.

Growth evolution was prescribed based on deviations of the fiber stretch λ_f from its homeostatic value $\lambda_{f,h}$, both taken with respect to the end-diastolic configuration. Specifically, the evolution of growth multipliers was of the form¹

$$\dot{\theta}_i = k_i(\theta_i, \lambda_f) \text{ for } i = f, s, n, \quad (3)$$

where $(\dot{})$ is the derivative with respect to time t , $k_i(\theta_i, \lambda_f)$ is a growth limiting function. The rate limiting function was defined as follows

$$k_i(\theta_i, \lambda_f) = \begin{cases} \frac{1}{\tau_{g,i}} \left(\frac{\theta_{max,i} - \theta_i}{\theta_{max,i} - \theta_{min,i}} \right)^{\gamma_{g,i}} (\lambda_f - \lambda_{f,h}) & \text{if } \lambda_f - \lambda_{f,h} \geq 0 \\ \frac{1}{\tau_{rg,i}} \left(\frac{\theta_i - \theta_{min,i}}{\theta_{max,i} - \theta_{min,i}} \right)^{\gamma_{rg,i}} (\lambda_f - \lambda_{f,h}) & \text{if } \lambda_f - \lambda_{f,h} < 0 \end{cases} \quad (4)$$

where subscript $i = f, s, n$ denote the association with the fiber, sheet, and normal directions. Parameters $\tau_{g,i}$, $\tau_{rg,i}$, $\gamma_{g,i}$, and $\gamma_{rg,i}$ control the rates of growth and reverse growth, respectively. The main purpose of the rate-limiting function is to restrict the evolution of the growth multipliers θ_i to lie within some prescribed limits⁸ (Figure 1). We adopted a similar approach to separate the time scale as described in Lee et al.,⁴ to integrate G&R with the electromechanics model.

Two cases differing in terms of the prescribed activation initiation location were simulated:

1. *Normal*: activation was initiated at the septum near the base,
2. *LVFW*: activation was initiated at the left ventricular free wall (LVFW) near the base.

RESULTS

There was no immediate substantial reduction in the pump function in the *LVFW* case (0 month). Changes were, however noticeable starting at 2 months in the form of a progressive LV dilation (Figure 2). Specifically, in the span of six months, LV end-diastolic volume (EDV) increased from 104.3ml to 113.7ml whereas end-systolic volume (ESV) increased from 55.65ml to 70.3ml. This led to a rightward shift in the LV pressure-volume (PV) loop that was accompanied by a slight change in ejection fraction (EF) from 48.7 % to 47.8 % in 6 months.

With appropriate calibration of the rate constants, the anisotropic G&R constitutive model predictions are quantitatively comparable to local and global measurements in a canine experiment with similar chronic LVFW pacing protocol⁶. In that experiment, both LV end diastolic volume and wall volume increased by 27 ± 15 % and 15 ± 17 %,

respectively, after 6 months of pacing. Locally, the early-activated LVFW became significantly thinner by 17 ± 17 % and the late-activated septum thickened by 23 ± 12 % in that duration. These changes were associated with a significant increase in the cardiomyocyte diameter (18 ± 7 %) at septum than that in LVFW. Our G&R constitutive model predicted comparable changes in global geometrical features in the form of an increase in LV end diastolic volume (9 %), wall volume (9.5 %). Comparable changes in local geometrical features were also captured by our model, which predicted an increase in septum thickness (18.5 %) and a decrease in LVFW thickness (19.7 %) (Figure 2).

DISCUSSION

Some of the chronic effects of LVFW pacing predicted by our model are also found in LBBB⁹, which produces mechanical dyssynchrony via an opposite activation pattern (i.e., septum is activated first follows by the LVFW). Similar to LVFW pacing, LBBB is typically associated with a significant increase in LV end diastolic volume (126.6 ± 19.3 %) in four months that is accompanied by the thickening of the late activated region and a thinning of early activated region. In contrast, LV ejection fraction decreases in LBBB (from 43 ± 4 % to 33 ± 6 %), which suggests that the associated asymmetrical hypertrophy may be different.

Future simulation studies on ischemic left and right bundle branch blocks cases using various pacing locations such as biventricular, right ventricular apex, His bundle, LV apex, etc., may help identify and optimize pacing locations. Such multiscale G&R simulation studies could be significant given that short-term clinical effects of pacing are not correlated with long-term outcomes³.

INTRODUCTION

Myocardial infarction is a prevalent cardiovascular event that occurs when there is insufficient blood flow to cardiac muscle, causing myocardial damage. The healing process replaces necrotic myocytes with collagenous scar, resulting in remodeling that affects the mechanical behavior of the infarct and surrounding myocardial tissue. The changes in cardiac mechanics are often complex, and they are highly dependent on the orientation and composition of the microenvironment. Previous work has demonstrated that infarct structure can be quite heterogeneous with stark spatial variations in collagen orientations [1,2].

It is known that the microscale plays an important role in myocardial mechanics, but there remains a significant need to understand how microscale fiber alignment and architecture affect overall tissue behavior in infarcted myocardial tissue. In this study, we use collagen fiber orientation maps from infarcted rat tissue sections to study the effect of network orientation by simulating biaxial extension with 3 different networks in a multiscale finite-element model.

METHODS

Post-infarction rat myocardial tissue was sectioned into 7 μm -thick square pieces (6mm x 6mm) and stained with picrosirius red in a previous study to obtain collagen fiber orientation maps (Fig. 1A) [1]. Due to the small section thickness, tissue was not present in some areas, and fiber orientation was not measured in those regions. A linear interpolation was performed on the fiber orientation scatter data to produce a full fiber orientation map for the entire sample (Fig. 1B).

A 26x26x1 finite-element mesh was created for each tissue piece by extruding the square to a thickness of 0.25 mm, resembling a 3-dimensional tissue slab. 3 different types of network (Fig. 2) were

Figure 1: A) Fiber alignment map of myocardial infarcted tissue.

Arrows indicate the circumferential (C) and longitudinal (L) directions. Angle in degrees is measured relative to the circumferential direction. Scale bar applies to both images. B) Interpolated grid of fiber alignment to fill in missing fiber information.

created to compare the effects of network orientation: 1) the same isotropic network used for every element (*isotropic* case), 2) the same aligned network used for every element, where the network was aligned in the average fiber direction for the whole sample (*homogeneous* case), and 3) differently aligned networks for each finite element based on the local fiber orientation in the area of the finite element (*heterogeneous* case). Networks were comprised of collagen fibers and a neo-Hookean component, to resemble nonfibrous material.

The network for the homogeneous case was aligned according to the overall sample orientation tensor [3],

$$T^{(sample)} = \frac{1}{1 + \sum_1^N \alpha^{(el)}} \left(\frac{1}{2} I + \sum_1^N \alpha^{(el)} T^{(el)} \right) \quad (1)$$

where $T^{(sample)}$ is the sample orientation tensor, N is the number of finite elements, $\alpha^{(el)}$ is the degree of alignment for each element

(ranging from 0-1, 0 = no alignment, 1 = fully aligned), I is the identity matrix, and $T^{(el)}$ is the orientation tensor for each element. The average fiber orientation was 43° relative to circumferential, and the degree of alignment was 0.36. The heterogeneous networks were created according to the orientation tensor for each element ($T^{(el)}$), where $T^{(el)}$ was of the same form as (1), created by averaging over the space of each individual finite element instead of the entire sample.

Figure 2: Isotropic (left), homogeneous (middle), and heterogeneous (right) network cases shown for the biaxial multiscale simulations.

A custom multiscale model (discussed extensively in [4]) was used to simulate equibiaxial extension of the square tissue piece for each network case. The edges of the tissue square were pulled to a final strain of 25%, with no shear stress on the boundaries.

RESULTS

Equibiaxial extension exhibited significantly different results for each of the 3 network cases (Fig. 3). The isotropic and homogeneous network case displayed a homogeneous stress and displacement field through the tissue square at 25% strain, while the heterogeneous network case exhibited significant stress and strain heterogeneity through the sample. The average von Mises stress in the isotropic case (79.19 kPa) was lower than the homogeneous (163.20 kPa) and heterogeneous cases (152.28 kPa), and the heterogeneous case exhibited the highest maximum stress (324.13 kPa) compare to the two other cases (163.39 kPa for homogeneous, 79.20 kPa for isotropic).

Figure 3: von Mises stresses shown at 25% equibiaxial strain for isotropic (left), homogeneous (middle), and heterogeneous (right) cases.

First Piola-Kirchhoff (PK1) stresses in the circumferential (S_{CC}) and longitudinal (S_{LL}) directions also showed differences between the 3 networks cases (Fig. 4). PK1 stresses in the isotropic case were similar in both directions, while the homogeneous and heterogeneous cases displayed anisotropy, having higher stresses in the circumferential direction compared to longitudinal. The homogeneous case reached the highest PK1 stress in the circumferential direction (943.84 kPa), compared to the lower PK1 stresses in heterogeneous (807.05 kPa) and isotropic (431.33 kPa) cases at 25% strain.

Figure 4: PK1 stresses averaged over the whole sample for the circumferential (blue) and longitudinal (red) directions for isotropic (left), homogeneous (middle), and heterogeneous (right) cases.

DISCUSSION

These results highlight the importance of the underlying tissue microenvironment, and its contribution to the overall macroscale mechanical behavior. By studying these 3 different network cases, our work shows that fiber orientation can significantly change the behavior of myocardial infarct tissue.

The von Mises stress field for the isotropic and homogeneous network cases was, as expected, homogeneous throughout, with minor differences in the maximum and minimum stresses exhibited. The homogeneous network case exhibited anisotropy, however, when comparing the directional circumferential and longitudinal stresses. Tissue anisotropy was expected, as the homogeneous network case had an alignment slightly closer to the circumferential direction.

The heterogeneous network case exhibited heterogeneity in the von Mises stress field, as well as the displacement field. Interestingly, areas of higher von Mises stress were seen in locations close to networks which were more closely aligned to the longitudinal direction. The heterogeneous network case exhibited similar anisotropy to the homogeneous network case when comparing circumferential and longitudinal PK1 stresses. The anisotropy was less pronounced in the heterogeneous case, however, which is most likely due to the heterogeneity allowing stiff and compliant sections to distribute displacements so as to reduce the overall anisotropy, similar to effects seen by Picu [5,6]. Thus, the heterogeneity leads to an increase in local stresses but a decrease in the global averaged anisotropy (and, to a lesser extent, stiffness).

Overall, this study shows how local network orientation plays an important role in the mechanics of scar tissue. Though fiber orientation is not necessarily always readily available, this work shows the need to consider network orientation when studying the mechanics of myocardial infarct tissue.

INTRODUCTION

Pulmonary hypertension (PH) is a disease resulting in increased right ventricular (RV) afterload, ventricular remodeling and myocardial hypertrophy [1]. Pressure overload due to PH results in increased RV contractility as well as increased end-systolic and end-diastolic volumes, which if left unchecked leads to decreased RV contractility and RV failure [1]. From a biomechanical standpoint, RV myocardium experiences increased stiffness and fiber remodeling in PH which results in increased anisotropy in certain anatomic directions. This is also partly due to decreased transmural variation of myocardial fiber architecture in PH [1]. RV failure remains the main cause of mortality for PH patients, with 34-66% survival rates at 5 years post-diagnosis [2]; however, few studies have aimed to characterize the effects of PH on RV structure and function [1,3]. To date, lung transplantation remains the only curative treatment for PH.

Sacubitril/Valsartan (Sac/Val; also known as LCZ696) is a dual acting drug composed of a 1:1 mixture of neprilysin inhibitor Sacubitril and angiotensin receptor blocker Valsartan [4]. While previous hypertension therapeutics include angiotensin receptor blockers and target the renin-angiotensin-aldosterone system (RAAS), Sacubitril/Valsartan has a mode of action that targets the RAAS and Natriuretic Peptides System together. Valsartan inhibits the effects of AT1 receptor stimulation which prohibits vasoconstriction and increase of vascular tone. Sacubitril, on the other hand, increases the natriuretic peptide levels via neprilysin inhibition which results in decreased blood pressure, hypertrophy and fibrosis. As a result of this unique mechanism of action, Sacubitril/Valsartan has shown promising outcomes in reducing the risk of death for heart failure in a large placebo-controlled trial [5]. In this study, we aim to characterize the effects of preventive treatment of PH with Sac/Val on failing RV tissue using an experimental model of PH [3].

METHODS

A total of 12 male Sprague Dawley rats (8-weeks old at the start of experiments) were studied in three groups: Controls (n=4), PH with placebo treatment (n=4) and Sacubitril/Valsartan treatment (n=4). PH was induced via pulmonary artery banding (PAB). Daily doses of Sacubitril/Valsartan and placebo (same volume of water) were administered via oral gavage. At three weeks post-surgery, terminal invasive hemodynamic measurements were performed on the rats to obtain pressure-volume loops. Following hemodynamic measurements, the heart was removed and the right ventricular free wall (RVFW) was dissected and attached to a biaxial testing device (Biotester, Cell-Scale Biomaterials, Waterloo, CA). Visual tracking markers were placed on the tissue and marker deformations were recorded using a CCD camera for strain estimations. Multi-protocol biaxial testing was performed on each RVFW specimen to investigate the tissue response in a wide range of possible loading scenarios, Fig.1. Equibiaxial stress-strain response of tissues was interpolated from the multi-protocol experimental data using previously established techniques [6]. The experimental stress-strain data under multi-protocol testing was used to model the response specimens using a nonlinear anisotropic constitutive model [7]:

$$W = B_0(e^{\frac{1}{2}b_1E_{11}^2} + e^{\frac{1}{2}b_2E_{22}^2} + e^{b_3E_{11}E_{22}} - 3) \quad (1)$$

here, B_0 is the scaling factor, b_1 is the stiffness in the longitudinal direction (apex to outflow tract direction), b_2 is the circumferential stiffness and b_3 is the coupled stiffness of the tissue. Parameter estimation was performed using a least-squares optimization algorithm (trust-region-reflective) in MATLAB (Mathworks, Natick, MA). All data were reported as sample mean \pm sample standard error of the mean (SEM). Statistical comparisons were made using an unpaired Student's t-test (two-tailed) with $\alpha = 0.05$.

Figure 1: Graphical abstract of the framework used to evaluate RV biomechanics.

RESULTS

PA banding results in significantly increased RV systolic pressures (72.5 ± 10.5 mmHg for PAB vs. 24.5 ± 1.7 mmHg for Control) while Sac/Val leads to decreased systolic pressures (44 ± 2.3 mmHg), Fig 2a. Increased thickness due to PA banding and tissue hypertrophy (0.68 ± 0.07 mm for control vs. 1.09 ± 0.03 mm for PAB) is not recovered with Sac/Val treatment (1.01 ± 0.05 mm), Fig. 2b.

Interpolated equibiaxial stress-strain response of RVFW specimens demonstrate increased stiffness and tissue anisotropy of the RV as a result of PA banding. Sac/Val results in decreased tissue stiffness, specifically in the longitudinal direction (Fig. 3a). Constitutive modelling reveals significantly increased tissue stiffness in the longitudinal direction due to PA banding (100.3 ± 18.0 vs. 211.3 ± 29.6 KPa) while showing no significant differences in the circumferential and coupled stiffnesses (Fig. 3b). Sac/Val treatment results in significantly lower longitudinal stiffness (94.5 ± 19.3 KPa) compared to the PH group, while no statistically significant differences were found between the control and Sac/Val treatment groups.

Figure 2: (a) In-vivo RV systolic pressures from terminal invasive hemodynamic measurements, (b) RVFW thickness for each cohort, * $p < 0.05$ represents statistical variation from the control group.

DISCUSSION

RV pressure overload through PA banding resulted in increased RV systolic pressures, tissue hypertrophy, increased tissue stiffness and thickness as well as increased anisotropy. RV systolic pressures and tissue thickness and stiffness of control and PA-banded rats match

Figure 3: (a) Interpolated equibiaxial stress-strain response of each cohort, (b) Constitutive model parameters, * $p < 0.05$ represents statistical variation from the control group, # $p < 0.05$ represents statistical variation from the PAB group.

previously reported values [1,3]. Sac/Val treatment resulted in decreased systolic pressures and lead to near-healthy tissue biomechanical properties, suggesting the potential of Sac/Val for PH treatment.

In this study, a preventive treatment approach was employed to analyze the effects of Sac/Val on PH in a 3-week period. For future investigations, different treatment windows as well as treatment scenarios after fully developing PH needs to be studied. Also, effects of Valsartan-only treatment vs. Sac/Val needs to be evaluated for comparison purposes. Nevertheless, preliminary results suggest the promising potential of Sac/Val in lowering RV end-systolic pressure, preventing increased tissue stiffness in the longitudinal direction and RV remodeling.

INTRODUCTION

All along pregnancy, the cervix undergoes important structural changes in order to fulfill its functional change, i.e. transforming from a closed rigid barrier to a highly deformable structure to allow safe passing of the baby at the time of delivery [1]. These structural changes known as cervical remodeling leads to a profound modification of the composition and organization of the cervix microstructure, which directly impacts the mechanical properties and function of the tissue. Abnormal and premature cervical remodeling represent a critical clinical challenge as it has been identified as a significant risk factor for preterm birth (PTB) [2], which still impacts approximately 12% of all birth [3], with often disastrous health consequences for premature babies. Hence, understanding and characterizing the biomechanical changes associated to the cervical remodeling process represent a necessary step toward a better identification of PTB etiology.

As for most soft biological tissues, the mechanical behavior of the cervix is mostly derived from the composition and organization of its extracellular matrix (ECM) [4]. Besides collagen and elastic fibers, the cervical ECM includes glycosaminoglycans (GAGs) which are macromolecules that greatly influence the mechanical behavior of the cervix as they are negatively charged. These electrical charges are embedded in the collagenous matrix and experience like-charge repulsion creating an imbalance in electrical charges between the tissue and the external environment [5]. As a result, this imbalance in charge density causes the tissue to imbibe water and swell in solutions, creating a net osmotic pressure altering the tissue mechanical properties enhancing its compressive strength [6] for instance, or increasing its rigidity [7].

With advancing pregnancy, the content of cervical GAGs evolves through the cervical remodeling process. In the mouse, while the

amount of sulfated GAGs remains rather constant along pregnancy, the amount of hyaluronan (HA, a non-sulfated GAG), increases significantly toward the end at day 18 of pregnancy [8]. While HA are believed to play an important role in cervical remodeling, through the ECM disorganization toward the end of pregnancy [9], their clear impact and contribution to the mechanical/swelling behavior of the cervix is yet to be identified.

Hence, the aims of this study are to investigate the swelling tendencies of the cervix in relation to the environment osmolarity, and identify the specific contribution of HA in those tendencies, using an animal model presenting a HA depletion in the cervix.

METHODS

Non pregnant (NP, n=12) and pregnant mouse cervixes at day 6 (d6, n=17), day 15 (d15, n=12) and day 18 (d18, n=17) of a 19 days pregnancy were collected and isolated from the reproductive tract. To examine the specific contribution of hyaluronan to the swelling behavior, two strains of mice were used in this experiment: a wild type control strain (WT) and an HA depleted strain (HAKO).

After dissection, the samples were weighed and immediately placed in a custom built swelling bath, suspended by the inner canal. The baths were filled with NaCl solutions of 0.15M (physiologic) or 2M (hyperosmotic) concentrations, with 2mM ethylenediaminetetraacetic acid (EDTA) protease inhibitor. The cervical volume change was assessed for 3h with two CCD cameras arranged perpendicularly, to image the cervix geometry during osmotic loading. Images were analyzed using a custom Matlab segmentation routine to extract measurements of the side area and the average length of the sample to estimate the cervical volume V and calculate the swelling ratio J as:

$$J = \frac{V}{V_{1st\ image}} \quad (1)$$

To quantitatively compare the swelling kinetic between the different specimen groups, we also calculated swelling rates defined as the slope of the J vs. time curve.

RESULTS

Swelling kinetic in normal pregnancy

The kinetic of swelling is significantly different between physiologic and hyperosmotic solutions. The analysis of the relative volume change rate (Fig.1A-B-C) shows almost all specimen groups present a statistically different kinetic of swelling in 2M compared to 0.15M. An equilibrium is reached in the physiologic 0.15M solution after approximately 2h, while cervix keeps on swelling after 3h in 2M, as evidenced by the mid and final slope values close to 0 for the 0.15M and >0 values for the 2M (Fig.1B-C). An initial shrinkage of the volume is observed in 2M, except for d6, followed by a continuous increase in volume (Fig.1A). In physiologic solution (0.15M) the swelling ratio at equilibrium (3h) increases with advancing gestation up to day 15 and stabilizes between day15 and day18 (Fig.1D).

Figure 1: A-B-C) Relative volume change rate at the beginning, middle and end of the swelling experiment with advancing gestation (NP, d6, d15, d18) in both the wild type and HA depleted strains. *indicates statistical difference between the different osmolarity solutions (one-way ANOVA, $p < 0.05$). D) Swelling ratio J after 3h of osmotic swelling.

Swelling behavior in the absence of HA

The swelling behavior of the HAKO animals is in no way different than the behavior of the wild type group. No significant difference is observed in the swelling kinetic or equilibrium properties between HAKO and WT at all gestation time point in both osmolarities (Fig.1A-B-C-D).

DISCUSSION

The different kinetic of swelling between the 0.15M and 2M conditions indicates that a different physical swelling phenomenon takes place in presence of excess NaCl ions. The Donnan equilibrium theory, usually taken to describe the swelling behavior of soft tissues

does not account for the volume expansion seen in 2M when the media is saturated with NaCl ions. Some configurational entropic effects [5] could be considered in modeling approaches to describe this phenomenon, when the excessive presence of ions shields the negative charges of the GAGs., diminishing the electrostatic effects but increasing the entropic pressure creating swelling tendencies.

The increase of the equilibrium swelling ratio seen in physiologic solution (Fig.1D) is in accordance with consideration about the ECM microstructural remodeling events with pregnancy. Indeed, the cervical remodeling process is associated with a progressive disorganization of the collagenous matrix with pregnancy inducing a softening between the early stage (NP, d6) and the late pregnancy (d15, d18) [10]. This disorganization comes with a large modification of the interfibrillar spaces, which therefore enables the tissue to imbibe more water through osmotic swelling.

The contribution of HA to the mechanical/swelling behavior of the cervix remains unclear. Akgul *et al.* [11] reported that HAKO animals presented a similar matrix disorganization and increase hydration with advancing pregnancy than WT. They also found that the apparent stiffness of the tissue during load-to-break tensile testing was not altered with the absence of HA. However, they reported that HAKO cervixes presented a reduced interfibrillar space compare to control animals, suggesting a possible modification of the swelling behavior. Interestingly, this reduced interfibrillar space does not influence the swelling behavior of the cervix in physiological or hyperosmotic solutions, as the swelling response of the HAKO group was not different than the WT, questioning the implication of HA in the swelling tendencies of the cervix. The swelling properties of HA have been studied through experiments conducted on HA gels or collagen-HA gels [12] showing that when they are not constrained and embedded in a collagenous matrix, HA gels swell significantly more. Those swelling characteristics also showed an important dependence on the osmolarity of the media. The absence of a distinct swelling signature of HAKO cervixes could hence be explained by the contribution of other components of the ECM (other GAGs like Versican) limiting the HA impact on swelling, or compensating their contribution in HA depleted cervixes.

Ultimately, the work presented here highlights that swelling tendencies of the cervix are significant and need to be accounted for in mechanical testing. Further investigation about the HA role and other GAGs contribution to swelling mechanism will help fully elucidate and further our understanding of the cervical remodeling process.

INTRODUCTION

The CD8 co-receptor contributes to TCR binding to pMHC by reducing the rate of dissociation between TCR/pMHC interaction [1]. On the MHC class one molecule, CD8 binds to the alpha 3 domain, distinctly separate from the TCR binding of the peptide, alpha 1 and alpha 2 domains [2]. Several studies have shown that the binding affinity of CD8 to MHC is independent of TCR specificity or affinity [3,4]. Using a micropipette adhesion assay, we have previously found a positive correlation between CD8 cooperation (described as synergy) and TCR affinity, with CD8 cooperation increasing with TCR affinity [5]. However, this study has been limited to a model system of transgenic mouse TCR against an array of altered peptide ligands. CD8 contribution in a native human antigen-specific T cell response remains elusive.

Here, using Hepatitis C Virus specific precursor CTLs spanning a large range of TCR affinities, we discovered that the functional responsiveness of any given TCR correlated with the contribution of CD8 to TCR/pMHC binding. Furthermore, we found that CD8 contribution to TCR/pMHC binding in the two-dimensional (2D) system was more accurately reflected by normalized synergy (CD8 cooperation normalized by total TCR/pMHC bonds) rather than synergy (total CD8 cooperation) alone. While synergy showed an increasing trend with TCR affinity, normalized synergy was demonstrated to decrease with increase of TCR affinity. Critically, normalized synergy was shown to correlate with CTL functionality and peptide sensitivity. Our results resolve the current discrepancy on CD8 contribution to TCR/pMHC binding, and demonstrate that naturally occurring high affinity TCRs are more capable of CD8 independent interactions that yield greater functional responsiveness even with CD8 blocking.

METHODS

Using a tetramer enrichment strategy described previously [6], we isolated a set of precursor CTLs that recognize human a single HCV epitope in complex with pMHC (here denoted as pMHC-CD8wt-HCV) from healthy HCV seronegative blood donors [6]. These precursor CTL clones allowed us to comprehensively examine the 2-dimensional (2D) affinity for viral antigen-specific polyclonal human TCRs. Using pMHC-CD8wt that enables CD8 binding and pMHC-CD8mut (with D227K/T228A mutations) that abrogates CD8 binding, we studied the contribution of CD8 binding to TCR mechanosensing induced T cell activation in human viral-specific T cells. The relationships between affinity and synergy and normalized synergy are defined as below. P_a , adhesion frequency; m_{TCR} or m_{CD8} , and m_{pMHC} denote site densities of TCR, CD8, and pMHC respectively; K_a , k_{off} , and t_c representing 2D affinity, 2D off-rate, and contact time; A_c is the contact area with the constant radius of $1\mu m$; The 2D affinity measured in this way uses a product of $A_c K_a$, which has a unit of μm^4 ; $\langle n \rangle / m_{pMHC}$, number of bonds formed per pMHC.

$$P_a = 1 - \exp[-m_{TCR \text{ or } CD8} m_{pMHC} A_c K_a (-k_{off} t_c)] \quad (1)$$

$$A_c K_a = -\ln[1 - P_a(eq)] / (m_{TCR \text{ or } CD8} \times m_{pMHC}) \quad (2)$$

$$\langle n \rangle / m_{pMHC} = -\ln[1 - P_a(eq)] / m_{pMHC} \quad (3)$$

$$synergy = \frac{\langle n_{TCR+CD8} \rangle}{m_{pMHC-CD8wt-HCV}} - \frac{\langle n_{TCR} \rangle}{m_{pMHC-CD8mut-HCV}} - \frac{\langle n_{CD8} \rangle}{m_{pMHC-CD8wt-PPI}} \quad (4)$$

$$normalized\ synergy = \frac{Synergy}{\left[\frac{\langle n_{TCR} \rangle}{m_{pMHC-CD8mut-HCV}} \right]} \quad (5)$$

RESULTS

The large affinity differences between high- and low- affinity TCRs and between TCRs and CD8 make it difficult to compare their ligand binding propensity. To simplify this comparison, we converted 2D affinity to number of bonds formed per MHC molecule [5].

For TCR, this parameter also spanned a 500-fold range similar to 2D affinity (Figure 1B). In contrast, the number of bonds formed per MHC molecule for CD8 were generally in the same range as low affinity TCRs and had little variation between TCRs where both TCR affinity and number of bonds formed per MHC molecule differed by orders of magnitude (Figure 1B). The previously described 2D method of evaluating CD8 cooperation for 2D affinity analysis subtracted the number of bonds formed by TCR/pMHC and CD8/pMHC interactions from (TCR+CD8)/pMHC interactions, and was named synergy or the change in number of bonds [5]. We demonstrated a similar trend between synergy and 2D TCR affinity as seen previously in the 2D TCR kinetic data, which showed that high affinity TCRs received more CD8 cooperation compared to low affinity TCRs (Figure 1C).

We hypothesized that the cooperation obtained as calculated by synergy was a total synergy that TCRs could receive, which was dependent on the total number of bonds that TCR/pMHC could form. Therefore, normalizing synergy by the number of TCR/pMHC bonds formed for each MHC molecule evaluates the synergy per TCR bond, which could be a more accurate parameter in the 2D setting to evaluate the cooperation between TCR and CD8. Indeed, converting synergy to normalized synergy showed that low-affinity TCRs received more cooperation, or help, from CD8 per TCR bond compared to medium- and high-affinity TCRs (Figure 1D). This corroborates the finding in previous 3 dimensional studies using protein engineered TCRs or APLs, that higher affinity TCRs are more likely to be CD8 independent in binding than low affinity TCRs. Among the three high-affinity TCRs, two were essentially independent of CD8 in terms of pMHC binding. We also have functional data to support that these CD8 minimally dependent TCR expressing CTLs are more resistant to CD8 blocking and are able to retain most of the functionality in cognate peptide stimulation compared to TCRs that are more dependent on CD8 when most of CD8 molecules are blocked. Thus, our analysis using the new parameter, normalized synergy, was able to reconcile the discrepancy between previous 3D and 2D affinity analysis on CD8 cooperation to TCR/pMHC binding.

DISCUSSION

We have shown that the T cells recognizing a naturally occurring viral peptide span an affinity range of three orders of magnitude. In our interrogation of the CD8 contribution, we established a new parameter to evaluate cooperation that can be attributed to CD8 and demonstrated that this normalized synergy correlates well with maximal functionality and peptide sensitivity. Finally, we demonstrated that CD8 independent T cells have increased functionality and sensitivity compared to those more dependent upon CD8 for binding. In the future, CD8 independent TCRs might prove beneficial for the field of adoptive cell transfer for cancer immunotherapy because these TCRs are highly sensitive and functional in response to antigen stimulation in comparison to TCRs that more heavily relied on CD8 contribution for TCR/pMHC binding.

A MATHEMATICAL MODEL FOR THE POST-IMPLANT COLLAGEN MATURATION BEHAVIOR OF ENGINEERED TISSUES

INTRODUCTION

The optimal vascular replacement should be able to accommodate somatic growth and closely mimic the structure, function and physiology of native vessels. The field of tissue engineering attempts to create such permanent viable conduit tissue replacements, and, critically, accommodate somatic growth. Since arterial geometry greatly influences hemodynamics, replacement conduits should closely resemble the native three-dimensional arterial shape.

The most relevant studies for developing a PA conduit were conducted by Gottlieb and Hoerstrup both utilized similar methods, choice of animal model, and most importantly were focused on long-term responses [1,2]. Interestingly, while some minor (not statistically significant) changes in conduit dimensions occurred in both studies, overall the conduits were surprisingly dimensionally stable. Yet, in all studies a continued increase effective tissue modulus was consistently observed, which then leveled out by about one-year post-implant. This suggests that a tissue maturing process akin to related collagen maturation phenomena observed. Moreover, this does not appear to be a conventional growth and remodeling (G&R) phenomena in the sense that some type of restoration in homeostasis is obtained. For example, in the now classic work on residual stress in arteries and subsequent remodeling due to altered vascular pressures, restoration in transmural wall stress distributions was considered the major driver. This has been followed up by seminal work by Humphrey, Taber, and others.

Yet, to the author's knowledge, a detailed theoretical approach for the maturation behaviors of engineered tissues has yet to be performed. Related work has been done on growth of the native PA, which have shown pronounced, anisotropic, and regionally heterogeneous growth. Such patterns have yet to be achieved with replacement conduits. Thus, an improved means of understanding tissue formation and remodeling in engineered tissues is necessary to further the field and ultimately develop functionally-equivalent tissues.

The principle driver of this work is to elucidate the long term in vivo remodeling processes in engineered cardiovascular tissues using models developed from first principles and based on quantifiable microstructural details. Manifestations of the maturation of collagen fiber network were explicitly modeled. Moreover, it will be shown that the growth and remodeling phenomena observed in the present study are driven by an increase in collagen modulus due the underlying process. To the best of the author's knowledge, this is the first time collagen maturation model of a large artery implant has been developed.

METHODS

Experimental database. Experimental data for this study was derived from studies by by Gottlieb and Hoerstrup [1,2]. Briefly, needle non-woven (NNW) PGA:PLLA scaffolds were cut and fabricated into conduits using manual and machine needle punching. Assemblies were mounted into a custom culturing device that immobilized the conduit and provided even seeding. BMSCs were isolated from 28 day female Dorset sheep and seeded on the conduits at $0.5\text{--}1.7 \times 10^7$ cells/cm³ in rotary culture (1 rpm).

Subsequent mechanical and structural analyses demonstrated, collectively, that the key experimental findings demonstrated that while the conduit was dimensionally stable, it underwent substantial tissue level remodeling. The specific key remodeling events are summarized in the following:

1. The conduit maintains its gross dimensions, including length, diameter, and thickness, over the entire remodeling period. Due to the stable conduit geometry and external loading conditions over the entire implant period of 100 weeks, the conduit is subjected to the same stress state throughout the maturation process. Using the Law of Laplace this is estimated to be $T_{cc} = 25$ kPa and $T_{LL} = 12.5$ kPa.

2. A rapid, near linear increase in γ_c that ceases at about one year. No further changes in collagen modulus occur.

3. A shift towards increased collagen fiber organization, manifested as a parallel increase in average value and reduction in variance of λ_s .

4. 0-50 weeks: Maturation of the collagen structure, manifested as increasing modulus and a shift in mean λ_s and a reduction in σ_s .

15 5. 50-100 weeks: Maturation process appears to be complete, with no further remodeling apparent.

Model: A summary of the key equations of the modeling approach are given in Figures 1 and 2. Novel to this study is the incorporation of the time evolving collagen fiber modulus γ_c .

Total stress:

$$\mathbf{T} = -p\mathbf{I} + 2\frac{\partial\psi_m}{\partial I_1}\mathbf{B} + 2\mathbf{F}\mathbf{S}_c\mathbf{F}^T$$

Where:

$$\mathbf{S}_c(\mathbf{C}, t) = \mathbf{S}_c^0(\mathbf{C}, t) + \mathbf{S}_c^t(\mathbf{C}, t)$$

Original fiber dissolution

$$\mathbf{S}_c^0(\mathbf{C}, t) = \phi_c \gamma_c(t) \int_{\mathbf{n}} \int_{\lambda_s} \frac{m_c^0(\mathbf{n}, \lambda_s)}{M_c(t)} \exp \left[-\int_0^t \eta_c(\mathbf{n}, \lambda_s, s) ds \right] \left[\frac{1}{\lambda_s} \left(\frac{\lambda_c(\mathbf{n})}{\lambda_s} - 1 \right) \right] (\mathbf{n} \otimes \mathbf{n}) d\lambda_s d\mathbf{n}$$

New fiber deposition

$$\mathbf{S}_c^t(\mathbf{C}, t) = \phi_c \int_0^t \left\{ \gamma_c(\tau) \int_{\mathbf{n}} \int_{\lambda_s} \frac{\Delta_c(\mathbf{T})}{M_c(\tau)} \exp \left[-\int_\tau^t \eta_c(\mathbf{n}, \lambda_s, s) ds \right] \left[\frac{1}{\lambda_s} \left(\frac{\lambda_c(\mathbf{n})}{\lambda_s} - 1 \right) \right] (\mathbf{n} \otimes \mathbf{n}) d\lambda_s d\mathbf{n} \right\} d\tau$$

Figure 1 – Key equations for the time evolving stress as a function of mass changes.

$$\bar{\gamma}_c(t) = \underbrace{\gamma_c(t) \int_{\mathbf{n}} \int_{\lambda_s} \frac{m_c^0(\mathbf{n}, \lambda_s)}{M_c(t)} \cdot \exp \left[-\int_0^t \eta_c(\mathbf{n}, \lambda_s, s) ds \right] d\lambda_s d\mathbf{n}}_{\text{Initial mass dissolution}} + \underbrace{\int_0^t \left\{ \gamma_c(\tau) \int_{\mathbf{n}} \int_{\lambda_s} \frac{\Delta_c(\mathbf{T})}{M_c(\tau)} \cdot \exp \left[-\int_\tau^t \eta_c(\mathbf{n}, \lambda_s, s) ds \right] d\lambda_s d\mathbf{n} \right\} d\tau}_{\text{New mass deposition}}$$

Figure 2–Key equation for the time evolving collagen fiber modulus γ_c .

RESULTS

The model was able to capture the mechanical behaviors at each time point (Figure 3). Most interestingly, the model was able to faithfully simulate gradual increase in effective collagen fiber mechanical behavior and fiber recruitment (Figure 4). It is interesting to note that this evolution is direct result of the increase in collagen modulus, which is part of the maturing process.

DISCUSSION

In the present study, a structural model-based formulation for the time evolution of a maturing collagen tissue was formulated and evaluated. The key findings included.

1. Modeling approach was able to account for time evolution of collagen crimp
2. Maintained angular fiber dispersion with an explicit constraint
3. First model known G&R structural model that is based on evolution of material properties (fiber modulus) and not changes in boundary conditions.

Current work includes extending the model initial implant phase and studies changes in boundary conditions (e.g. resulting from a change pressure).

Massachusetts Institute of Technology
Cambridge, MA, USA

INTRODUCTION

The mechanical properties of the microenvironment, cells, and their nuclei play a pivotal, interconnected role in fundamental cell processes, including cancer metastasis. But many experimental techniques used to assess mechanical properties of cells and nuclei are contact-based and/or intrusive (e.g. micropipette aspiration,ⁱ atomic force microscopy,ⁱⁱ micro-rheology, microfluidic constrictions, optical tweezers,ⁱⁱⁱ and magnetic twisting cytometry) and therefore have the potential to alter the property they are intended to measure.

Here we present the first integrated system of confocal reflectance quantitative phase microscopy (QPM) and Brillouin confocal microscopy (BCM) to assess the mechanical properties of cells. Unlike other methods, QPM and BCM non-invasively measure mechanical aspects of cells and their microenvironment. Confocal reflectance QPM measures nanometer-scale thermally-driven nucleic and plasma membrane fluctuations with high sensitivity. BCM employs Brillouin light scattering to quantify intracellular longitudinal modulus. Both of these non-invasive methods employed together offer the potential to shed new light on cell and nuclear mechanics.

The ultimate goal of this study is to provide a validated method for measuring the mechanical stiffness of the nucleus in a living cell in real time during processes such as cell migration or transendothelial migration. Once established, these measurements offer the promise of providing new insights, for example, into the role of the cell nucleus in limiting the rate of migration or transmigration of a cancer cell during metastasis.

Here we take an initial step, gathering information from QPM and BCM on the same cell populations before and after a treatment that causes the cell moduli to change.

METHODS

The interaction of spontaneous acoustic phonons in the cell with light results in Brillouin scattering. The spectrometer records the small resulting frequency shift, a measure that has been shown to correlate with the shear modulus and water content of the material.^{iv} BCM measures this modulus with μm level resolution in the x, y and z dimensions.

Confocal reflectance QPM can provide the μm level depth resolved optical phase information of the back scattered signal from nucleic and plasma membranes at ms temporal resolution. This phase information quantifies the height fluctuations of nucleic membranes, which are subject to thermal fluctuations around the stable equilibrium in a viscoelastic medium.

Combining the information from QPM and BCM provides the nuclear membrane and material mechanical properties.

A549 lung carcinoma cells (purchased from ATCC) were grown in cell culture in DMEM with 10% FBS and 1% Penicillin-Streptomycin. Samples for BCM were sparsely seeded on top of a 100 μm tall 2.5mg/ml collagen type I gel in a 14mm diameter MatTek and samples for QPM were seeded on an uncoated 14mm diameter MatTek glass bottom surface. One population of tumor cells was treated with the chemotherapeutic 0.5 μM Doxorubicin in DMEM for 24 hours and the wild-type population was grown in DMEM for 24 hours. Both samples were rinsed in complete media before imaging.

QPM measurements were carried out first. Fluctuations at the nuclear membrane over 14ms of 5 cells in the control population and 4 Doxorubicin-treated cells were measured 8 times per cell. After QPM,

we carried out BCM measurements on cells prepared the same week in the same manner for 4 cells of the control population and 4 cells of the Doxorubicin population, with 5 repeat measurements per cell in slightly different parts of the nucleus. Future experiments allow for measurement of the same 3D samples using QPM and BCM.

RESULTS

To compare QPM rheological measurements with those from BCM, we observed that 0.5 μ M-doxorubicin-treated A549 cells have higher nuclear fluctuations (softer nucleus) and lower Brillouin frequency (softer nuclei) (Figure 1).

Figure 1: Confocal reflectance QPM results (A) correlate with BCM findings (B): In both instances, A549 doxorubicin treatment softens the nucleus.

DISCUSSION

Several methods can be employed to measure the rheological properties of the nucleus; however, few can do so without perturbing

the cell and/or its microenvironment. Here we use light to quantify nuclear fluctuations and to quantify the Brillouin high-frequency longitudinal modulus. It has been argued that Brillouin measures water content rather than stiffness;^v however, we show here that these Brillouin measurements of the nucleus do correlate with nuclear fluctuation measurements from QPM, a measure of the nuclear membrane stiffness. At present, there is no comprehensive theory nor computational model for either method, linking the observable quantities directly to the low frequency shear modulus of the cytoskeleton and/or nucleoplasm. Future studies will continue to improve understanding of nuclear mechanics in unperturbed cells and seek to develop a fundamental understanding of how changes in membrane, cytoskeletal or nuclear moduli affect these measurements.

A MICROMECHANICAL MODEL FOR COLLAGENOUS TISSUES AND APPLICATIONS TO STUDY GROWTH AND REMODELING

Thao D. Nguyen

Johns Hopkins University
Baltimore, MD, 21218

INTRODUCTION

Soft collagenous tissues, such as the sclera, tendon, and arteries, exhibit a highly organized structure composed of elastin and collagen fibers arranged in a hydrated matrix of cells, proteoglycans and other non-fibril forming proteins. The collagen fibers in the tissues often exhibit a wavy morphology in an unloaded configuration. The initial compliant toe region of the stress response of soft collagenous tissues is attributed to the straightening of the collagen fibers, and the stiff linear region is attributed to the stretching of the fibers. The degree of waviness and alignment of the collagen fibers vary greatly between tissues and are tailored to the physiological loading state and structural function of the tissues. The collagen structure of soft tissues are actively maintained and altered through the processes of growth and remodeling. For example, in the sclera, the degree of fiber alignment decreases with age¹ and the toe region of the stress-strain curve shortens significantly², suggesting a decrease in the fiber crimp (waviness). The collagen morphology can also influence the processes of growth and remodeling. Huang and Yannas³ showed that deformation inhibits the enzymatic degradation of reconstituted rat-tail collagen. Furthermore, the degradation rate was lowest at the transition strain of the J-shape stress-strain curve separating the compliant region associated with fiber straightening and stiff region associated with fiber stretching.

To understand how the collagen structure influences the mechanisms of growth and remodeling and how they are in turn altered by growth and remodeling, we developed a micromechanical model for collagenous tissues that explicitly describe the anisotropic arrangement and crimp morphology of collagen fibers to describe the strain stiffening, anisotropic behavior of collagenous tissues⁴. We applied the model to investigate how these features are altered in engineered collagen constructs by cyclic loading⁵ and in the mouse

sclera by chronic pressure elevation. We added to the model micromechanisms of collagen enzymatic degradation and deposition to investigate how mechanical loading and the collagen structure affects the growth and remodeling processes.

METHODS

In the micromechanical model, the tissue is conceptualized as an anisotropic distribution of wavy collagen fibers, represented as sinusoidal beams, embedded in a incompressible, isotropic matrix. The planar wavy morphology has been observed in skin and the cornea, but for many other tissues, such as arteries, and engineered collagen constructs, it is an idealized representation of the non-straightness of collagen fibers that require them to bend, rotate, or be recruited before being stretched axially. The wavy fibers are assumed to be long and thin and the crimp angle is assumed to be small. This allows the analytical Euler elastica solution developed by Comninou and Yannas⁶ to be applied for the deformed rotation angle $\theta(\bar{X}_1)$ and axial stretch $\lambda_f(\bar{X}_1)$ of the fiber midline,

$$\theta(\bar{X}_1) = \frac{\beta}{\alpha(1+\alpha)+\beta} \theta(\bar{X}_1), \quad \lambda_f(\bar{X}_1) = 1 + \alpha \cos(\theta(\bar{X}_1)). \quad (1)$$

The \bar{X}_1 is the normalized coordinate X_1/L along the horizontal axis about which the fiber undulate, L is the fiber length projected onto X_1 , $\alpha = F/EA$, is the horizontal force applied to the wavy fiber normalized by the fiber modulus E and the fiber area $A = \pi r^2$, and $\beta = \pi r^2/L^2$ is the fiber slenderness ratio. The macroscopic fiber stretch along X_1 is defined deformed length over the original length,

$$\bar{\lambda} = \int_0^1 \lambda_f(\bar{X}_1) \frac{\cos(\theta(\bar{X}_1))}{\cos(\theta(\bar{X}_1))} d\bar{X}_1. \quad (2)$$

The fiber model is incorporated into a distributed fiber hyperelastic constitutive model for tissues⁴ by first applying the affine deformation assumption to connect the macroscopic stretch of a fiber

lying along an orientation $\mathbf{a}_0(\vartheta, \varphi)$ to the deformation gradient, $\tilde{\lambda} = (\mathbf{a}_0^T \mathbf{F}^T \mathbf{F} \mathbf{a}_0)^{1/2}$. We next define the fiber strain energy density as, $W_f = \int_0^L \frac{1}{2} E \beta [\theta(\tilde{X}_1) - \theta(\tilde{X}_1)]^2 d\tilde{X}_1 + \int_0^L \frac{1}{2} E [\lambda_f(\tilde{X}_1) - 1]^2 d\tilde{X}_1$. (3)

Then, the strain energy of the tissue can be defined within a distribute fiber hyperelastic framework as,

$$W = W_m(\mathbf{F}^T \mathbf{F}) + \langle W_f(\mathbf{F}^T \mathbf{F}, \mathbf{a}_0) \rangle, \quad (4)$$

where $W_m(\mathbf{F}^T \mathbf{F})$ describes the incompressible isotropic matrix response and $\langle \cdot \rangle = \int_0^{2\pi} \int_{-\pi/2}^{\pi/2} (\cdot) \rho_0(\vartheta, \phi) \sin \phi d\phi d\vartheta$ is the statistical average over the probability density distribution of the fiber orientation, $\rho_0(\vartheta, \phi)$. The distribution function has been estimated experimentally for many tissues using a variety of techniques, including TEM and X-ray scattering.

To model collagen deposition and degradation, we assume that collagen degradation works to reduce the fiber radius and collagen deposition works to increase the radius⁴ and length of collagen fibers growing under load. We derive an evolution equation for the axial growth stretch of the fiber by assuming that collagen is deposited onto a loaded fibril in an unstressed state then solving for the updated reference length of the fiber after unloading⁷. We further assume that the rate of collagen degradation and deposition can be inhibited and stimulated, respectively, by the fiber axial strain energy density⁴. The concurrent action of these mechano-regulated deposition and degradation mechanisms allow for anisotropic volumetric growth of the tissue and remodeling of the fiber orientation distribution and tissue properties. Moreover, by making the collagen deposition and degradation dependent on the axial strain energy density of the fiber, we allow the fiber crimp morphology to affect the growth and remodeling process.

RESULTS

We applied the model as described by eq. (1)-(4) to investigate the remodeling of the mouse sclera caused by 6 week chronic elevation in the intraocular pressure (IOP) to induce glaucomatous axon damage. The increased IOP causes the sclera to expand and thin or thicken depending on the location and mouse strain⁸, the pressure-strain response to stiffen significantly in the peripapillary region near the optic nerve head⁸, and the collagen fiber alignment, measured by wide angle x-ray scattering (WAXS), to decrease significantly⁹. The model was applied to fit the pressure-displacement response in inflation tests of the mouse eye to determine alterations to the collagen fiber morphology and to compare the contributions of the remodeling to the shape of the sclera, collagen anisotropy, and wavy morphology to the stiffened inflation response of the tissue. Initial results suggested that the alterations to the collagen anisotropic arrangement, while statistically significant, did not significantly alter the inflation response of the peripapillary sclera beyond the experimental variation.

The model was also applied to study alterations in the stress-strain response of an acellular engineered collagen tissue caused by cyclic loading. TEM measurements showed a slight increase in the collagen fibril alignment along the loading direction and uniaxial tension tests showed an increase in the stiffness and strength of the tissue¹⁰. We applied the model, extended to include a fiber-level damage criteria, to investigate the effect of the cyclic loading on the mechanical properties and morphology of the collagen fiber⁵. The results showed that the increase in the fiber alignment measured by TEM was not sufficient to explain the increase in the stiffness and strength of the tissue. Cyclic loading of acellular collagen constructs significantly decreased the collagen crimp and increased the collagen stiffness beyond the experimental variation.

The micromechanical model was extended to include the effect of enzymatic degradation of collagen as described in the above section

and applied the effects of mechanical loading observed in tissue-level degradation experiments for bovine corneal strips and pericardium strips⁴. The parameters of the energy-inhibited degradation law were fit to fibril-level degradation experiments¹¹, while parameters for the collagen fibers were fit to the tissue-level stress-strain curves^{12,13}. The model successfully predicted that crimped collagen fibers are degraded until straightened, such that tissue degradation was halted when the collagen tissue stretch reached the transition stretch of the stress-strain curve as observed in experiments. The mechanical inhibition mechanism also caused the preferred orientation of the anisotropic fiber arrangement to align with the directions of the maximum principal stretch and the degree of fiber alignment to vary with the biaxial stress ratio. These findings show that mechanical inhibition of collagen degradation may play an important role in tailoring the collagen crimp morphology and anisotropic fiber arrangement to the physiological loading state of the tissue.

Finally, the model was extended to include the concurrent effects of enzymatic degradation and deposition of collagen as described in the above section⁷. We applied the model to study the growth of a spherical tissue membrane, an idealized representation of the sclera, in response to a perturbation in the internal pressure. The model was able to predict the development of stress homeostasis in the tissue, where the membrane stress recovered, after the pressure perturbation, the equilibrium value attained before the perturbation. The homeostatic stress state was determined by the properties of the collagen fibers and kinetic parameters and energy inhibition/activation energy parameters of collagen deposition and degradation. For collagen tissues with a compliant bending response (e.g., slender fibers) strain homeostasis was also developed.

In conclusion, we have developed a versatile micromechanical for the anisotropic nonlinear stress response of soft collagenous tissues. The model has been extended to incorporate fiber-level mechanisms of damage, collagen degradation and collagen deposition. We have applied the model to study how remodeling affects collagen structure and properties, particularly in mouse models of glaucoma, and how the collagen structure affects both the active and passive processes of growth and remodeling. This relatively simple model, which only includes 2 fiber-level mechanisms, can describe many important phenomena of growth and remodeling, such as the development of stress homeostasis and remodeling of collagen structures along the direction of principal stress. Future work will continue to enrich the model to predict growth and remodeling of ocular tissues in glaucoma.

INTRODUCTION

The menisci are fibro-cartilaginous structures found in the knee joint that aid in joint stability, load distribution and act to protect the underlying articular cartilage from large pressures in the knee joint [1]. It has been long established that injuries to the soft tissues of the knee, primarily to the anterior cruciate ligament (ACL) and menisci, can induce post-traumatic osteoarthritis (PTOA) [2]. In order to return normal kinematics to the joint, current clinical treatment for damage to these soft tissues focuses on repairing macroscopic acute tissue damage by reconstructing the damaged ACL and removing the damaged portions of the meniscus. However, patients show signs of PTOA whether or not they receive surgical intervention [3].

A previous study by our group using a closed-joint impact lapine model demonstrated that 12 weeks following traumatic ACL and meniscal injury, there were significant morphological and mechanical changes to the menisci, which were consistent with clinical mid to late stage PTOA [4]. This study did not include surgical intervention in the traumatized joint.

The goal of the current study is to develop a new lapine model that combines a closed-joint traumatic injury with subsequent surgical repair and to determine mechanical changes in the meniscus through indentation-relaxation testing over time. It was hypothesized that damage to the menisci resulting from a controlled, traumatic impact would result in chronic changes in the mechanical properties of the tissue, even if the knee joint received surgical intervention following the traumatic injury. These results are expected to be consistent with the previous description of mid to late PTOA in the closed-joint lapine model.

METHODS

Seven skeletally mature Flemish Giant rabbits (6.81 ± 0.34 kg) were used for this study with an IACUC approval. With the animal under general anesthesia in sternal recumbency, the right knee and paw were secured into a custom fixture that allowed unrestricted anterior tibial subluxation, while constraining lateromedial motion. A controlled impact was delivered by a servo-hydraulic actuator (Instron, Norwood, MA), which thrust the tibia proximally at 0.5 Hz until ACL failure. Peak load and time to peak were recorded. Surgical reconstruction of the ACL was performed by an orthopaedic surgeon 2-3 weeks post-impact following debridement of the torn ACL and medial meniscus. The semitendinosus (ST) tendon was transected at the musculotendinous junction while its tibial insertion was left intact. The tendon's free end was rerouted through tibial and tunnel femurs (3.2mm in diameter), which overlapped the ACL footprint. The ST tendon was tensioned and then secured into the femoral tunnel using an interference fit screw and periosteal sutures. An anterior drawer test was performed to assess postoperative joint stability prior to routine closure.

Animals were euthanized 1 (n=4) and 3 (n=3) months post-impact. Menisci were harvested immediately after euthanasia and refrigerated until mechanical tests were performed (within 18 h). Indentation relaxation testing was performed in a room temperature saline bath on the menisci as previously described [4]. Following a 20mN preload, a cylindrical steel 1.59mm diameter indenter tip was used to indent the tissue to a depth of 0.25mm and held for 900 s to reach equilibrium. Hertzian contact was assumed between an elastic half-space (the meniscus), and a rigid sphere (indenter). A Poisson's ratio of 0.01 was assigned to the meniscus. The elastic modulus and Poisson's ratio of the indenter were 210GPa and 0.3 respectively.

A custom MATLAB code was used to obtain the instantaneous and equilibrium modulus from recorded data. These were then compared to

those from a previous study that utilized a similar knee injury lapine model, but without surgical repair of the traumatized joint [4]. Minitab software (Minitab 18, Park College, PA) was used for statistical analyses. Unpaired t-tests were used to compare differences in meniscal mechanical properties between impacted and reconstructed limbs and the contralateral control limbs. Similarly, these tests were performed between results in the 3-month group of the current study and those from a 3-month post-impact group in Fischenich et al. [4]. A p-value less than 0.05 was considered significant.

RESULTS

Mid-substance ACL tears were documented in 6/7 animals, while damage to the posterior attachment of the medial meniscus occurred in 4/7 animals. Mean \pm SD failure force was 900.3 ± 77.4 N.

Morphological analyses of the menisci showed increased damage in the medial meniscus compared to the lateral meniscus in the reconstructed limbs, with further degradation across time points. Tears were documented in both menisci across all time points, with increase in tear size and length at a 3-month time point. Increased maceration and synovium growth were documented on the outer 1/3 region of both menisci at a 3-month time point. Due to extreme thinning and tearing in the medial meniscus, not all three regions were able to be tested for mechanical properties.

Figure 1: Comparisons of the instantaneous and equilibrium modulus in each meniscus across both time points. * denotes significant differences

In order to perform statistical analysis, the regional data were averaged for a given meniscus and specimen. A significant decrease in instantaneous modulus was found in the medial meniscus in the reconstructed limb at a 3-month time point, compared to the contralateral controls at both time points. Similarly, a significant decrease in the equilibrium modulus of the medial meniscus was observed when compared to the other groups. A significant decrease in the equilibrium modulus in the lateral meniscus was observed between the 1-month contralateral control and reconstructed limbs at both time points (Figure 1).

Figure 2: Comparisons of instantaneous and equilibrium modulus between the current study and that of Fischenich et al. * denotes significant differences

A comparison of the current results with those from a previous study performed by our group [4] at the same time point (3-months post impact) showed no significant differences in the instantaneous modulus of the medial meniscus between the impacted and reconstructed limb and the impacted-alone limb when compared to the contralateral control group. Similar results were observed in the equilibrium modulus. However, there were no significant differences in the lateral meniscus between the contralateral control and reconstructed limbs (Figure 2).

DISCUSSION

The closed-joint impact model was able to successfully and reliably generate ACL tears and meniscal damage, comparable to what is observed in the clinical setting. Surgical intervention to repair the damaged ACL and meniscal debridement was successfully performed as well, which replicates the current clinical gold standard. Thus, a novel closed-joint impact and surgical intervention animal model was created. This model can provide a deeper insight into the progression of PTOA that previous animal models could not achieve.

The mechanical property results suggest that surgical intervention does not prevent degenerative changes in the meniscus, specifically in the equilibrium modulus. Although the goal of surgical intervention is to return stability to the joint, the observed degradation of the tissue could be attributed to occult damage caused by the impact at the cellular level.

Future work will include histological interrogation of the tissue and the addition of a 6-month time point, as well as the validation of poloxamer 188 (P188) in aiding to prevent the onset of PTOA by inhibiting cell death in the *in-vivo* setting.

INTRODUCTION

The meniscus serves a key function in knee load-bearing and in protecting the underlying articular cartilage against osteoarthritis (OA). The menisci are commonly injured, and injury impairs the meniscus' ability to distribute loads and often results in cartilage OA. This link between meniscus injury and OA risk is well-known in humans and has been established in small animal models [1,2,3], but the incremental progression of meniscus changes over time and the inter-relationship between cartilage and meniscus degeneration over time remain unknown. Observing this progression requires longitudinal studies with multiple time points, which in turn requires development of appropriate large-animal models and/or noninvasive human imaging.

Our group recently established a large-animal model (porcine) of meniscus injury that at one month showed loss of meniscus proteoglycan, higher contact pressure during joint loading, and cartilage degeneration that varied based on type of injury [4]. These findings demonstrated the usefulness of our model to study progressive knee joint changes after meniscus injury, but the measurement methods used were destructive and so cannot be directly translated to longitudinal studies in humans. To bridge this translational gap, non-invasive measurements with similar utility are needed.

Magnetic resonance imaging (MRI) permits noninvasive longitudinal assessment of structural and compositional changes in the knee, but MRI findings still need to be linked to tissue-level assessments to confirm their validity and interpretation. The purpose of this study was to establish this link between MRI measurements and tissue properties using our established large animal model. Specifically, we sought to identify MRI-observable pathologic remodeling in the meniscus itself and in the adjacent cartilage following meniscus injury, and to correlate these MRI findings to the joint changes previously observed in this model [4].

METHODS

Juvenile (6 month old) Yucatan minipigs underwent bilateral arthroscopic surgery in which each of the two medial menisci received one of the following interventions: sham (arthroscopy with no meniscus incision), DMM (destabilized medial meniscus, where the anterior attachment of the meniscus is transected), vertical longitudinal tear (1/3 arc length, red-white zone), or radial tear (50% of meniscus width) (n=3/treatment). Tears were created with a scalpel in the anterior part of the meniscus. Animals were sacrificed at one month and their joints were harvested for MRI followed by a series of destructive macro- and micro-scale measurements.

Two MRI sequences were acquired of the intact joints on a 3T Siemens Prisma: a multi echo T₂-weighted mapping sequence and a gagCEST sequence (both 0.58 x 0.58 x 3.00mm) and quantitatively analyzed. T₂ relaxation time is linked to water content and to deterioration of the tissue's fiber network (as fiber network degrades, water content increases and T₂ increases). GagCEST is a chemical exchange sequence that is correlated with a tissue's glycosaminoglycan (GAG) concentration [5,6]. T₂ time and gagCEST values were analyzed at and around the tear region of the anterior meniscus (or the same anatomical location in the sham and DMM cases) and in tibial cartilage in the regions covered and uncovered by the meniscus.

The destructive macro- micro-scale measurements were joint contact pressure, cartilage indentation modulus in regions covered and uncovered by the meniscus, and histology. Joint contact pressure was measured by a TekScan #6900-110 pressure sensor inserted into the medial compartment of the joint [7] under 1X body weight (400 N) at 15° of flexion. Cartilage indentation was done using a 2 mm spherical indenter on osteochondral plugs from the medial tibial plateau [8]. Histology was done using radial sections (16 microns thick) taken from the anterior horn stained with Safranin O/Fast green to measure

proteoglycan (PG) content [9]. MRI outcome measures were compared between treatments with one-way ANOVA followed by student's t-test. MRI measures were correlated with the destructive measures using a Pearson's correlations.

RESULTS

In the meniscus tear region, T₂ time was higher with a radial tear (Radial p<0.06); gagCEST was higher after DMM (p<.05) and lower after radial tear (p<0.06) (Fig 1). In the cartilage, T₂ time was higher in the covered region after DMM (p<0.05) and in the uncovered region after radial tear (p<0.05) (Fig 2). Cartilage gagCEST was higher in the covered region after DMM (p<0.09) (Fig 3).

There was a significant correlation of covered cartilage T₂ time with both contact pressure from TekScan and covered cartilage indentation modulus (p<0.05) (Fig 4). In the meniscus, histology slices where red stains proteoglycan were compared to gagCEST maps in paired samples and in the same region, showing similar patterns for all groups except DMM which was different than paired histology (Fig 5).

DISCUSSION

This study demonstrated that non-invasive MR assessment of knee joint health can reveal degenerative changes in meniscus and cartilage resulting from injury in a large animal model. For example, imaging successfully detected meniscus changes following injury in T₂ and gagCEST values that were confirmed by histology (Fig 1 and 4). These

meniscus changes likely led to altered joint loading (confirmed by TekScan, Fig 3) suggesting that increased joint loading occurred in the covered region after DMM and in the uncovered region after radial tear. This altered joint loading likely caused the cartilage degeneration that was also detectable using MRI (Fig 2, 3). Further supporting functional changes following meniscus injury and altered joint loading, cartilage indentation revealed a lower modulus in injured knees which also correlated with cartilage T₂. Since TekScan requires dissection, future work will address in situ loading changes using MRI.

The DMM injury resulted in a distinct meniscus phenotype that appears more degenerative than the vertical and radial tears, as is evident by the meniscus structure/shape, the pattern of GAG staining (histology) and the higher gagCEST values (Fig 4). Additionally, the DMM injury resulted in an unusual change in the gagCEST (suggested a higher GAG content) that was contrary to histology (had less GAG). This may be due to the DMM meniscus being at a later stage of degeneration. This potential explanation is based on human cartilage studies which show that gagCEST MRI is most useful in early stage degeneration that is dominated only by loss of GAG and that T₂ and morphological changes appear to bias the gagCEST in late degeneration [10]. Thus meniscus tissue remodeling and reduced fiber organization at the site of transection may cause an increased ability of water molecules to diffuse in and out of voxels during MR scanning and explain our unexpected observation of increased meniscus gagCEST in the DMM injury group. Nonetheless, the gagCEST measurement serves as an indicator that the meniscus is compositionally altered and no longer healthy (as confirmed by gross dissection and histology).

The non-invasive assessments confirmed invasive measurements, providing an important advance to allow longitudinal study of joint changes following different meniscus injuries and, ultimately, new ability to study functional changes. The correlations between invasive measures and non-invasive MRI observed here are particularly useful for guiding interpretation of MRI observations in human studies, for which longitudinal destructive measurements are impermissible, to help inform specifics about the change in function of the tissues of the knee joint. Future work will increase sample size and extend to longer time points. Our long-term goal is to determine mechanisms of post-meniscus injury joint damage and inform when and if surgical intervention should occur after meniscus injury.

Introduction

The mechanical, tribological, and biological functions of articular cartilage depend critically on its interstitial hydration, which comprises about 75% of the free-swollen tissue. During contact, however, water content decreases until the osmotic pressure from fixed charges within the collapsing matrix fully support the applied stress; this corresponds to vanishing levels of hydration at physiological stresses (~5 MPa).

Fortunately, there is strong experimental evidence that interstitial hydration, pressure, and lubrication remain high in-vivo. One hypothesis is that cartilage slowly compacts over the day and recovers passively when unloaded at night. Coleman et al. [1] showed that strains in the human knee increase by ~3% over the day and recover by the next morning. The surprising result is not that strains increased throughout the day, but how little they increased; the back of the envelope calculation suggests more than an order of magnitude more. Their observation that evening strain correlated inversely with number of steps taken suggests that movement played a significant role.

Several observations help explain how movement disrupts load-induced exudation. Caligaris and Ateshian [2] showed that a cartilage explant retained interstitial fluid, pressure, and lubrication as long as the contact moved across the cartilage before the fluid could respond. Linn's studies on dog ankles [3] add another dimension: holding load constant, articulation quickly reversed the static exudation process. He attributed recovery to free swelling during periodic exposure of the talus to the bath and concluded that the dynamic equilibrium involved balance between loss and recovery rather than the absence of flow. Both explanations are based on migration of the contact area (MCA). Our recent studies on tribological rehydration add a third dimension [4]: using the convergent stationary contact area (cSCA), we observed consistent loss, maintenance, and recovery dynamics without changing load, without migration, and without exposing the cartilage to the bath.

Thus, static unloading and loaded articulation appear to be equally rational actions for restoring cartilage hydration following static loading. In this paper, we quantify rehydration rates of cartilage under controlled conditions to clarify if one action dominates the other and to determine the relative contributions of free swelling (outside the contact area) and tribological rehydration (inside the contact area) to articulation-induced recovery.

Methods

Materials: This study used bovine stifles from two different local sources (Herman's Quality Meats and Bowman's Butcher). Following joint dissection, a coring saw was used to extract $n = 25$ $\phi 19$ mm osteochondral samples. Samples were stored in and lubricated by a solution of protease inhibitor (P2714, Sigma Aldrich) dissolved in

phosphate buffered saline (PBS). to a dilution of 1X based on the manufacture's recommendations. Samples were stored at 4 °C and tested within 4 days of harvest.

Measurement device: Interstitial fluid loss and recovery rates were quantified using compression measurements from one of two custom instruments. Tribological rehydration and passive swelling rates were quantified using a unidirectional pin-on-disk tribometer comprising a stepper motor to control sliding speed, a 6-channel load cell to measure forces (± 10 mN), and a vertical nanopositioning stage to control load and measure compression (± 100 nm). Free-swelling rates were quantified using an indenter with a two axis load cell (± 10 μ N) and a vertical nanopositioning stage to control load and measure compression (± 100 nm).

Figure 1. (A) Definitions of the three distinct fluid recovery modes measured here. (B) Illustration of a typical rehydration rate measurement. Cartilage exudes fluid during 90 min of static loading and recovers fluid during loaded sliding due to tribological rehydration; the tribological rehydration rate is the sum of the measured recovery and exudation rates (volume conservation).

Tribological rehydration: The tribometer was used to load $N = 7$ samples statically against a flat glass disk at a constant 5N of load. To begin, samples were loaded statically for times between 0 and 180 minutes (to vary exudation-induced strain). Following static loading, the disk began sliding at 100 mm/s (Figure 1A) to induce tribological rehydration. The recovery rate was defined as the linear regression of the first 10 seconds of this recovery process. The exudation rate was the slope of the static curve for the same strain range (Figure 1B). The tribological rehydration rate is the sum of these measured quantities (based on volume conservation).

Passive swelling: The tribometer was used to load $N = 2$ representative samples statically against the flat glass disk at 5N of load for 12.5 and 90 minutes, respectively. Following the static loading period, the load was reduced to 0.25 N, which allowed the instrument to track nominally unloaded passive swelling (Figure 1A). We defined the passive swelling rate as the linear regression of the first 10 seconds of this recovery process.

Free swelling: The indenter was used to load $N = 9$ samples statically with a $\phi 6$ mm porous plane-ended indenter to 75 mN for 10 min. and then unloaded to a tare load of 0.1mN, which allowed the instrument to track recovery for nominally unloaded free swelling (Figure 1A). We defined the free swelling rate as the linear regression of the first 10 seconds of this recovery process.

Results

The compression response of a representative cartilage sample to sliding following static loading is shown as a function of time for various static loading times in Figure 2A. After only 0.5 minutes of static loading, the sample continued compressing during sliding. The sample recovered thickness rapidly during sliding after 90 minutes of static loading. In all cases, sliding at 5N of load and 100 mm/s caused the sample to lose or recover fluid until reaching a dynamic equilibrium compression of 0.18 mm. Similar loaded dynamic equilibria were observed during articulation of dog ankles and human knees. It is also worth noting that every sample exhibited a specific and repeatable non-zero 'resting equilibrium deformation' between 0.05 and 0.15 mm during contact after the load was removed such that the change in strain from increased load was typically 3-10%.

Figure 2. (A) Compression response of a single representative sample during sliding following various static loading times. (B) Summary of results: exudation, free swelling, passive swelling, and tribological rehydration rates are all plotted together as functions of compression. The 'resting equilibrium' denotes the mean compression for contact at equilibrium following load removal.

All of the rehydration and exudation rates collected for this study are plotted as functions of compression in Figure 2B. Loaded exudation rates from cartilage against glass at 5 N decreased as expected with compression from ~ 200 nm/s near 0.1 mm of compression to 10 nm/s near 0.5 mm of compression. The free swelling rate was 1070 ± 230 nm/s based on $N=9$ samples. The tribological rehydration rate was 1150 ± 690 nm/s based on 93 measurements of $N=7$ samples. Passive swelling rates were 20 and 100 nm/s for 90 minutes and 12.5 minutes of loading, respectively. These passive swelling rates highlight the general fact that rates correlated better with time than compression, which depended on both time and widely varying sample moduli.

Discussion

While there have been suggestions that free swelling is the fastest possible mode of fluid recovery, these are, to our knowledge, the first direct measurements of its absolute and relative rates. Free swelling rates were on the order of 1,000 nm/s and did not appear to vary significantly with strain or between samples. More importantly, free swelling rates exceeded exudation rates by 10-100 times depending on the strain, which helps explain why very little activity appears sufficient to counteract the effects of long static loading periods. This

is not surprising given that free swelling occurs at a free surface and exudation requires flow through a contact area. The surprising result is that tribological rehydration rates within a **loaded contact** were indistinguishable. This is consistent with a fluid film enabling free swelling at the contact interface. However, it is inconsistent with the observation that the highest rehydration rates were accompanied by the highest friction coefficients (>0.4). Furthermore, our previous studies showed evidence that solutes were pushed across the contact area from the leading edge [5]. Our results appear consistent with hydrodynamic pressurization at the leading edge, but the mechanism is unclear. Passive recovery rates were far slower (10-100 nm/s) and comparable in magnitude to in-vivo measurements by the Eckstein group (27 nm/s) based on patellar recovery for human subjects resting in a scanner after deep knee bends (5% recovered in 90 minutes) [6].

Figure 3. Interpreted flow profiles and estimated rates for a cartilage on cartilage contact under: (A) static loading; (B) static unloading; (C) loaded movement.

To move or to rest – that is the question. Following a period of static loading (standing, sitting at a desk, or sitting in an airplane), there appears to be no question that joint movement rehydrates the contact area far quicker than static unloading. During motion, free swelling rehydrates the dehydrated zone on the migrating component about as quickly as tribological rehydration rehydrates the contact zone on the stationary component; this study demonstrates that these are comparable and complementary modes. Intermittent movement, we propose, is the primary reason joints avoid reaching dangerously low levels of hydration throughout the day. While static loading has been shown to thin human patellar cartilage by 50% in an hour [6], Coleman et al. showed that strains in the knee only increased by $\sim 3\%$ throughout the day [1]. Given that we are active less than 10% of the day, it appears likely that strain accumulation is mitigated by a competition between long periods of slow exudation and sparse but fast periods of recovery.

Prior to 2017, migration was the only known source of articulation-induced interstitial fluid retention and recovery. On this basis, it has been concluded that hip hemiarthroplasties, which create a cSCA, defeat interstitial hydration [7]. In 2017, we demonstrated that tribological rehydration restores interstitial hydration in the cSCA; this study demonstrates that tribological rehydration rates are competitive with those associated with migration. While it is unclear if these rates persist at physiological stresses, previous conclusions should be tempered in the light of this new evidence.

Finally, these results suggest that the cSCA is just as relevant for studies of cartilage mechanics and tribology as the MCA (sphere on cartilage) while offering far more convenience to the experimenter. It removes the challenges of sample curvature, it eliminates plowing, it subjects individual cells to constant yet controllable conditions, and it lends itself well to in-situ bio-imaging [5].

INTRODUCTION

Due to the avascular nature of the tissue, once articular cartilage is injured it has a limited healing capacity and significant damage can result in reduced quality of life and early onset osteoarthritis¹. As we develop new treatment modalities and tissue engineered replacements, it is critical to understand the structure-function relationship of the tissue throughout the full cartilage thickness. Previous work has described variation in collagen arrangement throughout articular cartilage thickness² as well as mechanical anisotropy within each cartilage zone³. This zonal-specific anisotropy serves to distribute joint loads. However, while properties of individual articular cartilage zones have been evaluated using small, excised samples from within each zone^{4,5}, these assessments are complicated by testing *ex-situ* in a non-native stress environment, with imperfect sample geometry and small sample dimensions that fail to enable one to evaluate anisotropy.

In contrast, microindentation testing enables mechanical property assessment within biological tissues (i.e., *in-situ*), thus allowing observation of spatial variation in behavior with nearly intact zonal structure. Beyond just quantifying the mechanical behavior of the osteochondral tissues, it is important to observe the underlying arrangement of the tissue to evaluate relationships between structure and function. Moreover, the ability to test individual micrometer-sized regions within a tissue enables regional assessment. Thus, microindentation provides insight to tissue engineers seeking to reproduce native properties and aids in assessment of disease progression. In the current work, we sought to elucidate the structural organization and material properties in all three orthogonal directions throughout human skeletally mature, zonal articular cartilage. This was accomplished by measuring the collagen fiber orientation via second harmonic generation (SHG) and two photon fluorescence (TPF)

imaging and the tensile modulus (E_t) and compressive modulus (E_c) using microindentation.

METHODS

Cartilage was obtained from the femoral condyles of two male and two female human donors (55-61 years old) without a clinical history of osteoarthritis. Specimen were fresh frozen, and experienced two additional freeze thaw cycles throughout the testing process. Three 5 mm cubed samples were obtained from each donor; samples were hydrated in phosphate buffered saline (PBS) during all preparation and all mechanical testing was performed with samples submerged in 1X PBS containing 1% (v/v) Protease Inhibitors (Halt, Thermo Fisher 78438) which was replaced with fresh fluid every three days.

Microindentation was performed on a Hysitron TI-950 nanoindenter. Arrays, five indents wide and spanning the full depth of the distance from the articular surface to the zone of calcified cartilage in all three orthogonal directions (Figure 1), were placed $\sim 10\times$ the contact radius from the tissue corner to avoid edge effects. Direction 3 testing was conducted on the articular cartilage gliding surface, middle zone, and the deep zone. Indents were performed using a cono-spherical probe ($R = 250\ \mu\text{m}$), spaced at $250 \times 250\ \mu\text{m}$, to a max indentation depth of $12.5\ \mu\text{m}$ under displacement control. The displacement rates were 1, 4, and $8\ \mu\text{m/s}$, hold time was 60 seconds, and unload rate was $1\ \mu\text{m/s}$. The articular cartilage was modeled as a nonlinear biphasic material with a Poisson's ratio near zero as proposed by Soltz and Ateshian⁶ and data was applied to the indentation equation by Burris *et al.*⁷. Using the "Hertz Burris Theory" (HBT) the tensile modulus (E_t) and equilibrium contact modulus (E_c) were evaluated.

The prevalence of collagen was investigated using SHG and TPF imaging (BioRad Radiance 2100 confocal and Coherent Chameleon Ultra II laser tuned to 800 nm wavelength). Imaging was performed

without staining or contrast agents on face 1 and face 2 spanning the surface, middle, and deep zones (Figure 2). Collagen I and II direction was observed from the SHG signal and measured using Image J and applying the Orientation J plugin and the finite difference gradient method⁸. The interface between articular cartilage and subchondral bone was taken as the zero axis and all collagen fiber angle measurements were calculated as the smallest absolute value from that zero axis with 90° being the highest obtainable angle.

For all statistical analysis, a linear mixed model was used with donor (and sample for mechanical analysis) as repeated variables and the direction and zone as fixed effects. A post-hoc Tukey's test was used for individual comparisons between groups with $p < 0.05$ considered significant. Lastly, a linear fit between collagen fiber orientation and average E_c and E_t across all zones was used to assess the correlation between the two measures.

Figure 1: Sample orientation and indent location. SHG was performed on two sides, the planes normal to direction 1 and 2.

RESULTS

No outliers were found for any of the measured collagen orientation data and no significant differences ($p > 0.05$) were identified between the directions 1 and 2 so data was grouped. The collagen fiber orientation was found to increase with depth relative to the articulating surface for all donors (Figure 2) and when assessed collectively the three zones were all significantly different from each other ($p < 0.05$). Average orientation angles were 45.4°, 20.6°, and 8.1° for the deep, middle, and surface zones respectively.

Figure 2: Left) SHG image and Orientation J vector analysis images Right) boxplot of collagen fiber orientation (face 1 and face 2 combined) vs zone*denotes significant difference.

Outliers, as determined using the Huber method⁹, were removed from the mechanical analysis results. The tensile modulus regardless of direction or orientation exceeded the compressive modulus (E_t/E_c mean = 2.04). Differences across directions were observed with direction 3 (normal to the articulating surface) being frequently significantly different ($p < 0.05$) from the other two directions (Figure 3). There were

also significant zonal differences identified in both the E_c and E_t . In all cases, modulus values were higher in the deep zone compared to the surface zone, and this trend was most obvious when comparing E_c values. When correlating collagen fiber orientation to modulus, the compressive modulus had a stronger correlation compared to the tensile modulus ($R^2 = 0.45$ and 0.8 , respectively) (Figure 3).

Figure 3: Left) modulus results for E_c and E_t as a function of direction and zone *denotes significant differences in zones within directions, #denotes significant difference with direction 3 within zone %denotes significant difference with direction 2 within zone Right) correlation of collagen fiber orientation and modulus

DISCUSSION

These results demonstrate that microscale mechanical properties of human articular cartilage are both directionally and zonally dependent. By combining SHG and TPF, the collagen fiber orientation was mapped and compared to micromechanical assessments. Findings suggest collagen fiber orientation may be more linearly related to equilibrium contact modulus rather than tensile modulus when modeled as a nonlinear biphasic material and tested in indentation at the micron level.

These results are in agreement with previous work on bulk samples highlighting the change in collagen fiber orientation with increasing distance from the articulating surface as well as mechanical anisotropy²⁻⁵. Work is ongoing to analyses site-matched Raman spectroscopy data to relate mechanical and structural properties to the chemical composition of the tissue. Collectively this work will represent one of the first studies to investigate structure, mechanics, and composition in all three orientations of human articular cartilage and will help to guide future disease studies and tissue engineering strategies.

INTRODUCTION

Collagen fibers act as structural, load-bearing components in most soft biological tissues. Often, these fibers account for a majority of the tissue's mechanical strength and stiffness. In articular cartilage specifically, collagen fibers make up 15-20% of the wet weight [1] and exhibit depth-dependent orientations and fiber diameters [2]. In addition to the depth dependency, degeneration of cartilage during the development of osteoarthritis (OA) affects the collagen and its arrangement and diameter [3]. Understanding how the collagen network evolves during early-stage OA can aid in understanding the impact of evolving intra-tissue mechanics on the progression of OA. We aimed to characterize changes in the density, diameter, and orientation of collagen during early-stage OA, and to provide high fidelity, through-thickness data for proposing, fitting, and validating constitutive models.

The diameter of a single collagen fiber falls between 10 – 300 nm making it impossible to resolve single fibers using standard light microscopy [4]. Instead of using photons as in light microscopy, electron microscopy (EM) uses high-speed electrons as the energy source allowing for higher resolution. Transmission electron microscopy (TEM) specifically offers a valuable method to observe the collagen network, because specimen preparation is well suited for applications where the specimen size is on the range of millimeters, and because one aims to observe the internal morphology. TEM methods also stabilize and preserve the microstructure of tissues during imaging; thus the results still reflect the character of tissues *in vivo*.

The aim of this study is to utilize TEM and custom image analyses to visualize and quantify distributions of diameter, principal orientation, and dispersion (about this principal orientation) of collagen fibers in the early stages of OA (OARSI grades of 0, 1, 2, 3 [5]) in the superficial (SZ), middle (MZ), and deep (DZ) zones through the thickness.

METHODS

Selecting Specimens: To study cartilage spanning the course of OA progression, we obtained tissues removed during total knee arthroplasties (TKAs) at Hartford Hospital. We stored tissue at -80°C in phosphate-buffered saline (PBS) to minimize structural changes prior to fixation [6]. First, we determined the local split-line direction (SLD) by pricking the surface of the cartilage with a dissecting needle dipped in India ink [7]. We then extracted ~1-3 mm cuboid, full-thickness cartilage specimens using razor and surgical scalpel blades while identifying and marking the edge of the cuboid parallel to SLD.

We also extracted a specimen adjacent to each primary specimen for histology and OARSI grading [5]. Trained individuals independently graded randomized histological images that contained two images from each specimen. We evaluated interobserver variability and averaged grades to obtain a single OARSI grade for each specimen. Based on these grades, we chose 17 specimens (spanning the progression of OA and from multiple patients) to process for TEM imaging. These specimens allowed us to assess the inter-grade and inter-patient variability in the measured network quantities.

Preparing Specimens and Imaging via EM: We fixed the primary specimens in 3.0% glutaraldehyde, 3.0% paraformaldehyde, 0.05% w/v tannic acid in 0.1 M PIPES buffer for 2 hours [8]. Next, we trimmed off all subchondral bone and sliced the cuboids into ~0.5 mm thick pieces parallel to the imaging plane (parallel to the SLD) using a surgical scalpel before placing in the fixative overnight. We performed post-fixation with 1% osmium tetroxide for 1 hour and *en bloc* staining with 2% uranyl acetate in 50% ethanol for 15 min, followed by 2.5% Reynold's lead citrate for 3 min. We dehydrated the specimens in graded ethanol before clearing with propylene oxide. We infiltrated and embedded the specimens with Spurr's resin and polymerized the resin in a flat-bottom embedding capsule for 24 hours at 70°C.

We then cut ultrathin (50 nm) sections using an Diatome Ultra 45° diamond knife on a Leica Ultracut UCT ultramicrotome and collected the ~1-2 mm sections on copper 50 mesh grids before staining with 2% saturated uranyl acetate for 8 min and 2.5% Sato's lead citrate for 3 min. We imaged sections using a FEI Technai 12 G2 Spirit BioTWIN.

Analyzing the Images: First, we implemented a custom code using Matlab [9] that divides the images into subimages and transforms them into the Fourier domain (which rotates any linearity by 90°) to determine the angle of the principal direction based on analytical minimization of a least-squares function. We found the dispersions of fiber orientations around this direction by comparing the weight of the alignment in these principal directions to the relative weight of the directions perpendicular. We determined the distributions in fiber diameters within each image by selecting $n = 100$ fibers, one from each region in a 10×10 grid overlay, and measured their diameter using ImageJ [10]. We assigned images to specific through-thickness zones by using the relative distances from the articular surface and the following zonal definitions based on total thickness: SZ (0-15%), MZ (15-70%), DZ (70-100%) [11]. We will determine the number of images from each specimen and zone using power analysis based on a preliminary comparison of inter-grade and inter-patient variability.

Figure 1: Representative (a,d) TEM images with local fiber orientations (red lines); polar histograms of principal directions (based on 16×16 subimages (b,e); and distribution in fiber diameters (c,f) for SZ (a-c) and MZ (d-f). Scale bar = 2 μm.

RESULTS

Figure 1 shows preliminary results from a single patient with one specimen taken from the SZ and one from the MZ. Lines overlaid on the TEM images represent the local principal orientations of collagen fibers and the degree of anisotropy ($\rho \in \{0,1\}$) by the angles and relative length of the lines, respectively [9]. The polar histograms of local principal orientations of collagen fibers where $\rho > 0.25$ (meaningful local alignment) quantify local fiber alignment by zone and visible differences between the SZ and MZ [9]. The difference in the distributions in fiber diameters between the SZ and MZ is significant ($p < 0.05$).

DISCUSSION

These preliminary results show a greater alignment in the SZ visually evident in the smaller angular distribution of local principal orientations of the fibers. This conclusion aligns with previous studies qualitatively assessing changes in fiber alignment through the thickness [2,12]. The fibers in the SZ are also on average thinner than those in the MZ, also a finding in previous studies [2,3]. However, our preliminary results show greater variation in fiber diameters in the MZ, which was not the case in [2]; additional images in our zonal comparisons will show a clearer picture. To resolve single fibers, we also needed to capture the images at a magnification that results in a single image of ~5×5 μm; to holistically characterize each zone, we will need multiple images from each zone.

Since the orientation of fibers is a key element in defining through-thickness zones within cartilage, we capture images from the through-thickness 'middle' of each zone to ensure that our images represent the respective zones. Our methods for quantifying both the local orientation and dispersion of the fibers requires dividing the initial image into sub-images. We determine and justify the optimal number of regions of interest following our previous studies [13]. Importantly, the network of collagen within human cartilage is truly three-dimensional, so our two-dimensional images do not capture any out-of-plane variations. However, based on the orientation of our imaging planes relative to the SLD, we assume that these variations are negligible.

We expect to see the local orientation and dispersion of the collagen network, and diameter of the fibers, change during to the remodeling that occurs with progression of OA (quantified via OARSI grades). The findings of this study will provide quantitative data to aid: (1) our understanding of the evolving intra-tissue mechanics on the progression of OA; (2) the development, refinement, and validation of biomechanical models of cartilage; and (3) the development of tissue-engineered biomaterials to serve as cartilage replacements.

INTRODUCTION

The collagen network in the extracellular matrix (ECM) of cartilage mainly consists of heterotypic collagen fibrils of types II, IX and XI, with minute amount of collagen I. Type III collagen (collagen III), another fibril-forming collagen type, is often considered to co-assemble with collagen I, rather than collagen II [1]. Interestingly, recent literature suggested that collagen III is also present in the collagen II-rich cartilage ECM, and can contribute up to ~10% of total cartilage collagens [2]. In addition, our recent study showed that heterozygous deficiency of collagen III (in *Col3a1*^{+/-} mice) results in abnormally thickened collagen II fibrils and reduced modulus of cartilage [3]. Further, literature has suggested that collagen III is more concentrated in the PCM [4], the microdomain where initial fibril assembly takes place [5]. Here, we studied the spatial distribution of collagen III in cartilage ECM and its role in mediating the structural integrity and micromechanics of cartilage. Specifically, we delineated the role of collagen III in the PCM and the further-removed, territorial/interterritorial matrix (T/IT-ECM). We focus on the role of collagen III in the structure and function of cartilage PCM.

METHODS

Sample preparation. Mice were harvested from 2-month old wild-type (WT) and *Col3a1*^{+/-} BALB/c male mice. Knockout mice were unavailable due to their perinatal lethality [6]. The human articular cartilage samples were obtained at the total knee arthroplasty and de-identified for non-human subject research.

Immunohistochemistry (IHC). For mice, whole knee joint were harvested, fixed in 4% paraformaldehyde, decalcified in 10% EDTA, 6- μ m-thick sagittal sections were obtained from paraffin embedded blocks, and used to stain for type III collagen (ab7778, Abcam) along with human cartilage specimen.

AFM nanoindentation modulus mapping. With the guidance of immune-labelled collagen VI (70R-CR009X, Fitzgerald) [7] on 8- μ m unfixed tibia sagittal cryo-sections assisted by Kawamoto's film method [8], then AFM-nanomechanical mapping was performed using microspherical tips ($R \approx 2.25\mu\text{m}$, $k \approx 1\text{ N/m}$, μMasch) and an MFP-3D AFM in PBS with protease inhibitors at room temperature. For each map, a 40×40 indentation grid was acquired over a $20 \times 20\mu\text{m}^2$ region of interest containing well-defined, ring-like PCM terrains [9]. The effective indentation modulus, E_{ind} , was calculated using finite thickness-corrected Hertz model [10].

Collagen Structural analysis. To assess collagen fibril structure, TEM was applied to tibia sagittal sections of middle/deep zone cartilage [11]. Tibia was fixed in Karnovsky's fixative, decalcified, dehydrated with series ethanol, infiltrated and embedded following established procedures [12]. Sections were examined and imaged at 80 kV using a TEM (JEOL Ltd., Tokyo, Japan) equipped with a Gatan Orius CC Digital camera (Gatan Inc., Pleasanton, CA).

Biochemical analysis. To quantify collagen cross-link density, femoral head cartilage was collected, reduced with NaB^3H_4 , hydrolyzed with 6N HCl and subjected to amino acid and cross-link analyses, as described previously [13].

Statistical test. All dataset was conformed to normal distribution after applying Kolmogorov-Smirnov test. For nanoindentation modulus and cross-link density analysis, two-sample *t*-test was applied. For collagen structural analysis, two-sample *z*-test was applied to compare the average fibril diameter, and *F*-test was applied to compare the variance. Significance level was set at $\alpha = 0.05$.

RESULTS

Collagen III immunoreactivity is found high in the PCM in healthy human cartilage, as well as in WT and *Col3a1*^{+/-} murine

cartilage (Fig. 1a,b). In contrast, in OA human cartilage, collagen III was present throughout the ECM (Fig. 1a). In accordance with the known role for collagen III in regulating collagen fibril structure [14] and its more localized distribution in the PCM, TEM images showed significantly increased collagen fibril diameters with a broader distribution, i.e., higher variance (Fig. 2a-c). Meanwhile, AFM-nanoindentation showed significant reduction in the modulus of *Col3a1*^{+/-} cartilage PCM, highlighting the important role of collagen III in mediating the collagen fibril assembly in the PCM (Fig. 2e). In the further removed ECM, we also observed fibril thickening and modulus reduction upon collagen III reduction, albeit to a lesser degree (Fig. 3b,c). At the tissue level, while the total collagen content was similar between the two genotypes (not shown), significant increases in the amount of both reducible (dihydroxylysinoxonolucine, DHLNL) and non-reducible (deoxypyridinoline, d-Pyr) cross-links were observed in *Col3a1*^{+/-} cartilage (Fig. 3d).

DISCUSSION

Given that the initial steps of collagen fibrillogenesis takes place in the PCM [5], our data showing localization of collagen III to the cartilage PCM (Fig. 1) provoke the hypothesis that collagen III could play critical roles in regulating the initial collagen fibril assembly of cartilage [5]. Indeed, the reduction of collagen III leads to pronounced structural defects of collagen fibrils networks (Fig. 2). These observations corroborate with literature showing collagen III can co-assemble with collagen II on fibril surfaces to regulate collagen II fibril assembly [15]. Taken together, our results point to a direct role of collagen III in regulating cartilage structural integrity by limiting the lateral growth of collagen II fibrils, as has been previously described for collagen I fibrils. Since the initial fibril assembly in the PCM serves the basis for the growth of T/IT-ECM [5], we also observed significant fibril thickening and modulus reduction in the T/IT ECM, despite the low concentration of collagen III. Notably, since the PCM plays key roles in mediating chondrocyte mechanotransduction [16], collagen III could also potentially regulate chondrocyte activities by influencing the PCM. We therefore propose a more comprehensive description of cartilage collagen fibrils to be a heterotypic fibrillar network of collagen II/III/IX/XI.

For articular cartilage, for the first time, we report that tissue modulus is negatively correlated with collagen cross-link density, as a result of genetic mutation. This finding may seem counter-intuitive, but it emphasizes the fact that mechanical properties are an integrated manifestation of both molecular composition and hierarchical structure [17]. While collagen cross-linking is crucial for the assembly and stability of collagen fibrils, tissue mechanical properties also largely depend on other factors such as fibril organization, packing and collagen-proteoglycan interactions. Here, loss of collagen III leads to increased cross-linking, but at the same time, disrupted collagen fibril nanostructure. With regards to the net impact of collagen III deficiency on tissue modulus, our results thus suggest that these structural defects outweigh the effect of increased cross-links. Interestingly, such observation is consistent with previous observations in fibromodulin-null tendon [18]. Therefore, for cartilage, perhaps other connective tissues such as tendon, while collagen cross-link density is an important determinant of tissue integrity, it cannot serve as a direct predictor for tissue biomechanical properties.

INTRODUCTION

Traumatic brain injury (TBI) is a common health problem across the world; approximately 1.7 million emergency department visits, hospitalizations, and deaths occurred per year due to TBI from 2002 to 2006 [1]. Forms of TBI can occur as a direct result of rapid mechanical deformation of brain tissue, potentially leading to diffuse axonal injury. The purpose of this study is to use tagged magnetic resonance imaging (MRI) to quantify how the brain deformation response differs in response to mild axial and sagittal loading of the skull. Such data is important for determining brain regions that are most vulnerable to injury, as well as for validating computational models of TBI.

METHODS

One healthy volunteer (male, 31 years of age at the time of the first scan) was evaluated under a protocol approved by the Institutional Review Board at the National Institutes of Health to measure brain deformation during a mild acceleration in the axial and sagittal planes. Two devices were constructed to create reproducible loading in each of the planes [2,3]. Acceleration in the axial plane was generated when the device shaft impacted a rigid stop after the subject rotated his head approximately 32 degrees towards the left shoulder; acceleration in the sagittal plane was generated when the head cradle impacted a rigid stop after a neck extension of ~5 degrees. Angular velocity and acceleration of the device shaft were measured using an angular position sensor (MICRONOR, USA).

MRI scans were performed using a 3 T Biograph mMR (Siemens, Erlangen, Germany). For acceleration in the axial plane, a series of 12 axial slices (tag lines along the left-right and anterior-posterior axes) and 6 orthogonal slices (30 degree rotation between slices with tag lines along the inferior-superior axis) were acquired. For acceleration in the sagittal plane, a series of 13 sagittal slices (tag lines along the anterior-

posterior and inferior-superior axes) and 13 axial slices (tag lines along the left-right axis) were acquired. Acquisition parameters were: temporal resolution = 18.06 ms, tag spacing = 8 mm, voxel resolution = 1.5 x 1.5 x 8 mm, slice thickness = 8 mm with a 2 mm gap between parallel slices, four repetitions per slice. The subject repeated the motion 120 times for the axial loading and 156 times for the sagittal loading. Displacement relative to the skull (\mathbf{u}) and Lagrangian strain (\mathbf{E}) were computed using the harmonic phase finite element (HARP-FE) method [4]. Eigenvalues and eigenvectors were estimated from \mathbf{E} . The first principal strain (E_1) was used in this analysis. Volume fraction, which is the number of voxels above a threshold value divided by the total number of voxels, was computed for a strain threshold of 3 percent.

Additional scans were acquired to relate measurements of brain deformation to brain anatomy and axonal structure. MPAGE (1x1x1 mm), T2 (0.98x0.98x1 mm), and 39 diffusion weighted images (2x2x2 mm, b = 1000 s/mm²) were acquired. The MPAGE was segmented into different brain regions [5]. Diffusion tensors were estimated from the diffusion weighted images using TORTOISE software package [6]. Eigenvalues and eigenvectors were computed from the diffusion tensors, and fractional anisotropy was calculated. In regions labeled as white matter via segmentation and with fractional anisotropy values greater than 0.2, the first principal eigenvector (\mathbf{n}) was used to infer white matter fiber orientation. Strain along white matter fibers (E_f) was computed; only positive E_f values (stretch) were analyzed.

$$E_f = \mathbf{n} \cdot \mathbf{E} \cdot \mathbf{n} \quad (1)$$

RESULTS

Average peak angular velocity and acceleration were 3.7 rad/s and -230.6 rad/s² for axial loading and 2.0 rad/s and -346.6 rad/s² for sagittal loading. Figure 1 shows the distribution of E_1 and relative displacement as a function of time and in various brain regions. The zero-point on the

time axis was set to be the time of peak angular velocity. Both relative displacement and E_1 values increased to their largest values at 24-28 ms after peak angular velocity and then decayed. The regions of high relative displacement and strain differed between the two loading conditions, though the median values of both measurements were similar – 0.41 mm and 2.4 percent for axial loading versus 0.50 mm and 1.8 percent for sagittal loading. Maximum values (99th percentile of the distribution) were larger under acceleration in the axial plane (1.84 mm and 7.5 percent) than the sagittal plane (1.19 mm and 5.1 percent).

Figure 1: The top row shows the distribution of E_1 and relative displacement versus time during acceleration in the axial (blue) and sagittal (red) plane. The bottom row shows the distribution at peak deformation in cerebral gray matter (GM), cerebral white matter (WM), cerebellar gray matter (cGM), cerebellar white matter (cWM), and the brainstem. Vertical lines show the distribution from the 1st to 99th percentile; the circle and square indicate the median of the distribution. For the axial acceleration, the image used as the reference was acquired just prior to the time of peak angular velocity.

Figure 2 shows the distribution E_f as a function of time and images at the time of peak deformation. The median and maximum (99th percentile) E_f values were similar during acceleration in the axial and sagittal planes – 0.2 and 4.4 versus 0.2 and 3.9 percent. For acceleration in the sagittal plane, E_f values were largest in the brainstem and cerebellar white matter, whereas they were largest in the corpus callosum for axial loading.

At peak deformation, the volume of brain with E_1 exceeding 3 percent was almost 3 times larger in axial loading versus sagittal loading – 32.8 versus 11.3 percent. However, when only the brainstem and cerebellum are considered, the volume fraction is almost twice as large for sagittal loading compared to axial loading – 18.2 versus 9.8 percent.

DISCUSSION

This study provides high resolution 3D displacement and deformation measurements over time in a healthy volunteer in response to mild acceleration in the axial and sagittal planes. This work extends to 3D previously published work [e.g., 2-3]. Additionally, these results provide the first in vivo measurements of fiber stretch in the live human brain. The results show that regions of high strain (both E_1 and E_f) and relative displacements vary under different loading conditions, with acceleration in the axial plane leading to increased cortical strains, and

acceleration in the sagittal plane yielding increased strains in the brainstem and cerebellum. These results can be compared to subject-specific computational models of TBI.

Figure 2: The top row shows the distribution of positive fiber strain (E_f) as a function of time. The vertical lines show the span of the distribution from the 1st to 99th percentile. The circle and square indicates the location of the median value for accelerative loading in the axial and sagittal planes, respectively. The bottom two rows contain images of E_f mapped to 3D ellipsoids that show the direction and orientation of the diffusion tensor.

INTRODUCTION

Single-season changes in brain imaging and cognitive function have been associated with head impact exposure (HIE) metrics in contact sport athletes, but the effect of HIE on white matter alterations over multiple seasons is not well understood [1-3]. Additionally, continued research is still needed in athletes ≤ 18 years old because athletes at this age are undergoing structural brain growth and development of memory, problem solving, and other cognitive skills [4]. Therefore, the objective of this study was to characterize changes in HIE across multiple seasons and determine whether changes in HIE correlate with changes in imaging metrics over two consecutive seasons among youth football players.

METHODS

On-field head impact data were collected among youth football athletes between 2012 and 2017 using the Head Impact Telemetry (HIT) System for all practices and games. Study participants also completed a pre- and post-season MRI protocol, including diffusion tensor imaging (DTI). Athletes that only participated in the study for a single season were excluded from the present analysis and only returning athletes with at least two consecutive seasons of data were included. HIE was quantified in terms of number of impacts, peak linear and rotational head acceleration, and risk-weighted cumulative exposure (RWE) [5, 6]. The change in HIE metrics between consecutive seasons was also computed for each athlete. HIE was evaluated overall and stratified by session type (i.e. practices and games). ANCOVA was used to evaluate HIE variation by season (i.e. season number 1, 2, and 3)

while controlling for repeated measures across seasons. Team was used as a covariate.

DTI scalar metrics, including Fractional Anisotropy (FA), Mean Diffusivity (MD), and shape anisotropy coefficients (linear anisotropy, C_L ; planar anisotropy, C_P ; and spherical anisotropy, C_S) were evaluated. A control group of 16 non-contact sport athletes were used to determine the total number of abnormal white matter voxels, defined as 2 standard deviations above or below the control group mean. The difference in the number of abnormal voxels between Season 1 and Season 2 was computed for each scalar metric and subject for regression analyses (Δ DTI scalar metrics: $\Delta FA_{\text{voxels}}$, $\Delta MD_{\text{voxels}}$, $\Delta C_{L-\text{voxels}}$, $\Delta C_{P-\text{voxels}}$, and $\Delta C_{S-\text{voxels}}$). The differences in DTI scalar metrics from Season 2 to Season 3 were not computed due to the small sample size ($N=6$). Linear regression analyses were performed to evaluate the relationships between changes in HIE metrics and changes in DTI scalar metrics between Season 1 and Season 2. The linear models were also adjusted for the covariates of average age between Season 1 and Season 2 preseason scans and the difference in pre- to post-season scan times between the two seasons.

RESULTS

Among the returning athletes, 33 athletes had 2 years of data, 13 athletes had 3 years of data, and 1 athlete had 4 years of data. This resulted in 109 athlete-seasons of head impact exposure data among the 47 individual returning athletes. Athletes included in the present study ranged in age from 9-13 years old. 19 of the 47 athletes had usable imaging data and HIE for two consecutive seasons.

A total of 41,148 head impacts were collected. The change in HIE measures varied among returning athletes, with some athletes experiencing increases in HIE and other athletes experiencing decreases in HIE from one season to the next. Among all returning athletes, there were no significant differences (all $p > 0.05$) in HIE metrics among season number.

There were athletes with increases in the number of abnormal voxels, while others had decreases from Season 1 to Season 2. The

change in total number of practice impacts demonstrated a significant positive association with all Δ DTI scalar metrics (Table 1). The change in 50th percentile impacts per practice and change in 50th percentile impacts per session were also significantly positively correlated with Δ FA_{voxels}, Δ CL_{voxels}, Δ CP_{voxels}, and Δ CS_{voxels}. Examples of the positive linear relationship between change in the number and frequency of practice impacts and Δ DTI scalar metrics are shown in Figure 1.

Table 1. Summary of linear regression analyses results between Δ HIE metrics (predictor) and Δ DTI scalar metrics (outcome) controlling for average age and the difference in time between scans between Season 1 and Season 2.

DISCUSSION

This longitudinal study evaluated changes in HIE metrics and the relationship between changes in HIE and changes in neuroimaging measures among a cohort of youth football athletes. The results demonstrate that HIE can increase or decrease between seasons among individual youth football athletes and that there were no significant changes in HIE from one season to the next in this cohort. There were both increases and decreases in the number of abnormal DTI voxels from Season 1 to Season 2 and those changes were significantly positively correlated with changes in the number of practice impacts, 50th percentile number of impacts per practice, and 50th percentile number of impacts per session. While prior studies have shown single-season associations between

HIE metrics and neuroimaging measures, this study suggests reduction in the number and frequency of head impacts, especially in practice, may reduce the number of abnormal imaging findings from one season to the next in youth football. The results from this study support continued efforts to reduce HIE in practice. Additionally, the study findings warrant future investigations into the long-term relationship between HIE and neuroimaging findings to better understand how reduction in subconcussive HIE may affect the brain over many years of participation in football.

INTRODUCTION

Computational modeling has become an important tool for studying the biomechanics of traumatic brain injury. Model accuracy depends on the adequate characterization of brain materials as well as surrounding bone and soft tissue [1]. Numerous studies have characterized the material properties of cortical grey and white matter, but few efforts have focused on the pia-arachnoid complex (PAC), which connects the brain to the skull and plays a role in constraining brain deformation during injury. In this study, we image the human pia-arachnoid complex via optical coherence tomography (OCT) and conduct *in situ* mechanical testing of the PAC through fluid pressurization of the subarachnoid space.

METHODS

Studies were reviewed by the University of Utah Institutional Review Board and determined to be exempt from human study regulation. Fresh-frozen human cadaver heads (male, ages 50-86 years old, n=7) were defrosted and allowed to reach room temperature. A large craniotomy was performed on each hemisphere of the skull using an autopsy saw. Dura between the sagittal sinus and temple region was removed, exposing the PAC. Heads were placed in a stereotactic frame for OCT imaging with a BiopTigen R2200 spectral OCT scanner (Leica USA) and a 12mm telecentric lens. Scan volume was 5mm x 5mm x 1.64mm with 800A-scans per B-scan, 400 B-scans, and a single C-scan. The axial resolution of the system was 1.6 μ m, the lateral resolution was 6.25 μ m, and depth resolution was 12.5 μ m.

In each imaging location, a 27-gauge needle was inserted through the arachnoid membrane to inflate the subarachnoid space to physiological intracranial pressure (10 \pm 1.5mmHg). This was achieved using a custom system consisting of a Pendotech pressure monitor (model 1-06-64-04-2) and syringe pump (NE-300 New Era Pump

Systems). Feedback control was provided by an Arduino Uno (Arduino AD) and MATLAB (Mathworks) program. Once the pressure had reached steady state, a volumetric scan was taken. The pressure was then increased to 20mmHg. During this inflation, a video recording of two planar B-scans was recorded using screen capture software. A second volumetric scan was obtained once subarachnoid pressure

Figure 1: A: Positioning of OCT lens and pressurization system in brain. B: Schematic of the pressurization system. C: Example of a 3D volumetric scan via OCT.

Figure 2: A: OCT image of arachnoid membrane and trabeculae. B: Segmented arachnoid trabeculae.

reached steady state. This process was repeated as the subarachnoid pressure was raised to 30mmHg. Between 8 and 12 locations were imaged for each hemisphere of each brain. Each hemisphere was subdivided into a 2x3 grid to classify regions as frontal, parietal, or occipital and as inferior or superior for a total of 12 regions per brain.

To quantify the density of trabecular fibers, three 2D slices were selected from each 3D volumetric stack. Images were masked and trabecular fibers segmented using a custom semi-automatic technique. Trabecular volume fraction (VF) was calculated by taking the ratio of segmented pixels to total pixels below the arachnoid membrane (Fig. 2). Traction stiffness of the PAC was measured in three of the seven brains. For these measurements, OCT B-scan videos captured the distance between the arachnoid membrane and cortical surface. A custom video analysis script tracked the displacement of the membrane throughout the inflation process. Displacement data were synchronized with pressure data and converted to stress and strain. Stress was defined as the measured pressure. Strain was defined as the displacement of the arachnoid membrane relative to the original segmented height. The average number of subarachnoid vessels at each location was also extracted. One-way ANOVAs with matched pairs were used to quantify regional dependencies of VF and elastic modulus. A two-way ANOVA was used to evaluate age and regional effects of modulus. A multiple regression evaluated the effect of VF and average vessel number on predictions of PAC stiffness.

RESULTS

Trabecular volume fraction, vessel count, stress, and strain were measured at 55 locations throughout the three subjects. The stress-strain response was linear in both 10-20mmHg and 20-30mmHg inflations (Fig. 3). Linear regression was used to quantify elastic moduli E_1 for 10-20mmHg tests and E_2 for 20-30mmHg tests. E_2 was significantly greater than E_1 ($p < 0.0001$).

VF significantly decreased from anterior to posterior regions of the brain ($p = 0.029$), while elastic modulus E_2 significantly increased from anterior to posterior regions of the brain ($p = 0.03$, Fig. 4). E_2 was significantly reduced in donors ≥ 60 years of age ($p = 0.02$). No significant trends were observed for E_1 . Multiple regression analysis indicated a significant interaction effect between the number of subarachnoid vessels and volume fraction when predicting elastic modulus ($p = 0.018$).

DISCUSSION

Mechanical testing of human cadaver PAC via fluid pressurization revealed a linear elastic material response. This finding matches results from an *ex vivo* test of bovine PAC in traction, and computational estimates of porcine PAC stiffness [2,3]. The overall average measured modulus of 11.7 kPa is comparable to the 61-148 kPa reported for

Figure 3: Stress-strain plots from 20-30 mmHg tests in superior frontal regions.

Figure 4: Regional analysis of VF (blue) and E_2 (green) in anterior-posterior groups.

bovine PAC by Jin et al. [2]. Variances between the values likely stem from species, age, and postmortem differences.

VF alone and vessel count alone did not correlate to PAC stiffness. Instead the interaction of both effects was significantly predictive of E_2 , which suggests that both arachnoid trabeculae and subarachnoid vasculature dictate the local stiffness of the PAC, and that understanding the interplay between the two may be critical for improved predictions of brain/skull displacement. Further quantification of vessel size in addition to the number of vessels may shed light on these connections.

One interesting finding was a significant decrease in PAC stiffness with age in brains from donors >60 years without a corresponding change in VF or vessel number. This suggests a natural degradation of the structures and warrants further investigation into the age-dependent properties of the PAC. One limitation of the study is the unknown effect of freezing and thawing on PAC material properties. This will be investigated in a future study. This study demonstrates the first known method of *in situ* imaging and material characterization of the human PAC. Results highlight the mechanical complexity of the subarachnoid space and suggest that the development of heterogeneous material models may aid in the improvement of computational models of TBI.

INTRODUCTION

In brain tissue it is understood that change in shear modulus can be related to pathology or intrinsic abnormalities (1). In the case of meningiomas, which account for up to 30% of all primary intracranial tumors, mechanical characterization ahead of surgery is crucial for surgical planning (2). Meningiomas are primarily treated by surgical resection. Two important determinants for complete resection include degree of firmness and adhesiveness to the surrounding healthy brain tissue (3). Recently, with magnetic resonance elastography (MRE), a novel non-invasive imaging technique, these two tumor characteristics can be addressed preoperatively (4, 5, 6). Especially, with the slip interface imaging technique, meningioma-brain interface adhesiveness can be quantified (7,8). In this study, we performed a broadband mechanical characterization protocol for meningioma through multi-frequency MRE. Multi-frequency MRE data has been transformed into frequency-independent domain through standard linear solid (SLS) model fitting by using the global mean storage and loss modulus values under three different actuation frequencies of meningioma and normal brain regions. The purpose of this is to create a consensus among neurosurgeons. Furthermore, we applied a phased-based video amplification technique on meningioma patients' data collected by cardiac gated balanced steady-state free precession (bSSFP) sequence which utilizes the heart as an intrinsic actuator (9).

Through the acquired phase offset time frames, tracking the relative motion of meningioma with respect to the surrounding healthy brain tissue boundary is targeted.

METHODS

Imaging Protocol

Institutional review board approval was obtained from the Mount Sinai Hospital IRB. Nine meningioma patients aged between 35-68 (3 Female & 6 Male) underwent MRI scans in which a 3T whole-body GE MR750 Discovery MRI system (GE Healthcare, Milwaukee, WI) is used. MRE data is acquired for 48 slices via multi-slice spin echo EPI pulse sequence in the axial plane (acquisition matrix: 128×128, TE/TR=60/2000, FOV=24, 8 phases). As an MRE actuator, a head pillow (Mayo Clinic) is used under actuation frequencies of 40, 60, and 80 Hz. 3D Direct Inversion is used to obtain elastograms. Through the bSSFP sequence a short cine MRI movie capturing the meningioma regions' movement with respect to surrounding healthy brain tissue over different phases of cardiac cycle is created. Each captured frame of the cine MRI scan contains a 2D acquisition matrix of 512×512 for 24 sagittal slices of the brain except one patient having 14 sagittal slices. For each sagittal slice, 84 different phase offset is captured during a cardiac cycle. Amplification of the cine MRI dataset is done by using a bandwidth having a lower cutoff frequency of 0.01 Hz and a higher cutoff frequency of 3.0 Hz with an amplification factor of 20 (9).

Neurosurgeon grading

The neurosurgeons were asked to fill out a survey to provide information about the meningioma consistency (Extremely soft:0 - Extremely firm:10), tumor vascularity (Avascular stage:0 - Metastatic Stage:10), brain-tumor interface, (Smooth, Lobular, Fingerlike expansion, Invasive), and the extent of normal tissue preservation after meningioma resection (Poor:0 - Excellent: 10).

Figure 1: MRE acquisition under three actuation frequency for normal brain tissue vs. meningioma.

Pathology grading

Tumor specimens were excised and evaluated by an experienced neuropathologist at the Icahn School of Medicine at Mount Sinai, New York, NY. A trichrome stain was used to evaluate extent of collagen within the tumor (1=focal - 3=diffuse) and the level of cellularity was classified as low, moderate, or high (Figure 2).

Figure 2: Pathology grading through trichrome staining. A) Score +1, B) Score +2.5, C) Score +3.

Relative Motion Tracking

On a single sagittal slice, with the *imfreehand* command in MATLAB, meningioma boundary and the nearby brain-meningioma interface boundary were manually drawn to create binary masks. This was followed by the use of minimum eigenvalue detection algorithm from MATLAB computer vision toolbox to tag traceable corner points inside these binary mask regions (Figure 3).

Figure 3: Relative motion tracking between meningioma and the surrounding healthy brain interface boundary region. A) Original image. B) Meningioma region. C) Interface boundary region. D)

Manually selected boundaries. E) Traceable tagged points inside the rectangular regions generated by the minimum eigenvalue detection algorithm. F) Traceable tagged points inside the masked rectangular regions.

RESULTS

Stiffness maps were acquired for each actuation frequency and meningioma volumes were separated from normal brain tissue. This was followed by obtaining the average stiffness ($|G|$), storage (G') and loss (G'') values for meningioma and normal brain tissue (Figure 1). Steady state stiffness (μ_1) and the viscosity (η) were obtained for each patient (Figure 4).

Figure 4: Standard linear solid (SLS) material model fitting for meningioma and normal brain tissue.

A thorough examination of the link between aMRI relative displacement and neurosurgeon's resection assessment is pending. However, if we consider Patient 7 (Figure 3), the neurosurgeon assessment revealed a well-preserved arachnoid region after resection (Score=7), implying a loose connection. Our aMRI tracking results with an amplification factor of 20 demonstrate that for this patient, the maximum relative motion between the tumor and the brain is on the order of several pixels.

DISCUSSION

Our study provides the first insight into the applicability of aMRI on the characterization of brain-meningioma interface. Further phantom validation studies are needed to quantify the limits of amplification for which no other sources of noise is introduced.

INTRODUCTION

Traumatic brain injury (TBI), including sports-related concussion, is a major public health problem in the United States (US) [1]. To date, much of the biomechanical work has centered on developing a scalar injury metric to describe head impact severity, based on which to further predict injury. Response-based injury metrics produced from impact simulations using finite element (FE) model of the human head are increasingly becoming important, as they can be related to tissue-level injury tolerances established from *in vivo/in vitro* experiments and clinical outcomes of TBI [2]. Studies have shown that model-estimated tissue response metrics are more effective in injury prediction than using kinematics-based brain injury metrics alone [3], [4].

An FE model of the human head provides unparalleled rich information about the state of brain mechanical responses such as strain. However, the most widely used responses from head impact simulation are either the peak maximum principal strain of the entire brain regardless of the incidence location, or the percentage of brain volume experiencing strains above a certain predefined threshold (i.e., cumulative strain damage measure; CSDM) [5]. These scalar measures treat the entire brain as a single unit. They do not and cannot inform the location or distribution of brain strains, even though such information is likely critical for studying mTBI, given the widespread neuroimaging alterations and a diverse spectrum of clinical signs and symptoms.

To account for this inherent limitation with scalar injury metrics, here we established a structural network-based “response feature matrix” to characterize brain response magnitude and distribution in both gray matter (GM) regions of interest (ROIs) and their white matter (WM) interconnections. The resulting features enabled a machine learning approach to perform a feature-based concussion classification. Three real-world injury datasets were employed to test and compare the

injury prediction performance against other commonly used injury metrics using univariate logistic regression.

METHODS

We used the recently upgraded anisotropic version of the Worcester Head Injury Model (WHIM [6]) to simulate head impacts in this study. Head impacts were drawn from three injury datasets. Two reconstructed impacts were the reanalyzed NFL head impacts (N=53, 20 concussions and 33 non-injuries [7]) and reconstructed head impacts from Virginia Polytechnic Institute (VT; N=55, 11 concussions and 44 non-injuries [8]). In addition, measured head impacts using mouthguards from Stanford University were also employed (SF; N=110, 2 concussions and 108 non-injuries [9]).

A brain structural network describes the anatomical connections linking a set of neural processing units, generally, cortical and subcortical ROIs [10]. Here, we employed the LONI Probabilistic Brain Atlas (LPBA40 [11]) to identify 54 cortical GM ROIs. They were used as seeding nodes to construct a brain structural network. Interregional connections between each pair of GM ROIs were identified by testing each WM fiber (obtained from the whole-brain tractography) whether it traversed the two GM ROIs under scrutiny. A global density-based thresholding was applied to the resulting connectivity matrix [12] to retain the top strongest links while removing weaker and spurious interconnections. The resulting binarized connectivity matrix was used to encode strain responses. For network nodes or GM ROIs, we choose to use the 95th percentile peak maximum principal strain to encode their responses. For network edges, injury susceptibility at a threshold level of 0.09 [13] based on WM fiber strains was used for encoding.

The utility of the network-based metric for injury prediction was illustrated using the two reconstructed injury datasets to measure “in-sample” injury prediction performance *via* leave-one-out cross-validation (LOOV). Support Vector Machine (SVM) was used as a

feature-based injury prediction method to maximize accuracy using a sequential forward feature selection (SFFS) method. The accuracy was compared with that from a single feature (i.e., a non-zero element in the matrix) and kinematics-based metrics *via* univariate logistic regression.

It was important to evaluate the performance of an injury predictor using impacts that have not been used in training for an objective comparison. Therefore, we re-trained each injury predictor using all of the samples in each of the two reconstructed impact datasets. They were then used to predict injury using impacts from the other reconstructed dataset as well as the Stanford dataset.

RESULTS

Fig. 1a shows the resulting binarized symmetric/unidirectional connectivity or adjacency matrix (1046 non-zero edges with an average of 79 ± 184 ROI-wise fiber connections; **Fig. 1a**). A global density-based threshold (of 0.18) led to the smallest adjacency matrix without leading to an isolated node (258 unique non-zero edges with an average of 153 ± 241 fiber connections; **Fig. 1bc**).

Fig. 2 illustrates the response feature matrices for two representative impacts drawn from each of the three injury datasets. The response feature matrices captured much richer information about the brain response state than, e.g., peak maximum principal strain.

Figure 1: Binarized adjacency matrix (a) before and (b) after a global density-based thresholding to generate the smallest network and fewest edges without leading to an isolated node. (c) Nonzero edges are encoded by the corresponding number of WM connecting fibers between each WM ROI pairs (capped to 200 to improve visualization).

Figure 2: Representative response feature matrices that encode peak maximum principal strains (node) and injury susceptibilities of the interconnecting WM fibers (edges) for a pair of head impacts for the NFL (a: concussed b: no injury), VT (c: concussed; d: no injury), and Stanford dataset (e: loss of consciousness; f: self-reported concussion), respectively.

Cross-validation performances for the two reconstructed NFL and

VT datasets are shown in **Table 1**. SVM always achieved the best accuracy as that was how it was trained. The SFFS method identified two network nodes/GM ROIs (inferior temporal gyrus left and inferior temporal gyrus right) as the most injury discriminative features for the NFL dataset. For the VT dataset, two edges/WM interconnections were identified (interconnections of inferior frontal gyrus left and middle frontal gyrus left, superior frontal gyrus left and precuneus left).

Table 1 further reports the out-of-sample injury prediction accuracy when using the same predictors re-trained on the entire NFL (VT) dataset while predicting injury occurrences for impacts in the VT (NFL) and SF datasets. Best performers were mostly the kinematic variables. However, none of the classifiers universally achieved the best out-of-sample accuracies across all of the three injury datasets.

Table 1: Summary of in-sample cross-validation accuracy (LOOV) using the reconstructed NFL and VT datasets. Out-of-sample prediction accuracies are also reported using NFL-trained predictors (NFL-trained) applied to the VT and SF datasets, and those using VT-trained predictors (VT-trained) applied to the NFL and SF datasets.

	dataset	SVM	Best single feature	a_{lin}	a_{rot}	v_{rot}
LOOV	NFL	0.887	0.849	0.755	0.849	0.793
	VT	0.891	0.891	0.873	0.836	0.782
NFL-trained	VT	0.818	0.836	0.800	0.873	0.818
	SF	0.873	0.746	0.918	0.818	0.936
VT-trained	NFL	0.642	0.736	0.755	0.830	0.774
	SF	0.846	0.646	0.927	0.736	0.855

DISCUSSION

The network-based brain injury metric is a compact matrix form to represent brain strain responses of important GM ROIs and their WM interconnections. A scalar metric, such as maximum principal strain of the whole brain or CSDM, is conceptually analogous to a degenerated network with only one node but no edges. Therefore, the network-based injury metric or response feature matrix extends previous scalar metrics by providing more complete information about the brain strain response state. Our performance comparisons suggested that a feature-based injury predictor *via* machine learning always outperformed others when assessed within the training samples. However, the accuracy of out-of-sample predictions depended not only on the injury predictor itself, but also on both the training and testing datasets as well. A universal “best-performer” across different datasets for out-of-sample predictions did not seem to exist based on the datasets evaluated here.

INTRODUCTION

Chiari malformation type I (CMI) is a neurological syndrome classified as the elongation of the cerebellar tonsils five millimeters below the foramen magnum. Patients with CMI experience symptoms including occipital headaches, neck pain, and cognitive/neurological deficits [1-3]. In addition to altered brain morphology, CMI patients demonstrate increased tissue motion [4-6], which may be the underlying cause of CMI symptoms due to repeated compression of the cerebellum, brainstem, and upper cervical cord.

Patients may be treated with posterior fossa decompression (PFD) surgery. The primary goal of this procedure is to relieve brainstem compression by altering craniocervical morphology. Eighty-four percent of patients have reported improvement in quality of life after being treated with PFD surgery [7]; however, improvement is not consistent across all symptoms or all subjects [8]. Additionally, selection of PFD candidates is primarily determined based on subjective symptomatology [8]. A quantitative assessment of brain tissue motion following PFD surgery may improve candidate selection for PFD surgery.

Brain tissue motion and strain has been previously quantified before and after PFD surgery using a select number of anatomical landmarks within the cerebellum and brainstem [6]. However, tissue motion over the entirety of brain structures has yet to be quantified before and after surgery. We have previously utilized displacement encoding with stimulated echoes (DENSE) MR images to quantify brain tissue displacement in healthy individuals [9]. Within the current study, we quantified changes in brain tissue displacement and strain that occur due to surgery. We hypothesize that CMI patients will demonstrate a significant reduction in brain tissue motion and strain within the craniocervical region following PFD surgery.

METHODS

DENSE MR images before and after PFD surgery were acquired for 12 CMI patients (10 females, age 38 ± 9) in a study approved by the institutional review board. CMI patients were identified from a previous clinical imaging study based on common CMI diagnostic criteria: greater than 5 mm tonsillar descent below the foramen magnum, and the presence of CMI symptoms. All patients were referred by a single neurosurgeon (DB). Cardiac-gated, spiral cine DENSE sequences were evaluated at the mid-sagittal plane on a 3T MRI scanner (Siemens Prisma, Erlangen Germany). Acquisition parameters included: two directions of in-plane motion encoding, an encoding frequency of 0.6 cycles/mm, two spiral interleaves per heartbeat, pixel size of 1.2×1.2 mm², slice thickness of 7 mm, four signal averages, and 16-27 frames over the cardiac cycle, depending on the heart rate.

A program developed in MATLAB (Mathworks, Natick, MA) was used to quantify tissue motion using DENSE phase images in two soft tissue structures: the cerebellum and brainstem (see Fig.1). These regions of interest (ROIs) were manually identified by a single observer (ME) using midsagittal DENSE magnitude images before and after PFD surgery. The peak tissue displacement and principle strain were identified on a pixel-by-pixel basis over the cardiac cycle using 2D displacement maps obtained from DENSE phase images. These maps were used to quantify principle Lagrangian Green strains for the cerebellum and brainstem as described previously [9]. Displacement maps acquired during the first two-thirds of the cardiac cycle were used for displacement and strain calculations due to a reduction signal-to-noise ratio at the end of the MRI sequence [10]. Spatially averaged values for each ROI were calculated to quantify significant changes in mean peak displacement (MPD) and mean peak principle strain in the cerebellum and brainstem.

Figure 1: High-resolution T2-weighted images (A) before and (D) after surgery, and peak magnitude displacement maps of one participant before and after surgery. (B & E) Brainstem displacement maps and (C & F) cerebellar displacement maps.

To isolate regions of brain tissue demonstrating large amounts of displacement, pixels with displacement values larger than a patient's MPD were spatially averaged and compared before and after surgery. Paired t-tests were used to evaluate changes in mean peak displacement and strain post-surgery. Statistical significance was evaluated as $p < 0.05$. The Chicago Chiari Outcome Scale (CCOS) was used to assess the surgical outcome of ten out of the twelve investigated patients [11]. The CCOS evaluates post-surgical changes in four different categories: pain, non-pain symptoms, functionality, and complications. Each category is scored between 1 and 4 with 16 as the largest possible score. Pearson correlation coefficients were calculated to determine the relationship between mean peak tissue displacement and strain before and after surgery with CCOS scores.

RESULTS

Figure 1 shows changes in peak displacement maps in the cerebellum and brainstem following PFD surgery. Figure 2 shows displacement in smaller regions of tissue within the brainstem (left) and cerebellum (right) before and after surgery.

Cerebellar MPD in the superior-inferior (SI) and anterior-posterior (AP) direction significantly decreased by 34% and 46% following surgery ($-51.9 \pm 44.2 \mu\text{m}$, $p = 0.002$ and $-28.0 \pm 22.5 \mu\text{m}$, $p = 0.001$, respectively). Brainstem MPD in the SI direction significantly reduced by 24% following surgery ($-52.0 \pm 64.9 \mu\text{m}$, $p = 0.02$). However, AP brainstem MPD did not significantly change after surgery ($-10.5 \pm 21.0 \mu\text{m}$, $p = 0.13$). After quantifying displacement in smaller regions of tissue with large motion, SI and AP cerebellar displacement demonstrated a significant reduction of 45% and 56% following surgery ($-103 \pm 62.7 \mu\text{m}$, $p < 0.001$ and $59.4 \pm 39.0 \mu\text{m}$, $p < 0.001$, respectively). Like brainstem MPD, smaller regions within the brainstem showed a 29% reduction in the SI direction after surgery ($-75.8 \pm 75.8 \mu\text{m}$, $p = 0.008$) and 14% in the AP direction ($-17.0 \pm 35.2 \mu\text{m}$, $p = 0.11$).

Additionally, the mean peak cerebellar compression and extension principle strains significantly decreased by 21% and 28% following surgery ($-0.16 \pm 0.18\%$, $p = 0.005$ and $-0.18 \pm 0.25\%$, $p = 0.03$, respectively). However, the mean peak compression and extension principle strains within the brainstem did not significantly change after surgery ($-0.005 \pm 0.13\%$, $p = 0.89$ and $-0.06 \pm 0.14\%$, $p = 0.19$, respectively). When comparing brain tissue *in vivo* deformation with surgical outcome, a significant positive correlation was found between cerebellar MPD in the SI direction before surgery with CCOS scores ($r = 0.69$, $p = 0.03$). Brainstem MPD in the SI direction before surgery was also significantly correlated with CCOS scores ($r = 0.66$, $p = 0.04$).

Figure 2: Changes in displacement in small regions of the brainstem (left) and cerebellum (right) before and after surgery (N = 12). Error bars represent standard deviations. * $p < 0.05$.

No significant correlations were found between mean peak soft tissue compression or extension strain with CCOS scores.

DISCUSSION

In this study, we evaluated how PFD surgery changes cerebellar and brain tissue displacement and strains using spiral DENSE MR images in 12 CMI patients before and after surgery. From this evaluation, we found a significant reduction in cardiac induced displacement (45-56%) and principle strain (21-28%) primarily within the most inferior portions of the cerebellum following PFD surgery. We also found a significant reduction in brainstem tissue displacement (29%) in the SI direction. Previously reported cerebellar tonsillar motion demonstrated a greater decrease in tonsillar displacement in the SI direction ($-480 \mu\text{m}$, -45% , $p < 0.001$) and in the AP direction ($-340 \mu\text{m}$, -48% , $p < 0.001$) [6]. Results of this same study showed a large reduction of tissue motion at the inferior portion of the spinal cord (cervicomedullary junction) in the SI ($-100 \mu\text{m}$, 17%) and AP direction ($-60 \mu\text{m}$, 14%) [6]. Additionally, Leung et al showed larger reductions in cerebellar strain (33%) following surgery. These discrepancies may be a result of using different MRI modalities and the use of single anatomical locations to quantify displacement and strain within brain tissue [6]. To address such limitations, we evaluated quantities for regions of the brain as compared to single anatomical locations.

In summary, we proved that cerebellar and brainstem tissue motion and strains within the craniocervical region reduced following surgery. Additionally, we were able to find a relationship between brain tissue mechanics and PFD surgical outcome. Our results suggest that patients with larger SI cerebellar and brainstem displacement prior to surgery may benefit from PFD surgical treatment. Such a correlation demonstrates the utility of brain tissue deformation measurements obtained from DENSE MR images to help identify which patients would benefit from surgery, and thus improve PFD selection criteria.

INTRODUCTION

There are an estimated 800,000 stroke patients in the United States every year, and a “loss of protective, proprioceptive, and touch sensation” occurs in up to 65% of patients [1]. The large number of stroke patients and relative lack of individualized therapy devices or specialists begs the question of how to effectively and consistently engage patients in therapy. Proprioceptive training sessions of one hour, spread over the course of fifteen sessions, showed that each patient “improved muscle contraction in one or more muscles” and “in 4 out of 6 patients the full range of voluntary active movement emerged after therapy” [2]. Vibrational therapy is a highly promising treatment for re-establishing neuronal connections to afflicted limbs, which is needed prior to beginning movement based physical therapy.

Of the very few available vibrational therapy devices, accessibility is inhibited through either cost or ease of use. Stroke patients who wish to rehabilitate their proprioception in an affected hand will only have one functioning hand to operate any device. Thus, an at-home device which is easy to operate with one hand, is inexpensive, and can track progress over long treatment periods is of great need.

PRODUCT DESIGN

The device is currently in its first prototype phase, with vibration motors in temporary housing and wired to DC power sources to undergo testing as seen in Figure 3. The final design is to include five vibration motors, each in a pulse oximeter finger clip, and wired to an Arduino microcontroller housing. All aspects of the circuitry such as the resistors will be stored in the housing, and the Arduino has an SD card reader attachment. The 9V output of the Arduino will power the vibration motors using an algorithm to randomly power individual motors. The Arduino will also be connected to an LCD display, which the patient will interact with. There are five buttons, one for each finger, for patient input during testing, as well as the general menu

buttons. This design has been created based on the faculty advisor Dr. Drzewiecki's

During a rehabilitation treatment, the patient will turn on the device and begin the program. The vibration motors will be randomly and individually turned on, and the patient will then enter their best estimation as to what finger was stimulated. The microcontroller will track all inputs and store the data in the SD card for analysis of total patient accuracy and individual finger accuracy. This data can then be viewed by the patient to reinforce the neuronal connections established through stimulation, or provided to a physical therapist to adjust the rehabilitation program.

BUDGET & MARKET ANALYSIS

The budget for the prototype is estimated at \$100. \$40 is budgeted towards an Arduino microcontroller along with an SD card attachment and SD cards. \$5 is for the vibration motors and \$25 is for pulse oximeter finger splints. The remaining \$30 is allocated towards wiring of the vibration motors, including resistors and breadboard, as well as the housing of the Arduino and the LCD display. Lab time and preliminary testing will not have a cost in prototype development due to Rutgers University resources being available and one stroke patient subject involved in development.

The potential market size is in the hundreds of thousands. There are an estimated 400,000 patients who have suffered a stroke for the first-time and have lost proprioceptive sensation in a limb every year. A further estimate yields 250,000 patients who would benefit from the prototype glove. At a projected \$180 sale price the revenue generated would be \$45MM. Investments into bulk production of vibration motors, molds or 3D printing finger splints, and mass production of the housing units would easily be able to easily bring the manufacturing cost down to less than \$60. A profit margin of \$120 would generate profit of \$30MM, so an investment of \$2MM would have an ROI of \$28MM.

METHODS

To validate and verify the procedures listed below, the team required specific equipment: five 12 mm diameter coin vibrator [3], five 9V power source, five 95 ohm resistors, strips of velcro, alligator clips, 25 ft of electric cable, and voltmeter/ammeter. Once collected, a temporary holding device was created to allow the team to start acquiring appreciable data. This holding consisted of a rectangular and a circular velcro strip and the 12 mm coin vibrator. (Figure 3)

Preliminary tests were used to determine at which voltage, resistance, and power the transducer would be run at for all future testing. The motor was rated for 2.7-3.3 V on the manufacturer's data sheets, after collecting data over these ranges a value of 3V was decided on. Primary tests were then conducted on Patient A's hand to determine how an injured patient would perceive the vibrational stimulation given off by the motor. The motor was attached to two of his fingers, and each was activated individually to determine if a localized region could be isolated. Three different tests were run: either one of the two transducers were activated, both the transducers were activated, or neither. Data was collected from these tests and compared from data acquired by previous iterations of designs which used a computer speaker in place of the more acute coin vibrators.

RESULTS

Figure 1: Data collected from Patient A's injured hand, with two 12 mm vibrators attached, they were randomly activated to determine if the individual finger can be localized from the vibration.

To acquire the data in figures 1 and 2 the same test was run with different vibration inducing devices. The data in figure 2 was from previous work done in the lab using a computer speaker. Patient A had the computer speakers attached via velcro to his fingertips and then a current was induced. He was then asked which of the five fingers he felt a sensation within. This test was then reproduced as a part of our study to determine the potential applicability of a coin vibrator instead. The data from figure one is from a shorter time period and smaller amount of tests but better results have already been found with these new devices. On single finger applied tests, there was a success rate of 80.65% while this number was never reached over the course of previous trials.

Figure 2: Data collected from a previous study on Patient A's hand, a computer speaker was used instead of the vibrating coin motor used above.

The two finger tests resulted, in zero success rates as there was an expectation that the patient would be able to realize two motors were on simultaneously. This proved to be difficult through testing, this will not prove to be a problem as later rehabilitation will be with only one activated motor at a given time.

DISCUSSION

These results have given us confidence in the approach we are taking and have allowed us to move on towards our new goal: applying this stimulation and then checking the patient for an improved sense of touch. Having a device that is capable of being discerned on each individual finger was the first step, now the group will move towards equipping the transducers with a clip to allow for single handed operation of the device.

The device will then be integrated into a system with a arduino component that will allow for randomized activation of the five transducers to allow for at-home individualized care. Altogether this system will potentially serve as a portable, user-specific system that can lead to patients strengthening the nerves required for touch in their fingers.

Separately, we wanted to acknowledge that tests were performed with two motors operating at the same time (figure 1) where the patient was unable to determine correctly that two motors were running. This was an issue as one of the 12 mm motors caused an overpowering vibrational feeling, but the fully functional device will only run one motor at a time where we have seen success.

Figure 3: Image of a 12mm coin vibrator in a temporary housing for acquiring preliminary data, also pictured is a 8 mm coin vibrator used in the early stages of the project to determine the appropriate motor choice.

ACKNOWLEDGEMENTS

We would like to acknowledge the Rutgers Biomedical Engineering Department for contributing to our budget as a part of our Senior Design Course and Dr. Jay Sy for guiding us through the design and innovation process.

INTRODUCTION

There are numerous types of jogging strollers that include different features at significantly different prices. However, there is not one jogging stroller attachment device currently on the market that allows the user to engage the arms in the natural, fluid arm swing motion that is exhibited while running. The user is limited to one's wrists being locked in one position for the duration of the run. Restricting the arms and hands to only holding the handle bars while running may cause the end user unwanted side effects in the wrists, discomfort, or an unsatisfactory workout. Arm swing during the human gait has been shown to be an important contribution to walking, and restricting the arms while running causes the body to make unwanted adjustments [1]. At walking speeds higher than 0.8 m/s, arm swing increases, the arms move out-of-phase, while the frequency of movement is synchronized with stride frequency, coinciding with a 1:1 frequency locking between arm and leg movements [1] [2] [3]. A study by Ford et al. [1] concluded that constraining one arm swing while walking caused the opposite arm swing to increase in order to maintain coordination between upper and lower body movement.

The objective was to produce a jogging stroller attachment device that encourages this "natural" arm motion instead of restricting it. The device followed strict design requirements: safe, portable, inexpensive (\$100 or less), easy to use, and adjustable to runners of varying heights and running styles. Prototype testing and literature reviews have proven the need for a device that prohibits the arms from being restricted while running.

PRODUCT DESIGN

The current design for the attachment involves two lever arms that attach to the bottom side bars of the stroller, which the team deemed to

be the safest attachment location by use of a Decision Matrix and a Pairwise Analysis. A telescoping clamp system allows the lever arms to retract from 3 feet to 4 feet max. Once attached to the stroller via a clamp, a cardan joint allows the lever arms to rotate along two different axes allowing any user to find the most comfortable grip for a forward-backward movement pattern.

Figure 1: Jogging Stroller Attachment Device

The design shown in Figure 1 is influenced by the movement seen from the lever arms on an elliptical machine. The user would be able to move the arms back and forward like one would if running freely. The user would be able to achieve the most natural arm swing while jogging with one's child. This sort of adaption would decrease the stresses seen at the wrist, influence proper running techniques, and minimize back problems that can occur from pushing a jogging stroller in a hunched over position.

The concept of the design was validated by building and testing a rudimentary prototype. The prototype was built using of 3/4" PVC pipes, a universal joint, a clamp, and duct tape. The prototype tests were to determine if a medical cart could be moved when using the attached prototype and was a success. To quantify and better visualize the movements associated with running with the attachment device, electromyography (EMG) data was collected. The current data is limited to:

1. Natural running (no attachment device or stroller)
2. Constrained running (only with stroller)

Further testing will include the use of the attachment device on the stroller. This will then be compared to the natural running to determine if the attachment devices actually influence natural running. Relevant literature has proved that the biceps brachialis and the deltoids are activated during free running and are found to give reliable EMG data [4]. Therefore, these were the muscle activations measured.

BUDGET & MARKET ANALYSIS

The jogging stroller attachments fall in the category of assistive devices because they assist the user in engaging the arms while running. They also provide leisure to parents who want to run with their infants; therefore, this device crosses both markets.

The evolving birth rate in the United States was used as a basis to determine the number of sales of strollers in the past years. Once analyzed, the growth in the number of people who go out to run during these last years was analyzed in order to estimate the total number of final users. This data was used to determine the market outlook of the proposed device. Figure 2 shows the evolution in the number of runners in the last couple of years.

Figure 2: Number of people who went jogging or running (in millions)

As you can see in Figure 2, since 2008 the number of people who decide to go out for a run has increased considerably. As of 2016, the number of runners who were able to finish the race were around 17 million [5][8]. This number has multiplied by three in the last 20 years. Around the world there exist races, especially marathons, that are home to nearly 50,000 people willing to run for 42 km. It should be noted that in many of these competitions, the strollers are not allowed due to the possible dangers they could cause. However, in the same way, the number of marathon events has increased considerably in recent years and so has the running competitions with strollers. Based on this analysis, it can be concluded that the runners market is an emerging market.

There is a diverse array of jogging strollers currently on the market that can range anywhere between \$70 to \$2,000. The more frequently purchased jogging strollers range from \$70 to \$450. The Babytrend Expedition Jogging Stroller is a popular selling jogging stroller at Walmart for the price ranging from \$73 to \$126, while the BOB Revolution Flex Jogging Stroller costs \$450 on Amazon. After \$450, the jogging strollers come equip with an array of luxury features since there are no limitations on cost. The Thule Chariot Chinook 1 Multi-Sport Child Carrier & Stroller sells for \$1,199.95 at Kohl's. Even the most popular jogging strollers do not incorporate natural arm movement.

The JogAlong stroller integrates the motion similar to that found on an elliptical machine. The designers define it as the only jogging stroller that can be considered ergonomic, since it stimulates the natural motion of the arms while the user is running. The problem with the mechanism is that it is included with the stroller. Therefore, the price increases greatly. In addition, this system is not adjustable for different heights, so as can be seen in their promotional video, it is not very ergonomic for those of a certain height. In the same way, this mechanism will not be able to adapt to any type of stroller. Therefore, it does not meet the design requirement for adaptability [5][6].

The second product currently on the market would be the elliptical stroller. The designers define this product as a mechanism composed of two fundamental elements: the stroller and the transmission mechanism of the elliptical movement. This mechanism is formed by two pedals that move up and down, moving together the stroller. The user can decide whether to engage the elliptical handle bar feature or just use the stroller as if it were a standard jogging stroller. This elliptical feature is similar to the mechanism of the teams design. However, the price is around \$1,250 [5][7]. There are many other start-up companies trying to incorporate natural arm movement in their designs, but none have successfully produced this feature in an affordable attachment design.

Based on the cost of buying the materials for all three prototypes, the estimated cost per unit is \$200. One of the requirements of this device is that it costs the average user \$100 at the most. Producing this product on a greater scale will significantly bring down the price for the end user. Given the amount of new runners since 2008 and the price individuals are willing to spend on jogging strollers, it can be hypothesized that this attachment device will sale very well.

Using retailers such as Walmart, Inc or Target Corporation to sale the device next to the popular jogging strollers will increase the likelihood of their purchase rate.

INTRODUCTION

Frozen shoulder syndrome, also known as adhesive capsulitis, is a condition where the shoulder joint has a compromised range of motion that results in extreme pain and discomfort to patients. The condition is caused by inflammatory changes in the connective tissues around the shoulder capsule area. Over time, the tissue thickens and becomes tight, allowing stiff bands called adhesions to develop. These adhesions make the movement of the joint very painful and can limit the shoulder joint's range of motion. Frozen shoulder syndrome affects various populations of people, especially, those with diabetes, hormonal imbalances, and thyroid disorders. Typically, patients of between the ages of 40 to 60 years old are most likely to develop this syndrome. Additionally, it has been seen that women are at an increased risk for frozen shoulder. [1]. The primary treatment for frozen shoulder syndrome includes a variety of strengthening and stretching exercises which are usually performed multiple times a day to improve shoulder flexibility. Some of these exercises, such as the upward arm stretch, requires assistance from another person, thereby causing dependency [2].

Therefore, the objective of this design is to make a portable assistive medical device that will allow patients to practice the upward arm stretch on their own, thereby eliminating the dependency on another person to perform this exercise.

The design as shown in Figure 1 consists of a frame (made of aluminum) on which a remote controlled electric winch (the Hiltex 11302 12V winch) is mounted. A custom made fabric strap attached to the hook at the end of the winch cable will be used to fasten the patient's elbow to the device. The included remote control on the winch will be used to raise the strapped elbow, allowing the patient to lift their arm and perform the upward arm stretch. The frame has an outer dimension of 15.5 inches x 21.3 inches. The height of the frame will accommodate a maximum patient height of 6'8", which covers up to the 99.99th percentile of US adult male heights. Since there is no constraint on lowering down the cable the device can not only accommodate shorter patient heights but can also support patients with disabilities confined to wheelchairs. The rectangular geometry of the frame will prevent the device from toppling in any direction during use when a load is applied perpendicular to the top face of the structure. Additionally, lockable wheels included inferior to the bottom face of the frame will allow for the device's portability.

A patent search was conducted prior to the development of the design and there were no similar medical devices for treating frozen shoulder syndrome available on the market or awaiting a patent approval.

PRODUCT DESIGN

Figure 1: 2D CAD Design

BUDGET & MARKET ANALYSIS

The current budget for designing, building, and testing of the prototype is \$1000. The parts for the design cost \$835 with a contingency of \$165. The building and testing of this prototype don't have any costs because the team is going to carry out these tasks themselves.

In 1995, the estimated cumulative incidence of frozen shoulder syndrome was found to be 2.4 cases per 1000 people a year [3]. With the United States having a population of 328.15 million people [4], this is equivalent to 787,560 cases of frozen shoulder syndrome a year. This means that up to 787,560 units could be sold a year. At this volume, the expected cost per unit is \$855. The projected sales price for the device is \$1,500 per unit. The profit made on one unit at this price would be \$645. If 787,560 units were sold a year, the total return on investment would be 508 million dollars in profit. Alternatively, a rental system could also be considered instead of a one-time purchase, where the device would be returned after the patient has recovered from the condition. If the patient were to be renting the device, the price would be \$50 a month. Typically the condition can last anywhere from 1 month to 5 years and hence a rental system would be beneficial for short term users while the one-time purchase would be favorable to long term patients.

ACKNOWLEDGEMENTS

INTRODUCTION

In the United States, more than 800,000 people suffer stroke every year where stroke is a leading cause of disabilities [1]. Nearly half of all stroke survivors experience loss of upper extremities function as the wrist is flexed due to increased tissue stiffness, which also means that there is an increase in required reflexive torque. Some studies have found that in a healthy wrist the static stiffness is around 20 N.mm/deg [2]. As a result of stroke, the wrist can have contractures of nearly 5° per week in the first 8 months, leading to increased stiffness of the wrist [3]. Wrist position a crucial factor in the range of motion (ROM) of the fingers. It was found that at the extreme wrist flexion and extension points, there is a lower ROM in the finger joints and hand grip force compared to when the wrist is in the neutral position. For instance, the ROM of the index metacarpophalangeal joint varies from 25.9° ($\pm 10.2^\circ$) to 84.7° ($\pm 8.6^\circ$) depending on the wrist joint angular position [4].

In order to address wrist contracture in post-stroke population, some products currently available in the market make use of splints to keep the wrist in a neutral position. According to a study done by the University of Sydney that tested the effectiveness of splints, it was concluded that wrist splinting was not effective in reducing wrist contracture after stroke [5]. Another study from the Netherlands found that static wrist-hand orthosis was not effective in preventing contractures and only caused discomfort to the stroke patients with long-term use [6]. However, studies have shown the effectiveness of dynamic wrist-hand orthosis where it was found that incorporating hand training into therapy to maintain the functionality of the wrist for the stroke survivors can help improve hand use [7]. Therefore, robot-assisted systems can be used to overcome the stiffness and dynamically put the wrist in desired positions. Soft robotic devices show promise as a therapy extender needed for motor learning while reducing the complexity, cost, and safety issues involved in conventional robotic systems. The soft robotic wrist actuator could also be used as a form of post-stroke rehabilitation in order to delay or reduce the effect of contractures in the wrist in order to help retain the ROM in the fingers.

A wrist rehabilitation has been developed for stroke patients that consists of a glove and elbow sleeve that is connected by soft robotic actuators and cable-driven mechanisms. Although this device is capable of providing wrist movement in all degrees of freedom, its effectiveness in overcoming stiffness at the wrist has not been reported [8].

PRODUCT DESIGN

Our current design is based on a soft robotic approach where it utilizes the inherent compliance of silicone rubber materials and air pressurization to generate simple bending motion of the wrist by overcoming the stiffness of the joint. This helps prevent contractures and restore mobility of the wrist and fingers.

Before determining the design parameters that could be changed in the wrist actuator, a fixed length, width, and height of the overall wrist actuator was set. After this was decided, different dimensions for the various features were set based off the shape of the bellow. The following design parameters that were set: height of the bellows, thickness of the base, thickness of the walls along the sides of the bellows, width throughout the bellows, and the heights of the inner and outer corrugations (Figure 1). Overall, there were two types of bellows used in the design process, rectangular and rounded bellows. Initially, the design began with one row of bellows spanning the entire width of the actuator. However, modifications were made to this design by creating two rows of bellows to decrease over inflation in the center. The optimized design consists of a rectangular and rounded bellowed actuator with two cavities, and inner and outer corrugations, shown in Figures 1A and 1B, which allows for lengthening and increased bending of the actuator.

Figure 1: Inner cavity view of (A) rectangular and (B) round bellowed actuator

The commercial software SolidWorks was used to design the CAD models of the actuator (Figure 2) along with the molds used for fabrication process. For the design optimization, a finite element model of both soft robotic actuator structures that interacts with a simplified

rigid multibody model of the wrist were developed in the commercial software ANSYS. As the actuator is symmetric, half the model was used for the simulations, which were run in order to see the effects of different design parameters on wrist rotation while adding pressure to the inner cavities (Figure 3). A torsional spring with stiffness of 10.475 N.mm/deg, half the stiffness found in a healthy wrist, was considered at the joint of the wrist model to replicate the natural stiffness of the wrist. The optimized design for both geometries was obtained in order to reach the desired wrist extension of 70° by pressurizing the actuator with a maximum pressure of 0.2MPa over a period of 20 seconds (Figure 4). The final designs for both wrist actuators were obtained by changing the values for each design parameter until the optimum angle of rotation was achieved.

Figure 2: CAD Model of (A) rectangular wrist actuator and (B) round wrist actuator

Figure 3: (A) Rectangular and (B) rounded wrist actuator simulation in ANSYS

Figure 4: Angle of rotation vs pressure input (A) rectangular ridge and (B) rounded ridge

The actuator was developed through liquid polymer fabrication processes such as injection and over molding along with a wax casting process. Molds were manufactured using a stereolithography type 3D printer (ProJet SLA 6000, 3D Systems). The fabrication process consists of four steps. First, the wax pieces are made to make the inner corrugations. Second, the half-bellowed part of the actuator and end pieces are made using silicone rubber in closed molds with injection molding process. Next, the cured bellowed silicone piece and wax piece are used to over-mold on the base mold. Finally, the wax is melted out and the two end pieces are attached.

The wrist actuator is used by being attached to the underside of the hand with the help of a brace (Figure 4). To keep the actuator in place, a piece of fabric is sewn onto the brace, creating a pocket for the actuator. The actuator is then pressurized gradually by a control box (Figure 5). With the use of the embedded inertial measurement unit (IMU), the angle of extension can be measured and controlled for people with varying degrees of stiffness as shown in Figure 6. The pressurization causes the bending of the wrist upwards, providing the user with increased range of motion in the fingers, assuming the wrist begins in a contracted position.

Figure 5: (A) Side view of actuator worn on hand (B) pressurized actuator

Figure 6: Schematic of sensorized soft robotic wrist and control unit

Currently, the wrist actuator is designed to be placed on the inner side of the hand and wrist, which can be difficult for some to wear if their hand is in the contracted position. However, modifications to the design can be made to overcome this issue.

BUDGET & MARKET ANALYSIS

The total cost of all the required parts to fabricate an actuator is approximately \$70 where the highest cost is associated with the use of 3D printed molds. However, multiple actuators can be fabricated with the same set of molds and therefore, the cost of molds can be distributed between them. The physical rehabilitation market in the US is estimated to be a \$30 billion industry growing at a rate of 7% CAGR. This is mostly due to the aging population in the US and people leading sedentary lifestyles. The robot-assisted rehabilitation market is expected to grow dramatically, reaching \$2 billion by 2020. With more than 800,000 people having strokes every year in the United States and depending on the effectiveness of the wrist actuator, the commercialization plan can be expanded to meet the demand by mass producing the wrist actuator at a lower cost thus increasing the market size.

ACKNOWLEDGEMENTS

This project is partially supported by the National Science Foundation under Grant No. 1605635 and the associated Research Experience for Undergraduate (REU) supplemental funding. We would like to thank Mr. David Manivanh assisting us with 3D printing, Ms. Alexandra Lindsay for her guidance in CAD modeling of the wrist joint and Ms. Allison Palomino for her contribution. Authors also would like to thank UTA Research Institute for providing facilities and equipment.

INTRODUCTION

Recently, it has come to the attention of medical professionals that surgery students are ‘losing dexterity to stitch patients,’ an essential skill of traditional open surgery that is sometimes the only viable option in many emergency cases including the operations in a battleground [1]. Moreover, research has shown that the physical and cognitive performance of surgeons deteriorates over time [2]. Since the chances of mistakes by fatigued, overloaded, or old surgeons increase, a system design augmenting their capabilities is necessary.

Regarding human augmentation, there has been a lot of developments in the field of virtual reality (VR) and medical training. Extensive research over the past two decades has signaled the importance of VR training in the medical field and has identified the unique benefits that such programs bring with them. As a result, Osso VR (Palo Alto, USA) has recently made successful partnerships with leading medical schools in the country. Hence, such an augmenting system needs to be developed in a way ensuring successful integration with a VR system to allow surgeons and medical students to improve their micromanipulation skills with relative ease [3].

The idea of a robotic glove (see Figure 1) was initiated by thinking about the issue above and the impact of augmenting the ability of humans in the domain of medicine. We believe that providing the surgeons with a custom-built robotic glove that can offer both a controlled motion and sufficient information allows them to achieve greater dexterity and safety mainly when they handle sensitive objects such as human organs. The system will support human motors by integrated actuators, constrain the hand motions in the desired, limited space, and provides various sensing capabilities such as precise haptics and proximity. Since the glove is manufactured using 3D printing techniques, based on the laser-scanned hand model of specific users, the fit will be natural and ergonomic, another significant attribute affecting the performance.

This paper introduces the design and mechanics of such a robotic glove augmenting human capability, focusing on the pinch motion with two fingers, thumb and index, generally used for micromanipulation, followed by our budget and market analysis.

PRODUCT DESIGN

The glove is primarily a 3D printed structure as opposed to silicone or fabric-based soft robotic gloves that have been widely

Figure 1. Schematics of a 3D printed robotic glove with actuators and sensors

studied. Although rigid materials aren't as adaptable and comfortable as their competitor, i.e. soft materials, they were used for the glove since it allows for more precise control and better repeatability of movements. Also, since the glove is 3D printed, customizable for specific users, it will improve the fit and ergonomics, leading to better task outcomes.

Since we focus on two-digit or pinch motions, the glove is designed to help control the motions of a user's index finger and thumb. The mechanism for the index finger consists of two individual 3D printed pieces that are driven by two linear actuators. On the other hand, the structure for the thumb is a single 3D printed piece that is driven by a single linear actuator. The linear actuators are PQ12-R Micro Linear Servos manufactured by Actonix (Victoria, Canada). A mechanics model was built (see Figure 2), and a set of experiments was conducted to validate the system performance such that the motors could resist the forces applied by the user's finger following a planned trajectory with precision. The study on resisting forces is important to verify the safe use of the designed system. If a user can break constraints pre-programmed by applying an excessive force on the linear actuators, the system loses controllability, resulting in undesired behavior. Using the model and a set of mechanics equations (see Figure 3), the results of this study for one of the motors has been shown in Figure 4. It basically shows the varying force applied on the linear actuator based on the actuation force provided by the tip of the index finger. As can be seen by the figure, it is evident that the forces are below 45N, which is the maximum force that can be sustained by the actuator. We performed experiments on the human subject whose hand was used to model the glove and determined the maximum forces

Figure 2. Mechanics model of a member of the glove

$$\alpha_2 = \cos^{-1} \left(\frac{S_4^2 + S_{m2}^2 - S_3^2}{2 * (S_4) * (S_{m2})} \right)$$

$$\theta_5 = \theta_4 - \alpha_2$$

$$\sum M_B = F_2 * L_2 - AF_2 [S_4 \sin(\theta_4) * \cos(\theta_5) - S_4 \cos(\theta_4) * \sin(\theta_5)] = 0$$

$$AF_2 = \frac{F_2 * L_2}{[S_4 \sin(\theta_4) * \cos(\theta_5) - S_4 \cos(\theta_4) * \sin(\theta_5)]}$$

Figure 3. Equations for actuation force calculation

(29.82N) applied at the tips of each segment and found that the forces were below the maximum force that could be sustained by the motor. Similar studies were conducted for all motors to validate the motor choice.

Regarding the sensing capabilities of the glove, each of finger tip parts is equipped with a proximity sensor and force sensitive resistors. The proximity sensors that we used, providing a prior-information of touch between the tip and objects for the enhanced safety, are the VCNL4040 sensors packaged within SparkFun's (Niwot, USA) Robotic Finger Sensor V2. The force sensitive resistors are Interlink's (WestLake Village, USA) FSR 402 short tail. Four of the FSRs are placed internally within the 3D printed members of the glove, sending measured interaction force values back to the microcontroller installed on the back of the hand. Based on the force information received from the FSRs, the microcontroller can actuate the members as desired. For instance, if the user wants to move the thumb upwards, he/she has to apply a force on the FSR placed on the inner top surface of the 3D printed structure for the thumb. Also, an FSR will be placed on the outside structure for the thumb as well as for the index finger. These can provide readings of the force applied by the glove on an external object. If the force exceeds a set limit, the linear actuators can prevent the user from moving it further. Similarly, the proximity sensors can

Figure 4. Results of the mechanics study

be programmed to detect a certain distance past which the actuators prevent the user from moving his/her finger.

The whole glove is powered by a 2000 mAh battery with the help of a PowerBoost from Adafruit (New York City, USA). Moreover, OLED screens made by MakerFocus are used to provide the user with visual feedback with respect to the force and proximity values. The microcontroller that is used is an Arduino Micro.

To summarize, the glove will:

- Provide user with force and proximity feedback.
- Enhance users' controllability and dexterous manipulation ability with the help of accurate actuators.
- Allow future development of VR applications with the addition of VR goggles like the Oculus.

BUDGET & MARKET ANALYSIS

The total cost of building the glove in its current state is just under US\$830, summarized in Table 1. The bulk of this cost comes from the VR goggles which cost \$349 and the other components make up the rest. This cost reflects a single batch run of the glove and we believe that by producing this glove in bulk would allow us to bring this cost down substantially. The only cost that might not come down would be the 3D printing manufacturing of the glove because we would not be able to make that in bulk like the other components due to the customizable nature of the system.

Table 1: Cost breakdown of a glove

Part	Quantity	Price(US\$)	Total(US\$)
PQ12R Motor	3	70	210
Arduino Micro	1	20	20
LiPo Battery (2000 mAh)	1	13.54	13.54
PowerBooster	1	19.68	19.68
OLED Display	2	10.99	21.98
Rocker Switch	1	0.5	0.5
FSR Sensor	6	5	30
SparkFun V2 Sensor	2	40	80
Glove Print	1	80	80
Screws	5	0.5	2.5
Oculus Rift	1	349	349
Total			827.2

INTRODUCTION

A reduction in bicep and shoulder muscle function can greatly alter a person's daily life. The design team's client suffers from monomelic amyotrophy [1], resulting in a major loss of muscle function in the right shoulder and bicep, and greatly limiting his ability to vertically raise the right arm. As such, his ability to perform everyday tasks has diminished, as well as the client's ability to participate in outdoor activities such as nordic skiing and hiking with poles. The proposed design is an assistive arm device, which will help an individual with decreased shoulder and bicep muscle function to regain some range of motion in the upper arm.

Many existing assistive arm devices require stationary supports, such as a table or chair, to raise an individual's arm. This greatly limits the ability to perform mobile activities for a person with reduced shoulder and bicep muscle function. In addition, current exoskeleton assistive arm devices are heavy, bulky, and require external energy devices, such as batteries or electric power. While these exoskeleton devices help to restore upper arm muscle function, the bulky and heavy design can be limiting and is not practical for everyday usage. A lightweight, mobile, self-sufficient design, such as the one proposed by the design team, would greatly improve the quality of life of individuals suffering from conditions which reduce upper arm muscle function.

This device would be useful for individuals suffering from monomelic amyotrophy, arthrogryposis multiplex congenita [2] affecting upper limb joints,

muscular dystrophy [3] affecting bicep and shoulder muscle function, the early stages of Lou Gehrig's disease [4] affecting the upper arm, as well as elderly persons with weakened upper body muscles. The proposed product will provide assistance to shoulder and bicep muscles, as well as restore the quality of life of an individual with decreased shoulder and bicep muscle function.

PRODUCT DESIGN

This assistive device will reduce the workload of the bicep and shoulder muscles during activities requiring an individual to vertically raise his arm. The design consists of three main components: an upper body brace, which utilizes the back for support; a spring-loaded system, which attaches to the shoulder; and a cable with a wrist attachment, which connects the spring system to the individual's forearm. As the individual lowers his arm from a raised position, the spring stretches and gains potential energy, which is used to pull the arm back into a raised position. This device can be used for everyday activities requiring an individual to raise his arm, as well as recreational outdoor activities, such as nordic skiing and hiking.

Many assistive arm devices require attachment to stationary supports, like tables and chairs, to raise a person's arm, which limits the person's mobility and activity level. This product relies on the back and upper body for support, allowing an individual to raise his arm during mobile activities. In addition, unlike current exoskeleton products, this design does not require any external energy sources, such as batteries, to function. This design relies on simple, lightweight, and self-sufficient components to function as an assistive arm device.

In order to verify the design of the device, the prototype will be tested against functional requirements on test

subjects as well as the client that inspired this design. Tests will include load cell actuation to monitor the forces generated by the device, which may be used to ensure a properly modulated response. Throughout the design process, feasibility will be ensured in a top-down manner. This is to say that as the product develops and gains maturity the failure modes and discrepancies will be recognised and accounted for. An important aspect of assistive devices is that they conform directly to the users' needs and lifestyle. This design will be tested with very specific needs in mind. The client has expressed a love of outdoor activities and a true desire to return to full confidence in completing rigorous hikes and nordic ski trips. The design team strives to restore the client's upper body biomechanics to the range required for efficient nordic skiing motion [5]. In response to this need, the design will be tested in harsher conditions than may normally be expected; the goal is to ensure resistive feedback, even in cold weather and under rigorous activity. This will lead to many feasibility tests to ensure that the device is robust enough to not only allow the user to complete daily tasks in the comfort of his home, but to complete various outdoor activities as well.

BUDGET & MARKET ANALYSIS

Over the course of designing, building and testing the prototype the design team should be able to stay within our \$5000 budget. For our initial prototype we will be exploring the use of different elastic bands as a source of flexion. This will cost around twenty-five dollars per band. Along with this, the team will need a system to connect the bands to the user's shoulder that will cost approximately forty to fifty dollars. This will include a brace and a clip system to connect the band to the brace. After producing and testing an initial prototype, we plan on designing at least two more prototypes in order to determine the best solution possible.

Table 1: Projected Prototype Costs

Item	Price
Theraband	\$25
Brace/Clip System	\$50
Total Cost	\$75

Our client suffers from monomelic amyotrophy [1], which typically occurs in Asia, with very few cases in the United States. The modular design enables the device to be used by a greater general population. Arthrogryposis multiplex congenita is a muscular degenerative disease that causes joints to be set in a permanently fixed or straightened position prior to birth. In some cases, a soft tissue release is necessary to improve range of motion [2]. However, muscles are weak due to the lack of motion and need assistance to initially move. Arthrogryposis multiplex congenita affects 1 in 3,000 individuals in the United States. Muscular Dystrophy causes progressive weakness and loss of muscle mass affecting 1 in 8,000 individuals worldwide [3]. The device could be used to aid those during the early stages of the disease when muscle loss has not fully progressed. Lou Gehrig's Disease affects just over 5,000 individuals in the United States per year. Lou Gehrig's Disease is a progressive

neurodegenerative disease that affects voluntary muscle action, thus people progressively lose muscle function [4]. With these diseases in mind, we estimate the market size would be approximately 800 per year.

The design team does not expect to meet the full market potential until several years after releasing the product. The return on investment for the design is estimated to increase every year due to a low initial resource investment compared to the estimated net profit acquired from the final design. The cost of production would be approximately fifty dollars with a selling price of one hundred dollars per unit.

INTRODUCTION

An arteriovenous fistula (AVF), which is created by surgically connecting an artery to a vein directly, is the preferred vascular access for chronic hemodialysis due to its fewer complications and longer durability compared to AV grafts and central venous catheters. However, a newly created AVF needs to mature before it is cannulated for routine hemodialysis. AVF maturation requires a sufficient increase in both the lumen diameter and flow rate of the AVF vein. Yet currently the rate of AVF maturation failure remains unacceptably high. Improving AVF maturation is crucial for realizing the benefits of the Fistula First strategy, and currently there are no effective clinical treatments to enhance AVF maturation.¹

Many factors contribute to AVF maturation failure and the exact mechanisms are not yet well understood. Disturbed and complex blood flow induced by the abrupt change in flow direction at the artery-vein anastomosis under a high flow condition may impede AVF maturation.² Anastomosis angles have been associated with the lumen diameter and flow rate in experimental porcine³ and the rates of reintervention⁴ and maturation⁵ in patients. Nonplanarity has also been associated with maturation.⁵ However, these previous clinical studies are limited in

patient numbers, time points, and image resolution. Here we report the AVF geometric parameters and their associations with AVF flow rates in a multi-center study, using high-resolution MRI to follow patients longitudinally.

METHODS

From 2011 to 2016, patients with end-stage renal disease (ESRD) undergoing a new vein end-to-artery side upper-extremity AVF creation surgery were recruited at the University of Florida, University of Utah, and University of Cincinnati. Two types of MRI techniques were performed at 1 day, 6 weeks, and 6 months postoperatively using 3.0T General Electric or Siemens scanner.⁶ Phase-contrast MRI was used to obtain the flow rate in the AVF. Flow rates were extracted using Segment (medviso.com/segment).⁷ A contrast-free double-inversion recovery MRI sequence was used to obtain the AVF lumen images in dark blood. The AVF lumen geometry was reconstructed from the dark-blood images in Amira, and the bifurcation origin at the anastomosis and the centerlines were extracted using VMTK (www.vmtk.org).

Three geometric parameters were extracted (Fig 1). The anastomosis angle was calculated as the angle between

the lines connecting the anastomosis origin with the proximal artery (PA) and AVF vein centerline points that are 10 mm away from the origin (Fig 1A). The three points on the centerlines of PA, AVF vein, distal artery, each being 10 mm from the anastomosis origin, form the anastomosis plane. The nonplanarity angle was calculated as the angle between the anastomosis plane and the line connecting the anastomosis origin and the AVF vein centerline point that is 40 mm away from the origin (Fig 1B). Tortuosity was calculated as $(\frac{L}{D} - 1)$, where L and D are the centerline curve length and straight line length, respectively, from the anastomosis origin to the AVF vein centerline point. D was set to be 40 mm (Fig 1B).

Fig 1. AVF geometric parameter definitions. (A) The anastomosis angle. (B) The nonplanarity angle and tortuosity.

Analysis of variance (ANOVA) and correlation analyses were performed to examine whether the geometric parameters changed over time and were associated with the AVF location (forearm vs. upper arm) and flow rates.

RESULTS

There were 114 patients with at least one MRI scan. There were more upper arm (63%) than forearm AVFs.

Table 1. The AVF geometric parameters and flow rates (Mean± SD) at three postoperative time points in different locations.

Anastomosis angle (degree)			
Locations	1 Day	6 Weeks	6 Months
Forearm	58.1±18.5	57.1±16.9	62.9±17.5
Upper arm	75.3±19.0	77.5±17.7	80.9±20.2
Nonplanarity angle (degree)			
Forearm	16.4±10.5	18.2±13.6	16.4±13.7
Upper arm	28.4±15.2	32.3±16.1	37.5±16.9
Tortuosity			
Forearm	0.10±0.07	0.11±0.08	0.11±0.09
Upper arm	0.13±0.09	0.16±0.11	0.17±0.11
Flow rate (mL/min)			
Forearm	408±249	543±326	674±422
Upper arm	633±367	821±492	887±503

Eleven AVFs were created using a two-stage method with the second surgery performed after the 6-week scan and before the 6-month scan. Due to the large geometric change of the second surgery, the 6-month scan data were not included in the analysis. The three geometric parameters and flow rates at three postoperative scans stratified by AVF locations are shown in Table 1.

Two-way ANOVA demonstrated that upper arm AVFs had significantly larger ($P < .001$) anastomosis angles, nonplanarity angles, and tortuosity than forearm AVFs, respectively; none of these geometric parameters changed significantly over time for either AVF. Similarly, upper arm AVFs also had significantly larger ($P < .001$) flow rates than forearm AVFs at all three scans. For both AVFs, flow rates increased significantly during 1 day and 6 weeks but did not increase significantly during 6 weeks and 6 months.

For both forearm and upper arm AVFs, flow rates were not significantly associated with any of the three geometric parameters at any of the three scans.

DISCUSSION

It has been well-recognized that hemodynamics affects vascular structure and function in health and diseases. Because hemodynamics is largely affected by geometric configurations, vascular geometric features have been investigated in atherosclerosis and aneurysm studies. We demonstrated that upper arm AVFs have larger anastomosis angles, nonplanarity angles, and tortuosity than forearm AVFs; however, flow rates do not correlate with these geometric parameters. The AVF flow rate is determined by the whole vasculature from the subclavian artery to superior vena cava. Geometric features in a wider range may be needed in order to explain the different AVF flow rate values. Further studies will examine the associations of these geometric parameters with the AVF lumen diameter and the rates of surgical and endovascular intervention and maturation.

INTRODUCTION

Hemodynamics is known to play a critical role in the progression and rupture of intracranial aneurysms (IA). Previous studies have linked hemodynamic parameters such as wall shear stress (WSS) and oscillatory shear index (OSI) to increased IA risk of rupture. However, contradictory conclusions among such studies, such as both high and low WSS linked to risk of rupture, have prevented establishing concrete mechanisms of the flow-induced aneurysm growth and the critical values of these hemodynamic risk factors.

When investigating these inconsistencies, the methodology and subsequent assumptions used must be considered. Most often, hemodynamic IA studies use patient-specific computation fluid dynamics (CFD) to solve for the velocity field within the IA. CFD studies typically assume laminar flow, rigid boundaries, Newtonian flow and neglect gravity. Some studies have measured velocities *in vivo* with three-directional phase-contrast MRI (4D Flow MRI), but the low spatiotemporal resolution of this modality inhibits accurate estimation of hemodynamic metrics in cerebral vessels. Further, because typically MRI imaging is acquired for only one patient orientation, the 4D Flow also neglects the effects of gravity. Limited experimental particle image velocimetry (PIV) studies have been completed in this domain, majority of which have been 2D - 2 velocity component studies, despite the known three-dimensionality of the flow, and have been imaged at a single orientation.

Neglecting gravitational forces is an assumption common to all hemodynamic IA studies, regardless of modality. However, the effect of gravity on the hemodynamics within a cerebral aneurysm may be significant. In this work, we experimentally investigate the effect of gravity on hemodynamic parameters in two patient-specific cerebral aneurysm models by imaging the flow at two orthogonal orientations. A “horizontal” orientation was imaged to represent a patient in a supine position in an MRI scanner and a “vertical” orientation was imaged to

represent a patient standing up. Both STB orientations are compared to CFD and *in vivo* 4D Flow data.

METHODS

In vivo 4D Flow MRI velocity fields were acquired for a basilar tip aneurysm at University of California San Francisco and an internal carotid artery (ICA) aneurysm at Northwestern Memorial Hospital. *In vivo* contrast-enhanced MR angiography (basilar tip aneurysm) and non-contrast time-of-flight MR angiography (ICA aneurysm) data were segmented, and 1:1 *in vitro* silicone block models were fabricated with 3D printing. A mock circulatory flow loop mimicked *in vivo* conditions, matching inflow waveforms as well as Reynolds and Womersley numbers, and used a water-glycerol-urea blood analog [1]. Volumetric particle velocimetry images (3D – 3 velocity component) were captured for both aneurysms at both orientations. The flow in the horizontal orientation was first imaged then the aneurysm model was rotated without removing it from the flow loop. The cameras and laser volume were rotated, and the flow in the vertical orientation was imaged. Particle images were processed using Shake the Box (STB), a particle tracking based algorithm [2]. All experimental results will be referred to as ‘STB’ herein.

Velocity gradients and WSS were computed using radial basis functions (RBF) [3]. Three component time averaged WSS (TAWSS) was computed according to the following equation:

$$\text{TAWSS} = \frac{1}{T} \int_0^T |\tau_w| dt \quad (1)$$

where τ_w is wall shear stress (dynes/cm²) and T is the period of the pulsatile cycle (s).

CFD velocity fields were also available for both geometries at only the same horizontal orientation as the *in vivo* 4D Flow data [4]. Horizontal STB data was acquired but post-processing of this test case is ongoing, thus comparisons herein are limited to the vertically-oriented STB and CFD.

RESULTS

Figure 1 shows the velocity pathlines for the vertically-oriented STB and horizontally-oriented CFD for both geometries. The pathlines demonstrate agreement of the general flow patterns across the two modalities for both cases.

Figure 1: Velocity pathlines for vertically-oriented STB and horizontally-oriented CFD data in the (a) basilar tip and (b) ICA aneurysms. Note: length scale is different between the two geometries. (Image adapted from [4])

Figure 2 compares the normalized WSS of both geometries computed using vertically-oriented STB and horizontally-oriented CFD. Despite the agreement of velocity pathlines (Fig. 1), significant differences in the low WSS regions of the STB and CFD data is observed. Specifically, for the basilar tip aneurysm a large low WSS region at the anterior proximal portion of the aneurysmal sac was present in the CFD but not the STB. For the ICA aneurysm, the vertically-oriented STB maintained a larger low WSS region than the CFD. In the horizontal orientation for both geometries, gravitational forces act in the anterior-posterior direction, pushing flow away from the anterior, towards the posterior region of the aneurysm. Conversely, in the vertical orientation, gravitational forces act in the proximal-distal direction, pushing flow in the proximal direction.

Figure 2: Normalized WSS contours for vertically-oriented STB and horizontally-oriented CFD data in the (a) basilar tip and (b) ICA aneurysms. Note: models are not shown in their acquired orientations. (Image adapted from [4])

DISCUSSION

From the preliminary results presented here, it is evident that even given the same geometry, the different assumptions and limitations of each modality have a major impact on hemodynamic parameters such as WSS. The different low WSS regions based on the STB and CFD could have subsequent impact on the assessed aneurysmal stability. Thus, given the importance of this difference in WSS contours, the source of this difference must be considered.

Although variations in the inlet flow rates are possible due to the different modalities among the preliminary results, previous studies have reported that different inlet waveforms can alter WSS magnitude, but do not affect the spatial variation of WSS [5]. Therefore, it is unlikely the observed spatial WSS differences are contributed by inflow variations. Further, the same rigid wall model was used for both modalities. In the CFD, laminar flow was assumed, while STB inherently does not. However, given the similarities of flow pathlines (Fig. 1) across the modalities, it is unlikely turbulent flow behavior caused this WSS difference.

The final major difference among this comparison was the orientation: the STB was vertically oriented while the CFD was horizontally oriented. Thus, the orientation of aneurysm with respect to gravity was rotated. In the basilar tip aneurysm, the low WSS region of the CFD is located in the anterior portion of aneurysmal sac, aligning with the direction gravity would push flow away from, thereby reducing the flow velocity and WSS in that area. In the ICA case, the tortuous ICA vessel is wrapping around the aneurysm, moving horizontally at the base of the aneurysmal sac. Thus, flow entering the sac in the vertical orientation would be moving against gravitational forces, while in the horizontal orientation flow entering the aneurysmal sac would be moving orthogonal to gravitational forces. The lower flow velocity and WSS in the aneurysmal sac for the vertically oriented STB as opposed to the CFD matches the expected differences if gravitational forces in the flow are significant. Therefore, preliminary WSS analysis of both aneurysms support the notion that gravitational forces affect hemodynamic metrics such as WSS in an aneurysmal sac.

With this notion, the effect of gravitational forces, which have previously been neglected in hemodynamic IA studies, could, in part, explain some of the contradictory results that have been reported. Given that cerebral aneurysms can occur at various locations in the cerebral vasculature, the effect of gravity in each case would vary, confounding the gravitational effect across studies. However, a cross-modality comparison, as shown herein, cannot unambiguously confirm this conclusion, as too many extraneous variables could influence the results, necessitating a more direct comparison. Thus, the forthcoming results of this work, comparisons among a single modality, STB, will mitigate many of the other dependent variables and assumptions that could affect the IA hemodynamics. Ultimately these results could also be used for generating and validating orientation-dependent models, thereby enhancing hemodynamic analysis of cerebral aneurysms.

INTRODUCTION

Endovascular coils treat intracranial aneurysms (IAs) by causing them to occlude by thrombosis. Ideally, coiled IAs eventually occlude in the long-term. However, 20.8% are found incompletely occluded at treatment follow-up [1]. Computer simulations of coiling and its effect on aneurysmal flow could help clinicians predict treatment outcomes *a priori*, but it requires accurate modeling of coils and their deployment procedure. In addition to being accurate, coiling simulations must be efficient to be used as a bedside tool. To date, several virtual coiling techniques have been developed, but they lack either accuracy or efficiency. For example, finite-element-based virtual coiling methods model the mechanics of coiling and are highly accurate, at the expense of high computational cost (and thus low efficiency) [2]. Geometric-rule-based coiling techniques ignore the mechanics and therefore are computationally efficient [3], but may produce unrealistic coil deployments. In order to develop a virtual coiling method that combines accuracy and efficiency, we propose a novel virtual coiling algorithm that models coil deployment with nonlinear mechanics and nonlinear contact. Our approach is potentially more accurate than existing “simple” techniques because we model coil mechanics. It is also potentially faster than finite-element techniques because it models the most time-consuming part of these algorithms – namely contact resolution – with a novel formulation that resolves contact faster with exponential functions. Moreover, we model the coil’s pre-shape as well as coil packaging into the catheter, both of which are important to model but are lacking from most existing techniques.

METHODS

In developing our algorithm, we considered three primary features of actual coiling procedures: coil geometry, coil packaging into the catheter, and coil deployment into the aneurysm. In Figure 1, we show these features in actual coil (left column) and in our model (right).

Figure 1: The three primary features of actual coil deployments were modeled in the virtual coiling algorithm.

Step 1. Modeling Coil Geometry Actual coils have a complex structure consisting of a primary wire, which is wound into a secondary spring-like structure. Moreover, in order to maximize coil distribution and clot formation in the aneurysm sac, the coils are made into a tertiary pre-shape (Figure 1, top left). To have a simplified representation of the coil structure and deployment, we modeled the coil’s secondary structure as a series of equal-length linear stretching springs (with spring constants k_s) connected at nodes (Figure 1, right column). The length of each spring (l_0) was set to the diameter (d) of the coil wire. To account for bending, neighboring spring elements were connected to each other by linear bending springs (with spring constant k_b) (Figure 1, right column). Modeling a coil’s geometry and mechanics as springs is more

efficient than finite-element approaches, which typically model them with higher-order beam element formulations [2].

Step 2. Deforming the Coil into the Catheter To accurately capture the mechanics of coil deployment it is important to take into account pre-packaging of the coil into the catheter, since the straightening of the coil from its pre-shape would store strain energy, which will eventually affect the deployment and final configuration of the coil. The actual physical process of packaging the coil into the catheter is depicted in Figure 1 (left middle). To deform the virtual coil into the catheter, we first determined the change in angles and orientations of neighboring spring elements required to move the coil from its pre-shape to the catheter shape. For that purpose, local coordinates were defined on each node between spring elements using Gram-Schmidt orthogonalization [4]. Then, the coil was deformed by applying the appropriate forces to the nodes. During this step, we assumed that only bending energy changes and neglect stretching energy of the coil. The total bending energy for the coil was defined by

$$W_b = \frac{1}{2} k_b \sum_j^m (\theta_j - \theta_0), \quad (1)$$

where m is the number of connections, θ_j is the angle between neighboring spring elements at the current state in the simulation and θ_0 is the angle between neighboring springs in the coil's reference pre-shape.

Step 3. Coil Deployment into the Aneurysm The final step in the coiling algorithm is deploying the coil into the IA sac (Figure 1). In the simulation, the IA sac was represented by a closed surface of tetrahedral elements. To deploy the coil, the coil was “pushed”, one spring element at a time, into the IA sac, from its deformed catheter shape. The nonlinear dynamic equation of motion for the coil during deployment is given by the following nonlinear equation:

$$m\ddot{x} + c \operatorname{sign}(\dot{x})(1 - e^{-|\dot{x}|/k}) = F_i + F_{c,w} + F_{c,c} + F_p. \quad (2)$$

In this equation, the second term on the left is a nonlinear damping term in which c is the damping constant and k is a constant. This nonlinear damping term stabilizes the coil during deployment to avoid large deformations and sharp angles between neighboring springs which would be unrealistic in real life coil deployments. The right hand side of (2) contains all of the relevant forces that act on each of the coil nodes during deployment. F_0 is the force used to “push” the coil into the aneurysm and F_i is the coil's internal force defined by

$$F_i = \frac{\partial W}{\partial x_i}, \quad (3)$$

where x_i is the position of i th coil node and W is the total internal energy. Although negligible during coil packaging, the total stretching energy for the coil W_s becomes important during deployment:

$$W = W_b + W_s, \quad (4)$$

where W_b is the bending energy defined in (1) and W_s is the stretching energy of the coil:

$$W_s = \frac{1}{2} k_s \sum_i^n (l_i - l_0). \quad (5)$$

Here n is the number of springs and l_i is the current length of spring elements in the simulation. In (2), F_i also contains the energy from $F_{c,w}$ and $F_{c,c}$, which are nonlinear coil-IA wall and coil-coil contact forces. These forces are defined as

$$F_{c,w} = |F_{c,w}|N, \quad (6a)$$

$$F_{c,c} = |F_{c,c}| \frac{(\bar{x}_i - \bar{x}_j)}{\operatorname{norm}(\bar{x}_i - \bar{x}_j)}, \quad (6b)$$

where N is the normal vector of one of the tetrahedral segments of the aneurysm wall in contact with a coil segment, and x_i and x_j are the

position vectors of two coil nodes involved in the contact. The magnitude of these contact forces were defined by [5]

$$|F| = \begin{cases} 0 & \text{for } \delta_g \geq c_0 \\ \frac{P_0}{1-e} [(1 - \delta_g/c_0)(e^{1-\delta_g/c_0})] & \text{for } -6c_0 < \delta_g < c_0 \\ \frac{P_0}{1-e} [7(e^7 - 1) - (6 + \delta_g/c_0)(8e^8 - 1)] & \text{for } -6c_0 \geq \delta_g \end{cases}, \quad (7)$$

where $|F|$ represents $|F_{c,w}|$ and $|F_{c,c}|$. In (7), $\delta_g = |x_i - x_j|$ is the distance between the two coil nodes in contact, and c_0 and P_0 are two model parameters that can be assumed to be approximately equal to the mean local pressure and two times the root-mean-square surface roughness of the aneurysm wall. Because the nonlinear contact forces increase exponentially as the contact distance decreases in (7), the computational time to resolve contact is fast. To solve (4) iteratively, we used a semi-implicit Euler scheme. The simulation ends once the coil is completely deployed into the IA.

Preliminary Test of the Algorithm We implemented the algorithm in Matlab and tested the code by simulating the deployment of a $3mm \times 6cm$ Stryker coil (radius $0.014605cm$) into a patient-specific internal carotid artery IA with a diameter of $3.5mm$. The pre-shape geometry of the coil was adopted from a previous study [2].

RESULTS

Figure 2 shows the intermediate and final results of the test coil deployment. It can be seen that the coil configuration changes over time during deployment, which echoes the real coil behavior when it is pushed into an aneurysm. This demonstrates that our nonlinear mechanics-based algorithm is able to capture the dynamics of coiling.

Figure 2: Coil configuration at two intermediate time points in the test deployment simulation and the final configuration.

DISCUSSION

We have demonstrated a new virtual coiling algorithm that is more realistic than existing “simple” algorithms. In one preliminary example we have shown that the simulation captures the dynamic behavior of real coil deployment. This novel method is potentially faster than the most accurate finite-element algorithms. We expect greatly increased computational efficiency from: (1) modeling a coil as a series of linear and bending spring while still maintaining coil mechanics, and (2) combining nonlinear dynamics of the coil with a novel nonlinear contact mechanics formulation. In the future, we will test the robustness of our algorithm in more patient-specific IA case, compare its efficiency against existing virtual coiling methods, and experimentally validate it.

INTRODUCTION

Discrete subaortic stenosis (DSS) is a congenital cardiac disease that is responsible for 8-30% of total left ventricular (LV) outflow tract (LVOT) obstructions in children, and up to 20% of obstructions that require surgical intervention [1]. It is characterized by a thin fibromuscular ring of tissue that forms on the interventricular septum immediately below, or sometimes fused with, the aortic valve (AV) [1]. A common morphological abnormality found among DSS patients is a steepened aortoseptal angle (AoSA), which describes the angle between the septal wall and the long-axis of the ascending aorta, and is presumed to cause turbulent blood flow conditions in the LVOT.

Present in 30-80% of DSS patients, aortic regurgitation (AR) is the most common complication of DSS [2]. AR is characterized by a reflux of diastolic blood from the aorta to the LV due to the malcoaptation of the leaflets [2]. In the context of DSS, AR has been hypothesized to result from the stenotic blood flow conditions imposed by the fibrotic lesion obstructing the LVOT [2]. Supported by observations that have shown AR progression post-obstruction relief is common with steep AoSAs, the hypothesis of this study is that LVOT abnormalities generate altered blood flow velocity, skewness, and displacement, which may contribute to abnormal leaflet dynamics and insufficiency.

Therefore, the objective of this study was to utilize 2D computational fluid dynamics (CFD) modeling incorporating patient-derived myocardial wall motion and boundary conditions to quantify the hemodynamic environment in normal (normal AoSA) and abnormal (steepened AoSA with/without DSS) LV geometries.

METHODS

LV images were obtained from a healthy 25-year-old adult male volunteer using a 3T MRI scanner (GE Healthcare Discovery MR 750w). A total of 29 temporal phases per cardiac cycle were acquired.

Segmentation and reconstruction of the mid-plane of the 4-chamber view were manually performed (Fig. 1A) using Segment v2.2 R6435 (<http://segment.heiberg.se>) [3]. To acquire smooth displacement motion over the entire cardiac cycle with the desired temporal resolution (0.5 ms), intermediate time points were generated using cubic spline interpolation between two consecutive time frames.

LV motion was generated via implementation of a one-way fluid-structure interaction (FSI) technique in ANSYS 19. Briefly, the wall displacement prescribed in ANSYS Mechanical was transmitted to the fluid domain in ANSYS Fluent. The resulting mesh displacement and fluid flow were calculated via the arbitrary Lagrangian-Eulerian (ALE) method. Three cases were considered to isolate the impact of AoSA abnormalities and DSS on LVOT hemodynamics: LV with normal AoSA (130°), LV with steepened AoSA (110°), and LV with steepened AoSA and DSS membrane attached to the septum (Fig. 1B).

Figure 1. LV geometrical model; A) complete LV geometry, and B) different LVOT geometries considered in the study.

The DSS lesion was modeled as an isotropic linear elastic material (elastic modulus: 2 MPa, density: 1060 kg/m³, Poisson's ratio: 0.49), and its motion was computed via two-way FSI [4]. Blood was approximated as an incompressible Newtonian fluid (density: 1050

kg/m³, viscosity: 0.0035 Pa·s) [1]. Following a mesh sensitivity analysis, the fluid domain of the normal, steepened, and DSS geometries was meshed with 153,852, 151,248, and 152,348 cells, respectively. The turbulent flow was computed by incorporating the transitional shear stress transport $k - \omega$ model in the Reynolds-averaged Navier-Stokes equations. This model is able to handle adverse pressure gradients and flow separation that are expected in DSS.

The analysis consisted of the characterization of the flow velocity field, and the velocity profile captured at the inlet of the LVOT (Fig. 2A). In-plane jet skewness and eccentricity were quantified in terms of flow angle, θ (angle between the mean flow vector and the unit vector normal to the interrogation plane, Fig. 2A) and displacement, d (distance between the center of the LVOT and the centroid of the top 15% of velocities in the interrogation plane, Fig. 2B).

Figure 2. Interrogation plane hemodynamic endpoints: A) flow skewness, and B) flow displacement.

RESULTS

Velocity Field

While the steepened AoSA did not drastically alter LVOT flow structures, the presence of a DSS lesion substantially affected the intraventricular vortex (Fig. 3), which is known to be crucial for proper LV function. Typically clockwise within a normal LV during diastole, this vortex exhibits counter-clockwise rotation in the presence of DSS. During systole, the model predicted slight variations in flow velocity between the normal and steepened AoSA cases. The normal AoSA appeared to have a recirculation bubble forming downstream of the mitral inlet, while the steepened AoSA exhibited higher velocity magnitude closer to the septal ridge. The presence of the DSS lesion resulted in the generation of a stenotic conditions marked by a systolic jet with increased velocity magnitude due to the narrowed LVOT inlet cross section. Recirculation and vortical structures are evident on the

Figure 3. LVOT velocity predictions during early diastole, mid-diastole, early systole, and at peak-systole (inset: LV pressure-volume curve).

aortic side of the DSS membrane.

LVOT Inlet Flow Characteristics

At peak systole, the velocity profile captured at the LVOT inlet reveals a 12% increase in velocity magnitude near the septal wall ($-0.903 < r/R < -0.733$) in the steepened AoSA relative to the normal AoSA (Fig. 4A). While both the normal and steepened AoSA cases generated relatively flat velocity profiles in the interrogation plane, the presence of a DSS lesion resulted in a high-magnitude (2-fold increase vs. normal AoSA) asymmetric profile with peak velocity occurring near the middle of the LVOT. Flow skewness was increased by the steepened AoSA relative to the normal AoSA (16.8° vs. 7.2° , respectively; Fig. 4B). In addition, while the normal AoSA generated a jet displaced toward the top of the LVOT ($d/R = 0.86$), the steepened AoSA resulted in a reversed eccentricity toward the septal ridge ($d/R = -0.70$; Fig. 4C). While the DSS lesion generated an asymmetric jet with increased velocity magnitude in the unobstructed LVOT region opposite to the lesion, it resulted in decreased flow displacement relative

Figure 4. Peak-systolic LVOT flow characteristics: A) velocity profiles at LVOT inlet, B) flow skewness, and C) normalized flow displacement (R : local interrogation section radius).

to the normal and steepened AoSA cases ($d/R < 0.001$).

DISCUSSION

2D LV simulations with realistic wall motion were performed to assess the effects of AoSA abnormalities and DSS on LVOT hemodynamics. In the absence of DSS, the steepened AoSA contributed to greater flow skewness and increased velocity closer to the septal wall. The presence of a DSS lesion inverted the rotation of the intraventricular vortex, a critical flow structure that aids in maintaining proper leaflet dynamics. Combined with the predicted stenotic flow conditions within the LVOT, these hemodynamic abnormalities could prove detrimental to proper leaflet function and may contribute to overall insufficiency.

Although limited by the simplified 2D geometry, this study demonstrates the existence of significant flow abnormalities in steep AoSA and DSS LVs, which may hamper leaflet dynamics and valvular function. Simulations integrating functional valve leaflets in the LV model are ongoing to elucidate valvular function and potential regurgitation in DSS.

INTRODUCTION

Treatment of intracranial aneurysm using flow diverting devices have become an attractive treatment option for large and complex aneurysms where coiling alone may not be very effective due to a high chance of movement or compaction of the coils [1]. Endo-luminal flow diverting devices are placed along the parent artery and across the aneurysm orifice in order to deviate the flow away from the aneurysm thus promoting aneurysm occlusion and subsequent endothelialization and artery reconstruction. However, the main drawbacks of this approach are that 1) it requires antiplatelet therapy to prevent thrombus formation, 2) they are difficult to use in bifurcation aneurysms as one branch will be jailed. In recent years, new intra-saccular flow diverting devices have been developed [2]. These devices are built as closed braided meshes and released inside the aneurysm cavity in order to disrupt the inflow jet into the aneurysm thus promoting aneurysm thrombosis and occlusion.

As with endo-luminal devices, not all aneurysms treated with intra-saccular devices are immediately occluded after the device is implanted and some need to be retreated in follow up procedures. The purpose of this work is to study the relationship between the hemodynamic conditions created inside the aneurysm immediately after treatment with intra-saccular flow diverters and the long term outcome (complete or incomplete aneurysm occlusion) of the procedure.

METHODS

A collection of 36 aneurysms treated with intra-saccular devices was studied. 3D rotational angiography (3DRA) images were obtained before treatment. 2D digital subtraction images angiography (DSA) images were obtained immediately before and after treatment. The aneurysms were treated with the Woven EndoBridge (WEB) device [2]. The device size was chosen to be 1mm larger in diameter than the

aneurysm width and 1mm smaller in length than the aneurysm depth, thus to allow the device to conform and attach to the aneurysm wall while having enough space to expand towards the fundus.

Computational models of the aneurysm and attached vessels were created from the 3DRA reconstructions [3]. A new tool called cheDeploy was created for deploying models of the intra-saccular devices within the anatomical models. The deployment procedure starts by computing the centerline of the parent vessel. From this centerline, a second straight line is created and positioned inside the aneurysm. A discrete cylinder composed of triangles is generated along this second line and expanded via a combination of radial and contact forces and also restricted to the dimensions of the target device. A braided mesh, represented as a collection of wires, is then generated based on the device characteristics (number of wires, braided angle) and mapped onto the triangular surface. If available, 2D angiography images showing the implanted device are loaded and rendered together with the vascular model and the device model using transparency. The vascular model is then interactively aligned and oriented with the aneurysm and vessels visible in the angiography images. The device model is then rotated and translated to match the implanted device. This procedure is repeated with all the available 2D angiography images until the device model matches the implanted device from all available viewpoints. Figure 1 shows the different steps of the virtual deployment procedure.

Tetrahedral meshes were generated from the anatomical models using an advancing front technique. Spheres matching the wire diameter were generated along the device model wires. Tetrahedral elements in the vascular model that were intersected by the spheres were refined several times in order to capture the effect of the wires on the blood flow (about 5 elements in the wire diameter) [4]. Meshes without the device typically contained between 2 and 5 million elements, while meshes with the deployed device ranged from 100 to 200 million elements.

Figure 1: Virtual Deployment Procedure: From top to bottom: 1) Generation and expansion of the support cylinder, 2) Mapping of an intra-saccular device design, 3) Transparency rendering of the vascular model, device model and available 2D angiography images used for precise device placement.

Unsteady Newtonian incompressible Navier-Stokes simulations were carried out for two cardiac cycles and results from the second cycle were saved [3]. An immersed boundary strategy was utilized to solve the blood flow in presence of the deployed devices [4]. Characterization of the intra-aneurysmal hemodynamic environment before and after treatment was done by the computation of the following quantities: a) mean inflow concentration index (ICI), b) mean inflow rate into the aneurysm (Q), c) mean aneurysm velocity (VE), and d) mean aneurysm vorticity (VO). The percentage change (reduction) of these variables between the pre- and post-treatment models were also computed.

RESULTS

The aneurysms were classified into two groups: A) complete occlusion group (no filling of the aneurysm or device or filling of the device proximal recession), and B) incomplete occlusion group (filling of the device proximal compartment or filling of the device distal compartment). Of the 36 aneurysms included in this study, 18 were classified as complete occlusion and 18 were classified as incomplete occlusion.

Changes in the intra-saccular hemodynamic variables between pre- and post-treatment (i.e. device performance) were compared between the complete and incomplete occlusion groups using the non-parametric Mann-Whitney test. P-values were adjusted for multiple comparison using the Bonferroni method. For each variable with statistically significant difference, univariate logistic regressions were carried out, receiving operating characteristic (ROC) curves were created, and the area under the curve (AUC) was calculated to assess the discriminatory power of each variables.

Figure 1 compares the reduction of flow variables in the complete and incomplete occlusion groups. Small reductions of inflow (ΔQ ,

$p=0.01$) and inflow concentration (ΔICI , $p=0.03$) from pre- to post-treatment is associated with incomplete occlusion. Additionally, the reduction of the mean aneurysm flow velocity tends to be larger for aneurysm in the completely occluded group.

Figure 2: Reduction in intra-aneurysmal hemodynamic variables between pre- and post-treatment. Statistically significant differences ($p<0.05$) are indicated with a “” in the univariate logistic regressions and with a “*” after adjusted for multiple comparisons.**

DISCUSSION

The results of this study indicate that incomplete aneurysm occlusion after treatment with intra-saccular devices is associated with small reduction in the inflow rate and inflow jet concentration from pre- to post-treatment conditions. These results are consistent with previous studies of endo-luminal flow diverting devices [5]. Our results suggest that the change in the aneurysm inflow rate could discriminate between incomplete and complete occlusions at follow up with a predictive power of approximately 82-83%. Interestingly, the univariate logistic regression analysis also indicates that the reduction in the mean aneurysm flow velocity, which could be measured with angiography as a MAFA ratio [6], could discriminate between these groups with approximately 72% accuracy.

This study has some limitations. Patient-specific flow conditions were unavailable and therefore they were adapted from measurements in normal subjects. Vessel walls were approximated as rigid, and blood as a continuous Newtonian fluid. Placement of the virtual devices inside the vascular models were approximated by visually matching the virtual and actual device visible in the DSA images

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) has emerged as a minimally invasive option for treating intermediate and high-risk surgical patients with symptomatic aortic stenosis. Despite its success, multiple clinical reports have emerged revealing adverse events such as leaflet thrombosis [1]. Upon implantation, the transcatheter aortic valve (TAV) stent presses against the native leaflets and acts as a divider between the TAV leaflets and the aortic wall. The space between the native leaflets and the aortic wall is defined as the anatomic (native) sinus while the space between the native and TAV leaflets is defined as the neo-sinus. Early *in vitro* mechanistic studies sought to understand whether flow in the neo-sinus contributed to thrombosis on TAVR leaflets, and it was found that stasis was a predominant flow characteristic in this region [2]. However, Kapadia et al. hypothesized that the anatomical sinus may be of equal importance, affecting flow characteristics of the neo-sinus [3]. Indeed, additional studies have shown that aortic root morphology affects blood flow patterns in the sinus, potentially explaining why thrombus was observed in some patients but not all [4, 5]. Therefore, the aim of this study was to investigate the effects of patient-specific anatomical characteristics (including sinus diameter and sino-tubular junction (STJ) height) on neo-sinus flows using computational fluid mechanics (CFD).

METHODS

3D Reconstruction of Post-TAVR Anatomies. Post-procedural computed tomographic angiography (CTA) of 10 patients who underwent an Edwards SAPIEN 3 (Edwards Lifesciences, CA, USA) valve implantation at University Heart Center Freiburg-Bad Krozingen were segmented using 3D Slicer to obtain 3D reconstructions of the post-TAVR anatomies. Due to imaging artifacts, the segmented valve obtained from the patient images was not well-defined, hence the stent of the SAPIEN 3 valve was obtained via μ CT scanning (Siemens

Medical Solutions USA, Inc., Malvern, PA) while a parametric leaflet model (PLM) was used to create the TAV leaflets. It was matched for each patients' valve characteristics, as obtained from CTA.

Creation and *in vitro* validation of the PLM. The PLM was developed in Rhinoceros® (Robert McNeel & Associates, Seattle, WA, USA). Variables that were parameterized included valve radius, belly curvature, leaflet height, commissure height, and valve opening. The flow results obtained from CFD simulations using the PLM-derived leaflets were validated using *in vitro* flow data. A GT-TAV was deployed into an idealized aortic chamber, where GT-TAV is an in-house valve replicating the dimensions of the TAV being tested and allows optical access into the neo-sinus by using a clear acrylic cylinder to replace the native leaflets. The validated Georgia Tech Left Heart Simulator was used to replicate physiological conditions at peak systole (cardiac output 25 L/min and downstream pressure 120 mmHg) while a 2D particle image velocimetry (PIV) system was used to image the neo-sinus at its center plane. Once validated, the PLM was then used to replicate the dimensions of the SAPIEN 3 valve and coupled with the patient-specific aortic root.

Computational Model for Patient Anatomies. The fluid domain was meshed in ANSYS ICEM CFD (ANSYS, Canonsburg, PA, USA). After performing mesh independence analyses, each patient geometry was mesh with 10-14 million tetrahedral elements. A peak systolic flow rate of 25 L/min was imposed at the inlets assuming a flat velocity profile, while a pressure of 120 mmHg was used at the outlet. All structures were assumed to be rigid and non-permeable, and a no-slip boundary condition was applied at the walls. Blood was assumed to be Newtonian with a kinematic viscosity and density of 0.0036 Pa·s and 1060 kg/m³, respectively. The governing Continuity and Navier-Stokes equations were solved using ANSYS CFX 17.1. The convergence was controlled by defining a root-mean-square residual of 10⁻⁶, which was satisfied after 10 iterations per timestep.

RESULTS

Flow at peak systole was characterized by a high velocity main jet with regions of recirculation in the anatomic sinus (Figure 1). Across patients with the same valve size, there were differences in the flow fields and peak velocities due to variations in ascending aorta diameters and curvature.

Figure 1: Streamlines of main jet velocities for n=10 patients

To better evaluate neo-sinus flow, the percentage of neo-sinus volume with low velocities ($\%Vol_{vel < v}$) was obtained for all patients. Velocity thresholds of $v = 0.02, 0.05, 0.07, 0.09$ and 0.1 m/s were evaluated, with the trend for $v = 0.05$ m/s shown in Figure 2. The results indicated that as the sinus diameter and STJ heights increased, the regions of low flow in the neo-sinus also increased.

Figure 2: Percentage volume of neo-sinus with velocities below 0.05 m/s ($\%Vol_{vel < 0.05 m/s}$) vs sinus diameter (left) and sinotubular junction (STJ) height (right)

Analysis of wall shear stress (WSS) also showed a positive correlation between sinus diameter and STJ heights with the fraction of TAV leaflet surface area with WSS lower than 0.4 Pa ($A_{WSS < \tau, \tau = 0.4 Pa}$) (Figure 3). As expected, these findings of low WSS are consistent with the regions of low velocities.

Figure 3: Fraction of TAV leaflet surface area with wall shear stress (WSS) less than 0.4 Pa ($A_{WSS < 0.4 Pa}$) vs sinus diameter (left) and sinotubular junction (STJ) height (right)

DISCUSSION

The proposed mechanism for thrombus formation on TAV leaflets is increased blood residence time on the leaflets as a result of reduced washout and regions of stasis of the neo-sinus [2]. It is anticipated that a combination of anatomical characteristics including sinus diameters and STJ heights, as well as TAV deployment characteristic including deployment height, tilt angle and rotation, governs the post-TAVR geometry and hence, the flow features observed. *In vitro* assessments of patient-specific hemodynamics in the neo-sinus are challenged by limited optical access of this region. Therefore, this study utilized CFD to evaluate the effects of patient-specific aortic root morphologies on neo-sinus flow under peak systolic conditions.

At peak systole, a positive correlation was observed between the anatomic sinus diameter and STJ heights and the volume of fluid in the neo-sinus with velocities below 0.05 m/s. A potential mechanism for this observed flow behavior is that as the blood entered a large anatomic sinus, its momentum was reduced and as such, had lower velocities. This in turn resulted in a slower moving fluid that entered the neo-sinus, contributing to the low flow in this region. Thrombosis is also most likely to occur in low flow or stasis regions with WSS less than 0.4 Pa, compared with an average value of 1.2 Pa in healthy vessels. Following the same trend as with the low velocity regions, WSS analyses revealed that as anatomic sinus diameter and STJ height increased, the fraction of leaflet area with WSS less than 0.4 Pa also increased.

Some simplifications and assumptions of the physiology and geometry were made in this study. First, the cardiac output was held constant across all patients in order to isolate the effects of patient-specific post-TAVR geometry on hemodynamics. Therefore, all changes in flow fields and related flow metrics were a function of geometry. Second, simulations at additional time points are necessary to quantify the transient progression of flow fields and calculate the blood residence or washout times in the neo-sinus. Third, coronary flow was excluded from the computational model in order to compare and validate with existing *in vitro* methods [2]. Fourth, the aortic wall along with the individual parts of the valve assembly (stent and leaflets) were assumed to be rigid, and the effects of the moving wall and leaflet motion would best be described via fluid-structure interaction (FSI) simulations. However, since this assumption was made for all patient anatomies, relative changes in flow fields are still valid.

Future studies of this work will involve performing FSI simulations of the TAV to simulate temporal variations in flowrate and leaflet kinematics over the cardiac cycle, enabling the quantification of washout in the neo-sinus regions.

INTRODUCTION

Transient Receptor Potential Vanilloid 4 (TRPV4) is a mechanosensitive ion channel that regulates chondrocyte differentiation, endochondral ossification and articular cartilage homeostasis by regulating intracellular calcium in chondrocytes. Mutations of this channel cause a gain of function of TRPV4 and leads to skeletal dysplasia, while excessive mechanical loading activation of TRPV4 has been associated with onset/progression of osteoarthritis (OA). Defining how TRPV4 regulates chondrocyte function and identifying molecular mechanisms that influence TRPV4-mediated calcium signaling may provide therapeutic targets for chondrocyte pathologies.

OA, the degeneration of the articular cartilage of diarthrodial joints, afflicts millions of Americans. While there are a number of risk factors associated with OA, aging is a dominant factor, impacting 50% of adults over the age of 65. During aging, many chondroprotective growth factors, such as Insulin-like Growth Factor-1 (IGF-1), decrease with age. IGF-1 has been shown to be chondroprotective, anti-inflammatory, and beneficial for chondrocyte function in both OA and fracture healing in the elderly (1,2) While Fraenkel, et al. (3) suggest that reduced IGF-1 levels during aging have no effect on the incidence of OA, increasing IGF-1 production in allogenic chondrocyte transplants significantly improved cartilage integrity and biomechanics of cartilage repair in the equine PTOA chip model. Here, we show that IGF-1 tonically suppresses TRPV4 activity through the actin cytoskeleton, leading us to postulate that age-related decline in IGF-1 may lead to a gain of function of TRPV4, suggesting a potential mechanism for the induction and progression of age-dependent OA.

METHODS

Human chondrocytes, murine ATDC5 chondrogenic cells (Sigma Aldrich) and HEK293 (ATCC) cells were used in these studies. Human chondrocytes with TRPV4 mutations (aa. P799L or aa. G800D) were obtained from the tissue bank at AI duPont Hospital for Children. HEK293 cells were either untransfected (HEK-UT) or transfected with TRPV4 wild type (HEK-WT) or with mutations at aa. P799L (HEK-799) or at aa. G800D (HEK-800). Chondrocytes were grown in DMEM and HEK cells were grown in MEM media (Corning) supplemented with 10% Fetal Bovine Serum (Atlas Biologicals) and 1% Penicillin/Streptomycin (Hyclone).

Calcium Imaging: Experiments were conducted as previously described (4,5). All experiments were conducted at room temperature to avoid temperature-sensitive spontaneous TRPV4-mediated calcium oscillations. Unless noted, cells were pre-treated with IGF-1 for 3 hrs prior to loading with either Fluo-4 AM or Fura-2 AM (Life Technologies). Cells were treated with cytochalasin D following loading with the fluorescent calcium chelator. Cells were challenged with 50% Hypotonic Swelling (HTS) after a 1 minute baseline was recorded.

Atomic Force Microscopy: Atomic Force Microscopy with ATDC5 cells was done as previously described (6). Cells were either untreated or treated for 3 hrs with 300 ng/ml of IGF-1, and then either treated with 1 μ M of cytochalasin D. Apparent elasticity was measured on a BioScope II (Veeco, Inc.) mounted on an inverted optical microscope.

Cytoskeletal Immunostaining: ATDC5 cells were treated for 0, 1, 2, or 3 hrs with 300 ng/mL IGF-1. Actin staining with Alexa Fluor 488 phalloidin was completed as described previously (6).

Statistical Analysis: One-way or two-way ANOVAS were used to determine statistical significance, with Tukey-Kramer or Dunnett's post-hoc tests used to compare between all treatment groups or to control, respectively. p-values < 0.05 were considered significant.

RESULTS

IGF-1 is a potent chondrogenic growth factor that is essential for chondrocyte survival, proliferation, and differentiation. IGF-1 can also stimulate actin stress fiber formation (7). To confirm that IGF-1 induces actin cytoskeletal reorganization in chondrocytes, we treated ATDC5 cells with 300 ng/ml of IGF-1. As was previously presented at this conference, IGF-1 increased actin stress fiber formation in a time-dependent manner that corresponded with an increase in cell stiffness (Figure 1A). IGF-1 treatment for 3 hrs significantly increased the apparent stiffness of ATDC5 cells from ~4 kPa to ~13.5 kPa. Disruption of the actin cytoskeleton with 1 μ M of cytochalasin D blocked the increase in cell stiffness induced by IGF-1. This increase in cell stiffness correlated with a significant attenuation of intracellular calcium influx in ATDC5 cells that were pre-treated for 1-3 hrs with 300 ng/ml IGF-1 (Figure 1B).

Figure 1: Time Course of IGF-1 on ATDC5 cells. A) a 3hr time course of actin staining indicates that 300 ng/ml IGF-1 increase actin stress fiber formation during 3 hrs of treatment, B) This increase in actin polymerization corresponds with a significant attenuation of Intracellular Calcium Concentration ([Ca²⁺]_i) when treating cells with IGF-1 over 180 minutes prior to challenging the cells with HTS. n = 3.

Suzuki, et al. suggested that actin can bind to the microtubule associated protein 7 (MAP7) domain of TRPV4 (aa. 798-809) to regulate activity of the channel (8). To confirm these results, we utilized TRPV4 mutations in the MAP7 domain, P799L and G800D, to determine if IGF-1 regulates TRPV4 at this domain. IGF-1 suppressed the Ca²⁺ response to HTS in HEK-WT cells, similar to the response observed in ATDC5 cells. The HEK-799 cells were not significantly suppressed and HEK-800 cells show a significant increase in [Ca²⁺]_i when treated with IGF-1 (Figure 2A). HEK-UT cells failed to respond to HTS, suggesting that osmosensation of HEK cells was TRPV4 dependent. These results indicate that IGF-1 exerts regulatory functions on TRPV4 through the MAP7 domain.

To further confirm that IGF-1 regulates TRPV4 through the MAP7 site, primary human chondrocytes were studied. Human Chondrocytes (HC) appear to be similarly suppressed as HEK-WT when treated with IGF-1 (Figure 2B). Human chondrocytes with a TRPV4 mutation at aa. P799L also show an attenuated response when treated with IGF-1. However, hypotonic challenge of chondrocytes with a TRPV4 mutation at aa. G800D stimulates [Ca²⁺]_i, as similarly seen in the HEK-800 cells.

Figure 2: Effect of IGF-1 on TRPV4 Mutations. A) HEK-WT cells show significant attenuation when pre-treated with IGF-1. No suppression in HEK-799 and HEK-800 cells is noted when they are pre-treated with IGF-1. n=3. A similar trend is seen when primary human chondrocytes (HC) and human chondrocytes with TRPV4 mutations (aa. P799L and G800D) are pre-treated with IGF-1 prior to challenge with HTS. n=1.

DISCUSSION

Our findings highlight how IGF-1 tonically suppresses TRPV4 activity via reorganization of the actin cytoskeleton. During treatment with IGF-1, chondrocytes increase actin stress fiber formation to also increase chondrocytes stiffness. This stiffness was abrogated when the cells were treated with cytochalasin D. This confirms previous studies that indicate that IGF-1 rapidly stimulates actin stress fiber formation (7). Our data indicate that IGF-1 mediates this suppression through the interaction of the actin cytoskeleton at the MAP7 binding domain. When HEK293 cells were transfected with two mutations at the MAP7 domain of TRPV4, IGF-1 failed to attenuate the response of these cells to HTS. Furthermore, our data indicates that human chondrocytes respond similarly to the TRPV4 transfected HEK cells during IGF-1 pretreatment, with the caveat that these experiments need to be repeated. Interestingly, a previous study indicates that supraphysiologic IGF-1 pretreatment of TRPV4 transfected HEK cells can induce a sensitivity of TRPV4 to HTS but studies were not conducted with physiologic treatments of IGF-1 (9).

Sen, et al. have shown that the stimulation of actin stress fiber formation during IGF-1 treatment occurs through the mTORC2 pathway in mesenchymal stem cells (10). Thus, future studies will investigate if this pathway also controls chondrocyte actin fiber formation/cell stiffness during IGF-1 treatment. Physiologically, these data suggest that IGF-1 tonic regulation of the TRPV4 channel is necessary for an anabolic phenotype, while hyperactivity of this channel may cause a catabolic effect. This information could prove useful to improve therapies for OA patients and patients with other chondrocyte pathologies.

INTRODUCTION

Traumatic brain injury (TBI) has become a critical health concern recently due to increased awareness of its potential to cause long-term neurological deficits. Annual estimates for the number of TBIs in the US range between 1.6 and 3.8 million, and approximately 5.3 million Americans live with a disability stemming from a TBI [1]. Severe TBI and repeated mild TBI increase the risk of Alzheimer's disease (AD) and chronic traumatic encephalopathy (CTE), neurodegenerative diseases marked by hyperphosphorylation and aggregation of the tau protein into neurofibrillary tangles (NFTs) in the brain [2,3]. In healthy neurons, tau stabilizes microtubules in central nervous system axons. In tauopathic neurodegenerative diseases, tau is hyperphosphorylated by CDK5 and GSK3 β , causing its aggregation into NFTs. The elevated presence of NFTs in the brains of former boxers and football players suffering from cognitive decline suggests that tau dysfunction mediates the neural deficits seen in CTE. However, it is unknown how these tau pathologies are elicited by mechanical insult of neurons during TBI.

In neurons with an AD mutation, tau is observed to mislocalize to dendritic spines, where it mediates synaptic dysfunction [3]. Here, we hypothesize that a similar mechanism is important in CTE. **We present an *in vitro* system for simulating TBI-like strains on hippocampal neurons that demonstrates a link between mechanical injury, neurodegenerative tau pathology, and functional synaptic deficits.**

METHODS

Construct Fabrication: Elastic membranes were spin coated with a 10 μ m thick layer of Sylgard 527 PDMS at a 1:1 ratio of base to cross-linker. Spin-coated membranes were suspended between two custom-designed metal brackets and a Sylgard 184 PDMS ring was adhered to

them to contain cell culture materials during incubation. Membranes were then coated with 100 μ g/mL poly-L-lysine and 4 μ g/mL laminin to permit cellular adhesion before stretching (Figure 1A).

Cell Harvest, Culture, and Transfection: Primary hippocampal neurons were harvested from newborn rat pups as previously described [3]. Hippocampi were isolated in ice-cold Earl's Balanced Medium with 1mM D-glucose before tissues were digested and cells seeded onto the stretching constructs. The day of plating was denoted as day-in-vitro 1 or DIV1. Weekly media changes were performed thereafter. A standard calcium phosphate precipitation method was used to transfect neurons with desired plasmids at DIV8. Neurons were co-transfected with DsRed and WT-Tau-GFP at a 2:1 ratio. DsRed was used to visualize the morphology of neurons, including the location of dendritic spines.

TBI Simulation, Imaging, and Electrophysiology: A high-speed linear motor was used to simulate TBI-like strains on the seeded neurons on DIV22. Strains ranged from 1-20% and strain rates from 1-1000% strain per second. Tau mislocalization to dendritic spines was quantified 24 hours after injury. Functional synaptic deficits were observed 24 hours after injury by recording miniature excitatory post-synaptic currents (mEPSCs) from neurons bathed in artificial cerebrospinal fluid with APV, tetrodotoxin, and picrotoxin to prevent action potentials [3].

RESULTS

Tau mislocalization to dendritic spines was measured after high velocity stretching (Figure 1B-C). In unstretched neurons the fraction of spines with tau was low, typical of healthy neurons. However, in neurons exposed to a single stretch of 20% strain (ϵ), at a strain rate ($\dot{\epsilon}$) of 1000%/s, we found significant tau mislocalization to dendritic spines

24 hours after stretch, demonstrating that stretch-injury can drive tau pathology *in vitro* (Figure 1D). This tau mislocalization was identical to that seen in previously studied models of AD [3]. mEPSCs are the currents associated with the stochastic release of a single vesicle of neurotransmitter, and their amplitudes and frequencies can be quantified as a proxy for synaptic health or functionality [5]. We found that after a single stretch of $\epsilon = 20\%$, $\dot{\epsilon} = 1000\%/s$, both the amplitude and frequency of mEPSCs decreased significantly compared to control neurons (Figure 1E-G). These results indicated that tau mislocalization and synaptic deficits can both be caused by mechanical injury alone.

Figure 1: Mechanical injury elicits tau pathology and synaptic deficits in neurons. (A) Schematic of stretching construct with seeded neuron. (B) Example stretching protocol for $\epsilon = 20\%$, $\dot{\epsilon} = 1000\%/s$. (C) Representative images of control and stretched neurons transfected with DsRed (red, left) to identify dendritic spines, and WT-Tau-GFP (green, center). Image overlay to quantify tau mislocalization (yellow, right). (D) Quantification of tau mislocalization. (E) Example mEPSC traces. (F) Amplitude of mEPSCs in control vs. stretched neurons. (G) Frequency of mEPSCs in control vs. stretched neurons. Error bars = standard deviation, * indicates statistical significance, NS indicates no statistical difference ($\alpha = 0.05$) in all Figures.

Tau mislocalization was shown to be dependent on the severity or type of simulated TBI in our *in vitro* model. Stretching neurons to a high strain ($\epsilon = 20\%$) over a range of strain rates ($\dot{\epsilon} = 1, 10, 100, 1000\%/s$) revealed that only the most rapid strain rate was able to cause significant tau mislocalization (Figure 2A). Similarly, tau mislocalization was dependent on the magnitude of strain. When stretched at a high strain rate ($\dot{\epsilon} = 1000\%/s$), over a range of strain magnitudes ($\epsilon = 1, 2, 5, 10, 20\%$), only neurons stretched past $\epsilon = 5\%$ displayed any significant tau mislocalization, with tau pathology worsening as strain increased (Figure 2B). To investigate whether repetitive, mild TBI simulations (like those associated with CTE) could lead to tau pathology, we stretched neurons with a previously inconsequential injury ($\epsilon = 2\%$, $\dot{\epsilon} = 1000\%/s$) up to 20 times. Results revealed a cumulative effect with respect to tau mislocalization, as 10 and 20 mild-TBI simulations elicited significant tau mislocalization (Figure 2C).

Figure 2: Tau mislocalization depends on injury severity, and is phosphorylation dependent. (A) Tau mislocalization vs. strain rate. (B) Tau mislocalization vs. strain magnitude. (C) Tau mislocalization vs. strain repetition.

In tauopathic diseases, tau is hyperphosphorylated by CDK5 and GSK3 β , leading to its mislocalization. To investigate if this mechanism was preserved in our model, we used Roscovitine and CHIR-09921 to inhibit CDK5 and GSK3 β , respectively. After drug treatment, severely stretched neurons did not exhibit tau mislocalization different than unstretched control neurons (Figure 3A). Additionally, these drugs prevented the decreases in mEPSC amplitude and frequency that were observed following a mechanical insult (Figure 3B-C).

Figure 3: Kinase inhibitors block tau mislocalization and prevent synaptic deficits following mechanical injury. (A) Tau mislocalization with kinase inhibitors. (B) mEPSC amplitude with kinase inhibitors. (C) mEPSC frequency with kinase inhibitors.

DISCUSSION

Prior work has shown tau hyperphosphorylation, mislocalization, and eventual aggregation into NFTs in the brain to be hallmarks in the degenerative cascade of AD. We present a novel method of *in vitro* TBI simulation that links mechanical neuronal injury to tauopathic cellular features of AD. We have shown mechanically-induced tau mislocalization to be phosphorylation-dependent and have characterized the degree of tau mislocalization with respect to various TBI simulations, providing a cell-scale link between AD and CTE. Additionally, our model provides a connection between the tauopathic consequences of TBI and actual functional deficits in synapses of affected neurons.

INTRODUCTION

In multicellular systems, cells interact with both their extracellular environment as well as neighboring cells. Collective cell behavior has been shown to affect cell behaviors including proliferation (1), morphology (2), and apoptosis (3). Cell-cell contact causes a transfer of forces between cells, which can influence cell behavior due to the stress field that they generate and in turn sense.

There is considerable interest in accurately modeling and calculating the stresses within cell monolayers to understand the underlying mechanical factors affecting cell behavior. Predicting the emergent stress fields is commonly performed with finite element models that simulate cell contractility as prestress or thermal cooling. Additionally, monolayer stress microscopy (MSM) is used for calculating cell-layer stresses from measured traction forces. Both predictions and calculations from TFM indicate high traction stresses in the substrate at the edges of the monolayers and high cell stresses in the central region of the cell layer.

In contrast, specific mechanosensitive biomarkers indicate high cell stresses on the periphery. For example, at the aggregate edge, alpha smooth muscle actin (α SMA), a contractile protein, is highest, apoptosis is lowest, and yes-associated protein (YAP) localizes to the nucleus (1,3,4).

We hypothesize that the discrepancy between predicted cell-layer stresses and measured stress-related biomarkers is the assumption of homogeneous contractile and mechanical properties throughout the cell layer utilized in current models and calculations. In this study, we model geometrically constrained cell monolayers with heterogeneous mechanical properties and compare the simulated and computed cell-layer stresses to stress-related biomarkers.

METHODS

Porcine valvular interstitial cells (VIC) were confined to micro-

contact printed circular collagen islands 200 μ m in diameter on 38.4kPa polyacrylamide (PA) gels prepared on glass coverslips. F-actin, G-actin, and α SMA were stained via phalloidin, fluorescent DNase 1, and anti- α SMA, respectively. Apoptosis and YAP presence were quantified via caspase-3/7 expression and anti-YAP, respectively.

For modeling of cell-layer stress, a thermal cooling finite element model of contraction was performed. Three distributions of contraction were modeled: 1) homogeneous coefficient of thermal expansion, 2) a step change heterogeneous model at half the radius of the aggregate, where the thermal expansion coefficient was reduced by 50%, and 3) an exponential distribution of thermal coefficient based on the measured distribution of cell spread area which is correlated with cell contraction in single-cell experiments (Fig. 2A). For calculation of cell-layer stress from measured traction forces, MSM was performed with three distributions of cell stiffness (modulus): 1) homogeneous, 2) step change in stiffness at half the radius, and 3) exponential distribution of stiffness (high at edge, low in center). Coefficients of thermal expansion (α) were normalized to have the same average value, where for each case, the integral of each curve would equal one another.

RESULTS

Protein markers associated with cell stress and contractility were first measured. It was found that the G-/F-actin ratio decreased radially from the center of aggregates to the edge (Fig. 1A). We measured a doubling of α SMA integration into stress fibers from the center to the edge of aggregates (Fig. 1B). Additionally, we observed a steady decrease of apoptotic activity from 50% present in the aggregate center to nearly 0% present in the periphery (Fig. 1C). Finally, we observed qualitatively YAP nuclear localization in peripheral cells and nuclear exclusion in central cells (Fig. 1D).

The localization of our experimental biomarkers – higher G-actin in central region, higher α SMA incorporation into stress fibers along the edge, apoptosis occurrence in the center, and YAP localization along the periphery – suggest higher cell stress presence along the aggregate edges compared to the center.

For our homogeneous model, cell-layer stress is highest in the center and decreases towards the edge (Fig. 2B, 2D). In the heterogeneous step change model, the 50% reduction in contractility resulted in an opposite trend, where stress increases towards the edge. Finally, the continuous heterogeneous exponential model revealed an even more pronounced trend where circumferential stress is lowest in the center and increases towards the edge. The predicted substrate-level traction stresses were similar between all three conditions (Fig. 2C, 2D).

Figure 1: A) Coefficient of thermal expansion vs. radius. Corresponds to cell area vs. radius, since cell area is linearly correlated with cell contraction in single-cell studies. B) Cell-layer radial (blue) and circumferential (red) stresses for three modeling conditions for contractility. C) Predicted von Mises stresses for three modeling conditions of cell contractility as a function of radius. D) Heat maps of predicted radial, circumferential, and traction stresses for all three conditions.

To calculate the cell-layer stress using MSM, measured substrate stresses from five different aggregates were averaged together to obtain an average radial traction stress versus radius (Fig. 3A). This was input into the finite element model to obtain radial and

circumferential cell-layer stresses for an average aggregate (Fig. 3B). Once again, the homogeneous case showed highest cell-layer stress in the center and lowest on the edges, while both heterogeneous cases exhibited the opposite trend.

Figure 3: A) Average radial traction stresses measured from five aggregates were averaged (black line) and fit with a best fit curve (red dashed). B) Cell-layer radial (blue) and circumferential (red) stresses for three modeling conditions cell stiffness.

DISCUSSION

Here, we have found that cell-layer stresses calculated with models incorporating *heterogeneous* contractile and mechanical properties better correlate with spatial distributions of measured stress-related biomarkers than models assuming homogeneous cell-layer properties. Homogeneous assumptions of mechanical properties led to predicted stresses that are opposite to those expected by the distribution of biomarkers.

These models show that even moderate changes in cellular contractility and stiffness can have drastic effects on the cell-layer stress distribution in confined multicellular systems. Additionally, the projected traction stresses have similar patterns for all conditions, which demonstrate the need for incorporating additional biophysical data (e.g., cell spread area, aspect ratio, etc.) to accurately estimate the stress fields within the cell layers.

We present the first experimental evidence suggesting that low stresses experienced by central cells drive the biological response of aggregates. The current model is the first to incorporate heterogeneous material properties, and data show that this added complexity is required for the accurate estimation of stress distribution in our aggregates. We plan to further tune and validate this model using higher-resolution biophysical data to adjust cell contractility distributions.

INTRODUCTION

Musculoskeletal tissue engineering (TE) is a promising strategy to treat degenerative disorders whereby progenitor cells are embedded in polymeric scaffolds to generate replacement tissues. Transforming growth factor beta (TGF- β) has emerged as one of the most extensively utilized mediators for promoting engineered tissue growth due to its efficacy in yielding rapid extracellular matrix (ECM) biosynthesis via cell receptor mediated signaling. Generally, TGF- β is delivered in culture medium during an *in vitro* growth phase or directly loaded into scaffolds to act on cells after *in vivo* implantation [1]. There is a growing emphasis on the importance of optimizing TGF- β delivery to cells, as growth factor excesses can lead to pathology in engineered tissues [2] or off-target pathology *in vivo* after implantation [3]. However, this optimization remains a considerable challenge, as limited work has been performed on mechanistic models that describe the transport and distribution of growth factors in engineered tissues.

We recently demonstrated that the uptake of TGF- β into engineered cartilage can be accurately described by reaction-diffusion models that account for critical interactions between TGF- β and molecular tissue constituents (scaffold, ECM, and cell receptors) [4]. In particular, TGF- β uptake is highly dependent on the rate of cell-mediated TGF- β degradation, a process that results from degradation following internalization of receptor-bound TGF- β . Accordingly, such transport models can potentially yield faithful descriptions of the distribution of TGF- β in tissues, when provided with accurate measures of this TGF- β internalization rate. Therefore, to expand our modeling capabilities, the aim of this investigation is to characterize the rate of TGF- β internalization over a range of doses that are conventionally administered in TE applications (0.3-300 ng/mL) [1] and to examine the influence of internalization on the distribution of TGF- β in constructs.

An additional characterization is performed to verify that TGF- β degradation results from receptor mediated cell internalization.

METHODS

Tissue source: Immature bovine chondrocytes were seeded in 2% agarose (30 \times 10⁶ cells/mL) to form Ø5 \times 1mm tissue constructs [4]. Freshly-cast constructs were maintained live in chondrogenic media or subjected to an initial freeze-thaw cycle to induce rapid devitalization.

Internalization Rate Measurements: Constructs were exposed to a chondrogenic media bath (500 μ L) supplemented with TGF- β 3 at an initial level of 0.3, 3, 30, or 300 ng/mL. The subsequent uptake of TGF- β 3 into the construct was monitored by measuring the concentration decrease in the bath over time (TGF- β 3 Duoset, R&D Systems). This transient bath decrease was modeled via our reaction-diffusion equation, which accounts for TGF- β diffusion into constructs, reversible binding to the construct scaffold/ECM, and receptor-mediated internalization by construct cells:

$$\frac{\partial C_F}{\partial t} = \underbrace{D\nabla^2 C_F}_{\text{Diffusion}} + \underbrace{(C_B k_r - C_F N_t k_f)}_{\text{Reversible binding}} - \underbrace{R_i C_F}_{\text{Internalization}} \quad (1)$$

C_F : concentration of free TGF- β , C_B : concentration of TGF- β bound to scaffold/ECM, N_t : total number of binding sites, D : TGF- β diffusivity, k_r : reverse binding constant, k_f : forward binding constant, R_i : internalization rate constant. In the presence of devitalized constructs, the TGF- β 3 bath concentration decreases as a result of reversible binding to the construct scaffold/ECM. This transient decrease (n=3 constructs per concentration) was compared to a model with our binding-only reaction-diffusion equation (where $R_i=0$) and finite element solver (FEBio) using previously acquired diffusivity and

binding constants ($D=23 \mu\text{m}^2/\text{s}$, $N_i=200 \text{ ng/mL}$, $k_r=2.5e-05 \text{ s}^{-1}$, $k_f=2.7e-06 \text{ ng}\cdot\text{mL}^{-1}\cdot\text{s}^{-1}$) [4]. In the presence of live constructs, the TGF- $\beta 3$ bath concentration decreases further, as a result of a combination of reversible binding and receptor-mediated TGF- β internalization by living cells. This transient decrease ($n=3$ per concentration) was curve-fit with our full reaction-diffusion equation to extract the internalization rate constant R_i , using the aforementioned parameters from the binding-only model. Subsequently, the TGF- $\beta 3$ internalization rate, V_i (ng/mL internalized TGF- β per second) was calculated as the product $R_i \times C_F$.

Concentration-Dependent TGF- β Uptake Model: To assess the effect of internalization rate of TGF- β transport in constructs, we implemented an FEBio simulation (using aforementioned parameters) to model the uptake distribution of TGF- β in constructs ($\varnothing 6 \times 2.5 \text{ mm}$) supplemented with 0.3, 3, 30, or 300 ng/mL TGF- β in a media bath.

Receptor Media Internalization Verification: To verify that the TGF- $\beta 3$ bath decreases observed with live constructs result from receptor-mediated cell internalization, decreases were monitored in the presence of an alternative isoform TGF- $\beta 1$, which also binds to the TGF- β type-II receptor, and thus competes for internalization with the TGF- $\beta 3$ isoform. Here, transient TGF- $\beta 3$ decreases were monitored in the presence of 0, 10, 100, or 1000 ng/mL TGF- $\beta 1$ and compared to the response with devitalized constructs.

RESULTS

Internalization Rate Measurements: For all initial bath concentrations, in the presence of devitalized constructs, TGF- $\beta 3$ bath levels decreased over time (Fig 1). These transient decreases were faithfully described by our binding-only ($R_i=0$) reaction-diffusion equation ($R^2=0.93 \pm 0.04$). In the presence of live constructs, the TGF- $\beta 3$ bath concentration decreased further, but this difference was less pronounced for higher initial bath concentrations. These transient decreases were faithfully described by our full reaction-diffusion equation ($R^2=0.99 \pm 0.01$), allowing for successful extraction of the internalization rate constant R_i . Accordingly, R_i values decreased with TGF- $\beta 3$ bath concentration (Fig 2A), ranging from $0.0123 \pm 0.0076 \text{ s}^{-1}$ at 0.3 ng/mL to $0.0002 \pm 0.0001 \text{ s}^{-1}$ at 300 ng/mL. The internalization rate, V_i , increased with TGF- $\beta 3$ bath concentration (Fig 2B), following a Michaelis-Menten reaction trend ($R^2=0.99$), whereby $V_{\max}=0.0704 \text{ ng}\cdot\text{mL}^{-1}\cdot\text{s}^{-1}$ and $K_M=57.34 \text{ ng/mL}$.

Concentration-Dependent TGF- β Uptake Model: Theoretical simulations show severe steady state concentrations gradients in constructs during the uptake of all initial bath concentrations (Fig 3). Although mitigated, gradients still persist for high 300 ng/mL dose.

Receptor Media Internalization Verification: The transient decrease of TGF- $\beta 3$ was mitigated in the presence of the competing TGF- $\beta 1$ isoform (Fig 4). At a 100-fold TGF- $\beta 1$ excess, this decrease relative to devitalized samples was no longer observed, suggesting that bath decreases are indeed attributable to TGF- β -specific receptor-mediated internalization.

DISCUSSION

Results demonstrate that our reaction-diffusion model can accurately describe the uptake of TGF- β in engineered tissues (Fig 1), allowing for the novel assessment of the TGF- β internalization rate and its variation with concentration. A striking aspect of this characterization is the remarkably high rate at which chondrocytes internalize this growth factor, as evidenced by pronounced transient concentration decreases even in the presence of the high 300 ng/mL dose. This internalization rate can be described by Michaelis-Menten reaction kinetics, consistent with an anticipated saturation of the cell receptor internalization rate at

high ligand concentrations. Given the exceptionally low doses of TGF- β required to induce ECM synthesis (pM-nM range), internalization rates can greatly influence the transport and distribution of TGF- β in engineered tissues, as evidenced by highly pronounced gradients in tissue constructs (even for 300 ng/mL dose) when administered in culture media (Fig 3). The internalization rate relations advanced in this study can serve as a foundation for the development of sophisticated transport models that can predict the distribution and activity of growth factors in musculoskeletal TE applications (media supplemented or direct scaffold loaded [1]). These models can yield critical optimizations of growth factor delivery protocols, allowing for substantial improvements in tissue homogeneity [4], tissue quality [2], and reductions in off-target pathology [3].

A MICROPATTERNING APPROACH TO STUDY CELLULAR COMMUNICATION VIA MECHANICAL FORCES IN FIBROUS MICROENVIRONMENTS

Christopher D. Davidson, Brendon M. Baker

Department of Biomedical Engineering
University of Michigan
Ann Arbor, MI, USA

INTRODUCTION

The ability of cells to communicate with each other to coordinate their activity is crucial to the specification, development, and homeostatic function of all tissues. Intercellular communication via secretion of biochemical signals or through cell-surface receptors has been extensively studied [1], but more recent studies suggest an additional means via cell-generated forces propagated through the extracellular matrix (ECM). Mechanical signals are potentially faster, longer range, and more directionally focused than diffusive factors, and such communication has been observed in a variety of settings spanning different cell types, distinct ECM settings, and at scales ranging from multicellular clusters to single cells [2,3]. Despite this breadth of evidence, however, we have yet to parse the specific means and code by which cells communicate mechanically.

The generation and transmission of mechanical signals (i.e. cellular traction forces) largely depends on the mechanical properties of the underlying ECM, and fibrous microenvironments have been theorized to be an optimal structure by which tensile forces can be transmitted [4]. However, commonly used fibrous materials to study cell behavior *in vitro*, such as collagen and fibrin, lack mechanical and architectural tunability for mechanistic studies. Thus, here we developed a microfabrication-based patterning approach to study single cell behavior on tunable synthetic fibrous matrices towards further understanding the relationship between ECM physical properties and the mechanical signals sent and received by cells.

METHODS

Cell culture: Human umbilical vein endothelial cells (ECs) were cultured in endothelial growth medium supplemented with 1% penicillin-streptomycin-fungizone. Lentiviral transduction of lifeAct-GFP was utilized for live cell time-lapse imaging. **Fiber network**

fabrication: Dextran methacrylate (DexMA) was dissolved at 0.5 g ml⁻¹ in a 1:1 mixture of milli-Q water and dimethylformamide with 0.1% Irgacure 2959 photoinitiator and 0.0025% methacrylated rhodamine. This solution was electrospun, stabilized by primary crosslinking under UV light (100 mW cm⁻²) for 60s, hydrated in varying concentrations of LAP photoinitiator solution, and then exposed again to UV light for 20s. Matrices were then functionalized with the peptide CCRGDS (RGD) to facilitate cell adhesion. **Single Cell Patterning:** DexMA fiber matrices were suspended over an array of microfabricated poly(dimethylsiloxane) (PDMS) wells fabricated by soft lithography. To position one cell in the center of each matrix, we fabricated a cell-patterning mold containing an array of microwells (comparable in size to a single EC) with alignment grooves corresponding to the arrayed fiber substrates (**Fig. 2a**). ECs were allowed to settle into the microwells for five minutes, and cells outside of the wells were gently flushed away with PBS. The fiber substrate was then carefully placed on top of the patterning mold via the alignment grooves and the assembly was inverted and incubated for 30 minutes to allow single cells to settle and adhere to the matrix. **Staining and Microscopy:** Three-channel time-lapse microscopy was performed over an 8h period during which cells spread, with imaging of F-actin, DexMA fibers, and 1 μ m fluorescent microspheres (Fl- μ S) embedded in fibers every ten minutes. Cells were fixed, permeabilized, and stained simultaneously with phalloidin and DAPI. For vinculin immunostaining, samples were fixed, permeabilized, blocked for 1 h in 1% fetal bovine serum, and incubated with anti-vinculin antibody (1:1000, Sigma #V9264) for 1h before counterstaining with phalloidin and DAPI. **Statistics:** Significance was determined by ANOVA or Student's t-test where appropriate, with significance indicated by $p < 0.05$. All data presented as mean \pm std.

RESULTS

To examine intercellular interactions in fibrous matrices, we first seeded ECs at a range of cell densities on compliant matrices. At high seeding density, ECs spread, physically reorganized matrix fibrils, and formed intercellular connections, as previously observed [5,6] (**Fig. 1a**). In contrast, at low seeding densities, isolated cells remained unspread. Although not controlling for paracrine signal effects, this experiment suggests spacing between cells and sensing of cell generated traction forces may impact cell spreading. Supporting this, cells seeded on stiff matrices showed a distinct response with a linear increase in spread area as a function of seeding density (**Fig. 1b**). Quantifying the formation of multicellular structures, we noted ECs on deformable matrices formed larger clusters than stiff matrices at the same seeding density (**Fig. 1c**).

Towards a deeper investigation of the generation and transmission of forces between cells in fibrous ECM, we sought to quantify matrix displacements from individual ECs. We developed a microfabrication-based method to precisely pattern single ECs onto fiber substrates of varying diameter (**Fig. 2a**). ECs patterned on 500 μm diameter suspended matrices of varying stiffness were stained for actin and vinculin to visualize the cytoskeleton and focal adhesions, respectively (**Fig. 2b**). Soft matrices revealed higher levels of fiber recruitment as compared to intermediate and stiff conditions. Furthermore, ECs on soft matrices exhibited increased focal adhesion size as compared to stiffer matrices (**Fig. 2b,d**). Combining this patterning technique with time-lapse confocal microscopy, we visualized matrix displacements as ECs spread and exerted traction forces. To quantify matrix displacements, FI- μS embedded within fibers were tracked during cell spreading (**Fig. 1c**). On soft matrices, FI- μS displacements were noted across the entire suspended matrix (up to 250 μm away from the cell centroid). With increasing matrix stiffness, however, the magnitude and range of displacements decreased, where stiff matrices displayed negligible displacements across the entire matrix (**Fig. 2c,e**).

Figure 1. a) Confocal fluorescent images of phalloidin-stained ECs (cyan) and rhodamine-labeled fibers (magenta). Cell spreading (b) and maximum cell cluster size (c) as a function of seeding density and matrix stiffness. Scale bar: 100 μm .

DISCUSSION

Mechanical interactions between cells and the ECM have been shown to be crucial in many biological processes. In this work, we integrated previously developed synthetic fibrous matrices [5] with a cell patterning approach to enable investigations into how physical properties of fibrous ECM regulate intercellular mechanical communication. In initial studies, we found that compliant matrices that deform under the action of cell forces also enable cell spreading and the formation of multicellular clusters, supporting the possibility of intercellular communication via mechanical forces. To further investigate how cells send mechanical signals in the form of cell force-mediated matrix deformations, we developed a multilayered microfabrication-based method to pattern single cells onto these matrices. We found that soft matrices that promote cell spreading and

clustering above threshold seeding densities reveal longer-range matrix displacements as compared to stiffer matrices. Furthermore, ECs within soft matrices also possessed larger focal adhesions than those on stiff fibers. As focal adhesion size has been previously been linked to force generation [7], this data suggests that compliant matrices could lead to increased force generation in ECs. Future work using this approach will investigate the role of other physical properties on cell adhesion, spreading, and tractions (matrix displacements) including fiber density and proximity to a rigid boundary condition (via variable fiber well diameters) with the goal of identifying the magnitudes and dynamics of force transmission that facilitate directed cell extension and migration.

INTRODUCTION

Endothelial cell (EC) dysfunction, defined as decreased nitric oxide (NO) production via endothelial nitric oxide synthase (eNOS), is a unifying precipitating factor in cardiovascular disease. NO regulates vascular tone, thrombosis, inflammation, dilation, and remodeling [1]. Steady laminar flow promotes a healthy, quiescent EC phenotype in which EC phosphorylate eNOS to produce NO [2]. However, EC in areas of oscillating disturbed flow have impaired NO production. These areas of disturbed flow are linked to EC dysfunction and diseases such as atherosclerosis [2,3].

In addition to phosphorylation, eNOS can also be glycosylated through the hexosamine biosynthetic pathway (HBP) at the same site where it is phosphorylated. In the HBP, UDP-N-acetylglucosamine (UDP-GlcNAc) is added to protein serine and threonine residues via O-GlcNAc transferase (OGT) and removed via O-GlcNAcase (OGA). EC cultured in high glucose have elevated HBP flux, which increased eNOS O-GlcNAcylation and thereby decreased eNOS phosphorylation and NO bioavailability [4-6]. eNOS O-GlcNAcylation also increased in diabetic animals, which inhibited eNOS phosphorylation and NO production [6].

While eNOS O-GlcNAcylation and its effect on eNOS phosphorylation has been studied in altered glucose conditions, eNOS O-GlcNAcylation has not yet been studied in flow. We hypothesized that steady laminar flow, but not oscillating disturbed flow, decreases eNOS O-GlcNAcylation, contributing to a healthy, quiescent phenotype. In support of this hypothesis, we measured eNOS O-GlcNAcylation in EC exposed to steady laminar and oscillating disturbed flow. We further determined how eNOS O-GlcNAcylation impacted eNOS phosphorylation, NO production, and EC dysfunction.

METHODS

Human umbilical vein endothelial cells (HUVEC) were maintained in Endothelial Growth Medium-2 supplemented with 10% fetal bovine serum, 1% penicillin-streptomycin, and 1% L-glutamine. For flow studies, 17,000 cells/cm² HUVEC were seeded on collagen Type 1 coated 60 x 15 mm culture dishes. A custom-built cone-and-plate device, with three independent, yet parallel samples, was used to apply shear stress to HUVEC. For laminar flow, the cone-and-plate device was programmed to administer unidirectional flow with 20 dynes/cm² shear stress. For disturbed flow, the device was programmed to administer oscillatory flow with 4±6 dynes/cm² shear stress. In some experiments, HUVEC were treated with 1 mM 2-deoxy-2-glucose (2-DG). Following 24 hours of flow, protein O-GlcNAcylation, OGT, OGA, p-eNOS, eNOS, GAPDH, and β -actin were analyzed via Western blot. Comparisons between two groups were analyzed by Student's t-test (# p<0.05, * p<0.01, ** p<0.001).

Glycolytic intermediates were quantified for isotopologue enrichment in stable isotope tracing experiments by mass spectrometry. 5 mM ¹³C₆-glucose was added to HUVECs for 5 minutes immediately after flow. 80:20 methanol:water was used to quench metabolic activity in cells. Following extraction, sample supernatants were dried under nitrogen gas and analyzed via liquid chromatography mass spectrometry.

For *in vivo* vessel analysis, the descending aorta and aortic arch from 5-month-old C57BL/6J wild type mice were dissected and sectioned. Sections were quenched in 30% hydrogen peroxide, blocked with Avidin D and Biotin blocking reagents, and analyzed for O-GlcNAcylation using a primary GlcNAc antibody (1:100), goat anti-mouse secondary antibody (1:100), and an HRP-conjugated ABC reagent. Samples were imaged using an Olympus DS60 microscope at 40x magnification.

RESULTS

We first measured how protein O-GlcNAcylation changed in EC exposed to 24 hours of static culture, steady laminar flow, or oscillating disturbed flow. While total protein O-GlcNAcylation was unchanged, O-GlcNAcylation of a ~140 kDa protein was decreased by approximately 75% in EC exposed to steady laminar flow. No change in protein O-GlcNAcylation was observed in cells exposed to oscillating disturbed flow (Figure 1). We confirmed that the 140 kDa protein was eNOS by immunoprecipitation and siRNA knockdown. Counterintuitively, OGT remained constant and OGA decreased in steady laminar flow by approximately 40%. These data suggest that the decrease in eNOS O-GlcNAcylation in steady laminar flow was not related to changes in OGT and OGA.

Figure 1: HUVEC adapted to steady laminar flow for 24 hours showed a specific decrease in eNOS O-GlcNAcylation without a change in total protein O-GlcNAcylation. Static ('S'), steady laminar ('L', 20 dynes/cm²), oscillating disturbed flow ('D', 4±6 dynes/cm²), or 5 mM glucosamine ('G', positive control) for 3 hrs. Data normalized to GAPDH.

To confirm that eNOS O-GlcNAcylation changes with flow conditions *in vivo*, we labeled mouse aortae for O-GlcNAcylation in areas of laminar flow (descending aorta) and areas of disturbed flow (aortic arch) (Figure 2). We observed increased O-GlcNAc labeling in the aortic arch endothelium, suggesting that protein O-GlcNAcylation is increased in disturbed flow areas of arteries.

Figure 2: Protein O-GlcNAcylation was higher in the aortic arch (disturbed flow) of C57BL/6J WT female mice (5 months old) as compared to the descending aorta (laminar flow). Arrows highlight the endothelium.

We next investigated several mechanisms which might decrease eNOS O-GlcNAcylation in steady laminar flow, including decreased glucose transport, UDP-GlcNAc, as well as OGT and OGA activity. The glucose transporter GLUT1 and OGT/OGA activity remained unchanged in steady laminar flow. However, we did observe decreased UDP-GlcNAc and overall glycolytic flux, as measured via ¹³C₆-glucose mass spectrometry, in HUVEC exposed to steady laminar but not oscillating disturbed flow (Figure 3A). When we inhibited glycolysis

in HUVEC exposed to disturbed flow via 2-DG, a glucose analog that is taken up by the cell but cannot undergo glycolysis, we effectively decreased eNOS O-GlcNAcylation (Figure 3B). These data suggest that the shear stress-induced decrease in glycolysis and hence HBP flux and UDP-GlcNAc substrate availability may lead to decreased eNOS O-GlcNAcylation.

Figure 3: (A) HUVEC adapted to steady laminar for 24 hours showed decreased UDP-GlcNAc by mass spectrometry. (B) HUVEC adapted to oscillating disturbed flow ('D') + 1 mM 2-DG for 24 hours showed decreased O-GlcNAcylation of eNOS compared to disturbed flow without 2DG (normalized to β-actin).

We further demonstrated that modulating OGT and OGA activity affects overall and eNOS O-GlcNAcylation. When OGA was inhibited in HUVEC exposed to steady laminar flow, eNOS O-GlcNAcylation increased and phosphorylation decreased. In contrast, when OGT was inhibited in HUVEC exposed to oscillating disturbed flow, eNOS O-GlcNAcylation decreased and phosphorylation increased. These data suggest eNOS phosphorylation and NO production can be increased in disturbed flow by decreasing eNOS O-GlcNAcylation. Thus O-GlcNAcylation may be a valid therapeutic target in EC dysfunction.

DISCUSSION

We now show for the first time that steady laminar flow, but not oscillating disturbed flow, decreases eNOS O-GlcNAcylation, which may contribute to enhanced eNOS phosphorylation and increased NO production. Additionally, modulation of eNOS O-GlcNAcylation in disturbed flow can restore eNOS phosphorylation. This research advances our understanding of EC dysfunction and may lead to novel therapies to prevent EC dysfunction. Targeting areas of disturbed flow for therapeutic interventions, such as decreasing O-GlcNAcylation, may increase NO and reduce EC dysfunction and the progression of cardiovascular disease.

INTRODUCTION

Identity has long been established as an integral facet of learning [1]. Social identity in particular, meaning the extent to which an individual perceives themselves as belonging to a social group, has been implicated as a key factor in determining an individual's sense of belonging and interest in a career or field [2]. More specifically, a STEM+M identity, a form of social identity that is the extent to which an individual feels accepted in STEM+M (Science, Technology, Engineering, Math, and Medicine), has strong implications in either affording or impeding an individual's engagement in STEM+M. This idea of STEM+M identity is of particular relevance to minority groups that have historically been underrepresented across STEM+M fields [3]. Factors limiting the STEM+M identity of minority groups include perceived lack of self-efficacy, limited mentorship opportunities, and established stereotypes in STEM+M [4,2]. If underrepresented groups felt a stronger identification as a member of the ingroup of STEM+M, there could be improved engagement and retention of these groups within STEM+M. Not only is this beneficial for the economic and social capital that these careers afford, but also for increased diversity of perspectives in STEM+M, potentially leading to innovation and better delivery of healthcare.

A necessary step in an individual developing this STEM+M identity is discovering self-efficacy in STEM+M. STEM+M self-efficacy is established when an individual constructs a belief that STEM+M has value and on that foundation finds that they are capable of success in STEM+M [4,5]. However, in order to effectively develop this self-efficacy as a means to fostering a long-term STEM+M identity, students must first be taught STEM+M through ideas that they will individually value. With emphasis on middle school age students (as research shows that career trajectories can be determined as early as middle school [5]) from underrepresented minority backgrounds, sports

are a natural choice of topic on which to focus STEM+M education. Previous work has shown a positive perception of STEM through sports [6].

In this study, a basketball camp was used as a platform for demonstrating to students that a proficiency in STEM+M can improve performance not only in the classroom, but also on the court. By doing so, the value these students associate with basketball was connected to STEM+M. We hypothesized that involvement in this program would result in improved perception of STEM+M and a higher value assigned to STEM+M fields.

METHODS

In order to engage middle school students from the community in STEM+M, the research team hosted the Youth Sports Lab (YSL), a week-long summer camp at Columbia University in collaboration with 4th Family, an Albany-based nonprofit organization. YSL was a basketball training camp that used athletic performance and biomechanics as a platform for STEM+M education. The students were recruited for their interest in basketball from a Harlem-based after school program and community partner, After-School All Stars. A week of curricula was executed, with a heavy emphasis on biomechanics, including basketball drills, engineering design, and engagement with STEM+M professionals (Figure 1). The research team served as the program coordinators and coaches, and consisted of faculty and students (graduate and undergraduate) in STEM, several of whom had collegiate athletic experience. We tested the hypothesis that sports based STEM+M education would increase participants' interest in STEM+M with a 15-question survey before and after the camp. Responses were on a 5-point Likert scale. Significance was determined with a Wilcoxon signed rank test for paired nonparametric data. This survey-based

protocol was approved by the Columbia University Institutional Review Board.

Figure 1. Sample schedule of the YSL programming.

The students were all male, about to enter grades 6-9 (age 11-14; $n = 14$). The ethnic backgrounds included African American ($n = 5$), Hispanic/Latino ($n = 1$), Caucasian ($n = 2$), and multiracial including 2 or more of the previous ethnicities (and Asian; $n = 6$) (6).

STEM Connections. Students participated in basketball drills and scrimmaging each day (as in traditional basketball camps). During the basketball drills, the students collected data on their teammates as an exercise on how data collection on metrics such as sprint speed and shooting percentage can help players work towards improved performance on the court. Students were led in a lesson on how to construct and use their own vertical jump measurement platform based on methods previously described [7].

Guest Speakers. Guest speakers were invited from STEM+M fields as examples of career paths that are available in close proximity to sports. Speakers included a Columbia Orthopedics Sports Medicine physician, a physical therapist, a motion capture technician, the Columbia women's basketball team, a Columbia Strength and Conditioning coach, and an NBA player.

Final Deliverable. The week culminated with a poster session wherein students presented the results of a research question that they answered using techniques learned during the week. Their poster session was attended by faculty members and graduate students from the Departments of Biomedical Engineering and Orthopedic Surgery. Figure 2 shows the students and coaches after finishing the poster session.

Figure 2. YSL coordinators and participants at the poster session.

RESULTS

The results from the pre- and post-survey are represented in Figure 3. A positive value indicates a greater value assigned to STEM+M. Results demonstrate significant increases in assigned value to STEM+M for 9 questions. These questions were (1) how confident are you in your ability to evaluate your strengths and weaknesses, (3) do you know what you need to practice to improve as a player, (4) do you think that math and science topics can make you a better athlete, (5) how familiar are you with sports analytics (the use of math and statistics to measure player performance in sports), (6) how familiar are you with sports science (the use of science to measure performance in sports), (8) how interested are you in pursuing a career in medicine, physical therapy, or athletic training, (9) do you think that you know how to use

sports analytics and science to improve your own athletic performance, (12) do you think that you know enough about your sport to reach your goals as a player, and (15) do you think that what you learn in math and science class can be used in sports analytics?.

DISCUSSION

The significant increases in survey responses, and therefore in perception of STEM+M, demonstrates that the students' self-efficacy in STEM+M was influenced by the program, with potential impact on their long-term STEM+M identity. Even after meeting collegiate and NBA players, interest in STEM+M increased without a change in interest in sports ((2) asked how important do you think athletics are for your future career?), suggesting the impact of the STEM+M content on the students. Exposure to STEM+M leaders provided an opportunity for students to see successful professionals who look like them and demonstrated the many ways that sports and career can overlap.

The long-term goal for this project is to build student self-efficacy in STEM+M and improve their STEM+M identity to increase their opportunities for success in STEM+M. Efforts at Columbia University have been made to forge a pipeline towards STEM+M collegiate programs and careers for students in under-resourced K-12 schools [8]. This project extends this pipeline for students with personal investment in sports. The hope is that this will imbue students who are underrepresented in STEM+M with the confidence and STEM+M identity to pursue higher education and careers in STEM+M. The long-term effectiveness of this program will be assessed by following the cohorts of students in coming years as they make college and career decisions.

Figure 3. Change in response from pre- to post-survey on interest in STEM+M. P values denoted by: * 0.01 to 0.05, ** 0.001 to 0.01, *** 0.0001 to 0.001. Standard deviation denoted with bars.

ACKNOWLEDGEMENTS

INTRODUCTION

Coronary artery disease is the leading cause of death in the United States in 2017.¹ Despite a decrease in myocardial infarction (MI) mortality rates in the last decade, the incidence of heart failure continues to grow and remains a major public health issue.² While fibrotic scarring is a vital repair process post-MI, long-term outcomes of cardiac remodeling can include left ventricular (LV) dilation, hypertrophy, and ultimately heart failure.

Myocardial strain is a powerful metric for characterizing infarcted tissues. Its ability to quantitatively characterize wall kinematics at the interface between healthy and infarcted myocardium is of particular interest in the study of infarct expansion. However, most ultrasound studies focus on evaluating global metrics of LV function, such as ejection fraction and global longitudinal strain,³ and rely on 2D analysis, which are sensitive to out of plane motion.⁴ To date, a longitudinal study investigating the spatial distribution of myocardial strain following an MI has yet to be conducted. Here, we extended ultrasound strain studies to 3D to characterize the mechanical behavior of the LV near infarct border zones to understand how strain contributes to tissue remodeling.

METHODS

Animal Surgery: Fifteen male, C57BL/6 mice (age = 14±1 weeks; weight = 27±3 grams; JAX Laboratories, Bar Harbor, ME) were separated into three surgery groups: 1) sham (n=5), 2) ischemia reperfusion (n=5), and 3) permanent ligation (n=5). Mice were anesthetized with isoflurane and endotracheally intubated prior to left-thoracotomy. To induce an infarct in the LV, we either temporarily ligated the left coronary artery for 30 minutes before reperfusion or permanently ligated the vessel. In the sham group, we looped the suture around the left coronary artery without ligating the vessel. Mice were then closely monitored during recovery.

Ultrasound Imaging: All cardiac ultrasound images were collected using the Vevo2100 ultrasound system (FUJIFILM VisualSonics Inc,

Toronto, Canada) with a 40 MHz transducer (MS550D). We acquired 4D ultrasound data as described previously.⁵ Briefly, successive cardiac and respiratory gated 2D ultrasound videos were acquired in short-axis at 1000 Hz from the apex to the base of the LV by utilizing a linearly translating 3D motor prior to spatial registration performed in MATLAB (MathWorks Inc., Natick, MA). Ultrasound images of the LV were acquired at baseline and on days 1, 2, 3, 5, 7, 14, 21, and 28 post-surgery.

Strain Estimation: We defined a rectangular coordinate grid on the 4D data and used non-rigid registration to estimate deformation gradients directly from warping functions as described previously.⁶ The estimated deformation gradient tensor **F** was then used to calculate the maximum principal component of the 3D Green-Lagrange (GL) strain tensor **E** (Equation 1), where **I** is the identity matrix.

$$\mathbf{E} = \frac{1}{2}(\mathbf{F}^T\mathbf{F} - \mathbf{I}) \quad (1)$$

Endocardial, epicardial, and sternal artifact boundaries of the LV were segmented in SimVascular⁷ at end-diastole and peak-systole and used to measure ejection fraction. We created binary masks from segmentations to isolate strain values within the myocardium. LV boundaries were then unwrapped from cartesian to polar coordinates relative to the LV apex to present maximum principal 3D GL myocardial strain in accordance to AHA's 17 segment-model.⁸ We then evaluated strain profiles to estimate infarct boundaries and size. Principal strains within the infarct zone and neighboring regions were plotted as normalized radial distance from the center of the infarct, with infarct boundaries located at 0.5 normalized units. Statistical analysis was conducted using a one-way ANOVA with Tukey post-hoc analysis.

RESULTS

Mice that underwent sham surgeries did not exhibit remarkable changes in either geometry or strain profiles, while those in the permanent

Fig. 1: Maximum principal 3D GL strain (E_1) maps of mouse LVs taken at baseline and 4 weeks post-surgery. **Top:** 3D representations of peak-systolic LV boundaries with surface strains overlaid to endocardial boundaries. Epicardial boundaries are shown in gray. Scalebar = 1mm. **Bottom:** Bullseye maps of maximum principal strain measured within the myocardium throughout a representative cardiac cycle. Strain-estimated infarct zones are outlined with solid black lines with infarct centers marked as black crosshairs. Sternal artifacts are outlined with black dashed lines.

ligation (PL) group experienced significant remodeling marked by wall thinning, LV dilation, and low strains within the infarcted myocardium (dark blue regions in **Fig. 1**). Mice in the ischemia reperfusion (I/R) group had smaller degrees of cardiac remodeling with smaller infarct sizes (IS) when compared to the PL group ($IS_{I/R}=11\pm4\%$ vs. $IS_{PL}=46\pm15\%$; $p<0.01$). Regional analysis revealed significant reductions in maximum principal strain within the infarct zone when compared to baseline and sham groups ($E_{I,Baseline}=0.41\pm0.04$, $E_{I,Sham}=0.39\pm0.05$ vs. $E_{I,I/R}=0.18\pm0.10$, $E_{I,PL}=0.06\pm0.03$; $p<0.05$). The remote, healthy myocardium maintained normal contractile function with strain values of 0.40 ± 0.03 (**Figs. 1, 2**). No statistical difference

in strain was observed in the sham group when compared to baseline. Regions of akinetic myocardium contributed to significant reductions in ejection fraction (EF) in infarcted LVs ($EF_{Baseline}=68\pm3\%$ and $EF_{Sham}=66\pm3\%$ vs. $EF_{PL}=23\pm12\%$ and $EF_{I/R}=50\pm7\%$; $p<0.05$).

DISCUSSION

The objective of this study was to investigate the role of myocardial strain on infarct expansion. Both permanent ligation and ischemia reperfusion models of MI have been reported in literature to have different degrees of remodeling in terms of infarct size.⁹ This distinction can be clearly visualized in **Fig. 1**, by comparing areas of low-strain (dark blue) regions. Interestingly, the two models exhibited distinct strain profiles in regions adjacent to infarct boundaries (**Fig. 2**). The sigmoidal distribution of strain, along with the steep spatial strain gradient observed in the permanent ligation group are key characteristics of this MI model that undergoes severe remodeling compared to the ischemia reperfusion model, which has lower spatial strain gradient at infarct boundaries. Future work will focus on quantifying how regional myocardial strain gradients influence early stage remodeling and the directionality of expansion in asymmetrical infarcts.

INTRODUCTION

A number of recent studies have shown higher rates of cardiac deaths following proximal compared to distal aortic stenting [1,2]. An improved understanding of the *in-vivo* mechanics of the aorta is required to uncover the biomechanisms underlying such adverse outcomes. In this study a novel 4D Flow MRI protocol is developed and implemented to allow visualisation of the dynamic deformation of and flow within the entire aorta for all stages of the cardiac cycle. For the first time, this *in-vivo* investigation uncovers a non-linear aortic compliance and heterogeneous pulse wave velocity (PWV) throughout the entire human aorta. Advanced dynamic image analysis software is developed to construct patient specific aortic finite element (FE) models. Simulations provide the first quantitative description of the *in-vivo* non-linear heterogeneous aortic material behaviour. Furthermore, a suite of histological analyses of human cadaveric aortic tissue are performed to uncover a micro-structural explanation for the aortic material behaviour uncovered by the MRI and *in-silico* investigations. Finally, the framework is used to simulate proximal and distal stenting procedures and for the first time the influence of stent position on aortic PWV is uncovered in a patient-specific model. Proximal stenting is shown to result in a higher increase in PWV than distal stenting, providing a mechanistic explanation for high mortality rates observed clinically.

METHODS

In the field of phase contrast MRI maximal sensitivity is obtained for protons moving at a velocity equal to the specified VENC value. This presents a particular challenge for determination of blood flow patterns in the aorta where flow is highly unsteady and non-uniform. The novel dual-VENC protocol proposed in this study generates a composite dataset, with a high-VENC of 200 cm/s targeted to systole

and a low-VENC of 50 cm/s targeted to diastole (Figure 1(a)) following a series of VENC scouts. Analyses are performed at 10 planes along the human aorta. The boundary of the fluid domain is isolated for each plane and phase of interest to determine the lumen area as a function of space and time based on a custom-built segmentation algorithm (Figure 1(b)). For each of the planes analysed, the cross-sectional-area change (ΔA), volumetric flow rate (Q) and PWV (Figure 1(c)) are determined. Additionally, temporal compliance is investigated by plotting instantaneous area versus pressure at each location along the aorta (Figure 1(d)).

The regional aortic bioarchitecture responsible for vessel compliance is also assessed using histological and stereological techniques. Previous studies have been limited to animal tissue [3], or to a single location of the human aorta [4]. Aortic samples are harvested from 5 adult human cadavers (age range 67 – 92 years, mean 77.6 years) with no reported history of aortic disease. By excising samples at various sites along the aorta (Figure 2(a)), localized tissue fractions of both elastin and collagen are determined (Figure 2(b)). Additionally, regional wall layer thicknesses and layer specific collagen fiber orientations are also investigated for each of the sample sites. A sample collagen fiber density histogram is shown in Figure 2(c).

Finally, a patient-specific FE model of the aorta is generated directly from the MRI data (Figure 3(a)), through custom built advanced dynamic image analysis software. The aorta is modelled as a compressible anisotropic material using the modified anisotropic (MA) formulation through an Abaqus UMAT (Figure 2(c)). Regional parameter sets are found through a Levenberg-Marquardt based optimization algorithm, which minimizes the error between experimental (MRI) and simulated pressure versus area curves. Collagen fiber orientations (θ) from cadaveric specimens are used in the anisotropic formulation. Finally, two commercially available nitinol

stent-grafts are deployed into the aorta to investigate the regional effects of stenting on the vessel. The pre- and post-stenting loss in cross-sectional-area change ($\delta\Delta\hat{A}$) and gain in PWV are shown in Figure 3(d).

RESULTS

The importance of the dual-VENC composite approach to characterising aortic flow in both systole and diastole is shown in Figure 1(a), where the aortic fluid domain in diastole is not captured using the High-VENC alone (HV_{Diastole}). Area and flow versus time profiles for a series of aortic locations are illustrated in Figure 1(b). Percentage change in area between diastole and systole ($\Delta\hat{A}$), (which decreases distally) in addition to local PWV (which increases distally) are presented in Figure 1(c). Figure 1(d) illustrates the patient-specific pressure boundary condition used in the calculation of temporal compliance and a sample pressure versus area plot, highlighting significant strain stiffening behaviour within each cardiac cycle.

Figure 1: *In-vivo* aortic biomechanics derived from 4D Flow MRI.

Excision sites from the aorta of each cadaver in the study series are shown in Figure 2(a), which also outlines the orientation of tissue sectioning performed for both area quantification (AF) and fiber orientation (FO) analyses. A sample of each staining procedure is shown in Figure 2(b) in addition to the elastin and collagen percentage breakdown of the aortic wall for each excision location. Elastin is shown to decrease (27% vs. 17%) while collagen increases (22% vs. 53%) with increasing distance from the heart. Figure 2(c) shows post-staining, the orientation of collagen fibers within the wall, in addition to the corresponding probability density histogram. The collagen fiber orientation and dispersion data (θ and κ) are implemented into the modified anisotropic (MA) constitutive law outlined in [5].

Figure 2: Characterization of regional aortic bioarchitecture.

The vessel construction algorithm used to generate a FE mesh directly from MRI data is shown Figure 3(a). Figure 3(b) (top) shows that the anisotropic non-linear MA model provides an accurate prediction of the *in-vivo* MRI behaviour, in contrast to the linear isotropic Neo-Hookean material model., Figure 3(b) (bottom) shows that a homogeneous set of material properties provides a highly inaccurate prediction of the *in-vivo* behaviour. Figure 3(c) shows the local tissue stiffness (K) plotted at each element highlighting the regional variation in compliance along the aorta in both the low- and high-pressure regimes of each cardiac cycle. Finally, the impact of stent deployment on regional compliance is shown in Figure 3(d), where a significantly larger drop in area change

($\delta\Delta\hat{A}$) in each cardiac cycle exists in the proximal (64%) compared to the distal (14%) aorta. Proximal stent deployment is also shown to have a greater increase on PWV compared to distal (129% vs 50%).

Figure 3: FE model and characterization of *in-vivo* biomechanics.

DISCUSSION

A novel dual-VENC 4D Flow MRI protocol is developed and implemented in a commercial scanner to achieve a complete characterization of the entire human aorta. Results confirm, for the first time, that the *in-vivo* aortic compliance is highly non-linear and cannot be characterized by a single value coefficient, as commonly assumed in clinical practice. In contrast, compliance is shown to alter significantly during the cardiac cycle, with significantly higher compliance being observed during periods of low blood pressure. Additionally, our *in-vivo* characterization reveals that aortic compliance is highest proximally, where a 65% change in lumen area is observed over a cardiac cycle, compared to a 15% change in lumen area in distal regions. Furthermore, the baseline PWV is lower in the thoracic than the abdominal aorta. Our comprehensive *in-vivo* characterization provides a significant advance on previous *in-vitro* mechanical testing of excised specimens of aortic tissue [6]. Our histological and stereological analyses show that elastin decreases in the distal aorta whereas collagen increases, providing a microstructural explanation for the heterogeneity in compliance observed in our *in-vivo* MRI measurements. The development of a FE model built directly from our *in-vivo* MRI data and using input from our histological studies represents a significant advance in the state of the art. Simulations provide the first computational characterization of the heterogeneity, non-linearity and anisotropy of the aorta *in-vivo*. We demonstrate that the assumption of homogeneous material behaviour, results in highly inaccurate predictions. Finally, our simulations reveal that insertion of a stent results in highly stiffened and linear vessel behaviour, in contrast to the highly compliant and non-linear behaviour of the native vessel. Proximal stenting is shown to result in a higher increase in PWV than distal stenting, providing a mechanistic explanation for the high mortality rates following proximal stent insertion clinically.

5-HT_{2B} ANTAGONISM CONTROLS BORDER ZONE MECHANICS TO IMPROVE OUTCOMES FOLLOWING MYOCARDIAL INFARCTION

INTRODUCTION

Over 1.5 million Americans present with myocardial infarction (MI) annually. While mortality from acute MI has dropped dramatically in recent years, heart failure cases are on the rise and there are no effective therapies that substantially mitigate fibrosis, the underlying cause of heart failure [1]. The pervasiveness of this pathology results in substantial societal and economic costs.

MI causes permanent cardiomyocyte death, which are replaced with a stiff, collagenous scar. Heightened stress on border zone cardiomyocytes leads to scar expansion into distal myocardium and ultimately, heart failure. Where replacement fibrosis is required to prevent cardiac rupture, reactive fibrosis results in tissue stiffening and exacerbates myocardial damage [2]. The intersection of dense, collagenous scar and compliant myocardium creates a highly active environment and is the focal point of tissue remodeling and scar expansion.

Serotonin signaling is highly upregulated during cardiac injury and plays a role in fibrotic activity. Signaling through the 5-HT_{2B} receptor cross-talks with TGFβ1 signaling to alter the pro-fibrotic activity of myofibroblasts [3]. The objective of this work is to understand the role 5-HT_{2B} plays in scar formation. Therefore, we hypothesize antagonizing the 5-HT_{2B} receptor can limit remodeling of the infarct border zone after MI to preserve cardiac function and prevent heart failure following MI.

METHODS

MI was induced in WT mice by permanent ligation of the left coronary artery. Echocardiography was performed prior to and following MI using the Vevo2100 system. Starting day of surgery and for the following 21 days, mice were treated with 1 mg/kg/day of the 5-HT_{2B} antagonist RS-127445 (RS) or DMSO control. Short axis M-mode images were analyzed for cardiac structure and function, and the

VevoStrain package (VisualSonics) was used to analyze long axis B-mode images for global longitudinal strain (GLS). Mice were sacrificed after 42 days. Hearts were frozen in OCT, cryosectioned at 7 μm thickness and subjected to atomic force microscopy (AFM) or histological analysis. BioScope Catalyst AFM (Bruker AXS, Santa Barbara CA) was operated in Peak Force–Quantitative Nanomechanical Mapping mode in fluid. Collagen fiber thickness was assessed using picrosirius red (PSR) staining imaged under polarized light and quantified using a color segmentation algorithm in MATLAB. Cardiomyocyte area was assessed using a wheat-germ agglutinin (WGA) stain and analyzed using a custom pipeline in the CellProfiler software. Quantitative polymerase chain reaction (qPCR) was performed on RNA isolated from flash frozen tissue. Data were analyzed using Student's t tests (for 2-group comparisons) or 2-way ANOVA (for multiple group comparisons) with mean ± SEM indicated. P < 0.05 was considered significant.

RESULTS

Ejection fraction in RS treated animals was preserved out to 42 days post-MI compare to control DMSO treatment (**Fig. 1A**). However, there was no change in cardiac structure indicated by similar left ventricular inner diameters during both diastole and systole (**Fig. 1B**). Since preserved structure was not the driver of improved function, we employed the VevoStrain software package to measure deformation caused by myocardial contraction to calculate GLS, a measurement of cardiac function independent of factors such as heart rate and loading conditions. GLS decreased similarly 7 days post-MI in both treatment groups, however, RS preserved contractility 21- and 42-days post-MI. Furthermore, GLS decreased from day 7 to day 21 and from day 21 to day 42 in the DMSO cohort, indicating a continued deterioration of contractility (**Fig. 1C**).

Fig. 1: Functional effect of 5-HT_{2B} antagonism in response to MI. Combined echocardiographic data in WT mice treated with RS or DMSO (N=10-25). A) Ejection fraction, B) Left ventricular inner diameter, C) Global longitudinal strain. * indicates difference between treatments. # indicates difference compared to previous time point.

We then proceeded to investigate the tissue properties that lead to increased myocardial contractility 42 days post-MI. AFM was used to quantify tissue stiffness in both the scar and border zone (BZ). While scar stiffness was not reduced, BZ stiffness was noticeably reduced with 5-HT_{2B} antagonism (Fig. 2A). PSR stain was subsequently used to assess fibrosis. There was no difference in the collagen volume fraction (data not shown). Imaging under polarized light revealed the birefringent properties of collagen fibers whose colors correspond to fiber thickness. As seen in Fig. 2B, there was no difference in collagen fiber thickness distribution in the scar. However, in the BZ, there was a decrease in the proportion of thicker collagen fibers with RS treatment. Control animals had more thick collagen fibers and fewer thin collagen fibers in the border zone compared to the scar.

Fig. 2: Histological effect of 5-HT_{2B} antagonism in response to MI. A) AFM quantification of tissue stiffness with topographical map overlaid with stiffness. B) Picrosirius red stain imaged under polarized light to assess collagen fiber thickness. * indicates difference between treatments. # indicates difference between scar and BZ.

Finally, WGA stain was used to identify the cell walls of cardiomyocytes. Quantification of the cross-sectional area determined that DMSO treated animals had larger cardiomyocytes, indicating cardiac hypertrophy (Fig. 3A-B). Non-scar tissue was digested and RNA isolated for qPCR analysis of *Nppa*, the gene encoding the heart failure marker ANP. We observed a decrease in *Nppa* transcription in RS treated animals (Fig. 3C).

Fig. 3: 5-HT_{2B} antagonism reduces heart failure markers 42 days post-MI. A) WGA stain shows decreased cardiomyocyte size and B) qPCR shows decreased expression of *Nppa*. * indicates significant difference between treatments.

DISCUSSION

Our findings indicate 5-HT_{2B} is a viable target for manipulating border zone remodeling that occurs post-MI. We see that cardiac function is preserved independent of cardiac structure out to 42 days post-MI with 5-HT_{2B} antagonism. This functional increase is due to preserved compliance of the left ventricle, as seen in the GLS measurement derived from wall deformation.

To understand the mechanism behind the preserved contractility, we probed the mechanical properties of the cardiac tissue. AFM analysis indicated no change in scar stiffness, however there was an effect of RS treatment in the border zone, resulting in softer, more compliant tissue. A contributing factor to this border zone stiffness is the distribution of collagen fiber thickness. RS treatment resulted in a higher proportion of thin collagen fibers, decreasing resistance to deformation.

Finally, we looked at markers of heart failure to understand the potential for 5-HT_{2B} antagonism to preserve cardiac function and prevent the progression to heart failure, which is pervasive among those who have suffered MI. We first noticed a decrease in cardiomyocyte cross-sectional area with RS administration, indicating less hypertrophy. Also, *Nppa* expression, the gene encoding the heart failure marker ANP, was reduced with RS.

Our data reveal a novel approach for therapeutically controlling the mechanical environment post-MI to optimize healing and prevent the progression to heart failure. Further studies to elucidate the cell population responsible for these effects as well as further characterization of the border zone tissue are needed to solidify 5-HT_{2B} antagonism as a viable therapy following MI.

INTRODUCTION

Accurate estimation of *in vivo* nonlinear, anisotropic mechanical properties of the aortic wall of individual patients remains to be one of the critical challenges in the field of cardiovascular biomechanics. Using multi-phase (e.g. diastole and systole) clinical images, traditional inverse methods are based on finite element (FE) updating schemes using stochastic-deterministic optimization algorithms, however, these methods are highly computationally-expensive, which can lead to thousands of nonlinear FE iterations, inhibiting rapid feedback for clinical use. Moreover, these approaches have only been validated by numerically-generated data.

In this study, we developed an integrated machine learning (ML)-inverse FE approach to identify the patient-specific material properties of the aortic wall from gated 3D CT scans. A ML model is utilized to expedite the identification process: once trained, the prediction can be made within one second. An inverse finite element method is developed using the multi-resolution direct search (MRDS) strategy, which can be applied to new aorta shapes beyond the ML training dataset. The number of iterations was significantly reduced comparing to the traditional approaches. The ML and inverse approaches have been integrated to achieve a balance between speed and accuracy (Figure 1): if the *in vivo* shapes are similar to those in the training dataset, the ML model will be invoked, otherwise the inverse method will be applied.

Figure 1: Framework of the integrated approach.

METHODS

Constitutive Model: A fiber reinforced hyperelastic material model [1] is used to characterize the aortic wall, given by

$$\Psi = C_{10}(\bar{I}_1 - 3) + \frac{k_1}{2k_2} \sum_{i=1}^2 [e^{k_2[\kappa \bar{I}_1 + (1-3\kappa)\bar{I}_{4i} - 1]^2} - 1] \quad (1)$$

where C_{10} , k_1 , k_2 , κ are material parameters. θ is another parameter that defines the mean fiber direction (not shown in Eqn. (1)). The five parameters $\{C_{10}, k_1, k_2, \kappa, \theta\}$ will be identified from CT image data.

Image Registration: After image segmentation, nonlinear image registration algorithms are applied to obtain the full displacement field (i.e. mesh correspondence). Rigid iterative closest point algorithm is used to remove the rigid motion of the aorta due to heart movement during cardiac phases.

Inverse Method: The optimal set of material parameters can be found by minimizing a geometry-matching based objective function. The pre-stresses of the aorta are incorporated using the generalized pre-stressing algorithm (GPA) [2], which avoids finding the unpressurised state by iteratively performing FE simulations. Many constitutive models have highly coupled material parameters, which causes identification difficulties known as local optima. In the MRDS, multiple level representations of material parameters are established using a data science approach, and searching is performed from coarse to fine in a new space derived from 10,529 sets of stress-stretch curves.

ML Model: the ML model consists of an unsupervised shape encoding module and a nonlinear mapping module. The systolic and diastolic shapes are encoded by shape codes using principal component analysis (PCA). The nonlinear mapping between the shape codes and the material parameters is established by a neural network. For new aorta shape, a threshold value of PCA reconstruction error is used to determine whether the ML model is appropriate.

RESULTS

Experimental Validation: The inverse method was validated using pre-operative gated CT scans and corresponding surgically-resected tissue samples of two ascending thoracic aneurysm (ATAA) patients (Patient 1: a 67 years old male; Patient 2: a 68 years old female). Using the MRDS, the node-to-surface errors between the image-derived and the FE-deformed systolic geometries were minimized to 0.41 mm and 0.77 mm for Patient 1 and 2, respectively.

Tissue samples were trimmed into 2~3 square-shaped specimens (2 specimens for Patient 1, and 3 specimens for Patient 2) with a side length of 20~25 mm. The specimens underwent planar biaxial tests to extract their experimentally-derived material properties. The inversely-estimated material properties were compared with the experimentally-derived material properties. Using the inversely-estimated and the experimentally-derived material parameters, stress-stretch response were computed analytically under equi-biaxial condition, and the stress-stretch curves were plotted in Figure 2. The two specimens of Patient 1 demonstrate almost identical stretch-stress response, whereas the three tissue specimens of Patient 2 show different stress-stretch responses, which indicate that the material properties are heterogeneously distributed. For both patients, the average experimental responses show relatively good agreements with the inversely-estimated responses.

Figure 2: Equi-biaxial stress-stretch curves determined from the inversely-estimated and experimentally-derived material parameters.

Training and Testing of the ML Model: Training/ validation and testing datasets were gathered from FE simulations. Using statistical modeling methods, a large number of material parameter sets are generated from 65 sets of experimentally-derived material parameters, and virtual aorta geometries at one physiological phase (i.e., systole) are generated from 3D CT images of 25 real patients. The diastolic aorta geometries are determined from FE simulations using the virtual systolic geometries and the generated material parameters. Finally, the training/validation dataset and the testing dataset consist of 15,366 and 225 input-output pairs, respectively. Using the training/validation dataset, the performance of the neural network was assessed through leave-one-out and ten-fold cross-validations, and the neural network structure was fine-tuned.

The trained ML-model was able to predict the material parameter within one second. To evaluate the prediction of the ML-model, i.e., to examine how accurate the prediction is compared to FE simulation data, the ML-model was trained on the training/validation set and then the trained ML-model was used to predict the material parameters using shapes in the testing set as the input. The actual versus predicted material parameters in the testing set are shown in Figure 3, which indicate that the ML-predicted material parameters are in good agreement with the actual material parameters in the testing dataset.

Figure 3: The actual and predicted material parameters.

DISCUSSION

The inverse method and experiments achieved relatively good agreement in the biaxial stress-stretch curves. The node-to-surface errors between the FE-deformed and the image-derived geometries were 0.41mm and 0.77mm for Patients 1 and 2, respectively, which are less than or equal to the size of a voxel ($0.75 \times 0.75 \times 1$ mm). This marks, to our knowledge, the first study that directly estimate *in vivo* nonlinear, anisotropic material properties of the ATAA from gated CT scans with validations on experimental data of planar biaxial tests.

The close match between the actual and predicted material parameters demonstrates that the ML model can predict constitutive responses with high accuracy. The computational efficiency is significantly improved using the integrated ML-inverse FE approach. If the aorta shapes are suitable for the ML approach, the material parameters can be predicted instantaneously and repeatedly, such that *in vivo* material parameter identification in real-time can be possible. If the aorta shapes are not similar with the training data, the inverse FE method can also identify the material properties in a fast and accurate manner using the MRDS strategy, which takes about 1~2 hours in a desktop PC with a quad-core CPU and a 32GB RAM.

It is known that the aortic tissue properties are heterogeneously distributed. The stress-stretch curves (Figure 2 (C) and (D)) also suggests material heterogeneity. In the current method, we only considered a simplified scenario, where the averaged *in vivo* wall thickness was used, and the averaged constitutive behavior of the aorta segment was investigated. The discrepancy in Figure 2 may be attributed to location-dependent material property distribution. In a previous study, we developed a stress-matching based strategy [3] for *in vivo* material identification, which leveraged the fact that the aortic wall is approximately statically determinate under physiological loading conditions. This strategy can be easily extended for element-wise identification of heterogeneous material parameters of the aortic wall. We are currently working to incorporate heterogeneous material parameters identification into the integrated approach.

INTRODUCTION

Despite the tremendous effort in the research and clinical communities to understand the symptoms and clinical sequelae of concussions, as well as clinical management of concussion [9, 14], there has been less information regarding the mechanisms of concussions [16–17], particularly differences in impact exposure at different levels of play (e.g., age, experience, size, etc.) [18, 19]. While head impact exposure for high school and collegiate levels has been widely studied, there are few comparative investigations across levels of play. Additionally, there is surprising divergence in the current literature on the comparative differences between youth and college head kinematics, with some studies showing high school athletes experience lower severity impacts, and others suggesting the opposite [2-4]. In many of these studies, however, the authors tested only one of the two age groups, and subsequently compared their kinematics parameters with those gathered by other groups, thus not accounting for the variability in experimental design and data processing.

Elucidating differences in the impact exposures experienced at different ages could guide the design of diagnostic systems and age appropriate protective gear. The purpose of this study is to compare biomechanical measures of head impact exposure, obtained through the use of our improved, instrumented mouthguard (MiG2.0), during a football season between a National Collegiate Athletic Association (NCAA) Division I football team and a small, mid-level high school football team.

METHODS

We developed an instrumented mouthguard, the Stanford MiG2.0 (*Figure 1a*), in collaboration with Intel Corporation, which measures six-DOF head impact kinematics. On the MiG2.0, linear acceleration is measured using a triaxial accelerometer (H3LIS331DL, ST Microelectronics, Geneva, Switzerland) with a range of ± 400 g, sampled at 1000 Hz. Angular kinematics are measured using a triaxial gyroscope (ITG-3701, InvenSense Inc., San Jose, CA, US) with a range of ± 4000 degrees/sec, sampled at 8000 Hz (*Figure 1b*). When a threshold of 10g is detected by the linear accelerometer in any of its components, the device is triggered to acquire and store 50ms of data

prior to the trigger and 150ms of data post-trigger. Data is stored in an on-board flash memory chip and can be wirelessly downloaded at a future time. This device has been validated extensively in previous studies in its accuracy in measuring angular and linear kinematics [6-9]. Raw angular velocity and linear acceleration data downloaded from the device was filtered at 300 Hz using a 4th order Butterworth low-pass filter with cutoff frequency of 300 Hz. After processing, an impact detection algorithm was used to distinguish between real impacts and false positives resulting from spitting, chewing, dropping, or other spurious signals [10].

The MiG2.0 was deployed to 24 collegiate football players during the 2017 Fall NCAA season and 2018 Spring season over all practices and games through human subject protocol IRB-34943. A total of n=460 video-confirmed impacts were collected during this time period. As part of on-going efforts to instrument over 1000 high school football players at 10 high schools with the MiG 2.0, we also deployed our device to 88 participants from three high schools over the 2018 Fall season in a pilot deployment through human subject protocol IRB-46537. Thus far, we have processed and analyzed n=128 impacts that have been identified using our impact detection algorithm [10]. All data were collected in accordance with the Stanford Administrative Panels for the Protection of Human Subjects guidelines and regulations.

Figure 1: MiG2.0 custom-made mouthguard instrumented with a triaxial accelerometer and triaxial gyroscope (a) EVA mold (b) sensory board with wireless charging and infrared sensor for proximity detection [5].

We analyzed peak linear acceleration ($a_{l,p}$), peak angular acceleration ($a_{a,p}$), and peak change in angular velocity ($\Delta v_{a,p}$) as biomechanical measures of interest. Probability distributions were fit to the aggregated data.

RESULTS

Head kinematics measures are summarized in **Table 1**, with the full distributions displayed in **Figure 2**. Concerning peak linear acceleration magnitudes, we found mean values of the two groups to be significantly different ($p < 0.01$), though the distributions have identical magnitudes for the 50th percentile values. Angular accelerations peak magnitude distributions, though not significantly different at the 0.01 significance level, report a higher mean impact acceleration for high school athletes than for college athletes.

Figure 2: Head kinematics distributions for peak linear acceleration, peak angular acceleration and change in peak angular velocity magnitudes. Normalized probability density functions are graphed on log scale. The third distribution follows a log normal distribution.

	Mean	50 th	95 th	99 th
Peak Linear Acceleration (g), $a_{p,l}$				
High School	11.71	10.69	19.85	26.08
College	16.37	10.63	29.96	47.42
Peak Angular Acceleration (rad/s²), $a_{p,a}$				
High School	3084	2107	7912	12395
College	2314	1643	6216	13111

Table 1: Head impact kinematics metrics at 50th, 95th, 99th percentiles and means.

DISCUSSION

Though the distributions of head impact kinematics seem rather similar between high school and collegiate football, we summarized two interesting findings. First, we found that the collegiate linear acceleration distribution had a significantly higher mean ($p = 0.01$), than that of high school. Additionally we found the mean peak angular acceleration to be higher in high school impacts than in college impacts (though not significant at $\alpha = 0.01$).

While the first finding is intuitive given the higher level of skill, weight and age amongst other factors, at a higher level of play such as collegiate NCAA, it is surprising that peak angular accelerations are of similar magnitude in high school athletes and collegiate athletes. Given that head rotation has been hypothesized as the primary contributor to brain tissue injury [13], high school athletes may be subjected to similar levels of brain injury despite the different level of play, expertise, and muscular build. An understanding of injury biomechanics, beginning at the level of impact magnitude, could elucidate the need for prevention methods to promote health of youth athletes.

Similar studies have also found peak impact magnitudes to be higher for high school athletes than for collegiate athletes [3]. The explanation suggested by the authors is that collegiate athletes may have a more developed musculature system, that is better able to control head motion after impact [3]. However, previous research has provided

evidence suggesting that the neck musculature plays a very minor role in impact biomechanics [20].

We hypothesize that the lack of high statistical significance for the difference in mean of angular acceleration magnitudes could be due to the relatively small sample size ($n = 128$) for high school impacts collected. As an ongoing goal to instrument over 1000 athletes at 10 high schools, we are currently processing and analyzing thousands more impacts. Moreover, we plan to assess the brain tissue strain-related response to angular and linear acceleration traces with a validated final element model of the human brain, the Global Human Body Model (GHBM), in order to quantify measures of brain injury such as maximal principal strain.

Finally, we note that, while our angular acceleration magnitudes are within range for the values previously reported in the literature (and mostly collected through the HITS system), our linear peak magnitudes are 50–79% lower than previously reported values, which range between 40g and 96g for the 95th percentile of youth football [12–15]. While early studies with instrumented helmet systems were extremely valuable in providing the first human studies in this field, our findings demonstrate increased accuracy of our measuring system, where the difference in measurements can likely be attributed to the relative motion of the helmet and the skull.

ACKNOWLEDGEMENTS

The authors would like to thank Stanford Athletics and the football teams involved in the study for their support in this research. We would also like to thank Camarillo Lab interns who aided in data collection. Research reported in this publication was supported by the National Institute of Neurological Disorders and Stroke of the National Institutes of Health under Award Number R24NS098518.

PLASTICITY AND ELASTO-PLASTIC DAMAGE MECHANICS USING REACTIVE CONSTRAINED SOLID MIXTURES: A MODELING APPROACH FOR BIOMEDICAL MATERIALS

Brandon K. Zimmerman (1), Gerard A. Ateshian (1)

(1) Department of Mechanical Engineering
Columbia University

INTRODUCTION

The design of biomedical devices frequently incorporates plastic deformation as a desirable behavior. For orthopedic implants, e.g. those in the hip and knee, the material must have a Young's modulus low enough to ensure that sufficient stress will be transferred to the surrounding bones to maintain their healthy function. The search for biocompatible materials with a low elastic modulus has led researchers to various titanium alloys [1], which tend to exhibit significant plasticity. Plastic deformation may also arise during device function, e.g. the large plastic strains required to expand a coronary stent. During material selection and device design, computational modeling is required to predict *in situ* function; consequently, plasticity must be incorporated into the constitutive models of the material.

FEBio is a free finite element software package designed to meet the computational needs of the biomechanics and biophysics communities (febio.org) [2]. This study describes the formulation of a novel theoretical framework for plasticity and elasto-plastic damage based on reactive constrained solid mixtures, and its implementation into FEBio. Although plasticity has been extensively studied within the field of continuum mechanics, its dependence on internal state variable theory requires specification of evolution equations for internal variables and adds significant complexity.

We propose to model plasticity in the context of reactive constrained solid mixtures [3,4], where mechanics are governed by breaking and reforming of bonds (e.g., chemical bonds) within the material; the mechanical response is thus controlled by the material composition. Breaking and reforming of bonds is governed by chemical kinetics, subject to the axiom of mass balance. In this framework, bond concentrations represent observable state variables, obviating the need for postulating evolution equations for internal (hidden) variables. The implementation of this model into FEBio extends the available material

behaviors of the software and allows simulation of the response of medical device materials to physiologic loading.

In this framework, loaded bonds break and reform in a stressed state. The deformation gradient of the stressed state is given by a constitutive assumption that describes the plastic strain field. This model naturally develops plasticity with kinematic hardening, which recovers the classical Bauschinger effect [5]. The framework is additionally enriched by allowing plastic deformation to produce damage, culminating in an elasto-plastic damage model.

METHODS

In this reactive framework, bonds which break and reform at a given time $t = u$ are referred to as u -generation bonds, where the earliest generation corresponds to $u = -\infty$. Kinematics are referred back to this earliest generation, which has a reference configuration \mathbf{X}^s and is called the master reference configuration.

Consider a loaded bond which breaks and reforms into a new bond at $t = u$ with a different reference configuration \mathbf{X}^u . The deformation gradient of this u -generation bond is the relative deformation gradient \mathbf{F}^u , related to the master deformation gradient $\mathbf{F}^s = \partial \mathbf{x} / \partial \mathbf{X}^s$ via

$$\mathbf{F}^s = \mathbf{F}^u \cdot \mathbf{F}^{us} \quad (1)$$

where the mapping $\mathbf{F}^{us} = \partial \mathbf{X}^u / \partial \mathbf{X}^s$ relates the reference configuration of the u -generation to the master reference configuration, and defines the plastic deformation. Unlike the Kroner-Lee decomposition in classical plasticity, \mathbf{F}^u is time-invariant and prescribed by constitutive relation; it does not represent a state variable in this formulation.

Plastic deformation is determined by a yield criterion

$$\varphi(\mathbf{F}^u) = \Phi(\mathbf{F}^u) - \Phi_m \leq 0 \quad (2)$$

where $\Phi(\mathbf{F}^u)$ is a yield measure (e.g. the von Mises stress) and Φ_m is the threshold at which yielding occurs. When $\varphi(\mathbf{F}^u) = 0$ and $\dot{\varphi}(\mathbf{F}^u) > 0$ at time $t = v$, u -generation bonds are breaking and reforming into

v – generation bonds, where $\phi(\mathbf{F}^v) \leq 0$. To satisfy the requirement that the reforming generation be below the yield threshold, we require that the increment in the deformation between $t = v - dt$ and $t = v$ be due to plastic deformation only, where dt is an infinitesimal time increment such that the u – generation is extant at $v - dt$. We further constitutively require that this plastic deformation be isochoric, in accordance with experimental results. These constraints imply

$$\mathbf{F}^{vs} = \left(\frac{\det \mathbf{F}^s(v)}{\det \mathbf{F}^s(v-dt)} \right)^{-1/3} (\mathbf{F}^u)^{-1}(v-dt) \cdot \mathbf{F}^s(v) \quad (3)$$

i.e. Eq. (3) constitutively defines the plastic deformation such that $\mathbf{F}^v(v)$, given by Eq. (1), satisfies $\phi(\mathbf{F}^v) \leq 0$.

The free energy density of each bond is only a function of the relative (elastic) deformation gradient \mathbf{F}^u , such that the referential mixture free energy density (free energy per unit referential volume) is $\Psi_r = \sum_{\alpha} w^{\alpha} \Psi_0^{\alpha}(\mathbf{F}^{\alpha})$, where the summation runs over all generations and w^{α} and Ψ_0^{α} are the mass fraction and referential free energy density of the α – generation. As only one generation is extant at any given time, $w^{\alpha} = 1$ for the extant generation and $w^{\alpha} = 0$ for the others.

Kinematic hardening behavior emerges naturally from the above framework by allowing multiple bond types $\alpha = 1, \dots, n$, to exist in the mixture, each with its own yield threshold Φ_m^{α} , producing a Masing-like model [5]. In this simple extension, each bond type yields when its threshold is reached, and different bond types do not interact.

Damage of bonds is introduced by reducing their mass fraction such that $w^{\alpha} = (1 - D)w_0^{\alpha}$ [6]. In this expression, $0 \leq D \leq 1$ is a scalar damage variable which is a function of the plastic strain and w_0^{α} is the mass fraction when there is no damage. If multiple bond types are used, each has its own damage variable which is a function of the plastic strain in that bond type.

RESULTS

Several characteristic plastic behaviors have been reproduced to validate the present models of reactive plasticity and reactive elasto-plastic damage and to demonstrate agreement with experimental results.

In stress-strain curves produced from uniaxial tension testing, both perfectly plastic and kinematic hardening behavior can be observed (Fig. 1a). Perfect plasticity occurs by having only one bond type that yields at a single threshold, whereas kinematic hardening occurs when multiple bond types yield at progressively greater thresholds. Real stress-strain behavior can be recovered by incorporating plastic strain-based damage into the model; e.g. see the fit for Al-2024 in Figure 1b.

Figure 1. (a) Stress-strain behavior for different plastic parameters, recovering both perfectly plastic and kinematic hardening behavior. (b) Stress-strain curve for Al-2024, fit by adding damage to the plasticity model.

Under cyclic loading, kinematic hardening naturally emerges from this framework and recovers the well-known Bauschinger effect, where loading in one direction affects the yield threshold upon reversal. Figure 2a clearly shows compressive yielding begins much earlier than tensile yielding, as the yield surface has shifted due to previous plastic flow.

Isochoric plastic deformation is a constitutive assumption supported by experimental evidence, although careful experiments measure nonzero volume changes during plastic flow. Due to our

formulation's use of multiple bond types, restricting the isochoric deformation to the plastic parts via Eq. (3) allows us to exactly predict the volumetric deformation experimentally observed during load-unload cycles (Fig. 2b) by curve-fitting the stress-strain data [8].

Figure 2. (a) The classical Bauschinger effect emerges from the model during cyclic loading. Grey arrows indicate loading path. (b) Predicted volume change during load-unload cycles, compared to results from maraging steel. Prediction was generated by first fitting the stress-strain curve, then simulating load-unload experiment.

Finally, strain-controlled tensile testing of a dogbone specimen produces familiar necking (Fig. 3) due to isochoric plastic flow.

Figure 3. Necking behavior observed during FEBio simulation of strain-controlled uniaxial tension. (a) Initial geometry and (b) final fractured geometry, simulated with octant symmetry.

DISCUSSION

This study presents the formulation and finite element implementation of a reactive constrained mixture theory for plasticity incorporating damage mechanics, based on observable state variables. The behavior of the model was validated through reproduction of well-known plastic behaviors, and demonstrated both the ability to curve-fit experimental results and predict separate experiments. In contrast to classical theories of plasticity, the presented model has no need to postulate evolution equations for internal variables governing the material response; rather, the observable evolving composition (microstructure) uniquely defines the mechanical behavior.

As medical device materials often involve significant plastic effects, incorporation of the present model for plasticity into a finite element code designed for the biomechanics and biophysics community allows the use of a single software platform for finite element analyses. Further, due to the tissue-specific constitutive models available in FEBio, device plasticity may be simulated simultaneously with accurate tissue behavior. The use of reactive plasticity may also provide a level of simplicity to computational analyses, as relatively few parameters are needed to define the model.

A reactive model for plasticity also enables incorporation of tissue plasticity into biological mixtures in a consistent theoretical framework; future work is directed along this avenue of research.

INTRODUCTION

Inferior synovial lubrication is a hallmark of osteoarthritis (OA)¹⁻³. Recent studies suggest that changes in synovial lubrication and composition are highly dependent on the type of OA^{4,5}, though a loss of high molecular weight hyaluronic acid (HA) and reduction in synovial fluid viscosity are common⁵. HA viscosupplementation is a widely used therapy for managing the symptoms of OA. However, it is unclear how the effectiveness of HA viscosupplements varies with OA phenotype. The objective of this study was to investigate the effects of the HA viscosupplement, Hymovis®, on the lubricating properties of diseased synovial fluid (SF) from patients with non-inflammatory and inflammatory OA.

METHODS

SF was collected from the knee joints of human donors with non-inflammatory OA (n=10, age 62±10 years) and inflammatory OA (n=10, age 44±26 years) where inflammatory patients were defined as having white blood cell counts above 2000/μL and a polymorphonuclear neutrophil percentage >25%. SF samples' biophysical properties were assessed alone or in a 1:1 mixture with Hymovis, a modified HA viscosupplement. Cartilage explants were harvested from neonatal bovine stifles and loaded onto a custom tribometer in a SF or SF:HA bath. Explants were compressed to 40% strain against glass and slid at speeds of 10-0.1mm/s as friction coefficients were recorded⁶. Viscosity was quantified by shearing the fluids from 1000-1x10⁻⁴ 1/s on a rheometer with a 25mm cone-and-plate geometry⁷. Stribeck analysis was used to examine the frictional properties of the fluids across different modes of lubrication including high friction boundary mode, mixed, and low-friction elastoviscous mode. Stribeck curves were made by plotting friction coefficients vs. Sommerfeld number, a dimensionless parameter calculated as⁷:

$$\eta v a / L_N \quad (1)$$

that accounts for the lubricant viscosity (η), sliding speed (v), contact width (a), and contact load (L_N). Lubricin was quantified using a peanut agglutinin sandwich ELISA with mAb 9G3 as the detection antibody and purified bovine lubricin as the standard⁸. A 3-factor ANOVA and a Tukey's HSD test were performed to compare viscosities. Lubricin concentrations were compared using a t-test, and friction coefficients (0.1mm/s sliding speed) were fit to a dose-response curve with lubricin concentration.

RESULTS

Inflammatory and non-inflammatory OA samples exhibited similar shear-thinning viscous behavior. HA significantly increased the viscosity ($p<0.001$) of the fluids by a factor of over 100 at low shear rates (Fig. 1). Non-inflammatory OA samples exhibited typical Stribeck behavior in which friction coefficients decreased with increasing Sommerfeld number (Fig 2. A, B). The addition of HA reduced friction coefficients, shifted the Stribeck curve toward higher Sommerfeld numbers, and revealed a high-friction boundary mode plateau not evident for pure non-inflammatory SF. However, for inflammatory OA samples, HA did not always reduce friction coefficients (Fig. 2C,D). Inflammatory OA samples showed inconsistent Stribeck behavior (Fig. 2C, D); while several exhibited a similar magnitude of friction coefficients and Stribeck behavior like the non-inflammatory OA SF, a subset showed a vastly different behavior in which friction coefficients were higher, more variable, and increased with Sommerfeld number. This non-Stribeck-like behavior was preserved when HA was added. Lubricin concentrations were highly variable and did not differ between inflammatory and non-inflammatory SF (Fig. 3, inset). Boundary mode

friction coefficients decreased with increasing lubricin concentrations (Fig. 3). Non-Stribeck-like behavior was associated with low lubricin concentrations.

Figure 1: Inflammatory and non-inflammatory synovial fluids exhibit similar shear-thinning viscous properties which are significantly enhanced by the addition of HA ($p < 0.001$, $n=9$).

Figure 2: (A) Example of a Stribeck curve for lubricated cartilage showing high-friction boundary mode and the transition to low-friction elastoviscous mode. (B) Non-inflammatory OA samples exhibit a Stribeck-like behavior in which the addition of HA shifts the transition to elastoviscous mode to higher Sommerfeld numbers. Individual inflammatory OA samples (C,D) show unique lubrication phenotypes; some patients (pink) exhibit typical Stribeck behavior similar to non-inflammatory OA samples in (B), while others (maroon) show increasing friction coefficients with increasing Sommerfeld numbers and a larger variability in friction coefficients. Note that each symbol shape represents a single patient (C,D). ($n=5-8$).

DISCUSSION

HA significantly enhanced the viscosity of inflammatory and non-inflammatory OA SF. Interestingly, HA viscosupplementation was effective in reducing friction coefficients for non-inflammatory OA samples, but not necessarily for inflammatory OA samples. For some patients, friction coefficients were increased by the addition of HA. Furthermore, Stribeck analysis revealed a subset of inflammatory OA samples exhibiting higher friction and atypical Stribeck behavior where friction coefficients increased with Sommerfeld number. These atypical behaviors appear to be associated with SF composition, including lubricin and possibly HA concentrations. We have identified tribological phenotypes within inflammatory and non-inflammatory human OA SF. This suggests that distinct lubrication therapies may be advised for specific OA phenotypes.

Figure 3: Lubricin concentrations were similar between inflammatory and non-inflammatory OA (inset, $p=0.82$). Boundary friction coefficients followed a dose-response relationship whereby increasing amounts of lubricin resulted in lower friction ($n=18$). Non-Stribeck-like samples (maroon) exhibited low lubricin concentrations and increased friction.

INTRODUCTION

The enthesis is a robust fibrocartilaginous tissue that effectively transfers load across two highly dissimilar materials: tendon (soft) and bone (hard). The connection is critical to joint function, and must be both strong and tough. Although a large body of work has established the sources of strength (*i.e.*, the onset of injury) [1], the sources of toughness (*i.e.*, the energy absorption that protects against failure following the onset of injury) are largely unknown. Clinically, bone avulsion fractures or tendon mid-substance ruptures are commonly seen in high-impact injuries and in pediatric patients [2], while insertion failures are prominent for the degenerative rotator cuff tears in adult patients [3]. Because many surgical repairs fail [4], there is a pressing need to identify and eventually reconstitute the natural toughening mechanisms in the enthesis. Therefore, our aim was to perform the first characterization of these toughening mechanisms in a well-defined laboratory model of enthesis failure. We hypothesized that failure mechanisms of mouse entheses would reveal distinct molecular level injury localization and propagation in quasistatic (acute) and cyclical (degenerative) loading, and that tissue pathologies would alter these mechanisms.

METHODS

All animal procedures were approved by the Columbia University Institutional Animal Care and Use Committee. Supraspinatus tendon-to-bone units were harvested from healthy adult (>12 weeks) male C57BL6/J mice (n=72). All samples were mechanically tested in a saline bath at 25 °C to prevent thermal collagen denaturation.

Quasi-static loading: Samples were subjected to a 0.05 N preload before being strained in tension at 0.2 %/s to 1 N, 2 N, 3 N (n=3 samples per force group), or failure (n=15). To examine the role of strain rate on

tendon enthesis failure, healthy samples were also tested under three different strain rates (2 %/sec, n=10; 20 %/sec, n=10; 200 %/sec, n=10).

Fatigue loading: After pre-loading to 0.05 N, samples were either subjected to 1 Hz sinusoidal loading from 0.1-1 N (1-20 % of failure force, n=4) or 1-3 N (20-70% of failure force, n=4). To investigate molecular level damage localization in the entheses, additional samples were loaded to 10,000 cycles (n=2), 40,000 cycles (n=2), and to failure (> 50,000 cycles, n=4) using the second protocol (20-70% max failure force). The control group consisted of samples that were prepared and mounted in the mechanical tester, but not loaded (n=5).

In vivo degeneration models: To examine the effect of pathology on enthesis failures, 10-week old C57BL6/J mice (Jackson Laboratories) were subjected to two degeneration models. Underuse degeneration was induced via muscle paralysis by injecting 0.2 U of botulinum toxin (Btx) into the supraspinatus muscle (4 wk, n=10). Overuse degeneration was achieved through downhill treadmill running for 4 weeks (-15°, 22 cm/sec for 40 min/day, 5x/week; n=10). All tendon-to-bone units harvested from degeneration models were quasi-statically loaded to failure at a strain rate of 0.2 %/s.

Imaging: After mechanical testing, samples were secured at terminal displacements and either submerged in a 5% mercury chloride (HgCl₂, Sigma-Aldrich) for 24 hours or fixed with 4% paraformaldehyde (PFA, Fisher Sci) overnight. HgCl₂ solution was used as a contrast agent to enhance enthesis visualization using high resolution x-ray computed tomography (microCT, Bruker Skyscan 1272). PFA fixed samples were stained with a 15 M fluorescein-labelled collagen hybridizing peptide (F-CHP, 3Helix) to detect molecular level mechanical denaturation of collagen [5] and visualized using fluorescence microscopy. Statistical analyses was performed using one-way ANOVA with Dunnet's post-hoc test.

RESULTS

Contrast-enhanced microCT imaging of an unloaded control specimen revealed that, hidden within the well-known larger apparent attachment footprint area (Fig. 1B, blue dotted line), is a smaller, much denser primary insertion site where tendon fibers insert directly into the bone surface (Fig. 1B, green dotted line). Depending on the loading regime, there were three distinct failure modes: bone avulsion, tendon mid-substance, and tendon-bone interface (Fig. 1B-E). Under quasi-static loading conditions, healthy tendon-to-bone attachments failed either at the interface between mineralized fibrocartilage (MF) and bone (B) or extending into the trabecular bone of the humeral head (B-T), both with a mineralized “bone plug” avulsed from the insertion site (Fig. 1C, Fig. 2). Imaging revealed that only 47.4 ± 5.1 % of the apparent attachment site was avulsed, revealing a previously unknown primary attachment. This failure behavior was largely unaffected by increasing the loading rate. While stiffness was not affected by strain rate, failure load and work to failure increased at higher strain rates ($p < 0.01$). All samples cyclically loaded at 20-70% failure force failed in the unmineralized fibrocartilage portion of the attachment (Fig. 1E). In contrast, samples cyclically loaded at 1-20% failure force did not fail, even after 100,000 (Fig. 1A).

Pathological tendon-to-bone attachments also exhibited exclusively avulsion-type failures. Healthy and overuse-degenerated attachments failed catastrophically, showing little post-yield behavior, while underuse-degenerated attachments failed at lower forces and showed distinct post-yield behavior (Fig. 2A). Stiffness was increased in the overuse-degenerated attachments ($p < 0.01$). Maximum force was decreased in the underuse-degenerated attachments ($p < 0.01$). There was an increase in fractured (avulsed) area in the underuse-degenerated attachments ($p < 0.001$) (Fig. 2B). Pathology caused changes in the fracture pattern: overuse-degeneration led to more failures at the interface between the MF-B, while underuse-degeneration led to more failures at the B-T interface (Fig. 2C). Bone morphometric analysis revealed that underuse-degeneration led to bone loss underlying the attachment (BMD, $p < 0.0001$), while that overuse increased bone volume of the humeral head (BV/TV, $p < 0.01$).

F-CHP fluorescence intensity, indicative of damage accumulation, increased with applied load or number of cycles (Fig. 3). For quasi-statically loaded samples, there was little to no fluorescent signal in the low force group (1-2N), followed by increased staining near the attachment site at higher loads (3N and failure). For cyclically loaded samples, F-CHP staining was initially concentrated in a few fibers near the tendon mid-substance (10K and 40K cycles) and ultimately propagated down the entire tendon in concentrated bands.

DISCUSSION

Mouse supraspinatus entheses exhibited three distinct failure modes: bone avulsion, tendon mid-substance failure, and tendon-bone interface failure. Results supported the hypothesis that failure mode is dependent on the loading regime. Under quasi-static loading, samples failed at the interface between mineralized fibrocartilage and bone. Consistent with previous studies of responses to monotonic loading [6,7], mechanical responses were largely strain-rate insensitive. However, avulsion area and/or the number of avulsed fragments increased with loading rate, consistent with previous observations on rate-sensitivity of bone failure [8]. For cyclical loading, samples failed at the unmineralized side of the fibrocartilage. Results suggested that the mechanisms protecting fibrocartilaginous tissue might be gradually attenuated over cyclical loading. This hypothesis was borne out by imaging of collagen damage: for quasistatic loading, damage was localized to the attachment site at loads above 3N, but for cyclical loading denaturation was attenuated at the attachment site, instead

propagating through the tendon and to the distal end of the enthesis for ultimate failure.

Both overuse and underuse reduced toughness. Overuse did so by reducing failure displacement without affecting failure force, while underuse did so by reducing failure force without affecting failure displacement. Continued efforts to identify sources of strength and ductility in the enthesis hold potential to design improved tissue engineered solutions. These results demonstrate the importance of the enthesis for effectively transferring load from muscle to bone.

INTRODUCTION

The optic nerve head (ONH) comprises a complex network of collagen fibers that undergoes remodeling and deformation with age and disease, such as in glaucoma [1]. The orientation and organization of collagen fibers, particularly those of the peripapillary sclera (PPS) and lamina cribrosa (LC), play an important role in the mechanical properties and deformations of the ONH [2]. Although standard polarized light microscopy allows visualizing the architecture of collagen fibers in ocular tissues, the technique requires acquiring and post-processing multiple images with different polarization states [3]. Reconstructing architecture from multiple images not only precludes time-sensitive applications, such as the study of collagen fibers dynamic response to external force, but also reduces the level of detail discernible, which prevents resolving sub-micron details.

In this study, we applied snapshot polarized light microscopy (snapshot-PLM) to ocular tissues to study their microstructure and dynamic deformations under controlled loading conditions. Compared to conventional imaging methods, snapshot-PLM captures both fiber orientation and alignment information in a single true-color image, and is therefore suitable for high-speed imaging and quantification. Our goal was to visualize load-induced changes in fiber bundle characteristics, such as shape, organization, and orientation, and to quantify tissue deformation in the LC and PPS regions. The dynamic visualization and quantification in ONH regions will provide valuable information towards better understanding of ocular biomechanics.

METHODS

Imaging setup – The snapshot-PLM imaging system was based on standard polarized microscope equipped with a pair of polarization components [4]. Objectives with 4x and 10x magnification were used for full-field or full frame rate imaging, respectively.

Sample preparation – Tendons from chicken legs were used as reference materials due to their relatively uniform architecture. The tendons were obtained fresh and fixed chemically (10% formalin) under longitudinal load to straighten and align the collagen fibers. The loaded tissues were then cryo-sectioned longitudinally at a thickness of 30 μm [5]. Sheep ONH tissues were used to investigate the structure visibility and load-induced deformations. Fresh ocular tissues from a trephined sheep ONH were cryo-sectioned into 16- μm thick sections. Note that no labels or stains or fixatives were applied to any ONH tissues or sections.

Figure 1. Circular interpolation of fiber orientation as a function of hue. The function was calibrated by imaging the chicken tendon at several known orientations. Five example orientations are shown in true color on the right-hand side.

Color-angle conversion – The color-angle conversion was calibrated by imaging at several known orientations a section of chicken tendon (Fig. 1). The tendon section rotated by a sequential increment from 0 to 90 degrees was imaged by snapshot-PLM. The

angle of rotation of the 46 images was measured by image registration, and hue was extracted. The function of hues was built by circular interpolation of the corresponding angles of rotation. The function was then used to convert snapshot-PLM images into angle maps.

Tensile testing and quantification – The ocular tissues were mounted on a custom biaxial-stretching device for dynamic testing with image acquisition at 30 frames per second. To visualize the collagen uncrimping process in the region of interest, we quantified angle distribution and generated crimp maps, which were weighted by the amplitude of crimps. We used digital image correlation (DIC) to track the fiber displacement, and then calculated the Eulerian strain from the displacement vector fields.

RESULTS

Fig. 2a shows collagen fiber organization of a sheep ONH section by snapshot-PLM before applying load. The external load altered structural features of the ONH. In the LC region, the realignment of collagen fiber bundles deformed the pores and beams. We highlighted examples where the pore width increased from 80.2 μm to 87.2 μm (white arrows), and the beam thinned remarkably from 19.0 μm to 11.7 μm (red arrows, Fig. 2b). The changes in pores or fiber bundles in LC may indicate substantial mechanical insult on the neural tissues and vasculature. The crimped collagen fibers in the LC beams were straightened under load. This is more readily visible in the PPS (Fig. 2c). This can be discerned in the reduced spread of the orientation distribution, which changed from bimodal, indicative of crimped fibers, into unimodal. (Fig. 2d).

Figure 2. Visualization of a sheep ONH section by snapshot-PLM in tensile testing (4x objective). (a) True-color image of collagen fiber organization of ONH before applying load. (b) Change in LC pore (white arrows) and beam width (red arrows) under load. (c) Uncrimping process of the PPS collagen while under load. (d) Change in fiber orientation distribution in a region of (c).

Fig. 3 shows uncrimping process in the LC region. A pair of purple/yellow bands in the crimp map represents one period of crimp, and the brightness of the bands represents the crimp amplitude. Upon loading, the purple/yellow bands became less visible with a grayish appearance due to the reduced crimp amplitude. After stretching, the crimp amplitudes varied.

To study the fiber deformations in the PPS, we imaged and analyzed 104 images at various steps of loading (Fig. 4a). Stretching made the crimp less visible and caused fiber displacement. Tracking

the fibers with DIC during deformation revealed that the motion trails were tortuous and anisotropic (Fig. 4b). The complex displacements indicate tissue shear, stretch, and compression. The first principal strain reached 40-80% (Fig. 4c).

Figure 3. Uncrimping process in LC beam collagen fibers under load (10x objective). Yellow/purple crimp maps (bottom) provide better visibility of the crimp changes than true-color (top).

Figure 4. (a) Recording the deformation of PPS under load (10x objective). (b) Motion trails of PPS under load; the color indicates displacement in microns. (c) The first principal strain map of PPS under load.

DISCUSSION

We demonstrated that the load-induced changes in the shape and orientation of collagen fibers in ONH regions can be visualized and quantified using snapshot polarized light microscopy. The high temporal and spatial resolution of snapshot-PLM revealed sub-bundle details and highly dynamic tissue deformations in both LC and PPS regions. To the best of our knowledge this is the first direct visualization of sub-bundle deformations and crimp loss in LC and PPS. The imaging and analysis techniques can be applied to other collagenous tissues.

INTRODUCTION

Injuries to dense connective tissues such as tendon and ligament are often the result of overuse or age-related degeneration. The predominant hypothesis is that repeated loading cycles cause “micro-damage” in the tissue, and in the case of injury, micro-damage exceeds the rate of repair and accumulates [1]. Although the mechanisms and structures involved in load-induced micro-damage are still under investigation, it is clear that damage to collagen, the primary structural component of tendon, is involved in the micro-damage process. Indeed, previous studies using cyclic fatigue to represent repetitive use loading of tendon have demonstrated material and mechanical changes in the form of matrix disruption at the level of the collagen fibril and fiber, and decreased tissue stiffness [2]. However, the effects of cyclic fatigue loading on collagen structure at the molecular level are unknown.

We demonstrated that collagen hybridizing peptide (CHP), which hybridizes with denatured or unfolded collagen α -chains [3], can detect and quantify mechanical damage to the collagen molecule, due to monotonic tensile overload [4]. CHP binding at subfailure levels of loading, and accumulation of damage with increasing strain, demonstrated that molecular level collagen damage is a critical component of tendon mechanical damage during tensile loading. The objectives of this study were to investigate the role of molecular-level collagen damage during tendon fatigue, and to identify possible molecular level mechanisms of triple-helical fatigue damage using steered molecular dynamics (SMD) simulation. The overlying hypothesis is that molecular-level collagen damage is fundamental to the initiation and progression of fatigue damage in tendon.

METHODS

Rat tail tendon (RTT) fascicles were dissected from fresh-frozen, 6-month old, male Sprague-Dawley rats and equilibrated in 1× PBS

prior to testing. Initial cross-sectional area was measured using an optical micrometer. Samples were preconditioned between 0.2 N (~2.3 MPa) and 4.6 MPa for 11 cycles, using a 6% s⁻¹ constant strain rate triangle wave, then allowed to recover while unloaded for 5 min. Samples were fatigue loaded between 0.2 N and 18.5 MPa (40% of tensile strength at 1% s⁻¹) using a triangle waveform at strain rates of 0.4, 4.0, or 40% s⁻¹. Cyclic loading was applied until peak cyclic strain reached one of three predefined levels, representing increasing levels of fatigue, or failure occurred (n≥5 in all 4 groups, at each strain rate). Unloaded samples served as controls (n=12).

Following fatigue testing, samples were removed from the test system and the amount of denatured collagen was measured using a CHP based microplate assay [5]. Sample wet weight was recorded and then samples were incubated overnight at 4 °C, in a 15 μ M solution of 5-FAM conjugate CHP (F-CHP; 3Helix, Inc.) to label denatured collagen. Samples were washed three times in PBS for 30 min to remove unbound F-CHP. Labeled samples were digested using proteinase K and F-CHP fluorescence was measured at 485 and 525 nm excitation and emission, respectively. Fluorescence was normalized to wet weight and the amount of denatured collagen was calculated using a standard curve for RTT fascicles. Data for peak cyclic strain and percent denatured collagen were plotted as a function of normalized number of cycles (cycle number divided by cycles to failure).

SMD simulations were performed using a representative homotrimeric collagen peptide comprised of twenty [Gly-Pro-Hyp] triplets in explicit water solution [4]. Periodic boundary conditions were applied to all directions. Each simulation was performed in the isothermal-isobaric ensemble (pressure = 1 atm and temperature = 310 K) with 1 fs simulation time step. Energy minimization and equilibrium simulations were performed before the simulated mechanical test. During equilibrium simulation, the ends of the collagen peptide were

anchored with a small force to prevent peptide bending. The SMD method was used to deform the molecule between 350 pN and 2085 pN with a constant loading speed of 3, 5, or 10 m/s. Simulations were performed with either tension dominant loading that stretches the whole triple-helical collagen molecule or shear dominant loading that corresponds to pulling a single strand out of the triple helix. Solvent accessible surface area (SASA), a measure of molecular unfolding, was computed throughout the loading simulation.

Experimental data were analyzed using mixed effects linear regressions to determine the effect of predictor variables and their interaction. Significance was determined at the $\alpha=.05$ level.

RESULTS

RTT fascicles demonstrated a significant increase in the amount of denatured collagen detected by CHP binding with increased fatigue loading ($p<.001$, Fig. 1b). However, there was not a significant effect of strain rate ($p=.451$) nor interaction between fatigue level and strain rate ($p=.220$). The number of loading cycles to failure displayed a significant effect of strain rate ($p<.001$), with 250 ± 195 , 920 ± 624 , and 3954 ± 1115 cycles (mean \pm SD) at 0.4, 4, and 40% s^{-1} , respectively. Using normalized number of cycles, however, the main effect of strain rate on peak cyclic strain was not significant ($p=.166$), while the effect of fatigue level ($p<.001$; Fig. 1a) and interaction between fatigue level and loading rate ($p=.006$) were significant.

Figure 1. Normalized tissue creep (a; mean \pm SD, $n=10$ each) and molecular damage (b; mean \pm SEM, $n \geq 5$ each) due to fatigue loading. Neither the mean peak strain nor the amount of denatured collagen, as a function of normalized number of cycles, was significantly affected by strain rate.

Collagen model peptides subjected to simulated cyclic creep loading revealed that molecular strain and triple-helical unfolding, as indicated by increasing SASA, demonstrated similar strain-rate behaviors to experiments, where more loading cycles were required at faster loading rates to produce similar levels of peak cyclic strain and collagen denaturation (Fig. 2). Increased molecular strain and SASA with increasing loading cycles were observed for shear dominant, but not tension dominant loading.

DISCUSSION

A mechanism for the development of overuse tendon injury and a source for effective clinical treatment of these injuries remain elusive. We have demonstrated that tendon fatigue results in the accumulation of denatured collagen even at early levels of loading, suggesting that mechanical unfolding of the collagen triple-helix is a critical feature of fatigue damage. Both tissue level fatigue, indicated by creep strain, and fatigue damage to the collagen molecule evolve with increasing loading cycles. When normalized to cycles at failure, this evolution was independent of strain-rate, suggesting that creep strain accumulation determines fatigue damage and that collagen molecule unfolding may be a mechanism for the generation of creep strain.

The SMD results mirror the experimentally observed strain-rate dependent increase of creep strain and triple-helical unfolding with

increased loading cycles. This demonstrates a possible molecular mechanism for tissue-level rate dependence of fatigue damage accumulation, and strongly indicates triple-helical unfolding as a foundational mechanism of tissue creep. Additional simulations of extended duration will enable us to assess molecular creep and SASA normalized to failure, to understand if simulated damage accumulation in isolated peptides further predicts tissue level observations. The stability of the collagen model peptide during simulated tension dominant loading, but unfolding due to shear dominant loading is in agreement with previous results demonstrating that shear load transfer via intermolecular crosslinks is the most likely mechanism for mechanical unfolding of the collagen molecule [4]. This suggests that the shear dominant loading mechanism is consistent for both monotonic and cyclic tension loading.

Figure 2. Applied force (top), measured strain (middle), and solvent accessible surface area (bottom) for the collagen model peptide subjected to simulated creep fatigue loading at 3, 5 and 10 m/s displacement rates. Consistent with tissue level experiments, individual molecules require more cycles to reach a similar level of creep strain or triple-helix unfolding at faster loading rates.

Our results support the hypothesis that molecular level collagen damage is fundamental to the initiation and progression of fatigue damage in tendon. Furthermore, progressive accumulation of collagen damage throughout fatigue supports the hypothesis that overuse injuries involve loading-induced damage to collagen that outpaces the remodeling capacity of the tissue, providing both a mechanistic explanation for micro-damage accumulation and a potential clinical target for the treatment and prevention of overuse injuries.

INTRODUCTION

Denatured collagen arises in many debilitating injuries and diseases involving connective tissues. Recently, our group has shown that permanent collagen denaturation can occur and accumulate in rat tail tendon fascicles at sub-failure levels of mechanical loading. This was the first study to definitively show that mechanical overload of musculoskeletal tissues causes permanent collagen denaturation at the molecular level [1]. However, there are differences in the structure, composition and function of different tendon types, which can be broadly categorized into either positional or energy storing tendons. The former includes tail and extensor tendons, while the latter includes the Achilles, patellar, and flexor tendons. These two tendon types differ mainly in their fibril type and the degree and type of crosslinking. Energy storing tendons have fibrils that exhibit high strain stiffening and resistance to molecular disruption, while positional tendons are more susceptible to molecular disorder upon rupture [2]. Furthermore, energy-storing tendons have trivalent crosslinks and exhibit a significantly greater crosslink density than positional tendons, whose crosslinks are divalent in nature [2,3].

A tool that has recently come to our disposal to study denatured collagen is collagen hybridizing peptides (CHPs). CHPs are short polypeptide chains that mimic the Gly-Pro-Hyp sequence of native collagen. Consequently, CHPs bind selectively with unfolded, denatured collagen strands, but not intact collagen. By using carboxyfluorescein bound CHPs (F-CHP), one is able to visualize the spatial distribution of denatured collagen. Additionally, the amount of fluorescence from F-CHPs is directly indicative of the amount of denatured collagen [4]. This study sought to characterize the evolution of denatured collagen in an energy storing tendon relative to applied strain at the tissue level. We hypothesized that denatured collagen in energy storing tendons will exhibit lower levels of denatured collagen

but with the same trend as positional tendons, due to increased levels of crosslinking resisting inter-molecular sliding of the collagen α -helices.

METHODS

Rat tail tendon (RTT) fascicles were dissected from 8-week old male Sprague-Dawley rats. The samples were mechanically damaged by applying a preload of 0.03 N and stretching them in uniaxial tension to strains of 0, 5, 7.5, 9, 12, and 13.5% (n=3 for each strain group) at a rate of 0.5%/s. Rat flexor digitorum longus (FDL) tendons were dissected from the hind legs of 12-16 week old male Sprague-Dawley rats and clamped using sandpaper covered grips and cyanoacrylate. The average initial cross-sectional area was measured using an optical micrometer. After applying a preload of 0.03 N, the rat FDL tendon samples were stretched in uniaxial tension to 0, 5, 10, 12.5, 15, 17.5, 20, 22.5, 25, 27.5, and 30% strain (n=3 for 25 and 27.5% strain groups, n=5 for all other strain groups) at a rate of 0.5%/s. All mechanical tests were performed at room temperature in 1xPBS.

All samples were unloaded from the clamps and stained in 15 μ M F-CHP (3Helix, Inc.) overnight at 4°C with gentle agitation. The samples were rinsed three times for 30 minutes with 1xPBS to remove unbound F-CHP. The unloaded regions of all samples were trimmed off, leaving the region subjected to tensile loading. These samples underwent proteinase K digestion as per our published protocol [4], and the fluorescence of the digest was measured in a 96-well plate using a microplate reader. The amount of fluorescence from F-CHP is directly indicative of the amount of denatured collagen in the sample.

Mean stress-strain curves for 13.5% strain and 30% strain were calculated for RTT fascicles and FDL tendons, respectively. The strain in the stress-strain curves for both tendon types was normalized to the strain at which the ultimate tensile strength (UTS) occurred. The strain values corresponding with each fluorescence measurement were also

normalized to the UTS strain. The F-CHP fluorescence at each strain level for both tendon types was calculated as a percent increase from the fluorescence of the unloaded controls (baseline).

Statistical analysis was performed by comparing the mean fluorescence of each strain group with the 0% unloaded controls within both tendon types using a two-tailed t-test. Significance was set at $\alpha=0.05$.

RESULTS

The mean fluorescence of mechanically damaged rat FDL tendons was significantly greater than the unloaded control group for each strain group. This indicates that there was some amount of collagen denaturation at all strain levels. However, the amount of F-CHP fluorescence and by extension denatured collagen did not increase and accumulate until reaching the UTS, where the percent increase rises from 200% to 1300% relative to baseline. In contrast, for RTT fascicles, mean fluorescence for strain groups greater than 5% were significantly greater than the unloaded control group (Figure 1). Unlike the FDL tendons, the percent increase of F-CHP fluorescence increases until the UTS strain, where there is no further increase. The percent increase peaked at 1000% greater than baseline (Figure 1). The mean maximum stress for FDL tendons was 34.5 MPa and occurred at a strain of 19.90%. The mean maximum stress for RTT fascicles was 17.7 MPa and occurred at a strain of 10.62% (Figure 2).

DISCUSSION

F-CHP staining of energy-storing rat FDL tendons stretched to incremental strains revealed that while small amounts of denatured collagen accumulated at moderate strains, there was not any large increase in denatured collagen until initial failure of the tissue. This differs from RTT fascicles, a positional tendon, where the amount of denatured collagen accumulated until reaching the UTS and remains constant. Despite these differences in the accumulation of denatured collagen relative to the strain at UTS, the results demonstrate that mechanical overload of both tendons eventually gives rise to denatured collagen. These results are consistent with Chambers et al. [3], who reported increased molecular disruption as measured by differential scanning calorimetry in energy storing tendons. Notably, they observed this at low strain rates (1%/s), whereas at high strain rates (10%/s), there was minimal molecular disruption. Our study used a strain rate of 0.5%/s, so the results correspond with the former case.

The differences in the accumulation of collagen molecular damage between positional and energy storing tendons may be a result of the increased levels of crosslinking in energy-storing tendons [3]. Specifically, the divalent crosslinks found in positional tendons are more susceptible to intermolecular sliding of the collagen molecule during tension, while the trivalent crosslinks in energy storing tendons allow the collagen molecules within the fibrils to resist molecular sliding. The stabilization due to trivalent crosslinking prevents denaturation of the collagen molecule and unravelling of the α -chains, which is necessary for CHPs binding. Therefore, extension of the tissue occurring due to stretching of the crosslinks and their attached α -chains [5].

Interestingly, the percent increase in F-CHP fluorescence and by extension denatured collagen relative to baseline was on the same order of magnitude between RTT fascicles and rat FDL tendons (1000% vs 1300% increase). This suggests that the while the onset and mechanisms differ between the two tendon types, the incremental change in the amount of denatured collagen that eventually accumulates during tensile overload is similar.

METABOLIC ACIDOSIS CAUSES PHYSIO-CHEMICALLY INDUCED MECHANICAL AND COMPOSITIONAL CHANGES TO MURINE BONES

INTRODUCTION

Over 30 million US adults are diagnosed with chronic kidney disease (CKD) each year. CKD is characterized by a slow degradation of the kidneys leading to insufficient acid secretion and dysregulation of bicarbonate (HCO_3^-) levels in the blood [1]. Without the ability to regulate the body's acid/base balance nearly half a million CKD sufferers will develop metabolic acidosis, a drop in blood pH below 7.35, annually [2].

Without the kidneys to regulate body pH during CKD induced acidosis, the primary method of physiological buffering becomes bone resorption and dissolution. Half of bone mass is composed of a carbonate substituted apatite containing PO_4 , Ca, CO_3 , and Na. Upon onset of acidosis, bone dissolution begins via physio-chemical dissolution as well as activation of bone resorbing osteoclast bone cells. In both cases, the dissolution process results in the release of alkaline carbonate and phosphate containing moieties that buffer the excess acid [3]. Although bone dissolution is advantageous to the regulation of CKD induced acidosis, it can also lead to significant bone loss, osteopenia and osteoporosis, and increased fracture risk.

Establishing what occurs during the early stages of metabolic acidosis and how the mechanical properties of bones change on a shortened time scale in the pursuit of acid/base equilibrium will be substantial to developing our knowledge of musculoskeletal pH regulation. This information will serve as a platform on which to develop therapeutics to combat the earliest signs of irreparable musculoskeletal damage due to acid buffering.

METHODS

80 5-6 month-old male CD-1 mice were separated into 4 groups. The first three groups were given modified drinking water containing 0.2 M ammonium chloride (NH_4Cl) for 1, 7, and 14 days. The control group was provided with normal drinking water. After the appropriate

time of acid exposure, submandibular blood draws were performed to determine blood gas concentrations after which the mice were sacrificed. Each mouse was dissected to collect the left and right femurs and supraspinatus-humerus (SH) tendon-bone complexes. Femur and SH complex samples were then analyzed via mechanical testing, micro-computed tomography (μCT), histology, and Raman spectroscopy.

For histological analysis, unfixed SH complexes were cut down to the tendon-to-bone attachment site and mounted in OCT. The samples were sectioned into $\sim 10\ \mu\text{m}$ sections using a cryostat and stained using Toluidine blue and Von Kossa. Light micrographs were taken using a Nikon Eclipse TE300 microscope. Thickness of the mineralized and unmineralized fibrocartilage layers was measured using Image J.

Both SH complexes and femurs were imaged via μCT and tested mechanically. For μCT imaging, the femurs were scanned after mechanical testing at a resolution of $12\ \mu\text{m}$ in a SCANCO 40 system. The SH complexes were positioned such that humeral head pointed down which allowed the tendon to hang freely to obtain tendon cross-sectional area prior to mechanical testing. The X-ray reconstructions were analyzed to obtain bone volume/total volume (BV/TV), the cross-sectional area of the tendon, and the moment of inertia of the femurs.

Mechanical testing was done on femurs, by 3-point-bending, and SH complexes, by tensile testing, using a Mach-1 (Biomomentum, Inc.) uniaxial tensile tester with a 25-kg load cell. In both cases, samples were tested while submerged in PBS at 37°C to simulate in-vivo bone mechanics. Femurs were tested in a standard three-point bending mount such that the medial side underwent tensile loading. The SH complex was loaded in tension using custom made 3D printed grips. The grips consisted of a bottom mount containing a bone shaped inclusion that restricted vertical movement of the humeral head to minimize the risk of growth plate failure, and a top mount consisting of a toothed clamp to secure the supraspinatus tendon. In both case, loads were applied at

constant rate until failure. The Mach-1 system provided force vs. displacement for all samples from which we calculated maximum load/stress, yield load/stress, stiffness, post-yield displacement, and the energy to failure using the μ CT data.

For Raman analysis, intact femurs were cleaned of soft tissue and analyzed via a Witec alpha300 system. Carbonate levels were determined from the ratio of the 1070/960 Δcm^{-1} peak areas. Mineral:matrix ratios were determined from the 960/1030 Δcm^{-1} ratios. All measurements were made at the medial midshaft. Statistical analysis was done using one-way ANOVA tests, Tukey tests, as well as two-tailed t-tests.

RESULTS

Blood gas results indicate that ammonium chloride treatment resulted in a significant drop in pH for mice after 1 day, accompanied by a decrease in bicarbonate. This is recovered after 7 days despite continued acid loading, Fig 1. Mechanical testing showed no change in the mechanics of the SH complexes after acidosis induction. The femurs showed no change in elastic properties. However, they did exhibit a significant increase in work-to-fracture and post-yield-displacement at 7 days compared to control, Fig. 2.

Figure 1: Standardized Changes of pH and Bicarbonate

Structurally, the tissues showed very little changes. μ CT analysis showed no change in BV/TV for either the humeral head or the femoral midshaft. Similarly, measurements of mineralized and unmineralized fibrocartilage thickness at the SH attachment site from histology showed no change with acidic diet. Compositionally, both mineral:matrix and bone mineral carbonate levels were shown to decrease in the midshaft of femurs exposed to 7 days of NH_4Cl doped water.

Figure 2: Mechanical Measurements of Mouse Femurs

DISCUSSION

The blood gas data confirmed that the addition of NH_4Cl to the water had induced metabolic acidosis in the mice as demonstrated by the pH and bicarbonate drop at 24 hours, Fig 1. However, despite continuous NH_4Cl administration in the mice, the pH was returned to

baseline by day7 indicating that kidney function and bone dissolution were able to overcome the excess acid loading.

Previous studies have shown that induction of acidosis leads to both physio-chemical and cell-mediated bone dissolution[3]. We therefore expected that the addition of an acidic diet would lead to measurable bone loss. However, μ CT analysis showed no change in BV/TV of the trabeculae in the humeral head nor the midshaft of the femur. This lack of change in the bone mass, indicated that dissolution or cellular resorption had no measurable effect on the quantity of bone present after short-term acidosis. Although this lack of change may be due to the low resolution of the μ CT data, it is further supported by the histological data that indicates that there is no change in the thickness of the mineralized fibrocartilage at the SH attachment site.

Regardless of the lack of change in bone mass, the femur did exhibit a change in plastic mechanical behavior after 7 days of acidic diet. Both the post-yield displacement and the work-to-fracture increased in the 7 day mice indicating that these femurs had become tougher with acidic diet. An increase in bone toughness is usually indicative of a change in collagen quality or a decrease in bone mineral content. The later hypothesis is supported by the fact that Raman measurements indicate a decrease in the mineral:matrix ratio of the femoral midshaft. Together, these results suggest that acidosis may initially lead to a decrease in bone mineral content but not a loss in bone mass. Since osteoclasts are known to remove both mineral and collagen during the resorption process, this may indicate that physio-chemical dissolution of the bone serves as the primary mode of dissolution in short-term acidosis. In addition, the drop in mineral carbonate content supports the theory that carbonated bone mineral is preferentially dissolved to increase the bone's buffering abilities.

It is also interesting to note that the change in mechanical properties is delayed compared to the time of acidosis. The blood gas results indicate that even with an early induction of acidosis, the animals are able to recover between days 1 and 7. Despite this, bones at 7 days display modified mechanics and composition. This suggests that there may be a delay in bone dissolution relative to the start of acidosis or that continuous dissolution is necessary to recover a healthy pH.

The SH complex had been selected as a tissue of interest because the mineralized tendon attachment site does not contain bone resorbing cells; therefore, it could probe for physio-chemical dissolution without cellular participation. However, unlike the femur there were no changes in the SH mechanical properties. The lack of statistical significance may be due to the SH requiring involvement of the bone, tendon, and cartilage in the tension tests. Participation of the compliant soft-tissues may have made it difficult to measure small changes in the bone; therefore, acidosis may have affected the SH in a manner too sensitive to be recorded in our data collection.

Generally, we conclude that buffering of acidosis via physio-chemical bone dissolution had a significant effect on the bone mechanics by modifying the bone mineral content.

EFFECT OF HYDRATION ON MECHANICAL PROPERTIES OF INDIVIDUAL COLLAGEN FIBRILS AND EXTRAFIBRILLAR MATRIX

Heber Martinez Barron, Wei Gao, and Xiaodu Wang

Mechanical Engineering,
University of Texas at San Antonio,
San Antonio, Texas, USA

INTRODUCTION

Bone is a natural composite material with a hierarchical structure consisting of three major components: mineral, organic matrix, and water. The mineral phase is considered to provide the strength and stiffness; whereas the organic matrix (collagen fibrils and non-collagenous protein matrix) is deemed to influence the toughness of bone. In addition, previous studies have shown removal of water (dehydration) from bone may lead to a significant decrease in the toughness and increase in the stiffness of bone, suggesting water plays a pivotal role in the mechanical behavior of bone [1,2].

Water is present in three different compartments in bone matrix: freely mobile water in pores, such as Haversian canals, canaliculi, and lacunae spaces; bound water at the surface of the collagen fibrils and between the collagen and mineral phase; and structural water as part of collagen and mineral molecules [3]. Water in every compartment contributes to different mechanical properties of the bone. From Granke et al [2], it has been found that amount of freely mobile water in pores correlates with the stiffness of bone, whereas bound water contributes to bone's ductility. Moreover, structural water, although its functional significance is not clear, may play a role to stabilize collagen conformation and assembly. It is known that bound water is present in both mineralized collagen fibrils (MCF) and extrafibrillar matrix (EFM). However, it is not clear on how bound water would affect the *in situ* mechanical behavior at the ultrastructural compartments. Therefore, continuing studies on nanomechanics of bone at ultrastructure levels will clearly define the role of water at these different ultrastructural compartments.

In this study, we investigated the effect of bound water on the mechanical properties (modulus and energy dissipation) of individual MCF and EFM under both dry and wet conditions using a high-

resolution atomic force microscopy (AFM) system and associated techniques.

METHODS

Bone slices were prepared from a cadaveric femur of a mid-aged female donor. The slices were dissected transversely to the longitudinal direction of the diaphyseal femur. Cortical bone cores (8 mm in diameter) were first extracted from the posterior aspect of the cross section within the mid-diaphysis of the femur. Then, the cores were cut into 1.0 mm thick slices using a low-speed diamond saw with continuous irrigation of deionized water. Thereafter, both bone slices were lapped with successive grit of sand papers to the thickness of 0.1-0.2 mm, and polished using submicron alumina powder paste. The orientation of collagen fibrils in osteons was identified using cross polarized optical microscope such that AFM scans could be focused on the lamellae that contained collagen fibrils oriented parallel only to the direction of the osteon axis.

To ensure wet conditions, a 3D-printed chamber was devised to partially submerge samples in water during AFM testing. Deionized water was used to hydrate the samples for at least 60 minutes before testing. For testing under both dry and wet conditions, Peak force tapping (PeakForce QNM) AFM method was used to capture the surface topography as well as other mechanical properties, such as adhesion, deformation, elastic modulus, and energy dissipation. Samples were imaged using RTESPA-150 (Bruker, Santa Barbara, CA) cantilevers with a nominal spring constant of 5N/m, and a tip radius of 10 nm. For imaging purposes, height, peak force error, modulus, and adhesion channels were used to identify the regions of MCF and EFM. For quantitative measurements, peak force curves at each location were captured with RTESPA-525 cantilever with a nominal spring constant of 200 N/m, and a tip radius of 18 nm.

Figure 1. Adhesion(A) and DMT modulus (B) of AFM scans in the cross-section of bone indicate that the softer mineralized collagen fibrils (MCF) are surrounded by the harder EFM (white arrows).

Figure 2. AFM force curves for mineralized collagen fibrils (MCF) and EFM under (a) dry and (b) wet conditions.

Approaching and retraction force curves of the MCF and EFM were recorded (**Fig 2**) using Nanoscope Analysis 1.9 software (Bruker). Young's modulus values were obtained from these curves and energy dissipation (yellow area between force curves) following the recommended models using a custom-written MATLAB script.

RESULTS

AFM scans on cross-sectional bone slices conducted in height, phase, modulus, and adhesion modes clearly demonstrated the ultrastructural features of MCF and EFM. The adhesion and modulus mapping results indicated that collagen fibrils, as a soft phase, were surrounded by a much harder EFM (**Fig.1 A-B**), showing that the modulus of the EFM was about two times greater than that of MCF. The average nanoindentation modulus of MCF in the longitudinal axis was estimated to be in the range of 11.5 ± 0.29 GPa. Comparing dry and wet conditions, there was about a 60% decrease in elastic modulus from dry to wet for both MCF and EFM ranging from 17.5-29.6 GPa to 7.4-9.7 GPa. EFM showed a higher energy dissipation (4.29 ± 0.99 mN-nm), approximately 30% more than that of MCF (3.32 ± 1.28 mN-nm) under wet conditions (**Table 1**).

DISCUSSION

The results showed that no significant differences in the elastic modulus (E) were observed between EFM and MCF under both dry and wet conditions, whereas E changed significantly from wet (7.4-9.7 GPa) to dehydrated (17.5-29.6 GPa) condition for both EFM and MCF. Such hydration dependent changes in elastic modulus are similar to the previous results obtained from bulk bone samples [4]. These results suggest that water plays a pivotal role in the elastic modulus and toughness of bone for both MCF and EFM. Under wet condition, EFM appears to be tougher (about 30% more) than that by MCF

(3.32 ± 1.28 mN-nm) ($p < 0.05$). This implies that EFM contributes more to toughening of bone tissues *via* hydration. Both MCF and EFM under the dehydrated condition lost their capability for permanent energy dissipation (0.3-0.4 mN-nm). This study provided important information regarding *in situ* mechanical properties of MCF and EFM, as well as their role in toughening of bone at ultrastructural levels.

Table 1. Experimental results under dry and wet conditions

	Sample No.	Elastic modulus (GPa)	Energy Dissipation (mN-nm)
MCF	Dry	01 17.5 ± 2.7	0.52 ± 0.42
		02 29.6 ± 8.5	
	Wet	01 7.4 ± 1.4	3.32 ± 1.28
		02 8.4 ± 1.7	
EFM	Dry	01 18.7 ± 2.4	0.77 ± 0.37
		02 21.5 ± 7.0	
	Wet	01 8.5 ± 1.9	4.29 ± 0.99
		02 9.7 ± 1.9

INTRODUCTION

Subchondral bone is the thin layer of cortical bone that provides an interface transmitting loads between the articular cartilage and trabecular bone. The changes in subchondral properties enable to investigate differences in joint loading conditions in comparative biology, and in biomedical studies of the etiology of joint diseases such as osteoarthritis (OA) and osteoporosis. Previous studies have focused on describing patterns of the subchondral bone apparent density and relating it to inferred differences in joint load orientation and magnitude in humans [1,2] and primates [3]. However, many considerable questions remain to determine how and where the osteological changes occur due to habitual loading, and what properties of the subchondral bone respond best to 1) exercise in general, or 2) altered load orientations.

The primary goal of this study is to test whether subchondral bone density and thickness respond to experimentally induced differences in knee postures, and exercise.

METHODS

Thirty healthy juvenile sheep were used for this study beginning at the age of 60 days. Sheep were divided into three groups: (i) flat treadmill exercise (0° grade; n=11), (ii) incline treadmill exercise (10° grade; n=11), and (iii) control (n=8). All the procedures were approved by the UIUC IACUC. Sheep from groups (i) and (ii) were first trained to walk on a motorized treadmill (Star Trac 4000HR, Star Trac, Irvine, CA) at moderate walking speeds and were exercised twice daily at 1.12m/s for 20 min/bout for 60 days. The duration of exercise has been shown a significant osteogenic response in sheep and other mammals [3, 4]. The control sheep were not exercised. All sheep were housed in a large indoor pen at the University of Illinois Sheep and Beef Cattle facility and were able to move freely. Access to food and water was not limited.

Figure 1: Sheep walking on treadmill: (A) Flat, and (B) Incline (10° grade).

Three-dimensional (3D) limb kinematic data were measured with a 6-camera Qualisys (qualisys.com) motion capture system at 160Hz. Kinematic data were collected for group (i) and (ii) only, since control group was not trained to walk on treadmill. Reflective markers were placed on standard hindlimb landmarks (Fig. 1). Joint angles were measured at mid-stance (the hoof is beneath the hip) when peak loads are experienced. All subjects were euthanized humanely, limbs were dissected, muscles and ligaments were removed, and their limb bones segments were frozen.

Subchondral bone thickness measurement was evaluated on the medial femoral condyle (MFC). Femora were scanned with microCT at 50µm voxel size using a Siemens Inveon microCT scanner

(siemens.com/inveon). Noise was removed using MATLAB (MathWorks Natick, MA, USA), and 3D representations created using AMIRA (v 6.4, Thermo Fisher Scientific, MA, USA). Each specimen was resliced through the long axis of the MFC to obtain images along the axis of the joint. Thickness data were obtained using the BoneJ plugin from imageJ. The thickness values were then extracted by fitting a contour line to the joint surface. The coordinate values were plotted in 3D surface plot in MATLAB by putting the thickness as a color matrix. Three hydroxyapatite (HA) phantoms were included in all scans (Model 092, CIRS) to convert Hounsfield Units to apparent HA density. All statistics were calculated in MATLAB with a type one error rate of $\alpha=0.05$.

RESULTS

Exercised sheep experienced around 3600 more loading cycles per day than non-exercised sheep. On the incline walking, sheep used significantly more flexed knees ($p < 0.0001$) postures at mid-stance than on flat treadmills. The difference of mean knee joint angle was 8° between these two groups. A similar pattern of difference was observed when comparing the position of subchondral bone thickness between the groups of sheep. The position of the maximum subchondral thickness moved more posteriorly for the inclined group compared to flat group (Fig. 2). The maximum thickness region was distributed on the lateral-posterior subchondral bone, whereas the highest density was on the medial-anterior region. The thickness of exercise groups on the anterior region was significantly higher than that of the control group ($p < 0.05$). Between flat and incline exercise groups, the flat group had a significantly higher thickness in some regions distributed over the surface than the incline group ($p < 0.05$).

Figure 2: Averaged subchondral thickness maps of control, flat exercise, and incline exercise groups.

Also, in density maps, the medial-anterior regions in exercise groups had significantly higher density than in the control group, but it was relatively small area compared to the region that had a significant change in thickness (Fig. 3). There was no significant difference between density distribution of exercise and control groups ($p < 0.05$).

Figure 3: Averaged subchondral density maps of control, flat exercise, and incline exercise groups.

DISCUSSION

The objective of this study was to investigate whether the patterns of subchondral bone density and thickness could be affected by exercise and joint posture. Overall, there was an exercise effect on subchondral bone thickness and good correspondence between thickness-based measurement and kinematic results. As expected, higher subchondral thickness in exercised group was observed compared to control group. Also, flat group had larger area of significant thickness changes than incline group, suggesting that incline group might be loaded with smaller area on subchondral surface. On the other hand, subchondral density did not significantly respond to the loading from exercise in both flat and incline groups. Anterior subchondral thickness was significantly affected by the exercise, which had the maximum density, and this will be confirmed by analysis of range of motion of knee joint during each exercise in the future.

This is the first study that performed three-dimensional analyses of thickness and density on subchondral bone and in the future, investigating the effect of posture changes during exercise on thickness and orientation of trabecular bone, which is in deeper bone than the subchondral bone, will be done to conclude all the effects of exercise on bone. Understanding bone organization and composition, and their relationship to joint loading, will allow for the inferences relates to gait based on changes in bone as well as improvements in exercise regimens aimed to restore function after disease or injury.

INTRODUCTION

Osteoporosis, a metabolic disorder which entails the reduction of bone density in terms of reabsorption and thinning of bone trabeculae, results in an altered bone strength which increases the risk of fracture. Among osteoporotic fractures, hip fracture represents a major economic and social burden in western countries [1], dramatically affecting quality of life and increasing mortality. A clinical prediction strategy accounting for specific elements of the osteoporotic patient's clinical presentation, able to assist clinicians in forming a judgment regarding treatment outcome, is therefore mandatory. At present, osteoporosis is diagnosed using Bone Mineral Density (BMD), measured through dual energy X-ray absorptiometry (DXA). Unfortunately, its predictive ability remains limited. Aiming to improve the standard diagnostic process, hip geometric features have been recently proposed as fracture predictors, although a consensus has not been achieved yet [1,2]. This study explores the risk of fracture predictive potency of specific femur shape features identified by applying a statistical shape modelling approach. The proposed approach promises to contribute to gain further insights in the role played by geometry in osteoporotic risk fracture.

METHODS

Statistical shape modelling framework Two-dimensional profiles of proximal femur were reconstructed from DXA images of twenty eight post-menopausal women. On reconstructed geometries, realigned along their shaft axes, shape analysis was carried out within the non-parametric statistical shape modelling framework proposed by Durrleman et al. [3] and implemented in *Deformetrica* (www.deformetrica.org). The first step of the analysis involves the generation of a template \bar{T} , which represents the mean anatomical shape, from the input subject-specific shapes. Subsequently, following a forward approach [3], \bar{T} is mapped to each single shape T_i in the dataset,

so that each T_i can be described in terms of a subject-specific transformation function ϕ_i deforming the template \bar{T} , and by some residuals ε_i , representing features not accounted for by the deformed template:

$$T_i = \phi_i \cdot \bar{T} + \varepsilon_i \quad (1)$$

The individual deformation functions ϕ_i are numerically parametrized by so-called moment vectors.

Shape analysis The existence of possible associations among shape features and the risk of an hip fracture was here explored applying the Partial Least Square (PLS) regression method. PLS could indeed estimate the optimal subspace best explaining both the observed shape variance and its covariance with an external variable [4]. Here, the moment vectors parameterizing the subject-specific template deformations were gathered in an $N \times 2r$ matrix X of PLS predictors, N being the number of subjects, r the number of moments, defined as x - y pairs; PLS was thus carried out to identify deformation modes most relevant to Risk Factors (RF) derived in a previous study [2], where FE analyses on three dimensional models of the same patients were performed reproducing a sideways fall condition and the RF assessed using a principal strains based criterion. A subset of q PLS modes accounting for the 95% of the shape and RF sample variance was then considered among those previously identified. Afterwards, in order to obtain a numerical representation of each patient's collection of shape features, shape vectors $\mathbf{t}^i = \{\mathbf{t}^{i,m}\}_{m=1,\dots,q}$ were derived projecting the r moment vectors onto the PLS subspace defined by the q selected modes. Shape vectors quantify how much the shape features contained within the m^{th} mode are included in the i^{th} patient [4]. The q shape vectors were then correlated with the response variable RF, as well as with standard

geometric descriptors [2]. Pearson correlation coefficient and Kendall's τ were calculated on normally and non-normally distributed variables, respectively. Eventually, Canonical Correlation Analysis (CCA) was applied on the shape vectors. It allowed to evaluate how much each mode correlates with the RF and consequently to estimate the deformations to be applied to the template for predicting the shape corresponding to a given RF [4]. Indeed, new moment vectors β_{RF} were calculated using CCA outputs as follows:

$$\beta_{RF} = \bar{\beta} + \frac{RF - \overline{RF}}{\sigma_{RF}} R \sum_k \rho[k] p^k \quad (2)$$

where $\bar{\beta}$ is the average sample moment vector, \overline{RF} the average RF value, σ_{RF} the RF standard deviation, and p^k the k^{th} deformation mode. R and ρ , the CCA outputs, are the overall correlation coefficient and the array containing the individual correlations between each k^{th} deformation mode and the RF, respectively.

RESULTS

It was found that 11 PLS modes were necessary to describe 95% of the RF variability and 97% of the shape variability, the first 4 modes accounting for 90% of the shape variability observed in the sample. The first mode turned out, as expected [4], to be the most correlated with RF (Fig. 1), but it represents, at the same time, the most relevant mode with respect to the hip axis length ($r = -0.68, p < 0.001$), narrow neck width ($\tau = -0.45, p < 0.001$) and intertrochanter width ($r = -0.29, p < 0.01$). Moreover, it accounts for 24.8% of the shape and 27.5% of the RF variability. As for the neck shaft angle, it was found to be almost equally

Figure 1: Correlation between the RF shape vector (associated to the first PLS mode) and RF. Below, visual assessment of the template (in grey) and of its deformations along the first PLS mode (in blue).

correlated with the second and third PLS modes (II mode: $r = 0.52, p < 0.01$; III mode: $r = 0.52, p < 0.01$). CCA returned an highly correlated model ($r = 0.97, p < 0.001$), used to predict the shapes associated to an increased or decreased RF ($\pm 2\sigma$) with respect to its average value (Fig. 2). As can be observed by visual inspection, although slight variations in the hip axis length can be appreciated, the most relevant changes pertain to the neck shaft angle and the narrow neck width.

Figure 2: Template shape (in grey) superimposed on shapes predicted using CCA moment vectors and corresponding to a 2σ increased (right) and decreased (left) RF (in blue).

DISCUSSION

A statistical shape modelling approach has been here adopted to investigate the role played by geometry in the context of osteoporotic hip fracture risk. The approach was able to identify PLS modes properly capturing the dataset shape variability relevant to femur rupture risk, enforcing the predictive potency of standard DXA geometric variables. Among the limitations that could weaken the findings of this study, the limited number of patients involved, the two-dimensional proximal femur geometries investigated, and the biased input data, derived only from post-menopausal women. Nevertheless, in spite of the cited intrinsic limitations, the method appears promising to become a diagnostic tool for increased fracture risk prediction from femur shapes, providing clinicians with an empowered instrument supporting their decision. From this perspective, larger datasets will undoubtedly enhance the reliability of the models predictive power. Due to the encouraging results obtained from 2D shapes, easily achievable from available clinical images, the same approach could also be successfully applied on the 3D geometries derived from CT scans [2], not only aiming to assess the relation between 2D and 3D PLS shape patterns relevant to rupture risk, but also due to the possibility to predict 3D patient-specific shapes, not otherwise commonly accessible for osteoporotic patients using DXA derived data.

To the authors' knowledge, this represents the first study to adopt this approach in the field and it strongly corroborates the particular relevance of narrow neck width, hip axis length and neck shaft angle for fracture risk prediction, on which a consensus has not been accomplished yet [1,4].

INTRODUCTION

Bone-implant biomechanics influenced implant stability and peri-implant healing [1]–[3]. The biomechanics of the bone-implant construct, including mechanical strain, is affected by many factors, including bone morphology [4]–[6] and mineral density [7]. Mechanical testing coupled with micro-CT was performed on dental implants that were placed in cadaveric mandible specimens to reveal relations of the bone-implant biomechanics and bone-implant contact areas. The contact area and mechanical strain in multiple bone-implant constructs were measured based on the micro-CT images. Strain distribution patterns in different specimens with different bone-implant contact areas were compared. The implications of the results on dental implant stability were discussed.

METHODS

In situ mechanical testing coupled with micro-CT were performed to nondestructively characterize 3D full-field bone-implant contact and peri-implant strain concurrently [8], [9]. Cadaveric specimens of human mandibles were obtained (IRB exempted), sectioned and imbedded. Selected teeth were extracted from each specimen and dental implants were placed immediately. A quasi-static compressive load of 100 N was applied to the implant through a mechanical tester (CT5000, Deben UK Limited, Suffolk, United Kingdom) to simulate the normal chewing and biting force. Micro-CT scans (Phoenix v|tome|x L300 multi-scale nano/microCT system, GE, Boston, MA) were carried out before and after loading, respectively. Micro-CT images were obtained and processed (Avizo, FEI Visualization Sciences Group, Burlington, MA) to calculate the 3D bone-implant contact areas. The displacement and strain field in the mandible bone were also calculated by digital volume correlation (DVC) of micro-CT images with and without loads (DaVis software, LaVision, Goettingen, Germany). Strain distributions in the

peri-implant bone with different bone-implant contact areas were compared.

RESULTS

The dental anatomy and implant-bone morphology can be observed from the micro-CT images (Fig.1). In a transverse slice of micro-CT images for one specimen, the mismatch of the cross-sections for the alveolar socket and the dental implant can be observed. The implant were only making contact with the alveolar socket on the distal and mesial sides, but not the buccal and lingual sides (Figs. 1 and 2). The bone-implant contact areas only partly covered the surface area of the implant, as shown in Figure.2. In a specimen with bone-implant contact area was 21.7 % of the total implant area, the maximum principal strain in the peri-implant bone strain was observed to be higher than that in another specimen with 53.6% bone-implant contact (Fig.3).

Figure 1: A virtual transverse slice of micro-CT images for a dental implant in a human cadaveric mandible

Figure 2: 3D rendered images showing bone-implant contact areas (highlighted in red)

Figure 3: 3D rendered images showing the maximum principal strain in peri-implant bone for two specimens with different bone-implant contact areas.

DISCUSSION

Conventional method for measuring bone-implant contact through histology [10]–[12] can only reveal the bone-implant contact at the cut-surfaces. In this study, 3D full-field bone-implant contact areas were mapped out from the micro-CT images nondestructively. Results show that the smaller bone-implant contact area results in higher peri-implant strain in two specimens. Directions of future work includes more systematic study with larger sample size and *in vivo* study on correlation of bone-implant contact and the bone remodeling after implant placement.

INTRODUCTION

Biomechanics is thought to play an important role in several ocular pathologies, including glaucoma, idiopathic intracranial hypertension, and Spaceflight-Associated Neuro-ocular Syndrome (SANS). The biomechanical environment of the posterior eye is particularly complex, since these tissues experience loading from blood pressure, intraocular pressure (IOP), cerebrospinal fluid pressure (CSFp), and choroidal deformation [1]. We focus on the optic nerve head (ONH), a region in the posterior eye which is the primary site of retinal ganglion cell injury in glaucoma and likely in other conditions. Retinal ganglion cells transmit visual information to the brain, and loss of these cells causes visual impairment; thus, understanding ONH biomechanics is an important research topic.

Here, we more specifically consider SANS, a syndrome associated with long-duration space flight and which may be related to the cephalad fluid shift and jugular venous congestion that occur in sustained microgravity [2]. A notable finding in SANS is choroidal thickening/folds, yet the functional effects of such choroidal thickening are poorly understood. Recent in-flight imaging studies indicate that the choroid swells significantly in space [3], thickening far beyond the swelling predicted to occur normally, e.g. 2.1–14.2 μL over a cardiac cycle [4]. Our goal was to develop finite element models to study how choroidal thickening and choroidal anatomy affect ONH biomechanics, with application to understanding the pathophysiology of SANS.

METHODS

We have previously described our ocular model and finite element approach [4]. In brief, we extended an existing model of the posterior eye [5], including the annular scleral ring, pia mater, dura mater, and optic nerve (Fig 1). The pia mater, dura mater and optic nerve were extended posteriorly 10 mm from the ONH. We also included a single

central retinal vessel to approximate the effects of mean arterial blood pressure. We incorporated an anatomically realistic choroid based on OCT scans and average choroidal thickness measurements from the literature at specific distances away from the ONH [2]. Further, we considered two anatomical representations of the choroid: one with a “blunt” choroidal insertion at the ONH, and a second with a “tapered” insertion (Fig 1).

Figure 1: Top: representative OCT images at the optic nerve head (ONH) adapted from Lee et al. [8], showing choroidal geometries. Note the different choroidal terminations at the ONH. Bottom: Geometric model of the ONH/posterior eye, showing “blunt” and “tapered” choroid insertions.

The open-source program Gmsh was used to create the geometric models and for mesh generation [6], and FEBio was used as the finite element solver [7]. The model was axisymmetric, and was represented as a 3° wedge about an axis of symmetry passing through the central retinal vessel due to constraints of the FEBio solver.

The prelaminar neural tissue (PLNT), lamina cribrosa, optic nerve, central retinal vessel, and Bruch's membrane were modeled as isotropic, linear-elastic and homogenous. All other tissues were modeled as Mooney-Rivlin solids with embedded collagen fibers, distributed according to a von Mises distribution. The Young's modulus, Poisson ratio, and stiffness of the collagen fibers for each tissue component were based on previously reported values [2]. The choroid was modeled as a mixture material consisting of a linear-elastic solid matrix capable of swelling based on Donnan equilibrium. This approach allowed us to control the degree of swelling within the choroid without requiring us to model the complex geometry and behavior of the vascular bed.

Based on in-flight peripapillary OCT scans of astronauts [3], we assessed the impact of up to 50 μL of choroidal swelling, as well as the normal systolic-diastolic choroidal volume (2.1–14.2 μL , depending on ocular rigidity and other factors [4]). In addition, we examined the impact of elevating IOP to 30 mmHg without choroidal swelling, since this level of IOP puts subjects at high risk for developing glaucoma and the resulting loss of vision. Our outcome measures were the peak 1st and 3rd principal strains (95th percentile and 5th percentile) in the PLNT. All deformations and strain values were taken relative to a baseline configuration with no choroidal swelling, IOP of 15 mmHg (normal value), and mean arterial blood pressure of 57 mmHg (suitable for upright posture on earth at the level of the eye).

RESULTS

Consistent with previously reports, elevating IOP caused significant compression in the PLNT, a tissue region consisting primarily of retinal ganglion cell axons. Choroidal swelling caused significant deformation at the ONH (Fig 2), with the degree and extent of deformation being larger in the blunt vs. the tapered geometry. These differences increased as choroidal swelling became more extreme.

Figure 2: Contour plots of the computed first (red) and third (blue) principal strains in ONH tissues under an elevated IOP (30 mmHg), the upper limit of normal (physiologic) choroidal swelling (14.2 μL), and the choroidal swelling estimated to occur in astronauts (50 μL), for blunt (left) and tapered (right) choroidal geometries. All deformations are relative to a baseline condition of IOP = 15 mmHg and no choroidal swelling.

Choroidal swelling within the expected physiological range, i.e. that occurring over a cardiac cycle, led to significant cyclic strain in the PLNT. For the largest predicted extent of choroidal swelling over the cardiac cycle, strain magnitudes were either comparable to or greater than those predicted to occur as IOP was increased from 15 to 30 mmHg. However, for a choroidal swelling of 50 μL , estimated to occur in microgravity, predicted strains in the PLNT were far beyond the physiological ranges for both "blunt" and "tapered" geometries (Fig 3).

Figure 3: First (left) and third (right) principal strain versus degree of choroidal swelling. The shaded box represents the expected changes in choroidal volume and strains occurring over a cardiac cycle (normal physiology). The dashed horizontal line is the strain expected to occur due to IOP of 30 mmHg.

DISCUSSION

The chronic and significant choroidal thickening observed in some astronauts by OCT imaging is predicted to lead to significant biomechanical insult in prelaminar retinal ganglion cell axons. Specifically, we expect that such supra-physiologic choroidal thickening will lead to chronic local strain elevations many-fold greater than normal physiologic levels. This level of strain may induce remodeling at the ONH and be related to the alterations in visual function that some astronauts experience. For context, these strains are 5-7 fold greater than those expected to occur due to an elevated IOP of 30 mmHg, which is a major risk factor for developing glaucoma.

Interestingly, we found that the predicted strains in the PLNT due to normal choroidal swelling over a cardiac cycle may also exceed the deformations predicted due to an elevated IOP of 30 mmHg. Under normal conditions, individuals do not develop visual impairments due to cardiac cycle-induced changes in choroidal volume, which suggests that both the magnitude and temporal duration of choroidal swelling are important: choroidal swelling over the cardiac cycle is transient, while elevated IOP is chronic. This may be important in understanding the pathophysiology of SANS, since significant choroidal swelling can occur within 10 days of exposure to microgravity and be maintained throughout the mission. As additional astronaut and ground-based analog experimental data are gathered, we will be well positioned to use our existing models to predict the utility of various countermeasures on ONH biomechanics.

We also found that subject-specific differences in choroidal geometry at the ONH modulate the magnitude of strains due to choroidal swelling. Such anatomic features could be important risk factors for SANS and other diseases, e.g. non-arteritic anterior ischemic optic neuropathy. These results indicate that modeling of subject-specific geometries coupled with quantified choroidal changes in SANS is warranted.

INTRODUCTION

Pulmonary arteries carry deoxygenated blood from the right ventricle to the lungs in a normal circulation. In disease, pulmonaries experience an altered mechanical environment, as, for example, an increase in pressure in hypertension or volume in a single ventricle pathology. Characterizing their active and passive mechanical properties in health is a critical first step towards modeling their biomechanical behavior and understanding their remodeling in disease. Much work has been done in biaxial characterization of arteries in the systemic circulation [1-3] but there has been much less attention directed to pulmonary arteries, especially in murine species (notwithstanding a few notable exceptions [4]). While the ultimate goal is to study the human circulation and pathology, availability of diverse murine genotypes and phenotypes promises to facilitate an increased understanding of genetic and molecular aspects of diseases. Insight derived from comparisons of diverse murine systemic datasets provides strong motivation to characterize pulmonary arteries using protocols and methods that are consistent with those used to study the systemic circulation. Such consistent biomechanical phenotyping can aid inter-circulation comparisons and provide guidance for surgeries such as Fontan or Ross procedures.

METHODS

All animal protocols were approved by the Institutional Animal Care and Use Committee of Yale University. Male C57BL6/J mice (14-20 weeks of age, $n = 5$ per group) were euthanized with an intraperitoneal injection of Beuthanasia-D (150 mg/kg) followed by exsanguination. The pulmonary arteries were harvested from the root of the main branch to the first branching site on the right and left branches. Perivascular tissues were gently cleaned, branches were ligated, and vessels were prepared for biomechanical testing as

described previously [1]. The vessel was ligated on custom-made glass cannula past the main pulmonary bifurcation at one end and at the first branching site at the distal end. The specimens were biaxially tested using a custom computer-controlled device [5]. Biomechanical testing consisted of two parts: an active characterization and a passive characterization. In the active characterization, the vessel was contracted from its in vivo state (15 mmHg and vessel-specific in vivo stretch) at isobaric conditions until the diameter reached a steady state value (after approximately 15 minutes). Here we report active results for contraction with 100 mM KCl (a membrane depolarizer) and 1 μ M phenylephrine (an adrenergic receptor stimulus). In the passive characterization, the vessel was subjected to two cycles of pressure-diameter tests (5-40 mmHg) at each of three different stretches (in vivo stretch, 0.95x in vivo stretch, 1.05x in vivo stretch) and two cycles of force-length tests at each of the four pressures (5, 15, 25 and 40 mmHg). Note that both active and passive tests were preceded by an appropriate preconditioning step, details of which can be found elsewhere [6]. The active characterization was performed in a Krebs ringer solution at 37°C, at a pH of ~ 7.4 , and bubbled with 95% O₂ and 5% CO₂; the passive characterization was performed in buffered Hanks solution at room temperature to reduce contributions from smooth muscle tone to passive mechanics.

Keeping the analysis consistent with that used for systemic arteries, the mean mechanical behavior was modeled using a 2-D formulation, neglecting residual and radial stress [1-3]. The nonlinear passive behavior was modeled using a scalar stored energy function, under a pseudoelastic assumption. The stress and stiffness were computed from first and second derivatives of the stored energy function. The passive behavior of the vessel was modeled with a neo-Hookean model, capturing amorphous material behavior (mainly

elastin), and a four-fiber family model (along axial, circumferential and diagonal directions), capturing contributions from the structurally significant oriented constituents - smooth muscle and collagen.

Vessels not used for mechanical characterization (n=3 per group) were fixed in 10% neutral buffered formalin and stored in 70% ethanol at 4°C for histology. The samples were stained with Verhoeff's Van Giesen (VVG) and Masson's Trichrome (MTCs). We checked for statistical differences in active, mechanical and morphometric properties between the left and right pulmonary groups using one-way ANOVA with Tukeys post-hoc analysis.

RESULTS

Results of biaxial testing are summarized in Table 1. Although right (RPA) and left (LPA) pulmonary arteries exhibit different structural behaviors, they have very similar material behaviors. That is, despite differences in size, the biaxial material properties, including passive stiffness, elastic energy storage and biaxial wall stress at in vivo pressures, are similar between RPA and LPA. Even the contractile capacity at in vivo conditions was similar between the vessels. Area fractions of the wall constituents, for example, elastin, smooth muscle and collagen, from histological quantifications were not significantly different between the left and right pulmonaries [6].

DISCUSSION

Our results show that the material properties and functional behaviors of the left and right pulmonary arteries are remarkably similar in

healthy murine species. At in vivo conditions, the pulmonaries are more contractile, smaller in size, are less stiff, and they experience lower stresses than the descending thoracic aorta [7,8]. Results from these consistent methods, protocols, and analyses should serve as baselines for future biaxial experiments on murine models of pulmonary pathologies and thereby enable meaningful comparative biomechanical phenotyping across circulations.

EFFECTS OF LONG TERM SPINAL CORD INJURY ON THE MECHANICAL BEHAVIOR OF THE URINARY BLADDER EXTRACELLULAR MATRIX

INTRODUCTION

The main function of the **urinary bladder (UB)** is to store and void urine through mechanical relaxation and contraction [1]. The micturition cycle is coordinated through neurological connection to the brain: when the bladder is “full” a signal is sent to the brain, which voluntarily initiates contraction of the detrusor muscle and relaxation of the external sphincter in order to empty. Loss of neurological connection inhibits perception of bladder fullness, leading to increased stored urine volume, which triggers wall remodeling. In extreme cases this leads to inability to control detrusor contraction and sphincter relaxation, preventing individuals from voluntarily emptying.

Neurogenic bladder is the term used to characterize loss of control of the UB due to brain, spinal cord, or nerve problems (e.g., parkinsonism, spina bifida, **spinal cord injury (SCI)**, and diabetes mellitus). The remodeling of the neurogenic bladder wall results in hypertrophy of the smooth muscle cells and deposition / removal of **extracellular matrix (ECM)**, i.e., fibrosis [2, 3]. Wall remodeling, particularly changes in the ECM composition, can alter the compliance, thickness, and capacity of the UB, thus changing the underlying mechanical properties. This, in turn, can significantly affect the capability of the organ to perform its physiological function. Therefore, it is important to understand how the mechanical properties of the UB wall change in the neurogenic bladder.

A previous study by Gloeckner et al. compared the passive biaxial mechanical properties of UBs from normal rats, as well as rats 10 and 14 days after SCI, and found an increase in

compliance after SCI [4]. In this study, we will look at long-term changes in the UB wall mechanics by quantifying mechanical properties of the ECM of rat urinary bladders 14 weeks after SCI.

METHODS

SCI surgery was conducted on Sprague-Dawley rats (n=5) to induce paraplegia. Two ligatures (6.0 silk) were tightened around the underlying spinal cord between the second and third thoracic segments (T₂-T₃) and the spinal cord was completely transected by cutting between the ligatures with scissors.

Figure 1: Front view image taken with CCD camera (left) converted to binary image (right).

Figure 2: Stress-stretch curves from ring tests of control (blue dotted) and paraplegic (red solid) rat UBs.

The UBs were voided by manual compression four times daily until the end of the acute recovery period (8 days), at which point the rats recover partial ability to empty independently and were manually emptied once daily. Control animals underwent the same surgical procedure, but the spinal cord was not transected ($n=3$). Rats were sacrificed after 14 weeks. Whole rats were frozen and stored at -20°C before dissection. The rats were thawed for 3 days at 2°C and the UBs were excised, cut into rings, placed into embedding medium for frozen tissue specimens, and frozen at -80°C .

Prior to mechanical testing, rings were thawed and decellularized to isolate the ECM. Preliminary work showed that freezing did not alter the mechanical response of decellularized rat UB rings. Based on a previous protocol for whole-heart decellularization [5], samples were soaked in heparinized saline solution for 15 minutes, 10% sodium-dodecyl sulfate solution for 48 hours, deionized water for 15 minutes, and finally 10% Triton X-100 solution for 30 minutes.

Uniaxial ring tests were performed on the decellularized UB rings. A preload of 2 gr. was applied to the samples prior to preconditioning and each set of cyclical tests. Preconditioning consisted of 10 cycles of .1 strain at a strain rate of $.01\text{ s}^{-1}$. The subsequent cyclical testing consisted of 5 cycles each for strains of .2, .3, and .4 at a strain rate of $.01\text{ s}^{-1}$. Tests were stopped if the sample ruptured or the load cell reached a maximum capacity (250 gr.). Top and side view images of the samples were captured before each set of cyclical tests. Images were converted to binary (see **Figure 1**). Median width and thickness were used to calculate cross-sectional area (A_0). The force applied to the rings was recorded during the tests with a 250 gr. capacity load cell. The length of the sample in pixels was continuously recorded with a charge-coupled device (CCD) camera.

RESULTS

Figure 2 shows the stress-stretch curves from the ring tests for both the control (blue dotted lines, $n=3$) and paraplegic (red

Figure 3: Stress-stretch curves of control (blue dotted) and paraplegic (red solid) rat UBs averaged by stretch at equally spaced increments of stress.

solid lines, $n=5$) rat UBs. For each sample, the 5th loading curve of the final complete set of cycles was used. For example, if a sample ruptured or reached maximum load cell capacity during the 40% loading cycles, the 5th loading curve of the 30% loading cycles was used. **Figure 3** shows the curves for control and paraplegic averaged by stretch at incrementally spaced values of stress. Stretch (λ) is defined as the length of the sample divided by the initial length, after preload. Stress is defined as the force divided by the current cross-sectional area. Assuming incompressibility, the cross-sectional area changes by A_0/λ , where A_0 is width multiplied by the thickness, determined from top and side view images of the samples (see **Figure 1**).

DISCUSSION

The ECM of the urinary bladders of animals 14 weeks after SCI seems to be more compliant when compared to urinary bladders of control animals. This result agrees with what was previously shown for animals 10 and 14 days after SCI [4]. More SCI and control rat UBs will be tested to help validate this observation. Furthermore, UBs from rats with SCI seemed to be markedly larger than UBs from control rats. Analysis of images of rings before stretching will be used to quantify UB ring diameter and confirm this observation. Finally, histological analysis will be done on control and paraplegic rat UB samples to quantify changes in tissue morphology and ECM composition.

INTRODUCTION

Pressure ulcers are a painful, costly, and even deadly type of injury that disproportionally affects the older adult population [1]. In fact, 7 to 23% of older adults in nursing homes and hospitals in the US suffer from pressure ulcers at one point in their stay [1]. Pressure ulcers have been described as excruciating, and their treatment costs accrue to more than 16 billion dollars every year in the US [2]. There are a multitude of factors implicated in pressure ulcer initiation and progression, including behavioral and biological factors [3]. However, one element that remains poorly understood is the effect of tissue mechanics, particularly changes in skin mechanics with aging, on pressure ulcer formation. It is now clear that compression of the tissue under applied pressure leads to ischemia, subsequently to hypoxia, and is the major driver of pressure ulcer initiation [3]. At the same time, changes in skin anatomy and mechanical behavior with aging have been documented [4]. Yet, the connection between applied pressure, ischemia, and skin anatomy and mechanical properties remains unsolved. Our work aims at bridging this gap through a novel multi-scale mathematical model.

Previous work has shown that perfusion decreases under applied loads leading to ischemia [5]. Microvasculature deformation has been suspected as a principal mechanism linking the applied loads to ischemia, but current imaging technologies are not capable of resolving the detailed deformation of the vasculature in realistic scenarios [6]. To address this challenge, we rely on a high-fidelity finite element model of a representative volume element (RVE) of the skin with a detailed microvasculature geometry. We define a homogenized metric from the RVE, the change in vessel volume fraction, and couple this variable to a tissue level model of skin mechanics and oxygen diffusion. Our model allows us to then investigate *in silico* how changes in loading, mechanical properties, and skin structure can affect susceptibility to pressure-driven ischemia and, subsequently, hypoxia.

METHODS

We create microvasculature geometries that match the geometric features of the vascular tree in the skin [7]. We adapt previous work on two-dimensional fractal generation algorithms [8] and extend these algorithms to three dimensions. The vessel tree in the skin starts at the interface between the dermis, the middle layer of the skin, and the underlying fat and muscle. At this location, the branches of the vasculature tree are 200 μ m in length and we assume a constant vessel diameter of 20 μ m [7]. The tree undergoes 8 to 10 bifurcations as it progresses through the dermis towards the interface with the epidermis, the top layer of the skin. The epidermis is avascular. Each bifurcation results in branches with a 40% reduction in length. A realistic geometry generated with our fractal algorithm is shown in Fig. 1A. The tree is imported into a CAD software and, after several postprocessing steps, results in a 1mm³ solid RVE with a microvasculature inclusion as shown in Fig. 1B.

Figure 1: A) Vascular tree from our fractal generation algorithm matching features of the skin microvasculature. B) RVE finite element mesh of a 1mm³ tissue with the vasculature inclusion.

We perform compression of the RVE in order to get the change in vessel volume fraction upon RVE deformation, see Fig. 2A. We assume the skin to behave as a compressible Neo Hookean material and we use values of the parameters reported before: $\mu_0 = 75$ kPa, $K = 350$ KPa [9]. The initial volume fraction of the vasculature is ϕ_0 . The volume fraction of the deformed tree is ϕ . We generate multiple RVEs, each with a slightly different initial volume fraction. Hence, we normalize the volume change for each RVE, $\hat{\phi} = \phi/\phi_0$. We drive the simulation of the RVE by specifying the deformation between the top and bottom surfaces of the RVE while prescribing periodic boundary conditions on the lateral surfaces. In other words, we impose an average normal compression λ_z to the RVE. By tracking the change in $\hat{\phi}$ we can then construct the function $\hat{\phi}(\lambda_z)$, which is the link to our tissue scale model.

At the tissue level we have two coupled problems, one is the solution of mechanical equilibrium, for which we continue to use the Neo-Hookean model and parameters as before. We also solve for the partial oxygen pressure P_0 profile through the differential equation

$$\alpha \frac{dP_0}{dt} + \nabla \cdot \mathbf{q} = s_{P_0} \quad (1)$$

Here, $\alpha = 3 \times 10^{-5}$ mlO₂/mm³mmHg is the solubility, the flux obeys Fickian diffusion with diffusivity $D = 1.5 \times 10^{-3}$ mm²/s [10]. The coupling of the tissue level to the RVE model is through the source term s_{P_0} . We assume that the volume fraction of the vessel geometry is correlated to the oxygen supply, we then propose $s_{P_0} = \hat{\phi} s_0$, with $s_0 = 1 \times 10^{-5}$ s⁻¹ [10]. Fig. 3A shows the setup of the tissue scale model.

RESULTS

Fig. 2A shows the contours of the normal component of the Green Lagrange strain, E_{33} , when the RVE is compressed by $\lambda_z = 0.8$. The strain on the outer surfaces of the RVE is fairly homogeneous. However, inspecting cross sections inside the RVE it is evident that there are strain concentrations around the vessels. The magnification of the geometry in Fig. 2B shows vessel collapse. In fact, vessel volume fraction reduces more than 40% with less than 20% compressive strain.

Figure 2: A) Compression of the RVE by an average stretch $\lambda_z = 0.8$ leads to homogeneous Green Lagrange strain over the RVE with higher strains near vessels. B) Magnification of vessel geometry shows collapse upon RVE compression.

We fit the function $\hat{\phi}(\lambda_z)$ based on the RVE simulations and couple to the oxygen and tissue mechanics problem of the tissue scale. Fig. 3A shows the setup of the simulation. At zero applied pressure we recover a physiological profile of partial oxygen pressure seen at the top of Fig. 3B. As the pressure is increased, the tissue deforms, leading to

compression and collapse of the vasculature, reduction in the oxygen source term, and subsequent hypoxia.

Figure 3: A) Axisymmetric tissue scale simulation accounting for the three skin layers. Pressure is applied at the top surface leading to tissue deformation. B) As the pressure increases, the coupling of normal strain and our RVE model predicts patterns of hypoxia.

DISCUSSION

Here we have shown that a multi-scale model can capture pressure-driven hypoxia in the skin. Previous work has investigated the skin microvasculature, but has disregarded full 3D vessel geometries and how these deform under applied loads [6]. We address this gap through a high-fidelity model of a RVE of the skin including realistic vessel trees. Furthermore, we then couple this model to the tissue scale oxygen diffusion tissue model, thus enabling prediction of patterns of hypoxia under applied pressure for realistic domains not available before.

One limitation of our model is the lack of a fluid problem coupling for solving the blood flow inside the vascular tree. We impose a pressure boundary condition at the inner vessel walls, but a fluid-structure interaction problem would be more realistic. Additionally, modeling blood flow would allow us to better link the RVE to the tissue scale model. Our current assumption is that vessel volume fraction is correlated with the oxygen source term. While this is a reasonable simplification it should be investigated further. Experimental calibration of the model is another key next step. Despite the limitations, this work increases our fundamental knowledge of pressure-driven hypoxia, crucial to improve treatment and prevention of pressure ulcers.

INTRODUCTION

Abdominal aortic aneurysm (AAA) is an asymptomatic aortic disease characterized by the enlargement of the infrarenal segment of the aorta. Untreated AAA can rupture, which has an associated mortality of up to 90%. The current clinical management of AAA is based on assessing the size and growth of the AAA sac and clinical intervention is recommended for AAA with maximum diameter (D_{max}) > 5.5 cm in men, D_{max} > 5.0 to 5.4 cm in women. We hypothesized that using geometric indices (that best describe the shape, size, wall thickness, and curvature of the AAA), demographic information (gender and age), and biomechanical wall stress, will yield a higher accuracy when classifying electively and emergently repaired AAA than by using only D_{max} . Furthermore, by comparing the prediction accuracy of eight machine learning algorithms, we aim to select the machine learning tool that best discriminates between electively and emergently repaired AAA.

METHODS

Two groups of patients were studied: Group I, with $n = 98$ asymptomatic electively repaired AAA and Group II, with $n = 50$ symptomatic emergently repaired AAA. The abdominal computed tomography angiography (CTA) scans of the 148 AAA patients, their age and gender were obtained from an existing database in the Department of Radiology at Allegheny General Hospital (Pittsburgh, PA). The 98 asymptomatic AAA image sets were taken during routine checkup and 50 symptomatic AAA image sets were acquired no later than 1 month prior to the intervention. All segmentations were performed using custom in house segmentation scripts written in MATLAB (Mathworks, Inc., Natick, MA), collectively known as AAASc [1] (v1.03, The University of Texas at San Antonio, San Antonio, TX). The segmentation process exploits the difference in contrast between the AAA and its surroundings to segment lumen, inner

wall and outer wall. Patient-specific geometric indices were calculated, using in house developed MATLAB scripts based on the biquintic Hermite finite element (BQFE) method. Using the point cloud generated from the segmentation process, 1D and 2D indices were calculated. Volume and surface meshes, generated with the in-house MATLAB script AAAMesh, were used to calculate the 3D indices while the BQFE method was used to compute the curvature based indices. Wall material properties were derived from the Mooney-Rivlin constitutive equation reported by Raghavan and Vorp [2]. The volume mesh file was imported to ADINA (Adina R&D, Inc., Watertown, MA) where the stress tensor components were calculated at peak systolic pressure. The protocol for generating the geometric and biomechanical metrics is illustrated in Fig. 1. Eight machine learning algorithms (Generalized Additive Model - GAM, Decision Tree - TREE, Support Vector Machine - SVM, Multivariate Adaptive Regression Splines - MARS, Random Forest - RF, Least Absolute Shrinkage and Selection Operator - LASSO, K-Nearest Neighbor - KNN, and Negative Binomial Regression - NB) were carried out to classify the 148 AAA based on 52 geometric indices, four wall stress metrics (50th percentile wall stress - 50thWS, 99th percentile wall stress - 99thWS, peak wall stress - PWS, spatially averaged wall stress - SAWS), and one demographic variable (gender). The leave-one-out-cross-validation (LOOCV) method was applied to report the accuracy of prediction for all eight algorithms. Other common performance metrics such as specificity, sensitivity and Receiver Operating Characteristic (ROC) Area under Curve (AUC) were also calculated by LOOCV.

RESULTS

The dataset consisted of 76% male patients and 23% females. It was observed that Group II AAA had a larger maximum diameter, vessel volume and surface area, and greater overall length and AAA sac

length, than Group I AAA. The intraluminal thrombus volume of Group II AAA was nearly half of that of Group I AAA, while symptomatic emergently repaired AAA have thicker walls than asymptomatic electively repaired AAA. Mean PWS for Group II was significantly higher than for Group I (139.92 ± 57.71 N/cm² vs. 97.45 ± 43.63 N/cm²). The mean of the 99thWS for Group II was 66.94 ± 20.94 N/cm² while for Group I was 50.14 ± 16.79 N/cm². Similarly, SAWS had a mean of 29.72 ± 10.84 N/cm² and 22.03 ± 7.53 N/cm² for Groups II and I, respectively.

Figure 1: Schematic of the protocol for segmentation, meshing, and evaluation of the geometric indices and biomechanical parameters.

Of the eight machine learning algorithms, GAM had the highest accuracy (87%), AUC (89%) and sensitivity (78%), and was the best performing algorithm for AAA classification (see Table 1). TREE had the second best accuracy (79%) and a high sensitivity of 74%, although exhibited the lowest specificity of 82%. KNN and SVM are inefficient in predicting symptomatic emergently repaired AAA as the sensitivities for both were low (KNN = 46%, SVM = 30%). SVM also had the lowest accuracy of prediction amongst all algorithms. KNN has the highest specificity, which indicated it is effective in recognizing Group I AAA. Figure 2 shows the ROC curves for all 8 algorithms. With the variables used by GAM, the models with geometric indices alone (GAM-GEOM) and with biomechanical parameters alone (GAM-BIOM) were compared to GAM (see Table 2). GAM-GEOM had an 84% accuracy while GAM-BIOM had a 78% accuracy. Since GAM with both index types exhibited 87% accuracy, both geometric indices and wall stress metrics are needed to obtain a high classification accuracy.

Table 1: Performance metrics of the machine learning algorithms.

Model	Accuracy	AUC	Sensitivity	Specificity
SVM	0.69	0.73	0.30	0.89
NB	0.75	0.80	0.52	0.87
MARS	0.78	0.81	0.64	0.85
RF	0.78	0.83	0.56	0.90
LASSO	0.79	0.79	0.50	0.94
TREE	0.79	0.60	0.74	0.82
KNN	0.79	0.79	0.46	0.96
GAM	0.87	0.89	0.78	0.92

DISCUSSION

In the present work, wall stress metrics, geometric indices and demographic information were used to classify AAA using eight

different machine learning algorithms. The techniques were applied to a data set of 98 asymptomatic and 50 symptomatic AAA, while the quality of the prediction was assessed based on the accuracy of the algorithms, sensitivity, specificity, and area under the ROC curve. While the overall accuracy of the algorithms was high, ranging from 69% to 87%, the sensitivity (i.e. the correct prediction rate for Group II AAA) was disappointingly low, ranging from 30% to 78%. In addition, to being the overall best classifier, GAM also had a high false positive detection rate or specificity (92%) which ensures that the Group I AAA are detected accurately. GAM, which is an extension of generalized linear models, assumes that the dependent variables are represented as nonlinear additive functions of the independent variables [3]. Four variables (TH_{median} - median of wall thickness; TH_{Dmax} - wall thickness at the maximum diameter; P_{above} - percentage of wall thickness below the mean thickness, in %; and SAWS) were found to have a nonlinear response to the predictor. The fast classification of GAM results largely from its use of an adaptive back-fitting procedure similar to that used in MARS to guide both the selection of variables and to identify their optimal degree of smoothing. The main contribution of this work is in finding a nonlinear predictive classifier (GAM) that makes use of patient-specific wall thickness, which significantly improves the classification of asymptomatic and symptomatic AAA based on quantitative geometric and biomechanical analyses.

Table 2: Characteristics of the three GAM models.

Model	Accuracy	AUC	Sensitivity	Specificity
GAM	0.87	0.89	0.78	0.92
GAM-GEOM	0.84	0.87	0.70	0.91
GAM-BIOM	0.78	0.80	0.58	0.89

DESIGN, CALIBRATION, AND PRELIMINARY TESTING OF A SYSTEM TO MEASURE THE VISCOELASTIC PROPERTIES OF A PACINIAN CORPUSCLE

INTRODUCTION

The Pacinian corpuscle (PC) is a dermal mechanoreceptor responsible for transducing high-frequency (80-1000 Hz) vibrations [1], making it potentially important for many haptics applications, such as tactile aids for the hearing impaired and for button-click sensations. The structure of a human PC is ellipsoidal with dimensions on the millimeter scale [1]. Each PC contains a single nerve ending, surrounded by an outer core of approximately 30 collagenous lamellae separated by fluid [2]. Interaction between the lamella and fluid is responsible for filtering and transducing vibrations from the PC's outer surface to its central nerve [3]. There are several *in silico* biomechanical models of the PC, but more detailed parameters of the physical mechanoreceptor are still needed for more accurate simulations of PC dynamics.

The linear viscoelastic behavior of the corpuscle is of particular interest because it functions at high frequencies and low amplitudes, where linear viscoelasticity generally applies [4-5]. Studies often estimate the PC's viscosity to be approximately the same as that of water, which is a likely under-approximation. A previous study by our group determined an apparent Young's modulus of PCs isolated from cadaveric human hands as 1.4 ± 0.86 kPa using micropipette aspiration under steady-state conditions [6]. Also relevant, a purely kinematic study of PC under vibrational load was performed as part of a modeling effort [7], but no force measurement was made. Because the PC responds to frequencies in the 80-1000 Hz range, dynamic measurements of its biomechanical properties is crucial to understanding how the mechanoreceptor responds to *in vivo* stimuli.

In the current study, we designed, constructed, and calibrated a device to measure viscoelastic properties of the Pacinian corpuscle under physiologically relevant, i.e. millisecond, timescales as they respond to frequencies in the 50-1000 Hz range.

METHODS

We designed a system (Fig. 1) to stimulate an isolated mechanoreceptor mechanically from beneath and to measure the displacement of the PC on the opposite (i.e. top) surface. The apparatus consisted of a flat piezoelectric buzzer that provided the vibrational stimuli. The sample was placed directly on the buzzer. A polystyrene cantilever was mounted to an adjustable holder and lowered until it contacted the sample. When the sample was stimulated, the response motion of the cantilever was recorded via a laser vibrometer controller with interferometer. The input waveform to the buzzer and the vibration recordings from the interferometer were recorded simultaneously. Approximately 20 periods were recorded at each frequency with a minimum sampling frequency of 10,000 Hz.

The waveforms were characterized with Fourier analysis and fit to sinusoids. The phase difference between the displacement of the buzzer and that of the cantilever was determined to calculate the overall complex Young's modulus, of the sample.

Figure 1: Schematic of the system. The sample lies between the vibrating buzzer and the cantilever. The cantilever length, L_c , cantilever thickness, t_c , sample height, h_s , and cross sectional area of the sample, A_s , are shown. Cantilever deflection at the center of the sample is measured with a laser interferometer.

Two initial calibrations were performed. First, the deflection of the cantilever under its own weight was used to estimate the modulus E of the polystyrene to be 2.3 GPa. Second, we used the system with silicone-oil viscosity standards (Brookfield Engineering Laboratories; Middleboro, MA) and analyzed only the lowest frequencies, for which it is reasonable to neglect cantilever inertia. In that limit, for a purely viscous sample, the phase, δ , is given by

$$\tan(\delta) = -E \frac{I h_s}{\eta \omega A_s L^3} \quad (1)$$

where I is the moment of inertia of the cantilever, h_s is the height of the sample, η is the viscosity of the sample, ω is the driving frequency, A_s is the cross sectional area of the sample, and L is cantilever length.

The University Anatomy Bequest program provided a hand specimen for PC collection. PCs were identified and isolated from the palm and finger as described previously [6]. Individual PCs were tested at room temperature. A small volume of PBS was added with a needle syringe as needed approximately every 5 minutes to maintain sample hydration. Each experiment took 20-30 minutes.

RESULTS

The phase shift between the displacement of the buzzer and the system response with 500 cP silicone oil is shown (Fig. 2a) for a range of frequencies and two cantilever lengths, 2 and 4 cm. The linear regime was used in subsequent analysis to calculate the viscosity.

Figure 2: a) The phase difference between the buzzer displacement and the cantilever displacement at each frequency with 500 cP silicone oil. b) The cotangent of the phase difference. The black line is the linear regression from the 2 cm cantilever ($-8.7 \times 10^{-3}f$, $p=3 \times 10^{-5}$), and the red line is from the 4 cm cantilever ($-0.03f$, $p=0.009$) forcing the line through the origin. Black squares show data from the 2 cm cantilever, red circles the 4 cm cantilever. Filled shapes indicate low- ω data used in subsequent analysis.

From eqn. 1, one would expect $\cot(\delta)$ to be linear in ω and cubic in L at low frequencies. As can be seen in Fig. 2b, the shorter cantilever gave excellent results, but the longer cantilever did not give a line passing through the origin, and the slope of the best fit line was only four times, not eight times that of the data for the longer cantilever. Based on eqn. 1, the viscosity of the 500 cP silicone oil was overestimated to be 1100-1600 cP (fig. 3).

Fig. 4 shows preliminary experiments on a PC. As expected, as the cantilever length or thickness was increased, the phase shift between the displacement of the vibrating buzzer and the responding cantilever decreased. The PC samples were not analyzed with eqn. 1 because there were not enough data in the low-frequency, linear regime and because the tissue was expected to have a significant elastic component.

DISCUSSION

The creation of a new testing system was necessary to obtain reliable measurements of PC properties at high frequencies and small

displacements and can be extended for measurements on other samples. Standard systems are challenged in terms of both acquisition rate and amplitude sensitivity. By coupling a laser vibrometer to the driving piezoelectric vibrator, we have overcome these barriers.

Figure 3: The cotangent of the phase difference vs. the constants from eqn. 1. Black squares show the low- ω data from the 2 cm cantilever, red circles from the 4 cm cantilever. The solid lines show the linear regression for the 2 cm ($y=-15.7x$, $p=1.8 \times 10^{-6}$) and 4 cm ($y=-11.1x$, $p=0.009$) lengths forcing the line through the origin.

Figure 4: Preliminary experiment on a PC. A PC was tested with cantilevers of different heights (0.25 and 0.50 mm) and lengths (2 and 4 cm).

For a quasistatic (inertia-free) beam, the solution to the force balance is relatively simple, and eqn. 1 is readily derived. For calibration and testing purposes, it was fairly easy to use lower frequencies, yet the estimated viscosity of the test oils was found to be larger than their standardized values, indicating possible confounding effects of inertia and finite sample size. To obtain more accurate estimates of the Young's modulus of the PC, especially at higher frequencies, a finite-element model of the PC and the cantilever will be needed for complete analysis.

ACKNOWLEDGEMENTS

THE EFFECT OF INTERMITTENT THETA BURST STIMULATION ON BICEPS CORTICOMOTOR EXCITABILITY IN NONIMPAIRED INDIVIDUALS AND INDIVIDUALS WITH TETRAPLEGIA

INTRODUCTION

Neuromodulation of the primary motor cortex (M1) in pair with physical therapy is a promising method for improving motor outcomes. Rationale for neuromodulation to target excitability of the corticospinal motor pathways (i.e., corticomotor excitability) is that increases in corticomotor excitability of upper limb muscles have shown to be associated with motor learning and skill acquisition [1-3]. Intermittent theta burst stimulation (iTBS) is a form of non-invasive brain stimulation which can increase corticomotor excitability and is advantageous over other forms of neuromodulation due to its short duration and low stimulation intensity [4].

The long-term goal of our study is to determine if iTBS paired with physical therapy can improve motor re-education of upper limb muscles after tendon or nerve transfer in individuals with tetraplegia. More proximal upper limb muscles, such as the biceps, can be surgically transferred to restore elbow extension. However, the ability for iTBS to increase the corticomotor excitability of proximal muscles such as the biceps brachii is currently unclear. The majority of studies involving iTBS have targeted the first dorsal interosseous (FDI) in non-impaired individuals. This is likely because the FDI is an easier target due to a high density of corticospinal neurons projecting to the muscle. These studies have found that iTBS can increase the amplitude of motor evoked potentials (MEPs) in non-impaired individuals for up to 30 minutes, however the effects often vary across participants resulting in negative findings group-wide. These results may differ in more proximal muscles, such as the biceps, due to differences in corticospinal control across flexors and extensors. One study which targeted the flexor carpi radialis (FCR), a muscle more proximal than the FDI, found that differences in the resting motor thresholds (RMT) between the FCR and its antagonist muscle (extensor carpi radialis) appeared to determine the efficacy of iTBS [5].

The purpose of this on-going study is to determine the effect of iTBS on the corticomotor excitability of the biceps, as measured by MEP amplitudes, in non-impaired individuals and individuals with tetraplegia. We hypothesize that iTBS will increase biceps MEP magnitude in non-impaired (NI) participants as well as persons with spinal cord injury (SCI). Furthermore, we hypothesize that the difference in RMT of the target and antagonist muscles (biceps and triceps respectively, RMT_T and RMT_A) will correlate with changes in MEP amplitude pre- and post-iTBS.

METHODS

Eight non-impaired individuals and four individuals with a low cervical (i.e., C5-C8) SCI have participated in this on-going study. Each participant completed three sessions of the protocol involving both active and sham iTBS, with each session separated by a minimum of three days in order to minimize the potential for carry over effects.

In each session, participants were instrumented with surface electromyography electrodes on the biceps and triceps of their dominant arm. The maximal compound muscle action potential (Mmax) was recorded from the biceps and triceps by delivering single pulse electrical stimuli to Erb's point via a bipolar stimulating electrode connected to a constant current stimulator (DS7AH, Digitimer Ltd.). Resting motor threshold (RMT) and active motor threshold (AMT) were then determined for the target muscle (biceps) by delivering single pulse transcranial magnetic stimulation (TMS) to the cortical area projecting to the biceps. RMT was also determined for the antagonist muscle (triceps). Single pulse TMS was delivered using a Super Rapid Plus stimulator (Magstim) via a 70 mm figure-of-eight coil. RMT was determined as the lowest stimulus intensity that induced MEPs of $\geq 50 \mu\text{V}$ in at least 5 of 10 consecutive stimuli with the target muscle fully relaxed. AMT was determined through the use

of an adaptive PEST software, developed by Borckardt et al., during sustained contractions of $10 \pm 5\%$ of the participant's maximum effort [6].

Fifteen biceps MEPs were recorded via single pulse TMS delivered at an intensity of 120% of RMT, at intervals 10, 20, and 30 min after sham and active iTBS. The iTBS parameters consisted of three pulses presented at 50 Hz, repeated every 200 ms for 2 s at an intensity of 80% of the participant's AMT. Two second bursts were repeated every 8 s for a total of 600 pulses [4]. iTBS was also delivered with the Super Rapid Plus stimulator. For the sham condition, a sham coil, looking identical to the active coil and making similar noise without delivering any active stimulation, was applied to the cortical area projecting to the biceps. Throughout each session, participants were kept unaware of the type of stimulation they were receiving.

Normalized MEPs (nMEP) were calculated as the MEP amplitude divided by the participant's average Mmax and averaged within each session separately for both active and sham coil in pre or post iTBS groups. A t-test was used to compare the change in nMEPs after iTBS between the active and sham coil data for both NI and SCI participant groups. Pearson's correlation was calculated for the difference between RMT_T and RMT_A , and nMEP post iTBS.

RESULTS

Magnitudes of nMEPs were increased after iTBS for the NI sham group, SCI sham group, and SCI active group ($p < 0.01$), but not NI active ($p = 0.40$). There was no difference between the post iTBS nMEP magnitudes between the active and sham coils in either group (NI $p = 0.52$, SCI $p = 0.15$). There were no correlations between post iTBS nMEP magnitude and RMT difference (1. sham coil NI; 2. active coil, NI; 3. sham coil, SCI; 4. active coil, SCI, respectively are: $r^2 = 0.014, 0.014, 0.116, 0.176$; all with $p > 0.05$). Mmax, RMT values, and MEP amplitudes are provided in Table 1.

Table 1: Average Mmax, resting motor thresholds (RMT) and MEP amplitudes for the NI group and SCI participants.

Subj	Sess-ion #	Mmax (mV)	RMT (Biceps)	RMT (Triceps)	pre-iTBS	post-iTBS
					MEP Amplitude (μV)	Δ MEP Amplitude (μV)
Avg NI	1	3.96	89	100	17.7 ± 15	-2.45 ± 12
	2	3.37	91	100	11.1 ± 8.6	1.45 ± 8.7

	2	0.297	94	100	4.17 ± 1.9	0.456 ± 0.48
	3	1.03	97	100	12.1 ± 8.3	0.354 ± 2.21

DISCUSSION

We expected that iTBS would increase the corticomotor excitability of the biceps, represented by an increase in MEP amplitudes, in both NI and SCI participants. While there did tend to be an increase in MEP amplitudes post iTBS in both groups, our t-test showed that there was no significant difference in the change of

nMEPs between sham and active protocols. Additionally, while we expected there to be a correlation between the RMT difference of the target and antagonist muscles and the changes in MEP amplitudes post iTBS for both groups, our Pearson's correlation tests showed that there were no correlations.

A key outcome of this study was that both groups had not only a high degree of inter-subject variability, but also a high degree of intra-subject variability in the measured change of biceps MEP amplitudes. This was evident as a result of evaluating MEPs across multiple sessions and utilizing a sham coil as a control. Similar research done with continuous TBS has also shown varying responses across multiple sessions for each individual [7]. In addition to the variable responses seen in studies targeting the FDI, there may be some benefit in investigating the effects of iTBS on each participant in each session, rather than a group-wide analysis approach. This is further supported by other work that found the effects of iTBS on the FDI were independent across multiple sessions [8].

RMT focused inferences are of limited value with this data, as RMT intensities were frequently near or above the maximum intensity available with our stimulation unit and coil. While the use of a single coil prevents us from stimulating at an intensity that could fully capture the magnitude of MEPs in participants with higher motor thresholds, it is more realistic for a clinical approach. To circumvent this shortcoming, other studies have used a separate stimulation unit and coil to record RMT and MEPs [5].

The lack of a MEP facilitatory effect of iTBS could be driven by variables that this pilot study did not account for, such as genetic factors or baseline excitability. Furthermore, the effects of iTBS may be better observed using other modalities than MEP magnitude, such as EEG measurements or MEP latency, which have been used as alternative metrics [9,10]. Finally, as this is a presentation of preliminary findings, limited sample size is a current limitation of our work.

Our preliminary data suggests that on average there are no group-wide effects of iTBS on biceps corticomotor excitability in either the NI or SCI subject groups. This provides rationale for investigating effects of iTBS on an individual basis, and suggests further work is warranted to understand factors that contribute to inter-subject and intra-subject variability.

INTRODUCTION

Of the 1.7 million wheelchair users in the United States (US), 90 percent, or 1.5 million persons use manual wheelchairs (MWCs) [1]. People with traumatic and non-traumatic spinal cord injuries (SCI) make up approximately 20% of the MWC users, and 12,000 new traumatic SCIs occur every year [2]. While MWCs are immediately available and enable independence, 63% of MWC users will have one or multiple tears of the stabilizing muscles of the humeral head in the shoulder (rotator cuff) after decades of MWC use as compared to 15% of age-matched able-bodied adults [3]. Additionally, up to 70% of MWC users will experience shoulder pain [4]. A crucial gap in knowledge exists in understanding how shoulder function of MWC users during daily living compares with the able-bodied population since MWC users function from an almost permanently seated position and use their arms as an agent for mobility and weight bearing. Further research is also needed to understand how this altered function translates to longitudinal declines in shoulder health.

Inertial measurement units (IMUs) provide an inexpensive and simple way to measure the angular velocity and acceleration of body segments in environments of daily living. IMUs have also previously been used to quantify shoulder elevation angles [5]. Shoulder angles have been associated with rotator cuff compression and impingement, which are thought to be contributing causes of shoulder pathology [6]. IMUs can be used in daily life to understand how the shoulder functions and measure the exposure of the shoulder joint to motion that increases the risk of tendon damage, which may aid in understanding the etiology of shoulder pathology.

This study aims to quantify shoulder joint motion in new (<3 yrs MWC use), mid (3-10 yrs MWC use), and chronic (>10 years MWC

use) MWC users and an age and sex matched (to the new MWC users) able-bodied cohort. We hypothesize that new MWC users would have a different functional arm elevation workspace compared to their matched controls, and that this workspace would be similar between new, mid and chronic MWC users.

METHODS

The Mayo Clinic Institutional Review Board approved the study and written consent was obtained from all research participants. As part of a larger on-going investigation, a sub-set of 15 participants with SCI (five new users, five mid users, and five chronic users) and five able-bodied individuals who were age and sex matched to the new users are reported (Table 1). Participants reported the presence or absence of shoulder pain on their dominant side.

Table 1: Participant Demographics.

	Age (yrs) Mean \pm SD	Sex	Level of Injury	Participants with dominant shoulder pain
Controls (New)	43 \pm 12	2 M/3 F	-	0
New MWC Users	43 \pm 13	2 M/3F	T4-T12	4
Mid MWC Users	33 \pm 12	4 M/1 F	C6-L1	1
Chronic MWC users	49 \pm 7	5 M	C6-L1	2

Participants wore three wireless IMUs (Emerald and Opal, APDM, Inc.); one on each lateral upper arm and one on the anterior of the torso. Data were sampled at 128 Hz. Participants were instructed to

wear the sensors during the entire length of a typical day, excluding bathing time. Participants performed a calibration which utilized the following movements: static upright neutral posture with upper arms resting against the thorax, right/left arm t-pose (shoulder abduction = 90°), and right/left flexion pose (shoulder flexion = 90°). Similar to El-Gohary and McNamers (2012) a Kalman filter was used to estimate the orientation of each IMU relative to an inertial frame [5]. Custom Matlab (Mathworks, Natick, MA) code was written to calculate the orientations of the anatomical axes relative to the IMU-fixed reference frames from each participant's calibration movements. Arm elevation angles relative to gravity were calculated throughout the day, as well as periods of wear time [7]. Data were excluded from analysis if they did not meet the specified criteria of movement every 30 minutes. The percentage of daily wear time each participant spent in five humeral elevation bins were calculated (0-30°, 30-60°, 60-90°, 90-120°, and 120-180°).

RESULTS

For the dominant shoulder, all groups averaged over 45% of their day in 30-60° of arm elevation (Figure 1, Table 2). The new MWC users spent over 75% of their day between 0-60° while the control group spent over 70% of the day between 30-90° (Table 2). Both the mid and chronic MWC users spent over 75% of their day in the 30-90° range. Overall, all groups spent less than 5% of the day above 120°. No statistically significant differences were detected in this data set.

Figure 1: Percentage of time the dominant arm of each individual spent in each arm elevation range for (A) new MWC users (SCI) and age and sex matched controls (Con) & (B) new, mid, and chronic MWC users (Chr) for a day long data collection. The solid lines represent the mean of the data.

Table 2: The mean \pm SD percentage of time participants spent in each arm elevation level.

	Control (%)	New (%)	Mid (%)	Chronic (%)
0-30°	13.1 \pm 9.0	23.5 \pm 22.0	14.2 \pm 9.4	6.2 \pm 6.2
30-60°	46.7 \pm 15.7	53.7 \pm 23.2	58.1 \pm 12.2	64.9 \pm 9.4
60-90°	24.6 \pm 18.2	12.8 \pm 5.7	18.2 \pm 9.3	23.3 \pm 7.6
90-120°	15.2 \pm 17.7	5.3 \pm 5.1	8.0 \pm 6.5	1.7 \pm 1.3
>120°	0.4 \pm 0.2	4.7 \pm 7.4	1.5 \pm 2.2	3.9 \pm 7.5

DISCUSSION

The purpose of this study was to report preliminary data for a subset of participants from a larger sample to demonstrate the shoulder motion of MWC users and matched controls during daily life. All groups demonstrated a primary functional workspace of the shoulder between 30-60° of arm elevation. Recent literature has suggested that the supraspinatus tendon of the rotator cuff has a higher incidence of tears than other rotator cuff tendons and impingement of this tendon likely occurs between 0-60° [8]. All MWC users spent over 70% of their day in this range, which could be indicative of a higher risk for tendon damage from impingement. A decrease in time spent in higher elevation angles (90-120°) for the MWC population is consistent with previous literature which suggests MWC users have a decreased range of motion (ROM) compared with able-bodied individuals [9]. Additionally, decreased time spent by new MWC users in the 60-90° range compared to the mid and chronic MWC users may highlight a decreased use of available ROM in the immediate years after injury due potentially to decreased trunk stability. Limitations of this study include the small sample size and the exclusion of arm plane of elevation data in our analysis (which will be enabled by an improved shoulder angle algorithm). Current understanding of shoulder impingement and pain are related to specific planes of motion. Additionally, shoulder loading was not measured.

This preliminary data demonstrated the ability to measure arm elevation throughout the day for MWC users and a matched control group. Additionally, the study reported real-world shoulder elevation trends which will be further investigated with a larger cohort and analyzed in combination with tendon pathology data. The long-term goal of this work is to understand the longitudinal connection between arm elevation angles and rotator cuff tendon pathology.

EXERCISE THERAPY AFFECTS GLENOHUMERAL KINEMATICS IN PATIENTS WITH ISOLATED SUPRASPINATUS TEARS

Luke T. Mattar (1), Camille C. Johnson (2), Tom H. Gale (2), Adam Popchak (3), James J. Irrgang (3,2), William J. Anderst (2), Volker Musahl (2,1), Richard E. Debski (1,2)

INTRODUCTION

Rotator cuff tears commonly occur in the supraspinatus tendon¹, which is a primary initiator of abduction and compressor of the humeral head into the glenoid². It has been theorized that maintaining the “force couple” within the rotator cuff can conserve glenohumeral joint stability in the anterior and posterior directions in the presence of a supraspinatus tear. Non-operative treatment is often the initial recommendation, but it remains unclear what factors are most important in determining whether one should undergo non-operative versus operative treatment. Structured exercise therapy programs can improve strength of the rotator cuff and scapular muscles, however it is unclear how these improvements in strength affect in-vivo translations of the glenohumeral joint. If stability is not maintained, it can lead to pain and disability limiting one’s ability to perform activities of daily living. This emphasizes the importance of understanding the effect that exercise therapy has on glenohumeral joint stability during scapular plane abduction. The objectives of this study were to determine the effects of a 12-week exercise therapy program on glenohumeral kinematics and the relationship between glenohumeral abduction strength and maximum glenohumeral anterior translation in subjects with isolated supraspinatus tears during abduction in the scapular plane.

METHODS

Ten subjects (mean age 58.7 ± 5.6 years, mean BMI 27.5 ± 3.8) with a symptomatic degenerative rotator cuff tear isolated to the supraspinatus tendon were recruited for the study after providing IRB-approved written informed consent. Exclusion criteria included asymptomatic tears, previous shoulder injury, or presence of severe capsule tightness. Each subject underwent computed tomography (CT) of the affected shoulder and the images were segmented to create a 3-dimensional (3D) subject specific surface model of the humerus and scapula using Mimics

20 software package. The glenohumeral joint was imaged using biplane radiography³. Three trials of the motion were captured over 2 seconds per trial, starting in an adducted position and ending after maximum abduction was reached. The subjects were seated with their back straight during all trials. Digitally reconstructed radiographs from each subject and the captured biplane radiograph images were matched frame by frame using a custom model-based tracking technique (accuracy $\pm 0.4\text{mm}$ and $\pm 0.5^\circ$)³. Local coordinates systems for the humerus and scapula were based on a glenoid modified variation of the International Society of Biomechanics (ISB) standards⁴. Outcome measures included anterior/posterior (AP) and superior/inferior (SI) translation of the humerus with respect to the glenoid and the contact center of the humerus on the glenoid. AP and SI contact positions were normalized to glenoid width and height respectively. The normalization of the glenohumeral contact data results in the total contact path length normalized to glenoid size. Due to the variation in the amount of elevation between subjects, comparisons between pre- and post-therapy were made on an individual basis using the largest shared range of motion between data collection sessions. For all kinematic data, the trial containing the maximum elevation rotation angle was used for all analyses. Strength of the glenohumeral abductors was measured pre- and post- exercise therapy using a handheld dynamometer (Lafayette Manual Muscle Testing System). Paired sample t-tests were used to determine the difference in maximum AP translations, contact path length, and glenohumeral abduction strength pre- and post-therapy with significance set as $p < 0.05$. Pearson’s correlation was used to relate the changes in strength with differences in maximum anterior translations between pre- and post-exercise therapy with significance set as $p < 0.05$.

RESULTS

All subjects successfully completed 12 weeks of exercise therapy. A significant reduction in maximum anterior translation of $1.7\% \pm 1.9\%$ of glenoid width occurred post-exercise therapy ($p=0.03$). Six subjects showed a decrease in maximum anterior translation with the largest decrease being 4.8%. No increase in maximum posterior translation of $0.7\% \pm 2.7\%$ glenoid width occurred post-exercise therapy ($p=0.40$). A significant reduction in contact path length of $16.3\% \pm 18.7\%$ of glenoid size occurred post-exercise therapy ($p=0.03$). Eight subjects showed a decrease in contact path length with the largest decrease in contact path length being 40.6%. A significant increase in glenohumeral abduction strength was observed post-exercise therapy with an average increase of $11.3N \pm 9.5N$ ($p=0.01$). Eight subjects showed an increase in glenohumeral abduction strength with the largest increase in strength being 24.5N. Although no significance was recorded, a moderate negative correlation was found (Figure 1, $p=0.17$, $R^2=0.29$, $r=-0.54$). As glenohumeral abduction strength improved there was a decreased maximum anterior translation. Post hoc power analysis was conducted and it was determined a significant correlation would be expected with statistical power of 80% if a subject size of 24 was tested.

Figure 1: Correlation between the difference in glenohumeral abduction strength and difference in maximum anterior translation post-exercise therapy. Values presented are the measurements recorded post-exercise therapy minus measurements recorded pre-exercise therapy.

Figure 2: Representative contact path kinematics for a single subject during the scapular plane abduction task. a) Pre-exercise therapy and b) post-exercise therapy. The contact path is represented by the white line.

DISCUSSION

Our data shows that a structured exercise therapy program that focuses on restoring range of motion and strength overall successfully reduced the contact path length and maximum anterior translation and increased glenohumeral abduction strength. A significant decrease in contact path length post-therapy is indicative of greater joint stability during scapular plane abduction. The observed improvement in stability may be due to improvements in compensatory rotator cuff and scapular stabilizing muscles post-therapy as shown by the improved measures of glenohumeral abduction strength and decrease in anterior translation during the scapular plane abduction task. This may demonstrate improvements in the “force couple” of the glenohumeral joint, and could potentially be used as a clinical diagnosis for joint stability in physical therapy settings. Other studies have shown similar results regarding significant improvements in strength and contact path length in coronal plane abduction⁵. However, with a highly controlled exercise therapy program we were able to show that there may be a weak relationship between glenohumeral abduction strength and maximum translations in the anterior direction during scapular plane abduction. These findings are important clinically, as a study has shown an increase in the contact path length after rotator cuff surgery at 12 and 24 month follow-ups⁶.

Limitations of the study include a small sample size and lack of cartilage on the glenoid and humerus in the model tracking technique. This may lead to overestimation of contact path length. However, because the primary objective was to determine the effects of a 12-week exercise therapy program on glenohumeral kinematics within the same subject, lack of cartilage in the model should not have affected the quantitative comparisons.

In the future, more subjects will be analyzed to determine if a significant relationship exists between the differences in clinically measured glenohumeral abduction strength and the change in maximum anterior translations during scapular abduction from before to after exercise therapy. Additionally, relationships between patient reported outcomes and glenohumeral kinematics should be investigated. Further studies should be done that analyze the effects of exercise therapy on glenohumeral kinematics longitudinally in subjects with isolated supraspinatus tears to determine if joint motion and stability is maintained over time.

INTRODUCTION

In cases of severe thumb arthritis, surgery is often the best solution to reduce pain and improve function [1]. The most common surgery is a trapeziectomy; this is where the wrist bone at the base of the thumb (trapezium) is removed. To improve the mechanical stability of the thumb, basal joint arthroplasty replaces the bone with an alternative support for the thumb metacarpal [2]. One specific form of this replacement is a mini tightrope suspensionplasty. After the trapezium is removed, holes are drilled from the base of the first metacarpal to the proximal third of the second metacarpal. A strong braided non-absorbable suture is threaded through the bones to suspend the first metacarpal from the second, secured by two button anchors [3]. Case studies on hand surgeries have shown that this procedure is effective at reducing pain; however, research that documents the amount of the complete three-dimensional range of motion and force production recovered is lacking [3].

Therefore, the goals of this work were to 1) determine changes in motion abilities and force generation for the thumb pre- and post-surgery and 2) develop a visual representation so that the magnitude and locations of changes in hand function can be easily identified. This work will help surgeons to better understand the outcomes of surgery

and could be used in the future to differentiate between surgical techniques.

METHODS

Patients undergoing a trapeziectomy with a mini tightrope suspensionplasty were enrolled in the study. Participants were tested prior to surgery, then after 6 weeks of rehabilitation and again 12 weeks post-surgery. At each time point, function was quantified through standard clinical measurements, range of motion tests, and force application. For the clinical assessment the participant filled out three questionnaires: a lifestyle/medical history, DASH (Disabilities of the Arm, Shoulder, and Hand questionnaire), and a visual analog pain scale. For reference: DASH is 0 (perfect function) to 100 (no function); the VAS pain scale is 0 (no pain) to 100 (worst pain). Also, Jamar dynamometers were used to measure power and pinch grip (Figure 1e).

Three-dimensional motion abilities were determined through four movements: 1) flexion and extension of the metacarpophalangeal joint (MCPJ) and interphalangeal joint (IPJ) (Figure 1a). 2) Radial abduction of the first carpometacarpal joint (CMCJ) and opposition to fifth MCPJ (Figure 1b). 3) Radial adduction of the first CMCJ and opposition to fifth MCPJ. 4) Palmar abduction and adduction of the thumb. Each movement was tested three times.

Figure 1: Testing procedure. Range of motion was measured through a) full flexion of the MCP and IP thumb joints and b) full ranges of opposition and abduction. Force capabilities were measured at multiple positions and directions; shown are c) the palm at 0° (horizontal) and force directed medially d) and palm at 60° with respect to horizontal with force directed towards the ground. Hand grip was measured using Jamar dynamometers: power grip (e) and pinch grip (f).

Maximum forces were determined in two directions in each of eight positions (Figure 1c-1d). The positions were based on varying rotation of the palm and abduction of the thumb. The palm was tested at four angles relative to the ground: 0°, 30°, 60° and 90°. At each rotation, the thumb was tested in two positions: full adduction (touching the palm) and maximal abduction of the thumb. At each position the participant was asked to apply maximal force towards the ground and then towards the hand.

RESULTS

Thus far, one patient has completed the full twelve-week study. We hypothesized that six weeks post-surgery the patient would experience reduced pain, but still demonstrate reduced function as healing of the hand was not complete. After twelve weeks we hypothesized reduced pain, improved force generation, and improved range of motion. Clinical measures confirm our hypothesis (Table 1). After six weeks pain is deceased, both grips had similar strengths, but the dash score worsened. After twelve weeks, all clinical measures had improved as hypothesized. The DASH represents how the participant feels her hand is able to function during the tasks of daily living.

Table 1: Clinical measures before and after surgery. Power pinch grips are the average of three dynamometer trials. VAS pain and DASH are questionnaires representing how the participant feels about her pain and function.

Measure	Pre	Post 6	Post 12
Power Grip (N)	56.5	60.9	90.3
Pinch Grip (N)	18.7	12.9	24.5
Pain (VAS)	83	8	2
DASH	35	47	17

Range of motion tests results also confirmed our hypothesis (Figure 2). The figure on the left depicts the 3D motion of the hand as viewed from the front, showing opposition to the fifth MCP joint. A semi-transparent hand has been added to indicate the orientation of the figure. All three ranges of motion are shown together overlapping. Shown on the right are the average forces (average of four trials) at each rotation of the hand. Six weeks post-surgery the motion space was decreased: the participant stated that while there was little pain in her hand, the CMC joint was stiff. At twelve weeks the motion space had returned to a similar size as before; however, the shape of the space had changed. Post-surgery the participant had increased palmar abduction and opposition but had reduced adduction (touch thumb to second MCPJ). Strength abilities did not change six weeks after the surgery. However, at the twelve-week test the magnitudes were 66% larger on average. This mirrors the dynamometry data, showing that force stayed

similar between pre-surgery and 6 weeks post-surgery and increased at the final test point.

DISCUSSION

The goals of this work were to determine changes in motion abilities and force generation for the thumb due to surgery and to develop a visual representation to identify the magnitude and locations of these changes. Force abilities increased for all test conditions. This was also shown in the dynamometry measures; however, current clinical measures cannot identify the specific contribution of the thumb as they are taken together with other fingers. From our data the force generation abilities increased 10-15 Newtons. Future work will correlate thumb strength abilities to thumb posture and include force direction. Differences in the motion shape are apparent (Fig. 2) and this is likely due to changes in the mechanics of the region. Prior to surgery, joint support came from the trapezium, a solid bone that supported load. Following surgery, the bone was removed and replaced by a suture suspension system (cable). This system is not rigid and can lead to different resultant forces on the base of the metacarpal. The suture will help stabilize the thumb motions, but differently that the solid bone structure. How the suture affects force transferal will also depend on where it is anchored in the second metacarpal. Future work will investigate suture tightrope and attachment locations and how they affect the range of motion and force production through modeling simulations.

The second goal of this project was to represent change in motion abilities visually. Figure 2 shows the range of motion of the participants thumb at each of the timepoints. Although this is a 2D representation of a 3D space, differences can be easily identified. Pre-surgery has a section to the right side showing higher extension of the thumb MCPJ. Many osteoarthritic patients exhibit hyper extension at the thumb MCPJ due to the development of a “Z” deformity, as the CMCJ subluxes progressively causing adduction of the first metacarpal generating extension forces at the MCPJ. Post-surgery tests both include a spike to the top representing the improved palmar abduction and increased opposition. These data can be viewed from any orientation, which permits easy comparisons with regard to the hand and the movement. In the future we will continue to improve the tools to display functional changes, both in making them easier to understand the orientation and adding strength abilities. We also plan to use these visualizations to compare between surgeries and treatments to understand differences in the functional outcomes.

INTRODUCTION

There are over 50,000 total shoulder arthroplasties (TSA) in the United States each year [1], making it the third most prevalent total joint arthroplasty behind total knee (TKA) and total hip (THA) arthroplasties. However, complication rates of between 10-15% in TSA [2] are higher than typically reported for TKA and THA. While the etiology of clinical failures is multi-factorial, complications related to the glenoid component have been cited as a primary cause of clinical failure in TSA [3]. Several researchers have characterized the morphology of glenoid component damage in order to elucidate the mechanisms and etiology of glenoid failure [4,5,6]. For example, repetitive translation of the humeral head along the superior/inferior (S/I) axis of the glenoid component has been associated with glenoid loosening, described as a “rocking horse” motion [7]. However, these insights have yet to result in new implant designs which demonstrate long-term clinical efficacy commensurate with other large-joint arthroplasties, suggesting that additional inquiry is required to fully understand *in vivo* biomechanical behavior and the progression of glenoid damage.

To address this issue, we analyzed the macroscopic surface deformation of twenty-five retrieved glenoid components spanning multiple component designs, surgeons and material formulations using a coordinate-measuring machine (CMM). Elucidating the macroscopic morphology of *in vivo* surface damage and comparing retrieved component geometries to their theoretical pristine conditions and patient information can provide unique insight into mechanisms of glenoid component damage and be a basis for design improvements.

METHODS

The articular surfaces of twenty-five retrieved ultra-high molecular weight polyethylene (UHMWPE) glenoid components (Table 1) were

scanned using a CMM at planar isotropic resolution of 254 μm (resulting in $\sim 10,000$ point-cloud coordinates per implant). Operative data on the implant manufacturer and model were used to identify the original radius of curvature of each glenoid (i.e. pristine pre-operative geometry). Then, a custom algorithm was used to generate point-cloud coordinates of a pristine implant (i.e. “control”), which enabled comparison of the retrieval surface to its original shape.

For each retrieval, deformation was computed by subtracting, point-by-point, the retrieval point-cloud from the control point-cloud. Thus, positive deformation values denote an opening-mode, whereby the glenoid was expanded from its original shape. Two primary outcomes were considered: 1) the magnitude of deformation and 2) the spatial distribution of deformation. The magnitude of deformation was determined by separately calculating the 90th percentile of positive and negative deformations for each implant and plotting these values as a function of *in vivo* duration. The spatial distribution of deformation was determined by first calculating the 90th percentile of the absolute value of deformation of the entire point cloud, then plotting any deformations above this value on the implant surface as red (positive deformation, opening-mode) and blue (negative deformation; closing-mode). These plots were then visually compared. Both outcomes were compared against available clinical data to identify correlations between implant deformation and patient-related factors.

Table 1: Patient demographic information. Values are mean \pm SD.

Time <i>in vivo</i> (months)	64.1 \pm 61.5
Age at implantation (years)	57.1 \pm 9.0 (n = 24)
Shoulder side	n = 14 right n = 11 left

RESULTS

Longer *in vivo* durations tended to result in larger amounts of deformation (Figure 1). The magnitude of the top 10% (90th percentile) of negative deformation was highly correlated with *in vivo* duration ($R^2 = 0.61$, Figure 1, blue) whereas the magnitude of positive deformation was not ($R^2 = 0.00$, Figure 1, red). Interestingly, summing the absolute values of the 90th percentile of positive and negative deformations slightly improved the correlation with *in vivo* duration ($R^2 = 0.63$, Figure 1, black), meaning that variation in damage accumulation is better explained by accounting for the interaction between deformation modes. Overall, *in vivo* duration was the best predictor of surface damage based on the available clinical factors.

In terms of the spatial distribution of deformation, the largest deformations occurred primarily at the implant edges (Figure 2). The top 10% of deformation for 76% of retrievals (19/25) was localized to the S/I edges, and of these retrievals, the mode of deformation was exclusively negative (closing) for 74% (14/19, Figure 2A) and exclusively positive (opening) for 26% (5/19, Figure 2B). Interestingly, for the 24% (6/25) of retrievals for which deformation was not localized to the S/I edges, the top 10% of deformation included a combination of both positive and negative deformations, and always involved the anterior/posterior (A/P) implant edges (Figure 2C).

Figure 1: Magnitude of top 10% of deformation vs. *in vivo* duration.

DISCUSSION

The glenoid component in TSA is subject to a complex biomechanical environment involving both rotation and translation through a large range-of-motion [6]. This complexity, coupled with confounding variables such as fixation scheme, scapular bone quality, patient age, and physical activities, makes understanding *in vivo* loading conditions difficult. Yet, our results show consistent patterns in the magnitude and spatial distribution of deformation. For most implants, the largest deformations congregated at the S/I implant edges and are dominated by a closing mode; for a second group, the largest deformations also occur at the S/I implant edges but are dominated by an opening mode; and for a third group, both the S/I and A/P edges are recruited and a combination of opening and closing modes are evident. There were no apparent trends with respect to damage pattern as a function of reason for retrieval (n=19/25 available), patient age, or shoulder side. However, the magnitude of closing-mode damage was correlated with time *in vivo* and this correlation slightly improved when both opening and closing-mode magnitudes were combined.

Based on our current understanding of shoulder biomechanics, there is likely not a force which directly “closes” the glenoid

Figure 2: Spatial distribution of deformation. A) 14/25 exhibited a closing mode at S/I edges, B) 5/25 exhibited an opening mode at S/I edges, C) 6/25 exhibited mix modes with recruitment of both A/P and S/I edges

component, making it more conforming to the humeral head. However, a previous study which also reported glenoid closing using laser surface scanning suggested that a combination of wear and UHMWPE cold flow could presumably result in this type of glenoid deformation [4] following axially compressive loads exerted by the humeral head. The correlation between *in vivo* duration and closing-mode deformation reported here lends supporting evidence to this hypothesis, as both wear and cold-flow are time-dependent phenomena.

The translation of the glenoid along the S/I axis, which is thought to be a factor in edge-loading and subsequent loosening [6], could plausibly explain the opening-mode of surface deformation. The fact that this deformation mode occurs at the S/I extremes of the implant is mechanically intuitive, as it is at these locations for which the compressive loading moment-arm is largest. Interestingly, the three implants which exhibited the largest amounts of opening-mode deformation were explanted after relatively short *in vivo* durations (Figure 2B), and opening-mode damage generally did not increase with time *in vivo* (Figure 1). It is therefore possible that at shorter *in vivo* durations, perhaps when cement fixation is strongest, S/I translation serves to deform the glenoid in an opening-mode, whereas if fixation breaks down due to repeated edge loading, the “rocking-horse” motion enables translation without material deformation. This speculative hypothesis warrants further investigation.

Overall, our study provides unique insight into macroscopic glenoid deformation sustained *in vivo*. The discrete deformation patterns identified can elucidate how existing designs behave under physiologic loading, and can therefore aid in the design of components which improve TSA efficacy.

INTRODUCTION

Glaucoma is an ocular disorder typically characterized by an increase intraocular pressure (IOP) that can lead to blindness.^{1,2} Controlling IOP is essential to prevent vision loss. When medications are ineffective, surgery is sometimes required to treat glaucoma. A common surgical procedure is the implantation of a glaucoma drainage device (GDD) which allows drainage of aqueous humor (AH) from the anterior chamber of the eye through a small silastic tube. With such devices, a fibrous capsule forms around the GDD in the 2 to 6 weeks following implant surgery, becoming the source of resistance to AH outflow. Prior to this, IOP can be too low if not controlled. Various modifications have been created to control post-surgical IOP with limited success.³ We have proposed a new method to modify GDDs in order to reduce the risk of early post-operative hypotony.^{4,5} We propose inserting a degradable suture of appropriate diameter and length into the tubing of the GDD to provide sufficient resistance to AH outflow to maintain an acceptable IOP in the early post-operative period.^{4,5} The insert would degrade over 2 to 6 weeks until fibrous capsule formation is sufficient to provide flow resistance.

METHODS

Theory

The resistance of a concentric annular insert can be modeled using Hagen-Poiseuille (H-P) theory for annular flow:⁶

$$\Delta P = \frac{8\mu L_t Q}{\pi} \left(r_2^4 - r_1^4 - \frac{(r_2^2 - r_1^2)^2}{\ln\left(\frac{r_2}{r_1}\right)} \right)^{-1} \quad (1)$$

where r_2 is the inner diameter of the tube and r_1 is the outer diameter of the insert. This model assumes fully developed, laminar flow of a Newtonian fluid. For a typical GDD tube, with an inner diameter of 300 μm and a flow rate of 2.5 $\mu\text{L}/\text{min}$, the Reynolds number is 0.20,

supporting the assumption of laminar, fully developed flow. The model assumes the annular insert is concentric with the tube.

To examine this assumption, we can look to Manning's equation of eccentric annular flow:⁷

$$\Delta P = \frac{12\mu L_t Q}{\pi} \left((r_2 - r_1)^3 (r_2 + r_1) \left[1 + 3 \left(\frac{e}{(r_2 - r_1)} \right)^2 \frac{r_2}{(r_2 + r_1)} + \frac{3}{8} \left(\frac{e}{(r_2 - r_1)} \right)^4 \frac{(r_2 - r_1)}{(r_2 + r_1)} \right] \right)^{-1} \quad (2)$$

where e is the distance between the centerlines of the tube and the annular insert. This model assumes that e is small. Nominally, it can be no larger than $r_2 - r_1$.

Figure 1. Hagen-Poiseuille theory and Manning equation show good agreement over the range of applicable suture diameters for a tube inner diameter of 300 μm . 3-0, 4-0 and 5-0 sutures of 8 mm in length would be appropriate for providing some resistance to flow during the early post-operative phase.

Figure 2. Flow resistance with 3-0, 4-0 and 5-0 sutures would be decreased with increasing eccentricity of the annular insert.

While the Manning equation is able to represent eccentricity in the annular insert, it has poor agreement with Hagen-Poiseuille when the annular insert has a very small diameter and pressure drops are low. In the case where the insert radius (r_1) is zero, Manning's equation should simplify to Poiseuille's law, but does not. However, the Hagen-Poiseuille equation for annular flow and the Manning equation do have good agreement over the relevant suture diameters (Fig. 1).

The Manning equation can be used to examine the effects of asymmetry of the centerline of the insert (Fig. 2). A concentric insert has the highest flow resistance. Flow resistance can be reduced by as much as 80% when the insert is against the tube wall.

These predictions of pressure assume the insert and tube diameters are exactly at the manufacturer specifications. Small variations in diameter would affect these results. Additionally, insert swelling and bends in the tubing or inserts could affect these predictions.

Experimental

The experimental setup consisted of a precision pneumatic pump, a bottle containing deionized (DI) water, microfluidic tubing and connections, a pressure transducer, a data logger, and a test section (Fig. 3)⁵. The test sample is connected in a

Figure 3: Schematic of microflow pressure-measuring test setup⁵

a temperature-controlled incubator (± 2 °F). A trial typically consisted of pumping DI water at the nominal human eye AH outflow rate of 2.5 μ l/min, and measuring the accompanying pressure drop across the length of tubing (test sample) of interest.

Three 4-0 and one 5-0 non-absorbable prolene sutures and one 4-0 absorbable monocryl suture were used to examine the alignment of these predictions with experimental data. Each suture was cut to a length of 8 mm and placed in a silastic tube with a nominal inner diameter of 300 μ m. The system was primed for approximately 10 minutes before the trials in order to ensure that undetected air bubbles were removed from the setup. A baseline pressure reading was taken prior to insertion of the sutures. This baseline pressure drop was subtracted for pressure data during the trial.

RESULTS

The initial pressures (one day into collection) were 0.235 ± 0.233 mmHg for the 4-0 prolene annular insert, 0.360 mmHg for the 5-0 prolene annular insert, and 0.448 mmHg for the 4-0 monocryl annular insert. Over days, the pressure increased on most of the samples (Fig. 4). Two 4-0 prolene samples had a dramatic pressure increase one after day 12 and one after day 27.

Figure 4. Flow resistance was examined for 5 suture samples. One sample had a dramatic pressure increase after day 12, possibly due to microbial contamination. Short pressure spikes are due to momentary oscillations in the flow control system.

DISCUSSION

The experimental results demonstrate general agreement with the predicted pressure, with a wide variability, likely due to variability in the actual suture diameter and possible eccentricity of the insert. Future work will look at using micro-CT to examine the exact dimensions of the inserts. Increases in pressure over the course of several days may be due to swelling of the suture. The monocryl appears to swell more than the prolene, but additional samples are needed to confirm this. The sudden dramatic increase in pressure of two prolene samples may be due to microbial contamination of the sample or displacement and bending of the sample. The monocryl sample continues to run and we expect that we should eventually see degradation of the sample and decreasing pressure. Future work will examine this degradation in order to make recommendations for the use of degradable sutures in glaucoma drainage devices.

AORTIC SINUS VORTEX SPATIO-TEMPORAL VARIATIONS WITH LEAFLET CALCIFICATION

Hoda Hatoum (1), and Lakshmi P. Dasi (1)

(1) Department of Biomedical Engineering
The Ohio State University
Columbus, Ohio, USA

INTRODUCTION

The aortic sinus vortex is one of the most important and prevalent fluid dynamic features in the aortic sinuses. It is now acknowledged that the aortic sinus vortex plays a role not only in the opening and closing mechanisms of the leaflets¹, but also in the context of sinus washout and overall energy efficiency of the aortic valve system²⁻⁴. In addition, it was demonstrated that aortic sinus vortices initiation, entrapment and evolution play an important role in sinus stasis and washout^{3,4}. Nonetheless, the factors impacting the spatio-temporal structure of the aortic valve sinus and how perturbation of this vortex can impact function, washout, and energy losses have not been completely addressed. Moore et al³ provided an experimental study highlighting the importance of heart rate and fluid viscosity on the spatio-temporal structure in the aortic sinus vortex. Experimental studies by Hatoum et al⁴ and numerical studies by Fukui et al⁵ highlighted the dependence of aortic sinus vortex spatio-temporal topology on the morphology and geometry of the aortic sinuses. However, the stiffness of the leaflets and how that could impact the vortex formation, propagation and topology have not been investigated. Leaflet stiffening and its impact on the sinus vortex is critical from the standpoint of progression of calcific aortic valve disease (CAVD). This is because, in addition to genetic characteristics along with predisposition for particular inflammatory pathways fluid shear stresses and hemodynamic factors have emerged as one of the major regulators for initiation and progression of CAVD⁶. The objective of this study is to visualize and characterize the variations of the aortic sinus coherent structures as they form and evolve throughout the cardiac cycle as a function of leaflet calcification degrees (stiffer leaflets with calcification).

METHODS

A degenerated 23mm Carpentier-Edwards Perimount Magna surgical aortic valve (SAV) extracted from a patient who underwent a redo surgery (Fig.1a,b) was implanted in an aortic root model. The valve is degenerated and characterized by three leaflets with three significantly different degrees of calcific nodules: mild calcification (volume of 0.001 cm³), moderate calcification (volume of 0.0592 cm³) and severe calcification (volume of 0.275 cm³). The chamber was set up into the aortic position of a pulse duplicator flow loop. Sinus hemodynamics were assessed for each of the three leaflets. Hemodynamic parameters for all conditions were maintained with a systolic to diastolic pressure of 120/80mmHg, a 1 beat per second heart rate and a cardiac output of 5L/min. 60 consecutive cardiac cycles of aortic pressure, pressure difference across the aortic valve (or pressure gradient as clinically recognized and as will be adopted in the sections below), and aortic flow rate data were recorded at a sampling rate of 100Hz. Time-resolved raw particle image velocimetry (PIV) images were acquired with a resulting spatial and temporal resolutions of 0.159mm/pixel and 4000Hz respectively. Circulation and viscous shear stress were calculated and leaflet tracking was performed.

RESULTS

Fig.1c and 1d show the valve configuration when it is closed and when it is open respectively. The mildly calcified leaflet almost completely opens while the severely and moderately calcified leaflets do not. Leaflet tip tracking shown in Fig.1e displays the differences among the three leaflets measured from a common point near the

centerline. As expected, the mildly calcified leaflet opens the most ($4.38 \pm 0.037 \text{ mm}$) followed by the moderately calcified ($2.23 \pm 0.07 \text{ mm}$)

Figure 1: (a) Calcification distribution on the (a) aortic and the (b) ventricular side of the valve; (c) Closed configuration and (d) open configuration of the valve; (e) Leaflet tip position from a common point above the centerline as a function of normalized time (0 = opening; and 1 = closing).

and the severely calcified ($2.16 \pm 0.02 \text{ mm}$).

Figure 2 shows exemplary velocity and vorticity fields obtained in the sinus for the three cases. For the moderate and the severe case, the distinct absence of counter clock-wise vorticity is notable and instead presence of clockwise vorticity emanating from the separated flow boundary layer at the sinotubular junction (STJ) is entrained into the sinus.

Evaluating the circulation in the sinus area; Fig.3a shows the alternating positive and negative circulation values in the severely calcified sinus with an average circulation of $-1.30 \times 10^{-4} \text{ m}^2/\text{s}$. Fig.3b shows a prevalent negative circulation with the moderately calcified leaflet with only positive variations at the beginning and the end of the cycle. The

Figure 2: Velocity and Vorticity during Acceleration phase for the three cases illustrating the drastic variation in the mechanism that drives sinus flow. Flow from left to right.

circulation found was $-9.47 \times 10^{-4} \text{ m}^2/\text{s}$. Fig.3c shows a prevalent positive circulation of total magnitude of $1.85 \times 10^{-3} \text{ m}^2/\text{s}$. In Fig.3d and 3e during systole, the mildly calcified leaflet sinus case shows the most spread-out and higher ranges of shear stress probabilities and highest magnitudes ranging from -1.5 to $+1.8 \text{ Pa}$. Significantly higher probabilities to develop higher shear stress magnitudes were found with the moderately calcified case compared to the severely calcified one. The severely calcified case has the highest shear stress probabilities around 0.0 Pa shear stress, followed by moderate then mild. During diastole, the severely calcified leaflet case was characterized by the smallest span of shear stress. The moderately and mildly calcified cases show almost similar probability distribution range going from -0.8 Pa to 1.0 Pa with similar likelihoods on the positive shear stress distribution side and higher likelihoods for higher shear stress for the mild on the negative range side.

DISCUSSION

The changes in the aortic sinus vortex evolution can be captured and explained in Figure 4 as deduced from circulation values and from particle image velocimetry images. The degree of calcification impairs valve opening and closing mechanisms and thus it directly affects the coherent vortex structure development in the sinus. The higher the calcification degree the lower the shear stress range and likelihoods of having higher shear stress. Cell expression profiles studied by Butcher

Figure 3: Variations in circulation versus time for the 3 different sinus cases with (a) severe, (b) moderate and (c) mild leaflet calcification along with Probability density function of varying shear stress distribution near the different leaflets in the sinus during (a) systole and (b) diastole.

et al⁷, suggest that valvular endothelial cells are protected from oxidative, inflammatory stress and calcification beginning and propagation by shear stress. Calcification disease process is thought to be initiated by several factors, low shear stress is one of the most important ones⁸. In this study, when the shear stress is quantified in each of the three cases, during systole and probably intuitively, the larger shear stresses and the larger probabilities to obtain high stress with the smaller probabilities for near-zero shear stresses were obtained when the leaflet has mild calcification (almost fully opens). The higher the calcification density on the leaflet, the significantly smaller the shear stress distribution becomes.

INTRODUCTION

Approximately 280,000 people worldwide receive a heart valve transplantation per year [1]. For patients with severe regurgitation, prolapse or calcification, this is one of the best treatment options. Mechanical heart valves are more commonly implanted in patients due to their durability [2]. However, the need for life-long anticoagulant therapy motivates physicians to consider an alternative valve, specifically, bioprosthetic heart valves (BHVs). BHVs are commonly made of bovine or porcine tissue and implanted only in elderly patients due to an average valve lifespan of 10-15 years.

To test the fatigue experienced by BHVs and determine the life span, the U.S. Food and Drug Administration mandates that BHVs be tested with an accelerated wear tester (AWT). This test must adhere to the ISO:5840 guideline which indicates the valve cycling rate, the pressures they should experience, the number of cycles, and any other testing conditions [3]. In a study performed by Iwasaki *et al.*, a polymer valve was cycled in three different AWTs [4]. They noticed that by increasing the cyclic rate, the lifespan of the valves were considerably shortened. Additionally the location of tears and fatigue experienced in the AWTs did not match animal experiments. Due to the high frequency testing and the non-physiological conditions observed in AWTs, the mechanism of *in vitro* fatigue may not accurately predict the fatigue mechanisms experienced *in vivo*. Therefore, this study aims to quantify the fluid dynamics of BHVs within an AWT, using high-speed particle image velocimetry (HSPIV). By developing an understanding of the fluid mechanics in an AWT environment, better fatigue tests for bioprosthetic surgical and transcatheter valves could be performed.

METHODS

To study the fluid mechanics of BHVs mounted in AWTs, an Electroforce[®] Durapulse[™] AWT (TA Instruments, New Castle, DE)

was modified for optical access. This system consists of a proximal chamber upstream of the valve, a distal chamber downstream of the valve, pressure transducers (Utah Medical Products Inc., Midvale, UT) at the base of each chamber, and a valve housing between the chambers (Figure 1A). This system was mounted on a Bose linear motor to develop pressure gradients consistent with ISO:5840. A 31 mm Hancock valve (Medtronic, Minneapolis, MN) was mounted in the Durapulse[™]. The Durapulse[™] cycled the Hancock valve at 900 bpm in a blood analog comprised of glycerin and water, producing a density of 1.13 g/ml and an asymptotic dynamic viscosity of 3.99 cP to match the viscosity of 40% hematocrit blood. To maintain consistency with ISO:5840, a transvalvular pressure of 100 mmHg was maintained across the closed valve for approximately 20% of the cycle. The Durapulse[™] recorded pressure waveforms at the distal chamber and proximal chamber and then, calculated a delta pressure (Figure 2).

Figure 1: A. HSPIV experimental set-up with the Durapulse[™], high speed camera, and laser. B. Zoomed-in view of near valve region in distal chamber. C. Front view of Durapulse[™] valve region denoting the HSPIV planes of interest.

Next, the Phantom Miro-Lab 110 high-speed camera (Vision Research, Wayne, NJ) was mounted to visualize the side of the Durapulse™ chamber (Figure 1A). The camera was focused on the region directly downstream, above, and below the valve (Figure 1B) using extension tubes. A high-speed Terra PIV laser (Continuum, San Jose, CA) produced three vertical planes for collection: the centerline (0 mm) and ± 5 mm (Figure 1C). Two sets of HSPIV data were collected, an averaged set and an interpolated set, at a resolution of 26 pixels/ μ m. For the averaged set, 1000 image pairs were collected at 11 time points. For the interpolated set, 53 images were rapidly collected consecutively, 1.2 ms apart, to visualize any random flow phenomena that may develop. Insight 4G (TSI, Inc., Shoreview, MN) triggered image pair capture at the peak of the distal waveform and the images were processed with Tecplot Focus (Tecplot, Bellevue, WA).

Figure 2: Durapulse™ waveform for each chamber and delta pressure. The trigger used for HSPIV is indicated.

Finally, the effective orifice area (EOA) of the heart valve was quantified. The Phantom high-speed camera was mounted to visualize the heart valve opening and closing over 11 time points through the cycle. Images were acquired in TSI's Insight 4G and processed with MATLAB (MathWorks, Natick, MA). To improve the image contrast between the valve and the open orifice area, an external light source was positioned. Valve EOA images were processed in MATLAB using the workflow shown in Figure 3.

Figure 3: Workflow of processing raw valve images in MATLAB to determine the EOA

RESULTS

Starting with the effective orifice data, the valve opened for approximately 44% of the 66 ms cycle, allowing for fluid to flow into the distal chamber. As demonstrated in Figure 4, the opening was asymmetric, and the jet profile of the systolic flow could be dependent on the valve orientation. Due to valve age, the valve also did not open completely, demonstrating some stiffness associated with the leaflets. Finally, while the leaflets coapted, a twisting or pinwheel effect was observed.

Data obtained using HSPIV showed a jet formed during systole. As shown in Figure 1C, the valve orientation was such that, the larger opening would be at the top of the valve and would narrow moving

downward. The jet reflected the valve opening by having the jet exit from near the top of the valve at the start of ejection (Figure 5). Looking further into the cycle, eddies randomly formed in the distal chamber. During valve closure, a large recirculation region formed consistently downstream of the valve base. This recirculation formed while the valve closed and continued until the start of the next cycle. The random eddies that formed around the valve and downstream of the valve demonstrated a level of three dimensionality.

Figure 4: Raw EOA images of 31 mm Hancock valve.

Figure 5: Centerline interpolated HSPIV flow field at the start of systole demonstrating an asymmetric jet caused by valve orientation.

DISCUSSION

These results are an initial step in understanding the flow associated with BHVs in an AWT environment, which has never been explored previously. The results demonstrated that the valve flow transitioned from a jet to a series of eddies downstream of the valve. This study was limited by the age of the valve (10 years old) which displayed a stiff behavior by not opening entirely. Gaining knowledge on the fluid mechanics, specifically, the influence of the jet, the random eddies and the non-physiological testing frequency could contribute to understanding fatigue mechanisms imparted by AWTs. The next step is to correlate the new understanding of AWT fluid mechanics to valve fatigue after cyclic testing and create new waveforms for increased physiological relevance.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) has been a life-saving procedure for inoperable high-risk patients with severe aortic valve stenosis, as an alternative to surgical aortic valve replacement (SAVR). In recent years TAVR devices are being implanted in younger lower risk patients as an alternative to SAVR. Although valve designs and procedure approach have been refined over the past 17 years[1], those are still subject to persistent clinical complications, including poor deployed valve performance, device migration, increased risk for stroke, flow stagnation leading to device thrombosis, and leak or regurgitation flows around the valve stent (PVL or paravalvular leaks)[2]. With TAVR deployed in younger patients the device durability becomes a critical design issue. Tissue-based TAVR valves suffer faster deterioration than SAVR valves, combined with new calcific mass formation in the xenograft tissues. Several studies suggest that the method of crimping (compressing the device stent and tissue to sizes below 16F) and deployment damages the xenograft tissues and negatively impacts the durability[1].

Polymeric TAVR valves have been conceptualized to address some of the clinical complications as well as the durability associated deterioration[3]. Recent advances in hemocompatible polymeric technology are harnessed to design optimized valves that achieve similar or less thrombogenic potential achieved by tissue valves, as well as the ability to cast higher precision valve morphologies with superior valve hemodynamic performance- additionally extending the durability of the valve by preventing calcific infiltration into the valve leaflets.

Development of TAVR devices conventionally relies on idealized bench testing methods and/or *in vivo* animal testing in healthy anatomies. The discovery of clinical failures/complications, along with refinement of the device design to address them, relies on clinical experience on patients. Experimental and computational models of

diseased patient-specific geometries would allow the development process of the TAVR device to study with greater detail these clinical complications and iterate device design before ever risking a patient's safety.

METHODS

Utilizing a novel self-expandable polymeric valve, PolyV-1 (PolyNova Cardiovascular Inc., Stony Brook, NY), it was compared

Figure 1. (A) Rendering of calcific pattern of one patient valve with matching aorta (B) Rendering of PolyV-1 design (C) Deployed PolyV-1 in the stenotic valve (D) Vascular Simulations Replicator simulator, black arrow highlighting location of patient specific anatomy placement.

against two tissue-based valves: the Carpentier-Edwards Perimount Magna Ease (PME) surgical valve (Edwards Lifesciences, CA) and the Innovare TAVR valve (Braile-Biomedica, Brazil), all of size 20mm or equivalent. Initial testing was completed in an ISO-compliant left heart simulator (Vivetro Labs, Victoria, BC) having an idealized anatomy.

Patient-specific experiments: Five patient models were reconstructed from CT scans of TAVR patients with procedural complications, obtained by Stony Brook Hospital: 3 with moderate to severe PVL, 1 with device migration, and 1 with poor post-deployment valve performance. The anatomies were scaled to fit the available TAVR valves and have equivalent oversizing in all the patients. Silicone models of the patient-specific aortic root and stenotic valve models were made by Vascular Simulations Inc (Stony Brook, NY) to interface with their Replicator simulator (Fig 1), which contains a complete silicone arterial tree of the major vessels with a functional beating left heart and a closed loop feedback system to maintain physiological flows and pressure waveforms. The anatomies were segmented with Materialise Mimics (Materialise NV, Belgium). The valves were cast with polyurethane (30A) with a uniform leaflet thickness of 400 μ m and semi-rigid calcifications. The aortic root was molded in a proprietary process with physiologically relevant silicone with a uniform thickness taken from the aortic lumen geometry. The Replicator simulator allows collection of hydrodynamic performance of the valves in accordance to the ISO-5840[4].

Clinical imaging: The simulator design allows the collection of imaging data comparable techniques available in the clinic. In each of the 5 geometries ultrasound continuous-wave (valve performance) and color doppler (# of regurgitant jets) are collected. Angiography images with contrast injections into the aortic root to assess leak patterns and severity as well as ventricular injections to study washout times for flow stagnations. Finally, cardiac MRA studies are collected both with phase contrast studies retrograde to the valve for accurate measures of the leak jet velocities and 4D flow analysis of the systolic jet and stagnations.

MicroCT and Computational Models: The deployed valves inside the stenotic native valves will be scanned in a μ CT scanner and segmented to obtain the leak channel geometries (Fig 2). This also allows the study of the eccentricity of the stent corresponding to the calcification distribution in the native valve. The segmented geometries will then be incorporated into patient-specific computational fluid dynamics (CFD) models to determine the shear stresses and thrombogenic potential of the leak paths.

Figure 2. (A) Example μ CT slice of the deployed PolyV-1 in patient-specific stenotic valve. Green highlight indicating the PVL channel (B) Rendering of segmented μ CT data: gray-stent frame, red-native valve, blue- polymeric TAVR sleeve, and green arrows showing the larger PVL channel

RESULTS

Comparisons of the idealized models tested in ISO regulated traditional pulse duplicator systems to that of a patient specific replica

tested in the Vascular Simulations Replicator indicates significant differences in various valve performance metrics[5]. In the idealized models (Fig 3) all three valves performed well when comparing their effective orifice area (EOA). The PolyV-1 (EOA 1.7 cm^2 at 5LPM) had equivalent or better performance as compared to a gold-standard SAVR (EOA 1.6 cm^2 at 5LPM). However, in the patient-specific anatomy, all the valves suffered a performance loss and the PolyV-1 (EOA 1.3 cm^2 at 5LPM) fell below the SAVR (EOA 1.4 cm^2 at 5LPM). This is most likely due to the fact the SAVR valve was deployed without the calcified native leaflets to mimic the dissection during the surgical procedure.

Figure 3. Hydrodynamic results of all three valves comparing the idealized geometry simulator to the patient-specific simulator.

DISCUSSION

As computational models progress with increasing complexity, so should experimental models, not only to provide validation for the computational models but also to bridge the gap with clinical measurements and techniques. The PolyV-1 performance was initially studied with a fluid-structure interaction (FSI) computational model in the idealized geometry[6] and with the advancement of these experimental techniques, the FSI can be expanded to the patient-specific model as well. The immediate goal is to establish a testing platform for testing clinical failure modes of TAVR devices and to consider these results in the device design iteration phase, the platform can also extend beyond this endeavor. The proposed methods serve to complement each other and provide deeper insight into TAVR valve performance. The simulator allows the direct comparison of many clinical imaging modalities, as well as assessment of the accuracy of the measurements. The ultimate impact and benefit to accurate and complete patient-specific models will be to reduce the risk to future patients with better devices and better-informed clinicians.

INTRODUCTION

Mitral regurgitation (MR) is the most common valvular heart disease, with a prevalence of 9.3% in the US population aged 75 and above [1]. Although Doppler echocardiography (echo) is the primary clinical tool to assess the severity of MR, quantitative assessment of MR remains challenging and a true gold standard technique is still lacking [2]. American Society of Echocardiography guidelines recommend quantifying MR primarily using two techniques [3]: the proximal isovelocity surface area (PISA) method, and the volumetric technique (VT) or the quantitative pulsed Doppler method. Clinical and *in vitro* studies have demonstrated that the 2D PISA method may significantly underestimate or overestimate the regurgitant volume (RVol) [2]. The VT method is simple in principle, however, it has not achieved a widespread usage in the clinical community.

The objectives of this study were to evaluate the fundamental assumptions in the clinical echo quantification of MR using computer modeling, identify the pitfalls in the assessment of MR severity, and propose methodologies that could correct its assessment in the clinical setting.

METHODS

Four left heart acute MR computer models with posterior mitral leaflet (PML) prolapse following chordae rupture were used in this study [4]. These models were developed from a previously validated subject-specific left heart fluid-structure interaction (FSI) computer model (72-year-old female patient), which serves as the control model [5]. PML prolapse was modeled by removing chordae elements from different chordae groups, starting from marginal and intermediate chordae, and then progressing towards partial and total chordal origins, representing a pathological process in which minimal chordae rupture precedes more extensive chordae rupture. Chordal rupture models were

named based on the ruptured chordae insertions on the PML: marginal & intermediate P1 (M&I P1), marginal & intermediate P2 (M&I P2), P2 & P1, and P2 & P3, where the lateral PML scallop is P1, the central scallop is P2, and the medial scallop is P3.

For simulated echo MR quantification, the flow data from the FSI models was extracted at four discrete time instances in systole (including the instance of peak MR). To emulate the measurement of PISA in clinical practice, velocity magnitudes (i.e., the aliasing velocity) were chosen to obtain a closed and nearly hemispherical shell proximal to the orifice. The continuous wave Doppler (CWD) velocity waveform was obtained by extracting the flow velocity along a beam aligned with the regurgitant jet. By doing so, we assumed that the ultrasound beam was optimally aligned with the jet, indicating no underestimation of the velocity due to misalignment in the simulated echo measurements.

In the computer models, to account for the effect of Doppler angulation, the ultrasound probe was located 13 cm away from the mitral valve (MV) in the apical direction, representing a scan depth of 12 to 16 cm in transthoracic echocardiogram (TTE) examination in clinical practice. By projecting the velocity vectors in the direction of the ultrasound beam, the altered velocity field was used to extract the proximal flow convergence (PFC) in the simulated echo measurements (i.e., the 3D-echo PISA). In general, the 3D-echo PISA should be smaller than the true PISA (without Doppler angulation effect), as shown in Figure 1a. The surface areas of true PFC and 3D-echo PFC can be readily extracted by triangulation in the models. The hemi-elliptic (3D-HE) PISA was calculated by the measurement of three orthogonal radii and integration to obtain the surface area. Furthermore, the 2D-echo PFC was obtained by slicing the 3D isovelocity contours in an apical 4-chamber (A4ch) view (Figure 1b), or an apical 2-chamber (A2ch) view (Figure 1c). The shell radius could be easily estimated by

delineating the border of the isovelocity contour (Figure 1b, 1c), and the averaged radius was used to calculate the surface area of hemispheres.

Figure 1: (a) A representative severe MR model due to P2 & P1 leaflet prolapse at peak MR from the FSI simulation. The velocity field is shown in a cross-sectional plane with a maximum MR jet velocity around 5 m/s. The red cylinder denotes the ultrasound beam direction of the CWD in the measurement of MR jet velocity. Representative 2D-echo PFC contours were measured (b) in an A4ch view, and (c) in an A2ch view from TTE.

RESULTS

The flow fields from the FSI simulations are treated as the ground truth values in this study. Figure 2 shows the flow rates across the aortic valve (AV) and MV during the entire cardiac cycle. The negative flow at the end of systolic in Figure 2a indicates the retrograde flow into the left ventricle (LV) during AV closing, while the negative systolic mitral flow in Figure 2b indicates the backflow into the left atrium due to the MV closing and MR. During systole, the control model had the largest forward stroke volume (SV). In the MR models, the forward SV decreased as the severity of MR increased, which is consistent with the increasing negative flow volume across the MV. Since the left ventricular size and wall motion were assumed to remain unchanged in all models, mimicking acute MR, it can be seen that the diastolic inflow rates across the MV were approximately the same for all models.

Figure 2: Flow rates across the (a) AV and (b) MV throughout the cardiac cycle from FSI simulations.

The ground truth $RVol_{MV}$ was obtained from the FSI models by integrating the negative MV flow rate curve over time. Similarly, the $RVol_{AV}$, SV_{AV} , and SV_{MV} were calculated and listed in the top section of Table 1. The combination of the SV_{AV} and $RVol_{MV}$ is known as the total SV of the LV (LVS_{SV}), which was used to calculate the regurgitant fraction, $RF_{MV} = RVol_{MV}/LVS_{SV}$. By using RF_{MV} as a quantitative parameter in the grading of MR severity, Table 1 shows that two MR models (P2&P3 and P2&P1) can be classified as severe MR, one moderate MR (M&I P2), and one mild MR (M&I P1). Note that the values in parenthesis denote the relative percentage error with respect to the ground truth values (i.e., FSI- $RVol_{MV}$).

Table 1: Summary of hemodynamic parameters obtained from the FSI simulations (ground truth) and calculated from the simulated echo measurements using the PISA method at peak MR.

	Control	M&I P1	M&I P2	P2&P3	P2&P1
FSI-$RVol_{AV}$ (ml)	4.27*	4.63	4.61	4.62	4.72
FSI-SV_{AV} (ml)	58.22	51.55	41.94	20.46	16.16
FSI-SV_{MV} (ml)	63.22	61.67	61.65	63.03	62.97
FSI-$RVol_{MV}$ (ml)	9.27*	14.75	24.32	47.19	51.53
FSI-RF_{MV} (%)	13.7	22.2	36.7	69.8	76.1
MR severity	Normal	Mild	Moderate	Severe	Severe
True PISA $RVol_{MV}$ (ml)	-	14.1 (-5%)	36.4 (50%)	82.9 (76%)	88.5 (72%)
3D-echo PISA $RVol_{MV}$ (ml)	-	12.3 (-17%)	29.8 (23%)	72.7 (54%)	76.3 (48%)
3D-HE PISA $RVol_{MV}$ (ml)	-	9.2 (-38%)	21.8 (-10%)	53.1 (13%)	58.2 (13%)
2D-A2ch PISA $RVol_{MV}$ (ml)	-	11.1 (-25%)	50.7 (108%)	92.9 (97%)	114.3 (122%)
2D-A4ch PISA $RVol_{MV}$ (ml)	-	8.1 (-45%)	28.5 (17%)	71.0 (50%)	49.1 (-5%)

DISCUSSION

We evaluated the accuracy of current echo techniques for the quantification of MR. First, we found that for the PISA method, the assumption that the isovelocity surface is perpendicular to the velocity vectors is incorrect for mitral prolapse patients, which causes inherent errors of MR measurement (overestimation). Second, the angle dependence of color Doppler imaging on the PISA may cause a systematic underestimation of MR, although is relatively small from our results (approximately 15%). Third, the 3D-HE PISA method gave the best estimation for the moderate and severe MR models. Fourth, the VT method, based on the mass conservation, is theoretically more robust. However, when calculating the SV, one should not treat the velocity measured from the pulsed wave Doppler as the mean velocity of the cross section. Our study suggested that a coefficient around 0.7 should be used to compensate for this overestimation. The accuracy of the VT method can be further improved by considering the closing volume of AV, especially in mild MR cases.

The findings of this study add in-depth insights into the identification of several pitfalls in current clinical MR quantification using 2D and 3D echo. The 3D-HE PISA method gave the best estimation for moderate and severe MR cases. Other PISA methods significantly overestimated the EROA for severe and moderate MR. The VT method is theoretically more robust compared to the PISA method. By considering correction factors due to non-flat velocity profiles and the closing volume of AV, the accuracy of the VT method can be greatly improved, even for mild MR.

INTRODUCTION

In mitral valve (MV) disease, poor valvular geometry (e.g. annular or ventricular dilation) or valve degeneration, results in mitral regurgitation (MR) or mitral stenosis (MS). These ailments are commonly treated with surgical annuloplasty repair or bioprosthetic replacement for those not at high-risk for surgery [1]. However, these procedures can result in recurrent MR or MS that need further treatment with patients that are likely now at high-risk for surgery. These patient groups created a pertinent demand for percutaneous MV interventions. With no dedicated devices currently on the market for transcatheter mitral valves, clinicians have resorted to placing transcatheter aortic valves (TAV) into mitral annular calcification (valve-in-MAC), mitral bioprosthetic valves (valve-in-valve), and mitral annuloplasty rings (valve-in-ring) [2].

Left ventricular outflow tract (LVOT) obstruction is a potential risk from transcatheter valve replacement in the MV [2]. This is due to the anterior mitral leaflet (AML) being permanently displaced into the LVOT by the stent of the transcatheter valve. One way to proactively relieve this is through prior surgical resection of the A2 scallop during placement of a surgical prosthetic MV [3]. Another is through a new percutaneous laceration of the A2 scallop known as LAMPOON [4]. Both the use of transcatheter prosthetic valves in the mitral position and the idea to relieve LVOT obstruction to at risk patients are developing areas. Assessment of how laceration of the AML affects the flow in the LV and LVOT with a transcatheter mitral valve could help in further understanding their effects and long-term outcomes.

Motivated by this need, we studied the effects of different length AML lacerations on the LV flow field with high-speed particle image velocimetry (HSPIV). This was done through modification of a previously developed *in vitro* left heart simulator that provided a

dynamically contracting LV phantom [5]. The simulator was modified to include MV leaflets and a more anatomic LVOT geometry.

METHODS

Experimental Setup

A previously developed *in vitro* left heart simulator that provided a transparent, dynamically contracting LV phantom [5] was modified to include transparent MV leaflets and a more anatomic LVOT geometry (Figure 1).

Figure 1. Schematic of left ventricle phantom and chamber.

The transparent MV leaflets were 3-D printed from μ CT images of an excised porcine valve that was sized for a 29mm SAPIEN 3. During μ CT, the native valvular anatomy remained intact and was mounted onto a plate where a cylinder with the dimensions of a 29mm SAPIEN 3 was inserted into the valve. This provided the correct leaflet geometry for when we place a TAV inside the rigid, printed leaflets of the

simulator. After μ CT, simulated AML flail into the LVOT was done in SolidWorks (2017, Dassault Systèmes, Vélizy-Villacoublay, France) at the hinge point where the TAV stent frame ends and the leaflet would no longer be taut. Lastly, different size sections of the A2 scallop of the AML were cut away in SolidWorks to mimic the resultant geometry from different lengths of LAMPOON (Figure 2).

Figure 2. Models of three LAMPOON geometries (0%, 50%, and 100%) and image of 100% LAMPOON with porcine MV and SAPIEN 3. The A2 scallop is lacerated allowing the AML to be pulled open by the TAV stent frame and the AML chordae.

The 29mm TAV used for this study was the previously validated Georgia Tech Transcatheter Aortic Valve (GT-TAV) [6]. This provided us with a transparent stent frame for better optical access during HSPIV.

Experimental Testing

Three AML lacerations of the A2 scallop were studied: 0% (no laceration), 50%, and 100% (best clinical outcome). The GT-TAV was deployed at an 80/20 ventricle/atrial ratio. A control condition with no MV leaflets and the GT-TAV placed upstream of the MV annular plane was also done to help better characterize native systole.

2-D HSPIV was performed along the central long-axis plane of the LV at 700 Hz. The resulting data was bin-averaged over 5 time points and phase-averaged over 20 cycles.

The left heart simulator was tuned to normal hemodynamics for all testing conditions (70 bpm, 35/65 systole/diastole ratio, 120/80 mmHg systolic aortic pressure) with varying cardiac output of 2.5, 5.0, and 6.5 Lpm. In order to control the pulsatile pump (Vivitro Labs, Victoria, BC, CA), record hemodynamics, and trigger HSPIV, a custom code was written in LabVIEW (2015, National Instruments, Austin, TX).

RESULTS

At 2.5, 5.0 (Figure 3A and 3B), and 6.5 Lpm, it was shown that each progression of laceration created a larger diastolic vortical structure and systolic LVOT.

For 0%, 50%, and 100% LAMPOON at 5 Lpm, the maximum length of the vortex measured during diastole was 2.51, 3.83, and 5.30 cm, respectively. Additionally, the average velocity measured in the LVOT during peak systole was 0.711, 0.646, and 0.553 m/s, respectively.

Figure 3. Left ventricular flow fields with progressing anterior mitral leaflet (AML) laceration in A) mid-diastole and B) mid-systole.

DISCUSSION

It was shown *in vitro* that the displaced anterior mitral leaflet altered the LV flow compared to the control. It was subsequently shown that with increasing AML laceration, the size of the LV diastolic vortices and systolic LVOT increased. The latter resulted in a lower velocity gradient through the LVOT with progressing laceration. Our work shows that proactively resecting or lacerating the leaflet before transcatheter mitral valve replacement can result in better flow conditions in the LV. Specifically, it can reduce obstruction of the LVOT and lead to better diastolic mixing of blood. This can translate to better function of the AV and lower blood cell residency time in the LV, respectively. The lower blood cell residency time could be important in minimizing risk of thrombosis associated with bioprosthetic devices.

Future *in vitro* work in the area will focus on the effects of different deployment heights and further understanding of the flow between the native leaflet and the prosthetic leaflet.

INTRODUCTION

Accurate assessment of the physiology and function of the cardiovascular system is of paramount importance in a world with a progressively ageing population. Newer and more refined tools are needed to distinguish normal from abnormal ageing and identify subjects at risk of developing cardiovascular disease in an early stage. Thanks to the massive improvement of medical imaging, image processing and computational resources, patient-specific modeling could assist the clinicians in their diagnosis. In particular, the evaluation of fluid dynamics inside cardiac chambers by means of Computational Fluid Dynamics (CFD) may provide a fundamental fluid-mechanical insight into cardiovascular pathologies – such as ischemic heart disease, heart failure or stroke – and guide the medical team in choosing the best available treatment to restore physiological flow dynamics. Most studies addressing cardiac fluid dynamics focused on the left ventricular (LV) chamber. The LV fluid dynamics is physiologically characterized by vortex formation, which is believed to enhance among others the wash-out of the endocardial wall and favorably affects ventricular energetics, interplaying with the kinetics of both the LV endocardium and the Mitral Valve (MV) leaflets. The development of CFD models of the LV, however, has been continuously limited by the presence of complex and irregular structures (MV valve, papillary muscles, trabeculae) and by the large impulsive motion of its structures (LV endocardium and MV leaflets), which increase considerably the complexity of the model. The starting point of this study was the CFD model developed by Bavo [1] based on an Arbitrary Lagrangian Eulerian (ALE) approach, which resulted to be cumbersome in terms of stability and convergence of the solution, due to negative volume errors which limited the simulation time to 1 cardiac cycle. The Chimera technique, still relatively unemployed within the biofluids community,

may overcome the aforementioned barriers as the technique describes the fluid domain with a moving 4D Boundary Layer (BL) mesh embedded in a 3D Cartesian background mesh, allowing to handle the large and impulsive motion of the LV. It is therefore our aim to develop a workflow, based on the Chimera technique, to build a patient-specific CFD model for quantitative assessment of LV flow starting from medical images. The robustness of the workflow, and especially of the Chimera technique, was tested by means of an application which aims to answer whether the torsional motion of the left ventricle has an impact on the fluid dynamics inside the chamber.

METHODS

The workflow used to build patient-specific models consists of the following steps:

1. Segmentation of the LV endocardial surfaces throughout a cardiac cycle from cine-SA MRI acquisitions;
2. Generation of the meshes: 4D BL hexahedral meshes of the LV (as component grid, cg) and an overlapping 3D Cartesian grid (as background grid, bg) [2];
3. Implementation of the torsional motion;
4. Temporal interpolation of the 4D BL LV meshes;
5. Quality check of the 4D BL meshes;
6. CFD set-up with overset meshes approach and moving boundaries.

The numerical stability of the solution was assessed by means of a mesh sensitivity study which tested the accuracy of 4 mesh combinations (2 mesh resolutions for both cg and bg). With the chosen mesh combination (edge length_{bg} = 0.5 mm, elements_{cg} = 300 k) 6 cardiac cycles were simulated in Fluent 18.2 with the assumption of Newtonian blood ($\nu = 2.9 \cdot 10^{-6} \text{ m}^2/\text{s}$) and a time step of 3 ms. Three different

CFD cases were compared to assess the impact of torsion on the LV flow field: (i) without torsion (no Torsion), (ii) with physiological torsional motion (Torsion X1) and (iii) with torsion multiplied by a factor 2 (Torsion X2) to enhance the differences. The comparison of the CFD cases with different torsion degree was established by evaluating velocity, vorticity, Wall Shear Stress (WSS) and Residence Time (RT).

RESULTS AND DISCUSSION

Our results provide two important insights. Firstly, regardless of the torsion degree, we observed an important cycle-to-cycle variation in every simulated case. This behavior is particularly evident in the first two cardiac cycles and is reported for the CFD case with physiological torsion (Figure 1), but it occurs in all the simulated cases.

Figure 1: Cycle-to-cycle variation of velocity and vorticity during end systole in the CFD case with physiological torsion.

Secondly, accounting for torsion only leads to minor differences in the shape of velocity and vorticity contours and maximum values (Figure 2A, 2B). The main differences are located in the medial plane (SA2), which has a wider high velocity values close to the endocardial wall and an increased vorticity in the CFD cases with physiological and exaggerated torsion. The WSS distribution does not show a clear global upward or downward trend with respect to the torsion degree (Figure 2C). Torsion has, however, an (unexpected) impact on particle residence time: exaggerated torsion leads to pronounced decrease of the particles staying for less than 1 cardiac cycle (-8.8 %) at the expense of particles staying longer within the LV (+6.8 % in the case of $1T < RT < 2T$).

2T, +2% in the case of $RT > 2T$). On the other hand, the case without torsion yields less particles with $RT > 2T$ (-1.1%). The difference between the no torsion and physiological torsion was less than one percent.

Figure 2: Investigated variables in the three simulated cases to assess whether the torsion has an impact on the LV fluid dynamics.

CONCLUSIONS

The proposed Chimera-based workflow was found to be robust for all the three CFD cases in terms of convergence and stability. Thanks to the new approach multiple cardiac cycles could be simulated, allowing us to appreciate a cycle-to-cycle variation of the flow field and how the stability of the numerical solution is reached after two cardiac cycles. This finding also raises caution with respect to our previous results, in which only one cardiac cycle was simulated. Our data further suggest only a limited impact of torsion on the studied parameters. The major differences due to the torsional motion occurred in the medial plane, where the areas associated with higher values of velocity and vorticity are more extended, but there are no pronounced differences in terms of RT and WSS. Therefore, we conclude that torsional motion by itself does not seem to largely influence the LV fluid dynamics, keeping in mind however that the model did not include the papillary muscles, the MV and assumed a smooth LV wall. The effects of the MV kinematics will be evaluated within a FSI simulation framework as further development of the current model.

INTRODUCTION

Pioneering works by Langille (e.g. [1]) have shown that arteries have an inherent capacity for altering their morphology in response to mechanical stimuli enabling them to maintain mechanical homeostasis; a constant, preferred mechanical state, despite altered mechanical loading. This capacity has been leveraged to develop cell-free, porous, biodegradable tissue engineered vascular grafts (TEVGs) which promote host growth and remodeling (G&R) to develop new arteries (neoarteries) in the tissue's functional site (*in situ*). These grafts offer a much-needed alternative to using Dacron, or often unavailable autologous grafts, for treating atherosclerosis due to their ease of fabrication, reduced regulatory burden and the ability to form an adaptive tissue that is capable of G&R. One such poly (glycerol sebacate) (PGS) graft developed by Wang et al. has demonstrated mature elastin and collagen formation in the rat aorta [2] and mice carotid artery [3]. However, the fundamental mechanisms guiding neoarterial G&R are yet unknown, impeding efforts to translate this success across age and species.

Constrained mixture theory-based G&R tools [4] have been employed to understand salient features of neotissue formation in the venous circulation [5]. They are based on the knowledge that vascular tissues adapt their structure and function to achieve a certain homeostatic stress state. However, there is a need to understand the final homeostatic condition for *in situ* engineered TEVGs to translate this tool for arterial circulation. Furthermore, there is a need for biological and mechanical data to understand mass kinetics to effectively use this tool for understanding mechanisms guiding G&R. In this study, we used a combined *in vivo*, *ex vivo* and *in silico* approach to develop a G&R model tailored with biological and mechanical data to model arterial TEVG G&R with age. Using these tools, we aimed to answer two main questions: What is the neoarterial remodeling process in young and old

animals? What is the role of graft degradation, extracellular matrix deposition and mechanics in long-term neoartery remodeling with age?

METHODS

Neoarterial G&R is modeled using the constrained mixture theory with the homogenized strain energy function (SEF) shown in equation 1. Q^α models graft degradation, $m^\alpha(\tau)$ models extracellular matrix deposition, $\widehat{W}^\alpha \mathbf{C}_{n(\tau)}^\alpha(s)$ is the strain energy for the “ α ” constituent (e.g. graft, elastin, collagen, cells),

$$\mathcal{W}(s) = \Sigma W^\alpha(s) = \frac{\rho^\alpha}{\rho(s)} Q^\alpha(s) \widehat{W}^\alpha(\mathbf{C}_{n(0)}^\alpha(s)) + \int_0^s \frac{m^\alpha(\tau)}{\rho(s)} q^\alpha(s - \tau) \widehat{W}^\alpha(\mathbf{C}_{n(\tau)}^\alpha(s)) d\tau \quad (1)$$

We tailored the G&R equations to young and old neoarterial remodeling by using histological and mechanical data from neoarteries in young ($n = 39$) and aged ($n = 15$) animals. Briefly, 800 μm inner diameter grafts comprised of an inner PGS core (thickness = 300 μm) and outer polycaprolactone (PCL) sheath (20 μm) were implanted in a rat carotid artery interposition model. Neoarteries were explanted at days 3, 7, 14, 30, 90 and 180 from young, and 90, 180 from old animals. Histological assessment was performed for inflammatory and synthetic cell markers. Microstructure-function relationship was assessed using a custom-designed biaxial pressure inflation system [3] which simultaneously images collagen microstructure using multiphoton microscopy (MPM) during loading. Collagen fiber orientation was assessed from MPM images obtained across the wall thickness using CT-FIRE [6].

RESULTS

Neoarterial remodeling is a highly nonlinear process. We identified two phases of remodeling for young neoarteries (YN), Phase I (Day 0 - 14) and Phase II (Day 14 – 180) (Figure 1). Phase I is dominated by a

heightened inflammatory cell response that occurs during graft degradation with an associated dramatic reduction in stiffness (day 1-7). This is followed by a sharp stiffening due to heightened collagen deposition (day 7-14) (Figure 2). Following this, Phase II

Figure 1 Schematic of qualitative features of time-course of inflammation and ECM deposition in young and old neoarteries based on histological and biochemical data at 6 time points.

response leads to a non-monotonic change in the circumferential stress-strain mechanical response in which there is an initial softening (day 14 – 90) followed by stiffening at day 180 (Figure 2). Six-month structure-function assessment of differences in homeostatic states of YNs and old neoarteries (ONs) shows that ONs have higher circumferential stiffness as compared to YNs, potentially due to the denser collagen network (Figures 2,3). YNs also exhibited bi-directional (circumferential and

Figure 2: Temporal evolution of stress-stretch curves for neoartery in young vs old animals. Homeostatic state is altered with age showing increased circumferential stiffness at 180 days.

Figure 3: Stacked projections of MPM images for collagen fibers in young vs old neoarteries at 6 months with corresponding plots of collagen fiber orientation as a function of distance from ablumen. Collagen fiber orientation in ONs is less distributed. axial) collagen fiber orientation whereas ONs had mostly axial fibers. YNs were also capable of fiber reorientation upon pressurization as opposed to ONs. Using this data for altered homeostatic states and histological data on synthetic smooth cell proliferation rates, we tailored

and validated our G&R model for YN and ON remodeling. We then used this tool to leverage the interplay of graft degradation and ECM deposition for improved TEVGs. In this regards, Figure 4 shows that ONs can fail through stenosis (inward remodeling) with a low graft degradation half-life ($S_{0.5}$) of 7 days and high deposition rate. This stenosis can be mitigated by reducing the ECM deposition rate. However, simulations using this tool demonstrate a clinically useful method to avoid stenosis is to increase the degradation half-life, leading to stable remodeling.

Figure 4: Predicted inner and outer neoartery radii for different graft degradation half-lives ($S_{0.5}$) and ECM deposition rates using tailored G&R tool.

DISCUSSION

To our knowledge, this is the first study that translates neoartery formation to old animals, determines factors responsible for recapitulation of ECM structure and function, and investigates their homeostatic condition. We observe that G&R in YN is a nonlinear process with an initial graft degradation and inflammation dominated phase followed by a phase of microenvironment driven mechanical remodeling toward a homeostatic state. Mechanically, collagen fiber reorientation in YNs leads to more native artery-like behavior with a toe region at lower strains and fiber recruitment at higher strain levels. In contrast, a dense collagen network combined with lack of fiber reorientation is associated with increased stiffness in ONs. Our G&R tool demonstrated the interplay of graft degradation and ECM deposition are crucial factors that need to be controlled to achieve stable long-term G&R. Biochemical evaluation show that ONs exhibit higher ECM deposition which, as our simulations suggest, coupled with slower polymer degradation half-life (faster graft degradation rate) can lead to stenosis. Thus, our results indicate that a balance of medium degradation half-life combined with lower ECM deposition rate is required for stable long-term remodeling. In summary, we assessed the longitudinal remodeling process of TEVGs in young and aged hosts. We used this knowledge to tailor our G&R computational tool and used the tool to assess salient mechanisms guiding neoarterial remodeling. In the future, this tool can be used for rational design of tissue engineered vascular devices.

INTRODUCTION

A myocardial bridge (MB) is a congenital abnormality in which a segment of the epicardial coronary artery, often the middle part of the left anterior descending (LAD) artery, tunnels into cardiac muscle (myocardium). Autopsy and angiographic findings showed that the incidence rate of MB is about 20-60% and up to 16%, respectively [1]. The electrocardiogram (ECG) and angiographic measurements demonstrated that MB leads to a transient vessel compression during systole and early diastole, leading to atherosclerosis in the proximal to MB and increasing the risk of myocardial infarction [2]. The hemodynamics disturbances induced by MB are also associated with angina, arrhythmia, myocardial ischemia, and even sudden cardiac death [3].

Despite the clinical prevalence of MB, there have been relatively few hemodynamic studies of MB due to 3D transient nature of MB. The limitations of previous computational fluid dynamics (CFD) studies such as 2D modeling may underestimate the actual effect of MB on coronary hemodynamics. Therefore, the aim of this study was to assess the presence of MB on coronary hemodynamics using patient-specific 3D computational modeling.

METHODS

A patient-specific LAD model was developed based on the biplane angiograms of a LAD of a 53-year-old male patient with coronary artery disease and myocardial bridge (bridge length of 43.43 mm and compression ratio of 80%). The angiographic images were acquired at 16 frames per second using Artis zee III floor (Siemens Ltd. China) with a pixel spacing of 154μm at Fuwai Hospital. To reconstruct a realistic LAD model, 2D vessel centerlines from right anterior oblique projection (RAO) with cranial (CRA) and caudal (CAU) angulation

(CRA30/RAO1 and CAU25/RAO25) were extracted from angiographic data at both end-diastole (ED) and end-systole (ES) (Fig. 1A). The coordinates and lumen diameter of 12 control points (from A to K) along each 2D centerline were imported into SolidWorks®. For each 2D view, Bezier spline was used to create the longitudinal centerline. The 2D centerlines were projected onto two orthogonal Cartesian planes and then combined to form a 3D centerline [4]. A lumen volume was generated by connecting the 12 circular cross-sections of each control point along the length of the artery using lofting (skinning) algorithm. The reduction in lumen volume was calculated as the ratio of the lumen volume change (with respect to the ED volume) to the ED volume, from ED to ES (Fig. 1B). Based on the angiographic frames, 40% of a cardiac cycle duration was related to vessel compression (VC) and the rest was for vessel relaxation (VR).

To simulate the vessel deformation, an arbitrary Lagrangian-Eulerian (ALE) formulation of mass and momentum conservation equations was implemented.

$$\frac{\partial}{\partial t} \int_V \rho dV + \int_S \rho(\mathbf{v} - \mathbf{v}_b) \cdot \mathbf{n} dS = 0 \quad (1)$$

$$\frac{\partial}{\partial t} \int_V \rho \mathbf{v} dV + \int_S (\rho \mathbf{v}(\mathbf{v} - \mathbf{v}_b) + p\mathbf{I} - \boldsymbol{\tau}) \cdot \mathbf{n} dS = 0 \quad (2)$$

Where V is the control volume, ρ the blood density, S the boundary surface, \mathbf{v} the velocity vector, \mathbf{v}_b the moving boundary velocity vector, \mathbf{n} the normal vector, p the pressure, \mathbf{I} the unit tensor, and $\boldsymbol{\tau}$ the stress tensor. Blood was modeled as a homogenous Newtonian fluid (density 1050 kgm⁻³ and dynamic viscosity 3.16mPa.s). The shear stress transport (SST) transition model was applied to capture the turbulent transition, if any occur. A user-defined function (UDF) was developed to update the new positions of the surface nodes during the simulation.

The mesh and time independency were investigated by comparing the time-averaged wall shear stress (TAWSS) over proximal, bridge, and distal segments. The results were considered reliable when the TAWSS difference became less than 3%.

Figure 1: (A) 2D angiographic images, (B) Temporal variation of lumen volume reduction (T=cardiac cycle duration). Proximal (A-B), bridge (B-F), distal (F-K).

A structured hexahedral mesh (258795 elements) was utilized to mesh the lumen using ANSYS Meshing (v17.1). A very fine mesh near the wall with the first layer thickness of 50μm was employed to meet the requirements of the turbulence model. The inlet and outlet sections were extended by 10 and 15 times the lumen diameter along the lumen centerline to minimize the effect of inlet and outlet boundaries (Fig. 2A) [5]. Due to the lack of patient flow data, the proximal and distal pressure waveforms for a 38-year-old male patient with myocardial bridge were used (Fig. 2B) [2]. The SIMPLE algorithm along with a second-order upwind scheme was employed to solve the governing equations. The convergence criterion was set at 10⁻⁶ for all the residuals. A second-order temporal discretization scheme was utilized to perform transient flow simulations over three cardiac cycles with a time step of 1ms. CFD simulations were performed using ANSYS FLUENT (v17.1).

RESULTS

Our simulations showed that the reduction in mean volume flow rate during VR (7%) was higher than the VC (1%) in the MB model as compared to model without MB, due to the generated recirculation zone (Fig. 2C). In addition, the presence of MB had insignificant effect on extrema of volume flow rate (<5%) while it reduced the mean volume flow rate by 6.3% (Table 1). The effects of MB on the wall shear stress (WSS) are different at proximal, bridge, and distal segments (Fig. 3). MB resulted in a 95.5% increment in TAWSS at bridge, 8.3% and 9.6% reduction in TAWSS at proximal and distal, respectively and increased the volume-averaged flow velocity by 6.4%.

DISCUSSION

Patient-specific CFD simulations of MB were conducted to better understand its effects on coronary hemodynamics. For the given patient, although the presence of MB altered the WSS distribution significantly, it had less effect (<10%) on blood flow rate.

There are a few limitations in this study. First, the coronary arterial motion was neglected due to its minor effect [6]. Second, the diameter of control points was estimated using linear interpolation between ED and ES diameters. Despite these limitations, the current results

illustrated the effects of MB on coronary blood flow and its potential role in atherosclerosis development. Further study will examine more patients with various level of MB to better understand its effects and provide inputs for clinical treatments.

INTRODUCTION

Lymphatic vessels serve as the major route to transport lymph from the interstitial space to the great veins. The dysfunction of the lymphatic system is associated with a wide range of pathologies, including lymphedema. Collecting lymphatic vessels play a key role in lymphatic transport as they serve as a pump to propel lymph against an adverse pressure gradient. These vessels are remarkably different from veins and arteries in that they have specialized smooth muscle cells that enable them to contract spontaneously. The vessels' rhythmic and synchronized contractions are orchestrated to propel lymph in an efficient way along a chain of vessels. Similar to veins and arteries, lymphatic vessels exhibit tonic constrictions (maintained contractions) to control vessel caliber as well. Mechanical stimuli (e.g., pressure/stretch), as well as biochemical stimuli (e.g., vasoactive agents such as nitric oxide), are believed to be key regulators of lymphatic contractility.

It has been shown that lymphatic muscle cells adapt their contractile force to maintain lymphatic flow under different working conditions. Mechanical regulators such as lymphatic flow and pressures modulate the vessel's contractile function via the change in calcium dynamics in lymphatic SMCs. In this regard, the mechanical stretch is believed to be a key player in the regulation of contractile force produced by lymphatic SMCs. Although mechanical regulation of lymphatic vessels in response to flow and pressure are well documented; however, less is known about the role of axial stretch in the modulation of lymphatic function. To date, there is no information available on the role of axial stretch on lymphatic contractility. Our study is the first to demonstrate the significance of axial stretch in the modulation of lymphatic contractility. We showed that collecting lymphatics from the rat tail are under axial pre-stretch and characterized

the response to change in the axial stretch. This study sheds light on the effect of axial stretch and its contributions to the pumping function of lymphatic vessels.

METHODS

Animal Model. Male Sprague Dawley (SD) rats (300-350 gr) were used to limit variability. An incision (~1 cm) was made on the left or right side, near the base of the tail to gain access to the lateral tail vein. Segments of lymphatic vessels (length~1.5-2 mm, diameter~250-300 μ m) were excised and were prepared for the experiments.

Ex-vivo Experiments. We improved a previously developed biaxial device to precisely measure and control transmural pressure, diameter, and axial stretch for lymphatic vessels (<300 μ m) (4). Using this system, the contractions under different transmural pressures/axial stretches in the mounted vessel were measured. After replacing the bath with Ca-free solution, the passive mechanical properties of lymphatic vessels were determined at different intermittent pressure and axial stretch.

Statistical analysis. A one-way ANOVA test in conjunction with Bonferroni's post hoc correction was used to determine statistical significance, ($P < 0.05$) of experimental data. Results were reported as means (\pm SEM).

Constitutive Model and Bootstrapping. To capture salient features of lymphatic vessel wall mechanics and to reveal its contribution to lymphatic contractility, we employ a two-dimensional constitutive framework to fit experimental data. A three-fiber family model (one-axial and two symmetric fiber families) was utilized to obtain the stored energy function as (2):

Figure 1 The results from the axial stretch experiments. A) A typical rat tail lymphatic vessel is under axial pre-stretch B) the raw data from the stretch protocol C-F) changes in contractility metrics in response to the axial stretch.

$$W = b(I_C - 3) + \sum_{i=1,2,3} \frac{b_1^i}{4b_2^i} \{ \exp[b_2^i((\lambda^i)^2 - 1)^2] - 1 \} \quad (1)$$

where b , b_1^i and b_2^i are material parameters, I_C is the first invariant of the right Cauchy-Green strain tensor ($I_C = \text{tr}(\mathbf{C})$, $\mathbf{C} = \text{diag}(\lambda_r^2, \lambda_\theta^2, \lambda_z^2)$), $(\lambda^i)^2$ is the stretch of the i th fiber family ($\lambda^i = C_{\theta\theta} \sin^2(\alpha^i) + C_{zz} \cos^2(\alpha^i)$), where α^i is the fiber angle (please see Ref. (1)). In addition, a bootstrap method with 2,000 bootstrap samples was used to check the uniqueness and respective confidence interval of fitted parameters in the constitutive model.

Confocal Imaging. An LSM 710 META inverted confocal microscope (Zeiss) was used to characterize the collagen distribution within the vessel wall. Since second-harmonic generates spectrally-isolated signals for collagen, The Non-Descanned Detector (NDD) along with the two-photon laser (800 nm) was used to excite and collect endogenous signals from the collagen fibers.

RESULTS

A typical rat tail lymphatic vessel, an isolated vessel where the vessel has been cleaned, mounted on glass micropipettes as well as H&E staining of the isolated vessel, along with the raw data from the stretch experiments are shown in (Fig. 1 A, B). The vessel is under axial pre-stretch ~20% in-situ. To determine the effect of axial stretch on lymphatic contractility, the isolated vessels were exposed to three axial stretches, 10%, 20% and 30% (Fig. 1 A-D). The amplitude of contractions decreased as the stretch increased from 10% to 20%, however, the significant reduction (50μm equal to ~90% reduction) occurred for the higher stretch of 30%. Similar trends were observed for the frequency as it decreased from 15 min⁻¹ to less than 5 min⁻¹ (~80% reduction), the ejection fraction decreased from 46% to 9% (~80% reduction), and fractional pump flow from 6.8 min⁻¹ to 0.58 min⁻¹ (~92% reduction).

The material properties of rat tail lymphatic vessels were characterized using biaxial tests (Fig. 2A). The two photon-imaging revealed that most collagen fibers are aligned in the axial direction in both low and high loading scenarios (Fig. 2B). The estimation of material and structural parameters of rat tail lymphatic vessel and their confidence interval (Eq. (1)) were obtained via regression analysis and the bootstrap technique respectively (Fig. 2C). The results suggest that rat tail lymphatic vessels show nonlinearity and experience axial stiffening with the increase in the axial stretch.

Figure 2 Passive biaxial data and modeling results. A) Representative of biaxial data from rat tail lymphatics and material properties associated with the model obtained from the nonlinear regression and bootstrapped method for four samples. B) Distribution of collagen fibers within the vessel wall obtained from the second harmonic generation (SHG) images.

DISCUSSION

Lymphatic vessels adapt their contractile function to various loading conditions (pressure, flow and external forces from skeletal muscles) which is key to serve their function as both a pump and conduit. Although there is heterogeneity in lymphatic muscle cells from different regions, previous studies suggest that muscle cells generate maximum force in a wide range of pre-load (stretch) to maintain lymphatic flow (3). Particularly, the lymphatic pressure is known to be a key regulator of lymphatic function. It is known that the increase in pressure changes the frequency and amplitude of contractions. It is believed that the change in the stretch due to the applied pressure and subsequently the change in extracellular calcium level plays a major role in the contractility changes. Here, we tested the hypothesis that the axial stretch is also a key modulator of lymphatic contractility. Our results show that the lymphatic vessels from rat tail lymphatics are under pre-axial stretch and change in the axial stretch can significantly alter the lymphatic contractions. In addition, the two-photon imaging and constitutive modeling of passive wall mechanics suggest that these vessels undergo axial loading and the most collagen fibers are aligned in the axial direction to bear the axial load.

INTRODUCTION

Cardiovascular diseases (CVDs) are the leading causes of mortality worldwide. The contraction and relaxation of left ventricle (LV) is the main driving force of blood circulation. Altered LV hemodynamics is believed to be associated with the initiation and progression of many CVDs. Thus, understanding and evaluating the flow pattern inside a patient LV is thought to be essential to capture, and subsequently treat, cardiovascular dysfunction at early stages to reduce the mortality and morbidity rates [1]. Computational fluid dynamics (CFD) models, often derived from patient-specific medical imaging, have been used to provide a more fundamental understanding of individual LV flow patterns and pressure fields. Such image-based modeling may advance diagnostic capabilities, treatment protocols and help guide clinicians to choose the most effective therapy of CVDs [1].

Most prior ventricular flow studies obtained LV wall geometries from *in vivo* ultrasound-based or cardiac magnetic resonance imaging (MRI) images with limited resolution [2-3]. The model geometries were often highly simplified and usually lacked the papillary muscles (PM) and the corrugated trabecular structures of the LV. Since the LV flow pattern is sensitive to geometry, it is important to understand the effect of this simplification on modeling intraventricular flow and pressure. Here we apply CFD modeling to a subject-specific porcine LV model with detailed ventricular structures and motion obtained from previous solid mechanics finite-element (FE) simulations based on high-resolution image data [4]. We simplified the detailed LV endocardial surfaces to remove PM and trabecular structures and built a smoothed model that resembles the resolution of *in vivo* MRI images. We then compare the simulated LV flow pattern and pressure of the simplified models to those of the complex model.

METHODS

Detailed model geometries were extracted from the endocardial surfaces of a subject-specific FE model constructed in a previous study [4]. Briefly, a healthy porcine heart was fixed and imaged by diffusion-tensor MRI with a high spatial resolution of $0.3 \times 0.3 \times 0.8$ mm. The constructed model preserved detailed representations of trabecular and PM structures. The biventricular model simulated realistic dynamic beating of the heart and was validated by subject-specific and independent *in vivo* strain data obtained from echocardiography. We obtained the simulated endocardial surfaces of a total of 41 time-steps for 1 cardiac cycle. We followed conventional approaches [5-6] to avoid boundary effects on the intraventricular flow: mitral opening (MO) and aortic opening (AO) were extended from the positions of valves along the axis of the aortic outflow tract.

Figure 1: a) LV geometry at systole with cut planes, complex and smoothed geometries b) at systole and c) at diastole

To smooth out the PM and trabeculae structures, on the most contracted mesh surface, we sampled mesh points on cut planes that are 8 mm apart from each other and normal to the LV long axis (fig. 1a). From those sampled points, we selected those that form the vertices of the convex hull of the point set. We then down-sampled or linearly

interpolated the selected points to maintain a uniform distribution of mesh vertices and applied a smoothing operation to remove sharp edges caused by mesh simplification. The same mesh vertices were chosen for other phases to maintain the mesh connectivity. **Fig. 1** display a comparison between the complex and the smoothed mesh.

We applied the Arbitrary Lagrangian-Eulerian formulation of the incompressible Navier-Stokes equations with a stabilized FE Galerkin method [7] in the open-source FEniCS project to simulate the intraventricular flow and account for the moving boundary. We created a volume mesh from one surface at the start of diastole and used cubic spline interpolation to obtain 3200 interpolated surface meshes to impose the movement on the volume mesh. **Fig. 2a** shows the LV volume curve obtained from the given boundary meshes. Diastole and systole phases were determined based on rapid increase and decrease of LV volume, while the phases when the LV volume holds steadily were determined as isovolumetric contraction (IVC), and isovolumetric relaxation (IVR) phases. Pressure boundary conditions were applied at the inlet during diastole and during IVC, and at the outlet during systole and during IVR. **Fig. 2b** displays the prescribed pressure curve on mitral inlet or aortic outlet.

Figure 2: a) LV volume curve and b) prescribed pressure boundary condition curve of 1 cardiac cycle.

RESULTS

Based on the simulations, flow rates, maximum velocity at mitral or aortic openings, intraventricular flow velocity and pressure drop were extracted during the cardiac cycle (Fig. 3). The pressure drop was defined as the difference in pressure between apex and mitral opening at diastole or aortic opening at systole. The maximum velocity, flow rate and pressure drop curves displayed similar trends for both smoothed and complex models, while some differences in magnitudes were observed. During diastole and IVC, the largest discrepancy of flow rate happened after middle diastole when the flow rate for the smoothed model was 15.7% smaller. The maximum velocities at mitral opening and pressure drop were similar between the two models. At middle systole, the maximum velocity and flow rate at aortic opening and pressure drop were smaller by 5.4%, 14.3% and 26.9% respectively for the smoothed model than for the complex model. During IVR, small fluctuations of maximum velocity and pressure drop were observed in the complex model and not in the smoothed model.

The intraventricular flow patterns during diastole were different between the complex and the smoothed models (fig. 4 left). At middle diastole, for the complex model, the PM blocked the mitral jet and created disturbed low-velocity flow near the PMs. The mitral jet then formed two major vortices. One vortex located near the center of LV, sweeping the flow from the lateral wall to the septal wall. The other vortex centered at the bottom of LV, creating a circulation near the apex region. Without the PMs, intraventricular flow of the smoothed model was dominated by only one dominant vortex during diastole. However, the circulation did not seem to cover the apex region for the smoothed model. From middle to late diastole, the LV flow patterns were similar while the velocity magnitude decreased for both models. During systole (fig. 4 right), the intraventricular flow patterns were similar between the two models.

Figure 3: a) Maximum velocity and b) flow rate at mitral or aortic opening and c) pressure drop for complex and smoothed mesh

Figure 4. Comparison of velocity streamlines between complex model and smoothed model at middle diastole and middle systole. Color map represents velocity magnitude (m/s)

DISCUSSION

Simplified LV geometries have been commonly used in image-based CFD modeling of intraventricular blood flow. Our study provides useful insights on the effect of geometry simplification on LV CFD simulation by applying realistic LV wall motions obtained from both complex and smoothed model geometries. Major differences resulted from using the smoothed model were a) reduced pressure drop between apex and aortic opening at systole and b) the lack of complex flow pattern near PMs and the absent of circulatory flow near the apex region at diastole. These results also provide potential understanding of the functions of PM and trabeculae structures and were consistent with earlier findings that used simplified LV wall motions [5]. Future improvements would include adding left atrium, mitral valve and aorta structures for a more realistic inflow and outflow boundary condition, and prescribing physiological and subject-specific inlet or outlet pressure boundary conditions.

A COMBINED MRI ARTERIAL SPIN LABELING AND COMPUTATIONAL MODELING STRATEGY TO QUANTIFY PATIENT-SPECIFIC BLOOD FLOW AND PERFUSION IN CEREBROVASCULAR OCCLUSIVE DISEASE

INTRODUCTION

Cerebrovascular occlusive disease, characterized by the buildup of plaque inside the vessel (stenosis), is a major cause of stroke. Diagnosis relies on velocity measurements in the cervical arteries via duplex ultrasonography, excluding quantification of cerebral blood flow (CBF) and tissue perfusion. However, estimation of the cerebral vasculature's capacity to compensate flow reductions via collateral pathways and autoregulation depends on this information. Considering the high anatomical variability in the Circle of Willis (CoW), there is a need to develop new clinical tools to precisely quantify CBF and perfusion.

Despite increasing use of CFD for clinical applications, patient-specific modeling of CBF has been limited by the lack of precise estimates of boundary condition parameters. Recently, a strategy to calibrate a 1D/0D model of CBF using SPECT perfusion data was proposed [1], but it required the injection of a radioactive tracer for imaging and modeled CBF was restricted to 1D.

In this work, we seek to overcome these limitations by combining a 3D multi-scale computational model of CBF with vessel-selective MRI arterial spin labeling (ASL) measurements of tissue perfusion.

METHODS

ASL measures tissue perfusion non-invasively by magnetically labeling a bolus of blood in the neck and imaging a volume of brain tissue after a short transit delay (Fig. 1). A standard (e.g. non-vessel-selective) ASL sequence was extended to acquire territorial perfusion maps by implementing cardiac-triggered super-selective pseudo-continuous ASL (SS-PCASL) [2]. In SS-PCASL, additional in-plane magnetic gradients are rotated to create a circular labeling spot which can be placed on the vessel of interest. Territorial perfusion maps provide measurements of the fractional contributions of each cervical artery to total tissue perfusion in each imaging voxel.

Figure 1: Cardiac-triggered SS-PCASL sequence. The sequence starts with a cardiac-triggered pre-saturation pulse, followed by vessel-selective labeling, background suppression pulses during the transit delay, and the image acquisition.

The 3D/0D framework CRIMSON [3] is used to model CBF. For physiologically meaningful results, the model needs to be informed on anatomy, flow, and pressure. Here, each outflow is coupled to a 3-element Windkessel model with parameters initially set to literature values. The goal of this work is to match the simulation to the vessel-selective ASL acquisition. Integration of ASL perfusion data into the

CFD model framework is performed in three steps (see Fig.2). 1) Segmentation of cerebral vascular territories to calculate flow splits in the CoW. 2) Estimation of cardiac-averaged CBF in each cerebral artery based on total CoW inflow through the cervical arteries (phase-contrast MRI). 3) Iterative adjustment of Windkessel parameters to match CBF estimates. In a post-processing step, Lagrangian particles are used as a metric to directly validate vessel-selective ASL images and to quantify collateral flow by counting particles at each outlet.

Figure 2: Workflow for estimating Windkessel parameters in the CoW using both ASL and phase-contrast MRI. LACA, LMC, and LPCA are the left anterior, middle, and posterior cerebral artery.

RESULTS

Figure 3 shows ASL territorial perfusion maps acquired in two healthy volunteers. Subject (a) presents a posterior circulation dominated by the left vertebral artery (VA). Subject (b) has an absent basilar artery and thus perfusion to the posterior circulation was solely provided by the right internal carotid artery (ICA) through the right posterior communicating artery. These perfusion results are confirmed by Time-of-Flight (TOF) MRI images.

Figure 3: Axial TOF and corresponding territorial perfusion map of two subjects. The posterior circulations were perfused by the left VA (a) and the right ICA via the right posterior communicating artery (b). The increased caliber of the supplying artery is indicated by the white arrow.

Preliminary simulation results on a different patient with a left ICA stenosis are summarized in Fig. 4. Fig.4a illustrates the segmented 3D

solid model based on MRI anatomical image data. Fig.4b shows the pulsatile velocity field at systole with high velocities in the stenosed vessel as well as in the contralateral ICA. Seeding of Lagrangian particles revealed an increase in contralateral flow to compensate for flow reduction in the stenosed ICA (Fig. 4c).

Figure 4: Computational modeling of CBF in a patient with left ICA stenosis. (a) 3D image-based reconstruction of the large arteries from the heart to the brain. (b) Simulated velocity field at systole. (c) Lagrangian particle tracking to quantify collateral flow.

DISCUSSION

Our ASL sequence offers brain perfusion measurements including territory mapping of individual cervical arteries. Our work focused on optimizing image quality and accuracy by compensating for magnetic field inhomogeneity, cardiac pulsatility, and subject movement [4]. Territorial perfusion maps have previously been successfully acquired in patients with cerebrovascular disease [5].

Simulation results reflected the contralateral flow compensation expected in a patient with carotid stenosis. However, since Windkessel model parameters were based on literature values, changes in distal vascular resistance, induced by cerebral autoregulation to compensate for the flow reduction, were not accounted for. Our proposed strategy accounts for these changes by measuring tissue perfusion. In the next step, ASL perfusion data will be processed according to the workflow outlined in Fig. 2 to calibrate the Windkessel model parameters. Our calibrated model of CBF will therefore match the patient's hemodynamics better than previously reported modeling approaches. This is a necessary step to accurately estimate collateral flow in the CoW and improve patient diagnosis and stratification in the future.

INTRODUCTION

In clinical practice, the decision whether to treat a newly discovered unruptured intracranial aneurysm (UIA) has been mainly based on IA size (>7mm) among other factors, as embodied in clinical scores such as ISUIA[1] and PHASES[2]: [1, 3]. However, most subarachnoid hemorrhage cases are small ruptured aneurysms(RIA) (<7mm) [4], which demonstrates that size alone is not a reliable indication of rupture risk. Identifying more reliable metrics for risk stratification is highly valuable.

Building true rupture prediction model needs longitudinal data. However, this data is scarce since the dangerous aneurysms are usually treated by clinic, which leaves us with mainly small and clinical indented as “less dangerous” UIAs. In practice, when managing UIAs, clinicians have an implicit assumption that the UIAs resembling ruptured aneurysms may be at greater danger of rupture. For instance, many studies have reported that most of the ruptured aneurysms are irregular shape; thus, clinicians are in favor of treating irregular shape UIAs [5]. Following this mindset, several studies have identified distinct morphological and hemodynamic features of ruptured IAs.

In our lab, Xiang et al. developed a composite rupture discriminator model using multi variate logistic regression based on aneurysmal morphology and hemodynamics [6]. This model could be applied on any aneurysm and identify its corresponding rupture class. The output of the predictive model can also be viewed as a continuous variable rather than just a classifier. This rupture probability for a UIA – known as ruptured resemblance score (RRS) – quantifies the similarity of the UIA to the past ruptured cohorts. In fact, those UIAs which resemble ruptured cohorts, having high RRS, may have higher likelihood of rupturing in the future, thus reasonable to get treated. The RRS model was also found to remain stable when a larger cross-sectional data was used. Recently, Varble et. al further improved the

model by incorporating 415 IAs and taking clinical factors into account along with morphological and hemodynamic factors[4].

All our previous classification models were built using multivariate logistic regression. Artificial Neural Networks (ANN) have been known to capture hidden nonlinear relationships of different input parameters [7, 8]. In this study, we aim to evaluate whether an ANN can better perform rupture discrimination. We also provide an example of potential application of RRS model in clinical settings.

METHODS

Data Collection, Morphologic and Hemodynamic Analyses

We took the training database used by Varble et. al [3]. The dataset consisted of 415 IAs (102 ruptured and 313 unruptured). Using the workflow shown in Figure 1, we calculated morphological and hemodynamic parameters (Table 1) for each IA. These analyses (including CFD) was already performed in Varble et al. [3].

Figure 1: Work flow of image-based morphology and hemodynamics

Table 1: Input features* for the Artificial Neural Network

Clinical	Morphological	Hemodynamic
Gender	Aneurysm Size	Normalized WSS
Age	Size Ratio	OSI
Location	Aspect Ratio	RRT
Hypertension	Undulation Index	Low shear area
Family history	Ellipticity Index	Max WSS
Earlier SAH	Nonsphericity index	-

*Defined in Varble et al [3]

Development and Testing of the Neural Network

The aneurysms were randomly divided into training and testing datasets at an 85% to 15% ratio. The ratio of unruptured (U) and ruptured (R) aneurysms in both cohorts was the same. The training set had 355 aneurysms (268 U vs. 87 R), while the testing had 60 aneurysms (45 U vs. 15 R). All the parameters listed in Table 1 were used in model training.

Using the training set we built a 3-layer ANN using hold-out cross-validation to tune the hyper parameters of the neural network. We then applied the trained ANN to the testing cohort. For comparison, we also tested combined RRS model by Xiang et al. [6]

$$Odds_{combined} = \exp(0.73(SR) - 0.45(WSS) + 2.19(OSI) - 2.09)$$

and aggregate Rupture Discrimination Model by Varble et al. [3]:

$$Odds_{combined} = \exp(0.37(UI) + 1.47(OSI) - 0.12(WSS) + 2.26(Prior\ SAH) + 1.4(ACA) + 1.44(PCOM) - 0.79(Multiple\ IAs) - 2.91)$$

The logistic regression models give the odds that an IA is ruptured, while $RRS = Odds / (1 + Odds)$ [9]. ANN outputs a continuous value as well however, the value is purely mathematical. In all the classification models, a cutoff value 0.5 was used to classify the testing cohort into ruptured and unruptured aneurysms.

We compared all the models by looking at the confusion matrix as well as the Receiver Operating Characteristic (ROC) curve. To quantify the goodness of fit, we also compared the Area Under the Curve (AUC).

Application of models to clinical cases

The potential utility of RRS has gained recognition with clinicians at our center. For ambiguous UIA cases where decision-making was not straightforward, our clinicians often request us to compute RRS to confirm their treatment decision *a posteriori*. We show one of these cases to demonstrate potential application of the RRS models.

RESULTS

Performance of Rupture Discriminator Models

Table 2 reports the performance of the models on the testing cohort of 60 aneurysms (45 unruptured vs. 15 ruptured) in classifying the aneurysm rupture status.

	Model by Xiang et. al [5]	Model by Varble et. al [3]	ANN
True Positives	7 (47%)	4 (27%)	11 (73%)
True Negatives	36 (80%)	43 (96%)	33 (73%)
False Positives	9 (20%)	2 (4%)	12 (27%)
False Negatives	8 (53%)	11 (73%)	4 (27%)

Table2: Confusion matrix of testing cohort

Neural network model had the highest true positive rate (the RIA correctly classified as ruptured) and lowest false negative rate (the ruptured aneurysms misclassified as unruptured). The ROC plots for the 3 models are shown in Figure 2. AUC for the ANN is comparable to the model developed by Varble et al [3].

Figure 2: ROC curves of all the models

Example of Clinical Application

Patient: A 55-year-old female on work-up for a headache. Angiography images revealed a 9 x 6 mm, narrow-necked UIA located at PComm.

Decision was made to treat the IA by coils.

Considering that the

clinically developed rupture assessment models provided inconsistent 5-year rupture risk scores (ISUIA[1]: 14.5% and PHASES[2]: 2.4%, respectively), clinicians approached us to evaluate the rupture resemblance in terms of morphology and hemodynamics for this UIA. **Potential application of RRS:** Our flow simulation revealed a stasis aneurysmal blood flow, thus low WSS on aneurysm dome. A combination of high size ratio and low WSS led to a RRS score of 95% (Xiang et al. model) for this UIA. While the treatment decision was made without the input of RRS, the neurosurgeons sought the RRS results to confirm their decision.

Figure 3: Velocity contours on an ambiguous UIA

DISCUSSION & CONCLUSIONS

In this study, we have applied a well-established machine learning model (ANN) and evaluated it as a potential rupture discrimination model. Compared to the logistic regression model by Varble et. al., ANN had higher true positive rate, and lower false negative rate; however, the AUC was found to be the same between the two. Both these models showed better performance than Xiang et al., benefitting from a larger database and including clinical information in training the model. However, ANN did not improve AUC beyond Varble et al. However, for a fair evaluation, these tools need to be tested on larger and equal datasets.

Statistical models built and validated on cross-sectional data are versatile and robust and are believed to be potentially useful in the treatment of IAs [9, 10]. Xiang et al. [11] argued that UIAs that were classified as ruptured by their classification model, i.e. false positive cases, in fact highly resembled ruptured aneurysms, although they were not yet ripe for rupture. In clinical practice, such UIAs are considered as high risk, thus favoring treatment. The single UIA case presented here also highly resembled RIAs. It had a high size ratio and low WSS, an environment promoting inflammatory-cell-mediated destructive wall remodeling [12]. Although the true rupture risk of the UIA was unknown, such adverse hemodynamic environment should be eliminated for the safety of the patient. This illustrates the potential clinical utility of RRS.

SYSTEMATIC MODULATION OF CELL-CELL ADHESION *IN VIVO* MODULATES EPITHELIAL TISSUE MECHANICS AND REMODELING

Xun Wang (1), Karen E. Kasza (1)

(1) Department of Mechanical Engineering
Columbia University
New York, NY, USA

INTRODUCTION

Tissue remodeling is a fundamental biological process that produces the diverse shapes and structures of tissues. Mechanical factors, including forces and tissue mechanical properties, play vital roles in tissue remodeling, during embryonic morphogenesis, wound healing, and cancer metastasis [1-2]. During *Drosophila* embryonic development, tissue remodeling can be rapid. Oriented cell rearrangements and cell shape changes in the embryonic epithelium rapidly double the length of the body axis in just 30 minutes (Fig 1a) [3-5]. Cell-cell adhesion mediated by junctional proteins and contractile tension generated by actomyosin networks are thought to be key parameters in controlling epithelial tissue mechanics and remodeling [5,6]. However, it is unknown how the balance between adhesion and tension determines the mechanics and remodeling of epithelial tissues. A recent vertex model predicts that epithelial tissue mechanical behaviors can transition from solid-like to fluid-like, which could promote tissue remodeling, and that this transition depends on the balance between adhesion and tension [7]. However, *in vivo* studies of the mechanical properties of remodeling tissues have not been extensively conducted due to limitations in experimental techniques. It remains largely unexplored how mechanical properties of tissues are modulated during remodeling and development.

Here, we systematically modulate the balance between adhesion and contractile tension in epithelial tissues *in vivo* by increasing or decreasing expression of E-cadherin (E-cad), a primary cell-cell adhesion protein. We combine *in vivo* confocal imaging and quantitative image analysis to study the effects of modulating adhesion on epithelial tissue mechanics and remodeling during *Drosophila* body axis elongation. We find that increased E-cad promotes more fluid-like behaviors in static tissues that are not actively remodeling. In contrast, increased E-cad promotes more solid-like behavior in actively

remodeling tissues. These quantitative *in vivo* studies of the mechanics of epithelial tissue remodeling are essential for building and testing models of epithelial mechanics. This work sheds light on the mechanical factors involved in controlling tissue remodeling during development and on the improper regulation of tissue remodeling associated with birth defects and cancer metastasis.

METHODS

Biological Materials. To visualize cell membranes, a red fluorescent marker sqh>gap43:mCherry [8] was integrated into *Drosophila* embryos. E-cad levels were modulated by the Gal4/UAS system. To decrease E-cad, expression was partially inhibited by RNAi (TRiP, Transgenic RNAi Program). To increase E-cad, overexpression was achieved using the UAS>shg:GFP transgene [9].

Time-Lapse Imaging. Embryos were dechorionated in 50% bleach and mounted in a 1:1 mixture of halocarbon oil 27 and 700, between a coverslip and an oxygen-permeable membrane (YSI). The ventrolateral region of the embryo was imaged on a Zeiss LSM880 laser scanning confocal microscope with a 40X/1.2 NA water-immersion objective. Two-color Z stacks were acquired at 1- μ m steps and 15-s time intervals. Maximum intensity z-projections of 3 μ m in the apical junctional plane were analyzed.

Cell segmentation, tracking, and quantification. Time-lapse movies were z-projected in ImageJ. Cells were segmented and tracked using the MATLAB-based software SEGGA [10]. Tissue elongation starts at $t = 0$. Cell shapes were quantified by the cell shape index:

$$p = P/\sqrt{A} \quad (1)$$

where P is cell perimeter and A is cell area [7]. Error bars represent standard deviations. Vertex lifetime was measured as the time between when a cell edge contracted to a vertex to when the two cells initially in contact were no longer in contact. Error bars represent standard errors. Mean values from normal distributions were compared by t-tests.

RESULTS

Cell shapes change dramatically during tissue remodeling. During *Drosophila* body axis elongation in wild-type embryos, the cell shape index p increases with time (Fig 1). At 10 min before the tissue begins to remodel, when the tissue is still relatively static, cells take on nearly hexagonal shapes, and p is close to the value predicted at the solid-fluid transition in the vertex model [7]. During body axis elongation when the tissue is dynamically remodeling, cell shapes become deformed and p begins to increase (Fig 1).

Figure 1: Cell shapes during tissue remodeling. **a**, The *Drosophila* body axis (yellow) elongates 2-folds in 30 min. Anterior (A), left. Dorsal (D), top. **b**, The cell shape index p increases with time. Predicted solid-fluid transition, red dashed line. Onset of tissue remodeling, black dashed line. Insets: Confocal images of cells. $n = 5$ embryos.

Cell shapes are tuned by cell-cell adhesion levels. To test the effects of adhesion on cell shapes and tissue mechanics, we systematically increased or decreased E-cad expression in the tissue. First, we examined the tissue when it is static, before remodeling begins. In embryos with normal E-cad levels, cell shapes at $t = -10$ min are close to that predicted at the solid-fluid transition point in the vertex model (Fig 2a). The vertex model predicts that increased adhesion should produce more fluid-like tissues [7]. We find that tissues with increased levels of E-cad display increased p , consistent with this prediction of more fluid-like behavior (Fig 1, 2a). Very strong decreases of E-cad produce severely disrupted cell shapes compared with normal embryos (data not shown). In contrast, when the tissue becomes dynamic and starts remodeling, the differences in p among embryos with different E-cad levels disappear (Fig 2b). Thus, cell shapes are tuned by E-cad expression in static tissues prior to remodeling and independent of E-cad expression levels in dynamic, remodeling tissues.

Figure 2: Cell shapes are tuned by cell-cell adhesion levels. The cell shape index p for embryos with different E-cad levels. Solid-fluid transition predicted by vertex model, dashed lines. **a**, At $t = -10$ min when the tissue is static, embryos with increased E-cad display significantly higher p compared to normal ($P < 0.05$). **b**, p is independent of E-cad levels at $t = 20$ min when the tissue is dynamic.

Cell rearrangement speed shows a biphasic response to cell-cell adhesion levels. A rearrangement has two steps. First, rearrangement is initiated by contraction of a cell-cell-contact, bringing cells together at a high-order vertex. Second, vertices are resolved by the formation of

new contacts between cells (Fig 3a). To test the effects of adhesion on cell rearrangement and tissue remodeling, we measured the lifetime of vertices formed during rearrangement as a measure of rearrangement speed. We find that vertex lifetime shows a biphasic relationship with E-cad levels. Reducing E-cad from normal levels produces faster rearrangement, while increasing E-cad produces slower rearrangement. Surprisingly, this trend shows that increased E-cad adhesion produces slower rearrangement, a signature of more solid-like behavior. For very high E-cad, rearrangement speed begins to increase again.

Figure 3: Cell rearrangement speed is modulated by cell-cell adhesion levels. **a**, Confocal images (top) and schematic (bottom) of cell rearrangement. **b**, Vertex lifetime shows a biphasic relationship with E-cad levels ($P < 0.05$). $n = 393$ -484 cell rearrangements.

DISCUSSION

This work, for the first time, quantitatively measures how systematic modulation of cell-cell adhesion levels influences epithelial tissue mechanics and remodeling *in vivo*, providing necessary input for models of epithelia. We find that modulation of E-cad levels influences both cell shape and rearrangement during *Drosophila* axis elongation. When the tissue is static prior to remodeling, cell shapes indicate that the tissue is at the solid-fluid transition predicted by the vertex model [7]. Increased E-cad modulates cell shapes in a manner consistent with more fluid-like behavior, at least within a working range around normal E-cad levels. When the tissue is dynamic and actively remodeling during elongation, cell shapes are independent of E-cad levels. Instead, we find that the timescale for cell rearrangement is modulated by E-cad levels in a biphasic manner, with increased E-cad producing slower rearrangement, consistent with more solid-like behavior. However, increasing or decreasing E-cad too far from normal levels produces severely disrupted tissues that abolish these trends. Together, these findings demonstrate an important role for cell-cell adhesion in tissue mechanics and remodeling during development, and indicate complex effects of modulating adhesion on the fluid-like and solid-like behavior of epithelia. Future studies of how adhesion couples to contractile tension will provide insight into how cells control tissue mechanics and remodeling, which will be essential for understanding development as well as birth defects, cancer, and wound healing in humans.

RELATING BONE STRAIN TO LOCAL CHANGES IN RADIUS MICROSTRUCTURE FOLLOWING 12 MONTHS OF AXIAL FOREARM LOADING IN WOMEN

Megan E. Mancuso (1), Karen L. Troy (1)

(1) Department of Biomedical Engineering
Worcester Polytechnic Institute
Worcester, Massachusetts, USA

INTRODUCTION

Bone is a mechanosensitive tissue, with microstructure adapting to novel loading. It is hypothesized that local mechanical signals related to bone strain (magnitude, rate) are sensed by osteocytes, which signal nearby osteoblast and osteoclast cells to add bone in high strain regions and remove bone in low strain regions. This concept of localized, strain-driven adaptation is supported by studies in mice showing caudal vertebra loading yielded bone formation in areas of high strain and resorption in areas of low strain [1]. In humans, Christen et al. (2014) showed that retrospectively estimated bone strain was related to local changes in radius microstructure in postmenopausal women [2]. However, the relationship between strain magnitude and adaptation of bone microstructure has not been prospectively quantified in humans.

Previously we established a voluntary forearm loading model, in which human subjects lean their palm onto a padded load cell that provides feedback to guide load magnitude [3]. We also validated subject-specific finite element (FE) models of the forearm to simulate this loading task, enabling us to characterize the strain environment within the radius [4]. Together, these methods can be used to prospectively assign and measure radius bone strain during the loading task. In a pilot study of 23 women, we found that 14-week percent changes in bone density in the distal radius, divided into local regions by quadrant, were positively correlated with continuum FE-estimated energy equivalent strain [5]. While these results provide preliminary support of strain-driven adaptation, the continuum FE models do not explicitly consider the effect of trabecular microstructure. Recently, we have validated a multiscale modeling technique, which incorporates a micro-FE section based on High-Resolution Peripheral Quantitative Computed Tomography (HRpQCT) into the continuum forearm FE models [6]. Here, our purpose was to relate microstructure-level bone strain estimated from multiscale FE models to local, 12-month changes in trabecular microstructure measured in a prospective loading trial.

METHODS

The data reported here were obtained as part of a prospective clinical experiment, in which healthy women aged 21-40 were asked to

perform four sessions of forearm loading each week over 12 months. Each session consisted of 100 loading cycles (target force 200-400 N) of the non-dominant arm. Data from all subjects (n=102) are reported elsewhere [7], and the current analysis involves a subgroup (n=7) of compliant loading subjects in the tertile experiencing the greatest increases in ultradistal bone mineral content, measured using clinical quantitative computed tomography. All subjects gave written informed consent to participate in this institutionally approved study.

HRpQCT scans were acquired for the standard distal radius site (9.02 mm axial region) with an 82 μm voxel size (XtremeCT, Scanco Medical, Switzerland) at baseline and 12 months (Fig. 1). Clinical CT scans (Brightspeed, GE Healthcare, Chicago, IL) including the scaphoid and lunate carpals and the distal-most 10 cm of the radius were acquired with a slice thickness of 0.625 mm and an in-plane resolution of 0.234 mm. A calibration phantom was included in each clinical CT scan.

Figure 1: Overview of methods used to calculate energy equivalent bone strain, $\bar{\epsilon}$, using CT-based multiscale FE models and identify bone adaptation sites from HRpQCT scans.

Bone strain was estimated using a previously described (6) multiscale FE modeling technique. Models consisted of proximal and distal continuum regions flanking a micro-FE region at the HRpQCT

scan site. Continuum regions were generated from segmented clinical CT scans, with 3-mm (nominal element size) quadratic tetrahedrons assigned inhomogeneous elastic moduli based on density [8]. The micro-FE sections were voxel-based meshes generated from segmented baseline HRpQCT scans. The micro-FE meshes explicitly modeled bone microstructure, with a homogenous tissue modulus ($E=15$ GPa) assigned to the hexahedral elements, allowing for void spaces between trabeculae. Boundary conditions were applied to the multiscale models to simulate the forearm loading task, with 300 N applied axially from the carpals towards the proximal radius. Models were solved using Abaqus 6.16 (Simulia, Providence, RI) on a parallel computing cluster. Nodal stresses and strains in the micro-FE section were exported for post-processing.

Adaptation of bone microstructure was quantified from baseline and follow-up HRpQCT scans using the algorithm presented in Christen (2018) [9] within Image Processing Language software (Scanco Medical, Switzerland). The greyscale baseline and follow-up images for each subject were aligned using 3D rigid registration [10]. The baseline and transformed follow-up greyscale images were cropped to the overlapping region, and subtracted to obtain voxel-by-voxel changes in density. Increases in density are indicative of bone formation, while decreases indicate bone resorption. To avoid the effect of noise, only clusters of at least five voxels with differences $\geq 225\text{mgHA/cm}^3$ were identified as adaptation sites. Trabecular bone adaptation sites were identified by taking the Boolean intersection of the adaptation masks and the trabecular contour generated during the standard Scanco analysis program. A final mask overlaying the segmented baseline scan and trabecular adaptation sites was exported for post-processing.

Custom code (Matlab, Mathworks, Natick, MA) was used to calculate bone strain within formation and resorption sites. Energy equivalent strain at each FE node was calculated as

$$\bar{\epsilon} = \sqrt{\frac{2U}{E}} \quad (1)$$

where E is elastic modulus and U is strain energy density calculated as

$$U = \frac{1}{2} [\sigma_1 \epsilon_1 + \sigma_2 \epsilon_2 + \sigma_3 \epsilon_3] \quad (2)$$

with σ_n and ϵ_n being the principal stress and strain components, respectively. The adaptation mask was aligned with the FE coordinates using 3D rigid registration [6]. For each voxel labeled as a formation or resorption site, an average $\bar{\epsilon}$ was calculated for all nodes within 200 μm of the voxel coordinates (36.6 ± 5.6 nodes for formation and 56.3 ± 2.3 nodes for resorption).

Our overall hypothesis was that bone formation occurs in high strain regions, while bone resorption occurs in low strain regions. A paired t-test was used to compare mean strain in formed versus resorbed voxels within subjects ($\alpha=0.05$). Formed and resorbed voxels were then pooled across subjects and binned into 25 $\mu\epsilon$ increments. Histograms of formation and resorption frequency, normalized to the total number of adapted voxels, were plotted as a function of strain.

RESULTS

The number of formed (33-8717) and resorbed (9-5331) voxels varied widely between subjects. On average, 0.27% of trabecular voxels were labeled as adaptation sites (formed or resorbed), while analysis of the total region showed a mean 2.01% increase in trabecular density. Mean $\bar{\epsilon}$ was higher in formed versus resorbed voxels in six out of seven subjects (Fig. 2A, paired t-test $p=0.104$). Across subjects, mean $\bar{\epsilon}$ in formed versus resorbed voxels was $314 \pm 84 \mu\epsilon$ versus $276 \pm 35 \mu\epsilon$. The area under the normalized histograms (Fig. 2B) indicates that 61.9% of adapted voxels were formed and 38.1% were resorbed. The formation and resorption curves had peaks at 300 $\mu\epsilon$ and 150 $\mu\epsilon$, respectively, indicating resorption is most probable at a lower strain than formation.

Figure 2: A) Mean $\bar{\epsilon}$ in formed versus resorbed voxels by subject. Error bars indicate standard error. B) Formation and resorption frequency, normalized to the total number of adapted voxels.

DISCUSSION

Our purpose was to characterize the local relationship between FE-estimated bone strain and adaptation following 12 months of forearm mechanical loading. In this small sample, we found a positive, but non-significant association between higher strain and formation, and between lower strain and resorption. While the histogram distribution for resorption was clustered at lower strains (100-250 $\mu\epsilon$), formation was more uniformly distributed between 150 and 400 $\mu\epsilon$, potentially indicating that the likelihood of bone formation is more stochastic than that of resorption.

The major strength of this study is that bone strain was calculated for a known, prospectively assigned loading task using physiological boundary conditions. This study is limited by small sample size. Additionally, while formation and resorption were identified in all subjects, the fraction of trabecular voxels identified as adaptation sites underestimated the changes in trabecular density observed when analyzing greyscale data from the entire region. One possible explanation for this observation is that changes in density were diffusely distributed through the trabecular region, such that they were excluded as localized formation sites. Also, the method used to identify adaptation was developed for and validated using data measuring age-related bone loss in post-menopausal women [2], and may not be sensitive enough to detect more subtle, load-driven changes. Further work is needed to validate appropriate thresholds for change in density and size of adaptation site for this application. Sensitivity to detect local bone changes is also limited by the scan resolution (voxel size 82 μm).

INTRODUCTION

The female skeleton undergoes dramatic bone loss during pregnancy and lactation [1]. Despite substantially increased bone formation after weaning, bone mass is recovered incompletely [2]. However, multiple clinical studies have shown that the history of pregnancy and lactation induces no adverse, or even a protective effect on postmenopausal fracture risk, forming a paradox. Our previous studies suggested that rats with three repeated cycles of pregnancy and lactation had attenuated estrogen-deficiency-induced bone loss later in life compared to age-matched virgins [3]. Recent studies reported that the osteocyte can actively remodel its peri-lacunar/canalicular (PLC) matrix during lactation [4, 5]. Therefore, we hypothesized that PLC remodeling induced by reproduction and lactation may prime the osteocyte microenvironment, leading to enhanced mechano-sensitivity to exert protective effects against estrogen deficiency post-menopause.

METHODS

All animal experiments were IACUC approved. 29 female, Sprague Dawley rats were assigned to 4 groups: Virgin-Intact (n=7), Reproductive-Intact (n=7), Virgin-OVX (n=8), and Reproductive-OVX (n=7). Reproductive rats underwent two reproductive cycles consisting of pregnancy, 3-week lactation and 6-week post-weaning recovery. Rats in OVX groups underwent bilateral ovariectomy surgery (OVX) at age of 10 months to simulate estrogen deficiency post-menopause. *In vivo dynamic loading*: All 6-week post-OVX and age-matched intact rats (without OVX surgery) were subjected to a 2-week dynamic, compressive loading protocol [6]. A peak load of 45N, corresponding to ~1500 $\mu\epsilon$ at the tibial shaft determined by strain gauges, was applied to the left tibia at 2 Hz (*i.e.*, 0.15s ramp up, 0.15s ramp down, and 0.2s dwell time), for 5 min/day over 2 weeks (5 days/week), while the right tibia remained as non-loaded control. *In*

vivo μ CT imaging: μ CT scans of proximal tibia (Fig 1A) and tibial midshaft were performed on both tibiae right before (week 0) and two weeks after loading (week 2) using VivaCT 40 (Scanco Medical AG, voxel size 10.5 μ m). Percent changes between week 0 and week 2 for non-loaded and loaded tibiae were calculated. *Dynamic histomorphometry*: All rats were injected with calcein green and alizarin red on day 4 and day 12 of loading. Dynamic histomorphometry analyses were performed to evaluate double-labeled bone formation. *bSEM imaging*: The non-loaded tibial cortex (n=4/group) was subjected to scanning electron microscope in backscatter mode (bSEM, Zeiss Supra 50VP) to assess lacunar and canalicular structure. *Immunohistochemistry*: Paraffin-embedded non-loaded tibial cortex was immunostained for MMP13 to evaluate PLC remodeling enzyme expression. Ploton silver staining was performed on tibial cortex to further investigate lacunar-canalicular interconnection [7, 8]. *Statistics*: A two-way ANOVA with baseline parameters as covariate and Bonferroni corrections were used to compare loading responses between virgin and reproductive rats. Student's t-test was applied to compare lacunar/canalicular structure.

RESULTS

OVX Rats: *In vivo μ CT* indicated that virgin and reproductive rats in the OVX group underwent 25% and 13% reduction in bone volume fraction (BV/TV), respectively, in the non-loaded tibia (Fig 1B). Dynamic loading attenuated the estrogen-deficiency-induced trabecular bone loss in virgin rats and abolished the bone loss in reproductive rats (Fig 1B). Loading also led to 7% increase in trabecular thickness (Tb.Th) in virgins and abolished the estrogen-deficiency-induced reduction in Tb.Th in reproductive rats (Fig 1C). However, the extent of loading responses (loaded vs. non-loaded) was not different in trabecular bone between post-OVX virgin and

reproductive rats. At the tibial midshaft, loading increased the polar moment of inertia (pMOI) by 7% in virgins and 13% in reproductive rats (Fig 2E). Similar results were found in cortical area (Ct.Area, Fig 2F). Moreover, ANOVA test indicated greater responses in pMOI and Ct.Area to loading (loaded vs. non-loaded) in post-OVX reproductive rats than in virgins. Dynamic histomorphometry suggested that loading led to 5, 16, and 96-fold increase in mineralizing surface (MS/BS), mineral apposition rate (MAR), and bone formation rate (BFR/BS) in reproductive-OVX rats (Fig 2G-I), while the loading responses in virgin-OVX rats were less pronounced. As a result, ANOVA test indicated greater response in MS/BS to loading in post-OVX reproductive rats than virgins.

Backscattered SEM images of tibial cortex showed a trend toward 11% greater lacunar area ($p=0.07$) and 33% greater canalicular area in post-OVX reproductive rats than in virgins (Fig 3). Additionally, post-OVX reproductive rats had 51% greater percent of MMP13+ osteocytes (Fig 4A) and a trend toward 10% higher canalicular number per lacunar surface than virgins ($p=0.09$, Fig 4D).

Intact Rats: There was minimal loading response in the tibial trabecular bone in both intact virgin or reproductive rats. Significant loading responses in pMOI and Ct.Area were detected at tibial midshaft; however, they did not differ between virgin and reproductive rats. Similarly, no difference in PLC structure, MMP13+ osteocytes, or canalicular number was found between intact virgin and reproductive rats (data not shown).

DISCUSSION

Our previous studies suggested that history of multiple cycles of pregnancy and lactation led to dramatic alterations in cortical and trabecular bone microstructure. Despite these changes, our current study found no influence of reproductive history on bone's mechano-responsiveness and osteocytes PLC structure in estrogen-replete rats. Intriguingly, when subjected to estrogen-deficiency, the history of reproduction and lactation significantly enhanced bone's mechano-responsiveness. Moreover, we found significantly increased canalicular area and osteocytic MMP13 enzyme activities, and a trend of increased lacunar area and number of canaliculi in post-OVX reproductive rats than virgins. These results suggested that the osteocytes that have experienced multiple reproductive cycles may actively regulate their lacunar-canalicular network system (LCS) and directly modulate the PLC matrix, leading to enlarged lacunae and canaliculi when subjected to estrogen deficiency. These altered osteocyte LCS microenvironment and cellular activities in response to OVX in reproductive rats may result from the osteocyte "memory" engendered by exposure to sharp estrogen withdrawal during lactation. The fluctuations in estrogen levels induced by reproductive history may condition the osteocytes to striking hormonal changes, leading to functional adaptation in osteocyte LCS microenvironment against estrogen deficiency later in life. According to the LCS fluid flow model established by Weinbaum *et al.* [9], the enlarged canaliculi and altered canalicular wall permeability due to the active PLC remodeling may change the peri-cellular fluid flow and dragging forces on pericellular matrix when subjected to loading, and thus affecting bone's mechano-responsiveness. Therefore, further tests with direct measurements of load-induced fluid flow in LCS [6] are necessary to establish the effects of osteocyte PLC remodeling on modulating bone's mechano-responsiveness in rats with different reproductive histories.

In summary, a history of reproduction and lactation may prime the microenvironment of osteocytes, leading to elevated mechano-sensitivity to protect maternal skeleton from estrogen deficiency. This investigation provided new insight into osteoporosis prevention and

treatment for postmenopausal women based on their reproduction histories.

BIPHASIC NETWORK MODEL OF COLLAGEN AND ELASTIN REMODELLING RECAPITULATES COMPOSITIONAL AND ORGANIZATIONAL CHANGES DURING AORTIC GROWTH AND DEVELOPMENT

Ryan R. Mahutga (1), Victor H. Barocas (1)

INTRODUCTION

Growth and remodeling (G&R) of biological tissue plays a key role in numerous diseases and is of vital importance for positive clinical outcomes. Any procedure that alters the tissue – from wound closure, to tissue grafting, to device implantation – relies on G&R. G&R processes are immensely complex involving many biological, chemical, electrical, and mechanical inputs, as well as numerous constituents making any one variable difficult to isolate. In particular, arterial G&R, including both normal and aberrant development (congenital defects, aneurysms), is fundamentally difficult to model both experimentally and computationally. Therefore, it is necessary to construct models of G&R processes that are understood to probe the effects one observes experimentally and clinically, and to isolate the interplay between stimuli. Toward this end, we have created a novel biphasic, fiber network model from primary experimental and clinical observations.

While there have been many studies on aortic development, there has been a lack of unifying theories on normal growth and maturation that can be similarly applied to aberrant development (i.e., most theories require the adjustment of many parameters to give different growth modes). Herein, we explore the idea that one can expect different growth modes from one feedback mechanism. To develop this idea, we propose two hypotheses. First, we hypothesize that tensional homeostasis drives fiber growth, maturation, and alignment, as well as dictating the time course of these actions. Second, we hypothesize that Donnan osmotic pressure due to the binding of proteoglycan-glycosaminoglycan (PG-GAG) complexes to the fiber network maintains tissue volume during loading and drives tissue growth.

METHODS

To explore our hypotheses, we have created a discrete fiber network model consisting of embedded Delaunay networks representing collagen and elastin. These networks are periodic in a unit

cube domain (the representative volume element, or RVE) where the scale is determined by the network fiber properties as shown in (Eq. 1).

$$\chi = \sqrt{\frac{\pi \sum r_f^2 l_f}{\phi V}} \quad (1)$$

where χ is the RVE scale in meters per computational unit length, r_f is the fiber radius, l_f is the fiber length, ϕ is the fiber volume fraction in the RVE, and V is the computational volume of the RVE.

The constituents in this model are collagen, modeled as in [1], elastin, modeled as linear elastic [2], and PG-GAG complexes modeled through osmotic pressure based on fixed charge density (FCD). The FCD was taken to be proportional to the total fiber length in the RVE. The stress on the RVE boundary was calculated using volume averaging theory applied to these constituents.

The RVE was loaded based on the boundary loads one may expect from a developing mouse, where the blood pressure starts low prior to birth and then ramps up in the immediate post-natal period [3]. The RVE was approximated as a very small representative piece of a cylinder, and the thick-walled cylindrical approximation was used to determine the boundary conditions.

As the RVE is loaded, the fibers are remodeled according to the relation below (Eq. 2).

$$\frac{dr_f}{dt} = \frac{1}{\tau} \left(\frac{\sigma}{\sigma_\infty} - 1 \right) r_f \quad (2)$$

where r_f is the fiber radius, t is time, τ is the growth time constant in days, σ is the fiber stress, and σ_∞ is the target fiber stress. The fibers are also allowed to lengthen treating the added radius as a parallel spring.

RESULTS

Simulations were performed assuming a wild-type mouse model system with typical blood pressure fit to [3] and aortic dimensions from [4]. The simulation encompassed the period from embryonic day 7.5 (E7.5) to 240 days after birth. Elastin production was ceased at day 18

(coinciding with the theory that elastin production stops shortly after birth), but collagen continued to remodel throughout the simulation.

Our simulation model system showed less growth than the experiments of Huang et al. (not shown) and Fournieri et al. (Fig 1A) [3,5]. This is likely due to the use of Delaunay networks, which are dissimilar to biological fiber networks in that they have a much higher connectivity which means there are many more redundant fibers (i.e., if a fiber is lengthened the load is shifted to another fiber that was previously unloaded rather than lengthening the whole network.). There is, however, a good agreement between the fiber volume evolution in our model system and in the experiments of Fournieri et al. (performed on rats) [5].

Figure 1. A. Normalized tissue growth. B. Fiber volume fraction evolution. Comparisons are made to experiments in [5] with 95% confidence intervals shown.

This model system also allowed us to track explicitly the fiber radii and rest lengths. As shown in Figure 2, collagen fibers tend to lengthen and thicken more than elastin fibers. We also note that our simulation collagen radii are comparable to those quantified by Liu et al. for mouse adventitia [6].

Figure 2. A. Fiber radii evolution; B. Fiber length evolution

Inspection of the networks themselves showed that in an unloaded state (i.e., with external loads removed, but still including osmotic pressure) fiber stress is held almost exclusively by elastin fibers. This is important because it implicates elastin having a major role in tissue residual stress. Additionally, as shown in Figure 4, we also see marked increases in oriented fiber area moving from the initial isotropic orientation toward the circumferential-axial plane. This is comparable to the orientations given by O'Connell et al [7].

Figure 3. Unloaded networks at 240 days for A. Collagen and B. Elastin. Fiber sizes are appropriately scaled to RVE size. The colorbar shows the fiber stress overlaid onto individual fibers.

Figure 4. Unloaded network orientation distribution for A. Collagen and B. Elastin at 240 days. Theta is the angle from circumferential toward axial, and phi is the angle from radial toward the circumferential-axial plane.

DISCUSSION

This simulation framework marks a divergence from the typical continuum mechanics approach to growth and remodeling of biological tissues. Our approach represents a new method for understanding the growth of tissues as a whole, as well as providing insight into fiber-specific properties such as orientation, diameter, and length.

We have demonstrated that this model can match many features of fibers in normal development including volume fraction, radius distribution, and orientation. To this point, our simulations have shown less growth than experimental observations suggest. It is clear that our simulation framework is likely missing some detail. We suspect that this is due to the networks used. Computationally generated Delaunay networks, unlike biological networks, tend to be highly connected. Thus, these networks are insensitive to modulation of individual fibers due to the high degree of fiber redundancy in mechanical loading.

As we move towards generating more realistic and complex networks based on imaging modalities such as second harmonic generation, we will be able to garner new insights into the stress response of fibrillar networks which will be particularly important in understanding disease states such as hypertension leading to spontaneous aneurysm, and genetic disorders affecting the extracellular matrix leading to aneurysm.

INTRODUCTION

During pregnancy and lactation, women experience hormonal and physiological changes that increase the risk of musculoskeletal joint disorders such as shoulder, lower back, wrist, and knee pain [1]. Estrogen levels rise dramatically during pregnancy followed by a rapid decline during lactation before returning to normal levels after weaning. Increased joint laxity from hormonal fluctuations [2] and substantial maternal bone loss due to increased calcium demands for fetal and infant growth [3] contribute to impaired joint function. We previously showed that rats with a history of reproduction exhibited inferior supraspinatus tendon and humeral trabecular bone properties despite a lengthy post-weaning recovery period [4]. However, the transient effects of pregnancy and lactation on the supraspinatus tendon and proximal humerus remain unknown. Therefore, the objective of this study was to evaluate changes in supraspinatus tendon mechanical properties and in the microstructure of the bony insertion site during pregnancy, lactation, and post-weaning recovery in female rats. We hypothesized that substantial bone loss during lactation would compromise the subchondral bone microstructure leading to reduced supraspinatus tendon mechanical properties.

METHODS

30 Sprague-Dawley female rats (IACUC approved) were used: virgin (n=7), end of pregnancy (n=9), 2-week lactation (n=7), and 2-weeks post-weaning (n=7). Rats in the pregnancy group were sacrificed at parturition, while the lactation group underwent pregnancy and 2 weeks of lactation. Rats in the weaning group underwent pregnancy, 2-weeks lactation, and 2-weeks post-weaning recovery. All rats were sacrificed at 7 months of age, and shoulders were harvested for supraspinatus tendon mechanical testing and subchondral and trabecular bone analysis. Mechanics: Supraspinatus tendons were marked with

stain lines, cross-sectional area was measured using a custom laser device, and humeri were secured in PMMA. Right supraspinatus tendons underwent viscoelastic tensile testing, consisting of pre-conditioning, stress relaxation at a 5% strain hold for 600s, a dynamic frequency sweep at 5% strain (0.1-10Hz), and a quasi-static ramp to failure at 0.3%/s. Left supraspinatus tendons underwent fatigue cyclic loading until failure at 2Hz between loads corresponding to 7% and 40% maximum stress, determined from quasi-static results. Peak cyclic strain, secant modulus, tangent modulus, hysteresis, and laxity, were recorded at two breakpoints (ends of the primary (BP1) and secondary (BP2) phases of a triphasic fatigue life curve). Subchondral and trabecular bone analysis: Prior to mechanical testing, left proximal humeri were μ CT scanned (6 μ m, μ CT35, Scanco). Trabecular bone proximal to the humeral growth plate was analyzed. Additionally, average thickness and the mineralization gradient was calculated (Amira 6.7) across the subchondral plate, defined as the mineralized fibrocartilage of the supraspinatus tendon enthesis and subchondral bone. Briefly, a 100x120x230 voxel volume was identified in the greater tuberosity at the supraspinatus tendon insertion site. After global thresholding, the innermost layer of the subchondral bone was defined to exclude trabecular bone. Individual layers were subsequently defined outwards towards the mineralized fibrocartilage boundary. Layer intensity values were averaged to construct a mineralization gradient, normalized to the total subchondral plate thickness. Bone mineral density (BMD) was compared at 0, 0.5, and 1.0, marking the boundaries between trabecular bone, subchondral bone, mineralized fibrocartilage, and tendon. Statistics: Comparisons across groups were made using one-way ANOVAs with Bonferroni post-hoc corrections. Significance was set at $p \leq 0.05$ and trends at $p \leq 0.1$. All data is presented as mean \pm SD.

RESULTS

Supraspinatus Tendon Properties. Cross-sectional area was significantly increased (Fig 1A) and midsubstance modulus trended higher (Fig 1B) during pregnancy compared to virgin. After weaning, however, modulus was significantly lower than both pregnancy and lactation groups and trended lower compared to virgin (Fig 1B). Percent relaxation was also significantly greater post-weaning compared to pregnancy and lactation (Fig 1C). For fatigue, tangent stiffness at BP1 for both lactation and weaning trended lower compared to virgin and was significantly lower compared to pregnancy (Fig 1D). However, there were no differences in cycles to failure, peak cyclic strain, hysteresis, or laxity (data not shown).

Figure 1: (A) Cross-sectional area and (B) midsubstance modulus were significantly greater after pregnancy. After weaning, modulus was reduced while (C) percent relaxation increased compared to pregnancy and lactation. (D) Tangent stiffness at BP1 also decreased during lactation and after weaning. Solid lines denote significance for $p \leq 0.05$ and dashed lines for trends $p \leq 0.1$.

Trabecular and Subchondral Bone Properties. Bone volume fraction (BV/TV) (Fig 2A) and trabecular number (Tb.N) (Fig 2B) was significantly lower while trabecular separation (Tb.Sp) (Fig 2C) was significantly greater during lactation compared to virgin and pregnancy groups. After weaning, BV/TV recovered with no significant difference from virgin. However, Tb.N and Tb.Sp trended lower and higher, respectively, post-weaning compared to virgin.

Figure 2: Lactation resulted in (A) decreased bone volume fraction, (B) decreased trabecular number, and (C) increased trabecular separation compared to all other groups. Solid lines denote significance for $p \leq 0.05$ and dashed lines for trends $p \leq 0.1$.

Since the predominant failure mode during quasi-static tendon testing was bony avulsion, failure properties reflect that of the insertion site and underlying subchondral bone (Fig 3A). Maximum stress (Fig 3B) and maximum strain (not shown) significantly decreased during lactation compared to virgin and pregnancy groups, but significantly recovered after weaning. At the trabecular bone-subchondral bone boundary, bone mineral density (BMD) was also significantly lower during lactation compared to virgin and pregnancy groups. After weaning, BMD remained significantly lower compared to virgin and trended lower compared to the pregnancy group. However, there were no differences in BMD between groups at 0.5, the subchondral bone-

mineralized fibrocartilage interface, or at 1.0, the mineralized fibrocartilage-tendon boundary (Fig 3C). Furthermore, subchondral plate thickness trended lower in the lactation group compared to both virgin and pregnancy groups (Fig 3D).

Figure 3: (A) The tendon insertion site transitions from regions of mineralized fibrocartilage to subchondral bone, forming the subchondral plate. (B) Maximum stress, (C) bone mineral density within the subchondral bone, and (D) overall subchondral plate thickness decreased during lactation. Solid lines denote significance for $p \leq 0.05$ and dashed lines for trends $p \leq 0.1$.

DISCUSSION

Pregnancy and lactation induced substantial changes in supraspinatus tendon and proximal humerus bone properties. Lactation impaired subchondral and trabecular bone, but properties recovered post-weaning. In contrast, supraspinatus tendon mechanical properties improved during pregnancy and these changes persisted during lactation before returning to pre-pregnancy levels post-weaning. Estrogen has been linked to increased collagen synthesis and tissue elasticity [5], providing a mechanism by which tendon properties increase by the end of pregnancy, the time at which estrogen levels peak. In contrast to bone tissue, the rapid decline of estrogen levels during lactation had no adverse effects on tendon properties, suggesting additional protective mechanisms associated with lactation.

Furthermore, bony avulsion failures and decreased maximum stress during lactation support further study into the subchondral plate microstructure. Reduced overall thickness and bone mineral density during lactation suggest that independent mechanisms modulated by osteoblast-osteoclast coupling regulation and osteocyte perilacunar remodeling, respectively, may be at play.

Supraspinatus tendon tears most commonly occur at the insertion site, and reduced bone mineral density of the humeral head is a known risk factor [6]. Our results provide insight into the mechanisms that may govern this increased risk due to compromised bone, which may arise with menopause, aging, and other metabolic diseases. To further elucidate the onset of rotator cuff disease and hormonal regulations on tendon health, future studies will investigate the biological mechanisms underlying transient changes in tendon and bone properties during reproduction and lactation.

INTRODUCTION

The human bladder is a highly compliant organ that can expand to store 450 ± 64.4 ml of urine at relatively low pressures of 43.5 ± 7.3 cm of H₂O in young adults (18 yrs) [1]. However, bladder compliance decreases with age [2] and the corresponding increase in wall stiffness is believed to cause lower urinary tract symptoms (LUTS) such as increased frequency of urination, urgency, incontinence, and residual volume [3,4]. In extreme cases, the associated increase in kidney pressure can lead to renal insufficiency [5].

To understand the change in bladder compliance, the bladder material properties were explored using uniaxial testing beginning in the early 70s [6] and, more recently using biaxial testing [7-10]. These studies reported the mechanical properties of bladder and suggested that bladder remodeled through alterations to material structure. However, no models of adaptive remodeling for the bladder have been introduced yet.

In this work, we integrate in situ mechanical testing and multiphoton microscopy to assess bladder mechanical properties while observing the transformation in collagen architecture under stretch. To explore the key physical mechanisms during bladder filling, a structurally motivated constitutive model is developed, driven by our database for the bladder wall [10]. A growth and remodeling framework with demonstrated success in arteries [11] is applied to bladder wall to investigate the aging process, informed by our experimental data.

METHODS

Mechanical Testing: Nine male Fischer rats (Species F344, adult and aged rats from National Institute on Aging of the NIH) were used in this study, separated by age with 4 adult rats (12 months) and 5 aged rats (21–24 months). Mechanical data (stretch vs. stress) was obtained using a customized biaxial testing system as described in [10]

Evaluation of Fiber Recruitment: Multiphoton image stacks were used to generate 3D reconstructions of collagen fiber architecture at chosen loading levels. Collagen fibers were traced in 2D slices through the depth of the 3D reconstructed model (Filament function in Imaris, Bitplane, Switzerland) [10].

Constitutive Model: The bladder was modeled as a constrained mixture [12,13] with contributions to the total strain energy per unit volume (Ψ) coming from three load bearing components within two wall layers – collagen in the detrusor smooth muscle layer (DSM) and both collagen and elastin fibers in the lamina propria layer (LP),

$$\Psi = \tilde{\Psi}_E + \Psi_C^{LP} + \Psi_C^{DSM} \quad (1)$$

The strain energies for collagen and elastin fibers are, respectively,

$$\tilde{\Psi}_E(\lambda_E) = \frac{k_E}{2} (\lambda_E - 1)^2 \quad (2)$$

$$\tilde{\Psi}_C(\lambda_C) = \frac{k_C}{2} (\lambda_C - 1)^2 \quad (3)$$

where k_E and k_C are stiffness parameters; λ_E and λ_C are the fiber stretches for the elastin and collagen, respectively. Collagen fiber recruitment distributions were modeled using a triangular distribution function as described in [11] based on fiber distribution analysis of the MPM data. Briefly, the probability density function for fiber recruitment is defined in terms of distribution parameters λ_R^{min} , λ_R^{mode} , and λ_R^{max} , which are estimated by fitting data for stretch versus fraction of recruited collagen fibers to the cumulative triangular probability function. The total collagen strain energy function for each layer is then

defined as the integral of the strain energy for all collagen fibers across all recruitment stretches

$$\Psi_c(\lambda) = \int_1^\lambda \tilde{\Psi}_c(\lambda_c) \rho(\lambda_R) d\lambda_R. \quad (4)$$

The probability density function for fiber recruitment, $\rho(\lambda_R)$ was defined to ensure unrecruited fibers do not contribute to strain energy.

Growth and Remodeling Framework: Motivated by [11], collagen fiber remodeling was assumed to maintain a homeostatic stretch distribution (λ_{C-AT}^{min} , λ_{C-AT}^{mod} , and λ_{C-AT}^{max}) at the maximum physiological pressure with a linear relationship for remodeling,

$$\frac{\partial \lambda_{C-R}^{min}}{\partial t} = \alpha_c \frac{\lambda_C^{max}|_{\lambda_T} - \lambda_{C-AT}^{max}}{\lambda_{C-AT}^{max}} \quad (5)$$

$$\frac{\partial \lambda_{C-R}^{max}}{\partial t} = \alpha_c \frac{\lambda_C^{min}|_{\lambda_T} - \lambda_{C-AT}^{min}}{\lambda_{C-AT}^{min}} \quad (6)$$

$$\frac{\partial \lambda_{C-R}^{mod}}{\partial t} = \alpha_c \frac{\lambda_C^{mod}|_{\lambda_T} - \lambda_{C-AT}^{mod}}{\lambda_{C-AT}^{mod}} \quad (7)$$

where $\lambda_C^{min}|_{\lambda_T}$, $\lambda_C^{mod}|_{\lambda_T}$ and $\lambda_C^{max}|_{\lambda_T}$ are the collagen stretch distributions at the threshold state; α_c is the remodeling rate. The remodeling rate of collagen in the DSM was assumed to be 3 times faster than that of the LP, motivated by experimental data where the remodeling process was found almost entirely in the DSM [10].

RESULTS

Collagen Fiber Recruitment Distribution: As shown in Figure 1, the aged bladder has a lower minimum recruitment stretch for both LP and DSM fibers compared with adult bladders. More importantly, in aged bladders, a much wider recruitment distribution was found in the DSM compared with the LP layer. The LP and DSM fibers had similar recruitment distribution length in adult healthy bladders.

Figure 1: Tissue stretch vs. fiber recruitment fraction and associated fitted curves for both LP and DSM layers for representative adult (left) and aged (right) bladders

Collagen Fiber Remodeling: The physiological maximum pressure of rat bladder has been shown to be relatively insensitive to age, with consistent values from 12 months to 18 months and only slightly increasing by 9% at 24 months [14]. Therefore, we conjecture the aging process is not driven by changes in mechanical load on the bladder. As a much wider recruitment distribution in DSM was found in aged bladder (Fig.1), we conjecture one trigger for age related remodeling in bladder is the evolution of homeostatic stretch. Based on this conjecture and supporting data, the DSM homeostatic stretch distribution was prescribed to evolve to a wider distribution; increasing λ_{C-AT}^{max} by 0.2 and decreasing λ_{C-AT}^{min} by 0.2. The resulting evolving changes in mechanical properties (Stretch vs. Cauchy Stress) were

simulated from 12 month old (adult) bladder to 24 month old (aged) bladder, Figure 2. As the DSM slowly developed a wider collagen recruitment distribution, the loading curves progressively shifted to the left, indicating a gradual loss of compliance. The predicted mechanical properties after the 48 weeks of adult bladder remodeling matched the mechanical data for aged bladder.

Figure 2: Experimentally measured loading curves for Adult (week 0) and Aged (week 48) bladder and simulated loading curves at multiple time points during age related remodeling

DISCUSSION

In this study, the collagen recruitment distribution was quantified and modeled using bladder data from Adult and Aged rats. A consistent feature in the aged bladder wall was an increased range in stretch for collagen recruitment in the DSM. Using our G&R approach, informed by experimental data, we examined the conjecture that age related changes in bladder wall result from aged related changes in homeostatic deposition stretch distribution. Collagen remodeling and associated changes to passive mechanical function were simulated and found to be consistent with physical data from aged rats.

INTRODUCTION

In comparison with the proliferation of viruses in nature, one of the important reasons leading to the gap between the huge number of NPs in laboratories and their poor performance in clinical applications is the lack of mechanistic understanding of the relation between NP properties and their biological activities. Despite the amount of effort that has been devoted to understanding the effects of NPs' geometry on the cellular uptake process, no solid conclusions have been drawn yet, (1) and results are inconsistent between experiments. Furthermore, the elasticity of NPs has recently attracted increasing attention for its significant role during blood circulation, penetration in solid tumors, and tumor cellular uptake. (2) Nevertheless, conflicting experimental results have been reported in terms of the relation between cellular uptake efficiency and NPs' elasticity. With these gaps between experimental results and the current understanding of the influence of NPs' geometry and elasticity in mind, we developed a coarse-grained molecular dynamics (CGMD) model for elastic NPs to systematically investigate the receptor-mediated membrane wrapping of elastic NPs with different sizes and shapes.

METHODS

Using coarse-grained molecular dynamics simulations, we systematically investigate the receptor-mediated endocytosis of elastic nanoparticles (NPs) with different sizes, ranging from 25 to 100 nm, and shapes, including sphere-like, oblate-like, and prolate-like. In our simulations, ligand and receptor densities are set as comparable to experimental values. The elastic NP is modeled by a thin elastic shell. Its elasticity can be systematically changed by tuning its bending constant. The settings in our simulations allow us to capture both the receptor diffusion kinetics and free energy changes during the membrane wrapping process.

RESULTS

As shown in Fig.1. B, the soft NP is much slower to be fully wrapped than the rigid NP. To further explore the interplay between the size and elasticity of spherical NPs, we systematically investigate soft NPs ($k_{bend} = 0.1\epsilon$) of different radii and compare them with rigid NPs in Fig.1. C. There are two key phenomena we can observe from this comparison. First, the minimum size of spherical NPs that can be fully wrapped by the cell membrane is increased to $R = 30$ nm for soft NPs compared to $R = 27.5$ nm for rigid spherical NPs. Second, all soft NPs are less efficiently wrapped than rigid ones, and the difference between them increases as the NP radius increases. It is noteworthy that this trend in our simulations seems to conflict with the theory, (3) where the soft NPs are predicted to be more efficient.

Figure 1. Membrane wrapping of soft spherical NPs. (A) Membrane wrapping of soft spherical NPs with the bending constant $k_{bend} = 0.1\epsilon$ and radius $R = 75$ nm. (B) Wrapping ratio evolution for rigid ($k_{bend} = \infty$) and soft ($k_{bend} = 0.1\epsilon$) spherical NPs with identical radii $R = 75$ nm. (C) Wrapping time for rigid and soft spherical NPs of different radii.

Figure 2. Free energy analysis of membrane wrapping process for spherical NPs. Comparison of (A) contact radius, (B) energy barrier change, and (C) bound receptor numbers between rigid and soft ($k_{bend} = 0.1\epsilon$) spherical NPs at $R = 75$ nm. (D) Comparison of the energy barrier change between soft NPs with different radii.

The soft and rigid NPs share the same contact radius at each wrapping ratio, f (Fig.2. A). The total energy barriers $\Delta E_{Barrier}$ of rigid and soft NPs are given in Fig.2. B., with $\Delta E_{Barrier}$ of a soft NP much larger than that of a rigid NP at each f . Therefore, the soft NP needs to recruit more receptors to overcome a larger energy barrier at each stage after $f = 0.4$ (Fig.2. C). Due to the similar contact radius, the soft NP needs to wait longer than the rigid NP to encounter and bind extra receptors. That is also the reason that the soft NP is slower to be fully wrapped. We further calculate energy barriers of soft NPs with different sizes in Fig.2. D. It is found that the energy barrier of a soft NP is increasing with the increment of the NP size. In comparison, the energy barriers of rigid NPs with different sizes are the same. This can explain how the wrapping time difference between rigid and soft NPs is increasing with their radii, as shown in Fig.1. C.

Figure 3. Membrane wrapping of oblate and prolate soft NPs with the bending constant $k_{bend}=3c$. (A, E) Membrane wrapping process of an oblate and a prolate soft NP. (B-D) Comparisons of the wrapping ratio, contact radius, and energy barrier for rigid and soft oblate NPs. (F-H) Comparisons of the wrapping ratio, contact radius, and energy barrier for rigid and soft prolate NPs.

As shown in Fig. 3. A-D for the comparison between soft and rigid oblate NPs, it is interesting to find that their wrapping ratio evolutions are almost the same before $f = 0.9$. After that, the soft oblate NP undergoes a slower wrapping. However, as shown in Fig. 3. E-H, the wrapping of the soft prolate NP is slower than that of the rigid NP almost during the entire wrapping process. The contact radii of rigid and soft NPs are similar at all wrapping ratios for both oblate and prolate NPs. Additionally, the soft prolate NPs need to overcome a larger energy barrier during wrapping than the rigid one. Moreover, the energy barrier values in the wrapping process of soft prolate and oblate NPs are on the same order (around 300ϵ). In short, the different in contact radius between oblate and prolate NP contributes to the different wrapping efficiency difference in NPs. The large contact radius of oblate NP make it have enough receptor recruiting speed to overcome the energy barrier. While, the small contact radius causes the less efficient of soft prolate NP compared to the rigid one.

We systematically investigate the wrapping efficiency of elastic NPs with different geometries, as given in Fig. 4. The energy barrier of NPs with the same geometry decreases as the bending constant increases, leading to the scaling law between the bending constant and membrane wrapping time. Moreover, because of the significantly large contact

edge length, soft oblate NPs have a high receptor recruiting speed to bind extra receptors for overcoming the increased energy barrier. Therefore, the oblate NPs are less sensitive to the variation of the bending constant.

Figure 4. Wrapping time as a function of bending constant for oblate, prolate, and spherical NPs.

DISCUSSION

As we mentioned, the membrane wrapping efficiency is determined by both contact edge length and energy barrier (or thermodynamic driving force). The softer NPs are proven to need to overcome a larger energy barrier because of their deformation in both theories and simulations. But the contact edge length difference between soft and rigid NPs is determined by their mechanical properties. Specifically, in theory, by removing the volume constraint and fixing the total area, the contact edge length of soft spherical NPs in Yi and Gao's work is 20% larger than that of the rigid counterpart. (3) However, in our simulations, both the total volume and area of elastic NPs are controlled by the potential functions. Thus, the soft spherical NP has a similar contact edge to their rigid counterpart. Because of this difference, the soft NPs in Yi and Gao's work are faster than the rigid NPs to be fully wrapped, (3) while, in our simulations, soft NPs are less efficient. In experiments, the LBL capsules are hollow particles after removing the template. These particles can easily change their volumes during cellular uptake, leading to large contact lengths and high efficiencies of internalization. (4, 5) On the other hand, for the lipid-based NPs, due to the hydrophobicity of the lipid bilayer, the interior water molecules are difficult to penetrate through the bilayer. Therefore, lipid-based NPs can be considered as incompressible with constant volume, similar to the elastic NPs in the present study, which have lower cellular uptake efficiency for softer NPs. (6, 7) Therefore, our works provide an insightful explanation for these conflicting experimental results.

INTRODUCTION

It has been shown in the past that the temperature variation at the neck skin surface, due to pulsatile blood flow in the carotid artery, can be used to estimate health vitals such as pulse rate [1]. Therefore, it can be established that the blood flow in the artery can be related to the heat transfer to the external neck skin surface. It is evident that the presence of the stenosis leads to a decrease in the blood flow in the carotid artery, and hence, a low blood flow to the facial and temporal arteries. In the past, using contact and non-contact thermographic methods, carotid stenosis is correlated to facial [2] or ocular [3] thermal maps. However, none of these studies investigated the effect of arterial stenosis on the heat transfer characteristics between the carotid artery flow and its surrounding tissue. The presence of stenosis will bring about changes in the heat transfer to the skin tissue, which is expected to be captured in the resulting temperature map over the external neck skin surface; possibly correlates to the degree of stenosis. Therefore, using computational and experimental methods, the present study investigates the external neck skin temperature alteration with the occurrence of stenosis in the carotid artery.

METHODS

In the present study, both computational and experimental methods are used to verify the diagnosis potential of stenosis through temperature features on the neck skin surface. In the computational work, using the geometrical data available in the literature [4], an idealized 3D carotid artery geometry is reconstructed (Fig. 1). Based on the blocked cross-sectional diameter, 75% stenosis tissue is introduced in the ICA. Further, the carotid geometry is encapsulated in a homogenous tissue, of which the thermal properties are taken from the literature [5]; resulting into a geometry resembling a trapezoid-shaped section of the human neck tissue (Fig. 1).

**Figure 1: 3D geometry and mid-plane sectional view of the model
(all dimensions are in mm)**

The blood flow is assumed to be incompressible and Newtonian, with constant thermal properties. On an overall mesh size of 5×10^6 , using finite volume method available in the FLUENT software (version 19.1) by ANSYS Inc, Navier-Stokes (blood flow) and energy (conjugate heat transfer) equations [6] are solved. Steady laminar solver, with Semi Implicit Pressure Linked Equations (SIMPLE) algorithm, is used. A convergence criterion of 10^{-10} , for velocity and temperature approximation residual, is applied. A fully developed velocity profile (at peak systolic, $U = 0.5332 \text{ m/s}$) is used at the CCA inlet, while pressure boundary condition is used at the outlet of ICA and ECA, respectively. Blood temperature is taken to be 37°C . The top external neck skin surface is applied with ambient ($T_{\text{amb}} = 21^\circ\text{C}$) convective heat transfer boundary condition (heat transfer coefficient, $h = 5 \text{ Wm}^{-2}\text{K}^{-1}$). The side walls of the encapsulated tissue are given adiabatic condition, while the bottom surface is given isothermal core body temperature (37°C) condition. Pennes bio-heat equation with a tissue perfusion rate of 0.4333 Kg/ms is used, along with a volumetric heat generation of 33 W/m^3 .

In the experimental part of the study, Infrared (IR) thermography (using VarioCAM IR thermal camera by Infratec) is performed on 8

patients (both male and female) in the age group of 45 to 71 years old, at National Heart Center Singapore, under an ethically approved study (CIRB Ref No.: 2017/2119). Of the 8 patients, 4 belongs to the control group (0% stenosis), while the other 4 belongs to the diseased group ($\geq 50\%$ stenosis). Given the two sides of the neck are screened separately, in all, there are 16 samples (N) available for the analysis. To extract the usable thermal features, the acquired thermal images are processed as shown in Fig. 2. Taking the minimum (T_l) and maximum (T_u) temperature from the non-zero pixels of the thermal image, the cold region extraction, using temperature threshold (T_{th}) value calculated in Equation 1, is performed.

$$T_{th} = T_l + 0.3 * (T_u - T_l) \quad (1)$$

Further, to quantitatively differentiate the two groups of patients, a ratio denoted by ' R_{cn} ', defined by the number of non-zero nodes with value $\leq T_{th}$ normalized with the total number of non-zero nodes in the image, is used. In case of the computational study, the value of T_{th} is selected based on the minimum temperature occurring in the two simulated cases (0% and 75% stenosis).

Figure 2: Thermal image processing flow chart

RESULTS

Fig. 3 shows the temperature contours, resulting from the computational study, at the mid-plane of the artery and the top skin surface. It can be observed that the presence of stenosis leads to the formation of low temperature regions in the carotid artery flow, which shall affect the heat transfer to the external neck skin surface. Fig. 4 shows the difference in the temperature features between normal and diseased case, which is found to be enhanced with the proposed cold region extraction method in the present study.

Figure 3: Temperature contours from the computational study

Figure 4: Original and extracted thermal images from thermography experiment

DISCUSSION

From the results, it is imperative that the occurrence of stenosis brings about changes in the thermal map on the external neck skin surface. This is marked by the presence of a vertical cold feature at the center of the top skin surface thermal map in 75% stenosis case (Fig. 3) and a higher colder region in the thermal image for 50%+ stenosis case (Fig. 4). This is further quantified by evaluating the value of R_{cn} in Table 1. For both computational and experimental studies, the value of R_{cn} , in the respective groups, is found to be alike. Furthermore, using student t -test, it is shown that the difference in R_{cn} value, in the two groups of patients, is significantly different (p -value < 0.05). Hence, the present study proves the potential of IR thermography as a measure of carotid artery stenosis.

Table 1: R_{cn} value for computational and experimental study

Group	R_{cn}	
	Computational	Experimental
Control	0.10	0.09 ± 0.05
Diseased	0.17	0.21 ± 0.08
Student t -test	NA	$P=0.002$

INTRODUCTION

The limited availability of living cells poses a major challenge to modern cell-based medicine like cell transplantation and cell therapy¹. The most widely used cell banking method is cryopreservation, which involves a slow freezing procedure and storage in liquid nitrogen (LN2) to keep the cells in a state of suspended animation. This process requires the use of cell-penetrating cryoprotectants (CPAs) to protect the cells from freezing damage. However, the organic solvents used as common CPAs like dimethyl sulfoxide (DMSO) can prove highly toxic at body temperature, both *in vitro* and *in vivo*, if not sufficiently removed from the cells after thawing²⁻³. Removing CPAs is time consuming and can result in significant loss of these precious cells¹.

Trehalose is a non-reducing disaccharide commonly found in many organisms that can survive extreme freezing and/or dehydration in nature⁴. This unique sugar has been investigated as a non-toxic alternative to traditional CPAs⁵. Unfortunately, mammalian cells lack the mechanism to synthesize trehalose and their membranes are impermeable to it. Trehalose has been successfully introduced into mammalian cells through nanoparticles, however, an incubation time of 24 hours was necessary for sufficient intracellular trehalose release for cryoprotection⁶. This makes the cryopreservation lengthy and tiresome.

To address these challenges, we synthesized a cold-responsive polymer nanoparticle (PNP) to provide for efficient intracellular delivery and release of trehalose in this study. We created a polymer nanoparticle to achieve the fastest disassembly and most efficient payload release upon experiencing cold temperature (14-16°C). We confirmed nanoparticle uptake and cold-triggered intracellular release through fluorescent microscopy. We reduced the incubation time necessary for sufficient intracellular trehalose for cryoprotection to only 4 hours for human adipose-derived stem cells (hADSCs). Preliminary data showed when the cold-responsive nanoparticles were used to

cryopreserve hADSCs through slow-freezing, the post-thaw viability, attachment, and proliferation proved comparable to results achieved by traditional DMSO cryopreservation. hADSC post-thaw quality was further confirmed through expression of stemness markers and multilineage differentiation capability. This success using PNPs in the slow freezing protocol led us to study their effectiveness for use in a fast freezing protocol using predehydration and ice seeding before plunging into liquid nitrogen.

METHODS

Preparation of Nanoparticles. Poly (lactic-co-glycolic acid) or PLGA (lactide:glycolid = 50:50, M_w = 5-30K) and poly (N-isopropylacrylamide-co-butylacrylate) or pNIPAM-B (NIPAM:B 8:1, M_w = 30K) were used in a double-emulsion (water-in oil-in water) method to make the nanoparticles. Trehalose (0.3mL 1.3M trehalose) was encapsulated in the aqueous core of the nanoparticles. A 2% solution of polyvinyl alcohol (PVA, M_w = 30-70K) was used as a stabilizer.

Characterization of Nanoparticles. The size and zeta potential of PNPs was examined using a dynamic light scattering system (DLS, Malvern). The morphology of PNPs was examined using a JEM 2100 LaB6 transmission electron microscope (TEM).

Cold-triggered Release. The release profile of trehalose from PNPs was quantified to confirm cold-triggered rapid release of trehalose from the nanoparticles. A tube of trehalose-laden PNPs was centrifuged ever 2 hours at 37°C/22°C for 6 hours. The tube was cooled on ice for 10 min at 4h. The amount of trehalose in the supernatant at each time point was quantified using a trehalose assay kit (Megazyme). The disassembly of the nanoparticles was also visualized by the change in turbidity of suspended nanoparticle solution.

Cell Uptake. Cellular uptake of PNPs was visualized by encapsulating doxorubicin (DOX) into the nanoparticle core instead of trehalose due to its fluorescence. hADSCs were cultured on type I collagen coated coverslips, and then incubated with medium containing DOX-loaded PNPs for 4h. Cells with or without ice cooling were studied in parallel. Cells were fixed and with LysoTracker Green and DAPI to visualize lysosome and nuclei, respectively.

Cell Cryopreservation. hADSCs were pretreated by incubation in either free trehalose in medium or trehalose-PNP medium for 4h. Cells cryopreserved without pretreatment were also studied in parallel. Cells were detached and re-suspended in culture medium containing 0.3M free trehalose. Fresh cells and cells cryopreserved using DMSO were also studied in parallel. For slow freezing, cells were transferred into a cryovial, the vial was hermetically sealed and placed into a Thermo Nalgene freezing container in the -80°C freezer overnight. Cells were then transferred to LN2 tank for storage. After 1 day of storage, cells were thawed in a 37°C water bath for further studies. For fast freezing, cells were first incubated with either free trehalose in medium or trehalose-PNP medium for 4h. Cells were washed with 1XPBS, collected, and then resuspended in 200 μ L medium containing 0.33M trehalose in a 600 μ L plastic microcentrifuge tube. This tube was submerged into a 10% (w/v) sodium chloride bath at -4°C for 5 min to equilibrate. The tube was touched with a precooled (in LN2) copper wire to seed ice in the cell suspension, and then was transferred back into the bath for 1 min of equilibration. The tube was then plunged into LN2 to cool to -196° and stored for 24h.

Cell Quality Post-Cryopreservation. Cell viability was assessed using calcein AM and ethidium homodimer dyes immediately post-thaw. The same quantity of fresh cells and thawed cells were cultured overnight and washed with 1XPBS the next morning. Attachment was quantified as the ratio of counted thawed cells still attached to fresh cells still attached. Proliferation was calculated as the ratio of the cell numbers on days 2 and 3 to the initial cell number on day 1. Stem cell marker CD44 and differentiation marker CD31 were studied on trehalose-PNPs cryopreserved cells compared to fresh. Multilineage differentiation of cells was evaluated by adipogenic and osteogenic differentiation.

RESULTS

PNPs show a size of ~150nm at room temperature with a size peak in the distribution of 122.4nm (Figure 1A). PNPs carry a slightly negative charge, showing a zeta potential of -13mV (Figure 1B).

Figure 1: Dynamic light scattering data showing size and zeta potential distribution of PNPs.

PNPs showed a distinct core-shell morphology, with the trehalose encapsulated in the core of the nanoparticle (Figure 2). Encapsulating trehalose inside the core of the thermally responsive nanoparticle allowed it to pass through the plasma membrane of the cell and reach the cells intracellular compartment.

Figure 2: PNP morphology at room temperature

The PNPs showed cold-responsiveness due to the high composition of pNIPAM-B, with a lower critical solution (LCST) temperature of 14-16°C, in the nanoparticle formulation. Above the LCST, pNIPAM-B acts as a hydrophobic polymer, and is able to form nanoparticles. Below the LCST, pNIPAM-B becomes hydrophilic, and the nanoparticles irreversibly dissemble in aqueous solution. This can be seen in Figure 3, where nanoparticles in solution at room temperature (3a) are in a stable colloidal solution, appearing milky and turbid. However, once they dissemble the solution becomes more transparent as the pNIPAM-B becomes hydrophilic (3b).

Figure 3: Cold-responsiveness of PNP in solution. (a) Room temperature (b) After ice treatment

DISCUSSION

The cold-responsive nanoparticles encapsulating trehalose synthesized in this study allowed for delivery of trehalose across the plasma membrane and controlled and rapid release of the nontoxic cryoprotectant inside of the cell. Intracellular trehalose has been shown to improve cryosurvival for mammalian cells, but previous attempts to deliver the impermeable sugar across the membrane either compromised membrane integrity (electroporation)⁷, modified the cell's machinery (trehalose transporter)⁸, or simply did not allow for enough intracellular accumulation in a timely manner (fluid-phase endocytosis)⁹. This method uses the cell's natural process of endocytosis to uptake the nanoparticle, and release is caused by cold temperature, which cells experience during the freezing process.

This is very different from a previous study⁶, as the nanoparticle incubation time is shortened to only 4h due to the capability for rapid release. Longer incubation times may increase the chance for nanoparticle removal from cells by exocytosis, so shorter incubation times are more favorable for efficient and successful delivery. This method requires no removal step, saving time and avoiding cell loss.

This rapid release should facilitate the use of this nanoparticle to achieve intracellular trehalose for protection in fast freezing of hADSCs using prededhydration and ice seeding. Prededhydration by extracellular trehalose can reduce cells to their minimal volume with minimized active water inside the cell to protect from osmotic shock and intracellular ice formation (IIF) which can prove lethal. Ice seeding can release the free energy that could cause ice recrystallization during rewarming, leading to cell damage.

INTRODUCTION

One of the principal impediments to the broad success of conventional chemotherapy is poor delivery to and transport within the tumor microenvironment (TME), caused by irregular and leaky vasculature, the lack of functional lymphatics, and underscored by the overproduction of extracellular matrix (ECM) proteins such as collagen. Coupled with limited specificity, the high chemotherapeutic doses needed to effectively treat tumors often lead to unacceptable levels of damage to healthy tissues. Bacteria-based cancer therapy (BBCT) is an innovative alternative. Engineered strains of species such as *Salmonella* Typhimurium have been shown to preferentially replicate in the TME, competing for cellular resources and imparting intrinsic and immune-mediated cytotoxic effects on cancer cells. Nevertheless, the myriad of successes observed *in vitro* and in murine models have not translated to the clinic, attributable to the lack of sufficient tumor colonization. High tumor collagen content has been shown to significantly hinder the intratumoral transport of macromolecules and nanoparticles [1]. Likewise, *S. Typhimurium* has been shown to poorly penetrate tumors of high collagen content relative to those with lower collagen content [2]. We hypothesize that engineering *S. Typhimurium* to express and secrete a recombinant collagenase to locally degrade tumor ECM will increase bacterial penetration, leading to enhanced retention and colonization within tumors.

Toward improving tumor colonization potential, we engineered the attenuated tumor-targeting strain *S. Typhimurium* VNP20009 [3] to secrete a heterologous collagenase and developed a microfluidic assay to systematically characterize its transport in the ECM. Results indicate significant collagen degradation and matrix remodeling by the collagenase-secreting bacteria. Our microfluidic assay allows us to visualize bacterial colonization in real time and estimate transport and growth parameters in a quasi-steady nutrient environment. This research

addresses the largely unexplored question of bacterial transport in the ECM toward developing translational BBCT.

METHODS

Cloning of a Heterologous Collagenase – The matrix metalloproteinase gene *prtV* [4] was cloned from *Vibrio parahaemolyticus* EB101 (ATCC 17802) into the multiple cloning site of the pBAD LIC (8A) plasmid vector (RRID:Addgene_37501). The *araBAD* promoter was replaced with the constitutive synthetic promoter BBa_J23100, and BBa_J04450 (excluding the BBa_B0015 terminator) encoding mRFP1 was cloned downstream of *prtV* to enable fluorescent imaging during experiments. Expression and enzymatic activity was confirmed by measuring the fluorescence of collagen type I supplemented with 1% dye-quenched (DQ) collagen type I during incubation with bacteria.

Microfluidic Device Design and Fabrication – The microfluidic device was designed with 7 parallel channels separated by series of hexagonal pillars (Fig. 1) and fabricated via standard soft lithography. SU-8 photoresist was patterned onto silicon wafers at a thickness of 300 μm and used to mold polydimethylsiloxane (PDMS)-based devices. The molded PDMS device was bonded to a coverslip. Polyethylene glycol diacrylate (PED-DA; 700 Da) was then polymerized between the outermost channels in order to create permeable barriers separating media flow from adjacent channels, and 5 mg/mL collagen type I was polymerized in the center channel.

Microfluidic Experiments and Data Collection – *S. Typhimurium* VNP20009 expressing *prtV* (hereafter referred to as VNP20009*prtV*) were suspended in a buffer solution at a concentration of 5×10^7 bacteria/mL and pipetted into one of the channels adjacent to the collagen matrix, while buffer solution alone was inserted into the opposite channel. Nutrient medium and buffer solution were flowed

Figure 1: Microfluidic Platform for Systematic Evaluation of Bacterial Transport in ECM.

constantly through the outermost channels in order to generate a quasi-static nutrient concentration gradient across the collagen barrier (Fig. 1). The device was maintained at 37 °C and imaged every 30 min for the duration of the experiment. Confocal reflectance microscopy (CRM) was performed following time-lapse experiments.

Mathematical Model for Parameter Estimation – The bacterial transport in and colonization of the collagen hydrogel can be described by

$$\frac{\partial B}{\partial t} = \nabla \cdot D_{\text{eff}} \nabla B + k_g B \left(g - \frac{B}{k_B} \right) \quad (1)$$

where B is bacterial concentration, D_{eff} is an effective bacterial diffusivity accounting for both swimming and diffusion, k_g and g are the maximum and local growth rates, respectively, and k_B is the maximum bacterial concentration [5]. Time-lapse data were used to fit D_{eff} of strains, providing quantitative transport information.

RESULTS

We confirmed *PrtV* secretion and enzymatic activity against collagen type I using DQ collagen type I, which releases fluorescein upon breakdown. Fluorescence intensity increased significantly in samples containing VNP20009*prtV* but was negligible in controls (Fig. 2a). We next performed time-lapse experiments using our microfluidic assay, demonstrating bacterial transport and growth through the central collagen barrier (Fig. 2b and c). Time-lapse fluorescent images allow

Figure 2: (a) Relative Fluorescence of DQ Collagen Type I, (b) Spatiotemporal Heatmap of Relative Bacterial Fluorescence, and (c) Representative Time-lapse Microscopy Images of VNP20009*prtV* Collagen Colonization.

for a determination of relative changes in spatiotemporal bacterial concentration.

CRM images recorded following experiments revealed structural differences between the collagen fiber networks of experiments with VNP20009*prtV* and controls (Fig. 3). Notably, treatment with VNP20009*prtV* led to fiber re-organization and bundling at shorter timescales (~20 hr) and a large increase in free open space within the hydrogel at long timescales (~40 hr).

Figure 3: Shadow Projections of CRM z-stacked Images Reveal Structural Modifications to Collagen Networks.

DISCUSSION

We have engineered a collagenase-secreting strain of tumor-targeting bacteria toward enhancing intratumoral transport and colonization. Our preliminary results demonstrate collagen hydrogel modification by this strain, which is expected to lead to significant differences in bacterial transport between *prtV* and control strains. Our novel microfluidic platform creates a quasi-static environment through which we can systematically characterize the transport of bacteria in ECM for the first time, which we will use to optimize *prtV* expression.

Today, the rational engineering of tumor-targeting bacteria enabled by recent breakthrough achievements in medicine and biology have put BBCT on the brink of being realized as a powerful new weapon against cancer [6]. BBCT has and continues to be proven in a plethora of *in vitro* and *in vivo* animal studies. The development of strains that have (1) been shown safe for human administration and (2) demonstrated a sufficient level of tumor colonization with minimal side effects in immunocompetent hosts are the primary hurdles for translation to the clinic. The first of these challenges has been repeatedly met; addressing bacterial transport limitations in desmoplastic tumors is a largely unexplored avenue and has the potential to surmount the second.

INTRODUCTION

Irreversible Electroporation (IRE) is an energy directed therapeutic used to treat patients with unresectable tumors. This non-thermal, minimally invasive technique can be used to target malignancies enveloping critical structures (blood vessels, major nerves, etc.) and is less influenced by the convective effects of local blood perfusion in comparison to thermal ablation technologies (radio frequency ablation, microwave ablation, etc.) [1-3]. However, in some instances, generating a sufficiently high pulsed electric field that concurrently maps the entire region of interest, while also avoiding undesirable thermal effects can be challenging. To overcome these difficult scenarios, thermal mitigation strategies have been explored [4, 5]. In many instances, surgeons performing IRE treatments use three or more monopolar IRE electrodes to encompass a large or irregularly shaped tumor. While the addition of electrodes may be useful in covering a larger ablation region, the existing method of pulse delivery has not been engineered to moderate thermal tissue damage for multi-electrode treatments. The NanoKnifeTM generator is currently designed to deliver the entirety of the set number of pulses for a given electrode pair before proceeding to the next electrode pair until all of the desired electrode pair combinations have been exhausted. However, by partitioning the pulse-train into subsets of pulses and cycling between electrode pairs until the desired number of pulses is reached, thermal damage could be managed. Figure 1 illustrates these different pulsing sequences.

This study investigates the effects of various cycled pulsing paradigms in comparison to traditional pulsing schemes via a multi-electrode IRE therapy (4-electrode configuration) on the IRE lesion size, deployed electrical current, temperature changes, and treatment time. This systematic approach has the potential to improve clinical outcomes.

Figure 1. Schematic illustrating the differences in traditional pulsing schemes compared to a cycled pulsing paradigm for a 4-monopolar array configuration.

METHODS

All IRE treatments were performed using a 4-monopolar electrode array and the previously validated perfused organ model (porcine liver tissue) [6]. A total of five cycled pulsing variations were performed and evaluated in comparison to the NanoKnifeTM (AngioDynamics, Latham, NY) pulsing scheme. After treatment, organs were dissected and treatment zones were stained using 2,3,5-triphenyl-tetrazolium chloride (TTC) to demonstrate viability. STB general purpose fiber optic temperature sensors (Luxtron m3300, LumaSense, Santa Clara, CA, USA) were positioned and adhered at the midpoint of each exposed electrode to measure temperature throughout treatments. Further, the electrical voltage and current were measured and employed to calculate the treatment energy deposition.

A finite element model was developed using a commercial finite element package (COMSOL Multiphysics, v.5.4; Stockholm, Sweden) to explore the effects of various cycled pulsing paradigms for multi electrode IRE procedures. The domain consisted of liver tissue modeled as a $12 \times 12 \times 8$ cm diameter ellipsoid and 4-monopolar NanoKnifeTM

electrodes modeled as cylinders of height, diameter, and spacing 1.5 cm, 1 mm, and 2 cm, respectively. The final mesh consisted of 187,418 tetrahedral elements with a maximum of 2,264,706 degrees of freedom. The electric potential distribution was captured using the Laplace equation (equation 1) and taking the gradient of the electric potential (equation 2),

$$0 = -\nabla \cdot (\sigma \nabla \Phi) \quad (1)$$

$$\vec{E} = -\nabla \Phi \quad (2)$$

This effect is captured in the model by using a sigmoidal curve previously characterized in O'Brien et al. for porcine liver tissue on the POM,

$$\sigma(|\vec{E}|, T) = \sigma_0 + \frac{\sigma_f - \sigma_0}{1 + D \cdot e^{-\frac{-(|\vec{E}| - A)}{B}}} \cdot [1 + \alpha \cdot (T - T_0)] \quad (3)$$

, where σ_0 is the initial non-electroporated conductivity, σ_f is the peak electroporated conductivity, $|\vec{E}|$ is the magnitude of the electric field at any given position, and D, B, and A are fitting terms. Further, α represents the temperature coefficient, T_0 the initial temperature, and T is the temperature at any given time.

Temperature profiles were simulated using a modified Pennes' bioheat equation and implements cycliced pulsing schemes using time dependent "thermal envelopes" that capture both changes in the number of cycles and cycle delays. Analytical functions enable the implementation of complex cycliced pulsing schemes, where an arbitrary coefficient χ is used to simulate the on ($\chi = 1$) and off ($\chi = 0$) period of the thermal envelope. This resulted in the following equation,

$$\rho c_p \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) - \omega_b \rho_b c_b (T - T_b) + \frac{\sigma \cdot |\vec{E}|^2 \cdot p}{\tau} \cdot \chi \quad (4)$$

, where p is the pulse width, and τ is the pulse period over which the energy was averaged.

RESULTS

The "1 pulse cycle, 0s delay" group produced the largest amount of energy, reaching an average of 2.33 ± 0.35 kJ, while the NanoKnife™ generated 2.09 ± 0.37 kJ on average. The "5 pulse cycle, 0s delay", "10 pulse cycle, 0s delay", and the "10 pulse cycle, 10s delay" produced the lowest amounts of energy during treatment, yielding an average of 1.98 ± 0.32 kJ, 1.88 ± 0.34 kJ and 1.89 ± 0.23 kJ, respectively. The "10 pulse cycle, 5s delay" pulse scheme generated an average of 2.14 ± 0.38 kJ. No statistical significance was found between experimental groups. All of the cycliced pulsing schemes presented a larger ablation area on average in comparison to the 1-pulse cycle groups. The "5 pulse cycle, 0s delay" pulse paradigm produced the largest cross-sectional area, with an average area of 11.81 ± 1.97 cm². This pulsing paradigm was significantly different from the "1 pulse cycle, 0s delay" (8.41 ± 1.97 cm², $p \leq 0.0395$). The NanoKnife™ generated a cross-sectional ablation zone of 8.90 ± 0.91 cm² on average. Figure 2 displays experimentally measured results.

Figure 3 illustrates numerically derived time-lapse images of the thermal distribution at the first cycle of each electrode pair. The rightmost panels illustrate the thermal distribution and electric field at 50s post-treatment. Further, the boundary at which the onset of thermal damage occurs ($\Omega=0.53$) is overlaid and outlined in green. The temperature distribution and thermal damage is much greater for the NanoKnife™ pulse paradigm than the cyclically-pulsed schemes. These results indicate that the "10 pulse cycle, 10s delay" pulse paradigm can reduce 1st degree thermal tissue injury by up to 73.95% in comparison to the traditional NanoKnife™ pulsing scheme. Further, the thermal distribution for the cycliced pulsing schemes are far more uniform.

Figure 2. Experimental results illustrating the (A) total energy deposition throughout treatment and (B) cross-sectional ablation areas.

Figure 3. Numerically derived thermal distribution at the completion of each initial electrode pair activation, as well as the final electric field and thermal distribution 50 seconds post therapy is presented for a (A) traditional NanoKnife™ pulsing scheme and (B) a cycliced pulsing paradigm (10 pulse cycles, 0s delay). The time at each electrode pair activation is displayed in the top left corner. The area in which the onset of thermal damage occurs ($\Omega = 0.53$) is overlaid with the thermal distribution and outlined in green.

DISCUSSION

This study demonstrates the use of cycliced pulse paradigms to reduce the effects of Joule heating while effectively maintaining and, in some cases, improving the IRE treatment lesion dimensions in comparison to treatments administered with a traditional pulse scheme. We have verified the effects of using pulse cycle patterns on electrical current, tissue temperature, tissue treatment lesion size, and total treatment time for several pulsing schemes experimentally using a perfused organ model. Additionally, finite element analysis verified that cycliced pulsing patterns can mitigate the overall temperature distributions and thermal damage in comparison to single-cycle pulsing schemes.

INTRODUCTION

The blood-brain barrier (BBB) keeps an optimal environment for normal brain function¹, but also excludes most molecules from entering the brain. Temporarily overcoming the BBB to deliver molecules to the brain is critically important to studying and treating brain diseases. Current methods for BBB opening, including osmotic shock², focus ultrasound disruption³ and vasoactive agents⁴, lack sufficient spatial resolution for delicate brain structures.

Here, we report a new method to temporarily open the BBB by optical excitation of vasculature-targeted plasmonic gold nanoparticles (AuNPs). Ultrashort picosecond (ps) laser pulse excitation of plasmonic AuNPs leads to *in vitro* transient BBB opening possible due to a calcium-based mechanism. We further demonstrate that *in vivo* BBB opening by visualizing extravasation of Evans blue (EB) dye. Moreover, we demonstrate that the temporary optical BBB opening allows passage of anticancer drugs and antibodies (human IgG) to the brain. Compared with other approaches to open the BBB, the optical opening offers unprecedented spatial resolution to locally allow molecule penetration into the brain.

METHODS

Nanoparticle synthesis and functionalization: AuNPs were synthesized by previous reported method⁵. Then, the AuNP were functionalized with antibodies (BV16: anti-human JAM-A, BV11: anti-mouse JAM-A) for targeting JAM-A⁶, one of the tight junction (TJ) proteins (Figure 1A).

In vitro experiments: Human cerebral microvascular endothelial cell D3 (hCMEC/D3) was used as an *in vitro* BBB model. The barrier was characterized by trans-endothelial electrical resistance (TEER), permeability and immunocytochemistry (ICC) staining. We then treated the monolayers by TJ-targeting AuNPs (AuNP-BV16), and ps laser

pulses (532 nm, Full width half maximum = 28 ps), measured the BBB opening by changes in TEER and permeability (Figure 1B).

In vivo experiments: C57BL/6 mice were injected 36.9 μ g/g AuNPs functionalized with BV11, followed by EB dye injection. We then applied ps laser through mouse skulls to excite the AuNPs on blood vessels. After 0.5 hr, mice were transcardially perfused with 25 ml PBS, followed by 4% PFA. The brain and other organs were extracted for EB extravasation imaging and histology staining (Figure 1C).

Figure 1. Methods of BBB opening *in vitro* and *in vivo*. (A) Synthesis of TJ-targeting AuNPs⁷. (B) Schematic of BBB *in vitro* model and TEER and permeability measurement. (C) Procedure of *in vivo* study.

RESULTS and DISCUSSION

Temporary BBB Opening *in vitro*

We performed ICC staining for JAM-A on hCMEC/D3 cells to determine the location of AuNP-BV16. The result shows good colocalization of AuNP-BV16 and tight junctions (Figure 2A). We, then, applied ps laser to monolayer treated with AuNP-BV16 and measured

the BBB temporary opening by changes in TEER and permeability. With the same pulse number, high laser energy leads to greater drop in TEER (**Figure 2B**). While with the same pulse energy, increasing pulse number leads to a larger drop in TEER values and larger permeability for 40 kDa FITC-dextran (**Figure 2C**). Cell viability testing by WST-1 assay indicates that the laser excitation of TJ-targeted AuNPs does not cause significant cell damage in our experimental conditions (Data is not shown). Moreover, we tested the Ca^{2+} response and found that Ca^{2+} transiently increased after laser illumination (**Figure 2D**).

Figure 2. *In vitro* BBB opening. (A) Co-localization of TJ-targeting AuNP and TJ. Green: JAM-A, red: nuclei. Scale bar, 10 μm . (B) Normalized TEER of hCMEC/D3 monolayer treated with different laser pulse energy (25 pulses and 5Hz). (C) Normalized TEER and apparent permeability (P_{app}) of 40 kDa FITC-dextran of hCMEC/D3 monolayer treated with various laser pulse numbers (35 mJ/cm^2 and 5Hz). (D) Ca^{2+} signal response to optical BBB opening (35 mJ/cm^2 , 1 pulse). The normalized intensity of fluo-4 indicates Ca^{2+} concentration. The intensity shows transient increase after laser excitation. Scale bar: 100 μm .

Temporary BBB Opening *in Vivo*

We demonstrate *in vivo* BBB opening by visualizing extravasation of EB dye, which binds to albumin in the blood and thus otherwise doesn't accumulate in a brain with an intact BBB. The result shows clear EB extravasation in the mouse treated with AuNP-BV11, while no EB extravasation in the mouse treated by AuNP-PEG (**Figure 3A**). Our optical BBB opening can reach high spatial resolution by manipulating the laser beam size. Here, we show different BBB opening area with laser beam size at 0.8 and 2.5 mm (**Figure 3B**).

To test the recovery of BBB, we administrated EB dye at 0 hour, 1 hour, 6 hours after laser excitation of TJ-targeting AuNPs. The BBB opening recovers in 6 hours with laser energy 5 mJ/cm^2 (**Figure 3C**). Next, we tested the effects of laser pulse parameters. When varying laser pulse number (1, 2, 5 pulses) with same laser pulse energy (25 mJ/cm^2), EB extravasation increased with laser pulse number (**Figure 3D**). By increasing laser pulse energy (0, 2.5, 5, 10, and 25 mJ/cm^2) and keeping the same laser pulse number (1 pulse), we observed EB extravasation starts at 2.5 mJ/cm^2 (**Figure 3E**). Analysis of the brain sections shows that the EB extravasation is deeper with increasing laser pulse energy (**Figure 3F**). Moreover, the immunohistochemistry staining shows that laser irradiation doesn't damage blood vessels (**Figure 3G**).

Lastly, we demonstrate that the temporary BBB opening allows delivery of functional molecules, such as anti-cancer drug (doxorubicin (Dox)) (**Figure 4A**) and human IgG to the brain (**Figure 4B**).

CONCLUSION

Here we report a novel method for BBB opening. Specifically, TJ-targeting plasmonic AuNPs open the BBB after excitation by a ps pulse laser *in vitro* and *in vivo*. This might be due to the nanoscale mechanical stress on the TJ molecules and Ca^{2+} -based mechanism. The biggest advantage of this optical BBB opening approach is the high optical

resolution to investigate drug accumulation. This will find broad application in delivery molecules to precise brain region.

RECAPITULATING THE COMPLEX BIOMECHANICAL PROPERTIES OF INTERVERTEBRAL DISC USING TUNABLE 3D PRINTING

INTRODUCTION

Severe back pain, one of the most common reasons for doctor visits, has been associated with degeneration of the intervertebral discs [1]. The intervertebral disc is a connective tissue between vertebral bodies that transmit load, and consists of two distinct anatomical regions with differing mechanical properties [2]. The center of the disc, called the nucleus pulposus (NP), is a highly hydrated tissue whose water content and negatively charged proteoglycans sustain the osmotic pressure that allows it to withstand large compressive forces. The annulus fibrosis (AF), which surrounds the NP, is comprised of highly oriented collagen fibers that have a high tensile strength to resist bulging [3]. The compressive modulus of native human NP ranges from 5 to 10 MPa, while the tensile modulus of native human AF ranges from 10 to 45 MPa [4,5].

Biomimetic tissue engineering approaches have been investigated to mimic the functional mechanical properties of the AF using electrospinning of PCL or PLGA fibers [6,7]. Many current research strategies for total disc engineering use two different materials for the AF and the NP and then combine these materials to create a disc composite, leaving the interface between the NP and AF vulnerable to failure under loading. Unfortunately, the biomechanical properties of the individual NP or AF scaffolds also remain orders of magnitude lower than the native disc tissue biomechanical properties.

To overcome these limitations of whole disc tissue engineering, we have developed a 3D printing approach with a flexible polymer (FPLA) to achieve a scaffold with regional elastic and viscoelastic mechanical properties that represent native AF and NP tissues. By using FPLA we can 3D print one construct that can mimic both the mechanical properties of the AF and the NP, without the need to interface two separate materials together, which can drive interfacial complications. These scaffolds may be filled with a hydrogel cell

carrier to drive the creation of biological matrices. In this study, we describe the elastic and viscoelastic properties, and initial biological validation for cellular biocompatibility, and degradation behavior of this novel 3D printed scaffold.

METHODS

Scaffolds were printed from FlexiFil, a thermoplastic copolyester elastomer/polymer blend (FPLA) (FormFutura) using a Makerbot Replicator+ 3D printer (Makerbot) with 0.4mm print nozzle. Scaffolds were printed with 0.4mm fibers with varying fiber spacing's of 1, 1.5, 2, 2.5, 3mm (Fig. 1).

Figure 1: (Left) Schematic of IVD, (Center) 3D printed IVD scaffold consisting of an AF and NP regions, and (Right) Representative images of printed FPLA scaffold sheets.

For evaluation of equilibrium mechanical properties, constructs were tested on an Instron UTM setup. For compressive testing, samples were compressed at a strain rate of 1 mm/min up to a maximum strain of 25% initial thickness. Young's modulus within the elastic deformation range was calculated. For tensile testing, constructs were placed under uni-axial tension and stretched until a load of 20N was reached; Young's modulus within the tensile elastic deformation range was calculated. Dynamic compressive and tensile DMA testing was done using a TA Electroforce DMA Mechanical Tester. A 5N preload was applied to samples prior to testing. For

compressive testing, samples were ramped to a 10% compressive strain after which a cyclic loading (5% to 15% strain) frequency sweep from 0.1 to 10 Hz was performed. For tensile testing, samples were ramped to 15% tensile strain followed by a cyclic loading (10% to 20% strain) applied at frequencies ranging from 0.1 to 10 Hz. Storage and Loss moduli were calculated using the DMA software. Data was analyzed with 1-way ANOVA with fiber spacing as the independent variable and Fisher LSD post-hoc test, with $p < 0.05$ significant.

For evaluating biocompatibility, cells were isolated from healthy bovine lumbar spine NP tissue and were expanded in DMEM+10%FBS+1%AA in standard culture conditions up to 2 passages after which they were seeded into 24 well plates for cytotoxicity testing. Scaffold samples were cultured in 24 well plates seeded with bovine NP cells for three weeks and compared to cells culture without scaffolds. Cells were stained with 4 μ M Calcein AM and 2 μ M Ethidium Homodimer-1 and imaged using confocal microscopy to determine cytotoxicity, with green indicative of live cells and red representing the nuclei of dead cells.

Degradation tests were also performed. Samples were incubated in PBS at 37°C up to 20 weeks. Every two weeks the samples were removed from the PBS bath, dried, weighed to record any mass loss, subjected to compressive DMA testing, and scanned in a μ CT to observe any mechanical degradation or morphological changes.

RESULTS

Both compressive (Fig 2a) and tensile elastic moduli (Fig 2b) of FPLA constructs decreased with increasing fiber spacing. Compared to constructs made of conventional PLA, FPLA had a significantly lower compressive elastic modulus (Fig 2a).

Figure 2: a) Compressive elastic modulus of FPLA constructs decreases with increasing fiber spacing. b) Tensile elastic modulus decreases with increasing fiber spacing. (* $p < 0.05$).

DMA compression showed that storage and loss moduli decreased with increasing fiber spacing at all frequencies, with fiber spacing having a significant ($p < 0.05$) effect on storage (Fig 3a) and loss (Fig 3b) moduli. Compressive storage modulus ranged from 1.8 MPa to 11.1 MPa, representing a range that mimics native NP tissue.

Figure 3: a) Storage modulus of FPLA constructs decreases significantly with increasing fiber spacing b) Loss modulus decreases significantly with increasing fiber spacing.

Cytotoxicity studies showed no significant changes in cell viability in either control or FPLA groups up to 3 weeks in culture, indicating FPLA scaffolds do not result in cytotoxic effects (Fig 3). From degradation studies, FPLA constructs were shown to be stable, with no signs of decrease in weight or mechanical properties to 20 weeks. μ CT scans (Fig. 3) do not show major change in morphology.

Figure 3: Representative images of live/dead Calcein AM (green) and Ethidium Homodimer-1 (red) staining of cells cultured without (a) and with (b) FPLA constructs. Representative μ CT scans of a printed scaffold before (c) and after 12 weeks of degradation testing (d).

DISCUSSION

These results demonstrate that the mechanical properties of FPLA scaffolds can be tuned using 3D printing to vary the fiber spacing, and recapitulate both the compressive properties of the native NP (Fig 2a) as well as the tensile properties of native AF (Fig 2b) using a single uniform polymer material. The ability to 3D print the FPLA scaffolds allows greater control of fiber spacing, direction, and placement than other fabrication methods (e.g. electrospinning). Furthermore, we demonstrate that we are able to modulate the viscoelastic properties (storage and loss moduli) of the scaffold by varying fiber spacing, in a manner that mimics the native NP and AF viscoelasticity [8,9]. This will permit tuning of a wide range and modality of mechanical properties, leading to a mechanically biomimetic scaffold for IVD replacement. Compared to PLA (non-flexible) scaffolds with the same fiber spacing, FPLA scaffolds exhibited compressive moduli orders of magnitude lower and more physiologically relevant than conventional PLA. Additionally, we have shown that FPLA scaffolds are stable for up to 20 weeks, and they do not exert cytotoxic effects on NP cells through 3 weeks in culture, supporting the biocompatibility of the polymer. Future studies will evaluate embedding cell loaded hydrogels in the FPLA scaffold to promote extracellular matrix deposition and integration with native tissue.

INTRODUCTION

Porcine models are a common large animal model to study musculoskeletal tissues [1]. In particular, pigs are frequently used for research involving the anterior cruciate ligament (ACL) [1]. Within research utilizing the porcine model, several breeds have been used including Yorkshire-cross breeds and Yucatan minipig breeds [2,3]. However, variability in breeds used across studies may result in issues regarding experimental repeatability due to major differences in anatomy, growth, and mechanical loading with a large range in animal size between breeds. Further complicating the issue, previous work in our group has shown that there are major changes in the anatomy of musculoskeletal soft tissues such as the ACL during growth in the Yorkshire pig, including increases in the angle of ACL orientation and variation in the relative sizes of the anteromedial (AM) and posterolateral (PL) bundles of the ACL [2,4]. These changes in tissues during growth are of interest in order to study pediatric and adolescent clinical treatments in relevant large animal models [3]. As such, the objective of this study was to compare the orientation and size of the ACL bundles as well as femoral and tibial bone size between Yucatan minipigs and Yorkshire cross-breed pigs at two ages in early adolescence.

METHODS

Hind limbs were collected from early adolescent female pigs representing Yorkshire cross-breed and Yucatan minipig breeds at 4.5 and 6 months of age (n=6 per age and breed, n=24 total). Stifle joints were imaged at full extension in a 7.0-Tesla magnetic resonance imaging (MRI) scanner (Siemens Healthineers, Erlangen) using a double-echo steady state (DESS, voxel size=0.42x0.42x0.4 mm) sequence. Image sequences were exported to commercial software (Simpleware) for analysis and 3D models of the anteromedial (AM) and posterolateral (PL) bundles of the ACL were generated along with

models of the tibial plateau and the femoral cortical bone. The cross-sectional area (CSA) of each tissue or bone was calculated, along with the length between insertion sites of each ligament using custom MATLAB code. The sagittal and coronal angles of the ACL were measured relative to the tibial plateau as described previously [2]. Statistical analysis consisted of a two-way ANOVA with age and breed as main effects and Tukey's post-hoc analysis (JMP, $p < 0.05$).

RESULTS

Overall significant differences between breeds were evident with much larger joints in the Yorkshire group. All limbs were skeletally immature, with no fusion in the tibial or femoral growth plates (Fig. 1).

Figure 1: Magnetic resonance images of Yorkshire and Yucatan stifle joints at early adolescence (4.5 and 6 months). Scale bars represent 20mm.

ACL sagittal angle increased with increasing age ($p<0.05$), with no significant difference due to breed or interaction term ($p>0.05$). Mean values ranged by 7° in the Yucatan breed, and by 2° in the Yorkshire breed (Fig. 2). In the coronal angle, there were differences due to age, breed, and the interaction term ($p<0.05$). In Yucatan pigs, coronal angle increased by 11° from 4.5 to 6 months ($p<0.05$), while Yorkshire pigs had similar values at both ages. The Yorkshire pigs had significantly greater angles, 14° - 22° higher than Yucatan pigs (Fig. 2, $p<0.05$).

Figure 2: Coronal (A) and sagittal (B) angles varied by age and breed. Summary data show mean \pm 95% C.I. * $p<0.05$ between breeds, bar indicates $p<0.05$ between ages.

The geometry of the AM and PL bundles of the ACL varied due to both age and breed between 4.5 and 6 months (Fig. 3, $p<0.05$). Specifically, the AM and PL bundle lengths varied as an effect of age and breed with a significant interaction term in the PL bundle ($p<0.05$). Mean AM bundle length values were significantly greater ($p<0.05$) in the Yorkshire breed (36.5 mm) compared to the Yucatan breed (22.1 mm) while increasing age resulted in a significant 2.0 mm increase in mean AM bundle length ($p<0.05$). In the PL bundle, the mean Yorkshire length increased by 31% with age ($p<0.05$), while the Yucatan length did not experience significant growth (Fig. 3A, $p>0.05$). An additional metric of ACL bundle size, bundle CSA, revealed significant differences in the AM bundle as an effect of age and breed ($p<0.05$) and in the PL bundle only as an effect of breed ($p<0.05$). The AM and PL bundle CSAs were 222-240% and 72-96% greater in the Yorkshire breed, respectively ($p<0.05$). The mean AM bundle CSA increased in the Yorkshire breed by 28% from 4.5 to 6 months ($p<0.05$), while the AM bundle CSA had similar values across ages in the Yucatan breed (Fig. 3B, $p>0.05$).

Figure 3: AM and PL length (A,B) and CSA (C,D) varied by age in some cases in Yorkshire pigs. Summary data show mean \pm 95% C.I. * $p<0.05$ between breeds, bar indicates $p<0.05$ between ages.

Values of bone CSA (tibial plateau and femoral cortical bone) varied between breeds ($p<0.05$) although there was no effect due to age or interaction term ($p>0.05$) in either metric. Tibial plateau CSA was much larger in the Yorkshire pig (2164 mm²) than in the Yucatan pig (603 mm²) (Fig. 4A). Femoral cortical bone CSA was larger ($p<0.05$) in Yorkshire (232 mm²) compared to the Yucatan joints (101 mm²) (Fig.

4D). Normalization of ACL and bone sizes revealed small effects of breed and age on tissue size, although there were significant differences between breeds in the CSA of both bundles relative to the femoral cortical CSA (Fig. 4E-F, $p<0.05$), and in the PL bundle CSA relative to the tibial plateau CSA (Fig. 4C, $p<0.05$). Age had a significant effect within both breeds in the of PL CSA normalized to femoral CSA (Fig. 4F), and in the PL CSA normalized to tibial plateau CSA in the Yucatan breed (Fig 4C, $p<0.05$).

Figure 4: Tibial plateau CSA (A) and femoral cortical bone CSA (D) were significantly larger in the Yorkshire breed compared to the Yucatan breed. Normalization of bundle CSA to bony parameters (B,C,E,F) showed similar results between breeds and ages. Summary data show mean \pm 95% C.I. * $p<0.05$ between breeds, bar indicates $p<0.05$ between ages.

DISCUSSION

Differences existed in overall ACL size, bone size, and some metrics of ACL orientation between Yorkshire and Yucatan pigs in early adolescence. Coronal plane ACL orientation angle experienced larger change with growth in Yucatan pigs compared to Yorkshire pigs. On the other hand, the size of the AM and PL bundles of the ACL experienced greater changes with age in Yorkshire pigs compared to Yucatan pigs. Interestingly, these soft tissue changes occurred despite no age-related changes in bone sizes in either breed. Furthermore, mean differences in ACL bundle sizes were much smaller between breeds when normalized to bone size. These results can be partially explained as the slope of the growth curves varies widely between domestic pigs and minipigs during early adolescence with increased rates and longer periods of weight gain in domestic pigs [6]. This study highlights the importance of animal breed in musculoskeletal tissue engineering studies, as age-related changes were breed-specific in both size and orientation and certain breeds may better approximate human changes [5,7]. In the future, this we will expand this study to include juvenile and late adolescent groups, and specimens will undergo functional testing to assess differences in tissue and joint mechanics. Overall, we have presented both breed-specific and age-specific changes in the orientation and size of the porcine ACL.

FOR LIGAMENTS, MATERIAL STIFFNESS IS NOT WHAT IT APPEARS TO BE: HOW TO BUILD MORE ACCURATE MATERIAL MODELS AND IMPLICATIONS ON ACL GRAFT SELECTION

INTRODUCTION

The anterior cruciate ligament (ACL) is the most commonly injured knee ligament, and it plays a critical role in the mechanical stability of a healthy knee. Computational models can help us better understand these injuries by examining the effects of injury risk factors on ACL strain, but material models capable of predicting 3D deformations and injury continue to elude us. Our recent work has focused on how geometry can obscure mechanical measurements. We specifically address the implications of this work on the current understanding of ACL graft selection and how full-field methods may overcome this issue.

Currently, the middle third of the patient's own patellar tendon (PT) is the most commonly used graft for ACL reconstruction, but it is debated whether its material properties are sufficiently similar to that of a native ACL, as several studies have reported a larger tangent modulus for the PT than the ACL [1,2]. While it is possible that true material differences exist between the ACL and PT, we suggest that it is also possible that this difference in apparent stiffness is largely the result of differences in specimen length-to-width ratio.

Tensile tests of anisotropic materials must use samples with much larger length-to-width ratios than the isotropic standard (4:1) to achieve homogeneous uniaxial tension in the gauge section. Boundary effects create strain inhomogeneity near the gripped ends of a specimen, and mathematical analysis indicates that the length over which these effects decay is about one specimen width for isotropic materials, but much larger for anisotropic materials [3]. This finding was experimentally confirmed by Arridge and Folkes, who found that the apparent tensile modulus of a transversely isotropic polyethylene significantly increased with increasing length-to-width ratio, requiring an aspect ratio of 100:1 or more to achieve uniaxial tension [4].

While a standard PT graft has a width similar to that of the ACL, the PT graft is significantly longer than the ACL. Thus, the PT has a larger length-to-width aspect ratio than the ACL; this geometric difference alone would make the PT appear stiffer even if there were no material differences. Little of the published work comparing the mechanical responses of the PT and ACL has controlled for specimen aspect ratio. Therefore, it remains uncertain whether the PT is, in fact, a stiffer material than the ACL. Thus, the first objective of this study was to address this question by determining the effect of aspect ratio on the apparent moduli of the ACL and PT.

If homogeneous deformation states are unachievable in the ACL and PT, as we suggest, how can we build models of their material behavior? While strain inhomogeneity is a non-starter for standard material modeling methods, inhomogeneous strain fields are an asset, rather than a limitation, for full-field methods. Therefore, the second objective of this study was to use full-field methods to build material models of the ACL bundles and PT, with no assumption of strain homogeneity.

METHODS

Ovine knees were acquired from a local abattoir. The PT and anteromedial (AM) bundle of the ACL were removed, leaving small bone blocks attached at each end. The posterolateral (PL) bundle was not used due to its more complex fiber arrangement. The bone blocks were encased in moldable thermoplastic (McMaster-Carr, Aurora, OH) within a custom-made wax mold, to yield a regular shape that would be easily integrated into a horizontal materials testing system (ADMET). Samples were stretched in the mean fiber direction at 0.1 mm/s. Each specimen was tested at 4-6 length-to-width aspect ratios by removing a few fascicles from the edge of the specimen to reduce the width for subsequent tests. Statistical analysis was performed using analysis of

covariance to compare the apparent modulus vs. aspect ratio relationships.

Additionally, we recently collected full-volume displacement maps of six AM and PL bundles under tension using dual-MRI [5]. Strain fields computed from this data proved to be largely inhomogeneous. Thus, the Virtual Fields Method (VFM) was used to fit constitutive models to each full-volume displacement field. VFM is a full-field inverse method which uses the principle of virtual work to fit constitutive models to inhomogeneous deformation fields [6]. First, polynomial descriptions of the bone-ligament boundaries (enthesees) were constructed using a custom MATLAB script. These polynomials were used to build virtual fields – kinematically admissible displacement fields with constant displacement along these boundaries. Collagen fiber directionality in the undeformed configuration was described with spatially continuous functions to model the splayed fiber alignment near the entheses. Custom MATLAB code was used to find the set of constitutive parameters that minimized the difference between the external and internal virtual work, according to the method described by Promma, et al [6]. Three constitutive models were considered: the Holzapfel-Gasser-Ogden (HGO) model [7], an HGO-inspired model recently published by our group [8], and a Fung-type model [9].

RESULTS

Figure 1: The peak apparent tangent modulus increased with aspect ratio for both the AM and PT (data points shown with filled dots). Medically relevant aspect ratios for each tissue (open circles) suggests that a PT graft could appear stiffer than a whole AM.

Figure 2: (a) High-resolution MRI images of ACL bundles just prior to testing show that the AM bundle has a larger length-to-width ratio than the PL bundle. (b) Volume-averaged stress-strain curves for the AM and PL bundles obtained with dual-MRI show that the AM appears stiffer than the PL.

Increased sample length-to-width aspect ratio was found to significantly increase the apparent tangent tensile modulus for the AM

bundle and PT ligaments ($p < 0.001$). Additionally, AM bundle specimens exhibited a larger apparent modulus than PT specimens for a given aspect ratio ($p < 0.001$).

Volume-averaged stress-strain dual-MRI data showed that the intact AM bundle appeared stiffer than the PL bundle (see Fig. 2b), which is consistent with previous studies [9]. However, this difference could be explained by their differences in aspect ratio (see Fig. 2a). In fact, material models fit to the full-field data with VFM found no significant difference in constitutive parameters between the AM and PL bundle, with the exception of an HGO parameter which describes the degree of collagen fiber alignment ($p = 0.0017$). This is a known microstructural difference between the AM and PL bundle [10], although it has not been detected by previous modeling efforts.

DISCUSSION

The first part of this study indicates that the mechanical response of the AM bundle of the ACL and PT are significantly affected by specimen length-to-width ratio. Controlling for geometry, the AM bundle appears to be a stiffer material than the PT, contrary to the most published work on the subject [1,2]. These studies used the middle third of the PT and the whole ACL, which yielded PT and ACL samples with aspect ratios of about 9 and 3, respectively. Our results suggest that at these aspect ratios, the PT appears to be slightly stiffer than the AM bundle (see open circles in Fig. 1), even though the AM bundle is likely a stiffer material. This interpretation is supported by the recent study of Ristaniemi et al. who found that, for samples with a constant length-to-width ratio of 5, the bovine ACL was stiffer than the PT [11]. This work has two important implications beyond ACL graft selection: 1) global mechanical data cannot discern whether material differences exist between ligament groups unless all samples have the same length-to-width ratio, and 2) if accurate material models are desired for ligaments, strain inhomogeneity caused by end effects cannot be ignored.

The second part of this study demonstrates how full-field methods can take advantage of the unavoidable strain inhomogeneity when building constitutive models of ligaments and other highly anisotropic materials. Using full-field displacement measurement techniques and inverse methods, a known microstructural difference between the ACL bundles (previously identified by microstructural investigations [10]) was independently detected by a constitutive parameter found with full-field mechanics methods. This underscores the advantage of using full-field methods over standard characterization techniques to study the mechanics of biological tissues.

INTRODUCTION

Articular cartilage consists of a dense extracellular matrix that allows the tissue to undergo fluid pressurization during compressive loading. Cartilage defects compromise this function, introducing free boundaries that result in the flow of proteoglycans and other matrix elements out of the tissue [1]. Decreases in matrix density at defect boundaries make them vulnerable to progressive erosion, instigating a vicious cycle that gradually increases defect size and concludes with joint-wide osteoarthritis (OA). A barrier at this interface may functionally restore the mechanical properties of the defect boundary [2], however synthetic materials may wear or delaminate with time. In this study, we aimed to direct the formation a living fibrous barrier at the damaged cartilage interface (via targeted progenitor cell recruitment and differentiation – Fig 1A), to restore normal cartilage biomechanical function. Specifically, we sought to establish a biomaterial microenvironment (modified hyaluronic acid) that 1) enhances the attachment and mechano-biological response of MSCs at the damaged cartilage interface, 2) induces the cells to undergo fibrogenesis via mechanical cues, and 3) promotes the deposition of fibrous matrix.

METHODS

Biomaterial Microenvironment: Methacrylated hyaluronic acid (MeHA; 75kDa, 35-42% modification) was conjugated with fluorescent peptides (FITC) for visualization and fibronectin-mimicking peptides (RGD) for cellular adhesion (Fig 1B). The material was oxidized to introduce aldehydes (~30% substitution), which form covalent linkages with exposed amines in damaged tissue [3].

Cellular Response: Bovine cartilage plugs were retrieved and sectioned (6mm diameter x 100µm thick). These discs were maintained as naïve samples (ND; mimicking a focal defect) or were digested in collagenase (0.01% for 30 minutes) to mimic degenerated cartilage (D).

Biomaterial was applied with 0, 5 or 15 minutes of UV cross-linking, followed by PBS washes to remove non-adhered biomaterial. Cartilage discs (both ND and D) without biomaterial served as controls. Disc-biomaterial composites were seeded with juvenile bovine MSCs (P1-P3, 500 cells per disc) for 24 hours. Samples were fixed in 10% buffered formalin, followed by staining for F-actin with phalloidin to quantify cellular spread area and for the nuclear co-factors YAP/TAZ to quantify cell mechano-response (Fig 1C) [4]. YAP/TAZ signal intensity in the nucleus and cytoplasm were quantified to obtain a measure of nuclear localization (>100 cells per group).

Figure 1. Approach Schematic. [A] Schematic of biomaterial binding to damaged cartilage, promoting MSC adhesion, and ultimately guiding cells towards formation of a barrier. [B] Biomaterial design with modifications to hyaluronic acid (HA). [C] Example of material applied to cartilage disc, with an adhered MSC.

Fibrogenesis and Matrix Deposition: Additional cartilage discs (both ND and D) were subjected to biomaterial application/cross-linking. Discs were seeded with 500 cells and cultured for seven days in basal media. Cells on the discs were fixed and stained for α -smooth muscle actin (α -SMA), a marker of fibrogenesis [5]. The percentage of cells positive for α -SMA fibers was calculated for six replicates. Lastly, additional samples were fixed, dehydrated, and visualized for matrix deposition via scanning electron microscopy (SEM).

Statistical Analysis: Cell area and YAP/TAZ nuclear ratio were analyzed with a one-way analysis of variance (ANOVA) with post-hoc Tukey's test. α -SMA data was compared using a replicate-matched Kruskal-Wallis test. ND and D samples were analyzed separately.

RESULTS

Confocal microscopy showed that the MeHA biomaterial infiltrated throughout the 100 μ m section prior to cross-linking, forming an integrated biomaterial microenvironment, around and in between chondrocytes in the cartilage matrix (Fig 1C). The biomaterial also promoted MSC adhesion (Fig 1C, Fig 2A) to the tissue-biomaterial interface, increasing cell spread area (Fig 2B). Biomaterial application and cross-linking increased YAP/TAZ nuclear localization (Fig 2C) of MSCs on both non-degraded and degraded cartilage, consistent with the increased MSC spread area (Fig 2B) and higher substrate mechanical properties (Fig 2A – insets) with biomaterial augmentation.

MSCs cultured for 7d on both nondigested and digested cartilage discs (without biomaterial; Fig 3A top) yielded a low percentage of cells positive for α -SMA fibers (13.96 and 6.95%, respectively). Biomaterial application/cross-linking (Fig 3A, bottom) significantly increased (Fig 3B) the percent of α -SMA positive MSCs on both nondigested and digested discs, indicating enhanced fibrogenesis.

Finally, samples without biomaterial (ND, D) showed little to no matrix deposition, as visualized by SEM (Fig 4, top). Conversely, application of biomaterial prior to cell seeding promoted new matrix formation (Fig 4, bottom). In fact, in the non-digested + 15min UV sample, dense collagen-like matrix was observed, to the degree that the underlying cartilage surface and MSCs were not visible.

DISCUSSION

The results of this study detail the use of a modified biomaterial to 1) promote attachment and mechano-sensation of MSCs; 2) guide attached cells towards a fibrogenic phenotype; and 3) promote matrix deposition to cover cartilage defects. These findings support the promise of creating tunable microenvironments to home and retain stem cells at the defect interface, and ultimately control their biologic response. The behavior of cells in this study is consistent with prior cell-hydrogel studies, in that cell attachment and fibrogenesis increase with substrate stiffness. The biomaterial microenvironment in this study does just that, as it utilizes both cell-adhesive and mechanical cues at the damaged interface to induce a fibrotic response. Future studies will investigate the ability of the tissue barrier to functionally seal defects and preserve cartilage integrity in an *in vivo* setting.

INTRODUCTION

Articular cartilage plays a key role in movement of joints by providing low-friction during articulation while providing resistance to compressive loading. Cyclic loading and overloading during physiological activities may induce articular cartilage defects, and lack of blood supply limits self-healing capacity of the tissue. Current treatment strategies for cartilage defects include microfracture, drilling and abrasion arthroplasty, however, they exhibit noticeable drawbacks [1-3]. Mesenchymal stem cell (MSC) based strategies have been at the center of cartilage repair; however, induction of chondrogenic differentiation of MSCs and obtainment of engineered cartilage tissue with robust mechanical properties is an ongoing challenge

The current study proposes a novel cartilage regeneration by using a heparin-conjugated collagen fabric that is capable of releasing TGF- β 3 sustainably to induce resident MSCs toward chondrogenic lineage

METHODS

Collagen biofabric: Collagen thread was prepared by an electrochemical compaction process (Fig. 1(a)) [4]. Uncrosslinked collagen threads were woven in a zig-zag pattern around a set of equidistant pins with 1 mm diameter to make a woven collagen scaffold (Fig. 1(b)). The scaffold was crosslinked in genipin solution for 72 hrs.

Heparin conjugation: Genipin crosslinked scaffolds were then treated with peracetic acid / ethanol solution treatment to increase swelling ratio of collagen fabric for 4 hrs [5]. 1-Ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC) and N-hydroxysuccinimide (NHS) (life technologies) were used to crosslink heparin molecules to the scaffold, to enhance retention and to sustain the release of TGF- β 3 via affinity binding [6]. Followed incubation in

70% ethanol overnight for disinfection, 12 μ l of 10 μ g/ml TGF- β 3 solution was applied to the scaffold and incubated overnight prior to pellet seeding.

Cell Pellets: Bone marrow derived human mesenchymal stem cells (hMSCs, passage 3) were pelletized by spinning at 500g for 12 mins (1,000,000 cells per pellet), and transferred into the scaffolds (Fig. 1(c)). The scaffolds were cultured in chondrogenic medium.

Experimental groups: 1) Negative Control: Negative control group cells in heparinized collagen biofabric without TGF- β 3, 2) Treatment group: TGF- β 3 was not added to the medium, however, it was loaded in heparinized collagen biofabric to demonstrate whether biofabric mediated delivery is comparable to the positive control group, 3) Positive control: the growth factor was added to chondrogenic media at 10 ng/ml.

Figure. 1 Scaffold preparation. (A) Electrochemically compacted collagen thread preparation, (B) Scaffold preparation by weaving around a set of pin, (C) hMSCs pellets transfer into the scaffold.

Mechanical properties: At the end of a culture period of 28 days, the samples were loaded in unconfined compression at a constant strain-rate (0.5%/s, Rheometrics Solid Analyzer RSAII, Rheometrics Inc.,) up to 10% strain. Stress values reached at 10% strain are reported as the maximum compressive stress. Apparent Young's modulus was determined by calculating the slope of stress-strain curve

in the range of 3% to 6% strain by linear regression. 1,9-dimethylmethylene blue (DMMB) assay was performed to evaluate glycosaminoglycan (GAG) production at day 28. The amount of DNA in the cell pellet was measured by Quant-iT™ PicoGreen™ dsDNA Assay (ThermoFisher). Briefly, 100 µl of papain digested samples were mixed with 100 µl Picogreen assay solution, and fluorescence was measured by the microplate reader. Colorimetric Sircol assay (Biocolor Life Science Assays) was used to measure the amount of collagen in pellets following digestion in pepsin/acid solution at a concentration of 0.1 mg/mL of 0.5 M acetic acid at 4°C overnight. Amounts of GAG and collagen produced were normalized to amount of DNA per pellet.

Data obtained in this study were reported as mean ± standard deviation. The data were analyzed statistically using one-way ANOVA test with Tukey's pairwise comparison (Minitab 16 software, Minitab Inc.). Statistical significance is set at 95% confidence level for all tests ($p < 0.05$). Error bars in figures represent the standard deviations of the means. Six samples ($N=6$) were analyzed.

RESULTS

Tissue mass and mechanical properties: Weight of the treatment group (3.05 ± 0.41 mg) was significantly greater than the negative control group (0.87 ± 0.27 mg), while there was no significant difference between the treatment group and the positive control group (3.83 ± 0.31 mg) (Fig. 2(b)). Compressive modulus of the treatment group (664.95 ± 102.31 kPa) was significantly higher than the negative control group (219.47 ± 84.25 kPa), and it was not significantly different from that of the positive control group (636.51 ± 52.73 kPa) (Fig. 2(c)). Strength at 10% compressive strain in the treatment group (78.17 ± 13.24 kPa) was significantly higher than the negative control group (23.99 ± 10.46 kPa), and the positive control group (61.17 ± 4.66 kPa) (Fig. 2(d)).

Figure 2 Mechanical properties of scaffold / hMSCS pellet at Day 28. (A) Image of pellets after 28 days of culture, (B) Weight (mg), (C) Compressive modulus (kPa), (D) Strength at 10% compressive strain (kPa), (E) Typical stress-strain curves. *, $p < 0.05$.

There was no significant differences in the amount of DNA per hMSC pellet among the three groups at day 28 (Fig. 3(a)). The amount of glycosaminoglycan (GAG) and collagen productions per hMSC pellet in the treatment group was significantly higher than the negative control, and there was no significant difference between treatment group and positive control group (Fig. 3(b), Fig. 3(c)). Values of the assays were shown in Fig. 3(d).

Figure 3 Extracellular matrix synthesis of hMSCS pellets at Day 28. (A) Amount of DNA per pellet (µg), (B) Amount of glycosaminoglycan (GAG) produced per pellet (µg), (C) Amount of collagen produced per pellet (µg), (D) Values of the assay *, $p < 0.05$.

DISCUSSION

The most significant finding of this study was that sustained release of TGF-β3 from heparinized collagen scaffold had chondro-inductive effect on pelleted hMSCs. The effect was comparable to positive control groups, in which hMSC pellets were cultured in chondrogenic media supplemented with 10 ng/ml of TGF-β3. While no significant difference was found in amount of DNA per pellet among three groups, significantly higher quantities of GAG (15 fold) and collagen (5 fold) were produced by hMSC pellets in Heparin-TGF-β3 groups, compared with pellets in control group. These data indicate that TGF-β3 released from TGF-β3 bound to heparin conjugated scaffolds has potential to enhance extracellular matrix production by hMSCs. Heparinized TGF-β3 conjugated collagen scaffold may deliver growth factors locally to specific site and cells. The delivery also can guide chondrogenic differentiation of hMSCs while suppressing osteogenic differentiation of the cells. Future research will focus on utilization of TGF-β3 bound heparin conjugated scaffolds for functional cartilage tissue regeneration for cartilage defect healing in vivo.

A COMPUTATIONAL AND EXPERIMENTAL STUDY OF SHORT BOWEL SYNDROME BIOMECHANICS

Hadi S. Hosseini (1), Jordan S. Taylor (1), James C. Y. Dunn (1)

(1) Department of Surgery (Division of Pediatric Surgery), Stanford University
Stanford, CA, USA

INTRODUCTION

Intestinal failure (IF) is a rare multifactorial clinical condition that results in patient inability to sustain normal growth, nutritional and hydration status. Short bowel syndrome (SBS) is the most common cause of IF which is a devastating condition owing to loss of significant intestinal length thereby affecting the organ ability to absorb nutrients. The incidence rate of the syndrome was 22.1 per 1,000 neonatal intensive care unit admissions and 24.5 per 100,000 live births while even a higher rate was reported in premature infants [1].

Recent treatment focuses on distraction-enterogenesis where it exploits mechanical forces to increase length of small intestine. Although different techniques have been suggested to provide the mechanical force, however self-expanding springs (Figure 1A) as the source of mechanical force have shown great success in lengthening the small intestinal tract [2].

Despite great focus of recent studies on establishing a practical platform to study distraction-enterogenesis as a treatment for SBS, biomechanical factors that drive this process remained poorly studied. From previous studies and experimental observations, we hypothesized that mechanical perturbation in axial direction of intestinal tract triggers some molecular signaling pathways. This causes the tissue thickening in radial direction as well as further communication within intestinal tract even outside of distracted segment through these signaling pathways. Here, using a combination of experiment and computational modeling, we study the biomechanics involved in distraction-enterogenesis to examine plausibility of our hypothesis.

METHODS

All animal procedures were performed in accordance with the Institutional Care and Use Committee (APLAC Protocol# 32216).

Figure 1. Experimental set up for (A) distraction-enterogenesis with lengthened distracted tissue. (B-C) Representative experiments for calculating tension and strain respectively.

Placement of in-continuity small bowel spring for distraction-enterogenesis was performed on female Yucatan pigs (S&S Farms). In brief, juvenile pigs, ages four to six weeks, were placed. Spring was confined within the bowel by plication sutures. Pigs were euthanized on day 7, 21 and 60 after the original operation. Normal segments and segments of intestine containing the springs were removed and evaluated for lengthening as well as for histologic evaluation. To characterize stress in the intestinal tract, a series of longitudinal (antimesenteric), transverse and angled cuts (Figure 1B) were made in the bowel wall with scissors. Photos were obtained of the bowel to measure the cuts characteristics for tension estimation. For strain estimation, a marking pen was used to mark points on the bowel wall to

aid in tracking the immediate expansion (Figure 1C). Coordinates of the marked dots were traced over time to be used as inputs for customized MATLAB code to analyze the elastic strains of the bowel.

Computational models for distracted-enterogenesis and cutting experiments were developed using the commercial finite-element software ABAQUS (version 2017, SIMULIA, Providence, RI). Constitutive relations (material properties) and tissue proliferation were defined via the ABAQUS user subroutine UMAT [3-5]. Here, distraction-enterogenesis processes were simulated using a continuum mechanics theory for large deformation and growth of soft tissue based on theory of Rodriguez

$$F = F^* \cdot G \quad (1)$$

Where G and F^* are the growth tensor and elastic deformation gradient tensor, respectively. A Neo-Hookean strain-energy density function was chosen

$$W = \frac{\mu}{2} (\bar{I}_1 - 3) + \frac{1}{D} \left[\frac{1}{2} (J^{*2} - 1) - \ln J^* \right] \quad (2)$$

Where μ and D are the shear modulus and volumetric compliance respectively. Values for D and μ are calculated from mechanical testing of fresh intestinal tissue along with incompressibility assumption for soft tissue.

RESULTS

Successful lengthening was observed over short (7 days) and longer (21 and 60 days) time periods after spring placement surgery. Normal segment showed an average thickness of $200 \pm 30 \mu m$ and $700 \pm 80 \mu m$ for muscularis and mucosa layers respectively, while distracted segment of jejunum showed an increase in thickness of both muscularis and mucosa layers at different time points (Figure 2).

Figure 2. Representative H&E stained of segments of jejunum under different conditions (A) normal jejunum with no spring. (B) Jejunum with a compressed spring at post operation day 60.

Similar to experiment, the simulation distraction-enterogenesis begins with compressing of spring, after full compression diameter of intestinal tract was reduced by 50% at the antimesenteric side of plication segment. Lastly spring was released to be able to move back with to simulate the distraction step. As spring is expanding, it stretches the distracted tissue to increase its length. Different view of model for different time points are represented in Figure 3C. Similar to experimental observations, different radial growth rates are defined for mucosa and muscularis layers with muscularis layer is growing faster. We examined the ability of our model to capture results given by pharmacological perturbations, as well as measures of deformation and stress. For cutting experiment, computational models were developed to mimic the condition for cutting experiment where the models include a cut in the initial geometry with length and angle of cut like experiment, then opening angle was measured at the end of the simulation. Overall results from the model agree reasonably well with the experimental measurements (Figure 3E). Strain predicted by model is consistent with

Figure 3. (A-B) Initial geometry of finite element model for distraction-enterogenesis using real geometry of self-expanding spring. (C) Different views of model at different post operation days. (D) Finite element models for different types of cut.

experimental measurements (Figure 3F). Taken together, these additional tests of the model support the plausibility of the model as well as our hypothesis.

DISCUSSION

Our experimental and modeling results show that not only there is a biomechanical feedback between axial mechanical force and lengthening but there is also a strong correlation between this mechanical force and changes in thickness of the intentional wall layers. However, our observations show muscularis layer is being more effected from the mechanical force compare to mucosa layer. First, we validated our computational models with our experimental measurements and then tested our model with further tests. Importance of modeling becomes critical for the clinical purposes where this platform can be used for predicting elastic deformation and tissue proliferation for any patient size as well as any spring characterization. This could reduce surgery risks before spring placement operation where approximate required force (spring characterizations) can be predicted by developing patient-specific finite element models

INTRODUCTION

As one of the major extracellular matrix (ECM) components, elastin imparts the elastic property to the arterial wall in order to accommodate the physiological cyclic deformation. In aortic media, elastin forms concentric layers of elastic lamellae, within which the elastin fibers interweave into an interconnected network.

Motivated by tissue structure, constitutive models of arterial wall incorporating experimentally measured structural information have been broadly studied. However, continuum mechanics based constitutive models lack fiber level geometric realism and often rely on affine deformation assumption [1]. Discrete fiber network (DFN) models have been developed to overcome the aforementioned limitations as well as to capture the local microstructural kinematics of fibrous tissue [2]. In DFN models, inter-fiber crosslinking is modeled by the intersections of two segments. Usually, these intersections were treated as pin joints [3].

In this study, a DFN model of elastin network in the arterial wall was developed based on multiphoton microscopy measured geometric features to study the contribution of inter-fiber crosslinking to ECM mechanics and fiber kinematics. Multiphoton microscopy was performed to capture the in-plane distributed cross-linked elastic fiber network within the elastic lamellae. The inter-fiber crosslinks were assumed to have a rotational stiffness that varies from zero (pinned joint) to infinity (welded joint). Finite element simulations of DFN under equi- and nonequi- biaxial stretch were performed in ABAQUS. Tissue-level stress-stretch behavior and fiber-level deformation was studied in order to understand the role of inter-fiber crosslinking properties in the response of elastin network at multiple scales.

METHODS

Sample preparation

Porcine thoracic aortas (12-24 month old) were harvested from a local abattoir and transported to laboratory on ice. Samples of approximately 20×20 mm square were cut with one edge parallel to the longitudinal direction and the other edge parallel to the circumferential direction of the artery. Purified elastin was obtained using a cyanogen bromide (CNBr) treatment to remove cells, collagen and other ECM components. Elastin samples were placed in 1× phosphate buffered saline (PBS) for further mechanical testing and imaging studies.

Mechanical testing

Equi- and nonequi-biaxial tensile tests were performed on a biaxial tensile testing device to characterize the mechanical properties of elastin network (n=3). After preconditioning, samples were subjected to eight cycles of biaxial stretch up to 1.12 with λ_l : λ_c = 1.12:1.12, 1.06:1.12, and 1.12:1.06, where λ_l and λ_c refers to stretch in the longitudinal and circumferential directions, respectively.

Multiphoton microscopy

A multiphoton microscope system (Carl Zeiss LSM 710 NLO Microscope system) with a tunable femtosecond IR pulse laser (810 nm) was used to generate two-photon excited fluorescence (2PEF) from elastin (525/45 nm). The laser scanning system was coupled with an upright microscope with a 20× water immersion objective lens for imaging acquisition (Fig. 1A). Image processing was performed in FIJI (<http://Fiji.sc/Fiji>, Ashburn, VA) to obtain areal density (Fig. 1B). The fiber diameter was measured in ImageJ [4]. Fiber orientation distribution was obtained using two dimensional fast Fourier transform (2-D FFT) analysis (with the Directionality plug-in). Fiber orientation

distribution function was averaged through the thickness and used to guide the DFN generation.

Network generation

A DFN model was generated by randomly placing line segments into the given domain following the obtained orientation distribution until the desired fiber areal fraction was reached. Intersections of two segments were treated as crosslinks. Dangling ends of line segments projecting beyond the crosslinks were removed. Periodic boundary conditions were prescribed so that the DFN is continuous when tiled up in both horizontal and vertical directions (Fig. 1C).

Finite element modeling

Finite element simulations were performed in ABAQUS 6.14 (Dassault Systemes, Waltham, MA). A single layer of elastic lamella with inter-lamellar spacing was chosen to be the representative volume element (RVE). The thickness of elastic lamella is set to be the diameter of elastin fiber, while the inter-lamellar spacing was measured from cross-sectional images of elastin network to be $10\mu\text{m}$. Since the structure has two planes of symmetry, only one quarter ($1\text{mm} \times 1\text{mm}$) of the sample was modeled [5]. The displacement of each boundary point was prescribed according to experimental settings to impose displacement boundary condition. The applied load is computed as the sum of the reaction forces at the corresponding boundary. Cauchy stresses were calculated by assuming plane stress and incompressibility. Timoshenko (shear flexible) beams elements B21H was selected considering the length to diameter ratio of the elastin fibers [5]. Fiber intersections were modeled by connector elements with rotational stiffness changing from freely rotating to welding. The fiber diameter was set to be $3.5\mu\text{m}$ for all the fibers. The response of elastin fibers are modeled using an entropy-based freely-jointed chain model [6]. Material parameters in the finite element model were varied to fit the tissue-level stress vs. stretch results from the DFN mode to experimental data.

RESULTS

The DFN model well recapitulated the anisotropic behavior of elastin network under equi-biaxial loading (Fig. 2A) ($r^2 = 0.99$). The model with the same material parameters was then used to predict the stress-stretch behavior of elastin network under nonequi-biaxial stretch with a good agreement with experimental data ($r^2 = 0.98$) (Fig. 2B).

To study the effect of inter-fiber crosslinking properties on tissue level behavior, we plotted the stress-stretch curves of the DFN with free rotating (pin) and welded (weld) crosslinks under equi- and nonequi-biaxial stretch in Figure 2. Changing the fiber intersection properties has little effect on the equi-biaxial stress-stretch behavior (Figure 2. A), while the model with pin joints performs slightly better in predicting nonequi-biaxial stretch. Overall, the influence of inter-fiber properties on the tissue-level response is rather small.

Figure 1: (A) Elastin network from multiphoton microscopy. (B) Binary image using the Otsu's method [4]. (C) DFN used for finite element simulation.

To further examine the effect of inter-fiber intersection properties on fiber-level deformation, we computed the stretch of each fiber segment with pinned and welded joints under tissue-level biaxial

loading. Our findings revealed that under nonequi-biaxial stretch, the intersection properties have the most obvious effect on fiber stretch distribution. Histogram plot of fiber stretch distribution with pin joint shows two peaks that are aligned with the tissue-level stretch (1.06 and 1.12) applied at the boundary (Fig. 3A). The fiber stretch distribution of the DFN with welded joint, however, shows a single peak at a stretch value that is between 1.06 and 1.12 (Fig. 3B).

Figure 2: Comparison of the elastin stress-stretch response from simulation using the DFN model and experimental data under equi-biaxial (left) and nonequi-biaxial (right) loading.

Figure 3: Fiber-level stretch distribution while pinned and welded intersection properties were assumed in the DFN model. The elastin network was subjected to nonequi-biaxial stretching.

DISCUSSION

Here we created a DFN model of arterial elastin that resembles the ECM structural properties (fiber orientation, fiber diameter, and areal density) as well as inter-fiber crosslinking. The model captures well the anisotropic and hyperelastic stress-stretch response of elastin network, and shows good fitting and predicting capabilities of elastin network under equi- and nonequi-biaxial loading conditions.

One of the main advantages of the DFN model is that it allows us to study the microstructural kinematics of fibrous tissue at large deformation. The effect of inter-fiber crosslinking properties on ECM network mechanics was studied by assuming pinned and welded intersections. Our results show that the inter-fiber crosslinking properties have an effect on fiber-level deformation. However, the tissue-level stress-stretch response remains similar despite the difference in fiber-level responses. This suggests that rotational stiffness of the crosslinks plays an important role in local fiber-level responses in the ECM network. Future work is underway to examine fiber reorientation with different inter-fiber crosslinking properties under nonequi-biaxial loading.

INTRODUCTION

The protein Lamin A/C in nuclear lamina forms a mesh-like structure that is thought to provide mechanical integrity and support the geometric shape of the cell nucleus. Abnormal expression or lack of Lamin A/C leads to a large class of diseases termed laminopathies, which affect mechanically stiff tissues [1]. The mechanical role of Lamin A/C is mostly elucidated through *in vitro* single cell experiments that indicate a compromised Lamin A/C leads to abnormal nuclear shape and increased strain transfer to the nucleus. However, the role of Lamin A/C *in vivo* is largely unknown. We investigated the nuclear shape and chromatin organization in normal and Lamin A/C knockout mice using intact (load- and non-load-bearing) tissues. Further, we performed *in vivo* multiscale strain measurements of skeletal muscle at tissue and intranuclear scales to understand the functional relevance of strain patterns and transfer.

METHODS

Animals: All animal experiments were performed under IACUC approved protocols. B6129S1(Cg)-*Lmna*^{tm1Stw/BkknJ} mice were purchased from Jackson Laboratory (Bar Harbor, Maine).

Visualization of nuclear shape and chromatin organization: Fibroblasts were maintained on tissue culture dish using a protrusion culture from mouse skin tissue. Skin, skeletal muscle (SM), heart, lung, and brain were collected from the euthanized animals, and were then fixed, sliced, stained (DAPI) and imaged by confocal microscopy (Nikon Eclipse Ti A1R). Skewness of the chromatin intensity distribution was calculated using a custom MATLAB code to quantify the chromatin segregation ($n=3$ animals, 20 nuclei/sample).

Multiscale spatial mechanics: For *in vivo* tissue and nuclear deformation measurement, we applied a neuromuscular stimulation on live mice to image and subsequently quantified the strain in skeletal muscle tissue and nucleus [2] ($n=6$ animals, 18 nuclei/sample).

Elastic property of tissue: Skeletal muscle was harvested from freshly euthanized mice ($n=4$). Elasticity of tissue was measured using atomic force microscopy (Keysight 5500 AFM System, Santa Rosa, CA, USA) using a 5 μm spherical glass tip. Further, a Hertz contact model was used to quantify the Young's modulus.

Statistics: Multifactorial ANOVA was used to test differences in sample populations. *p-value of <0.01 represents statistically significant difference in all cases.

RESULTS

Skin fibroblast nuclei showed characteristic abnormal (rough, blebbed) nuclear periphery in Lamin A/C knockout mice when plated on tissue culture plastic (TCP), but maintained the normal nuclear shape in intact tissue (Figure 1). Moreover, chromatin segregation

Figure 1: Lamin A/C deficiency compromises the nuclear shape in cells cultured on tissue culture plastic (TCP), but not inside intact tissue. Intracellular chromatin architecture is not affected by Lamin A/C deficiency on TCP, but is compromised inside intact tissue.

was similar in all cases of culture on TCP, whereas in intact tissue Lamin A/C knockout cells displayed a diffuse chromatin architecture characterized by lower chromatin segregation. Besides skin, diffuse chromatin architecture in Lamin A/C knockout nuclei was observed in other relatively stiff tissues such as SM and heart (Figure 2), but not in relatively soft tissues such as brain and lung.

Figure 2: In stiff tissue, such as skeletal muscle and heart, intracellular chromatin architecture is altered by Lamin A/C deficiency. Chromatin architecture is not affected by Lamin A/C deficiency in soft tissue such as brain and lung. Scale bar: 5 μ m in all images.

Figure 3: Multiscale strain measurement *in vivo* in murine skeletal muscle tissue and nucleus reveals that for the same tissue strain, the nuclear strain is almost half in Lamin A/C deficient mice. Elastic modulus of skeletal muscle is also nearly half in Lamin A/C deficient mice.

Intranuclear strain maps (Figure 4) showed that in wild type and Lamin A/C hemizygote mice the heterochromatin (dense chromatin region) mostly carries the tensile strain burden while the euchromatin (less dense region) carries the compressive strain burden of nuclei. In

Lamin A/C knockout mice, the euchromatin carries a significantly higher tensile strain burden in nuclei.

Figure 4: Intranuclear strain pattern reveal a compromised intranuclear strain distribution caused by Lamin A/C deficiency.

DISCUSSION

Nuclear shape on dish is compromised by Lamin A/C deficiency as per the findings of other groups [3], but in intact tissue it is maintained irrespective of the tissue stiffness. Our findings show that bulk nuclear mechanics is not affected by the Lamin A/C deficiency, whereas the intranuclear mechanics in SM and chromatin architecture are compromised in stiff tissues; which are affected in laminopathies. A simple scaling analysis using the strain in the nucleus and tissue (Figure 3), and estimated stresses (not shown) reveals that *in vivo* bulk elastic modulus of the nucleus is similar in all mice types, i.e. $E_{LMNA}^{+/+} \sim E_{LMNA}^{+/-} \sim E_{LMNA}^{-/-}$ (with E as the elastic modulus of the nucleus). This study indicates that *in vivo* the nuclear shape is mostly maintained by three-dimensional tissue architecture and Lamin A/C has deeper roles of maintaining chromatin architecture in a mechanically-dependent way, possibly through epigenetic mechanisms [4].

INTRODUCTION

DNA origami nanostructures have strong potential for biophysical experiments because they have precisely controlled shape, tunable motion, and mechanical properties, and can be functionalized with a number of biomolecules¹⁻². Potential biophysical applications include probing molecular structure and forces, particularly on the nanoscale. Current biophysical methods have limitations for nanoscale measurements such as challenges with determining site-specific deformations, in addition to being challenging and expensive. Dynamic DNA origami can address such challenges by providing versatile devices to accommodate shape, conformational changes, and force response of biomolecules on the 10-100nm length scale. The major goal of this work is to leverage DNA origami to develop tools to study biophysical properties of the biomolecular complexes. We previously demonstrated the use of DNA nanocalipers to probe the structure and stability of nucleosomes³, which are the fundamental packing unit of genomic DNA in cells. Here we focus on enhancing the function of DNA nanocalipers to apply tensile and compressive forces to incorporated samples. In particular, we demonstrate our ability to apply compressive forces by forcing a DNA sample into highly bent states.

METHODS

Nanocaliper Design and fabrication. The nanocaliper was designed in using the software cadnano⁴ based on an 8064 nt single-stranded DNA (ssDNA) scaffold derived from the M13MP18 bacteriophage virus prepared in our laboratory⁵. The nanocalipers were folded as previously described³. Briefly, folding reactions contained 20 nM of scaffold and 200 nM of each staple in a solution containing ddH₂O, 5 mM Tris, 5 mM NaCl, 1 mM EDTA, and 18 mM MgCl₂, pH 8.0. This folding reaction was subjected to a thermal annealing similar

to a previously published method³. Specifically, the thermal ramp consisted of rapidly heating the solution to 70 °C for 15 minutes, cooling down to a ramp from 63-57 °C for 3 hours per degree, and cooling it for 30 minutes at 4 °C. Folding results were characterized via agarose gel electrophoresis as previously described, and bands of well-folded structures were also characterized by transmission electron microscopy (TEM)^{3,5}.

Nanocaliper Force Application. Internal strut connections can be engaged or disengaged through strand displacement⁶ reactions to open or close the calipers. For displacement reactions, displacement strands for the opening actuation were added to gel-purified nanocalipers such that the staples were in 200x excess per strut and incubated for 18hrs at 37°C followed TEM imaging to verify opening. Then, displacement staples for the closing actuation were introduced to open samples in 400x excess per strut, incubated for 6hrs at 37°C, and subjected to TEM imaging. To verify force application, a 249 bp dsDNA sample (~80 nm long) was incorporated between the ends of the arms via a biotin-streptavidin interaction. Open nanocalipers were incubated with a 2-fold excess of the dsDNA sample for 30 min at 37 °C at 250 rpm. The dsDNA-nanocaliper assemblies were then subjected to the closing actuation and prepared for TEM imaging.

RESULTS

Nanocaliper Design and Characterization. The nanocaliper design (**Fig. 1A**) is comprised of 2 arms made up of 20-helix bundles organized in an 8x3 square lattice cross section with 4 internal helices removed from the middle layer. The arms measure ~70 nm in length, ~20 nm in width, and ~7.5 nm in height. The nanocaliper arms are connected along one edge by 8 ssDNA scaffold loops, alternating between short 2nt connections to define the hinge axis of rotation and long 70 nt connections that mediate caliper mechanical properties.

Figure 1: A) Nanocaliper design showing ssDNA linkers on the back of the hinge (blue lines) that mediate mechanical properties. B) Representative TEM images of nanocalipers. Scale bar = 100nm. C) Probability distribution and free energy landscape of nanocalipers with the linker design shown in the inset.

Gel-purified nanocalipers were imaged via TEM to confirm well-folded structures and to analyze the angular conformations (Fig. 1B-C). We tested a variety of nanocaliper designs where the 70 nt connections were varied from completely single-stranded to partially base-paired in a number of ways (data not shown). For the specific nanocaliper design used in this work, the 70 nt connections were pinched into a compact state (Fig. 1C, inset) to bias the calipers towards open angles. We analyzed at ~1500 nanocalipers over triplicate experiments. The nanocaliper exhibited a mean angle of $95^\circ \pm 2^\circ$. The uncertainty was determined by subdividing the distribution into three random subgroups, and the calculating the standard deviation of the means of those three groups. Figure 1C shows the probability distribution and corresponding free energy landscape, calculated assuming a Boltzmann Distribution³.

Figure 2: Nanocaliper (A) initially closed via struts, (B) actuated to open, and (C) actuated to re-close.

Nanocaliper Actuation and Force Application. We modified the nanocalipers to include 4 pairs of complementary overhangs protruding from the internal faces of the arms to form a strut that latches the arms at a specific angle. We incorporated a 19bp strut located 12nm from the vertex. The resulting probability distribution of (Fig. 2B, left) exhibited a mean angle of 32.7° and standard deviation of 17.0° . The internal struts were designed with a 5nt toehold to facilitate dissociation of the strut via strand displacement. Introducing the displacement strands for the open actuation resulted in a shift back to the open state (Fig. 2B). The slight deviation may be due to not all struts being fully displaced; nevertheless the vast majority of calipers

clearly open. We further demonstrated the ability to re-close the caliper through a second strand displacement reaction illustrated in Fig. 2C. These results illustrate our ability to toggle from closed to open and from opened to closed, which would translate to tensile and compressive forces, respectively, when a sample is incorporated between the arms.

Finally, to verify our ability to apply compressive forces that influence the conformation of a biomolecule, we incorporated a 249 bp dsDNA sample across the ends of the arms of open calipers followed by actuating the closing nanocalipers (i.e. compression of the dsDNA sample). Fig. 3 illustrates the closed nanocalipers with the incorporated dsDNA sample in highly bent states, which we do not observe for open nanocalipers or free the dsDNA sample, which confirms our ability to influence the biomolecule conformation through a compressive force.

Figure 3: TEM images of (A) free nanocaliper with no sample, (B) open nanocalipers with 249bp dsDNA sample, and (C) closed nanocalipers that induce bending in 249bp dsDNA sample. The white arrows highlight the position of dsDNA. Scale bar = 50nm.

DISCUSSION

DNA self-assembly allows for the development of nanodevices with controlled shape and mechanical properties that can be actuated to reconfigure. Here we leverage these features to engineer a nanocaliper that can be toggled between an open and fixed angle state and can incorporate a biomolecule sample between the arms. We demonstrate the ability to apply compressive forces to a dsDNA sample, which forces the sample into low probability highly bent conformations. This ability to apply compressive forces opens new possibilities in force spectroscopy, since applying compression to individual biomolecules is highly challenging with other force spectroscopy methods such as optical tweezer, magnetic tweezers, or atomic force microscopy⁷. Our next steps will pursue improved quantification of applied forces and implementation of this calipers to study nucleosomes and chromatin under applied forces.

INTRODUCTION

The well-known hierarchical structure of tendon governs its mechanical function. However, despite decades of imaging and mechanical testing, the 3D microstructure and tendon load transfer mechanisms are still not fully known. Recent serial block-face scanning electron microscopy (SBF-SEM) has visualized three-dimensional microstructure in tail tendons [1-2] but not yet quantified the structure. Further, several load transfer mechanisms between fibrils have been suggested, including interfibrillar matrix and shear lag [3-4]. Based on the observed helical wrapping of tendon fibrils in this study, we hypothesized that these helical structures can induce frictional contact between fibrils, allowing for mechanical load transfer without a mediating matrix. The objective of this study was to quantify the 3D microstructure of rat tail tendon using SBF-SEM imaging and to study the mechanics of these helical structures via finite element (FE) analysis. The microstructure and load transfer at this scale are particularly important because the cells and the surrounding collagen fibrils interact, and these mechanical interactions may have important physiological contributions.

METHODS

A fascicle from a 3 month old male Sprague-Dawley rat was dissected and processed for SEM imaging [5]. The transverse cross-section was scanned using Apreo VolumeScope (ThermoFisher Scientific) and at the end of each scan, a 200 nm layer of the block's face was removed by means of a mechanical slicer and the scanning was repeated. We scanned 432 slices that covered a total volume of (20.27 $\mu\text{m} \times 16.74 \mu\text{m} \times 86.20 \mu\text{m}$), where the 86.20 μm is along the fascicle's axial direction and the in-plane resolution was 10 nm/pixel.

The SBF-SEM technique is hindered by large datasets and difficult segmentation compared to 2D. Thus, for this study, a single

fascicle was manually segmented in 3D (Seg3D, seg3d.org), (n=42 fibrils that spanned the entire scan length) (Fig. 1A). We confirmed that the manually segmented fibrils represented the overall population by comparing the cumulative distribution function of the fibril diameter from the 3D manually segmented fibrils to 2D automatically segmented full population for several distributed scans (not shown). Approximately half of the segmented fibrils (n=21) were in helical groups; for these fibrils we calculated the pitch (λ) by dividing the scan length (86.20 μm) with the number of turns in the helices.

To study load transfer in helically wrapping fibrils, we developed a three-dimensional FE model of a pair of helical fibrils in contact (diameter = 200 nm, helix pitch = 40 μm) in FEBio (v2.8 febio.org). The model included three full fibril turns. The boundary condition was set so that each fibril had one free-end and the other end was either anchored or displaced in the axial direction for 8% of the length.

Figure 1: (A) Representative SEM image and in-plane segmentation (scale bar = 5 μm), (B) SBF-SEM imaging process showing sequential stacks of images along the tendon length.

Figure 2: Many helical groups were observed in the axial view of the fibrils that are evident in the figures (A) with and (B) without the cell nuclei that were both left (-) and right (+) handed. (C) Examples of the groups of helically wrapping fibrils.

A compressible neo-Hookean constitutive relation was used with fibril properties of Young's modulus ($E = 1\text{ GPa}$) and Poisson's ratio ($\nu = 0.2$). We used a frictional contact based on penalty methods in FEBio [6]. We studied three friction coefficient cases for $\mu = 0, 0.5$, and 2 . For analysis, we calculated the axial stress (σ) and axial normalized displacement (\bar{u}) along the fibrils' length, defined as

$$\bar{u}(z) = \frac{1}{\lambda} \left(u(z) - u\left(\frac{L}{2}\right) \right). \quad (1)$$

Where, $u(z)$ is the axial displacement for distance along the fibril z -axis.

RESULTS

We observed a complex fibrillar structure, where several fibrils locally wrapped around each other (Fig. 2). These groups contained two, three, or more fibrils with both left and right-handed helical configurations (Fig. 2). Half of the fibrils (21 out of 42) of the segmented fibrils were in helical groups, although the sampling was not purely random. Of these helical fibrils, 13 fibrils had a right-handed twist and 7 were left-handed (Fig. 2B). These fibrils made an average of 2.2 ± 1.4 turns around each other along the scan-length (Fig. 2C), that also results in an overall $\sim 39 \pm 18 \mu\text{m}$ helical pitch.

The FE simulations indicated that the frictional contact can mediate load transfer and it was sensitive to frictional coefficient (Fig. 3). The fibril stress was zero with no friction ($\mu = 0$, Fig. 3B) and it increased with higher μ (Fig. 3C and D). Similarly, for the fibril deformation in the zero-friction case, there was no axial deformation, hence the fibrils slide freely (Fig. 3E). When friction is increased, the induced stress and deformation also increased, with zero-derivative plateaus at the free ends indicating no strain (which confirms the imposed stress-free boundary condition) (Fig. 3F and G).

DISCUSSION

This study used a novel serial block-face scanning electron microscopy (SBF-SEM) to demonstrate that approximately half of the segmented tendon fibrils wrapped around each other in helical groups (although additional analyses and samples are needed to confirm the ratio). Moreover, we showed that the helical mechanical contact can contribute to interfibrillar load transfer, as an additional load transfer mechanism advancing our knowledge about the structure-mechanics relationships at this length scale.

The existence of helical fibrils was previously reported, which were suggested to be left-handed [7]; however, our findings showed a

Figure 3: FE simulation of the fibrils with helical wrapping showing axial stress in (A) the undeformed (top), and deformed (bottom) ($\mu = 0.5$). With no friction ($\mu = 0$) there was no (B) stress or (E) normalized deformation (\bar{u}). As the frictional coefficient increases, the stress and the deformation increases for $\mu = 0.5$ (C,F) and $\mu = 2$ (D,G).

similar number of the left-handed and right-handed helical fibrils (Fig. 2B). The helical structures have been used as an explanation for the macro-scale mechanical behavior of tendon, in particular for the low stiffness of tissue at small deformations and the large Poisson's ratio in tension [8-9]. According to this study, it is possible that the grouping of these fibrils can mediate load transfer by inducing frictional contact between fibrils during axial loading.

The FE simulations indicated that frictional load transfer can be induced between fibrils, without requiring connecting matrix. This was according to the assumption that the helical fibrils have an effective free boundary condition. This is in accord with the interfibrillar sliding phenomenon that is a well-documented experimental observation in tendons, which suggests that there is some form of free boundary along the fibrils that are mechanically coupled [8]. Yet, it is unclear if these effects are caused by weak areas in the fibril or tapered ends.

In conclusion, we used SBF-SEM to visualize the three-dimensional microscale tendon structure of the fibrillar network, including helically wrapped fibrils, and performed FE analysis to demonstrate the implications of helical structures as a frictional mechanisms for interfibrillar load transfer. This mechanism should be considered as another potential mechanism for interfibrillar load transfer, in addition to interfibrillar matrix and shear lag mechanisms.

INTRODUCTION

To better understand the onset of damage occurring in the brain upon traumatic events, it is essential to analyze how external mechanical loads propagate through the skull and meninges and down to the brain cortex. However, despite their putative role as structural dampers protecting the brain, the mechanical properties and dynamic behavior of the meningeal layers are still poorly understood [1]. Here, we characterized the deformation characteristics following a multimodal imaging technique, where we observed the local mechanical heterogeneity of rat pia-arachnoid complex (PAC) at the microscale via atomic force microscopy (AFM) indentation experiments and the deformation response of intact PAC via OCT imaging.

METHODS

Fresh tissue staining protocol: Rat brains were dissected from adult rats immediately after death. Fragments of dura mater that had not remained on the skull were removed, and the thin PAC tissue was carefully peeled under a dissecting microscope with the help of ultrafine tweezers while the brain was still immersed in PBS. All animal and tissue work was in compliance with the Institutional Animal Care And Use Committee (IACUC) regulations.

After isolation, the meningeal tissue samples were incubated with blocking solution (0.5% milk powder in PBS) for 90 min at RT. Three PBS washing steps followed (5 min, RT). The tissue was then directly incubated overnight in a 1:300 solution of primary antibody in 0.1% milk powder in PBS, including anti-collagen I and anti-vimentin. After three more washing steps, incubation with appropriate secondary ABs for 90 min at RT. The PAC was then counterstained with Hoechst nuclear stain (20 min, RT) and washed three more times in PBS (5 min, RT). The tissue samples were immediately imaged or used for microindentation thereafter while immersed in a PBS bath.

AFM protocol: Portions of rat PAC were adhered to tissue-treated glass slides following the staining protocol. AFM indentation curves were performed on different positions of PAC immersed in PBS using tipless cantilevers ($k=0.25$ N/m) modified by the attachment of spherical beads ($R=2.5$ μ m). 9×9 or 16×16 force maps at different indentation velocity (i.e. loading rate) were acquired. Contact points of indentation curves were found by combining Ratio of Variances [2] and Double Alarm [3] methods reported in literature. Force relaxation curves were obtained setting the AFM in height-clamp mode where the indentation to sample is kept constant while observing the variation of the reaction force on the cantilever. All measurements were performed within 48 hours of the animal's death. A hyperelastic material model (Ogden) was used to fit the indentation portion of the curves [4]. To avoid the large indentation regime, only the first 5 mm of the indentation curves were analyzed. The dwell curves were fit by a two term viscoelastic time relaxation model (Maxwell) [5]. Immunofluorescence stainings for confocal imaging were performed following a standard tissue staining protocol optimized for collagen-I and vimentin recognition.

OCT protocol: To determine the best scanning protocol, preliminary test scans were performed on fixed rat brains. We used the following scanning settings for imaging: 800 A-scans per B-Scan, 200 B-scans, and 3 volume repetitions over a field of view of 3 mm by 3 mm by 1.2 mm. Isolated rat brains with intact PAC were first immersed in PBS, then placed in a petri-dish and hydrated with PBS regularly. After imaging intact PAC with OCT, different levels of weight were placed on the brain and fixation were performed with 10% formalin. Same scanning settings were used to image the PAC after deformation with different loading settings.

RESULTS

Tissue stiffness probed at the microscale revealed large local heterogeneities, with a distribution mean of 4.7 ± 2.8 kPa. In particular, the Young's modulus (E) of

vascularized tissue resulted significantly higher than that of non-vascularized PAC (see Fig.1B and C and Fig.2A). We therefore hypothesize that the microanatomy of tissue must cause differential load propagation properties in different regions of the pia-arachnoid complex.

Force map showing local stiffness values and D. Young's modulus distribution as calculated from fitting all force-indentation (F-d) curves. E. Three examples of F-d curves.

Fig2: A. Non-vascularized vs. vascularized PAC stiffness values. B. Low density vs. high density trabecular PAC stiffness values. C. Low density vs. high density trabecular PAC first relaxation term. D. Low density vs. high density trabecular PAC second relaxation term.

Higher trabecular density area showed higher stiffness values and longer relaxation times (see Fig.2), supporting the hypothesis that the trabecular structure of the PAC is an enclosing structure around the brain with higher stiffness and damping values, possibly contributing to protect the brain against impacts.

The OCT images were obtained for intact PAC on the brain and peeled-off PAC (Fig.3). The observation of trabecular structure suggests that the PAC preserve its form after removing the dura and peeling-off the PAC.

Fig3: A. Intact rat PAC anatomy observed via OCT. B. Peeled off PAC observed via OCT.

DISCUSSION

It is known that mammalian PAC displays a high regional variability both in arachnoid trabeculae density and subarachnoid vasculature distribution [6,7]. Our data highlight strong local variations in the mechanical response of this tissue, possibly relating to the differences in local vulnerability to TBI reported by [8]. Future work will attempt to better quantify the most relevant microanatomical parameters (e.g., cellular density, local trabecular orientations) and correlate them with the deformation and recovery response of tissue via coupled AFM-confocal microscopy experiments and OCT imaging.

Exploring the mechanics of this peculiar bridging structure would also be highly relevant for a number of computational applications. From a biomechanical perspective, a popular hypothesis considers the random three-dimensional structure of the collagen sheets and pillars that make up the trabeculae as a mechanically redundant structure, capable of contributing to damping and constraining brain deformation following head rotation and movement despite the small volumetric contribution of the PAC to the intracranial space [9]. The multi-phasic (liquid, solid, ions, etc.) nature of bio-interfaces make their characterization a rather challenging task. Lack of accurate experimentally-derived material parameters characterizing the brain-skull interface is a key part in TBI research. Obtaining a comprehensive quantification of the mechanical response of the meningeal interfaces would therefore bring us one step closer to accurately modeling and understanding the nature of such a complex biomaterial.

INTRODUCTION

Patient-specific computational modeling of vascular mechanics is an emerging area which has developed various computational tools on individual treatment. It aids in the clinical treatment by optimizing the diagnosis and prognosis prediction, and classifying staging. In vascular modeling, however, multiscale models have become more complicated and they require long computation time, which is often not acceptable in clinical practice. Therefore, there remains a pressing need for a powerful tool to reduce the computational cost while maintaining adequate accuracy. Surrogate models (SM) are methods where computational expensive physical models are approximated by faster metamodels. Although SM is promising, it reduces the complexity of the physical system, which increases modeling uncertainty. Motivated by this challenge, we present a novel framework to minimize the uncertainty caused by SM, using multi-fidelity surrogate model (MFSM) and Gaussian process upper confidence bound (GP-UCB) regression. Furthermore, a comprehensive uncertainty analysis algorithm is designed to quantify the uncertainties associated with SM and physical model respectively. For purpose of demonstration, this framework is applied to estimate patient-specific evolution prediction of abdominal aortic aneurysms (AAA) using follow-up CT images from 26 patients.

METHODS

Given two physical models that simulate for the same vascular system, a multi-fidelity vascular surrogate model (MFVSM) using the co-Kriging approach is developed to reduce the computational cost. Among two physical models, the more expensive one which provides more accurate results is taken as the high-fidelity model (HFM) while the other is defined as low-fidelity model (LFM). In this study, both are computational growth and remodeling (G&R) models which share the

same constitutive relations. The HFM treats the geometry of aorta as a three-dimensional membrane model while the LFM uses a two-dimensional axisymmetric model. Moreover, in order to simulate for patient-specific aneurysm growth, two key parameters are chosen for the calibration, whereas the other parameters are fixed as given from references [1] and [2]. The first calibrated parameter is a scalar parameter that controls the stress mediated-growth of collagen fiber, K_g , which plays an important role in determining $m^k(t)$, the mass production rate of constituent k at time t per reference area. The control equation is assumed by

$$m^k(t) = \frac{M^c(t)}{M^c(0)} (K_g(\sigma^k(t) - \sigma_h^c) + m_{basal}^k), \quad (1)$$

where $\sigma^k(t)$ is the stress on fiber family k at time t , σ_h^c is the homeostatic stress of collagen fiber, $M^c(t)$ is mass density with respect to the reference configuration at time t , $M^c(0)$ is the mass density of a healthy vessel at time 0 , and m_{basal}^k is a basal rate of mass production for constituent k . The second calibrated parameter is a scalar parameter that determines the elastin damage shape called θ_2 . The elastin damage function, $f(s)$, is given by,

$$f(s) = \theta_1 \exp\left(-\frac{|s-\alpha|^2}{2\theta_2^2}\right), \quad (2)$$

where s is the coordinate defined on the centerline, θ_1 determines the magnitude of elastin degradation, and α controls the position of aneurysm, which can be identified via patient-specific CT images.

In this study, we focus on the prediction of maximum diameter of the aorta along its center line at different time, d , which is able to provide useful information in clinical practice. Then, the simulated d at different s and t from both HFM and LFM, given as functions of multiple parameter sets of K_g and θ_2 , are generated for training data in MFVSM. A hierarchical random sampling is used for choosing the

initial parameter values. Due to the expensive computation, the number of samples from HFM is limited, while a larger number of samples from cheap LFM improve the prediction. Then, given the set of inputs $\mathbf{x} = \{K_g, \theta_2, s, t\}^T$ and the corresponding maximum diameter d , the co-kriging method is able to model $d(\mathbf{x})$ by representing the local features of physical models by the Gaussian process [3]. Specifically, Gaussian process $Z_l(\cdot)$ and $Z_h(\cdot)$ represents the local features of LFM and HFM respectively. $Z_h(\cdot)$ can be approximates by $Z_l(\cdot)$ multiplied by a scaling factor ρ plus their difference, which is the Gaussian process $Z_d(\cdot)$:

$$Z_h(\mathbf{x}) = \rho Z_l(\mathbf{x}) + Z_d(\mathbf{x}). \quad (3)$$

The covariance among different Gaussian process can be calculated through an optimization algorithm and the best linear unbiased prediction of the intermediate values can be interpolated.

Using the follow-up CT image dataset and the trained MFVSM, a data-fitting algorithm using the least-square method is presented to estimate the physical parameters (K_g, θ_2) as well as their uncertainty. To reduce the estimation uncertainty (EU) of parameters due to the SM, GP-UCB, an optimal algorithm to find the global maximum, is employed to explore new samplings [4]. The GP-UCB chooses a new sample location \mathbf{x}_t by providing tradeoff between exploration and exploitation:

$$\mathbf{x}_t = \arg \min_{\mathbf{x} \in D} \mu_{t-1}(\mathbf{x}) + \sqrt{\beta_t} \sigma_{t-1}(\mathbf{x}), \quad (4)$$

where μ_{t-1} is average prediction of the data-fitting error, σ_{t-1} is uncertainty of the data-fitting error. It greedily selects points \mathbf{x}_t such that the data-fitting error on \mathbf{x}_t should be a reasonable upper bound, so that the optimized fitting results can be iteratively obtained. Based on the optimal fitting results, predictions of different physical quantities can be obtained using either HFM or MFVSM. Moreover, to provide better aid in clinical practice, we design a systematic algorithm to analyze the prediction uncertainty. First, bootstrapping, a random resampling method, is employed to provide EU of parameters caused by HFM. Second, the prediction uncertainty (PU) caused by SM and HFM modeling are estimated, respectively.

RESULTS

A test is made to exam the method. In this test, we choose $\mathbf{x} = \{K_g, t\}^T$ and d is the maximum diameter of the aorta. The samplings, HFM prediction, LFM prediction and MFVSM prediction are shown in **Fig. 1**. Based on the MFVSM, an optimal fitting to a follow-up CT images from a patient and associated uncertainty are obtained and shown in **Fig.2**.

DISCUSSION

The presented method provides a validated patient-specific prediction with a low computational cost. It also enables a systematic uncertainty analysis towards the computation prediction for the first time, which is essential in aiding clinical treatment. The test shows that a limited number of physical simulations is able to provide a promising MFVSM for the prediction and uncertainty analysis (**Fig. 1**). The result of uncertainty analysis gives a reasonable range of prediction, thus improving the confidence of using patient-specific computational modeling (**Fig. 2**). Furthermore, this study utilizes all 26 patient follow-up CT images to estimate computational parameters K_g and θ_2 , which cannot be obtained from experiments. The population-based parameter distribution from 26 patients can be applied to improve patient-specific simulation. For example, a more practical prior distribution of K_g and θ_2 can be utilized in Bayesian Calibration studies of aorta [5].

EFFECT OF CALCIFICATION & FIBROUS TISSUE FEATURES ON RUPTURE RISK IN ATHEROSCLEROTIC PLAQUES

INTRODUCTION

A major cause of myocardial infarctions and stroke events is atherosclerotic plaque rupture (1). Plaque rupture is a mechanical failure of the plaque tissue and is demonstrated to correlate with high mechanical stresses in plaques (2). Biomechanical studies have identified large lipid pool and thin fibrous cap as risk factors for plaque rupture as they lead to increased cap stresses (3). Another highly prevalent structural component in atherosclerotic plaques is the calcification. Biomechanical studies on the impact of calcifications are limited to cap and lumen stresses; however, calcification-fibrous tissue interface is a potential stress concentration location due to the large stiffness mismatch of the two tissue types (4). Recent histopathological examinations demonstrated plaque ruptures spanning from this interface to lumen (5).

The current study investigates stresses at the calcification-fibrous tissue interface in atherosclerotic plaques, their dependency on local anisotropy of the fibrous tissue and the calcification geometric features. First, morphometric analyses was conducted to identify the fiber alignment around the calcifications and the calcification geometric features regarding its shape, size and location. Secondly, computational stress analyses were performed with the local fibrous tissue anisotropy and measured calcification morphometry incorporated.

METHODS

Morphometric analyses

Carotid atherosclerotic plaques (n=16) were collected from endarterectomy operations performed in Erasmus Medical Center. The plaque samples were processed for histology. Hematoxylin&eosin-stained histology cross-sections at every 3 mm (n=380) from the decalcified plaque samples were analyzed and calcifications were

identified on the high resolution histology images. The following morphometric features were measured on the histology images using NDP.view2 [Hamamatsu Photonics KK] software (Figure 1): 1) normalized radial location, D_{norm} (distance to lumen/plaque thickness), 2) normalized width, W_{norm} (calcification radial width/plaque thickness) and 3) aspect ratio, AR (calcification circumferential length/radial width). Additionally, the fiber alignment in the fibrous plaque tissue surrounding the calcification was identified.

Figure 1: Illustration of the morphometric features measured and the idealized geometry used in the computational models

Computational stress analyses

Based on the morphometric analyses, 2D finite element (FE) models of the calcifications in plaques were generated (Figure 1). The idealized geometries used in the models were generated from the three morphometric measures (D_{norm} , W_{norm} , and AR) and calcification-specific models were produced. Anisotropic, hyperelastic (Holzapfel-Gasser-Ogden) material models were used for the fibrous plaque, arterial wall (adventitia & media) and calcification components in the

plaque models (6). With the FE models an intraluminal pressure of 140 mmHg was simulated under plane strain assumption and plaque stresses were computed. Maximum plaque tissue stresses along the fiber direction (S_{11}) and across the fiber direction (S_{22}) at the calcification-fibrous tissue interface were further analyzed using multivariate regression analyses and non-parametric Kruskal-Wallis H test for correlations to the three morphometric features and fiber orientation.

RESULTS

Of the 380 histology cross-section analyzed 65 contained calcification and was not damaged during the histology processing, allowing morphometric analyses. In these cross-sections 145 calcifications were identified and analyzed.

Of the 145 calcifications, four distinct fiber patterns in the surrounding fibrous plaque tissue were clearly identified (Figure 2). “Attached” type fiber pattern, defined as fiber alignment in the circumferential direction along the radial sides of the calcification and seems to attach to the calcification at the circumferential sides, was present for 40% of the calcifications. Twenty-five per cent of the calcifications had an “encircling” fiber pattern, where fibers encapsulated the calcification. “Pushed aside” fiber pattern was present for 15% of the calcifications and in 10% the fibers were “random”ly oriented.

Figure 2: Four distinct fiber patterns identified in the plaque tissue surrounding the calcifications

The radial location of the calcifications in the plaque tissue, quantified by the normalized radial distance, D_{norm} (range 0-1, 0=lumen, 1=media), showed great variation for all fiber patterns but the “random” pattern, which was located statistically significantly abnormally (Figure 3). Regarding the shape and size of the calcifications, “attached” pattern clearly showed presence around larger (high W_{norm}) and more slender (high AR) calcifications than the other patterns (Figure 3).

Figure 3: Measurements of the three morphometric features

The computational stress analyses demonstrated that the maximum stresses were always located at the circumferential side of the calcifications, possibly due to the high interface curvature there. The “attached” pattern showed statistically significantly greater maximum tissue stresses along the fibers (S_{11}) (median [Q1:Q3] = 274

[155:535] kPa) than the other patterns. The median S_{11} value was 85 kPa for “pushed aside” pattern, and <5 kPa for the “encircling” and “random” patterns (Figure 4). For maximum tissue stresses across the fibers (S_{22}), the stress levels were lower than S_{11} in general. “Attached” and “pushed aside” patterns had statistically significantly higher values (median= 8 & 21 kPa, respectively) than “encircling” and “random” patterns (Figure 4).

Multivariate regression analyses revealed that W_{norm} and AR correlated significantly and positively with S_{11} and S_{22} , implying that larger and/or slender calcifications have higher interface stresses along and across the fibers. D_{norm} was only correlated with S_{11} and correlated negatively, meaning that calcifications close to lumen have greater interface stresses along the fibers.

Figure 4: Computational interface stress analysis results

DISCUSSION

This study, to the authors’ knowledge, is the first one performing high detail, comprehensive morphometric analyses of calcifications in atherosclerotic plaques and calcification-tissue interface stress analyses with anisotropic tissue properties implemented. The study clearly identified four distinct fiber patterns, not reported before, in the plaque tissue surrounding calcifications in atherosclerotic plaques. “Attached” pattern is the most prevalent one and calcifications with this pattern show the largest variance in radial location, size and shape.

Study results demonstrated that the interface stresses can reach the stress levels considered as high risk for rupture (2). This provides mechanistic explanation for the rupture observations at the calcification interfaces in histopathological examinations (5). The stresses were shown to be strongly affected by calcification location, shape and size, and the fiber pattern. “Attached” pattern showed the highest S_{11} stresses as the fibers in this pattern are in the circumferential direction, which is the main loading direction in atherosclerotic plaques. S_{22} stresses are much lower in general; however, they might play a critical role in plaque rupture, especially for “attached” and “pushed aside” patterns with higher S_{22} values, as possibly tissue strength across fibers is possibly lower,.

INTRODUCTION

Aortic dissection (AD) involves the pathological separation of the layers of the aortic wall [1]. It is widely believed that this separation begins with some intimo-medial injury (entry tear). This entry tear is the antecedent for further crack propagation which is thought to occur between the elastic lamellar sheets of the media [2]. AD typically initiates in the ascending aorta near the aortic root (type A) accounting for 65-70% of cases, whilst the rest of occurrences occur distal to the left subclavian artery (type B) [3,4]. 48.6% of patients who have type A AD events do not survive long enough to reach the hospital, and the 30-day mortality rate for those who do is 47.4% [4]. These high mortality rates are due to the propagation of this crack and the creation of the pathological conduit known as the “false lumen” which frequently extends to the pericardium (3 in 4 cases of type A AD) leading to cardiac tamponade and subsequent death [5]. The false lumen may also propagate distally (particularly in type B AD) resulting in a range of malperfusion syndromes, these most commonly include stroke, acute kidney injury (AKI), paralysis, intestinal ischemia, and lower-limb ischemia [3], [6], [7].

To date no *in silico* models have been developed to examine the intramural tractions in the aortic arch and the role it plays in initiation and propagation of AD. In the present study a cohesive zone modelling approach is developed to simulate the initiation of AD in the aortic arch. An examination of the role of various geometric and material parameters in the initiation of AD under a variety of anatomical loading modes is presented.

METHODS

An idealized aortic arch geometry is created with an arch radius (R), a wall thickness (t), internal lumen radius (r), and thoracic aortic length (L). The aortic arch consists of two anatomical layers; an

adventitial-medial layer (with stiffness parameter E_i); and an intimo-medial layer (with stiffness parameter E_o). The aortic arch is subject to time-dependent physiological intraluminal pressure ($P_L = 120\text{mmHg}$).

A cohesive zone model [8] is implemented at the interface between the two layers of the aortic wall. In this fully coupled formulation both the normal and shear interface tractions are a function of the normal and tangential separations, Δ_n and Δ_t , respectively:

$$T_n(\Delta_n, \Delta_t) = \sigma_{max} \exp(1) \left(\frac{\Delta_n}{\delta_n} \right) \exp \left(- \sqrt{\frac{\Delta_n^2}{\delta_n^2} + \frac{\Delta_t^2}{\delta_t^2}} \right) \quad (1)$$

$$T_t(\Delta_n, \Delta_t) = \tau_{max} \exp(1) \left(\frac{\Delta_t}{\delta_t} \right) \exp \left(- \sqrt{\frac{\Delta_n^2}{\delta_n^2} + \frac{\Delta_t^2}{\delta_t^2}} \right) \quad (2)$$

σ_{max} is the maximum traction during a pure mode I separation while τ_{max} is the maximum traction during a pure mode II separation. δ_n and δ_t are the normal and tangential characteristic lengths, respectively.

Displacement boundary conditions are applied at the aortic root based on cine-MRI scans using imageJ [9]. Arch geometries containing supra-aortic vessels (brachiocephalic, left common carotid, and the left subclavian arteries) are generated using the GIBBON toolbox for MATLAB [10].

RESULTS

As shown in **Figure 1**, simulation of an applied cranial displacement at the root of the arch predict that a higher value of t/r results in

higher traction. Peak tractions are computed at the center of the arch on the inner curve. Shear tractions along the outer curve are not highly sensitive to the value of t/r . Additional traction localizations are computed at $L_{Aorta} = 0.6$, where the arch connects with the descending thoracic aorta. T_T/τ_{Max} is near-zero at $L_{Aorta} > 0.7$.

Figure 1: (a) Tangential traction (T_T) over cohesive strength (τ_{max}) vs. normalised aortic length (L_{Aorta}) for the highest and lowest permutations of t/r . The contour plots (b) and (c) show the (T_T/τ_{Max}) for $t/r = 0.125$ and $t/r = 1$ respectively.

Figure 2a shows the variation of shear traction at the interface for three configurations of R/r_o . Maximum traction occurs in the arch when $R/r_o = 1.25$. Significant localizations are predicted in the center of the arch and also at the beginning of the descending thoracic aorta. **Figure 2b** shows the magnitude of the tangential traction along the path of the inner curve of the aorta for an anterior displacement $\bar{V} = 0.15r_o$ for all values of R/r_o . Peak tractions occur in the centre of the arch along the inner curve at $L_{Aorta} = 0.4$. Two secondary peaks occur either side of $L_{Aorta} = 0.4$ with one occurring at the location of the descending thoracic aorta at $L_{Aorta} = 0.6$. Note the peak in traction at $L_{Aorta} = 0.6$ increase as the curvature of the arch increases.

Figure 2(a) Contour plot of T_T/τ_{Max} for various values of R/r_o . (b) T_T/τ_{Max} vs. L_{Aorta} for each configuration of R/r_o .

Figure 3 shows the effect of branching vessels on shear traction in the aortic arch. Significant localizations are predicted at the ostia of the brachiocephalic, the left common carotid, and the left subclavian arteries. The peak tractions occur on the outer curve of the aortic arch between $L_{Aorta} = 0$ and $L_{Aorta} = 0.6$. The presence of supra-aortic vessels significantly increases the tractions in the arch, more so than any other geometric or material parameter identified in this study.

Figure 3: Contour plot showing T_T/τ_{Max} of two simulations of lumen pressurization to 120mmHg. The image on the left shows the aortic arch with supra-aortic branches, the image on the right show the aortic arch without branches.

DISCUSSION

This study explores the underlying mechanics of AD through a parametric study of the geometry of the aortic arch. Increased wall thickness is a known result of chronic hypertension, which is the primary risk factor of AD [11]. The findings of this study suggest that increased wall thickness causes significantly higher tractions in the aortic arch, resulting in an increased risk of AD. The results of this study may also suggest that for an arch with increased curvature, type A dissection is more likely to occur than type B. This principle is demonstrated in Figure 2, where for a low R/r_o (high curvature) peak tractions suggest that dissection is most likely to occur in the ascending aorta at $L_{Aorta} = 0.1$ and $L_{Aorta} = 0.4$. Whereas, for a higher R/r_o (lower curvature) peak tractions occur in the descending aorta at $L_{Aorta} = 0.6$ suggesting a type B dissection. The current study represents the first analysis of the intramural traction state in the aortic arch under anatomical loading conditions. Results provide mechanistic insight into the relationship between arch geometry and AD risk.

INTRODUCTION

Cardiovascular disease continues to be a leading cause of morbidity and mortality, and the central vasculature plays key roles in many disease manifestations. Although much has been learned from clinical studies, the inability to collect full, longitudinal data sets in patients necessitates the use of complementary animal and data-driven computational models. Of the many animal models available, the mouse has emerged as most commonly used in cardiovascular research for many reasons, including the wide availability of antibodies for biological assays and the ability to edit the genome quickly and reliably. Yet, the small size of the murine vasculature presents technical challenges in studying both the wall mechanics and the hemodynamics. Among others, our laboratory has developed unique experimental systems and approaches to enable rigorous quantification of the biomechanics of central arteries in mice. Given that one of the key advantages of mouse models is the ability to explore diverse genetic, pharmacological, and surgical manipulations, there was also a pressing need for consistent methods of both data collection and analysis. Hence, we first focused on developing custom computer-aided methods designed specifically to promote reproducibility across diverse mouse models.

In many papers, one reads of the vascular phenotype in mouse models in terms of the development or not of an aneurysm, atherosclerosis, dissection, tortuosity, and so forth. We suggest, however, that there is also a pressing need to examine the “biomechanical phenotype,” not just the clinical phenotype. That is, there is a need to quantify and compare characteristic biomechanical metrics, including multiaxial wall stress and stiffness, elastic energy storage, and contractile function in response to multiple vasoactive agonists. In this presentation, we will briefly review methods and results that enable comparative biomechanical phenotyping of murine arteries.

METHODS

Details of our methods of data collection and analysis can be found elsewhere [1-5], but briefly note the following. Central arteries experience multiaxial stresses and finite strains upon every beat of the heart. Hence, we first sought to develop a computer-controlled system capable of imposing and measuring biaxial loads and mechanical responses by cylindrical specimens. This system consists of a pump and opposing micro-stepper motors to impose multiaxial loads, and both a video-microscope and optical coherence tomography system to monitor finite deformations. Symmetrically placed upstream and downstream pressure transducers allow one to avoid complexities of geometric and viscous losses along the fluid path and thereby to infer the pressure experienced by the central region of the sample that is monitored optically. Finally, a precision load cell allows one to infer the imposed axial force. Temperature and pH control allows short-term culture and/or maintenance of endothelial and smooth muscle cell viability, and thus both active and passive testing.

Because of the existence of residual stresses and their tendency to homogenize the transmural distribution of wall stress, we often use a 2-D formulation to analyze the data [3], which is sufficient for informing fluid-solid-interaction simulations [6]. Nevertheless, we also use 3-D, layer-specific analyses to interpret results that are important for understanding mechanobiological function [4]. Regarding the former, we also use the theory of small deformations superimposed on large to compute values of the stiffness matrix that are appropriate over a cardiac cycle [2].

Whereas biaxial testing of cylindrical samples provides considerable insight into arterial health and many diseases, more complex geometries demand more complex approaches. Hence, we also developed a panoramic digital image correlation method that yields full-field geometry and surface deformations and thus, when

combined with appropriate inverse methods, information on local multiaxial wall stress and stiffness as well as local elastic energy storage [5,7]. Briefly, specimens are mounted on a custom cannula that is placed within and co-axial to the long axis of a conical mirror. A single digital camera is then moved to multiple positions to collect data on the surface of the sample sufficient for digital reconstruction of the entire surface. Following fiducial characteristics resulting from a speckle pattern placed on the surface of the sample allows one to infer local displacements at multiple levels of axial loading and pressurization, which can then be analyzed using inverse methods to determine best-fit values of material parameters in an appropriate nonlinear constitutive relation.

RESULTS

Understanding the biomechanics of vascular disease first demands an understanding of vascular health. Just as healthy humans have diverse genetic backgrounds, so too healthy mice. We have thus compared biaxial mechanical properties of so-called wild-type mice across multiple genetic backgrounds (including C57BL/6, sv129, C57BL/6 x sv129) and found that, in most cases, these mice exhibit very similar biomechanical behaviors unless generated as non-induced conditional knock-outs [8-10]. Importantly, however, there are slight differences in axial properties across different genotypes, which emphasizes the need to quantify properties biaxially [8]. Consistent comparisons of carotid artery behavior across multiple genetic, pharmacological, and surgical models reveals further that both circumferential wall stress and material stiffness tend to be maintained near normal values, even in hypertension, thus supporting the notion of a mechanical homeostasis [9].

Interestingly, an inability to control circumferential material stiffness near normal appears to be characteristic of ascending aortas that are either predisposed to aneurysmal dilatation or that have already become aneurysmal. This observation was discovered using standard biaxial testing [11], but was then confirmed using an independent panoramic digital imaging based method [5]. This finding appears to be consistent with an emerging hypothesis that thoracic aneurysms result, in part, from failed mechano-sensing or mechano-regulation of matrix [12].

It is well known that aneurysms tend to manifest within the central vasculature in either the abdominal or the thoracic aorta, the latter often in the ascending segment. There is thus a pressing need for consistent comparisons across regions to determine reasons for such predilections. Using a single model – chronic infusion of angiotensin II in *Apoe*^{-/-} mice – we discovered marked regional differences in mechanical responses to the same insult [13]. In particular, the ascending aorta tended to exhibit aneurysmal dilatation, the descending thoracic aorta a marked fibrosis, and the suprarenal aorta dissection. Interestingly, the infrarenal abdominal aorta alone mechano-adapted to the induced hypertension. Again, the aneurysmal dilatation correlated with an increased circumferential material stiffness. In contrast, the fibrotic response correlated with an exuberant inflammatory cell infiltration while circumferential stiffness was restored whereas the dissection appeared to involve an early loss of collagen that was not sufficiently replaced during the pressure elevation, probably most importantly near branch sites. Quantifying both mechano- and immuno-biological factors is thus important in assessing regional differences in disease progression.

Finally, along with hypertension, aging is a key risk factor for cardiovascular disease. We used consistent methods to compare biomechanical changes of the aorta due to both natural aging of mice, to 100 weeks of age, and accelerated aging, due to genetic knock-out of the elastin associated glycoprotein fibulin-5. The latter proved to

result in a more severe phenotype, due in part to an increased accumulation of fibrillar collagen and glycosaminoglycans.

DISCUSSION

Biomechanical phenotyping of central arteries from diverse mouse models represents a tremendous opportunity to understand better both vascular health and disease. Toward this end, however, there is a pressing need for both rigorous and reproducible methods of data collection and analysis, as called for by the NIH. Given the many different methods used by different laboratories, it is becoming increasingly more difficult to compare results across studies. In an attempt to render results easier to compare across models and regions, we developed and continued to use consistent methods of testing and data analysis. These methods have now been used to test multiple regions of the central vasculature in dozens of different mouse models. Whereas comparison of one particular manipulation – genetic, pharmacological, or surgical – against an appropriate control provides considerable insight, comparisons across multiple models provide significantly more insight [cf. 8-11,13-15]. Such biomechanical information enables a deeper understanding of both the mechanics and the mechanobiology, which of course are inextricably linked. Indeed, it is now clear that understanding the mechanobiological processes that govern extracellular matrix turnover and phenotypic modulation of the associated cells is critically important to understanding the mechanics [16]. Hence, in the words of Y.C. Fung – in his foreword to the inaugural issue of the journal *Biomechanics and Modeling in Mechanobiology* – let us continue to “enjoy the work.”
