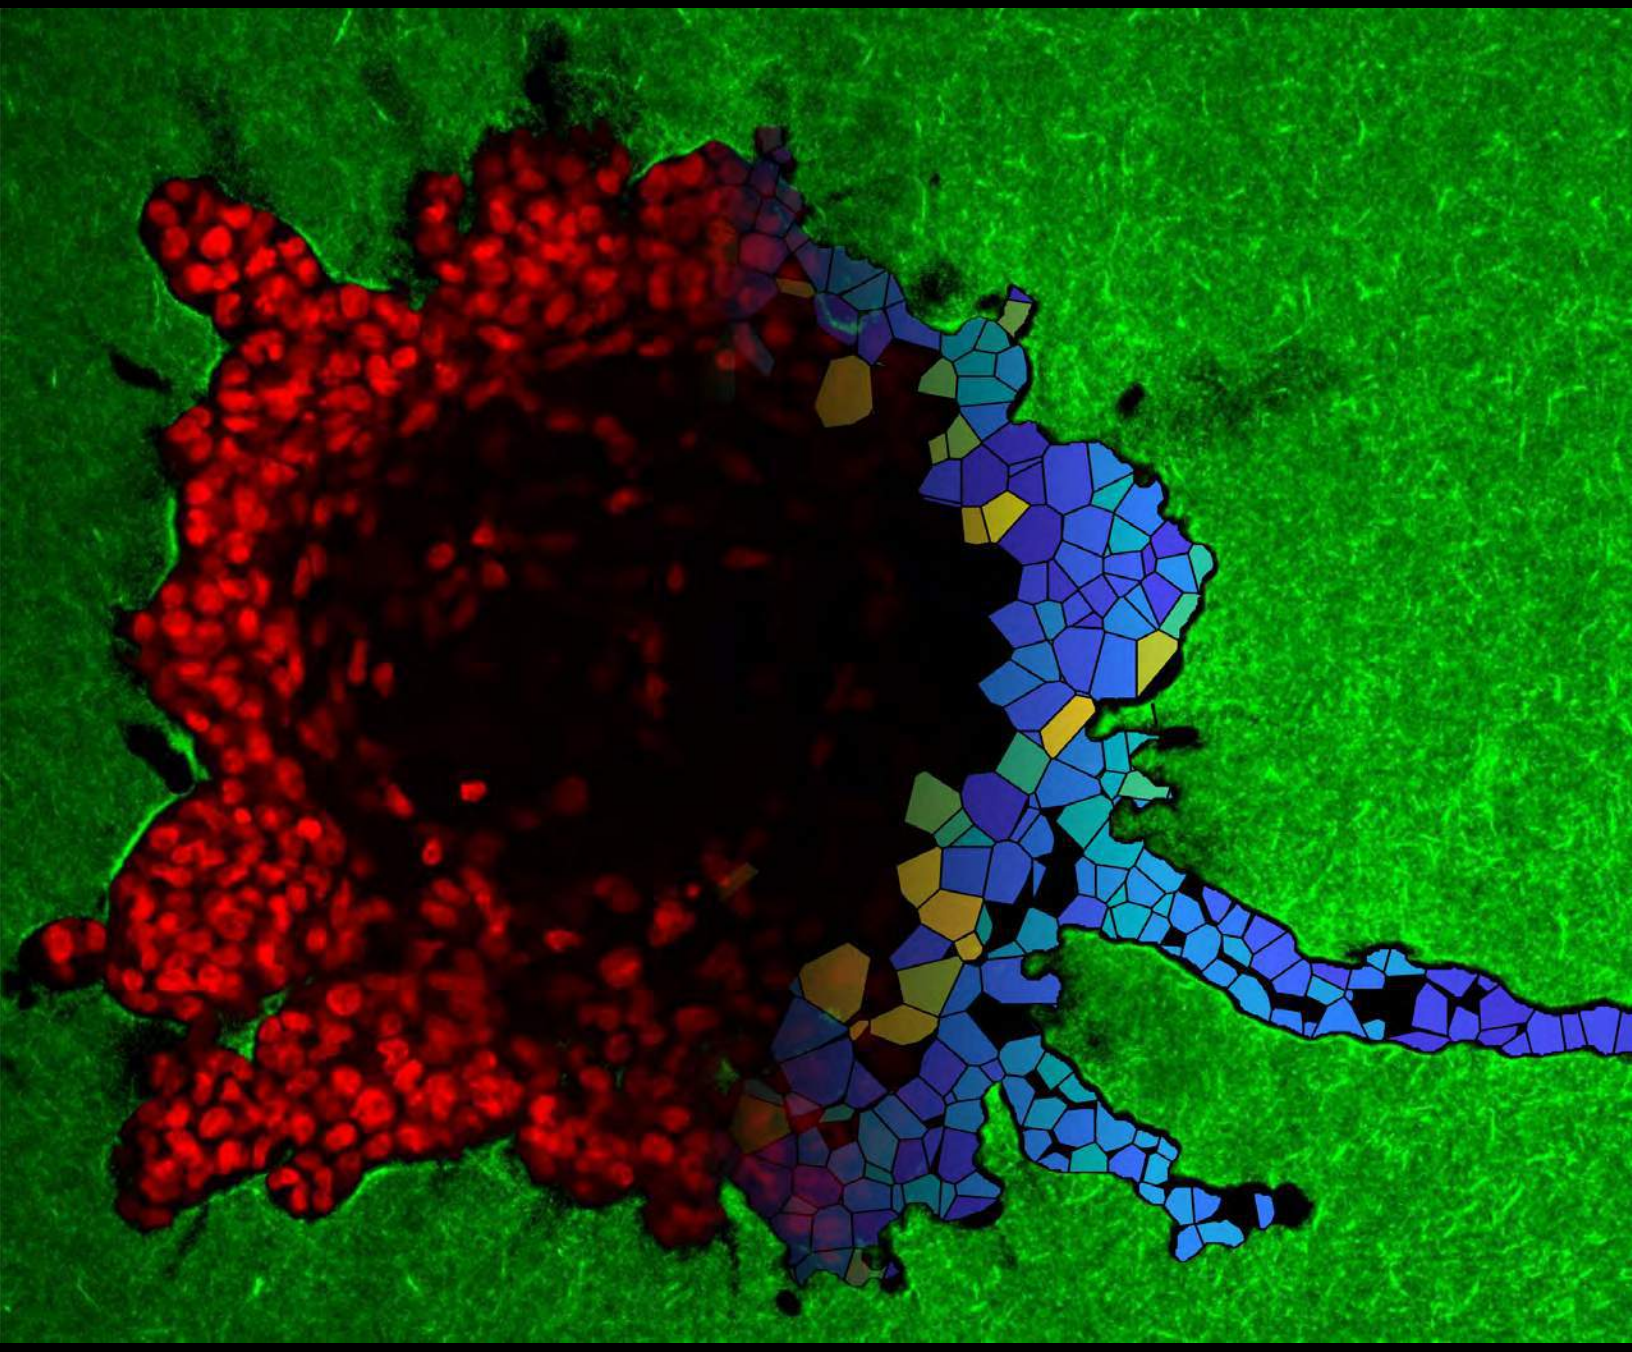
2021 Summer Biomechanics, Bioengineering, and Biotransport Conference



Virtual Meeting

June 14-18, 2021

Proceedings Book

Funding for this conference was made possible (in part) by the National Science Foundation's Civil, Mechanical and Manufacturing Innovation Division (Biomechanics and Mechanobiology) #2017872. Funding for this conference was also made possible (in part) by 1R13EB028126-01 from the National Institute of Biomedical Imaging and Bioengineering. Prizes and other support for the Student Paper Competition were provided by the Bioengineering Division of the American Society of Mechanical Engineers. The views expressed in written conference materials or publications and by speakers and moderators do not necessarily reflect the official policies of the Department of Health and Human Services; nor does mention of trade names, commercial practices, or organizations imply endorsement by the U.S. Government. The conference organizers gratefully acknowledge Aletea vanVeldhuisen from Purdue University for her help with the Program Book and Proceedings.

The 2021 Summer Biomechanics, Bioengineering, and Biotransport Conference (SB^{3}C) organizers gratefully acknowledge the support of the National Science Foundation, the National Institutes of Health, and American Society of Mechanical Engineers.

Congratulations to the 2021 Cover Art Contest Winner:

Jacopo Ferruzzi, University of Texas at Dallas/Boston University
Title: Jamming and Unjamming Transitions Govern the Invasion of Tumor Spheroids within 3D Extracellular Matrices
Description: Metastatic MDA-MB-231 breast cancer spheroids undergo a jamming transition during collective migration in high density collagen. The image displays the equatorial cross-section of an MDA-MB-231 spheroid (initially comprising $\sim$ 1000 cells) invading in a 4 mg/ml collagen matrix for 48 hours. The entire spheroid volume is captured in the image stack by combining optical clearing and multiphoton imaging. DAPI-stained cell nuclei are shown in red and collagen fibers from second harmonic generation signal (SHG) are shown in green. Cell shapes are estimated using a bounded Voronoi tessellation of the cell nuclei and subsequent calculation of the shape index (SI) as the normalized surface area: $SI = \frac{S}{\sqrt[3]{V^2}}$, where S and V represent, respectively, the surface area and the volume of the Voronoi tile approximating each cell within the spheroid. The 2D cross-section of the 3D cell shapes are color coded according to their respective SI value and show a decreasing radial gradient, consistent with the presence of an unjammed fluid-like phase in the spheroid bulk and a jammed solid-like phase while cells invade collectively under confinement from the dense collagen matrix. The field of view has a size of 824.57 x 824.57 μm^2. Fading between Voronoi tiles and cell nuclei was included for artistic e
ect.

Permission to download, print, and photocopy a single, individual copy of any of the works contained in this file for personal use in research and/or educational pursuit is granted by the SB3C Foundation, Inc. SB³C 2021 Virtual Meeting Table of Contents

Monday, June 14	12:30PM – 2:00PM EDT

Advances in Biomedical Engineering Education

Alpine Drift

Session Chair: Debanjan Mukherjee, University of Colorado Boulder
Session Chair: Zhongping Huang, West Chester University

12:30PM **Efficacy of Teaching Biomedical Engineering Laboratories Using Virtual Reality**
Anita Singh[1], Arun Ramakrishnan[2], Sriram Balasubramanian[2]
[1]Widener University, [2]Drexel University

12:43PM **"Hands-On, Minds-On, and Science-Up": A Concept-Based Learning Laboratory With a Taste of Research Experience for an Undergraduate Biomedical Engineering Course**
Cyrus Fiori[1], Taisiya Sigaeva[1], Maria Jose Pino Alban[2], Youssef Beauferris[2], Donovan Stagg[2], Elena Di Martino[2]
[1]University of Waterloo, [2]University of Calgary

12:56PM **Developing Community to Support First Generation Freshman in an Engineering Programming Course**
Sara Wilson[1], Molly McVey[1], Nolan Norton[1]
[1]University of Kansas

1:09PM **Development and Implementation of an Engineering Research Course for a College-In-Prison Program**
Julie Speer[1], Zain Clapacs[1]
[1]Washington University in St. Louis

1:22PM **Incorporating Engineering Standards into a Biomechanics Laboratory Course**
Kristen Billiar[1]
[1]Worcester Polytechnic Institute

1:35PM **Virtual Research Mentoring Between Graduate and Undergraduate Students During the Covid-19 Pandemic**
Julie Speer[1], Max Lyon[1], Julia Johnson[1]
[1]Washington University in St. Louis

Monday, June 14	12:30PM – 2:00PM EDT

Bone Mechanics

Saddle Ridge

Session Chair: Arun Nair, University of Arkansas
Session Chair: Lindsey Westover, University of Alberta

Copyright 2021 SB³C Foundation, Inc.

12:30PM **Multi-Scale Cortical Bone Morphology Varies Across Mice of Different Genetic Backgrounds**
Nicole Migotsky[1], Matthew Silva[1]
[1]Washington University in St. Louis

12:43PM **Investigation of Elastic Moduli of Mineralized Collagen Fibril and Extrafibrillar Matrix in Bovine Cortical Bone Using Peakforce Tapping Atomic Force Microscopy**
Yuxiao Zhou[1], Jing Du[1]
[1]Penn State University

12:56PM **Understanding Mechanisms of Load Transfer in the Tendon-To-Bone Attachment**
Mikhail Golman[1], Jonathan Almer[2], Stavros Thomopoulos[1], Alix Deymier[3]
[1]Columbia University, [2]Argonne National Laboratory, *[3]University of Connecticut Health Center*

1:09PM **Determining Tibial Stress and Strain During the Stance Phase with 3D Finite Element Modeling in a Healthy Running Population**
Patricia Butler[1], Ali Vahdati[1], Stacey Meardon[1], Stephanie George[1]
[1]East Carolina University

1:22PM **Digital Volume Correlation Using Deep Learning-Denoised Synchrotron Micro-CT Images to Study Bone Mechanical Behavior**
Yoshihiro Obata[1], Michael Sieverts[1], Daniel Pelt[2], Claire Acevedo[1]
[1]University of Utah, [2]Centrum Wiskunde & Informatica, Amsterdam, Netherlands

1:35PM **Tendon Enthesis Toughness Relies on Position-Dependent Fiber Recruitment and Bony Attachment Geometry**
Mikhail Golman[1], Victor Birman[2], Stavros Thomopoulos[1], Guy Genin[3]
[1]Columbia University, [2]Missouri University of Science and Technology, [3]Washington University in St. Louis

Monday, June 14	**12:30PM – 2:00PM EDT**

Emerging *In Vitro*, Experimental, Computational and Visualization Methods in Biofluid Mechanics

Mud Springs

Session Chair: Jimmy Azarnoosh, Marquette University
Session Chair: John LaDisa, Marquette University

12:30PM **Rapid Automatic Reconstruction of Heart Valves and Cardiac Structures from CT Images for Pre-TAVR Evaluations Using a Parametric Leaflet Model**
Huang Chen[1], Beom Jun Lee[1], Sri Krishna Sivakumar[1], Breandan Yeats[1], Vinod Thourani[2], Venkateshwar Polsani[2], Lakshmi Dasi[1]
[1]Georgia Institute of Technology, [2]Marcus Valve Center, Piedmont Heart

Copyright 2021 SB³C Foundation, Inc.

12:43PM **A Computational Fluid Dynamics Formulation with Solute Transport Derived from Mixture Theory and its Finite Element Implementation in FEBio**
Jay Shim[1], Steve Maas[2], Vijay Vedula[1], Clark Hung[1], Jeffrey Weiss[2], Gerard Ateshian[1]
[1]Columbia University, [2]University of Utah

12:56PM **Comparison of Nonlinear Membrane, Shell, and 3D Formulations for Vascular Biomechanics**
Nitesh Nama[1], Miquel Aguirre[2], Rogelio Ortigosa[3], Antonio Gil[4], Jay Humphrey[5], C. Alberto Figueroa[1]
[1]University of Michigan, [2]Mines Saint-Etienne, [3]Technical University of Cartagena, [4]Swansea University, [5]Yale University

1:09PM **The Effect of Hematocrit on the Thickness and Asymmetry of the Cell-Free Layer in Arterial Bifurcations**
Sayan Roychowdhury[1], Peter Balogh[1], Amanda Randles[1]
[1]Duke University

1:22PM **Potential Biofluidic and Geometrical Biomarkers of Thoracic Aortic Aneurysm Outcome in the Fbln4SMKO Mouse**
Marisa S. Bazzi[1], Ramin Balouchzadeh[2], Shawn N. Pavey[2], Jessica E. Wagenseil[2], Victor H. Barocas[1]
[1]University of Minnesota, [2]Washington University

1:35PM **A Platform for Studying the Effects of Nanotopography and Reactive Chemical Species on Integrin Selection**
Ryan Fasse[1], Novella Bates[2], Alex Guerra[3], Joe Baio[1], Monica Hinds[2], Patrick Jurney[3]
[1]Oregon State University, [2]Oregon Health & Science University, [3]San Jose State University

Monday, June 14	**12:30PM – 2:00PM EDT**

PhD Student Paper Competition 1: Biotransport, Biosensors and Biomaterials

Mogul Madness

Session Chair: Sara Roccabianca, Michigan State University
Session Chair: Guy Genin, Washington University in St. Louis

12:30PM **Sophorolipids Demonstrate Promising Anti-Cancer Efficacy in 2D, 2.5D, and 3D Breast Cancer Models**
Cassandra Roberge[1], David Kingsley[1], Lillian Murphy[1], Filbert Totsingan[1], Rebecca Miceli[1], Richard Gross[1], David Corr[1]
[1] Rensselaer Polytechnic Institute

12:45PM **Fibrous Microenvironments Regulate Nuclear Shape in a Diameter-Dependent Manner**
Aniket Jana[1], Amrinder Nain[1]
[1]Virginia Tech

Copyright 2021 SB³C Foundation, Inc.

1:00PM **Conductive Polypyrrole-Encapsulated Silk Fibroin Fibers for Myocardial Regeneration**
Yeshi Liang[1], James Goh[1]
[1]National University of Singapore

1:15PM **Diamond: Digital Plasmonic-Nanobubble Detection for Homogeneous Assay with Enhanced Sensitivity**
Yaning Liu[1], Haihang Ye[1], Zhenpeng Qin[1]
[1]University of Texas at Dallas

1:30PM **Successful Cryopreservation of Rabbit Jugular Vein Using Magnetic Nanoparticles Enhanced Single-Mode Electromagnetic Resonance Rewarming System**
Shen Ren[1], Zhiquan Shu[2], Ziyuan Wang[1], Ye Jin[1], Ruidong Ma[1], Shaohang Hao[1], Dayong Gao[1]
[1]University of Washington, [2]University of Washington Tacoma

1:45PM **Modulating the Blood-Brain Barrier by Picosecond Laser Stimulation of Molecular-Targeted Nanoparticles**
Xiaoqing Li[1], Vamsidhara Vemireddy[2], Qi Cai[1], Hejian Xiong[1], Peiyuan Kang[1], Xiuying Li[3], Monica Giannotta[3], Heather Hayenga[1], Edward Pan[2], Shashank Sirsi[1], Celine Mateo[4], David Kleinfeld[4], Chris Greene[5], Matthew Campbell[5], Elisabetta Dejana[3], Robert Bachoo[2], Zhenpeng Qin[1]
[1]University of Texas at Dallas, [2]University of Texas Southwestern Medical Center, [3]FIRC Institute of Molecular Oncology Foundation, [4]University of California San Diego, [5]Trinity College Dublin

Monday, June 14	**2:30PM – 4:00PM EDT**

Biofluids Mechanobiology and Pathology I

Mud Springs

Session Chair: Claudio Chiastra, Politecnico di Torino
Session Chair: Mette Olufsen, North Carolina State University

2:30PM **T Cells from Cadherin-11-Deficient Mice Promote Neointima Formation Following Vascular Injury**
Matthew Bersi[1,2], Matthew Madden[1], Tessa Huffstater[1], Lance Riley[1], Ethan Joll[1], Michael Raddatz[1], Victoria Le[3], Aaron Baker[3], Jeffrey Rathmell[1], David Merryman[1]
[1]Vanderbilt University, [2]Washington University in St Louis, [3]University of Texas at Austin

2:43PM **Linking Gene Expression, Hemodynamics and Cellular Dynamics in a Patient-Specific Multiscale Model of In-Stent Restenosis**
Anna Corti[1], Monika Colombo[1], Stefano Casarin[2], Jared M Rozowsky[3], Yong He[3], Sara Bridio[1], Francesco Migliavacca[1], Jose F Rodriguez Matas[1], Scott A Berceli[3], Claudio Chiastra[1]
[1]Politecnico di Milano, [2]Houston Methodist Hospital, [3]University of Florida

Copyright 2021 SB³C Foundation, Inc.

2:56PM **Multiscale Computational Model Predictions of Shear Stress and Cyclic Stretch in the Pulmonary Vasculature**
Michelle Bartolo[1], Nicholas Hill[2], Naomi Chesler[3], Mette Olufsen[1]
[1]North Carolina State University, [2]University of Glasgow, [3]University of California Irvine

3:09PM **Multiscale Hemodynamic Predictions in Chronic Thromboembolic Pulmonary Hypertension**
Mitchel Colebank[1], Mette Olufsen[1]
[1]North Carolina State University

3:22PM **Elucidating the Role of Wall Shear Stress in Aortic Wall Remodeling in Ascending Thoracic Aortic Aneurysms**
Selene Pirola[1], M Yousuf Salmasi[1], Serena M Fisichella[1], Sumesh Sasidharan[1], Omar A. Jarral[1], Declan P O'Regan[1], James E. Moore Jr[1], Thanos Athanasiou[1], Xiao Yun Xu[1]
[1]Imperial College London

3:35PM **Effects of Prolonged, Altered Hemodynamics on Zebrafish Embryonic Heart Development**
Yoke Yin Foo[1], Efthymios Motakis[2], Zenia Tiang[3], Shuhao Shen[1], Peiyuan Kang[1], Jason Kuan Han Lai[1], Wei Xuan Chan[1], Hadi Wiputra[1], Nanguang Chen[1], Ching Kit Chen[1], Christoph Winkler[1], Roger Foo[3], Choon Hwai Yap[4]
[1]National University of Singapore, [2]Jackson Laboratory, [3]Agency for Science Technology and Research, [4]Imperial College London

Monday, June 14	**2:30PM – 4:00PM EDT**

Biomechanics of Joints and Tissues

Saddle Ridge

Session Chair: Corinne Henak, University of Wisconsin-Madison
Session Chair: Andrew Kemper, Virginia Tech

2:30PM **Effect of Total Ankle Arthroplasty Implantation and Adaptive Gait on Ankle and Adjacent Joint Kinematics During Simulated Gait**
Jeffrey Hoffman[1], Jaeyoung Kim[1], Brett Steineman[1], Rogerio Bitar[1], Daniel Sturnick[1], Jonathan Deland[1]
[1]Hospital for Special Surgery

2:43PM **Additional Distal Femoral Resection Increases Mid-Flexion Laxity of Posterior Stabilized TKA with Flexion Contracture: A Computational Model**
Shady Elmasry[1], Brian Chalmers[1], Cynthia Kahlenberg[1], Peter Sculco[1], Timothy Wright[1], David Mayman[1], Geoffrey Westrich[1], Michael Cross[1], Carl Imhauser[1]
[1]Hospital for Special Surgery

2:56PM **Influence of Chondrolabral Damage and Labral Repair on Hip Joint Mechanics With Cam Fai Morphology**
Jocelyn Todd[1], Travis Maak[1], Gerard Ateshian[2], Andrew Anderson[1], Jeffrey Weiss[1]
[1]University of Utah, [2]Columbia University

Copyright 2021 SB³C Foundation, Inc.

3:09PM **Physiological Loading Conditions to Simulate Standing**
Stephanie Rossman[1,2], Eric Meyer[1], Jorge Isaza[3], Steven Rundell[2]
[1]Lawrence Technological University, [2]Explico Engineering, [3]Spine Specialist of Louisiana

3:22PM **Role of Muscle Activation on Lumbar Spine Force in Frontal Impact Loading**
Sagar Umale[1], John Humm[1], Narayan Yoganandan[1]
[1]Medical College of Wisconsin

3:35PM **PID Controlled, Finite-Element Simulation of Bipolar Radiofrequency Ablation of Porcine Spinal Muscle**
Hanife Tugba Kumru[1], Anilchandra Attaluri[1], Daniel H Cortes[1]
[1]The Pennsylvania State University

Monday, June 14	**2:30PM – 4:00PM EDT**

Image-based Characterization of Soft Tissues

Mogul Madness

Session Chair: Jacopo Ferruzzi, University of Texas - Dallas
Session Chair: Colleen Witzenburg, University of Wisconsin-Madison

2:30PM **Lamina Cribrosa Deformations Induced *In Vivo* by Acutely and Chronically Elevated Intraocular Pressure**
Fuqiang Zhong[1], Yi Hua[1], Junchao Wei[1], Manik Bansal[1], Juan Reynaud[2], Brad Fortune[2], Ziyi Zhu[1], Ian Sigal[1]
[1]University of Pittsburgh, [2]Devers Eye Institute, Legacy Health Research Institute

2:43PM ***Ex-Vivo* Local Plaque Rupture Analysis of Atherosclerotic Human Carotid Arteries Through Nano-Indentation, Tensile Testing and Digital Image Correlation**
Su Guvenir[1], Pablo de Miguel[2], Ali C. Akyildiz[1]
[1]Erasmus Medical Center, [2]Delft University of Technology

2:56PM **On the Relative Sensitivity of AAA Rupture Potential Index to Sex, Intraluminal Pressure, and Familial History**
Balaji Rengarajan[1], Satish Muluk[2], Mark Eskandari[3], Ender Finol[1]
[1]University of Texas at San Antonio, [2]Allegheny Health Network, [3]Northwestern University School of Medicine

3:09PM **Damage Modeling of the Human Meniscus: Validating Finite Element Models with Digital Image Correlation**
Derek Nesbitt[1], Trevor Lujan[1]
[1]Boise State University

3:22PM **The Effect of Age-Related Advanced Glycation End-Products on Tissue Mechanics Depends on Underlying Collagen Organization**
Austin Gouldin[1], Jennifer Puetzer[1]
[1]Virginia Commonwealth University

Copyright 2021 SB³C Foundation, Inc.

3:35PM **Polarized Spatial Domain Imaging for Simultaneous Tissue Strain and Fiber Orientation Measurements**
Coinneach Mackenzie Dover[1], Will Goth[2], James Tunnell[1], Michael Sacks[1]
[1]University of Texas at Austin, [2]SpectraWAVE, Inc.

Monday, June 14	**2:30PM – 4:00PM EDT**

Multi-Scale Modeling and Characterization of Soft Tissues

Alpine Drift

Session Chair: Pim Oomen, University of Virginia
Session Chair: Sara Roccabianca, Michigan State University

2:30PM **A Novel Three-Layered Model of Mouse Distal Colon and Rectum Capturing Through-Thickness Biomechanics**
Yunmei Zhao[1], Bin Feng[1], David M. Pierce[1]
[1]University of Connecticut

2:43PM **Protein Spreading Patterns in Alzheimer's Disease: Exploring the Difference Between a Connectivity-Based and Proximity-Based Connectome Model**
Shima Jalalian[1], Johannes Weickenmeier[1]
[1]Stevens Institute of Technology

2:56PM **Fiber Network-Based Multiscale Models Predict Experimentally Measured Volume Reduction of Stretched Mouse Skin**
Nathan Witt[1], Alan Woessner[2], Kyle Quinn[2], Edward Sander[1]
[1]University of Iowa, [2]University of Arkansas

3:09PM **The Mechanical Similitude of Positive- Versus Negative-Pressure Ventilation in Mouse Lungs**
Kathrine Anduaga[1], Talyah Nelson[1], Samaneh Sattari[1], Crystal Mariano[1], Arzu Ulu[1], Tara Nordgren[1], Mona Eskandari[1]
[1]University of California Riverside

3:22PM **Cortical Thickness Distribution of the Human Cerebral Cortex Identified by Curvature at Local Scales**
Nagehan Demirci[1], Maria Holland[1]
[1]University of Notre Dame

3:35PM **Interaction Mechanisms of Peptoid and Neuronal Cell Receptors and its Dependence on Peptoid Sphere Size and Chain Length**
Mohan Yasodharababu[1], Shannon Servoss[1], Arun Nair[1]
[1]University of Arkansas

Tuesday, June 15	11:00AM – 12:30PM EDT

Biofluids Mechanobiology and Pathology II

Mud Springs

Session Chair: Ryan Pedrigi, University of Nebraska-Lincoln
Session Chair: Atefeh Razavi, Georgia Institute of Technology

11:00AM **Leveraging Endothelial Glycocalyx Integrity in Atherosclerotic-Relevant Flow Conditions for Targeted Intravenous Nanoparticle Delivery**
Ronodeep Mitra[1], Ming Cheng[1], Gerard O'Neil[1], Praveen Kulkarni[1], Rajiv Kumar[1], Srinivas Sridhar[1], Craig Ferris[1], James Hamilton[2], Hanjoong Jo[3], Eno Ebong[1]
[1]Northeastern University, [2]Boston University School of Medicine, [3]Emory University

11:13AM **Regulation of TXNIP and the Role of ER Stress in the Anti-Inflammatory Effect of Empagliflozin to Glycocalyx Degradation**
Marc-Antoine Campeau[1], Richard Leask[1]
[1]McGill University

11:26AM **Computational Models to Evaluate the Impact of Coronary Collateral Artery Flow in Adult and Postnatal Mice**
Suhaas Anbazhakan[1], Kristy Red-Horse[1], Alison Marsden[1]
[1]Stanford University

11:39AM **Mean and Transverse Wall Shear Stress Correlate with Enos Expression in Endothelial Cells Under Orbital Flow**
Jaideep Sahni[1], Glenn Richardson[1], Ryan Pedrigi[1]
[1]University of Nebraska-Lincoln

11:52AM **Wall Shear Stress Topological Skeleton Variability Predicts Myocardial Infarction**
Maurizio Lodi Rizzini[1], Alessandro Candreva[2], Claudio Chiastra[1], Takuya Mizukami[2], Diego Gallo[1], Jean-Paul Aben[3], Olivier Muller[4], Bernard De Bruyne[2], Carlos Collet[2], Umberto Morbiducci[1]
[1]Politecnico di Torino, [2]OLV-Clinic, [3]Pie Medical Imaging BV, [4]Lausanne University Hospital

12:05PM **Designing a High-Throughput Water Channel to Assess Bone Tissue Development *In Vivo* Under Different Mechanical Environments**
Gina Georgadarellis[1], Craig Albertson[1], Juan Jiménez[1]
[1]University of Massachusetts Amherst

Tuesday, June 15	11:00AM – 12:30PM EDT

Brain and Injury Mechanics I: Kinematics

Saddle Ridge

Session Chair: Amanda Esquivel, University of Michigan-Dearborn
Session Chair: Songbai Ji, Worcester Polytechnic Institute

Copyright 2021 SB³C Foundation, Inc.

11:00AM **The Effect of Head Impact Exposure in NCAA Division I Football on Concussion Symptom Severity**
Jack Seifert[1,2], Alok Shah[2], Jared Muench[2], Jaroslaw Harezlak[3], Steve Rowson[4], Jason P. Mihalik[5], Stefan Duma[4], Paul Pasquina[6], Steve P. Broglio[7], Thomas M. McAllister[3], Michael McCrea[2], Brian D. Stemper[1,2]
[1]Marquettte University, [2]Medical College of Wisconsin, [3]Indiana University, [4]Virginia Tech, [5]University of North Carolina, [6]University of Health Sciences, [7]University of Michigan

11:13AM **Investigating the Effect of Sports Helmets on the Frequency Response of the Human Brain**
Fargol Rezayaraghi (R. Araghi) [1], Javid Abderezaei[1], Efe Ozkaya[1], Colleen E. Shea[1], Mehmet Kurt[1]
[1]Stevens Institute of Technology

11:26AM **Statistical Interpretation of Predictive Factors of Kinematics in Traumatic Brain Injury from Head Impacts**
Ylheng Li [1], Xianghao Zhan[1], Yuzhe Liu[1], David Camarillo[1]
[1]Stanford University

11:39AM **Biomechanics of Headers in Youth and Collegiate Female Soccer**
Tanner Filben[1], Nicholas Pritchard[1], Logan Miller[1], Christopher Miles[1], Jillian Urban[1], Joel Stitzel[1]
[1]Wake Forest School of Medicine

11:52AM **A Strategy for Validating the Kinematics of a Vehicle-Specific MADYMO Model of A Low-Speed Rear-End Collison**
Dominic Demma[1], Keith Button[1], Elizabeth Kappler[1], Stephanie Rossman[1], Steven Rundell[1]
[1]Explico Engineering Company

12:05PM **Effects of Aggressiveness, Confidence, and Perceived Coach Support on Head Impact Exposure Metrics in Youth Football**
Madison Marks[1], William Flood[2], Joel Stitzel[1,2], Jillian Urban[1,2]
[1]Virginia Tech, [2]Wake Forest School of Medicine

Tuesday, June 15	**11:00AM – 12:30PM EDT**

Device, Design and Rehabilitation I

Alpine Drift

Session Chair: Michael Moreno, Texas A&M University
Session Chair: Anita Singh, Widener University

11:00AM **Biomechanical Effects of Cycling Crank Length on Resultant Hip and Knee Joint Forces and Range of Motion**
Avery Newman[1], Abigail Fisk[1], Christiane O'Hara[1], Reymil Fernandez[1], Robert Clark[1]
[1]California Polytechnic State University

11:13AM **Measuring Prosthetic Foot Use by Activity Level with Step Activity Monitoring**
John Chomack[1], Alexis Sidiropoulos[1], Michael Poppo[1], Jason Maikos[1]
[1]Veteran Affairs New York Harbor Healthcare System

11:26AM **Three Different Office Postures: Determining Pelvic Tilt, Torso Openness, Ground Reaction Forces and Blood Perfusion**
Archana Lamsal[1], Garrett Weidig[1], Teresa Bellingar[2], Tamara Reid Bush[1]
[1]Michigan State University, [2]Haworth Inc.

11:39AM **Wearable Sensor Validation for Tasks Requiring High Acceleration**
Sarah Moudy[1], Yein Lee[1], Shelby Alfred[1], Rita Patterson[1]
[1]University of North Texas Health Science Center

11:52AM **Evidence of Sex Bias in Finite Element Modeling of Hip Arthroplasty**
Syeda Lamia[1], Chien-Yu Lin[2], Richard Hughes[1], Elizabeth Dailey[1], Megan Killian[1]
[1]University of Michigan, [2]University of Texas

12:05PM **Development and Validation of an Ultra-High Field Compatible MR Elastography Actuator**
Emily Triolo[1], Aymeric Pionteck[1], Akbar Alipour[2], Oleksandr Khegai[2], Paul Kennedy[2], Priti Balchandani[2], Mehmet Kurt[1]
[1]Stevens Institute of Technology, [2]Icahn School of Medicine at Mount Sinai

Tuesday, June 15	**11:00AM – 12:30PM EDT**

PhD Student Paper Competition 2: Bladder, Lung, and Ocular Biomechanics

Mogul Madness

Session Chair: Rebecca Heise, Virginia Commonwealth University
Session Chair: Joseph Sherwood, Imperial College of London

11:00AM **Lung Mechanics of Positive- and Negative- Pressure Ventilation Under Varied Inflation Volumes**
Samaneh Sattari[1], Crystal Mariano[1], Mona Eskandari[1]
[1]University of California, Riverside

11:15AM **Deformation of Peripapillary Sclera and Retina in Response to Elevated Intraocular Pressure**
Sunny Kwok[1], Manqi Pan[1], Yanhui Ma[1], Xueliang Pan[1], Jun Liu[1]
[1]The Ohio State University

11:30AM **Assessing the Comparative Strains Between Positive and Negative Pressure Ventilation Using Digital Image Correlation**
Crystal Mariano[1], Samaneh Sattar[1], Mona Eskandari[1]
[1]University of California, Riverside

Copyright 2021 SB³C Foundation, Inc.

11:45AM **Integrating Capillary Flow Modeling and Geometric Quantification Into Reconstructed 3D Capillary Networks of the Optic Nerve Head**
Po-Yi Lee[1], Jason Walker[1], Yi Hua[1], Bryn Brazile[1], Ian A. Sigal[1]
[1]University of Pittsburgh

12:00PM **Investigating the Effect of Varied Breathing Rates and Volumes on the Mechanics of Murine Lungs**
Talyah Nelson[1], Kathrine Anduaga[1], Samaneh Sattari[1], Crystal Mariano[1], Arzu Ulu[1], Tara Nordgen[1], Mona Eskandari[1]
[1]University of California, Riverside

12:15PM **Inflammasome Nlrc4 Gene Knockout Increases Stiffness of Bladder Wall in Rat Model**
Eli Broemer[1], Christina Chan[1], Sara Roccabianca[1]
[1]Michigan State University

Tuesday, June 15	**1:00PM – 2:30PM EDT**

Cartilage Mechanics: Measurement and Injury Biomechanics

Saddle Ridge

Session Chair: Deva Chan, Purdue University
Session Chair: Chris Price, University of Delaware

1:00PM **Vibrometry as a Nondestructive Alternative to Dynamic Mechanical Testing in Cartilage**
Gabriela Espinosa[1], Gaston Otarola-Pezzani[1], Jerry Hu[1], Kyriacos Athanasiou[1]
[1]University of California, Irvine

1:13PM **Crosslinking of Cartilage Collagen Via Nonlinear Femtosecond Laser Activation of Riboflavin**
Jiashuai Fan[1], C.V. Sise[1], Kimberly R. Kroupa[1], Clark T. Hung[1], Gerard A. Ateshian[1], Sinisa Vukelic[1]
[1]Columbia University

1:26PM **Manipulating the Initiation and Propagation of Microcracks in Collagen Networks of Cartilage**
Stephany Santos[1], Corey P. Neu[2], Bryanna Samolyk[1], David M. Pierce[1]
[1]University of Connecticut, [2]University of Colorado Boulder

1:39PM **Crosslinking of Collagen Across Cartilage Tears for Improved Interface Strength**
Kimberly Kroupa[1], C.V. Sise[1], Clark Hung[1], Sinisa Vukelic[1], Gerard Ateshian[1]
[1]Columbia University

1:52PM **Transition from Stress-Governed Fracture to Pressure-Induced Fragmentation in Cartilage Failure**
Dipul Chawla[1], Guebum Han[2], Melih Eriten[1], Corinne Henak[1]
[1]University of Wisconsin-Madison, [2]University of Minnesota

Tuesday, June 15	1:00PM – 2:30PM EDT

Patient Specific Flow and Physiology I

Mud Springs

Session Chair: Zahra K. Motamed, McMaster University
Session Chair: Alejandro Roldan-Alzate, University of Wisconsin-Madison

1:00PM **Assessment of Sex Differences in Ventricular Vascular Coupling of Left Ventricular and Aortic Flow Derived from 4D Flow MRI in Healthy, Young Adults**
Cody Johnson[1], Ryan Pewowaruk[1], David Rutkowski[1], Amanda Wolfinger[1], Alejandro Roldan-Alzate[1]
[1]University of Wisconsin-Madison

1:13PM **Comparing Tissue-Engineered Vascular Grafts in Fontan Patients to the Standard of Care Using Computational Fluid Dynamics**
Erica Schwarz[1], John Kelly[2], Stephanie Lindsey[1], Kan Hor[2], Aekaansh Verma[1], Ethan Kung[3], Jay Humphrey[4], Christopher Breuer[2], Alison Marsden[1]
[1]Stanford University, [2]Nationwide Children's Hospital, [3]Clemson University, [4]Yale University

1:26PM **Computational Assessment of Renal Hemodynamic Disturbances in a Canine Model of an Abdominal Aortic Coarctation**
Christopher Tossas-Betancourt[1], Yunus Ahmed[1], Petrus van Bakel[1], Drew Braet[1], William Sherk[1], Luis Hernandez-Garcia[1], David Williams[1], Daniel Myers[1], Thomas Wakefield[1], Dawn Coleman[1], Jonathan Eliason[1], James Stanley[1], C. Alberto Figueroa[1]
[1]University of Michigan

1:39PM **Effect of Surgery on Coronary Flow Hemodynamics in Children with Anomalous Aortic Origin of a Coronary Artery (AAOCA): A Patient-Specific Computational Study**
Atefeh Razavi[1], Jayanthi Parthasarathy[2], Yasaman Farsiani[2], Silvana Molossi[3], Carlos Mery[4], Rajesh Krishnamurthy[2], Lakshmi Prasad Dasi[1]
[1]Georgia Institute of Technology, [2]Nationwide Children's Hospital, [3]Baylor College of Medicine, [4]University of Texas at Austin

1:52PM **Virtual Treatment Planning in Williams and Alagille Patients with Peripheral Pulmonary Artery Stenosis**
Ingrid Lan[1], Weiguang Yang[1], Jeffrey Feinstein[1], Thomas Collins[1], Alison Marsden[1]
[1]Stanford University

2:05PM **Tracheomalacia Affects Neonatal Respiratory Airflow in the Upper Airway**
Chamindu Gunatilaka[1], Erik Hysinger[1], Andreas Schuh[2], Deep Gandhi[1], Nara Higano[1], Qiwei Xiao[1], Daniel Ignatiuk[1], Andrew Hahn[3], Sean Fain[3], Robert Fleck[1], Jason Woods[1], Alister Bates[1]

Tuesday, June 15	1:00PM – 2:30PM EDT

PhD Student Paper Competition 3: Bone and Head Injury Biomechanics

Mogul Madness

Session Chair: Mariana Kersh, University of Illinois at Urbana-Champaign
Session Chair: Richard Debski, University of Pittsburgh

1:00PM **Comparison of Head Impact Exposure Across Common Training Activities in Youth Soccer**
Nicholas Pritchard[1], Tanner Filben[1], Sebastian Haja[1], Logan Miller[1], Mark Espeland[1], Joel Stitzel[1], Jillian Urban[1]
[1]Wake Forest School of Medicine

1:15PM **Investigation of the Hindbrain Motion in Chiari Malformation I Patients Through 3D Amplified MRI**
Javid Abderezaei[1], Aymeric Pionteck[1], Ya-Chen Chuang[1], Itamar Terem[2], Leo Dang[3], Miriam Scadeng[3], Peter Morgenstern[4], Raj Shrivastava[4], Samantha Holdsworth[3], Yang Yang, Mehmet Kurt[1]
[1]Stevens Institute of Technology, [2]Stanford University, [3]University of Auckland, [4] Icahn School of Medicine at Mount Sinai

1:30PM **The Structure-Function Relationships of the Human Vertebral Endplate**
Yuanqiao Wu[1], Elise Morgan[1]
[1]Boston University

1:45PM **Maternal Bone Adaptation to Mechanical Loading During Pregnancy, Lactation, and Post-Weaning Recovery**
Yhan Li[1], Chantal de Bakker[1], Hongbo Zhao[1], Ashutosh Parajuli[2], Wei-Ju Tseng[1], Shaopeng Pei[1,2], Tan Meng[1], Rebecca Chung[1], Liyun Wang[2], X. Sherry Liu[1]
[1]University of Pennsylvania, [2]University of Delaware

2:00PM **Solution Composition Affects Dissolution-Recrystallization Mechanisms of Biomimetic Apatite**
Stephanie Wong[1], Mikayla Moynahan[1], Alix Deymier[1]
[1]University of Connecticut

2:15PM **The Skeletal Response to Varied Models of Metabolic Acidosis**
Mikayla Moody[1], Anna Peterson[1], Brian Wingender[1], Katya Morozov[1], Iris Nakashima[1], Tannin Schmidt[1], Alix Deymier[1]
[1]University of Connecticut Health Center

Poster Session

Poster Session I	Tuesday, June 15, 2:30PM – 4:00PM EDT

Posters: Cardiovascular Biomechanics

Aspen Glade

Session Chair: Thao (Vicky) Nguyen, Johns Hopkins University
Session Chair: Kristin Myers, Columbia University

Theoretical Assessment of Focused Septal Hypertrophic Growth in Hypertrophic Cardiomyopathy
Sandra Hager[1], Will Zhang[2], Renee Miller[1], Jack Lee[1], David Nordsletten[1,2]
[1]King's College London, [2]University of Michigan

Right Ventricular Strain Estimation in Rodents from High-Frequency Ultrasound
Conner Earl[1], Frederick W. Damen[1], Melissa Yin[2], Kristiina Aasa[2], Sarah Burris[2], Craig J. Goergen[1]
[1]Purdue University, [2]FUJIFILM VisualSonics

Aortic Valve Dynamics Coupled with Growth and Remodeling Due to Aging and Calcification
Mohammadreza Soltany Sadrabadi[1], Mona Eskandari[2], Amirhossein Arzani1
[1]Northern Arizona University, [2]University of California, Riverside

A Multiscale Computational Model for Cell-Signaling Driven Growth and Remodeling of Arteries
Linda Irons[1], Marcos Latorre[1], Jay Humphrey[1]
[1]Yale University

Effect of Arterial Wall Inclusions on Failure Mechanics of Intracranial Aneurysm Tissue
Ronald Fortunato[1], Anne Robertson[1], Chao Sang[1], Spandan Maiti[1]
[1]University of Pittsburgh

Biomechanics of Human Fetal Hearts with Critical Aortic Stenosis and Evolving Hypoplastic Left Heart Syndrome
Chi Wei Ong[1], Meifeng Ren[2], Hadi Wiputra[2], Joy Mojumder[3], Wei Xuan Chan[2], Andreas Tulzer[4], Gerald Tulzer[4], Martin Buist[2], Citra Nurfarah Zaini Mattar[2], Lik Chuan Lee[3], Choon Hwai Yap[5]
[1]Agency for Science Technology and Research, [2]National University of Singapore, [3]Michigan State University, [4]Kepler University Hospital, [5]Imperial College London

Effects of Cardiac Geometric Remodeling During Heart Failure on Cardiac Function
Yu Zheng[1], Wei Xuan Chan[1], Choon Hwai Yap[2]
[1]National University of Singapore, [2]Imperial College London

Determination of an Appropriate Strain Energy Density Function for the Tricuspid Heart Valve Leaflets Using Constant Invariant-Based Mechanical Testing
Devin Laurence[1], Chung-Hao Lee[1]
[1]The University of Oklahoma

Copyright 2021 SB³C Foundation, Inc.

Design and Fabrication of a Novel Polymeric Transcatheter Aortic Valve
Hieu Bui[1], Susan James[2], Lakshmi Prasad Dasi[1]
[1]Georgia Institute of Technology, [2]Colorado State University

Embryonic Aortic Arch Material Properties by Optical Coherence Tomography Guided Micro-Pipette Aspiration
S.Samaneh Lashkarinia[1], Gursan Coban[2], Erhan Ermek[1], Merve Celik[1], Hummaira Siddiqui[1], Yap Choon Hwai[3], Kerem Pekkan[1]
[1]Koc University, [2]Istinye University, [3]Imperial College London

Measuring the Anisotropic Mechanical Properties of Single Neonatal Mouse Cardiac Myocytes
Taylor Rothermel[1], Patrick Alford[1]
[1]University of Minnesota - Twin Cities

Transcatheter Heart Valve Leaflet Design Affects Local Leaflet Strain: An *In-Vitro* Study
Beatrice Ncho[1], Katelynne Berland[1], Vahid Sadri[1], Jillian Ortner[1], Ajit Yoganathan[1]
[1]Georgia Institute of Technology

Stress Analysis of Intracranial Aneurysm Based on *In Vivo* 3D Model and Intraoperative Image: A Case Study
Yuanming Luo[1], Xiaodong Zhai[2], Peng Hu[2], Hongqi Zhang[2], Yadong Wang[2], Lan Cao[3], Jia Lu[1]
[1]University of Iowa, [2]Xuanwu Hospital Capital Medical, [3]Boea Wisdom (Hangzhou) Network Technology Co., Ltd.

Model-Directed Design of Kink-Resistant Vascular Grafts with High Compliance
David Jiang[1], Andrew Robinson[1], Elizabeth Cosgriff-Hernandez[1], Lucas Timmins[1]
[1]University of Utah

Myofibril Disarray Decreases Peak Stress & Efficiency in a Finite Element Model of Muscle Fiber
Charles Mann[1], Hossein Sharifi[1], Alexus Rockward[1], Joy Mojumder[2], Lik Chuan Lee[2], Kenneth Campbell[1], Jonathan Wenk[1]
[1]University of Kentucky, [2]Michigan State University

The Effect of Hematocrit on the Viscoelastic Behavior of Embolus Analogs
Bryan Good[1]
[1]University of Tennessee

Optimizing Transcatheter Heart Valve Use in Mitral Annular Calcification
Breandan Yeats[1], Huang Chen[1], Pradeep Yadav[2], Venkateshwar Polsani[2], Vinod Thourani[2], Lakshmi Dasi[1]
[1]Georgia Institute of Technology, [2]Piedmont Hospital

High-Speed Simulation of the 3D Behavior of Myocardium Using a Neural Network PDE Approach
Wenbo Zhang[1], David Li[1], Tan Bui-Thanh[1], Michael Sacks[1]
[1]The University of Texas at Austin

Copyright 2021 SB³C Foundation, Inc.

The Effect of Endothelial Dysfunction on Aortic Mechanics and Extracellular Matrix Microstructure During Age-Related Vascular Remodeling
Liya Du[1], Jeffrey Rodgers[1], Tarek Shazly[1], John Eberth[1], Susan Lessner[1]
[1]University of South Carolina

Nanoparticle-Mediated Controlled Myocardial Delivery for Hypertrophic Cardiomyopathy
Jun Liao[1]
[1]University of Texas at Arlington

Development of a Fully Degradable Heart Valve for Implantation *In Utero*
Hieu T. Bui[1], Sanchita S. Bhat[1], Christopher K. Breuer[2], Aimee Armstrong[2], Martin Bocks[3], Ajit P. Yoganathan[1], Lakshmi Prasad Dasi[1]
[1]Georgia Institute of Technology, [2]Nationwide Children's Hospital, [3]Case Western Reserve University School of Medicine

A Comparative Biomechanical Study of Porcine Epicardial Layer and Endocardial Layer
Jun Liao[1]
[1]University of Texas at Arlington

Biomechanical Characterizations of Acellular Neonatal Porcine Ventricles
Jun Liao[1]
[1]University of Texas at Arlington

Optimization of Perivascular Region Geometry and Material Properties for Application in Patient-Specific Model of a Coronary Artery
Caleb Berggren[1], David Molony[2], Habib Samady[2], Lucas Timmins[1]
[1]University of Utah, [2]Emory University School of Medicine

Fiber-Gel Coupling in Coated Elastomeric Scaffolds for Replacement Heart Valves
Shruti Motiwale[1], Madeleine Russell[1], Megan Wancura[1], Andrew Robinson[1], Elizabeth Cosgriff-Hernandez[1], Michael Sacks[1]
[1]University of Texas at Austin

***In-Vivo* Estimation of Myocardial Elasticity in HFpEF Using Four-Dimensional Ultrasound Imaging**
Maziyar Keshavarzian[1], Sunder Neelakantan[1], Lilly McAllister[1], Carl Tong[1], Reza Avazmohammadi[1]
[1]Texas A&M University

Developing a Reduced Order Modelling Methodology for Simulating Transcatheter Aortic Valve Replacement Procedures
Imran Shah[1], Milad Samaee[1], Atefeh Razavi[1], Alessandro Veneziani[2], Lakshmi Dasi[1]
[1]Georgia Institute of Technology, [2]Emory University

Patient Specific Modeling and 3-Dimensional Printing for Planning of Redo Transcatheter Aortic Valve Replacement
Sri Krishna Sivakumar[1], Huang Chen[1], Breandan Yeats[1], Sarah Tucker[1], Scott Hollister[1], Pradeep Yadav[2], Venkat Polsani[2], Vinod Thourani[2], Lakshmi Dasi[1]
[1]Georgia Institute of Technology, [2]Piedmont Atlanta Hospital

Copyright 2021 SB³C Foundation, Inc.

Modelling Collagen Fiber Recruitment in Aortic Tissue Using Kinetic Average
Xuehuan He[1], Jia Lu[1]
[1]University of Iowa

Patient Specific Computational Modeling Towards Planning of Valve in Valve Transcatheter Aortic Valve Replacement
Sri Krishna Sivakumar[1], Breandan Yeats[1], Venkateshwar Polsani[2], Pradeep Yadav[2], Vinod Thourani[2], Lakshmi Dasi[1]
[1]Georgia Institute of Technology, [2]Piedmont Atlanta Hospital

A Semi-Automatic Approach for Aortic Wall Segmentation to Improve Rapid and Repeatable Assessments of Regional Wall Strain Using Dense MRI
Patrick Jones[1], John Wilson[1]
[1]Virginia Commonwealth University

Stress-Driven Fiber Remodeling in a Finite Element Model of Cardiac Tissue
Alexus Rockward[1], Charles Mann[1], Hossein Sharifi[1], Joy Mojumder[2], Lik Chuan[2], Kenneth Campbell[1], Jonathan Wenk[1]
[1]University of Kentucky, [2]Michigan State University

Categorization Based on *In-Vivo* Imaging and Histological Data Improves Prediction Capability of a Structured-Based Constitutive Model for Aneurysmal Aortic Tissue Mechanics
Tuan Thinh Tong[1], Miriam Nightingale[1], Michael Scott[2], Alex Barker[3], Taisiya Sigaeva[4], Paul Fedak[1], Elena Di Martino[1]
[1]University of Calgary, [2]Northwestern University, [3]University of Colorado Anschutz Medical Campus, [4]University of Waterloo

Collagen Microstructural Organization Contributes to Neovessel Guidance During Angiogenesis
Jason Manning[1], Adam Rauff[1], Jeffrey Weiss[1]
[1]University of Utah

Posters: Computational Biofluid Mechanics I

Aspen Glade

Session Chair: John LaDisa, Marquette University
Session Chair: Alejandro Roldan-Alzate, University of Wisconsin-Madison

Enhanced Hemodynamic Predictions in a Calcified Aortic Valve Geometry Using the Quemada Model
Asad Mirza[1], Amanda Barreto[1], Tisha Boodooram[1], Sharan Ramaswamy[1]
[1]Florida International University

Dynamics of Morphological Remodeling and Impact of Hemodynamics on Restenosis in Human Stented Superficial Femoral Arteries
Monika Colombo[1], Yong He[2], Anna Corti[1], Diego Gallo[3], Federica Ninno[4], Stefano Casarin[5], Jared M Rozowsky[2], Francesco Migliavacca[1], Scott Berceli[2,5,6], Claudio Chiastra[1,2]
[1]Politecnico di Milano, [2]Politecnico di Torino, [3]University of Florida, [4]University College of London, [5]Houston Methodist Hospital, [6]Malcolm Randall VAMC

Investigating Structural Covariance Networks by Using Graph Measures to Analyze Brain Connectivity for Schizophrenia
Madison Lewis[1], Nicholas Theis[1], Brendan Muldoon[1], Konasale Prasad[1]
[1]University of Pittsburgh

A General Protocol for Simulating Resting Cardiovascular Physiology Using a Closed-Loop Lumped Parameter Model
Akash Gupta[1], Aseem Pradhan[1], Surya Prakash Sharma[1], Tyler Schmidt[1], Ethan Kung[1]
[1]Clemson University

Developing a New Surrogate Model for Computational Fluid Dynamic Simulation of Aorta Using Statistical Shape Modeling and Deep Neural Networks
Pan Du[1], Xiaozhi Zhu[1], Jianxun Wang[1]
[1]University of Notre Dame

Numerical Investigation of Hemodynamics at Initiation of Pulmonary Arterial Hypertension Associated with Congenital Heart Disease
Melody Dong[1], Ingrid Lan[1], Weiguang Yang[1], Marlene Rabinovitch[1], Jeffrey Feinstein[1], Alison Marsden[1]
[1]Stanford University

Development of a Computational Platform to Evaluate a Positive End-Expiratory Pressure in Patients with Tracheostomy
Shiori Kageyama[1], Naoki Takeishi[1], Hiroki Taenaka[1], Takeshi Yoshida[1], Shigeo Wada[1]
[1]Osaka University

Development on a Computational Framework to Express Patient-Specific Intracranial Cerebrospinal Fluid Flow Based on Phase-Contrast Magnetic Resonance Images
Syusaku Maeda[1], Tomohiro Otani[1], Shigeki Yamada[2], Yoshiyuki Watanabe[2], Selin Ilik[1], Naoki Takaishi[1], Shigeo Wada[1]
[1]Osaka University, [2]Shiga University of Medical Science

Modelling Mechanical Feedback Mechanisms in Multiscale Sliding Filament Model of Lymphatic Muscle Pumping
Peter Xie[1], Christopher Morris[1], James Moore[1]
[1]Imperial College London

Junction Modeling in Patient-Specific Blood Flow Simulations
Elena Martinez[1], Martin Pfaller[2], Jonathan Pham[2], Alison Marsden[2]
[1]Loyola Marymount University, [2]Stanford University

Posters: Design Dynamics and Rehabilitation and Education

Aspen Glade

Session Chair: Michael Moreno, Texas A&M University
Session Chair: Anita Singh, Widener University

Wednesday, June 16	11:00AM – 12:30PM EDT

Brain and Injury Mechanics II: Soft Tissue Mechanics

Saddle Ridge

Session Chair: Jillian Urban, Wake Forest School of Medicine
Session Chair: Haojie Mao, Western University

11:00AM **Studying the Variation of Biomechanics During Myelination Using an *In Vitro* Neuron-Oligodendrocyte Co-Culture Model**
Ya-Chen Chuang[1], Mehmet Kurt[1], Carmen V. Melendez-Vasquez[2], Ace Alcantara[2]
[1]Stevens Institute of Technology, [2]Hunter College

11:13AM **Effects of Pia-Arachnoid Complex Constitutive Formulations on Predictions of Concussion**
Nikolaus Benko[1], Brittany Coats[1]
[1]University of Utah

11:26AM **Head Impact Simplification Using Effective Kinematic Triplets to Preserve Brain Strain**
Kianoosh Ghazi[1], Shaoju Wu[1], Wei Zhao[1], Songbai Ji[1]
[1]Worcester Polytechnic Institute

11:39AM **Time Course of the Cumulative Strain Damage Measure for Frontal and Lateral Impacts**
Tyler F Rooks[1], John Humm[1], Jamie Baisden[1], Narayan Yoganandan[1]
[1]Medical College of Wisconsin

11:52AM **Development and Multi-Level Validation of a Human Aorta Model for Traumatic Injury**
Wei Zeng[1], Adrian Caudillo[1], Sayak Mukherjee[1], Matthew Panzer[1]
[1]University of Virginia

12:05PM ***In Vivo* Injury Thresholds of Neonatal Brachial Plexus Nerves When Subjected to Stretch**
Virginia Orozco[1], Rachel Magee[1], Mitali Sahni[1], Sriram Balasubramanian[1], Anita Singh[2]
[1]Drexel University, [2]Widener University

Wednesday, June 16	11:00AM – 12:30PM EDT

Development and Morphogenesis

Alpine Drift

Session Chair: Yubing Sun, University of Massachusetts, Amherst
Session Chair: Victor Varner, University of Texas, Dallas

11:00AM **Modulating Epithelial Fluid Secretion and Transmural Fluid Pressure to Regulate Proliferation and Branching Morphogenesis in the Embryonic Lung**
Shelby Mohr-Allen[1], Victor Varner[1]
[1]University of Texas at Dallas

11:39AM **Computational Modeling of Borderline Left Ventricular Circulation for Clinical Decision-Making**
Yurui Chen[1], Isao Anzai[1], David Kalfa[1], Vijay Vedula[1]
[1]Columbia University

11:52AM **Tracking of the Left Atrial Appendage Motion in Time Resolved CT**
Sophia Bäck[1], Lilian Henrikson[1], Carl-Johan Carlhäll[1], Anders Persson[1], Matts Karlsson[1], Tino Ebbers[1]
[1]Linköping University

12:05PM **Focal Enhancement in Intracranial Aneurysms – Effects of Local Hemodynamics On VW-MRI Signals**
Franziska Gaidzik[1], Mariya Pravdivtseva[2], Jana Korte[1], Naomi Larsen[2], Sylvia Saalfeld[1], Gábor Janiga[1], Philipp Berg[1]
[1]University of Magdeburg, Germany, [2]University Hospital Schleswig-Holstein Kiel, Germany

Wednesday, June 16	**11:00AM – 12:30PM EDT**

PhD Student Paper Competition 4: Soft Tissue Biomechanics

Mogul Madness

Session Chair: Liyun Wang, University of Delaware
Session Chair: Joel Boerckel, University of Pennsylvania

11:00AM **A High-Fidelity 3D Micromechanical Model of Ventricular Myocardium**
David Li[1], Emilio Mendiola[1], Reza Avaz[2], Frank Sachse[3], Michael Sacks[1]
[1]The University of Texas at Austin, [2]Texas A&M University, [3]The University of Utah

11:15AM **Novel Multiscale Structure-Based Model of the Bovine Caudal Disc Motion Segment**
Minhao Zhou[1], Grace O'Connell[1]
[1]University of California, Berkeley

11:30AM **Measuring *In Situ* Lumbar Facet Capsular Ligament Strains Due to Joint Pressure and Residual Stress**
Elizabeth Gacek[1], Arin Ellingson[1], Victor Barocas[1]
[1]University of Minnesota - Twin Cities

11:45AM **From Microstructure to Micromechanical Properties of Soft Tissues**
Amir Ostadi Moghaddam[1], Woowon Lee[2], Zixi Lin[3], Heidi Phillips[1], Mayandi Sivaguru[1], Barbara McFarlin[4], Kimani Toussaint[3], Amy Wagoner Johnson[1]
[1]University of Illinois at Urbana Champaign, [2]University of Colorado Boulder, [3]Brown University, [4]University of Illinois at Chicago

12:00PM **Actomyosin Contractility Regulates Multi-Scale Mechanobiology of Nucleus Pulposus Cells in Inflammation**
Timothy Jacobsen[1], Paula Hernandez[2], Nadeen Chahine[1]
[1]Columbia University, [2]University of Texas Southwestern Medical Center

Copyright 2021 SB³C Foundation, Inc.

12:15PM **Mechanical Response of Mouse Cervices Lacking Decorin and Biglycan During Pregnancy**
Nicole Lee[1], Lei Shi[1], Mariano Caraballo[2], Shanmugasundaram Nallasamy[2], Charles Jayyosi[1], Mala Mahendroo[2], Kristin Myers[1]
[1]Columbia University, [2]University of Texas Southwestern Medical Center

Wednesday, June 16	**1:00PM – 2:30PM EDT**

Biotransport in Tumor Microenvironment and Immunotherapy

Mud Springs

Session Chair: Kunal Mitra, Florida Tech
Session Chair: Fateme Esmailie, Georgia Institute of Technology

1:00PM **Re-Engineering the Mechanical Tumor Microenvironment with Dexamethasone Enhances Efficacy of Cisplatin-Loaded Nanocarrier in Metastatic Breast Cancer**
Fotios Mpekris[1], John D. Martin[2], Myrofora Panagi[1], Thahomina T. Khan[2], Margaret R. Martin[2], Chrysovalantis Voutouri[1], Jumpei Norimatsu[2], Triantafyllos Stylianopoulos[1], Kazunori Kataoka[3], Horacio Cabral[2]
[1]University of Cyprus, [2]University of Tokyo, [3]Kawasaki Institute of Industrial Promotion

1:13PM **Spatiotemporal Progression and Modulation of the Blood-Brain-Tumor Barrier**
Qi Cai[1], Xiaoqing Li[1], Hejian Xiong[1], Xiaofei Gao[2], Robert Bachoo[2], Zhenpeng Qin[1]
[1]The University of Texas at Dallas, [2]University of Texas Southwestern Medical Center

1:26PM **Targeted Heating of Mitochondria Greatly Augments Nanoparticle-Mediated Cancer Chemotherapy**
Jiangsheng Xu[1], Xiaoming He[1]
[1]University of Maryland, College Park

1:39PM **A Novel Local Tumor Progression Prediction Method for Multi-Mode Thermal Ablation**
Xinyi Wang[1], Jianlong Yang[1], Aili Zhang[1], Lisa X. Xu[1]
[1]Shanghai Jiao Tong University

1:52PM **Mechanotherapeutics Combined with Cytotoxic Nanomedicine Overcomes Vessel Compression and Resistance to Immunotherapy in Triple Negative Breast Cancer**
Myrofora Panagi[1], Fotios Mpekris[1], Chrysovalantis Voutouri[1], John D. Martin[2], Kazunori Kataoka[3], Horacio Cabral[2], Triantafyllos Stylianopoulos[1]
[1]University of Cyprus, [2]The University of Tokyo, [3]Kawasaki Institute of Industrial Promotion

2:05PM **Quantitative Assessment of the Effects of Interstitial Flows, Macrophage Polarization and Immunotherapy on Tumor Immune Cell Infiltration**
Huu Tuan Nguyen[1], Nadia Gurvich[2], Christie Zhang[2], Giovanni Offeddu[1], Mark Gillrie[1], Sharon Lee[1], Seng-Lai Tan[2], Roger Kamm[1]
[1]Massachusetts Institute of Technology, [2]Elstar Therapeutics

Wednesday, June 16	1:00PM – 2:30PM EDT

Growth and Remodeling Mechanics I: Growth and Remodeling

Mogul Madness

Session Chair: Kyoko Yoshida, University of Virginia
Session Chair: Adrian Buganza Tepole, Purdue University

1:00PM **3D Growth and Remodeling in Ascending Thoracic Aortic Aneurysms**
Joan Laubrie[1,2,3], Jamaleddin Mousavi[1,2,3], Stéphane Avril[1,2,3]
[1]Mines Saint-Etienne, [2]University of Lyon, [3]University of Jean Monnet

1:13PM **Remodeling of the Thoracic Aorta Due to Ageing in Mice**
Yasmeen Farra[1], Jacqueline Matz[1], Chiara Bellini[1]
[1]Northeastern University

1:26PM **Computational Modeling of Stress-Mediated Vascular Remodeling in Pulmonary Arterial Hypertension**
Reza Pourmodheji[1], Zhenxiang Jiang[1], Christopher Tossas-Betancourt[2], C. Alberto Figueroa[2], Seungik Baek[1], Lik Chuan Lee[1]
[1]Michigan State University, [2]University of Michigan

1:39PM **Alterations to the Maternal Bony Pelvis and Pelvic Floor Muscle Complex During Pregnancy: a Statistical Shape Analysis**
Megan Routzong[1], Liam Martin[1], Ghazaleh Rostaminia[2], Pamela Moalli[1], Steven Abramowitch[1]
[1]University of Pittsburgh, [2]University of Chicago

1:52PM **Effect of Elastase Digestion and Maternal Age on Murine Vagina Wall Biaxial Mechanics**
Shelby White[1], Laurephile Desrosiers[2], Leise Knoepp[2], Kristin Miller[1]
[1]Tulane University, [2]Ochsner Clinical School

2:05PM **A Hybrid Discrete-Continuum Multiscale Kinematic Growth Model**
Elizabeth Gacek[1], Ryan Mahutga[1], Victor Barocas[1]
[1]University of Minnesota - Twin Cities

Wednesday, June 16	1:00PM – 2:30PM EDT

Ligament and Tendon Mechanics: Modeling and Measurement

Saddle Ridge

Session Chair: Megan Killian, University of Michigan
Session Chair: Babak Safa, Georgia Institute of Technology

1:00PM **An Inverse Mechanics Approach to Determine Changes in the Mechanical Heterogeneity of the Lumbar Facet Capsular Ligament**
Jill Middendorf[1], Victor Barocas[1]
[1]University of Minnesota

Copyright 2021 SB³C Foundation, Inc.

1:13PM **Tuning Shear Wave Tensiometry to Improve Subject Specificity in Achilles Tendon Loading Measurements During Walking**
Stephanie Cone[1], Dylan Schmitz[1], Darryl Thelen[1]
[1]University of Wisconsin

1:26PM **Sensitivity of the Shear Wave Speed-Stress Relationship to Ligament Fiber Alignment – A Probabilistic Finite Element Study**
Jonathon Blank[1], Darryl Thelen[1], Joshua Roth[1]
[1]University of Wisconsin-Madison

1:39PM **Fatigue Loading of Mouse Achilles Tendon Explants Does Not Induce Collagen Denaturation**
Krishna Pedaprolu[1], Spencer Szczesny[1]
[1]Pennsylvania State University

1:52PM **Signal to Noise Ratio of Polarization Imaging Parameters Is Dependent on Light Intensity and Microstructural Anisotropy of Soft Tissues**
Leanne Iannucci[1], Yingkai Chen[2], Viktor Gruev[2], Spencer Lake[1]
[1]Washington University in St. Louis, [2]University of Illinois at Urbana-Champaign

2:05PM **Label-Free Quantification of Soft Tissue Alignment by Polarized Raman Spectroscopy**
Hui Zhou[1], Janny Pineiro[1], Malisa Sarntinoranont[1], Ghatu Subhash[1], Chelsey Simmons[1]
[1]University of Florida

Wednesday, June 16	**1:00PM – 2:30PM EDT**

Tissue Engineering and Regeneration

Alpine Drift

Session Chair: Brendon Baker, University of Michigan
Session Chair: Alix Deymier, University of Connecticut Health Center

1:00PM **Sustained Il-10 Delivery Enhances Recovery from Volumetric Muscle Loss Injury Through Immunoregulatory Factors**
Tai Huynh[1], Cassandra Reed[1], Zain Blackwell[1], David Zaharoff[2], Jeffrey Wolchok[1]
[1]University of Arkansas – Fayetteville, [2]University of North Carolina - Chapel Hill

1:13PM **Mechanosensing as a Therapeutic Target in Synovial Fibrosis**
Edward Bonnevie[1], Carla Scanzello[1], Robert Mauck[1]
[1]University of Pennsylvania

1:26PM **Mechanosensitive Notch Signaling Regulates Phenotypic Changes in Vascular Smooth Muscle Cells**
Cansu Karakaya[1], Valery Visser[1], Tommaso Ristori[1], Carlijn Bouten[1], Cecilia Sahlgren[1,2], Sandra Loerakker[1]
[1]Eindhoven University of Technology, [2]Åbo Akademi University

Copyright 2021 SB³C Foundation, Inc.

1:39PM **Reversible Inhibition of Myofibroblast Activity to Improve Elbow Range of Motion After Capsulectomy**
Jordan A Jensen[1], Venkat Ganesh[1], Mariam Y El-Hattab[1], Jaidev Chakka[1], Juliana C Quarterman[1], Timothy P Fowler[1], Emily Petersen[1], Douglas Fredricks[1], James A Martin[1], Aliasger K Salem[1], Edward A Sander[1]
[1]University of Iowa

1:52PM **Stiffness and Anisotropy Dependent Proangiogenic Potential of Mesenchymal Stromal Cells**
Michael Nguyen-Truong[1], Seungil Kim[2], Courtney Doherty[1], Megan Frederes[1], Samantha Kaonis[1], Soham Ghosh[1], Peiman Hematti[3], William Wagner[2], Zhijie Wang[1]
[1]Colorado State University, [2]University of Pittsburgh, [3]University of Wisconsin, Madison

2:05PM **Fibril Strain Promotes Addition of Type I Collagen Molecules to Single, Native Collagen Fibrils *In Vitro***
Seyed Mohammad Siadat[1], Jeffrey Ruberti[1]
[1]Northeastern University

Poster Sessions

Poster Session II	**Wednesday, June 16, 2:30PM – 4:00PM EDT**

Posters: Biotransport

Aspen Glade

Session Chair: Joanna Dahl, University of Massachusetts, Boston
Session Chair: Zhenpeng Qin, University of Texas, Dallas

Peristaltic Pumping in Sub-Wavelength Perivascular Models
Jessica Shang[1], John Brennen Carr[1], Caroline Cardinale[1], Delin Zeng[1]
[1]University of Rochester

A Continuum Mechanics Approach to Model Stiffness Sensing by Smooth Muscle Cells
Ali Akbar Karkhaneh Yousefi[1,2], Claudie Petit[1,2], Stephane Avril[1,2]
[1]Mines Saint-Etienne, [2]University of Lyon

Excess collagen deposition in diabetic kidney disease enhances cellular communication: A mathematical model
Haryana Thomas[1,2], Ashlee Ford Versypt[1,2]
[1]Oklahoma State University, [2]University at Buffalo

Pulsatile Perfusion Optimization within a Multi-Organ Preservation Device
Daniel Portillo[1], Stephen Rivas[1], Gabriela Pineda[1], Sukhwinder Kaur[1], Lauren Bayliss[2], Leon Bunegin[3], R. Lyle Hood[1]

5:00PM **Modeling the Three-Way Chemo-Mechanical Feedback between Cellular Contractility, Actin Polymerization, and Adhesion Turnover in the Remodeling of Endothelial Junctions**
Eoin McEvoy[1], Tal Sneh[2], Emad Moeendarbary[3], Xingyu Chen[2], Tatyana Svitkina[2], Roger Kamm[4], Vivek Shenoy[2]
[1]National University of Ireland Galway, [2]University of Pennsylvania, [3]University College London, [4]Massachusetts Institute of Technology

5:13PM **Multiscale Model of Heart Growth During Pregnancy: Integrating Mechanical and Hormonal Signaling**
Kyoko Yoshida[1], Jeffrey Saucerman[1], Jeffrey Holmes[2]
[1]University of Virginia, [2]University of Alabama at Birmingham

5:26PM **Modeling Wound Healing Mechanobiology: Multi-scale Coupling of a Cell Adhesion Model to a Finite Element Model of Tissue**
Yifan Guo[1], Julian Jimenez[1], Sarah Calve[2], Adrian Buganza Tepole[1]
[1]Purdue University, [2]University of Colorado Boulder

5:39PM **Force Transmission within the Migrating Endothelium Regulates Shunt Formation during Angiogenic Remodelling**
Lowell T. Edgar[1], Miguel O. Bernabeu[1]
[1]University of Edinburgh

5:52PM **Local Tissue Heterogeneity Surrounding Neurons May Modulate Their Responses Via Altered Axonal Strain Fields**
Jill Middendorf[1], Meagan Ita[2], Beth Winkelstein[2], Victor Barocas[1]
[1]University of Minnesota, [2]University of Pennsylvania

6:05PM **Evolving structure-function relations in aortic maturation and aging**
Cristina Cavinato[1], Sae-Il Murtada[1], Alexia Rojas[1], Jay D. Humphrey[1]
[1]Yale University

Wednesday, June 16	**5:00PM – 6:30PM EDT**

Multiscale Biotransport in Drug Delivery

Mud Springs

Session Chair: Jifu Tan, Northern Illinois University
Session Chair: Zhiquan Shu, University of Washington

5:00PM **The Impact of Injection Timing and Location on Microparticle Delivery for Tumor Targeting in a Patient-Specific Liver**
Tim Bomberna[1], Charlotte Debbaut[1], Geert Maleux[2], Chris Verslype[2], Lawrence Bonne[2]
[1]UGent, [2]UZ Leuven

5:13PM **Constant Pressure CED Infusions with Controlled Catheter Movement in Agarose Gel Brain Tissue Phantoms**
Jason N. Mehta[1], Brianna E. Morales[1], Christopher G. Rylander[1]
[1]The University of Texas at Austin

Copyright 2021 SB³C Foundation, Inc.

5:26PM **Mechanism of Enhanced Thermal Transport and Photoacoustic Effect for Silica-Coated Gold Nanoparticles**
Peiyuan Kang[1], Jonghae Youn[1], Zhenpeng Qin[1]
[1]University of Texas at Dallas

5:39PM **Design and Evaluation of Faciliflow: A Lymph Node Prosthetic for Prevention of Surgically Induced Lymphedema**
Jennifer Frattolin[1], Arushri Swarup[1], Alain Vella[1], Fatima Al-Khal[1], Anaös Schaschkow[2], Pierre Gianello[2], Guido Giacalone[2], James E. Moore Jr.[1]
[1]Imperial College London, [2]Université Catholique de Louvain

5:52PM **A Mechanistic Study of the Interstitial Transport of Collagenase-secreting Tumor-targeting Salmonella Typhimurium Toward Improving Tumor Colonization**
Eric Leaman[1], Bahareh Behkam[1]
[1]Virginia Tech

6:05PM **Enhancement of Drug Delivery to Pancreatic Cancer Targeting Fibrin Matrix**
Sae Rome Choi[1], Hye-ran Moon[1], Yi Yang[2], Matthew J. Flick[2], Bumsoo Han[1]
[1]Purdue University, [2]University of North Carolina

Wednesday, June 16	**5:00PM – 6:30PM EDT**

Ocular and Reproductive Mechanics I: Form and Function

Saddle Ridge

Session Chair: Katrina Knight, University of Pittsburgh
Session Chair: Hamed Hatami-Marbini, UIC

5:00PM **Changes in Vaginal Shape Throughout the Lifespan**
Liam Martin[1], Megan Routzong[1], Pamela Moalli[1], Ghazaleh Rostaminia[2], Victoria Martin[1], Katherine Lebrun[1], Steven Abramowitch[1]
[1]University of Pittsburgh, [2]Northshore HealthSystems

5:13PM **Effects of Maternal Geometry and Gestational Age on Loading of the Gravid Human Uterus and Cervix**
Erin Louwagie[1], Lindsey Carlson[2], Joy Vink[1], Timothy Hall[2], Helen Feltovich[1], Kristin Myers[1]
[1]Columbia University, [2]University of Wisconsin-Madison

5:26PM **The Effects of Fetal Head Size on Maternal Coccyx Rotation During a Vaginal Delivery**
Sheng Chen[1], Megan Routzong[2], Steven Abramowitch[2], Michele Grimm[1]
[1]Michigan State University, [2]University of Pittsburgh

5:39PM **Effect of Osmotic Loading on Vaginal Viscoelastic Mechanical Properties**
Gabrielle Clark-Patterson[1], Laurephile Desrosiers[2], Leise Knoepp[2], Raffaella De Vita[3], Kristin Miller[1]
[1]Tulane University, [2]Ochsner Clinical School, [3]Virginia Polytechnic Institute and State University

Copyright 2021 SB³C Foundation, Inc.

5:52PM **The Impact of Tissue Property Variations on Optic Nerve Head Deformation Under Physiological and Supra-Physiological Loading**
Andrew Feola[1,2], C. Ross Ethier[2], Brian Samuels[3]
[1]Atlanta VA Medical Center, [2]Georgia Institute of Technology, [3]University of Alabama at Birmingham

6:05PM **Factors Influencing Minimum Lamina Cribrosa Oxygen Concentration**
Yi Hua[1], Jason Walker[1], Po-Yi Lee[1], Fengting Ji[1], Haiden McDonald[1], Pedro Pallares[1], Bryn Brazile[1], Ian Sigal[1]
[1]University of Pittsburgh

Poster Session

Poster Session III	Wednesday, June 16, 6:30PM – 7:30PM EDT

Posters: BS Finalists Poster Session

Aspen Glade

Session Chair: Megan Killian, University of Michigan

Proposed Injury Threshold for Drone Blade Lacerations
Lauren Duma[1], Mark Begonia[1], Barry Miller[1], Stefan Duma[1]
[1]Virginia Tech

3D Image Correlation of Porcine Adipose Tissue Under Compression
Dari Samson[1], Bryce Chapman[1], Brenda Burke[1], Dr. Lakiesha Williams[1]
[1]University of Florida

Engaging Biomedical Engineering Students with Gamification in Online Learning
Nina Dorfner[1], Rana Zakerzadeh[1]
[1]Duquesne University

Simulation of Oxygen Mass Transport in a Complaint Abdominal Aortic Aneurysm Model
Alexis Throop[1], Burton Carbino[1], Alexander Guy[1], Nina Dorfner[1], Rana Zakerzadeh[1]
[1]Duquesne University

The Effect of Stenosis Severity and Arterial Wall Mechanics on Functional Diagnostic Parameters
Angelica Alday[1], Talha Lone[1], Rana Zakerzadeh[1]
[1]Duquesne University

Whitewater Helmet STAR: Evaluating the Biomechanical Performance and Risk of Head Injury for Whitewater Helmets

11:00AM **A Convolutional Neural Network Algorithm for 3D Super-resolution of Pelvic Floor MRI Based on Low Inter-slice Resolution Data**
Fei Feng[1], James A. Ashton-Miller[2], John O.L. DeLancey[2], Jiajia Luo[3]
[1]Shanghai Jiao Tong University, [2]University of Michigan, [3]Peking University

11:13AM **Biomechanical Properties of Post-Menopausal Vaginal Samples in Relation to Pelvic Organ Prolapse**
Elvis Danso[1], Laurephile Desrosiers[2], Leise Knoepp[2], Kristin Miller[1]
[1]Tulane University, Ochsner Clinical School

11:26AM **A High-Accuracy Digital Volume Correlation for Soft Tissue Biomechanics Characterization Using Optical Coherence Tomography**
Fuqiang Zhong[1], Yi Hua[1], Junchao Wei[1], Manik Bansal[1], Juan Reynaud[2], Brad Fortune[2], Ian A. Sigal[1]
[1]University of Pittsburgh, [2]Devers Eye Institute, Legacy Health Research Institute

11:39AM **The Curvature and Collagen Network of the Human Lamina Cribrosa in Glaucoma and Control Eyes**
Cameron Czerpak[1], Yik Tung Tracy Ling[1], Joan Jefferys[1], Harry Quigley[1], Thao Nguyen[1]
[1]Johns Hopkins University

11:52AM **Assessment of the Poroelastic Mechanical Properties of Porcine Optic Nerve Head Using Micromechanical Testing and Biphasic Mixture Modeling**
Babak N. Safa[1], A. Thomas Read[1], C. Ross Ethier[1]
[1]Georgia Institute of Technology

12:05PM **Do Glycosaminoglycans Act as a Structural Constituent of the Scleral Tissue?**
Hamed Hatami-Marbini[1], Mohammad Pachenari[1]
[1]University of Illinois at Chicago

Thursday, June 17	**11:00AM – 12:30PM EDT**

PhD Student Paper Competition 5: Cardiovascular Fluid Biomechanics

Mogul Madness

Session Chair: Rana Zakerzadeh, Duquesne University
Session Chair: **Anne Robertson,** University of Pittsburgh

11:00AM **Spectral Bandedness in High Fidelity CFD Predicts Rupture Status in Intracranial Bifurcation Aneurysms**
Daniel MacDonald[1], Mehdi Najafi[1], Lucas Temor[1], David Steinman[1]
[1]University of Toronto

11:15AM **A Deep-Learning Approach for Direct Whole-Heart Mesh Reconstruction**
Fanwei Kong[1], Shawn Shadden[1]
[1]University of California, Berkeley

Copyright 2021 SB³C Foundation, Inc.

11:30AM **Unraveling the Etiology of Discrete Subaortic Stenosis: Focus on Hemodynamics**
Jason Shar[1], Sundeep Keswani[2], K. Jane Grande-Allen[3], Philippe Sucosky[4]
*[1]*Wright State University*, [2]*Texas Children's Hospital*, [3]*Rice University, [4]Kennesaw State University

11:45AM **Wall Shear Stress Topological Skeleton Analysis in Image-Based Stented Coronary Bifurcation Models**
Valentina Mazzi[1], Claudio Chiastra[1], Diego Gallo[1], Umberto Morbiducci[1]
[1]Politecnico di Torino

12:00PM **Harmonic Distortion as a Noninvasive Means to Assess Blood Pressure Waveform and Arterial Stiffness**
Nicholas Milkovich[1], Anastasia Gkousioudi[1], Francesca Seta[1], Bela Suki[1], Yanhang Zhang[1]
[1]Boston University

12:15PM ***In Vitro* Assessment of the Effects of Cardiac Output and Valve Orientation on Bioprosthetic Pulmonary Valve Hemodynamics**
Nicole K. Schiavone[1], Christopher J. Elkins[1], Doff B. McElhinney[1], John K. Eaton[1], Alison L. Marsden[1]
[1]Stanford University

Thursday, June 17	**1:00PM – 2:30PM EDT**

Cardiac Function and Modeling

Saddle Ridge

Session Chair: Jonathan Wenk, University of Kentucky
Session Chair: **Anna Grosberg,** University of California, Irvine

1:00PM **Multiscale Model of Heart Growth During Pregnancy: Integrating Mechanical and Hormonal Signaling**
Kyoko Yoshida[1], Jeffrey Saucerman[1], Jeffrey Holmes[2]
[1]University of Virginia, [2]University of Alabama at Birmingham

1:13PM **ATP Utilization During Generation and Maintenance of Contractile Stress in Striated Muscle**
Andrew Schmidt[1], Alexander Grosberg[2], Anna Grosberg[1]
[1]University of California, Irvine, [2]New York University

1:26PM **Multiscale Modeling of LV Growth Under Autonomic Regulation of Baroreflex Feedback Loop**
Hossein Sharifi[1], Charles Mann[1], K Alexus Rockward[1], Kenneth Campbell[1], Jonathan Wenk[1]
[1]University of Kentucky

Copyright 2021 SB³C Foundation, Inc.

1:39PM **Histo-Mechanics of the Passive Right Ventricular Myocardium**
Sotirios Kakaletsis[1], Gabriella P. Sugerman[1], Tomasz Jazwiec[2], Marcin Malinowski[2], Tomasz A. Timek[2], Manuel K. Rausch[1]
[1]University of Texas at Austin, [2]Cardiothoracic Surgery Spectrum Health

1:52PM **Sex Differences in Right Ventricular Functional Remodeling in an Animal Model of Pulmonary Arterial Hypertension**
Ethan Kwan[1], Daniela Velez-Rendon[2], Hao Mu[1], Daniela Valdez-Jasso[1]
[1]University of California San Diego, [2]University of Illinois at Chicago

2:05PM **Evaluation of Constrained Mixture Theory on Cell-Sparse Systems: Application to Cerebral Aneurysms**
Elizabeth Shih[1], Victor Barocas[1], Patrick Alford[1]
[1]University of Minnesota – Twin Cities

Thursday, June 17	**1:00PM – 2:30PM EDT**

Cardiovascular Design, Devices and Imaging

Mud Springs

Session Chair: Choon Hwai Yap, Imperial College London
Session Chair: **Caitriona Lally,** Trinity College Dublin

1:00PM **Annular Holding Strength and Microstructure in a Diseased Animal Model: An *Ex Vivo* Study**
Sanchita Bhat[1], Beatrice Ncho[1], Md. Tausif Salim[1], Emma Hazenberg[1], Dharani Balakumar[1], Andrew Siefert[1], Robert Gorman[2], Joseph Gorman[2], Ajit Yoganathan[1]
[1]Georgia Institute of Technology, [2]University of Pennsylvania

1:13PM **Made to Measure: 3D Printing Patient Specific Paediatric Stents**
Orla McGee[1], Sam Geraghty[1], Celia Hughes[1], Parastoo Jamshidi[2], Damien Kenny[3], Moataz Attallah[2], Caitriona Lally[1]
[1]Trinity College Dublin, [2]University of Birmingham, [3]Our Lady's Hospital, Crumlin

1:26PM **Hemodynamic Diversities Between Four Stent Graft Systems Via Patient-Based Simulations**
Anastasios Raptis[1], Michalis Xenos[2], George Kouvelos[3], Konstantinos Spanos[3], Athanasios Giannoukas[3], Miltiadis Matsagkas[3]
[1]Institute of Vascular Diseases, Larissa, [2]University of Ioannina, [3]University of Thessaly, Larissa

1:39PM **Experimental Framework for MRI-Based Measurement of Myocardial Stiffness in 3D-Printed Heart Phantoms**
Fikunwa Kolawole[1], Tyler Cork[1], Michael Loecher[1], Seraina Dual[1], Marc Levenston[1], Daniel Ennis[1]
[1]Stanford University

Copyright 2021 SB³C Foundation, Inc.

1:52PM **Factors Explaining the Differences in 2D and 3D Fetal Echocardiography Strain Measurements**
Meifeng Ren[1], Wei Xuan Chan[1], Aimee Armstrong[2], Andreas Tulzer[3], Gerald Tulzer[3], Martin Lindsay Buist[1], Choon Hwai Yap[4]
[1]National University of Singapore, [2]The Heart Center, Nationwide Children's Hospital, Columbus, Ohio, [3]Dept of Pediatric Cardiology, Kepler University Hospital, Linz, [4]Imperial College London

2:05PM **Hypertrophic Cardiomyopathy Progression Characterized via Spatiotemporal Strain Mapping from 4D Ultrasound**
Frederick W. Damen[1], Daniel P. Gramling[1], Craig J. Goergen[1]
[1]Purdue University

Thursday, June 17	**1:00PM – 2:30PM EDT**

PhD Student Paper Competition 6: Mechanobiology and Musculoskeletal Tissue Engineering

Mogul Madness

Session Chair: Brianne Connizzo, Boston University
Session Chair: **Ryan Pedrigi**, University of Nebraska-Lincoln

1:00PM **Slow Stretch Mirroring ACL Growth Rates Drives Zonal Ligament-To-Bone Enthesis Maturation**
Ethan Brown[1], Jennifer Puetzer[1]
[1]Virginia Commonwealth University

1:15PM **Unilateral, Daily Bouts of Muscle Loading Leads to Mineral and Extracellular Adaptation of the Immature Achilles Enthesis in Mice**
Elahe Ganji[1], Bill Duncan[1], Angela Livingston[1], Noelle Whyte[2], Matthew Stepanovich[2], Megan Killian[2]
[1]University of Delaware, [2] University of Michigan

1:30PM **Mechano-Regulation of Embryonic Meniscus Development**
Tonia Tsinman[1], Xi Jiang[1], Saima Ahmed[2], Aurelie Levillain[2], Yuming Huang[2], Eiki Koyama[3], Niamh Nowlan[2], Nathaniel Dyment[1], Robert Mauck[1]
[1]University of Pennsylvania, [2]Imperial College of London, [3]Children's Hospital of Philadelphia

1:45PM **Targeting Hedgehog Signaling to Improve Zonal Tendon-to-bone Repair**
Timur Kamalitdinov[1], Keitaro Fujino[1], Xi Jiang[1], Mary Kate Evans[1], Miltiadis Zgonis[1], Andrew Kuntz[1], Nathaniel Dyment[1]
[1]University of Pennsylvania

2:00PM **Curvature Sensing IRSp53 Is Critical for Migrational Persistence in Cells Crawling On Suspended Nanofibers**
Apratim Mukherjee[1], Bahareh Behkam[1], Shiro Suetsugu[2], Amrinder Nain[1]
[1]Virginia Tech, [2]Nara Institute of Science and Technology

Copyright 2021 SB³C Foundation, Inc.

2:15PM **Mechanical Stimulation Mediates the Changes in Multiscale Tendon Mechanics Observed During Embryonic Development**
Benjamin Peterson[1], Spencer Szczesny[1]
[1]Pennsylvania State University

Poster Session

Poster Session IV	Thursday, June 17, 2:30PM – 4:00PM EDT

Posters: Computational and Experimental Biofluid Mechanics II

Aspen Glade

Session Chair: John LaDisa, Marquette University
Session Chair: Alejandro Roldan-Alzate, University of Wisconsin-Madison

Validation of Hepatic Factor Computational Fluid Dynamics Simulations for Pre-Surgical Planning
Reza Rasooli[1], K. Banu Kose[2], S. Samaneh Lashkarinia[1], Kerem Pekkan[1]
[1]Koc University, [2]Istanbul Medipol University

Automated Estimation of Patient-Specific Boundary Conditions for Cardiovascular Simulations: An Optimal Control Approach
Elisa Fevola[1], Francesco Ballarin[2], Laura Jimenez-Juan[3], Stephen Fremes[3], Piero Triverio[4], Stefano Grivet-Talocia[1], Gianluigi Rozza[2]
[1]Politecnico di Torino, [2]SISSA - International School for Advanced Studies, [4]St Michael's Hospital and Sunnybrook Research Institute, [4]University of Toronto

Computational Assessment of a Novel Design of Trileaflet Mechanical Heart Valve Implanted in Aortic Position
Syed Samar Abbas[1], Iman Borazjani[1]
[1]Texas A&M University

Characterizing the Local Resistance and Inertance of Aneurysm Segment to Study the Changes Induced by Flow Diverters in 0D Brain Model
Sara Hadad[1], Fernando Mut[1], Juan R. Cebral[1]
[1]George Mason University

Effect of Blood Pressure Conditions on Transcatheter Aortic Valve Performance and Coronary Flow
Brennan Vogl[1], Rajat Gadhave[1], Mohamad Alkhouli[2], Scott Lilly[3], Hoda Hatoum[1]
[1]Michigan Technological University, [2]Mayo Clinic, [3]The Ohio State University

A Computational Investigation of the Impact of Graft Geometry on Hemodynamic Performance for a Right-Heart Pump Anastomosis
Nicolas Tobin[1], Bryan Good[1], William Weiss[2], Keefe Manning[1]
[1]The Pennsylvania State University, [2]Penn State Hershey Medical Center

Copyright 2021 SB³C Foundation, Inc.

Effect of Postural Adjustment and Repositioning on Contact Penetrations in Human Body Models
Juliette Caffrey[1], Casey Costa[1], Wade von Kleeck[1], Ashely Weaver[1], Jason Hallman[2], F. Scott Gayzik[1]
[1]Wake Forest University, [2]Toyota Motor Eng. & Mfg.

Pre-Surgical Planning of Femoropopliteal Bypass Operation Based on Patient Specific *In Silico* Simulation
K. Banu Kose[1], Muhammed Bayram[2], Cagdas Topel[2], Senol Piskin[3]
[1]Medipol University, [2]Istanbul Mehmet Akif Ersoy Thoracic and Cardiovascular Surgery Training and Research Hospital, [3]Istinye University

The Effect of Aorta Shape on Type a Dissection Risk
Jessica Williams[1], David Marlevi[2], Marie Billaud[1], Thomas Gleason[1], Elazer Edelman[2]
[1]Brigham and Women's Hospital, [2]Massachusetts Institute of Technology

Computational Analysis of Quantitative Echocardiographic Assessments of Functional Mitral Regurgitation: Vena Contracta Area (VCA) Method
Tongran Qin[1], Andres Caballero[1], Rebecca Hahn[2], Raymond McKay[3], Wei Sun[1]
[1]Georgia Institute of Technology, [2]Columbia University Medical Center, [3]The Hartford Hospital

Significance of Gags in Unconfined Compression Response of Posterior Porcine Sclera
Anshul Bhardwaj[1], Hamed Hatami-Marbini[1]
[1]University of Illinois at Chicago

Posters: Soft Tissue Biomechanics

Aspen Glade

Session Chair: Thao (Vicky) Nguyen, Johns Hopkins University
Session Chair: Kristin Myers, Columbia University

The Effect of Permeability Boundary Conditions on the Reserve Zone Chondrocyte Subjected to Different Loading Rates
Masumeh Kazemi[1], John Williams[1]
[1]University of Memphis

A Continuum Mechanics Approach to Model Stiffness Sensing by Smooth Muscle Cells
Ali Akbar Karkhaneh Yousefi[1], Claudie Petit[1], Stephane Avril[1]
[1]Mines Saint-Etienne, Université de Lyon

Tissue Growth and Resorption Finite Element Model to Evaluate Expanders That Aid in Cleft Palate Repair
Tyler Gathman[1], Katherine Brought[2], Robert Tibesar[1], Arthur Erdman[1], David Nedrelow[1]
[1]University of Minnesota, [2]Iowa State University

Mechanical Testing of Type II Collagen Networks: Towards Modulating Mechanics, Identifying Single-Fiber Properties, and Establishing Multiscale Models
Phoebe Szarek[1], David M. Pierce[1]
[1]University of Connecticut

Copyright 2021 SB³C Foundation, Inc.

Spatial Heterogeneity of the White Matter Stiffness in the Corpus Callosum of the Mouse Brain
Xuesong Zhang[1], Johannes Weickenmeier[1]
[1]Stevens Institute of Technology

A Volumetric Growth and Remodeling Framework Towards Predicting the Progression of Osteoarthritis in Articular Cartilage
Muhammed M. Rahman[1], Thomas S. E. Öst[2], Corey P. Neu[3], David M. Pierce[1]
[1]University of Connecticut, [2]FOI Swedish Defense Research Agency, [3]University of Colorado Boulder

Lung Lobar Sliding Helps Reduce Parenchymal Distortion During Breathing
Adam Galloy[1], Ryan Amelon[1], Joseph Reinhardt[1], Madhavan Raghavan[1]
[1]University of Iowa

Numerically Modelling Skin-PPE Interaction to Reduce Injury in Healthcare Workers During the COVID-19 Pandemic
Rikeen Jobanputra[1], Sravani Royyuru[1], Jack Hayes[1], Marc Masen[1]
[1]Imperial College London

On the Characterization of Embryonic Curvatures Using Bezier Curves
Ashok Ramasubramanian[1]
[1]Union College

Specimen-Specific Fiber-Based Modeling and Simulation of Sclera Collagen Fiber Microstructure and Biomechanics
Fengting Ji[1], Manik Bansal[1], Bingrui Wang[2], Yi Hua[1], Felix Matuschke[3], Markus Axer[3], Ian Sigal[1]
[1]University of Pittsburgh, [2]Southwest Jiaotong University, [3]Forschungszentrum Jülich GmbH

The Anisotropic Mechanical Properties of Human Uterus
Shuyang Fang[1], James McLean[1], Joy Vink[1], Christine Hendon[1], Kristin Myers[1]
[1]Columbia University

Implementing Variable-Stiffness Springs for Modeling the Viscoelastic Behavior of the Porcine Urinary Bladder
Tyler Tuttle[1], Sara Roccabianca[1]
[1]Michigan State University

A Nonlinear Fibrous Viscoelastic Model Describes the Experimental Tensile Material Behavior of Human Cervix
Lei Shi[1], Joy Vink[1], Ronald Wapner[1], Kristin Myers[1]
[1]Columbia University

Investigating Conforming and Nonconforming Meshes in Human Lamina Cribrosa Subdomain Simulations
Hirut Kollech[1], Jonathan Vande Geest[1]
[1]University of Pittsburgh

Copyright 2021 SB³C Foundation, Inc.

A Two-Scale Homogenization Scheme for Saturated Porous Media in Three Dimensions
Ashkan Almasi[1], Tim Ricken[2], David M. Pierce[1]
[1]University of Connecticut, [2]University of Stuttgart

Probing the Mechanical Properties of Chick Embryos Using Atomic Force Microscopy
Joel Lefever[1], Jack Edson[1], Ashok Ramasubramanian[1]
[1]Union College

Changes to Micturition Patterns and Urinary Bladder's Extracellular Matrix Mechanical Behavior in an Animal Model of Radiation Cystitis
Marissa Grobbel[1], Bernadette Zwaans[2], Elijah Ward[2], Laura Lamb[2], Sara Roccabianca[1]
[1]Michigan State University, [2]Beaumont Health

Modeling the Human Lens Capsule with Implanted Accommodative Intraocular Lens
Kurt Ameku[1], Ryan Pedrigi[1]
[1]University of Nebraska-Lincoln

Crosslinks and Toughness of Gelatin Hydrogels for Tissue Engineering
Anshul Shrivastava[1], Namrata Gundiah[1]
[1]Indian Institute of Science, Bengaluru

Ocular Biomechanics due to the Ground Blast Reinforcement of an Improvised Explosive Device at Various Heights
Alireza Karimi[1], Reza Razaghi[2], Christopher A Girkin[1], J. Crawford Downs[1]
[1]University of Alabama at Birmingham, [2]Research Department, Heel of Scene Ltd., Tokyo

Parallel Stage Mechanism for Image Guided and Targeted MR Elastography
Efe Ozkaya[1], Waiman Meinhold[2], Derek Petti[1], Emily Triolo[1], Paul Kennedy[3], Lazar Fleysher[3], Jun Ueda[2], Mehmet Kurt[1]
[1]Stevens Institute of Technology, [2]Georgia Institute of Technology, [3]BioMedical Engineering and Imaging Institute

Development of a Method to Quantify Elastin Content in Large Datasets of Bladder Tissue Histology with Machine Learning Algorithm
Eli Broemer[1], Sara Roccabianca[1]
[1]Michigan State University

Effect of Stent Orientation on Aortic Root Stress during Transcatheter Aortic Valve Deployment: A Computational Study
Atefeh Razavi[1], Srikrishna SivaKumar[1], Breandan Yeats[1], Vinod Thourani[2], Venkateshwar Polsani[2], Pradeep Yadav[2], Lakshmi Prasad Dasi[1]
[1]Georgia Institute of Technology, [2]Piedmont Heart Institute

Decoupling Hydrostatic and Deviatoric Strain Energy Density in Biomaterials with Poisson's Ratio Larger Than 0.5
Amevi Semodji[1], Katherine Hollar[1], Gunes Uzer[1], Trevor Lujan[1]
[1]Boise State University

Copyright 2021 SB³C Foundation, Inc.

Effect of Region and Direction on Meniscus Elasticity as Measured by Atomic Force Microscopy
Kevin Orton[1], Wyndham Batchelor[1], Noel Ziebarth[1], Francesco Travascio[1], Alicia Jackson[1]
[1]University of Miami

Stress and Strain Distribution Analysis of Specimen-Specific Interweaved Fiber Sclera Model Under Equi-Biaxial Strain
Manik Bansal[1], Fengting Ji[1], Yi Hua[1], Fuqiang Zhong[1], Ian A. Sigal[1]
[1]University of Pittsburgh

Effect of Temperature on Equilibrium Compressive Modulus of Immature Bovine Articular Cartilage
C.V. Sise[1], Kimberly Kroupa[1], Jiashuai Fan[1], Clark Hung[1], Sinisa Vukelic[1], Gerard Ateshian1
[1]Columbia University

Inverse Finite Element Modeling of *Ex-Vivo* Organ-Scale Porcine Lung Based on 3d Digital Image Correlation and Controlled Pressure-Volume Loading
Mohammad Maghsoudi-Ganjeh[1], Crystal Mariano[1], Samaneh Sattari[1], Mona Eskandari[1]
[1]Univeristy of California-Riverside

Energy Dissipation in the Meniscus: A Parametric Study on Tissue Properties and Mechanical Loading Conditions
Massimiliano De Rosa[1], Alicia Jackson[1], Francesco Travascio[1]
[1]University of Miami

Efficacy of Combinational Therapy on Bone Restoration and Compensation After Contusion Spinal Cord Injury
Valerie Lallo[1], Michael Feeley[1], Anita Singh[1]
[1]Widener University

The Role of Glycosaminoglycans in Anterior and Posterior Scleral Swelling and Tensile Behavior
Mohammad Pachenari[1], Hamed Hatami-Marbini[1]
[1]University of Illinois at Chicago

Effects of Covid-19 Inflammation on the Regional Behavior of the Lung: A Computational Study
Sunder Neelakantan[1], Hamed Babaei[1], Reza Avazmohammadi[1]
[1]Texas A&M University

It Takes Both: on the Protein Interactions of Neurofibrillary Tangles and Amyloid Beta Plaques in Alzheimer's Disease
Trisha Gollamudi[1], Shima Jalalian[1], Johannes Weickenmeier[1]
[1]Stevens Institute of Technology

Development of a Novel Testing System to Evaluate Microscale Mechanics at the Vitreoretinal Interface
Joseph Phillips[1], Brittany Coats[1]
[1]University of Utah

Copyright 2021 SB³C Foundation, Inc.

Posters: Tissue Engineering

Aspen Glade

Session Chair: Feng Xu, Xi'an Jiaotong University

Methacrylated Recombinant Collagen Peptide (RCP-MA) As Collagen Mimicking 3D Hydrogel Model for Cardiac Tissue Engineering
Dylan Mostert[1], Ignasi Jorba[1], Leda Klouda[1], Nicholas Kurniawan[1], Carlijn Bouten[1]
[1]Eindhoven University of Technology

Characterization of Oxidatively Responsive Thiol-Ene Networks for Tissue Engineering Applications
Tyler Touchet[1], Samuel Briggs[1], Lance Graul[1], Duncan Maitland[1]
[1]Texas A&M University

Characterization of an Electrospun Polyurethane with Tunable Chemistry and Thiol-ene Crosslinking for Biomedical Applications
Samuel Briggs[1], Scott Herting[1], Grace Fletcher[1], Mary Beth Browning Monroe[2], Duncan Maitland[1]
[1]Texas A&M University, [2]Syracuse University

Image Based Evaluation of *In Vivo Degradation* for Shape Memory Polyurethane Foam in Embolic Applications
Lance Graul[1], Thomas Cheung[1], Staci Jessen[1], Landon Nash[2], Duncan Maitland[1]
[1]Texas A&M University, [1]Shape Memory Medical Inc.

Investigating the Role of Patterned ECM Stiffness and Proliferation During Branching Morphogenesis in the Embryonic Kidney
Somdutta Chakraborty[1], Thomas Carroll[2], Victor Varner[1]
[1]The University of Texas at Dallas, [2]University of Texas Southwestern Medical Center

Computer-Aided Molecular Design of Water Compatible Monomer for Dental Application
Yonas. Rufael[1], Ruben Molina[1], Farhana Abedin[1]
[1]California State Polytechnic University Pomona

A Microfluidic Approach to Create Gradients in Collagen Fiber Anisotropy
Indranil M. Joshi[1], Mehran Mansouri[1], Adeel Ahmed[1], Steven W. Day[1], Vinay V. Abhyankar[1]
[1]Rochester Institute of Technology

Fabrication of 3D Printer Associated Rotatory Bioreactor for Vascular Tissue Engineered Structures
Khemraj Deshmukh[1], Arindam Bit[1], Esther Beltran[2], Kunal Mitra[3]
[1]National Institute of Technology, [2]University of Central Florida, [3]Florida Tech

Macroscale Mechanical Characterization of Heterogeneous Fibrin Gels with Varying Density
Julian Jimenez[1], Yifan Guo[1], Adrian Buganza-Tepole[1], Sarah Calve[2]
[1]Purdue University, [2]University of Colorado, Boulder

Copyright 2021 SB³C Foundation, Inc.

An *In Vitro* Model of Bone Ingrowth in a Porous Titanium Scaffold
Alyssa Oberman[1], Brett English[2], Weidong Tong[2], Glen Niebur[1]
[1]University of Notre Dame, [2]DePuy Synthes

Development of a 3D *In Vitro* Vascularized Human Skin Equivalent Utilizing Collagen/Keratin Hydrogels
Kameel Zuniga[1], Neda Ghousifam[1], Mark Van Dyke[2], Marissa Rylander[1]
[1]University of Texas at Austin, [2]University of Arizona

Development and Utilization of a Vascularized 3D-Printed *In Vitro* Physiologically Representative Skin Tissue Platform for Burn Injury Investigation
Sean Brocklehurst[1], Neda Ghousafim[1], Kameel Isaac[1], Danielle Stolley[1], M. Nichole Rylander[1]
[1]University of Texas in Austin

Accelerated Degradation of Electrospun Polycaprolactone Tissue Engineering Scaffolds Under Dynamic Loading Conditions
Emily Clement[1], Johane Bracamonte[1], Joao Soares[1]
[1]Virginia Commonwealth University

Thursday, June 17	**4:00PM – 5:30PM EDT**

Computational and Experimental Modeling of Cardiovascular Interventions

Mud Springs

Session Chair: Luke Timmins, University of Utah
Session Chair: **Jessica Oakes,** Northeastern University

4:00PM ***In Vivo* Estimation of Regional Mechanical Properties of the Aortic Wall Accounting for the Active and Passive Effect of Periaortic Structures with an Inverse Finite Element Approach**
Johane Bracamonte[1], John Wilson[1], Joao Soares[1]
[1]Virginia Commonwealth University

4:13PM **Engineering Analysis of Aortic Wall Stress and Root Dilation in the V-Shape Surgery for Ascending Aortic Aneurysms**
Hai Dong[1], Minliang Liu[1], Tongran Qin[1], Liang Liang[2], Bulat Ziganshin[3], Hesham Ellauzi[3], Mohammad Zafar[3], Sophie Jang[3], John Elefteriades[3], Wei Sun[1]
[1]Georgia Institute of Technology, [2]University of Miami, [3]Yale University

4:26PM **Impact of Flow Rate on High Frequency Flow Instabilities in Intracranial Aneurysms, with Implications for Wall Vibration**
David Bruneau[1], Mehdi Najafi[1], Thangam Natarajan[2], Kristian Valen-Sendstad[2], David Steinman[1]
[1]University of Toronto, [2]Simula Research Laboratory

4:39PM **Hemodynamic Simulations to Predict Successful vs. Unsuccessful Catheter Interventions: Proof-of-Concept and Experimental Validation in Swine**
Ryan Pewowaruk[1], Luke Lamers[1], Alejandro Roldan-Alzate[1]
[1]University of Wisconsin - Madison

Copyright 2021 SB³C Foundation, Inc.

4:52PM **A Novel Dynamic Blalock-Taussig Shunt Regulator: An *In Vitro* Study**
Milad Samaee[1], Subhadhara Shashidharan[2], Kevin Maher[3], Ajit Yoganathan[1], Lakshmi Prasad Dasi[1]
[1]Georgia Institute of Technology, [2]Emory University School of Medicine, [3]Children's Healthcare of Atlanta

5:05PM **Haemodynamic Analysis of Branched Endografts for Complex Aortic Arch Repair**
Sampad Sengupta[1], Yu Zhu[1], Mohamad Hamady[1], Yun Xu[1]
[1]Imperial College London

Thursday, June 17	**4:00PM – 5:30PM EDT**

Mechanobiology in Tissue and Cellular Engineering

Alpine Drift

Session Chair: Eno Ebong, Northeastern University
Session Chair: **Spencer Szczesny,** Penn State University

4:00PM **Tensional Homeostasis Regulates Chromatin Accessibility and Represses Matrix Degradation Pathways Through Yap/Taz**
Dakota Jones[1], Xi Jiang[1], Eddie Bonnevie[1], Elisabeth Lemmon[1], Mary Kate Evans[1], Su-Jin Heo[1], Nathaniel Dyment[1], Robert Mauck[1]
[1]University of Pennsylvania

4:13PM **Long-Term Effect of TBI-Like Shear Stimuli on Astrocytes**
Tasnim Shireen[1], Susan Hua[1]
[1]University at Buffalo SUNY

4:26PM **The Primary Cilium Regulates Mechanoresponsive Pathways in Tenocytes**
McKenzie Sup[1], Fei Fang[1], Stavros Thomopoulos[1]
[1]Columbia University

4:39PM **Mechanical Stiffness Regulates Chromatin Remodeling in Mesenchymal Stem Cells**
Samantha Kaonis[1], Soham Ghosh[1]
[1]Colorado State University

4:52PM **On the Relation Between 3D Aortic Valve Interstitial Cell Shape and Contractile Behavior**
Alex Khang[1], Quan Nguyen[1], Xinzeng Feng[1], Michael Sacks[1]
[1]The University of Texas at Austin

5:05PM **Escaping the Stiffness Trap: Adhesion Strength and Contractility Enable Metastatic Cells to Become Adurotactic**
Benjamin Yeoman[1], Gabe Shatkin[1], Pranjali Beri[1], Afsheen Banisadr[1], Parag Katira[2], Adam Engler[1]
[1]University of California, San Diego, [2]San Diego State University

Thursday, June 17	4:00PM – 5:30PM EDT

Undergraduate Design Competition Live Session

Mogul Madness

Session Chair: Michael Moreno, Texas A&M University
Session Chair: **Ted Conway,** Florida Institute of Technology

4:00PM **The Development of a Mechanized Stepped Tension Brace for Treatment of Achilles Tendonitis in Collegiate Athletes**
Sneha Jeevan[1], Jack Latella[1], Mary Murray[1]
[1]University of Pittsburgh

4:15PM **Ventilators for the Developing World**
Grace L. Bugara[1], Taylor A. Corpuz[1], Maeve X. Enright[1], John B. Fortescue[1], Laurie A. Trainer[1], Vanessa S. Zighelboim[1], Michael Jaeggli[1], Lee Makowski[1], Marc Fuller[1]
[1]Northeastern University

4:30PM **Haptic Feedback to Aid the Visually Impaired**
John C. Tereck[1], Carter M. Roper[1], Peyton D. Duersel[1], Brandon M. Jackson[1], Matthew J. Kamin[1], Dario Martelli[1]
[1]The University of Alabama

4:45PM **Automatic Reclining Car Seat**
Md Joynal Abedin[1], Mohammad Shah Jalal[1], Alex Sullivan[1], Ahmee Cho[1], El Mokhtar Majdoub[1], Ahmed Ahmed[1], Parisa Saboori[1]
[1]The City College of New York

5:00PM **DynaCon PLS**
Robert Anhalt[1], Brooke Towns[1], Peter DiNapoli[1], Sebastian Moreno[1], Warren Dixon[1], Sean Niemi[1], Kimberly Stubbs[1]
[1]University of Florida

5:15PM **The MultiFlex Catheter - A Variable Stiffness Endovascular Catheter**
Halle R. Lowe[1], Vinay D. Chandrasekaran[1], Chase M. Hartquist[1], Jin V. Lee[1], Mohammed Zayed[1], Joshua W. Osbun[1], Eric C. Leuthardt[1], Michael Talcott[1], Guy M. Genin[1]
[1]Washington University in St. Louis

Thursday, June 17	4:00PM – 5:30PM EDT

Vascular Functioning and Modeling

Saddle Ridge

Session Chair: Hai-Chao Han, University of Texas, San Antonio
Session Chair: **Chiara Bellini,** Northeastern University

Copyright 2021 SB³C Foundation, Inc.

4:00PM **Computational Modeling on Transmural Distribution of Coronary Perfusion and Myocardial Work**
Lei Fan[1], Ravi Namani[1], Jenny Choy[2], Ghassan Kassab[2], Lik Chuan Lee[1]
[1]Michigan State University, [2]California Medical Innovation Institute

4:13PM **A Probabilistic and Anisotropic Failure Metric for Risk Assessment of Ascending Thoracic Aortic Aneurysm**
Minliang Liu[1], Liang Liang[2], Qing Zou[1], Yasmeen Ismail[1], Xiaoying Lou[3], Glen Iannucci[3], Edward Chen[3], Bradley Leshnower[3], John Elefteriades[4], Wei Sun[1]
[1]Georgia Institute of Technology, [2]University of Miami, [3]Emory University, [4]Yale University

4:26PM **Bent Buckling of Arteries with Non-Circular Cross Section**
Yasamin Seddighi[1], Hai-Chao Han[1]
[1]University of Texas San Antonio

4:39PM **Differential propensity of dissection along the aorta**
Ehsan Ban[1], Cristina Cavinato[1], Jay Humphrey[1]
[1]Yale University

4:52PM **AI-Accelerated Multiscale Modeling for Multi-Platelet Aggregation at Millisecond And Molecular Resolutions**
Peng Zhang[1], Yicong Zhu[1], Changnian Han[1], Jawaad Sheriff[1], Yuefan Deng[1], Danny Bluestein[1]
[1]Stony Brook University

5:05PM **Coupling NO-cGMP-PKG Chemical Pathway with Hemodynamics Model to Understand Regulation of Vascular Tone in the Pulmonary Vascular Tree**
Haritha Mullagura[1], Vasilina Filonova[2], Hamidreza Gharahi[2], C. Alberto Figueroa[2], Seungik Baek[1]
[1]Michigan State University, [2]University of Michigan

INTRODUCTION

Nanocarriers (NCs) accumulate in tumors through the enhanced permeability and retention (EPR) effect [1]. As NCs and other nano-sized therapies are in clinical practice, translatable strategies that increase the magnitude of their accumulation and penetration while reducing heterogeneity of microdistribution may improve treatment outcomes. One such strategy to increase and conform NC penetration and accumulation involves re-engineering the non-cancerous components of the tumor, which collectively are known as the tumor microenvironment (TME), to reach normal levels [2]. Without normalization of TME, tumor vessel function is compromised because the TME promotes vessel leakiness and compression [2]. Dexamethasone is a glucocorticoid steroid with anti-inflammatory properties used to treat many diseases, including cancer, in which it helps manage various side effects of chemo-, radio-, and immunotherapies. Here, our research objective was to investigate the TME re-engineering effects of dexamethasone in metastatic murine breast cancer (BC). We found that low dose dexamethasone normalizes vessels and the extracellular matrix, thereby reducing interstitial fluid pressure, tissue stiffness, and solid stress [3]. Also, dexamethasone increases the tumor accumulation and efficacy of ~30 nm polymeric micelles containing cisplatin (CDDP/m) against murine models of primary BC and spontaneous BC lung metastasis, which also feature a TME with abnormal mechanical properties. These results suggest that pretreatment with dexamethasone before NC administration could increase efficacy against primary tumors and metastases.

METHODS

Orthotopic models for murine mammary tumors were generated by implantation of $5x10^4$ 4T1 and 4T1-luc cancer cells in 40 µl of serum-free medium into the third mammary fat pad of 6-week old BALB/c female mice. Treatment was initiated when tumors reached ~90mm^3. Dexamethasone at 3mg/kg was administered daily from days 0 through 8. CDDP/m at 1mg/kg was administered by retro-orbital injection during sedation with isoflurane on days 2, 5, and 8. The tumors were measured every 1-2 days using calipers by an investigator blind of the treatment groups.

RESULTS

Vascular endothelial growth factor (VEGF) is the major driver of the pathophysiology of tumor vessels and blocking it promotes vascular normalization [4]. Dexamethasone reduces VEGF expression in murine models of brain cancer [5], so we hypothesized it would do so in BC. We treated immunocompetent BALB/c mice bearing orthotopic 4T1 BC daily for 4 days with 3 or 30 mg/kg dexamethasone. Dexamethasone reduced the levels of VEGF as assessed by immunofluorescence staining of tumor sections (Figure 1A,B). We next tested the effect of dexamethasone on vessel structure by using histology. Dexamethasone at 30 mg/kg reduced the microvessel density (Figure 1C,D), whereas dexamethasone at 3 mg/kg avoided pruning yet increased vessel maturity, as indicated by the association of NG2+ pericytes with CD31+ endothelial cells (Figure 1E,F).

We then tested whether dexamethasone re-engineers the tumor extracellular matrix (ECM). We focused on collagen I and hyaluronan because they have been identified as matrix components that contribute to solid stress accumulation and vessel compression. With histological staining we found that dexamethasone reduced levels of hyaluronan (Figure 2A,B) and not collagen I (Figure 2A,C) in the tumors. Based on these results, we tested whether the mechanical TME was normalized. We found that 30 mg/kg dexamethasone reduced tissue stiffness, whereas 3 mg/kg only produced a trend (Figure 2D). On the other hand, by using the "tumor-opening" assay, which indicates the amount of

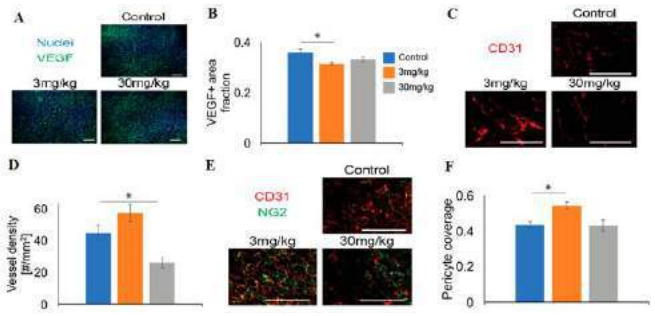

Figure 1: Dexamethasone induces vascular normalization. (A) Representative images of VEGF (green) with nuclear counterstain (blue) immunofluorescence. (B) Quantification of area fraction positive for VEGF immunofluorescence staining. (C) Representative images of CD31 (red) immunofluorescence marking tumor vessels. (D) Immunohistological quantification of the tumor vessel density, as assessed by the number of vessels normalized to the image area. (E) Representative images of CD31 (red) and NG2 (green) immunofluorescence marking endothelial cells and pericytes, respectively. Yellow areas indicate colocalization of both cell types. (F) Quantification of the pericyte coverage of microvessels, as assessed by the fraction of CD31-positive staining area that is also positive for NG2.

residual solid stress held within the tumor tissue by the amount it opens after cutting, we confirmed that both doses reduced solid stress (Figure 2E). A larger opening is associated with more solid stress. Furthermore, we found that dexamethasone reduces interstitial fluid pressure in 4T1 tumors (Figure 2F). Thus, the results from the histology, and mechanical experiments suggest that dexamethasone re-engineers the ECM in tumors by reducing hyaluronan levels.

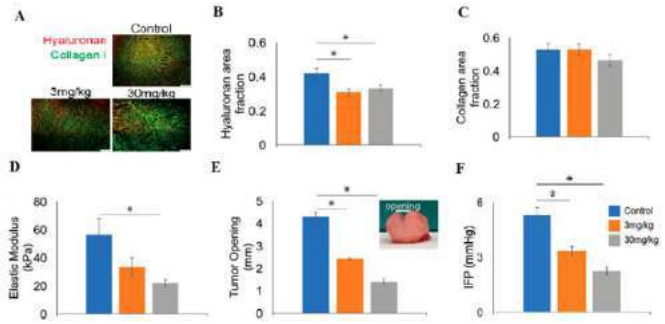

Figure 2: Dexamethasone induces ECM normalization. (A) Representative images of hyaluronan (red) and collagen I (green) immunofluorescence. Yellow areas indicate colocalization of both ECM components. (B) Quantification of area fraction positive for hyaluronan immunofluorescence. (C) Quantification of area fraction positive for collagen I immunofluorescence. (D) Tumor tissue elastic modulus, which is a measure of stiffness. (E) Solid stress levels, which was assessed by length of the tumor opening after cutting the tissue. (F) Interstitial Fluid Pressure levels.

After confirming that dexamethasone normalizes vascular structure, ECM, and vessel function, we next hypothesized that dexamethasone would affect the rate NCs transport across tumor vessels and penetrate toward cancer cells. Thus, to test our hypothesis, we used CDDP/m, which are ~30 nm. Firstly, we tested the therapies in a primary tumor growth delay study against orthotopic 4T1-luc tumors, with an end point of days until 1000 mm^3 tumor volume. We found that CDDP/m (1 mg/kg) monotherapy increased the number of days for the tumors to reach 1000 mm^3 compared to control (Figure 3A). Combining dexamethasone (3mg/kg) with CDDP/m (1 mg/kg) significantly increased this time period compared to that with CDDP/m monotherapy (Figure 3A). Thus, dexamethasone enhances the efficacy of CDDP/m against 4T1 primary tumors.

Next, we investigated the effects of the combination of dexamethasone and CDDP/m on lung metastases. To mimic the clinical treatment protocol of metastatic disease and produce spontaneous metastases, we surgically removed 4T1 primary BC tumors when they reached ~300 mm^3. Then, after waiting 2 days post-surgery for the mice to rest and metastases to develop further, we administered two cycles of CDDP/m with daily dexamethasone. In these mice, we found that only the combination of dexamethasone (3mg/kg) and CDDP/m (1mg/kg) provided a survival advantage (Figure 3B). Thus, dexamethasone increases the efficacy of CDDP/m against BC pulmonary metastasis.

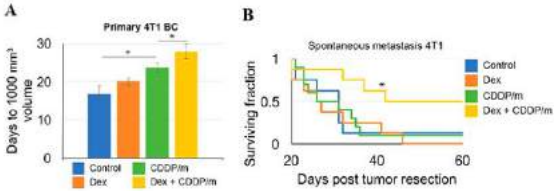

Figure 3: Dexamethasone increases the efficacy of 30 nm CDDP/m in 4T1 tumors. (A) Quantification of tumor growth rate. Graph of the number of days between treatment initiation and 1000 mm^3 tumor volume. When tumors reached ~90 mm^3, they were size- and time-matched into control, dexamethasone monotherapy, CDDP/m monotherapy, and dexamethasone and CDDP/m combination. (B) Animal survival in mice with spontaneous metastases, which developed after surgical primary tumor resection at 300 mm^3. Mice were size- and time-matched into control, dexamethasone monotherapy CDDP/m monotherapy, and dexamethasone and CDDP/m combination.

DISCUSSION

Our results demonstrate the value of TME normalization in improving the efficacy of NCs. By identifying dexamethasone as a therapy that re-engineers both the ECM and vessels, we confirm that the combination of normalization strategies is effective in potentiating the efficacy of cytotoxic NCs in models of metastatic BC.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is an emerging minimally invasive intervention for patients with aortic stenosis (AS) *across a broad risk spectrum* (1). Despite recent improvements in the design of transcatheter valves and implantation techniques, paravalvular leak (PVL, leak around the prosthesis) remains a foremost complication and an independent predictor of mortality (2). As Pibarot (2019) stated *"Paravalvular regurgitation is considered the main Achilles' heel of transcatheter aortic valve replacement"* (3). It is important to note that mild PVL arises in 20% to 80% of patients, whereas moderate and severe PVL happen in 5% to 22% of them (4). As use of TAVR increase, we must advance our understanding of its interactions with diseases of other valves and the ventricular state. However, despite the prevalence of PVL, the quantitative understanding of the interplay between pre-existing valvular pathologies, PVL, LV and post-TAVR recovery is inadequate.

"Cardiology is flow"(5). Abnormal fluid dynamics lead to initiation and advancement of cardiovascular disease. Such abnormalities are often displayed by disturbed flow, altered biomechanical forces, and in some cases a rise in the heart workload. There has thus been an emergent call by many for quantitative investigations of hemodynamics that take into account the interactive coupling of the valves, left ventricle, and the arterial system (6–8). This is what we seek to do.

In this study, we developed a Doppler-based and patient-specific lumped-parameter modeling framework, that takes interactions of the valves, left ventricle and arterial system into account, to estimate the LV workload (*global hemodynamics)* non-invasively. In addition to the global hemodynamics, we quantified the effect of PVL on the 3-D flow structures in the LV and LV outflow tract (*local hemodynamics*) using a computational fluid mechanics and lumped parameter modeling framework based on and correlated with clinically measured hemodynamic metrics and images in both pre and post-TAVR states.

METHODS

Global hemodynamics (LV workload). We developed a patient-specific lumped-parameter model that considers interactions of the aortic valve, LV and arterial system to estimate the LV workload non-invasively in both pre and post intervention states. The model uses a limited number of input parameters all of which can be reliably obtained using Doppler echocardiography and a sphygmomanometer (9).

Local hemodynamics (blood flow dynamics). We developed a fluid-solid interaction and lumped parameter modeling framework to calculate 3-D blood flow dynamics in the LV. As described above, the lumped parameter model in this framework used few input parameters all of which can be measured using Doppler echocardiography and a sphygmomanometer.

RESULTS

LV workload (global hemodynamics). The LV workload is an effective metric of the LV load and clinical state and represents the energy that the ventricle delivers to the blood during ejection plus the energy necessary to overcome the viscoelastic properties of the myocardium itself. Pre-TAVR, untreated AS increased the load on the LV due to the augmented flow resistance which caused a LV pressure overload. Although the flow resistance and consequently the LV pressure decreased greatly post TAVR, the LV workload did not improve because PVL contributed to a switch from a ventricular pressure overload to a ventricular volume overload (Figure 1).

SB³C2021-003
Copyright 2021 SB³C Foundation, Inc.

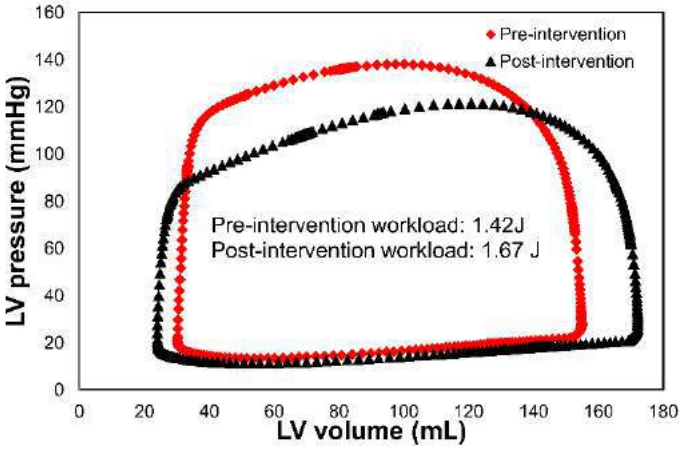

Figure 1. LV workloads in a sample patient between baseline and 90 days post-TAVR. *Pre-TAVR:* brachial pressures: 75 - 141 mmHg, aortic valve effective orifice area: 1.4 cm^2, no aortic regurgitation, moderate mitral regurgitation, LV stroke volume: 85 mL; *Post-TAVR*: brachial pressures: 60 - 123 mmHg, aortic valve effective orifice area: 2.3 cm^2, mild-moderate PVL, moderate-severe mitral regurgitation, LV stroke volume: 100 mL. *LV workload did not improve by TAVR.*

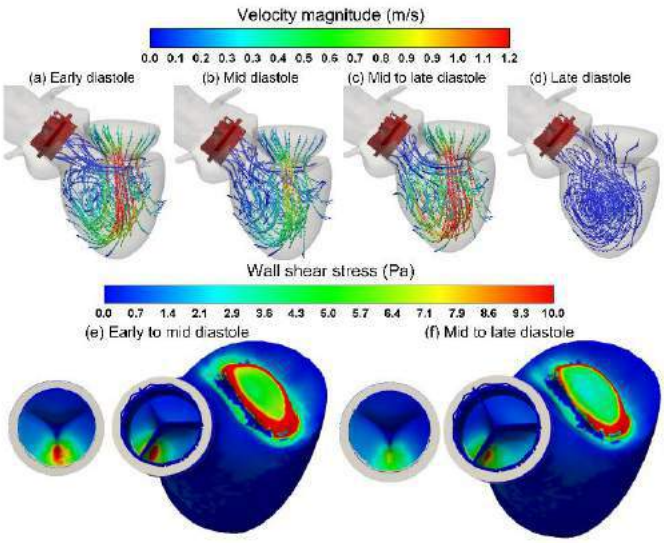

Figure 2. Flow modeling in a LV with mild PVL in a sample patient. (a) Velocity vector during diastole. (b) Wall shear stress during diastole.

LV fluid dynamics (local hemodynamics). During filling of the healthy heart, the blood entering the LV through the mitral valve forms a vortex that minimizes energy dissipation and optimizes the pumping efficiency. The vortical structure in the LV is altered in presence of valvular and ventricular diseases. In such cases the vortex dynamics becomes less synchronized with the heart contraction than the healthy vortex ring is, and other vortices may emerge and interact with one another. PVL following TAVR substantially alters the vortical structure in the left ventricle outflow tract and LV, creating disturbed flow (Figure 2). The jets emerging from PVL orifices diverge within the LV. This unfavorable flow condition leads to high shear stresses on TAV and mitral valve leaflets (Figure 2) which can cause tissue inflammation which can ultimately lead to the mitral valve failure. Moreover, PVL, characterized by multiple jets, enters the LV chamber, directly interacts with the mitral inflow, hinders formation of normal fluid vortical structures in the LV and may worsen the mitral regurgitation post-TAVR. We observed similar flow characteristics in other patients with mild, moderate, and severe PVL.

DISCUSSION

PVL limits the benefit of TAVR: may increase the LV load, may potentially worsen MR, and worsens heart failure. MR and its exacerbation by PVL will likely play an important hindering role in success of TAVR. The findings of this study suggest that beyond routine clinical indices for hemodynamic evaluation of the valvular disease (e.g, Doppler pressure gradients), valvular and ventricular hemodynamics and their interactions should be clinically quantified and considered to better conduct the aortic valve management and treatment planning.

INTRODUCTION

Glaucoma is the second leading cause of blindness worldwide [1]. Glaucomatous damage initiates at the optic nerve head (ONH) with characteristic cupping of the ONH in advanced stages of pathology [2]. Elevated intraocular pressure (IOP) has been identified as a primary risk factor for glaucoma onset and progression. IOP-related mechanical damage of neural and connective tissues [3] play a central role in glaucoma pathophysiology. Therefore, characterization of the biomechanical response of the ONH and its surrounding tissues in response to IOP elevation may serve to further our understanding of the biomechanical contributors to glaucoma damage.

We have developed and validated a technique applying high frequency ultrasound to measure tissue deformation in the posterior eye [4] and reported ONH and peripapillary sclera (PPS) strains during IOP elevation [5]. In this study, we aimed to characterize the deformation of the peripapillary retina (PPR) to gain insights into the biomechanical response of this critical neural tissue to IOP elevation.

METHODS

Ten donor globes (20 – 74 years old, 4 male and 6 female) were obtained within 12 h postmortem from the Lion's Eye Bank of West Central Ohio (Dayton, OH, USA) in accordance with the Declaration of Helsinki.

Before inflation, extraocular tissue was removed from the globe and the optic nerve was trimmed close to the surface of the sclera for ultrasound imaging from the posterior side. Two spinal needles were inserted through the equator of the globe to secure the eye to a custom-built holder (Fig. 1A). Two 20G needles were inserted into the anterior chamber of the eye, one connected to an infusion pump (Ph.D. Ultra, Harvard Apparatus, MA) and the other to a pressure sensor (P75, Harvard Apparatus, MA) to control and record IOP.

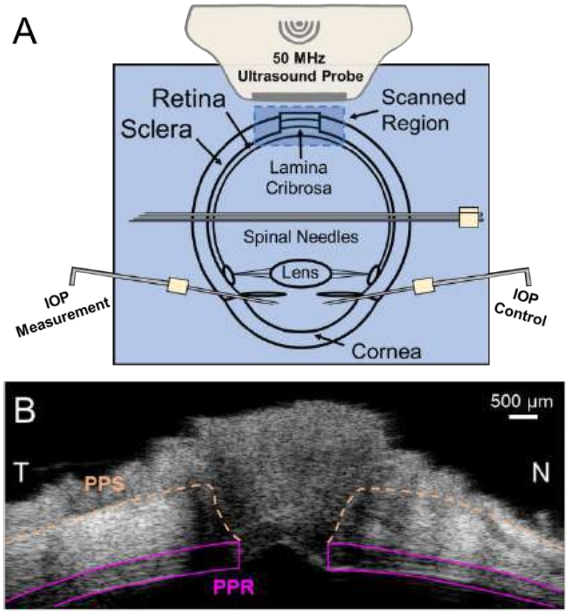

Figure 1: A) Experimental setup of human donor globe inflation with high-frequency ultrasound imaging of the ONH and peripapillary region. B) A representative ultrasound image of the scanned region along the nasal-temporal (NT) axis. PPS (dashed tan) and PPR (solid pink) segmentation are shown.

The globes were first preconditioned with 20 cycles from 5 to 30 mm Hg at 2 seconds per cycle before equilibrating at 5 mm Hg for 30

Copyright 2021 SB³C Foundation, Inc.

minutes. The inflation tests were then performed by increasing IOP from 5 to 30 mm Hg with 0.5 mmHg steps. The IOP was held constant at each IOP level for 30 seconds before ultrasound scans were acquired using a 50MHz ultrasound probe (Vevo2100, VisualSonics). Each eye was inflated twice to capture 2D scans (approximately 4 mm × 10 mm) of the posterior eye centered at the ONH along the nasal-temporal (NT) and superior-inferior (SI) axes.

A correlation-based ultrasound speckle tracking algorithm was used to compute tissue displacements [4]. Briefly, the ultrasound radiofrequency (RF) data were sampled at 1.5 µm × 19 µm (axial × lateral). A region of interest (ROI) was manually defined to include the PPS, PPR, and ONH at the reference/initial IOP. Within the ROI, the RF data were divided into kernels (75 µm × 570 µm, 50% overlap). The displacement of each kernel was computed by cross-correlation between successive RF frames within a search window. The cumulative displacement vectors were calculated with respect to the kernel location at the initial IOP.

Strains were calculated using least squares estimation based on the local displacement gradient [4]. Radial, tangential, and shear strain was obtained by coordinate transformation. PPS and PPR were defined by manual segmentation based on tissue boundaries visible in ultrasound images (Fig 1B). Strain maps were generated for each region with spline interpolation to the pixel level. Average strains in each region were obtained at IOP = 30 mmHg.

RESULTS

The average radial strain within the PPR was -0.55±0.25%, while the shear and tangential strains were 1.49±0.65% and 0.29±0.19%, respectively, at 30 mmHg. In comparison PPS had greater radial strain (-2.32±0.74%, p<0.001), less shear strain (1.13±0.32%, p=0.029), and similar levels of tangential strain (0.38±0.19%, p=0.13, Fig 2A). Exploratory analysis showed no significant differences in strains between quadrants in either PPR or PPS (Fig 2B).

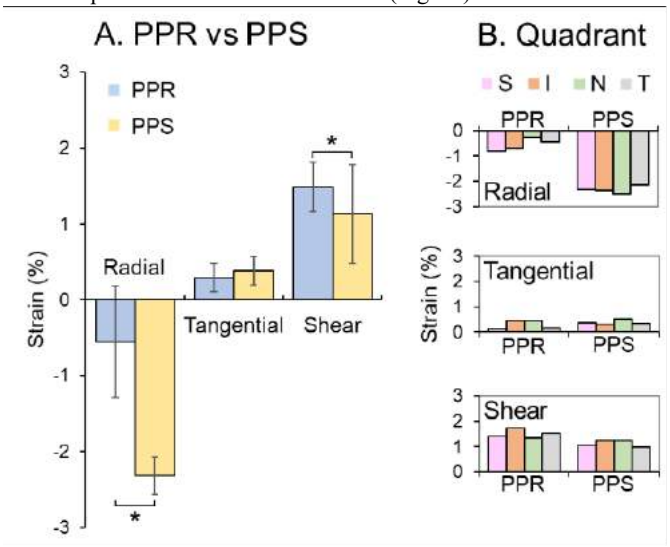

Figure 2: A) Comparisons of the radial, tangential, and shear strains between PPR and PPS at 30 mmHg (* denotes p<0.05). B) PPR and PPS strains showed no significant differences across quadrants. S: superior, I: inferior, N: nasal, T: temporal.

Localized high shear strains were observed in PPR in the region close to the ONH (up to 10%, Fig 3). In some cases, higher tangential strains were also seen in the same location of high shear, especially along the anterior boundary of the PPR.

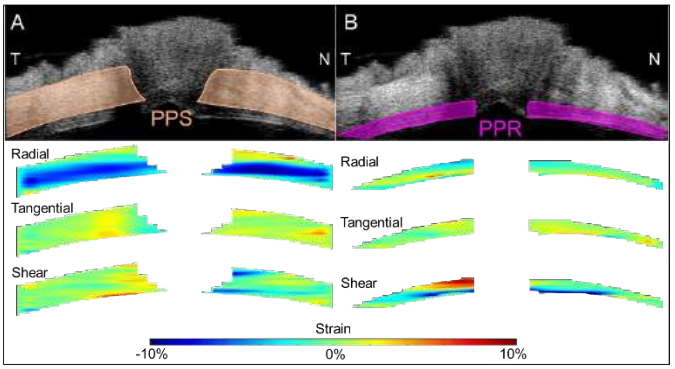

Figure 3: Radial, tangential, and shear strain maps of A) PPS (shaded in tan) and B) PPR (shaded in pink) in a representative eye at 30 mmHg.

DISCUSSION

Our results suggest that the PPR tissue mostly experienced shear strains in response to IOP elevations, with minimal radial compression and tangential stretch. Furthermore, high shear appeared to concentrate in the region close to the ONH. Although the overall PPR tangential strain was low, localized higher tangential strain was observed along the anterior surface of PPR, which may correspond to the retinal nerve fiber layer (RNFL) consisting of axons. These localized high strains could contribute toward mechanical vulnerability in these regions to IOP-related glaucomatous damage.

Interestingly, although PPR experienced minimal radial compression, the PPS had high radial compression, especially in the more anterior region adjacent to the PPR. The ability of the PPS to compress may serve as a protection for the neural PPR against large compressive impact during acute IOP rise. In contrast, PPR deformation was dominated by shear in the region close to the ONH. PPS also displayed localized shear in the ONH-PPS conjunction, suggesting that this region is likely more susceptible to mechanical damage during IOP elevation.

This study has a few limitations. The ex vivo inflation model does not fully represent the complexities of the in vivo system. Although several other mechanical stressors such as blood or cerebrospinal fluid pressure affect the ONH, IOP has been shown to be the dominant load affecting ONH stresses and strains [6]. The small sample size may also warrant future studies to verify the results.

Optic neuropathy, most notably within and around the ONH, is characteristic of glaucoma. High-frequency ultrasound has enabled us to capture the deformations of the PPR and PPS in the same eye, showing a similar shear response but different radial response. These findings may provide new insights into IOP-related mechanical insults to the neural and connective tissues in and around the ONH, where glaucomatous damage initiates.

INTRODUCTION

Failure of the annulus fibrosus (AF) due to mechanical overload can accelerate intervertebral disc (IVD) degeneration and cause debilitating pain. Previous studies suggested that fiber mechanics could largely determine AF and thus disc failure behaviors.[1-2] However, directly measuring *in situ* AF fiber mechanics (*e.g.* fiber stress and strain distributions) is challenging due to experimental limitations and can result in contradicting reported data with large variations.[2-4] Earlier joint-level studies that measured AF fiber strains under physiological axial compressions reported fiber strains that varied considerably from 3 to 55%.[3-5] Thus, despite recent advancement in experimentations, *in situ* AF fiber mechanics at joint level remains poorly understood.

Finite element models have been used to complement experimental studies, providing a powerful tool for predicting hard-to-measure, fiber-reinforced tissue mechanics. However, most IVD models employ homogenization theory and describe every AF element as a combination of fibers and matrix and are thus not capable of explicitly examining subtissue-level mechanics, such as interfibrillar stress and strain distributions.[6] To address the limitation, we previously developed a multiscale structure-based AF model, where fiber bundles and the extrafibrillar matrix were explicitly modeled to occupy separate volumes. Parameter calibration was conducted at the subtissue level using tissue subcomponent mechanical testing data (*e.g.* fiber bundles and matrix). The model was then validated at tissue level under uniaxial tension, biaxial tension, and shear.[7-8] In this study, we will employ this modeling-validation framework to evaluate *in situ* AF fiber mechanics by developing and validating a joint-level model based on discs.

METHODS

We developed the model based on bovine caudal discs using the reported geometry data.[9] The multiscale structure-based modeling-validation framework used for our tissue-level AF tissue-level models was employed (**Fig. 1A**).[7-8] Gradients in fiber orientation and solid volume fraction from inner to outer AF were described based on literature data (**Fig. 1A**–**B**).[10] The current model was created at 1:5 scale for computational efficiency; thus, preliminary work was performed to ensure that scaling did not alter model validation results. All model parameters were directly linked to physical or biochemical tissue properties, including modulus, Poisson's ratio, and fixed charge density (**Fig. 1C**), and were determined based on data in the literature.[11-14]

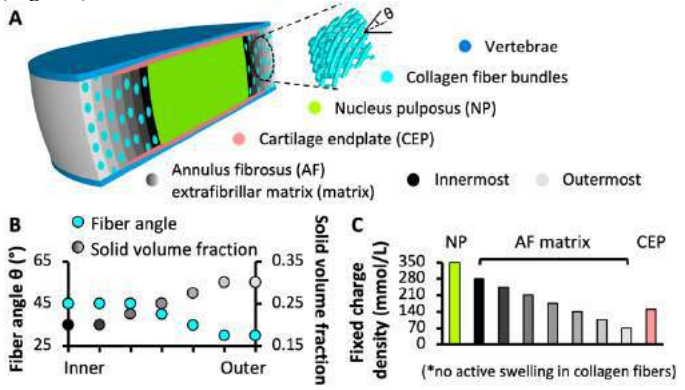

Fig. 1: (A) Disc model at 1:5 scale. (B) Annulus fibrosus structural parameters. (C) Disc fixed charge density distribution.

The model was loaded in two steps: first, the disc was allowed to swell (triphasic) in 0.15 M saline. Intradiscal pressure (IDP) was assessed as the average nucleus pulposus pressure and was compared to human IVD experimental IDP data for validation, due to the lack of IDP data from bovine discs. The second step was one of the three cases: 0.5 MPa axial compression (**Case *A***), 10 N·mm axial rotation (**Case *B***), or 0.5 MPa axial compression followed by 10 N·mm axial rotation (**Case**

Copyright 2021 SB³C Foundation, Inc.

C). Average AF fiber stretch and stress distributions were assessed at 0.5 MPa axial compression for **Case *A*** and at 10° axial rotation for **Case *B*** and ***C*** to represent the higher rotation of bovine discs, where the post-swelling configuration was considered as the reference configuration. Model-predicted compressive and torsional stiffness were normalized by geometry and validated with experimental data.

RESULTS

Across models of three different scales (1:4, 1:5, 1:6), the predicted intradiscal pressure was 0.18±0.006 MPa post-swelling and 0.48±0.006 MPa under 0.5 MPa axial compression. The predicted normalized compressive stiffness was 8.12±0.28 MPa and the predicted normalized torsional stiffness 36±8 kPa/°. These model predictions agreed well with literature (**Fig. 2**). Thus, we considered the current model valid for describing swelling, axial compression and rotation behaviors.

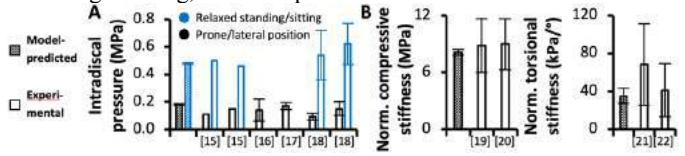

Fig. 2: Model-predicted (A) intradiscal pressure and (B) normalized (norm.) compressive and torsional stiffness vs. experimental data.

Under pure axial compression (**Case *A***), the average AF fiber stretch was ~1.05 and was consistent throughout the AF (**Fig. 3A**–black circles). Fiber stretch was comparable under pure rotation (**Case *B***), but a linear increase was observed from 1.04 in the innermost AF layer to 1.07 in the outermost layer (**Fig. 3A**–blue circles). Under combined loading (**Case *C***), the average fiber stretch nearly doubled, increasing from ~1.05 (**Case *A*** & ***B***) to ~1.10 (**Fig. 3A**–red circles).

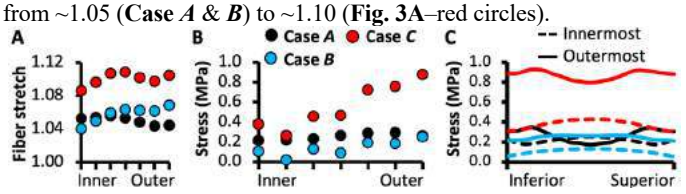

Fig. 3: Average annulus fibrosus (AF) post-loading fiber (A) stretch and (B) stress. (C) AF post-loading fiber stress profiles along the fiber length in the inner- and outermost AF layers.

Strain concentrations were observed near cartilage endplates in inner AF (**Fig. 4A**). Under pure compression, average AF fiber stress was relatively consistent throughout the AF (0.22–0.29 MPa; **Fig. 3B**–black circles). The rotation-only loading (**Case *B***) reduced fiber stress in the inner-middle AF by ~60% but did not alter the fiber stress in the outer AF (**Fig. 3B**–blue vs. black circles). Under combined loading (**Case *C***), the average fiber stress increased linearly from inner to outer AF, where the combined compression rotation resulted in a more than 1.5-fold increase in inner AF fiber stress and a more than 3-fold increase in the outer AF fiber stress (**Fig. 3B**–red; **Fig. 4**).

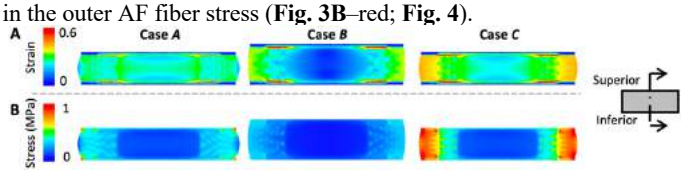

Fig. 4: Post-loading disc (A) strain and (B) stress distributions.

Fiber stress profiles were tracked along the fiber length from the superior to inferior vertebra. In all cases, peak fiber stress was observed near the vertebrae in outer AF (**Fig. 3C**–solid lines). Pure axial compression or rotation generated comparable fiber stresses across AF. However, the combined loading amplified the difference between outer and inner AF fiber stresses (**Fig. 3C**–red vs. black & blue lines).

DISCUSSION

The recent shift towards multiscale modeling is important for understanding the IVD subtissue-level degeneration-induced changes that act to preserve the joint-level properties. Our previous multiscale joint-level model assessed disc swelling behaviors and proved that a computational model developed with parameters directly representing tissue physical or biochemical properties (*e.g.* fiber modulus or fixed charge density) was capable of replicating morphological changes of degenerated discs, such as the decrease in disc height and the inward bulging of inner AF.[23] This study expanded upon that work by further validating the joint-level mechanics under axial compression and rotation. Additionally, we further expanded the model's capability by modeling AF fiber structure to evaluate fiber mechanics and assess the ability to predict disc failure. Lastly, the multi-scale model-validation framework further expanded our previous tissue and subtissue-level work,[7-8] as results of this study proved that the framework is still valid at the joint level, demonstrating its robustness and predictive power.

Physiological disc-joint loadings resulted in a fiber stretch ranging from 1.04 to 1.10, agreeing with previous *in vitro* photogrammetry-based studies, [4-5] and indicating a low likelihood of failure based on experimental AF fiber bundle failure stretch data (1.14±0.03).[24-25] The structure-based modeling technique partially addressed the prior concern about homogeneous models overestimating fiber stretches and thus predicting premature disc failure under physiological loads.[5] In a previous study, a fiber stretch of ~1.13 was observed under physiological axial rotation; the stretch reached up to ~1.20 under combined loading configurations, indicating a high likelihood of tissue failure under physiological loading.[6] We will use the current model to examine more combined loading modalities to strengthen this finding.

Disc failure has been shown to occur through endplate fracture, AF damage in the outer AF, or inward bulging starting from the inner AF. Under all loading conditions, strain concentrations (**Fig. 4A**) and peak fiber stresses (**Fig. 3C**) were located near the AF-endplate-vertebrae interfaces, which might help explain the large likelihood of endplate rupture during *in vitro* joint-level tests.[26] Interestingly, compared to the pure compression or rotation case, the increase in outer AF stresses result from the combined loading was disproportionally larger than the increase in outer AF strains (**Fig. 4**). These results agree with observations of AF-only failures that occurred in the outer AF with multiaxial loading applied to ovine lumbar discs.[27] Taken together, these findings suggest that disc failure might be driven more by peak stresses than strains, which could serve as an important reference when modeling disc tissue damage.

Concentric and radial annular tears, rim lesions, and annular fissures are common in degenerated discs. Thus, a comprehensive understanding of *in situ* fiber mechanics is essential for predicting AF damage initiation and accumulation, which can be applied to development of workplace loading limits (*e.g.* factory workers). The modeling framework described here provides a powerful tool for investigating multiscale disc mechanics with degeneration and can be used to develop clinically relevant models that use noninvasive imaging to determine biochemical composition. Ongoing work is leveraging this framework to evaluate changes in biochemical composition on stress distributions between tissues and within tissues to assess how the disc preserves joint-level mechanics during early degeneration.

PROPOSED INJURY THRESHOLD FOR DRONE BLADE LACERATIONS

Lauren A. Duma, Mark T. Begonia, Barry Miller, Stefan M. Duma

Institute for Critical Technology and Applied Science (ICTAS)
Virginia Tech
Blacksburg, Virginia, United States

INTRODUCTION

As the use of drones becomes increasingly popular and more widespread, the number of drone related injuries is increasing. Drone accidents have caused a variety of injuries, including head injuries, open globe eye lacerations, and skin lacerations, which are the most common observed injury [1-3]. The objective of this study was first to examine the different properties of drone propellers that cause skin lacerations, and second to propose an injury threshold that can be used to design drones that reduce the risk of these injuries.

METHODS

A total of 17 experiments were performed using nine different drones. The selected drones were the Phantom 4 Advanced (A), Air Hogs Axis 200 (B), Air Hogs Battle Tracker (C), Air Hogs 4T2010 (D), Star Wars X-Wing Fighter (E), Gyroscopes System (F), Syma FPV Real-Time (G), Holy Stone HS-Series (H), and Air Car A380 (I). For each drone, the blade tip thickness and blade length were measured, and angular velocity (rpm) was recorded using a laser tachometer. Blade tip velocity was then calculated using the angular velocity and blade length.

For each experiment, the skin surrogate made full contact with the drone blade (Figure 1). The skin surrogate, second trimester fetal bovine skin, was selected due to its ability to accurately model drone blade laceration injuries in human skin [4]. The skin was mounted on gelatin and held in place by hemostats [5]. The skin was harvested and tested within 24 hours according to approved IRB procedures. The skin mount was placed on a slide system to contact the drone blades. The observed injury caused by the drone was then assigned a level of injury severity: 0 for no injury, 1 for a minor abrasion, and 2 for a minor laceration. A new skin sample was used for each test.

Figure 1: Testing configuration with fetal bovine skin mounted on a slide moved into the Phantom 4 blade.

RESULTS

Five of the 17 experiments resulted in no injury (Table 1). Minor abrasions were observed in eight tests at blade tip speeds higher than 80 ft/s. Minor lacerations were observed in four tests at blade tip speeds higher than 200 ft/s. For example, the Air Car A380 caused no injury, minor abrasion, and minor laceration in three different tests depending on blade tip speeds ranging from 66.9 ft/s to 104.0 ft/s to 313.1 ft/s accordingly (Figure 2).

Copyright 2021 SB³C Foundation, Inc.

Overall, injury severity had the strongest correlation to tip speed (r^2=0.79). There was separation from no injury to minor abrasion at 80 ft/s, and also separation between minor abrasion and minor laceration at 200 ft/s (Figure 3).

However, injury severity did not correlate as strongly to angular velocity (r^2=0.56), which ranged from 1,526 rpm to 33,226 rpm. Blade length also did not correlate to injury severity (r^2=0.03), and ranged from 1.08 in to 4.70 in. Blade tip thickness correlated the least to injury severity (r^2=0.01), and ranged from 0.015 in to 0.035 in.

Table 1: Test configuration, data, and injury results.

Test - Drone	Blade tip thickness (in)	Blade length (in)	Angular Velocity (rpm)	Blade tip Speed (ft/s)	Observed Injury
1-A	0.035	4.70	8115	332.8	Minor laceration
2-B	0.020	2.52	2181	48.0	No injury
3-C	0.016	3.77	1526	50.2	No injury
4-D	0.016	3.08	3330	89.4	Minor abrasion
5-E	0.018	2.38	4605	95.6	Minor abrasion
6-F	0.021	3.82	2569	85.6	Minor abrasion
7-G	0.027	2.63	2719	62.4	No injury
8-G	0.027	2.63	5730	131.5	Minor abrasion
9-H	0.021	2.86	2971	74.2	No injury
10-H	0.021	2.86	6125	152.9	Minor abrasion
11-H	0.021	2.86	6072	151.5	Minor abrasion
12-I	0.015	1.08	7099	66.9	No injury
13-I	0.015	1.08	8658	81.6	Minor abrasion
14-I	0.015	1.08	11030	104.0	Minor abrasion
15-I	0.015	1.08	24960	235.2	Minor laceration
16-I	0.015	1.08	30493	287.4	Minor laceration
17-I	0.015	1.08	33226	313.1	Minor laceration

Figure 2: The fetal bovine skin surrogate showing no injury in test 12-I (top), a minor abrasion in test 14-I (middle), and a minor laceration in test 16-I (bottom).

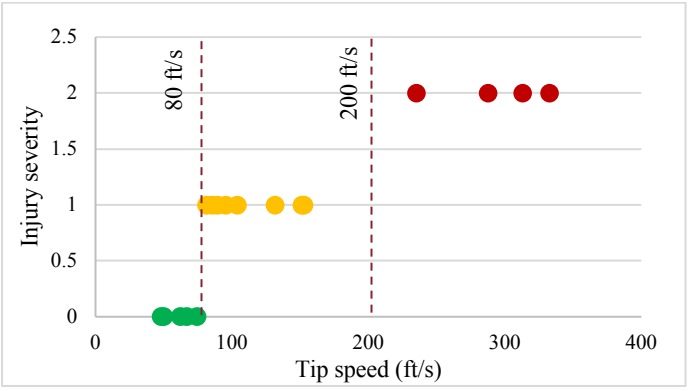

Figure 3: Injury severity vs tip speed for all tests with proposed injury thresholds. Green represents no injury, yellow represents minor abrasions, and red represents minor lacerations.

DISCUSSION

Blade tip speed proved to correlate the most to laceration injuries caused by drone blades, with speeds above 80 ft/s causing minor abrasions and speeds above 200 ft/s causing minor lacerations. In order to avoid severe injuries caused by drone propellers, maximum blade tip speed should stay below the threshold of 200 ft/s, especially for drones designed for toy use.

Interestingly, all other parameters (blade tip thickness, blade length, and blade angular velocity) did not seem as critical to injury risk. This implies that manufacturers can create drones with many different blade designs as long as they evaluate blade tip speed as the injury criteria.

The nine different drones were selected to represent a broad range of commercial and toy drones that are most likely to be handled and flown in close proximity to people. Seven of the nine drone types produced injury with a range of blade designs. The two drones that did not result in injury were tested at their maximum speed. The minor abrasions represented damage to the epidermis while the minor lacerations included damage through the epidermis to the underlying dermis skin layer.

There are two limitations of this study. First, the skin surrogate is not human skin. While previous researchers utilized human volunteer testing, the unknown severity prevented this option [6,5]. Second, there are countless drone blade configurations and additional testing could provide additional insight into their safe design.

ACKNOWLEDGEMENTS

INTRODUCTION

Mild traumatic brain injury (mTBI) is mainly caused by the rapid rotation of the head impact. Because of the inertia, the brain will be deformed. Both angular velocity and angular acceleration can be used to describe the head rotation. However, how each parameter decides brain strain is unclear because of the interdependency between them (angular acceleration is the derivative of the angular velocity). Previous studies based on statistical analyses found that angular velocity peaks correlated better with the brain strain peaks [1], and the brain injury models based on angular velocity peaks were found to have higher predictability of brain strain [2,3]. However, these findings contradict with the volunteer experiment [4]: volunteers experienced angular velocity higher than the injury threshold [5], but had no brain injury and low brain strains. The classification of the head kinematics according to the impulse duration gave an explanation [6]: the brain strain peak depends on angular velocity peak in short-duration impacts, on angular acceleration peak in long-duration impacts and on both in moderate-duration impacts. However, the mechanism underlying this classification is still unclear.

Different from previous studies, we propose to describe the head impact in the skull frame of reference (FoR). In the skull FoR, the effects of angular acceleration and angular velocity are represented by the inertial force. In this way, we can separate the brain strain caused by each kinematic parameter. We use the rigid-body rotation of brain (RRB) as a bridge to explain how the inertial force associated by each kinematics parameter causes brain strain. Furthermore, we also provided an explanation of the classification according to the impact duration. [6]

.

THEORETICAL ANALYSIS

Different from the description in ground FoR (**Fig.1A**), in the skull FoR (**Fig.1B**), the skull does not move and the brain is deformed the inertial forces as,

$$\begin{aligned}\boldsymbol{F}(\boldsymbol{r}) &= \rho(\boldsymbol{r})\boldsymbol{a} - \rho(\boldsymbol{r})\boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}) - \boldsymbol{\beta}\times\boldsymbol{r} \\ &= \boldsymbol{F}_{\mathrm{LinAcc}}(\boldsymbol{r}) + \boldsymbol{F}_{\mathrm{AngVel}}(\boldsymbol{r}) + \boldsymbol{F}_{\mathrm{AngAcc}}(\boldsymbol{r}) \qquad (1)\end{aligned}$$

Where $\boldsymbol{F}(\boldsymbol{r})$ is the inertial force per unit mass at the location $\boldsymbol{r}$; $\boldsymbol{a}$, $\boldsymbol{\omega}$ and $\boldsymbol{\beta}$ are the linear acceleration at the coordinate origin, the angular velocity, and the angular acceleration of the head, respectively. Here we assume the Coriolis force can be neglected. $\boldsymbol{r}$ is the position vector, and the coordinate origin of $\boldsymbol{r}$ is set at the center of gravity (CoG) of the brain (**Fig.1A**). The inertial force by each kinematics are,

$$\boldsymbol{F}_{\mathrm{LinAcc}}(\boldsymbol{r}) = \rho(\boldsymbol{r})\boldsymbol{a} \qquad (2)$$

$$\boldsymbol{F}_{\mathrm{AngVel}}(\boldsymbol{r}) = -\rho(\boldsymbol{r})\boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}) \qquad (3)$$

$$\boldsymbol{F}_{\mathrm{AngAcc}}(\boldsymbol{r}) = -\rho(\boldsymbol{r})\boldsymbol{\beta}\times\boldsymbol{r}(1) \qquad (4)$$

Then, the inertial torque associated with each kinematic parameter can be calculated by integrating Eqs. (2-4) over the whole brain,

$$\boldsymbol{T}_{\mathrm{LinAcc}} = \iiint \rho(\boldsymbol{r})\boldsymbol{r}\mathrm{dv}\times\boldsymbol{a} = \boldsymbol{0} \qquad (5)$$

$$\boldsymbol{T}_{\mathrm{AngVel}} = \iiint \rho(\boldsymbol{r})(\boldsymbol{\omega}\cdot\boldsymbol{r})\boldsymbol{\omega}\times\boldsymbol{r}\mathrm{dv} \qquad (6)$$

$$\boldsymbol{T}_{\mathrm{AngAcc}} = \iiint \rho(\boldsymbol{r})\left(\boldsymbol{r^2}\boldsymbol{\beta} - (\boldsymbol{r}\cdot\boldsymbol{\beta})\boldsymbol{r}\right)\mathrm{dv} \qquad (7)$$

Assuming the brain shape is close to a sphere with r_0, Eqs.6 and 7 are,

$$\boldsymbol{T}^{\mathrm{sphere}}_{\mathrm{AngVel}} = \boldsymbol{0} \qquad (8)$$

$$\boldsymbol{T}^{\mathrm{sphere}}_{\mathrm{AngAcc}} = \frac{8}{15}\rho_0\pi r_0^5\boldsymbol{\beta} \qquad (9)$$

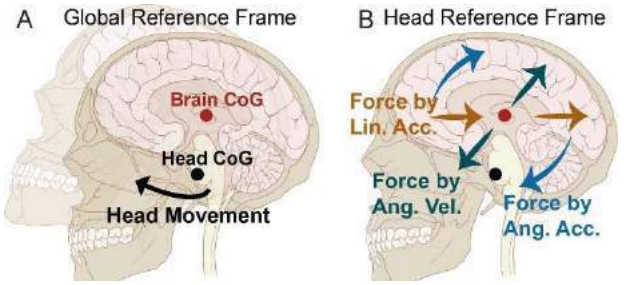

Figure 2. The diagrams of how head impact causes the brain strain at (A) the ground frame of reference (FoR) and (B) the skull FoR.

For the actual brain,

$$\boldsymbol{T}_{\mathrm{AngVel}} \ll \boldsymbol{T}_{\mathrm{AngAcc}} \quad (10)$$

According to the conservation of angular momentum, the angular momentum ($\boldsymbol{L}$) at skull FoR is only decided by $\boldsymbol{T}_{\mathrm{AngAcc}}$. We define the equivalent angular velocity of brain ($\dot{\boldsymbol{\phi}}$) as,

$$\boldsymbol{L} = I_C \dot{\boldsymbol{\phi}} \quad (11)$$

Then, the equivalent angle $\boldsymbol{\phi}$ can be calculated by quaternion integrating $\dot{\boldsymbol{\phi}}$. $\boldsymbol{\phi}$ describes the RRB and has the same variation of brain strain. Since $\boldsymbol{\phi}$ is decided by $\boldsymbol{L}$, which is further decided by $\boldsymbol{T}_{\mathrm{AngAcc}}$, the angular acceleration is the kinematic parameter that decides the brain strain.

VALIDATION

We simulated 118 head impacts collected by Stanford Instrumented Mouthguard using KTH head model [7]. The simulations were performed at both ground FoR and skull FoR, and the brain strain was very close. (difference in the peak of 95th percentile maximal principal strain (95% MPS) <0.0009).

Then, we gave $\boldsymbol{F}_{\mathrm{LinAcc}}$, $\boldsymbol{F}_{\mathrm{AngVel}}$, $\boldsymbol{F}_{\mathrm{AngAcc}}$ separately and compared the brain strains with the simulation with all inertia. As shown in **Fig.2**, the brain strain caused by angular acceleration is almost the same as that by all inertia force, and the brain strain caused by other kinematic parameters can be neglected.

DISCUSSION

The theoretical analysis is limited by that the 95% MPS and $\boldsymbol{\phi}$ are only linearly correlated in simulation. Although the correlation coefficient is high, we do not know the exact corresponding relationship. The idea of using the rotation of the brain respected to the skull was adopted in the reduced-order models [8,9] and these models manifest high predictability of the brain strain. Future studies about this relationship should be performed with more detailed head models.

THE EFFECT OF PERMEABILITY BOUNDARY CONDITIONS ON THE RESERVE ZONE CHONDROCYTE SUBJECTED TO DIFFERENT LOADING RATES

M. Kazemi (1), J. L. Williams (1)

(1) Biomedical Engineering Department
University of Memphis
Memphis, TN, USA

INTRODUCTION

The growth plate consists of a thin layer of hyaline cartilage trapped between the epiphysis and metaphysis and is responsible for longitudinal growth through an endochondral ossification process. Histologically, growth plate cartilage has three zones reflecting the activities of the chondrocytes from the epiphysis toward the metaphysis: a reserve, proliferative and hypertrophic zone. Mechanical loading modulates chondrocyte activity in the proliferative and hypertrophic zones. As growth continues the growth plate develops into a three-dimensional interlocking interface of hills and valleys, called mammillary processes, and a layer of compact subchondral bone and calcified cartilage arises at the border of the reserve zone and epiphysis. The undulations on the metaphyseal side of the growth plate are formed by endochondral ossification. However, the mechanism by which the subchondral bone plate forms to create an epiphyseal interface parallel to the metaphyseal one has not been investigated. Recent discoveries of stem-like cells in the reserve zone suggest that reserve zone cells close to the subchondral bone border may modulate growth under mechanical loading and contribute to epiphyseal mammillary processes development [1][2][3]. Experimental findings indicate that the morphology of mamillary processes and the thicknesses of subchondral bone and calcified cartilage along the border of the reserve zone changes during skeletal development [4][5], resulting in changes in the permeability of the reserve zone-epiphyseal bone interface. Such changes may affect the microenvironment of reserve zone cells close to the subchondral bone border and thereby change the cells' response to applied mechanical loading. The main objective of this study was to develop a poroelastic multiscale finite element model of bone/growth plate/bone to investigate the microenvironment of reserve zone cells close to the subchondral bone and evaluate the effect of permeability boundary conditions on the reserve zone cell response close to epiphyseal border.

METHODS

A poroelastic multiscale axisymmetric finite element model of bone/growth plate (GP)/bone (radius of 2.5 mm) was developed using Abaqus (CAE 2019, USA). A stress relaxation test in unconfined compression was simulated by applying a ramp displacement function to the macroscale model of 0.025 mm (5% strain of the height of growth plate) at four strain rates of 0.18%/s, 5%/s, 50%/s, and 200%/s, after which the displacement was held constant. The material properties and dimensions of different regions within the macro- and micro-scale models are summarized in Tables 1&2.

Table 1. Material properties of different layers in the macroscale model

Tissue	E (MPa)	ν	K_0 (mm⁴/N.s)	e_0	M	Thickness (mm)
Subchondral bone (SB)	2000[6]	0.200[6]	90[7]	0.176 [6]	-	0.6
Calcified cartilage (CC)	300	0.200[8]	90 [9]	1.1[9]	-	0.06
Reserve zone (RZ)	0.98[10]	0.125[11]	1.41×10^{-3} [12]	4.25[11]	5.48 [9]	0.25
Proliferative/Hypertrophic zone (PZ/HZ)	0.49[10]	0.125[11]	5.8×10^{-3} [12]	3.6 [11]	6.43 [9]	0.25
Provisional calcification (PC)	100	0.200	22.5× 1	3.5	-	0.15
Epiphysis (EP) Metaphysis (MP)	1000 1000	0.200 0.200	45.3× 10^5 45.3× 10^5[7]	3.7[9]	- -	0.5 0.5

Table 2. Material properties used for the microscale model

Region	E (MPa)	ν	k_0 (mm4/N.s)	e_0	$Radius$ (μm)
Cell	0.002 [10]	0.04 [13]	4.2× 10-3 [6]	4.88 [6]	5 [14]
Cell membrane	4× 10-2 [6]	0.04 [13]	3× 10-9 [6]	3 [6]	0.1 [6]
Pericellular matrix (PCM)	0.265 [10]	0.04 [13]	4× 10-5 [15]	4 [15]	0.5 [14]

The microscale model included one cell close to the reserve zone (RZ)-calcified cartilage (CC) border. The strain-dependent hydraulic permeability was defined for GP regions in the macroscale model and for cell, cell membrane and pericellular matrix in the microscale models using equation (1) [4][9].

$$k = k_0 \left[\frac{e}{e_0}\right]^2 exp\left(\frac{M}{2}\left(\left(\frac{1+e}{1+e_0}\right)^2 - 1\right)\right), \quad (1)$$

where k_0 is the initial hydraulic permeability (mm^4/N.s), e_0 and e are initial and current void ratios, and M is a non-dimensional constant. To get the hydraulic conductance (mm/s) used in Abaqus, the hydraulic permeability (mm^4/N.s) was multiplied by the specific weight of the wetting fluid (9.81×10^{-6} N/mm^3) [9]. CAX4P elements were used for all regions. Mesh convergence was confirmed for the cellular maximum principal strain and fluid velocity. To study the effect of the permeability boundary conditions at the calcified cartilage (CC) interface on the transient response of the cell and fluid flow across the cell membrane, another model was developed with very low CC permeability ($k_0 = 5.8\times 10^{-3}$ mm^4/N.s). Intracellular maximum principal strain (logarithmic) and fluid pressure, transmembrane effective fluid velocity (mm/s) and cell membrane maximum tensile strain (logarithmic strain) were calculated at 95% of the peak applied displacement to avoid any possible numerical artifact due to the transition to fixed displacement following ramp loading.

RESULTS

Figs.1a&b compare the intracellular maximum principal strain and fluid pressure between the permeable and impermeable boundary conditions for cells located at the CC border at four strain rates. The highest strain value of 9% is related to the 5%/s strain rate, indicating a 2-fold amplification of applied tissue strain. In contrast, the smallest value of strain occurs at 200%/s. Decreasing the permeability of the CC drops all the strain values, however, it does not change the overall cellular strain pattern. The highest maximum principal strain still occurs for a strain rate of 5%/s, but is closer in magnitude to the applied tissue strain. Intracellular fluid pressure increases with the applied strain rate. The pressure is greatest (0.58 MPa) at 200%/s when the fluid has less time to move through the tissue, thereby providing higher fluid resistance. Preventing fluid exchange across the CC results in a slight increase in cell fluid pressure for all strain rates as the fluid cannot flow across the CC border (Fig. 1b).

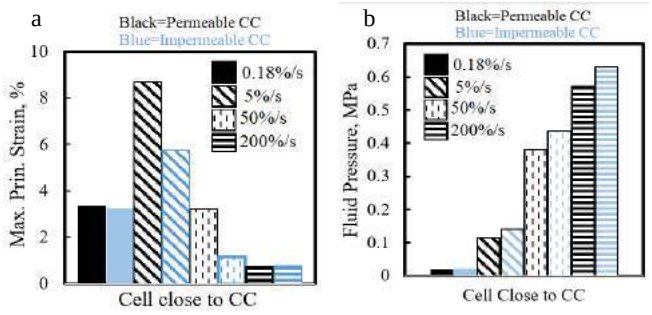

Fig. 1. Comparing maximum principal strain (logarithmic strain) and intracellular fluid pressure between permeable and impermeable calcified cartilage (CC) properties, at the 4.5% strain time point and 0.18%/s, 5%/s, 50%/s, and 200%/s strain rates for reserve zone cells close to CC.

Fig. 2a shows the percent decrease in transmembrane fluid velocity due to employing the impermeable boundary condition. The greatest change occurs for the two faster strain rates (70%), while at the slowest strain rate the transmembrane fluid flow changes slightly by 4%. Tangential tensile membrane strain follows a similar trend to that of maximum principal strain at each equivalent strain rate. Restricting fluid from crossing the CC decreased the tangential membrane strain for the three slower strain rates, however it has an opposite effect at the fastest applied load, and impermeability of CC increases the tangential tensile membrane strain slightly by 10% (Fig. 2b).

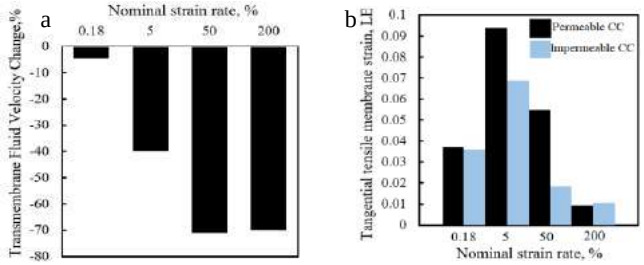

Fig. 2. a) Change in the peak fluid velocity across the cell membrane close to calcified cartilage (CC) due to impermeable CC properties. b) Comparison of peak tangential tensile membrane strains for a permeable and an impermeable CC.

DISCUSSION

The results of this study revealed that the magnitudes of cellular maximum principal strain and peak tangential membrane strain are highly dependent on the applied loading rate and also the permeability of the CC between the subchondral bone (SB) and RZ. The effect of increasing loading rates on cellular strains shows a different pattern which can be explained by the transmembrane effective fluid velocity, which itself depends on intracellular fluid pressure. Fluid pressure provides a pressure gradient within the fluid phase of the porous solid and determines the directions and values of fluid velocity. The highest cellular strain value at the slower loading rate (5%/s) can be attributed to the higher fluid flow out of the cell across the cell membrane which results from higher cellular fluid pressure and higher-pressure gradient across the cell membrane.

In this study, we investigated quantitatively how changing the permeability of CC at the border of the RZ can change the microenvironment of RZ cells. During skeletal development, epiphyseal subchondral bone (SB) and CC, located between the RZ and epiphysis, undergo fundamental changes in their thickness, morphology and porosity. Such morphological changes can act to provide a barrier to fluid flow and decrease the permeability across the border of RZ-CC/SB. Decreasing the permeability changes the micromechanical environment of RZ cells and that may act to signal the RZ cells to stop growth and begin the process of growth plate fusion.

STRUCTURAL AND NON-STRUCTURAL DETERMINANTS OF SPEED AND TIMING OF CONDUCTION IN AUDITORY NEURONAL AXONS

J. Xu

Department of Engineering and Computer Science
Tarleton State University
Stephenville, TX, USA

INTRODUCTION

The speed of action potential conduction in the myelinated auditory axon is fundamental to information processing in the brain. However, its regulatory mechanisms are not fully understood. Here we report findings from a computational study to examine both structural and non-structural factors in the Ranvier nodes and internodes of auditory axons. The structural element we looked at included mainly the internode length. The non-structural factors included three main ionic currents and a leak current.

METHODS

The model of Ranvier nodes includes the potassium current I_K, the fast sodium I_{Na}, the hyperpolarization-activated cation current I_h, and a leak current I_{Leakn}. While only the leak current I_{Leaki} is included in the myelinated axon. The propagation of the electrical signal through axons is modeled by cable theory [1, 2]. The computational task is to numerically solve the following transient cable equation.

$$C\frac{\partial V}{\partial t} = \frac{\partial^2 V}{\partial x^2} - (I_{Na} + I_K + I_h + I_{Leak}) \quad (1)$$

where C is the membrane capacitance. Spatial discretization of above equation produces a family of ordinary differential equations of the form

$$C_k\frac{dV_k}{dt} = \sum_l \gamma_{l,k}(V_l - V_k) - (I_{Na} + I_K + I_h + I_{Leak})_k \quad (2)$$

where k and l index compartments, C_k is the capacitance for compartment k, V is the transmembrane voltage, $\gamma_{lk} = 2/(\rho_k+\rho_l)$ is the coupling conductance between adjacent compartments, and the sum is over all compartments l connected to compartment k. The capacitance of a compartment k is defined as $C_k=C_m\pi dk\Delta x_k$ and the axial resistance is defined as $\rho_k=Ra\Delta x_k/\pi r_k^2$. C_m is the specific capacitance of the membrane, R_a is the axoplasmic resistivity, r_k is the radius, and Δx_k is the length of the compartment, respectively. Currents injected through a simulated microelectrode are added to the first node of Ranvier. Sealed end boundary conditions are used.

All the channels are expressed in the nodes of Ranvier except for myelinated axon where only internode leak current I_{Leaki} is included. Except where otherwise noted, the ion channel kinetics were taken from published models [3-6]. The peak conductances are: G_{Na}=0.588 S/cm^2, G_K=0.04 S/cm^2, G_h=0.095×10^{-3} S/cm^2, internode leak conductance G_{Leaki}=0.1×10^{-3} S/cm^2, and nodal leak conductance G_{Leakn}=1.76×10^{-3} S/cm^2. The simulation programs was written in C/C++ programming language and run in MS Visual Studio Academic 2019.

RESULTS

Figure 1a shows that conduction velocity indeed decreases as the K conductance increases (without h channels). Furthermore, with only Na channel presents, the conduction velocity is about 14.4 m/s, corresponding to the zero conductance data point on the left in Figure 1a. Figure 1b shows the conduction velocity increases as the h channel conductance increases, indicating that h channels facilitate AP conduction along the axon. Please note that the conduction velocity was calculated from the time needed for the AP to travel from the 71st to the 90th internode.

Figure 2a shows the axonal current that would be conducted into cell body to depolarize the cell body. The bigger the current, the easier the cell body is depolarized. The result shows that this is indeed the case. In addition, the result shows that the depolarization would happen faster as the current travels faster compared with the constant-spaced model. In Figures 2a and 2b, the internode length linearly decreases from 197.7

micron to about 53.5 micron before injecting into the cell body (soma). Please note that the distal end length varies from 197.7 to 1 micron. In addition, the all internode lengths are linearly decreasing from the first to last internodes.

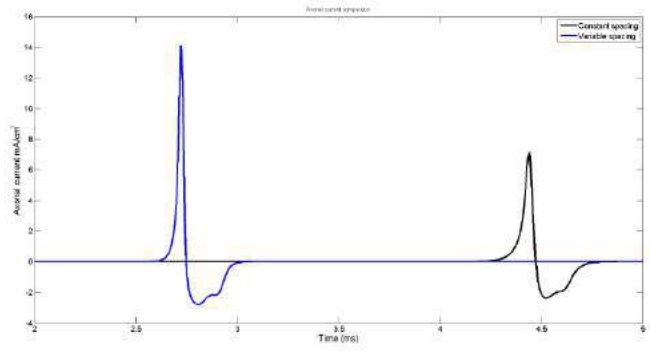
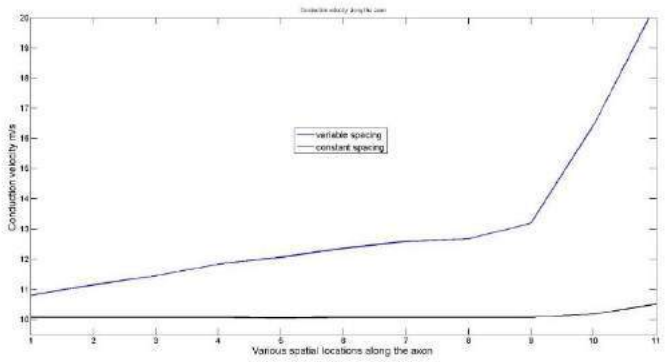
(b)

Figure 1: Effects of ion channel K+ and h conductances on Conduction Velocity (CV).



(a)



(b)

Figure 2: Effects of Internode spacing on CV and axonal current.

DISCUSSION

Simulations predicted that the internode length helps to adjust the conduction speed and timing of action potentials. The spatial properties of the myelinated axon deviated significantly from the traditionally assumed structure. Previous studies showed internode length decreased and Ranvier node diameter increased progressively along with the distal axon segments, which our simulations show this special structural arrangement leads to a higher axonal current that would be conducted into a cell body to depolarize the cell body. The bigger the current, the easier the cell body is depolarized. The result confirms that this is indeed the case. In addition, the results show that the depolarization would happen faster as the current travels faster compared with the traditionally assumed constant-length internode model. Moreover, our simulations show that conduction velocity decreases as the k conductance increases and increases as the h channel conductance increases indicating that h channels facilitate AP conduction along the axon. The spatial arrangement of internodes and ionic currents can be the potential temporal regulatory mechanism of the auditory signals.

ENHANCED HEMODYNAMIC PREDICTIONS IN A CALCIFIED AORTIC VALVE GEOMETRY USING THE QUEMADA MODEL

Asad M. Mirza, Amanda Barreto, Tisha Boodooram, Sharan Ramaswamy

Department of Biomedical Engineering
Florida International University
Miami, Florida, United States of America

INTRODUCTION

When conducting computational fluid dynamics (CFD) simulations around the aortic valve, blood is often assumed to be a Newtonian fluid [1]. This assumption is supported through previous studies of similar large vessels in arteries where shear rates are relatively large, (>1000 s^{-1}), which is the case in the region surrounding the aortic valve [2]. However, for more tortuous arterial geometries [3], the Newtonian assumption fails to properly quantify the wall shear stress (WSS) which results in false identification of regions prone to thrombogenesis [4]. These inaccuracies could also occur when this assumption is applied to the aortic valve geometries, where leaflet flexure and calcifications can induce regions of very low shear rates on the fibrosa side. The following study investigated and compared three viscosity models: Newtonian, Carreau, Quemada on a calcified aortic valve geometry to determine which model would facilitate maximum accuracy in hemodynamic predictions.

METHODS

A construction of a human aortic heart valve, taken from an 82-year-old patient at the early diastolic phase, was purchased (Valve – 012 - Heart Print catalog, Materialize Inc, Plymouth MI). Geometry was then imported into a commercial modeling software (ANSYS Spaceclaim; ANSYS Inc, Canonsburg, PA) for mesh repair, smoothing, shrink-wrap, labelling, and fluid volume extraction. A mesh independence study was done on the valve and calcifications resulting in a finalized mesh with 1.7 x 10^6 and 5 x 10^5 elements, respectively, with an average mesh quality of .82. Inlet velocity of 1 cm/s along with an 80-mmHg pressure condition on the outlet were prescribed.

Blood flow was assumed to be incompressible and modeled using the Navier-Stokes equations (Eq 1 and 2)

$$\rho\left(\frac{\partial \vec{u}}{\partial t} + (\vec{u}\cdot\nabla)\vec{u}\right) = \nabla p + \rho g + \mu\Delta\vec{u} \quad \text{(Eq 1)}$$

$$\nabla\cdot\vec{u} = 0 \quad \text{(Eq 2)}$$

where $\vec{u}$ and p represent, respectively, the fluid velocity vector and the pressure. ρ is the density of blood, which was set to 1060 kg/m^3.

Blood viscosity, μ, was defined using three different models. Newtonian model used a constant viscosity of 3.3 cP. A non-Newtonian Carreau model given in (Eq 3) with μ_∞ = 3.2 cP; μ_0 = 45.6 cP; λ = 10.03 s; n = 0.344.

$$\mu = \mu_\infty + (\mu_0 - \mu_\infty)\left(1 + (\lambda\gamma)^2\right)^{\frac{1-n}{2}} \quad \text{(Eq 3)}$$

And the non-Newtonian Quemada model given in (Eq. 4) with μ_p = 0.001123 Pa; μ_0 = 3.9 cP; μ_∞ = 1.766 cP; γ_c = 5 cP s; and Hct = 48%.

$$\mu = \mu_p\left(1 - \frac{1}{2}\frac{\mu_0 + \mu_\infty\sqrt{\dot{\gamma}/\gamma_c}}{1 + \sqrt{\dot{\gamma}/\gamma_c}}Hct\right)^{-2} \quad \text{(Eq 4)}$$

All parameter values were found by curve fitting experimental blood data (Fig 1) using a non-linear least squares algorithm in MATLAB (MathWorks, Natick, MA, USA).

Simulations were conducted on an MSI GT73EVR 7RE Titan with 64 GB RAM, 2.90 GHz Intel i7, and a NVIDIA GeForce GTX 1070. Simulation was done in ANSYS Fluent with ANSYS Mosaic Meshing, using the SST k-ω model. Steady state convergence criterion was set to 1x10^{-6}.

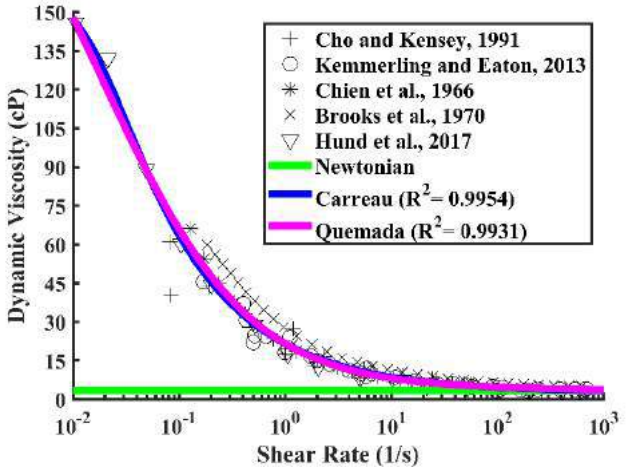

Figure 1. Viscosity model fittings for Newtonian (green), Carreau (blue), and Quemada (purple). Experimental data taken from whole blood from 5 different sources.

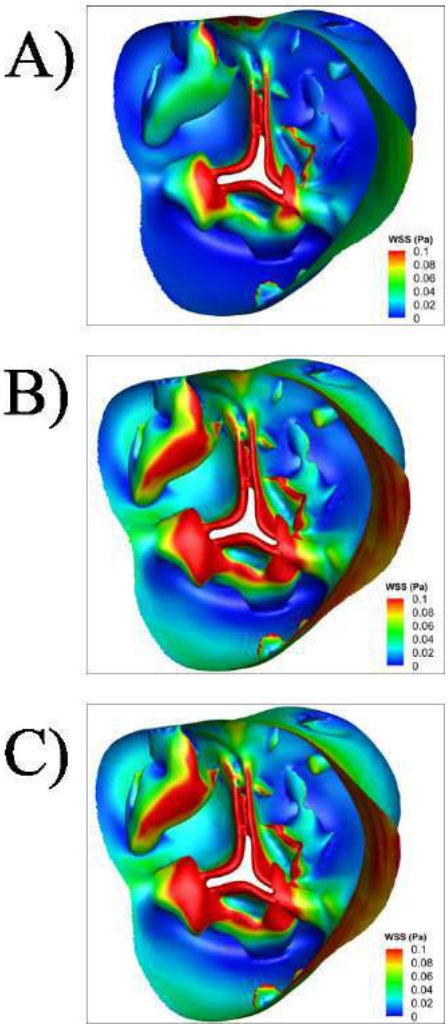

Figure 2. Wall shear stress distribution on the calcified fibrosa side of the aortic valve under three different steady state viscosity model conditions: A) Newtonian B) Carreau C) Quemada.

RESULTS

Model fittings (Fig 1) showed great agreement with experimental data (R^2 > .99) for both Carreau and Quemada models. On the other hand, the Newtonian model only partially fit the data (shear rates > 100 s^{-1}).

Simulations under all three viscosity conditions showed drastically greater WSS on the ventricularis side of the aortic valve (>1000 s^{-1}) compared with the fibrosa (< 1 s^{-1}). Along the free edge of the leaflets there was similar agreement in shear rates and WSS between all three models. For the majority of the fibrosa side, the Newtonian model (Fig 2A) greatly underestimated WSS when compared with both Carreau (Fig 2B) and Quemada (Fig 2C) models. Within the cusp regions or in pocket regions formed by the calcifications WSS was often greater under both non-Newtonian models (> 0.4 dynes/cm^2), than in the same area under the Newtonian model.

DISCUSSION

Many previous works in large arterial vessels have been justified in their use of the Newtonian model for blood viscosity due to the large shear rates present in them [5-7]. However, applying this assumption to a calcified aortic valve is suspect as, on the fibrosa side, shear rates can be below 1 s^{-1} during diastole. This results in low WSS, < 1 dynes/cm^2, which are primarily found in the inner regions of the cusps, which have been noted as being sites prone to thrombosis [8]. The Quemada and Carreau models exhibit an excellent response across a wide range of shear rates. However, the Quemada model has the added benefit of accounting for changes in blood hematocrit, a parameter that has been noted to vary with both age and gender of patients [9]. We conclude that that the Quemada model is most applicable for calcified aortic valve geometries so as to more accurately capture leaflet WSS and to identify regions of flow stagnation, which are vulnerable to thrombosis.

PERISTALTIC PUMPING IN SUB-WAVELENGTH PERIVASCULAR MODELS

Jessica K. Shang (1), J. Brennen Carr (1), Caroline D. Cardinale (1), Delin Zeng (1)

(1) Department of Mechanical Engineering
University of Rochester
Rochester, NY, USA

INTRODUCTION

Cerebrospinal fluid (CSF) flows through the annular perivascular spaces (PVSs) surrounding the surface arteries of the brain. One hypothesis is that the flow is peristaltically driven by traveling-wave pulsations of the arterial walls, a mechanism termed "perivascular pumping" [1]. The hypothesis has been supported by *in vivo* measurements, which show an unsteady movement of CSF that is correlated with the cardiac cycle and modulated by varying arterial pulsation [2,3].

Idealized models of the PVS have been employed in theoretical and computational studies of perivascular pumping (see [4] for a review). These studies have reached differing conclusions on the feasibility of perivascular pumping. One variable between studies is the the choice of domain length, which can be of integer wavelength, or shorter than a wavelength. The peristaltic wavelength is expected to be about 0.1 m, but each PVS segment is short, 10^{-4} to 10^{-3} m [2, 3], so a sub-wavelength domain may be more realistic. Simulations showed that mean flow rate is orders of magnitude smaller in sub-wavelength models compared to integer-wavelength models, and only applying a small pressure difference across its length can increase the net flow rate to a physiologically relevant value [5, 6].

In this study, we extend the lubrication approximation of peristalsis employed by others [7-9] to sub-wavelength planar channels ($n < 1$). Non-integral wavelengths were previously studied by [9] for cylindrical tubes greater than a wavelength. Here, analytically explore the regime where the domain is sub-wavelength in length, which is relevant to perivascular flow. Our model demonstrates a significant effect of domain length on mean and instantaneous flow rate, and sheds light on the appropriateness of simple peristaltic models to describe perivascular pumping.

METHODS

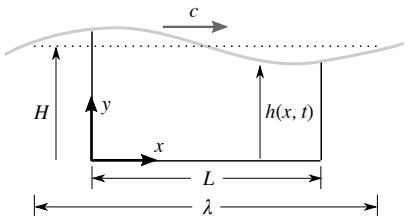

Figure 1. Peristaltic model.

The channel is modeled as a two-dimensional, rectangular domain of height H and length $L = n\lambda$, where λ is the wavelength of the peristaltic wave (Figure 1). The peristaltic wave propagates along the upper wall in the longitudinal (x) direction, and its position is given by $h(x,t) = H\big(1 + G(x - ct)\big)$, where c is the wavespeed, t is time and G is a waveform that is continuous and periodic over $x = [0, \lambda]$. The bottom wall is fixed. The channel is filled with an incompressible, Newtonian fluid of density ρ and dynamic viscosity μ, and is open, not porous. The upper and lower walls are impermeable.

In the lubrication approach [7-9], non-dimensionalization of the Navier-Stokes equations shows that inertial effects are negligibly small, resulting in the lubrication equations:

$$0 = -\frac{\partial p}{\partial x} + \mu\frac{\partial^2 u}{\partial y^2};\ 0 = \frac{\partial p}{\partial y}. \qquad (1)$$

where u and v are the x- and y- components of velocity, respectively, and p is the pressure. We also note that the average Reynolds number calculated from experiments is also small, $Re = \frac{\rho \overline{u} H}{\mu} \approx 10^{-2}$, where $\overline{u}$ is the mean velocity. No-slip boundary conditions are applied at $y = 0$ and $y = h(x,t)$ to solve for the velocity profile

$$u(x,y,t) = \frac{1}{2\mu}\frac{\partial p}{\partial x} y(y-h). \quad (2)$$

We can integrate continuity $\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0$ with respect to y. Substituting the velocity profile u, we obtain

$$\frac{\partial}{\partial x}\left(\frac{h^3}{12\mu}\frac{\partial p}{\partial x}\right) = \frac{\partial h}{\partial t}. \quad (3)$$

We can integrate this to obtain $p(x,t)$. For brevity, we consider the case where there is no applied pressure difference over the channel, $p(x=0) = p(x=L)$. The flow rate q is determined by integrating u:

$$q = \int_0^h u\, dy = -\frac{h^3}{12\mu}\frac{\partial p}{\partial x} \quad (4)$$

and substituting the pressure,

$$q = -\int_0^x \frac{\partial h}{\partial t} dx' + \frac{\int_0^L \frac{\int_0^{x'} \partial h/\partial t\, dx''}{h^3(x',t)} dx'}{\int_0^L h^{-3}(x',t)\, dx'}. \quad (5)$$

We can apply a transformation of variables (see [8] for details) and substitute our definition for $h(x,t)$ to manipulate q into the form

$$\frac{q}{cH} = 1 + G(x,t) - \frac{\int_0^L \{(1+G(x,t)\})^{-2}\, dx}{\int_0^L \{(1+G(x,t)\})^{-3}\, dx}. \quad (6)$$

RESULTS

We calculate flow rates using Eq. 6 and prescribe an experimental *in vivo* arterial wave [3] as our wall wave $G(x,t)$, as shown in Fig. 2. We also show $q(x,t)$ at various locations and $n \leq 1$. For $n = 1$, q has the same amplitude for all x, and is in phase with $G(x,t)$. In contrast, for smaller values of n, q varies with x in amplitude and phase shift, and the flow rates are not in phase with G.

In particular, for $n << 1$, the flow rates at the inlet and outlet are of opposite sign and mimic the wall velocity dG/dt, and the flow in the middle of the channel is small. The local slope of the wall wave is small (the wavelength is much larger than the amplitude), so a short channel contracts and expands nearly uniformly as the wave passes through. When the channel contracts, fluid is squeezed out of the ends, and when the channel expands, fluid rushes back in. Hence the inlet and outlet flow oppose each other and follow the wall velocity. As the channel length increases to a wavelength, the velocity-like behavior fades, and $q(x,t)$ favors the wall displacement function $G(x,t)$.

For the mean flow rate, we integrate over the period $\tau = \lambda/c$:

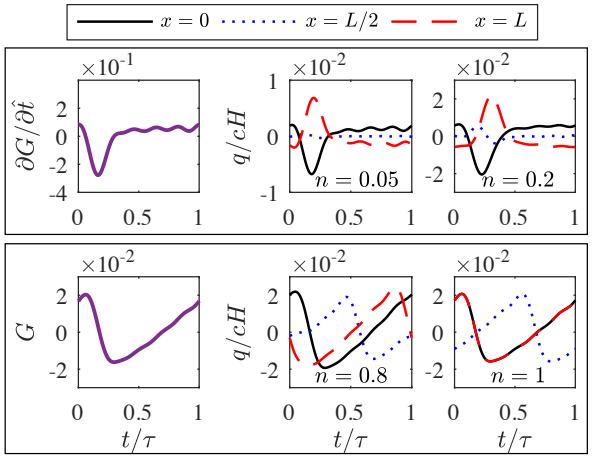

Figure 2. Instantaneous flow rates for varying channel length and at different channel positions.

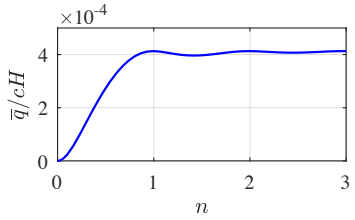

Figure 3. Mean flow rate as a function of n.

$$\bar{q} = \frac{1}{\tau}\int_0^\tau q(x,t)\, dt. \quad (7)$$

The mean flow rate is shown in Fig. 3, and is very small for $n << 1$. The mean flow rate varies periodically with n, and is maximized when n is an integer. For non-integer $n > 1$, the mean flow rate is slightly less than for integer n, which was also noted by [9] for finite tubes.

DISCUSSION

We have examined the flow rate produced by a peristaltic wave in sub-wavelength channels. While our model is 2D and does not mimic the PVS-specific annular geometry, our observations can be extended to 3D geometries, since the lubrication approximation will apply.

At low values of n, the fluid predominantly oscillates in and out of the ends, synchronous with the wall velocity. This wall velocity-like behavior was observed in simulations [5, 6, 10], though they did not explicitly show velocity profiles at locations other than the inlet or outlet. However, *in vivo* measurements did not show significant changes in amplitude and phase along a perivascular segment [3].

In agreement with previous studies, the mean flow rate at low n is very small compared to n = 1 [5, 6, 10]. Applying a pressure difference can increase the mean flow rate [5, 6]. However, even if the applied pressure is pulsatile, its unsteady component does not vary spatially, so the instantaneous flow rate is still unphysiologically spatially inhomogeneous in phase and amplitude at small n. A full-wavelength model is spatially homogeneous, but as noted by [5], the flow amplitude is unrealistically large compared to mean flow rates.

In conclusion, idealized models of perivascular pumping thus far do not adequately represent the desired flow. The inclusion of additional physics through complex boundary conditions coupled to perivascular flow models are a rich area for future study, that can be improved with expanded *in vivo* measurements.

INTRODUCTION

Cells respond to mechanical and biochemical stimuli to maintain homeostasis; changes in the magnitude or type of stimuli can lead to various diseases. For example, the heart and lung tissue stiffen over time potentially leading to cardiovascular disease and lung fibrosis, respectively [1,2]. In this study, we focus on back and spine pathologies that affect ~8 million people in the United States and cost over $100 Billion annually [3,4]. The most identifiable and widely studied source of back pain is due to degeneration or failure of the intervertebral disc [5,6]. Disc degeneration, stemming from disruption of the annulus fibrosus (AF), leads to increased pain and reduced mobility [7,8]. To enable regenerative medicine strategies, a better understanding of AF cell mechanobiology during tissue development is needed. A method is required to quantitatively and reliably replicate intradisc loading to test potential disease mitigators at the cellular and nascent tissue levels. Advancements in microfluidics have enabled micromechanical testing of small cohorts of cells [9,10]. However, a chip that emulates more physiological strains observed in the AF is needed. Therefore, we present a deformable chip that emulates the AF's cyclical and multiaxial strains. We demonstrate a method to evaluate the effects of these strains on the initiation and propagation of AF tissue degradation. We bolster development of the chip by using the Finite Element Method (FEM) to validate lab measurements and examine strains within a cell monolayer.

METHODS

We designed a deformable microfluidic chip using principals of beam mechanics to target clinically relevant, multiaxial loads in the AF. Our previous work created a polydimethylsiloxane (PDMS) chip that enclosed a single microchannel (Figure 1A) [11]. The chip was deformed over a rigid cylinder (radius = 10.6 mm) to create uniform depth-dependent strains, due to bending. A microscope slide was positioned beneath the chip to help visualize cells throughout loading (Olympus CKX31 microscope; Figure 1B). When the chip is bent around the cylinder, uniform depth-dependent strains, ε, are assumed to follow the mechanics of a beam in pure bending: $\varepsilon = Y/\rho$, where Y is the vertical distance from the Neutral Axis (NA), and ρ is the radius of curvature [12]. We assumed that the NA bisects the chip. Two configurations of the chip were fabricated with differing Y-positions of the microchannel relative to the NA: 5% target strain (Y=0.63mm) and 10% target strain (Y=1.26mm) conditions as measured in the X direction. These represent the intradiscal radial strains observed in the AF during compression and bending [13,14]. We measured strain in the X direction by tracking the 1D displacements of the chip's channel walls using edge detection in MATLAB (MathWorks, Inc).

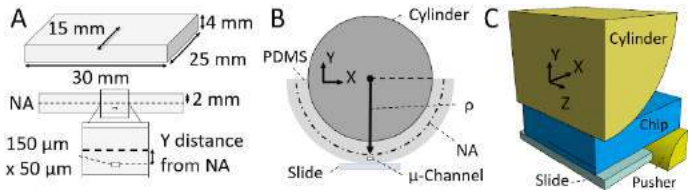

Figure 1: Schematic of (A) chip design with the microchannel, (B) loading setup, and (C) quarter computational model.

A solid model of a quarter symmetrical chip was created in Solidworks (Dassault Systemes) with the channel positioned for three configurations (0%, 5%, and 10% target strain). We imported geometries into GMsh [15] to construct meshes with tetrahedral elements. Then, the meshes were individually imported into Finite Elements for Biomechanics (FEBio) Preview 2.1.1 [16]. We then added the cylinder, the microscope slide, and a "pusher" (Figure 1C). All parts

except the chip used a rigid material model and were meshed using hexahedral elements. The PDMS chip used a Neo-Hookean material model with a Poisson's ratio of 0.45 and a Young's Modulus of 1.7 MPa [17]. We added symmetry boundary conditions and defined frictionless contacts between contacting surfaces. We applied a Y-displacement of 7 mm on the "pusher" to enforce the chip's curvature during the test cycle. The cycle is defined as when the chip starts to bend until it reaches its maximum curvature. We verified the curvature match between the model and the setup by comparing radii of curvature using ImageJ [18] (data not shown). Lab-based strain measurements at the chip's center were compared to beam-theory estimates and model predictions.

For the 10% target configuration, we placed an idealized bovine chondrocyte monolayer, in the shape of a rectangular prism, at the base of the channel to model the strain transfer from the chip to the cells. We filled the channel with a 9 µm tall monolayer and applied a Neo-Hookean material model with a Young's Modulus of 14 kPa and a Poisson's ratio of 0.34 [19]. We added a no-slip contact between the channel bed and the monolayer. We neglected any adhesion between the channel walls and the monolayer. Lastly, we applied a structured hexahedral mesh to the monolayer. We compared the monolayer model's strains to those observed in the AF via magnetic resonance imaging (MRI) [20]. X and Y direction strains in the model correspond to radial and axial strains reported in the AF, respectively. We ran all models in FEBio 2.9.1, then analyzed outputs in FEBio Postview 2.5.

RESULTS

A linear fit of the model results ($\varepsilon = 8.8*Y+1.74$) showed that the NA was 0.198 mm above the midline and not at the midline as predicted by beam mechanics (Figure 2). Compared to the measured strains, the beam mechanics and model predictions had a 24.1% and 4.55% average percent error, respectively. The range of radial and axial strains in critical locations of the AF, as measured by MRI [20], are approximately -4 to 10% and -10 to 0%, respectively (Figure 3). The monolayer model covered a range of 0 to 15.1% and -6.9 to 0% strain in the radial and axial directions, respectively. The monolayer model overshot the positive radial strains by 5.1%. The model was unable to cover -10 to -6.9% axial strain or any negative radial strain.

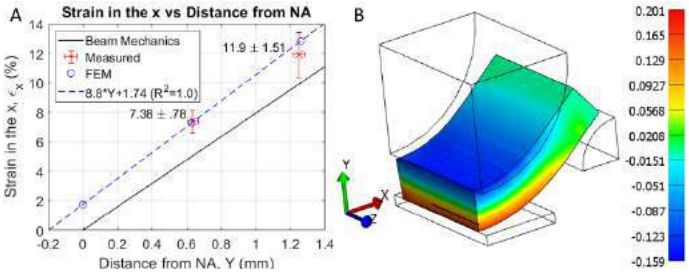

Figure 2: (A) Comparison plot of models to measurements. (B) The model strain results for the 10% target strain chip.

DISCUSSION

The work presented here builds upon our previous development of a deformable organ-chip system that aims to replicate strains experienced by AF cells *in situ*. Results from this study indicate that the computational model provided a more accurate approximation of chip strains than simple beam theory. To cover the full range of axial and radial strains observed *in situ*, we can use modeling to inform us how to scale our chip, position our channel, and alter the chip's bending magnitude.

While many microfluidic platforms exist to evaluate the effects of fluid shear stress on cell behavior [9,10], evaluation of physiologically relevant applied multiaxial strains on AF cells remains unexplored. Our chip provides a controllable method of applying these strains. Since the applied strain in the monolayer model follows a predictable curve over the test cycle (Figure 3), we can adjust bending amplitude to meet target strains. Also, while modeling is often used to characterize factors like mechanical or fluid loading applied by the chip onto the cells, modeling of the cells themselves is often missing. By modeling the cellular mechanics and confirming them empirically, we can estimate internal cellular stresses and strains in three dimensions which otherwise would be difficult to observe. While the current application of our chip is for the AF, biological systems that undergo similar stretching patterns, such as cardiovascular walls, the cervix, or the bladder, can also be investigated by altering the chip geometry to represent healthy or diseased loading conditions. For example, the maximum absolute strain in the left ventricle is 20% in healthy tissues but decreases to 15% right before heart failure [1]. Ongoing work is focused on directly measuring strains in the monolayer to validate model predictions. We will also evaluate cellular responses to different applied strain conditions representative of healthy and degenerated discs.

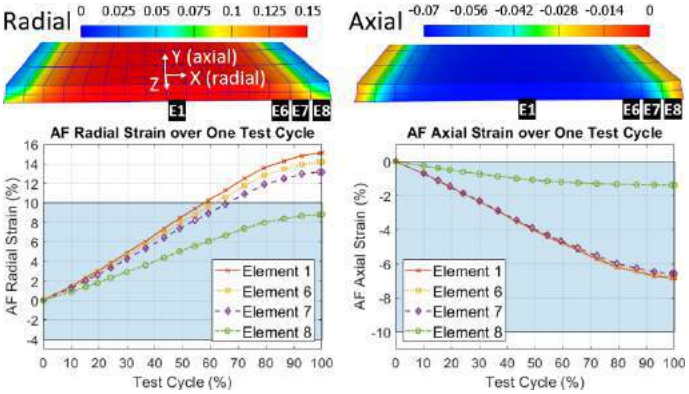

Figure 3: (Left) Radial and (Right) axial direction strains in the chip model were compared to the range of strains reported during AF flexion and extension (shaded region) [20].

INTRODUCTION

The cell surface-attached extracellular glycocalyx (GCX) layer, a heterogeneous polysaccharide chain, is a major contributor to endothelial cell (EC) function and EC-dependent vascular health, acting as a first line of defense against vascular diseases including atherosclerosis [1]. It largely consists of cell-linked sialic acid and glycosaminoglycans including heparan sulfate, hyaluronic acid, and chondroitin sulfate. The endothelial GCX acts as a buffer between the endothelium surface and blood-flow derived shear forces and contributes to vascular barrier functionality [2]. Endothelial surface GCX shedding plays a role in endothelial dysfunction, compromising endothelial barrier function and increasing vascular permeability [2]. This GCX degradation increases lipid flux thereby promoting lipid deposition in the vessel walls and cascading to an inflammatory response, a hallmark of atherosclerosis.

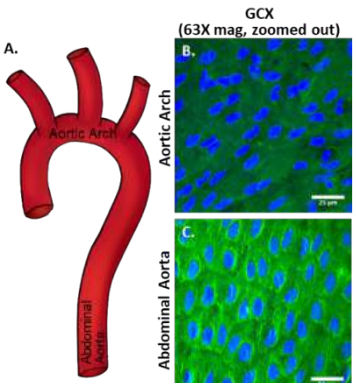

Fig. 1. Flow-dependent regulation of GCX (green) is confirmed in vivo, showing a decrease in GCX expression in aortic arch in comparison to abdominal aorta of mice. (Adapted from Harding et al. *J Transl Med,* 2018.)

The impact and influence of flow on the GCX have been conducted in previous studies. For instance, it provides protection of the endothelium along vessel walls exposed to uniform blood flow and relatively good health [3]. However, in geometrically complex vasculature structures, such as the aortic arch or carotid bifurcation, vessel walls exhibit non-uniform flow patterns with low wall shear stresses due to blood recirculation, attributing to GCX shedding (Figure 1). Van den Berg et al. [4] demonstrated a thinned endothelial GCX at the bifurcation region of a mouse internal carotid artery compared to the common carotid artery with impaired barrier properties of the GCX, contributing to enhanced pro-atherogenic low density lipoprotein accumulation in the intima at the carotid artery bifurcation.

A unique surgical procedure was developed by Nam et al. [5] to perform partial left carotid artery ligation in mice. This was characterized as a model of disturbed flow with characteristics of low and oscillatory wall shear stress. However, this study did not examine GCX expression after acutely inducing disturbed blood flow. The first part of our study sought to elucidate the impact on GCX integrity post-one week of partial left carotid ligation in mice to validate endothelial GCX shedding and correlate that to endothelial dysfunction.

The second part of this study examined vessel wall permeability after GCX shedding by examining resultant macrophage infiltration, related to atherosclerosis onset, as well as nanoparticle infiltration, related to targeted drug delivery for early atherosclerosis intervention. In mice, the left carotid artery (LCA) that was partially ligated to acutely induce disturbed blood flow exhibit both enhanced macrophage infiltration as well as enhanced infiltration of 10-nm polyethylene-glycol (PEG) coated gold nanospheres (GNS) after they were intravenously administered.

METHODS

For the first study, six to seven week-old C57Bl/6-background apolipoprotein (ApoE-KO) male mice were subjected to a partial (LCA) ligation procedure [5] to induce disturbed blood flow patterns in the LCA while the right carotid artery of each mouse was not surgically intervened, to provide a control in each mouse (Figure 2). Ultrasound was performed immediately and magnetic resonance imaging (MRI) was performed on days 1, 5, and 7 post-ligation to demonstrate changes in blood flow in ligated LCAs along with counterpart RCAs. Mice were sacrificed post-one-week ligation surgery and the LCA and RCA were dissected and immunohistochemically stained for GCX to determine percent coverage and thickness. Values of GCX coverage and thickness in LCA vessel walls were normalized to their RCA counterpart. Macrophage infiltration similarly detected, measured, and normalized. The normalized results were expressed as mean ± standard error of

mean (SEM). Normalized data sets were compared using Graph Pad Prism software and a two-way ANOVA test to analyze statistical significance between groups with an alpha value of 0.05.

For the second study, C57Bl/6 male mice at four weeks of age underwent partial LCA ligation surgery. Ultra-small gold nanospheres (GNS) coated with PEG were fabricated. At day 26 post-ligation, anesthetized mice intravenously received 25 mg of biotin-conjugated PEGylated GNS in 150 uL of sterile phosphate buffer solution (PBS). GNS were then allowed to circulate in the mice for 48 hours. The animals were euthanized, fixed, and dissected after 28 days post-ligation surgery, 2 days after GNS treatment. The carotid arteries were then extracted. Fluorescent staining of biotinylated GNS uptake in vessel wall, and GCX expression on the inner surface of the vessel wall, were performed. Measurements were reduced to mean ± SEM. Graph Pad Prism software was used to perform ANOVA statistical analysis to determine statistical significance.

RESULTS

The initial analysis was intended to ensure that partial ligation surgeries were conducted correctly, by qualitatively and quantitatively collecting data through MRI and ultrasound, respectively (Figure 3).

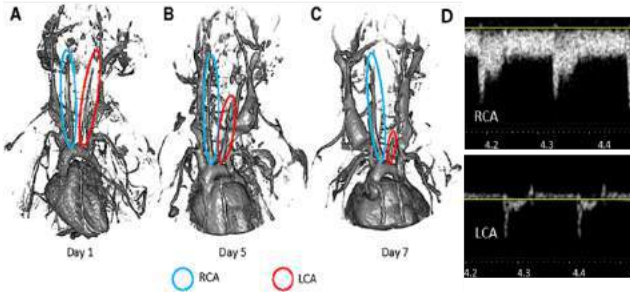

Fig. 3. A, B, and C. Representative MRI images detecting ferumoxytol flowing through mice vessels. Blue circles indicate RCAs and red circles indicate LCAs. Over time, reduction of detectable ferumoxytol in LCA suggests reduced blood flow, corresponding to lower shear stress along LCA wall. **D.** Depicts ultrasound of mouse blood flow velocity in RCA and LCA, demonstrating low shear and oscillation of blood in LCA in comparison to RCA.

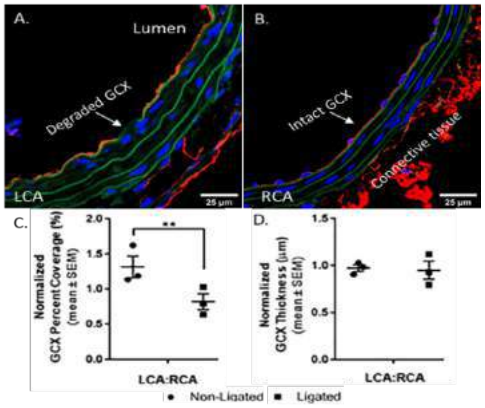

Fig. 4. Partial ligation surgery did cause GCX shedding after one week, in correlation to endothelial dysfunction. There was no change in GCX thickness.

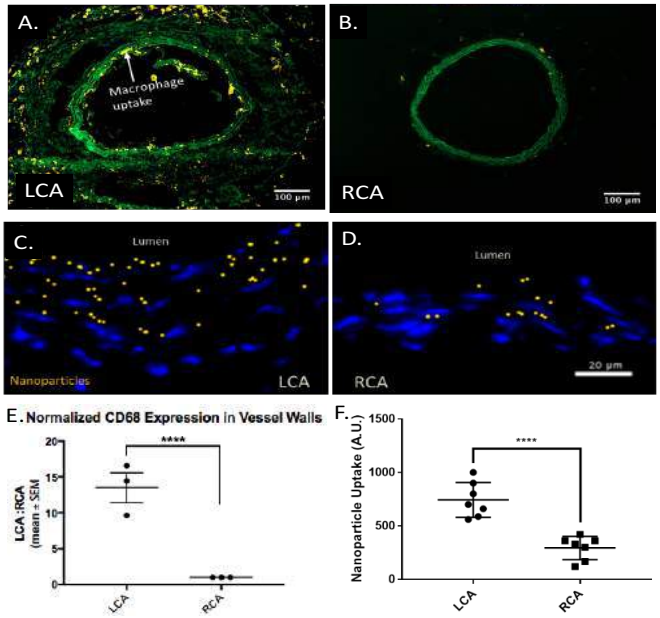

Fig. 5. Histology of mouse LCA and RCA. Elastin (green), Macrophage CD68 (A. & B. yellow), Cell nuclei (blue), and GNS (C. and D. yellow). Data indicates a higher infiltration of macrophages (A.) with a 14-fold increase (E.) and nanoparticles (C.) with a 4-fold increase (F.) in the LCA in comparison to the RCA (B. & D.) due to lower expression of GCX in LCA in comparison to RCA.

DISCUSSION

In summary, we successfully performed a partial LCA ligation to acutely disturbed blood flow in a mouse vessel and we observed subsequent blood vessel remodeling, particularly with respect to GCX, and endothelial dysfunction, both associated with atherosclerosis and cardiovascular disease. We also observed passive targeting of GNS to affected areas. The GCX is often neglected even though it acts as a first line of defense against atherosclerosis, demonstrating that targeting dysfunctional vessels based on GCX shedding offers an innovative approach in early cardiovascular disease therapy and prevention.

INTRODUCTION

During pregnancy, maternal pelvic organs and tissues undergo dramatic remodeling due to hormone-induced biochemical changes and the altered mechanical environment created by the growing fetus [1]. In the levator ani muscles, reduced active force and less shortening during contraction have been detected during pregnancy [2,3]. Meanwhile, the stiffnesses of pelvic connective tissues decrease, corresponding with pelvic organ descent and increased mobility [1,4,5]. These alterations purportedly prepare the maternal pelvic soft tissues for vaginal delivery as a mechanism to prevent stretch-related tissue injury [6].

Evidence suggests that this maternal remodeling and response to a changing mechanical environment alters the shape of the maternal pelvic floor and bony pelvis. Imaging studies have identified increased levator hiatal dimensions during pregnancy, while statistical shape modeling has identified midsagittal pelvic floor shape differences in late pregnancy [5,7]. With robust quantification, maternal pelvic shape could be used to determine the extent of remodeling undergone during pregnancy, which, in turn, could contribute to prediction models estimating risk for stretch-related injury during vaginal delivery.

The aim of this study was to quantify maternal bony pelvis and pelvic floor muscle complex shape variation in pregnancy and to determine relationships between shape and gestational age, maternal age, and parity (i.e. the number of times a woman has given birth). We hypothesized that in the levator plate and coccyx we would see inferior-posterior motion towards a more vertical orientation and straightening with increased gestational age, maternal age, and parity.

METHODS

This was a retrospective study approved by the Institutional Review Board at the University of Pittsburgh and considered exempt at Northshore University HealthSystem. Pregnant women age 20-49 who underwent pelvic MRI without contrast as instructed by their physician for medical indications at Magee-Womens Hospital or Northshore University HealthSystem between 2005 and 2018 were included.

The pelvic floor and bony pelvis were segmented. In this study, the pelvic floor muscle complex included the coccygeus, levator ani, anal sphincter complex, perineal body, and superficial perineal structures (including the bulbocavernosus and transverse perineal muscles and the perineal membrane) all segmented as a continuous structure (Figure 1). To reduce computational costs and improve point correspondence, the perineal membrane and other superficial tissues were segmented as one instead of leaving gaps in between individual structures. The bony pelvis included the coccyx, sacrum, and left and right innominate bones.

To smooth the segmentations and calculate corresponding points, a template pelvic floor and bony pelvis were generated and deformed onto the patient-specific segmentations. Because the coccyx bones are geometrically less complex, an ellipse was used as the template. Once corresponding points were determined, each patient's pelvic floor, bony pelvis, and coccyx were recombined into the correct positions. Then these combined bony pelvis-pelvic floor geometries were imported into Mathematica™ to carry out the remaining statistical shape modeling (SSM) workflow previously established by our lab [7]. This process involves a Procrustes analysis to align the shapes; a principal component (PC) analysis to identify modes of variation; and a parallel analysis to determine significant modes (i.e. those that explain more variance than noise). This results in PC scores—projections of patient-specific data onto eigenvectors—for each patient and significant mode which become the dependent variables in ensuing statistical analyses.

A multiple linear regression was performed to determine which modes were significant predictors of gestational age. Subsequently, t-tests and ANOVAs were used to evaluate potential shape differences associated with age (< 35 vs ≥ 35) and parity (0 vs 1 vs >1).

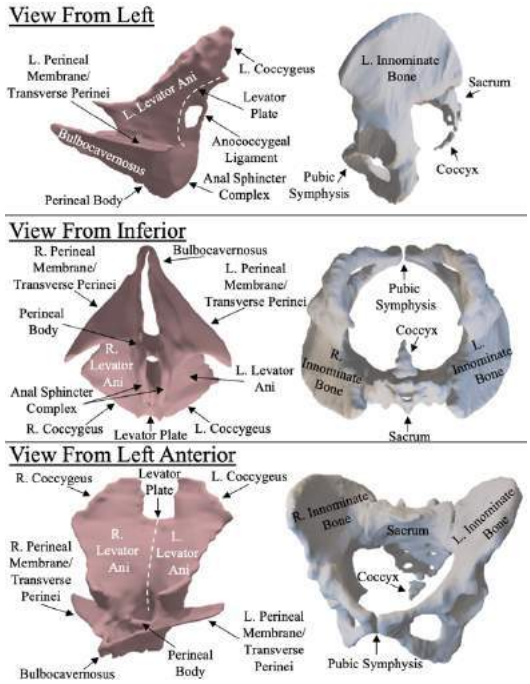

Figure 1: A pelvic floor muscle complex (left) and bony pelvis (right) from multiple views with relevant labels.

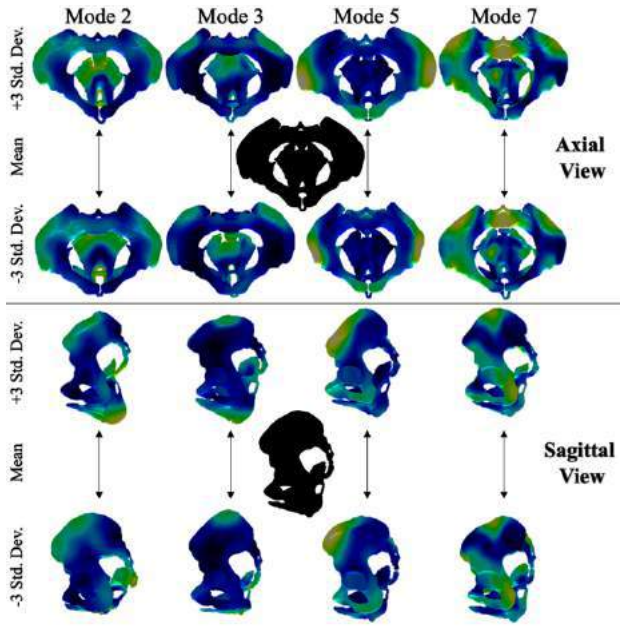

Figure 2: Visualization of relevant modes. Dark to light colors signify regions with minimal to maximal variation from the mean shape.

RESULTS

A total of 25 pregnant anatomies were included with gestational ages ranging from 5 to 36 weeks, maternal age from 21 to 41 years, and parity from 0 to 3. Three women were in the 1st trimester, 10 in the 2nd trimester, and 12 in the 3rd trimester of their pregnancy.

There were 7 significant modes of variation that explained 22%, 20%, 8.4%, 6.8%, 6.3%, 5.3%, and 4.3% of the total shape variance, respectively. Note that across all modes, only 4 PC scores were further than 2 standard deviations from the mean shape. The linear regression revealed that modes 2, 5, and 7 were significant predictors of gestational age (β=0.408, 0.345, and -0.453 and p=0.016, 0.038, and 0.008, respectively) with a model significance of 0.002. Qualitatively, mode 2 indicates perineal descent, levator plate straightening in a more vertical orientation, and coccyx straightening; mode 5 a more anterior pubic symphysis and flatter iliac crest; and mode 7 a more platypelloid shaped (proportionally wider) pelvis with increased gestational age (Figure 2).

Younger vs older shapes significantly differed for mode 2 (p=0.001), with older shapes corresponding with more positive mode 2 PC scores as also seen with increased gestational age. Shapes of varying parity significantly differed across mode 3 (p=0.040), with those with a parity of 1 demonstrating shorter superior-inferior pelvic floor muscle complex length (more negative mode 3 PC scores).

DISCUSSION

These results indicate that pregnancy, age, and parity significantly influence specific aspects of maternal bony pelvis and pelvic floor muscle complex shape. The hypothesized levator plate and coccyx straightening and more vertical levator plate were observed, though a more vertically oriented coccyx was not directly associated with gestational age. This supports the idea that in pregnancy the maternal pelvis remodels to generate shape alterations that would reduce the amount of stretch experienced by pelvic soft tissues during delivery, thereby preventing acute, childbirth-related injuries. Additionally, mode 2 suggests that some of the shape changes observed during pregnancy may also be observed with age.

The findings agree with previous studies that evaluated pregnancy-related changes to the levator plate and perineal body in 2D but build upon these studies with the creation of objective, continuous definitions of bony pelvic and pelvic floor shape variation [4,7]. SSM delivers robust shape quantification while providing shapes that can be used as geometric inputs for finite element models. This will improve computational simulations of, in this case, vaginal delivery, which are currently limited by the frequent use of single, patient-specific anatomy from non-pregnant women. The modes of variation from this study will allow for the generation of anatomies representative of a population of pregnant women to create more generalizable simulation results.

This study was limited by the small number of subjects in subgroups of interest, making it hard to isolate certain relationships—such as those of young, nulliparous women during their first pregnancy specifically. Due to its retrospective design, we only had images at a single time point for each woman. Future steps will include collecting prospective data in order to evaluate women multiple times within a single pregnancy and to correlate shape with delivery outcomes.

INTRODUCTION

Recent advances in cancer nanomedicine have led to the development of several new systemically administered nanoparticles to treat various tumor types. However, the efficacy of those nanomedicines to highly desmoplastic tumors such as breast is hindered by abnormalities in the structure of the tumor vasculature, which can reduce drastically tumor perfusion and subsequently drug delivery. To overcome these obstacles, two strategies, which have been traditionally used separately, are applied in the clinic: vascular normalization and normalization of the tumor stroma [1]. The former involves the judicious use of anti-angiogenic agents to target vessel permeability, while the second is based on the use of mechanotherapeutic drugs exerting anti-fibrotic properties to alleviate intratumoral mechanical forces and thus, decompress tumor blood vessels and improve perfusion [2–4]. The scope of this study is to explore the potential of the anti-fibrotic drug tranilast to act as mechanotherapeutic and improve antitumor efficacy of the nanomedicine Doxil and immunotherapy in murine breast tumors.

METHODS

Animal tumor models. 4T1 and E0771 tumor models were generated by orthotopic implantation of either 5×10^4 4T1 or E0771 mouse breast cancer cells in serum-free medium into the mammary fat pad of BALB/c and C57BL/6 female mice, respectively. Animals were treated with saline (Control), tranilast (200mg/kg, daily, orally), Doxil (3mg/kg, intravenously, once a week) and tranilast-Doxil. Immunotherapy was intraperitoneally applied as a cocktail of 5mg/kg cytotoxic T lymphocyte-associated protein 4 (anti-CTLA-4) and 10mg/kg programmed cell death 1 (anti-PD1).

Immunohistochemical assessment of TME. Vascular perfusion and functionality: Prior to primary tumor removal, animals were anesthetized and intracardially injected with biotinylated lycopersicon esculentum lectin (4mg/kg). Harvested tumors were fixed, sectioned and immunostained accordingly. Blood vessel number was measured from the positive staining of the endothelial marker CD31 while the area fraction of perfused vessels was determined as the ratio of lectin and CD31 overlapping staining to CD31 positive staining. Pericyte coverage of perfused vessels was determined by the co-localization of CD31 and lectin with the pericyte marker, αSMA. Hypoxia: Mice bearing E0771 tumors were injected with pimonidazole HCl (60mg/kg) 2hr prior to tumor removal. ECM content: Fixed tissue cryosections were incubated with anti-collagen I and anti-hyaluronan antibodies. Fluorescence signal was quantified using an in-house MATLAB code.

Biomechanical analysis. Interstitial fluid pressure was measured *in vivo* using the wick-in-needle method just before tumor harvesting. Characterization of the mechanical properties and calculation of the elastic modulus were determined using an unconfined compression experimental protocol.

RESULTS

Re-purposing of tranilast as a mechanotherapeutic agent enhances antitumor efficacy of Doxil by producing a more than 3-fold increase in tumor doubling time, while tranilast or Doxil monotherapies do not have any impact on the growth of either syngeneic mammary tumor model, 4T1 or E0771 (Figure 1A, B). Consistent with this pertinent delay in tumor growth was the prolonged survival of animals treated with tranilast-Doxil combination. Tranilast alone had no effect on animal survival, whereas Doxil monotherapy produced a modest effect (Figure 1C).

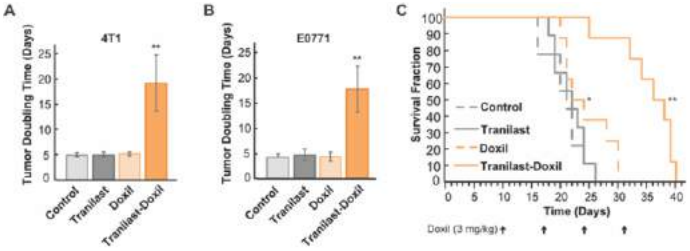

Figure 1. Tranilast potentiates anti-tumor efficacy of Doxil nanomedicine. Quantification of tumor growth rate, based on the time to reach double the initial volume, for 4T1 (A) and E0771 (B) tumors. (C) Kaplan-Meier survival curves for E0771 tumors treated as indicated.

As tranilast has been previously found to modulate TME by altering the expression of the two abundantly found extracellular matrix components (ECM), collagen and hyaluronan, we sought to examine whether its combination with cytotoxic nanomedicine may yield to a more efficient normalization phenotype. To address this question, we performed immunofluorescence staining and found that Doxil potentiates tranilast's effects in terms of ECM remodeling resulting to a further reduction in collagen and hyaluronan levels (Figure 2A-C).

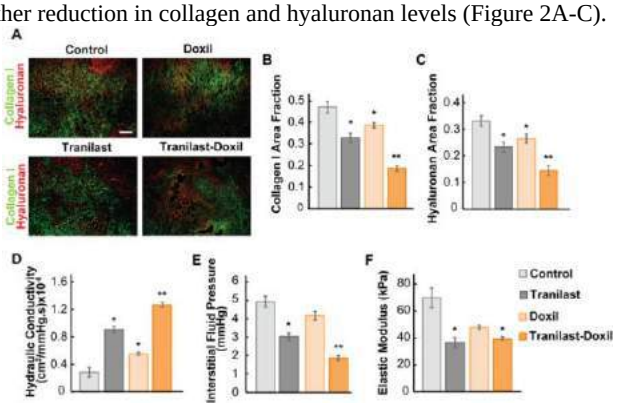

Figure 2. Nanomedicine promotes tranilast-mediated normalization effects. (A-C) Fluorescence images and quantification of collagen I (green) and hyaluronan (red) of 4T1 tumors. (D) Hydraulic conductivity, (E) interstitial fluid pressure and (F) elastic modulus measurements.

To further explore the additive effects of cytotoxic nanomedicine in reducing the mechanical forces and stiffness, we assessed tumor hydraulic conductivity, interstitial fluid pressure (IFP) and elastic modulus. Both tranilast and Doxil increased tumor hydraulic conductivity, while the most prominent effect (6-fold increase) was observed following their combination, in both 4T1 and E0771 tumors (Figure 2D). Tranilast-Doxil also produced a 2-fold decrease in IFP (Figure 2E) and tumor elastic modulus similarly to tranilast (Figure 2F).

Since ECM constituents develop reciprocal interactions with tumor blood vessels, we next investigated the impact of the combinatorial treatment on vascular perfusion. We found that the percentage of perfused vessels was increased by 66% after tranilast-Doxil co-administration compared to control (Figure 3A,B). This improvement in vascular functionality is explained by an analogous increase in vessel diameter and pericyte coverage (Figure 3D). Normalization of the tumor vasculature also improved tissue oxygenation as indicated by the reduction in hypoxic fractions (Figure 3C).

Moreover, we studied the antitumor effects of normalization combined with the immune checkpoint blockers (ICB) cocktail consisting of a mixture of anti-CTLA-4 and anti-PD1 to treat 4T1 and E0771 tumors.

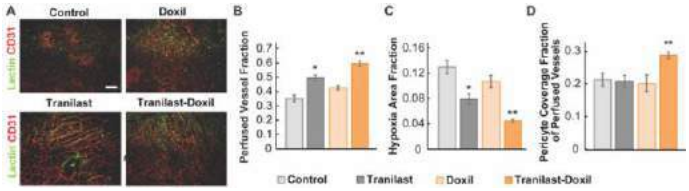

Figure 3. Enhanced tumor normalization by tranilast-Doxil improves vascular functionality, perfusion and oxygenation. (A) Fluorescence images of 4T1 sections stained for lectin (green) and CD31 (red). (B) Quantification of CD31 and lectin co-expression indicating vascular perfusion. (C) Quantification hypoxic fraction in E0771 tumors and pericyte coverage of perfused vessels (D).

We first employed an overall survival study and found that animals receiving the tranilast-Doxil-ICB combination displayed a significant survival benefit compared to all other groups for both tumor models (Figure 4A). To investigate the mechanism of the improved therapeutic outcome of the triple therapy, we repeated the experiment in 4T1 tumors and excised the lungs 10 days after resection of primary tumors. Our findings indicate a significant decrease in the macrometastases following tranilast-Doxil-immunotherapy treatment (Figure 4B).

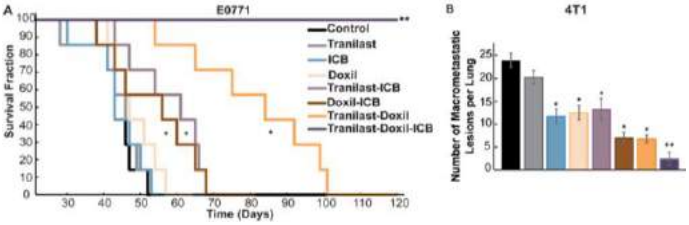

Figure 4. Tranilast increases the efficacy of nano-immunotherapy by prolonging survival (A) and reducing metastasis formation (B).

DISCUSSION

Our findings suggest that tranilast enhances drug efficacy in both primary and metastasis site and acts with Doxil to further reduce ECM and alleviate tumor mechanical stresses. Stress alleviation promotes tumor vessel decompression and functionality leading to improved perfusion. Subsequently, the increased tumor oxygenation potentiates immune stimulation and therapeutic outcome of immunotherapy extending animals survival and inhibiting metastasis. Our results demonstrate the potential of mechanotherapeutic agents to improve the efficacy of standard-of-care cancer therapies.

A CONTINUUM MECHANICS APPROACH TO MODEL STIFFNESS SENSING BY SMOOTH MUSCLE CELLS

A. Karkhaneh Yousefi (1), C. Petit (1), S. Avril (1)

INTRODUCTION

Aortic Smooth Muscle Cells (SMCs) play a vital role in maintaining homeostasis in the aorta by sensing and responding to mechanical stimuli. In the healthy aorta, SMCs are essential for the regulation of the wall stiffness as they can maintain mechanical homeostasis through variations of their active tone [1, 2]. Therefore, missensing of mechanical stimuli by SMCs can alter the maintenance of mechanical homeostasis and induce impaired adaptations that are responsible for the progression of the aortic aneurysm [3]. However, the mechanisms that underlie the ability of SMCs to sense and respond to stiffness change are still partially unclear.

Recent studies have highlighted the significant role of contractile acto-myosin units in the cytoskeleton that can act as stiffness sensors [4]. In the present study, we investigate stiffness sensing through the contractile acto-myosin units. We develop a new computational model based on the principles of thermal strains for the contractile behavior of SMCs that can account for the variations of cellular Traction Forces (TFs) with the surrounding stiffness [5]. To account for the inherent variability of cellular responses, large populations of SMCs are modeled with the Finite Element (FE) method, each cell having a random number and a random arrangement of Stress Fibers (SFs) as they are the main contributor to the force-generating capacity inside a cell.

METHODS

We assume that SFs uniformly shorten after myosin activation. As SMCs are attached to the substrate at focal adhesions, shortening results in a deformation of the substrate. If the substrate is sufficiently compliant, the deformation is large and SFs only withstand a small tensile force, but if the substrate is rigid, the deformation becomes negligible and SFs have to withstand large tensile forces. Therefore, TFs tend to increase with the substrate stiffness, which is consistent with recent Traction Force Microscopy (TFM) results [5]. However, for too stiff substrates, TFs can potentially reach a certain elastic limit, which corresponds to sliding between actin and myosin filaments [6].

To model shortening of SFs induced by myosin activation, we introduced an eigenstrain, denoted $\alpha\Delta T$, analogously to a thermal contraction: α is the contraction coefficient and ΔT represents the level of myosin activation, satisfying $0 \leq \Delta T \leq 1$, in which $\Delta T = 1$ corresponds to the maximal activation and $\Delta T = 0$ to no activation. Let us consider a SMC on the surface of a substrate. After some myosin activation $\Delta T > 0$, the actual shortening of SFs satisfies $\epsilon_a < \alpha\Delta T$ as they are adherent to the substrate. Therefore, we assumed that SFs have a stress-strain response that is composed of two parts (Figure 1):

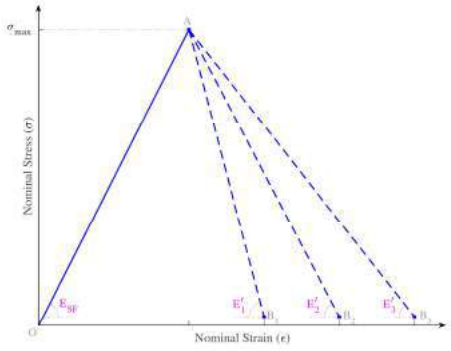

Figure 1: Schematic stress-strain behavior of a SF.

$$\sigma = E_{SF}(\alpha\Delta T - \epsilon_a), \qquad \epsilon \leq \epsilon_{max} \qquad (1)$$

$$\sigma = \sigma_{max} + E'_{SF}(\epsilon - \epsilon_{max}), \qquad \epsilon > \epsilon_{max} \qquad (2)$$

in which E_{SF} is the Young's modulus and E'_{SF} is the softening coefficient. It was also assumed that the strain threshold satisfies: $\epsilon_{max} = \xi\alpha\Delta T$, where $0 < \xi < 1$. For the FE modeling, we assumed that the stiffness of a SF was a constant, with $E_{SF} = 50$ MPa and the cross-section being circular with a diameter 0.2 µm [7]. The model parameters α, ΔT, ξ, and E'_{SF} need to be determined by experimental data.

Aortic SMCs usually exhibit a spindle shape with focal adhesions at both ends. In our model, we consider a semi-spindle of dimensions 250 x30 µm^2 which corresponds to the average size of SMCs [5]. The model includes the cell membrane, cytoplasm, nuclear envelope, and nucleus. We assumed that the cytoplasm of SMC includes a random number of SFs (mean = 25, standard deviation = 6.05). At least half of the SFs were connected to focal adhesions on both sides, the others being connected to the nuclear envelope at one end.

This single SMC and the underlying substrate (0.4x5x5 mm^3) were meshed and computed with the Abaqus software. A tie constraint was assigned between the cell membrane and the substrate surface at the focal adhesion (surface of 148.84 µm²). We assumed that the sum of reaction forces at a focal adhesion area was a prediction of the TFs measured in the TFM. The cell membrane and the nuclear envelope were modeled as neo-Hookean materials with a shear modulus of 600 kPa [8]. The same behavior was also assumed for both the cytoplasm and the nucleus with a shear modulus of 100 Pa. Equivalent Poisson's ratios of 0.45 and 0.49 were assigned to the substrate and to all the cell components, respectively.

RESULTS

To identify the model parameters, we confronted its predictions with the TFM results of SMCs on the surface of substrates with different elastic modulus 4, 8, 12, and 25 kPa [5]. By fitting an exponential probability distribution function to the experimentally measured TFs, we estimated the average activation level $\Delta T = 0.132$. Then, 300 cells were generated for FE simulation. Each cell had a random arrangement, a variable number of SFs, and an exponential distribution of the activation level. By fitting the FE results to experimental data, we obtained $\alpha = 0.034$, $\xi = 0.68$, and $E'_{SF} = -19.9$ MPa.

In Figure 2a, we show the strain field around the focal adhesions on the surface of the substrate simulated for one of the randomly generated SMC with the FE model, using 25 SFs, in which 13 of them connect one focal adhesion to the other one. The predicted force was $TF = 15.9$ nN for the 12 kPa stiffness substrate. Figure 2b also shows the experimentally measured strain field on the surface of the same substrate for a SMC. The strain field patterns in both figures are similar.

In Figure 3, we compare the measured TFs with the average values among 300 random SMC predicted by the numerical model. It can be observed that the identified model with the softening behavior is in very good agreement with the experimental results, whereas the absence of softening in the material model misses reproducing precisely the stiffness sensitivity for substrates of large stiffness.

DISCUSSION

In the current study, we have developed the first continuum mechanics model of SMCs accounting for stiffness sensing through the contractile acto-myosin units. Model predictions were in very good agreement with cellular tractions measured on different substrates. One of the most important aspects of the proposed model is to account for the intercellular variability of acto-myosin contractility. The variability is modeled through a random arrangement of SFs, a variable number of SFs, and an exponential distribution of activation levels.

The predictability of the model combined to its relative simplicity are promising assets for further investigation of stiffness sensing in 3D environments. Eventually, this could contribute to decipher the effects of mechanosensitivity impairment, which are known to be at the root of aortic aneurysms. In addition, our future studies will be extended to investigate changes in the load applied to the nucleus in different environments as it can affect gene expression [9].

HETEROGENEOUS BLOOD PERFUSION MAPPING IN CANCEROUS LESIONS

Manpreet Singh

Department of Mechanical Engineering,
University of Maryland Baltimore County,
Baltimore, MD, USA

INTRODUCTION

Perfusion mediated heat-sink impede the treatment efficacy of cancer treatments. The heat-sink effect is detrimental to thermally-driven ablation therapies as it induce cooling with its functional blood supplying vessels which carries away heat via thermal convection mode of heat transfer. It has profound implications within zones of conductive heat transfer while designing an effective cancer treatment protocols for thermal ablation therapies. With the recent advancements in medical imaging and computational resources, patient- or tumour specific extraction of heterogeneous perfusion is feasible. Dynamic contrast-enhanced sequences-Magnetic Resonance Imaging[1] (DCE-MRI) and Doppler ultrasound demonstrates such extraction of heterogeneous blood perfusion rates in human malignancies which varies very widely i.e. in the range of 5-15 mL per 100 g per min. Furthermore, tumours exhibit dead necrotic core region having zero perfusion, and intermediate and peripheral blood flow regions which may have low, moderate or high perfusion depending on shape, size and the growing stage of tumour.

Due to the large density variations of soft healthy tissues than diseased tissues, the tumour appears with brighter voxels in MRI slices after contrast injections. For the breast tumour reported discussions, only homogeneous blood perfusion (isotropic) is considered to perform any kind of computational simulation. As per our understanding, there is no reported work in context of breast cancer that has considered the heterogeneous blood perfusion (anisotropic) on spatial co-ordinates of the computational domain to compute results for clinical relevance.

METHODS

Clinical breast MRI examination was performed at Post Graduate Institute of Medical Education and Research, Chandigarh, India with Siemens MAGNETOM Aera at magnetic field of 1.5T using a standard and consistent clinical breast MRI protocol. MRI uses magnetic fields instead of x-rays to produce very detailed, cross-sectional images of the body. One Woman was imaged in the prone position using a dedicated multichannel surface array breast coil. After the native scan was obtained, DCE were acquired in axial plane employing 3D T1-weighed fast gradient echo-based DCE series with one pre and three post-gadolinium contrast-enhanced sequences. Gadodiamide (Omniscan GE Healthcare) at a dose of 0.01 mmol/kg was injected manually. Technical parameters employed were Plane: axial, multichannel (8 channel) breast coil, 3-D mode, SPIR fat suppression, parallel imaging factor 1.5 R/L, TR-5.6 ms, TE-3 ms, slice thickness of 1 mm and a flip angle of 10 degrees. MRI exams for breast imaging use a contrast material (usually gadolinium-DTPA) that was injected into a vein in the arm before or during the exam to improve the ability to capture detailed images of breast tissue.

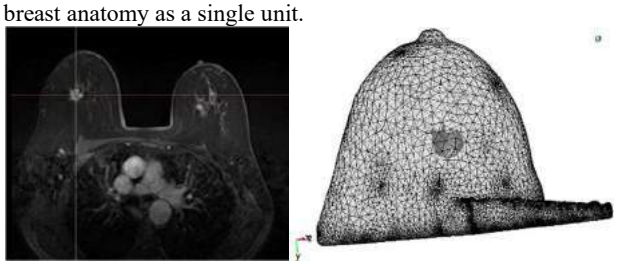
MRI Dicom data has information about both breasts including other organs such as lungs but only breast tumour specific information is extracted as part of this analysis. Therefore, available Dicom images (.dcm format) are first converted into (.tiff format) with IrfanView 64 software in order to successfully import into NRecon®; Reconstruction software package provided by Microphotonics to select the region of interest i.e. left breast only. We have used NRecon software to remove all other information except region of interest i.e. breast tumour tissue located in fibro-glandular tissue compartment. All necessary information like slice thickness for MRI scan were noted through MIMICS v. 19.0. The resultant reconstructed images were greyscale images where the pixel intensities are between 0-255 where 0 being black and 255 being white. All the voxels represents the coordinates for the generated mesh through 3-matic software. A Matlab® (Natick, MA)

code is written to convert all 108 reconstructed images into similar number of text files (.txt format) which contains information about the co-ordinates of breast tumour anatomy. The brighter pixels from individual slices represents some values against co-ordinates which we have used to identify the tumour irregular boundaries as extracted through MIMICS software 19.0. These co-ordinates will be mapped with the Comsol-multiphysics 5.2 co-ordinates of the three-dimensional geometry of tumour. Thereafter, all text files generated through Matlab will now be merged into single Excel file (.csv format) through software SAS® (SAS Institute, Cary, NC) which is widely used for data analysis and statistics. This large excel file is successfully used to define heterogeneous tissue blood perfusion on mesh co-ordinates. Volumetric linear interpolation function and constant extrapolation is used between elements to achieve smooth distribution without incurring singularities while loading the .txt file/spreadsheet for blood perfusion.

The present computation uses image-based mesh generation and interpolation features of Comsol Multiphysics 5.2 to define blood perfusion based on nearest neighbor method and then using these interpolation functions to define blood perfusion as a function of mesh coordinates. The nearest neighbor of tumour (subpart node T) node corresponds to the node *i* in the breast (object) mesh having the minimum Euclidean distance (ED) to the tumour node via eq. 1 as:

$$ED = \sqrt{(x_{nodeT} - x_i)^2 + (y_{nodeT} - y_i)^2 + (z_{nodeT} - z_i)^2} \quad (1)$$

where *x, y, z* represents the nodal coordinates. It is ensured that tumour offers a higher level of refinement compared with the mesh for the breast anatomy as a single unit.



(a) (b)

Figure 1: DCE-MRI slice of breast cancerous lesion in axial plane and extraction of three-dimensional breast anatomy[2].

RESULTS

Fig. 1 illustrates one slice from a set of 108 images of DCE-MRI acquisition. Three-dimensional model of female breast is generated using imaging segmentation tools. It is ensured that each individual pixel location must be mapped through mesh coordinates to visualize the pronounced heterogeneity. One experimental study[3] based on positron emission tomography reports the values of mean blood flow of tumour as 29.8±17.2 (SE) ml/dl/min in comparison to healthy breast tissue blood flow of 1.4 ml/dl/min. Thus, the perfusion metrics shown in fig. 2 for a breast malignancy shown in present scenario is in agreement and typically follows similar order of magnitude[4] i.e. 5.3×10^{-3} to 5.3×10^{-2} m^3s^{-1} m^{-3} as reported and used in estimation of temperature fields through priori-simulations[2]. It is to note that the experimental and histological studies on breast tumours suggests existence of a delicate vasculature than normal surrounding tissue, thus one would suspect to have lower prevailing perfusion micro-environment but the findings from in-vitro and in-vivo studies reveals counterintuitive higher mean blood flow. Such an inference is an indicative reflection of increased metabolic demand by the tumour.

DISCUSSION

The present study is expected to unveil a deeper understanding on inclusion of heterogeneous perfusion source maps in computation of temperature fields during thermal ablation treatments. We have presented means to generate anistropic perfusion maps which were simply ignored over homogeneous perfusion assumptions and thus, may results in the suboptimal treatment efficacy of breast cancer treatments. Our present study reveals the need of inclusion of such heterogeneities into computational experiments to understand the thermal variations within tumour parenchyma. The computational approach we propose here will open new avenues to further develop the therapeutic strategies that specifically target cancerous lesion. This can successfully be deployed with unprecedented accuracy in clinics to better understand the physics behind in-vivo results, rather than simply relying on purely experience driven repetitive clinical trials. It is still the choice of the medical practioner/physicist which computational model to use and usually such selection is restricted based on purpose, and available imaging details. We believe that the extracted blood perfusion rate would be useful to improve accuracy of theoretical simulation, especially when the simulations are used to design heating treatment protocols. Future work should extend our computational framework to patient-specific complex irregular tumour anatomies in the near vicinity of blood vessels.

INTRODUCTION

A significant consequence of ventricular remodeling, which contributes to both decreased cardiac function and heart failure (HF), is increased passive (diastolic) myocardial stiffness [1]. However, there exists no accepted clinical method to measure changes in myocardial stiffness. Myocardial stiffness can be measured by *ex vivo* mechanical testing which is not feasible for clinical applications. Passive myocardial stiffness can also be inferred from the left ventricle (LV) end diastolic pressure-volume (*P-V*). However, *P-V* relationships inherently depend on ventricular geometry and boundary conditions. Hence, this method does not extract intrinsic myocardial stiffness.

Constitutive modeling is one method of obtaining *in vivo* myocardial stiffness. Constitutive models provide stress-strain relations that describe the material's response to different loading conditions, and the model parameters define the material stiffness. Hence, the material stiffness can be deduced from measured deformation and loading conditions. Cardiac magnetic resonance imaging (MRI) combined with measured loading pressures and a finite element modeling (FEM) framework has been used to obtain patient-specific myocardial stiffness [2]. However, quantifying the accuracy and precision of these MRI and FEM-based stiffness estimation techniques is understudied due to the challenge of obtaining ground-truth measures of *in vivo* myocardial stiffness. Validation of these methods necessitates the development of a highly controlled *in vitro* stiffness estimation framework that incorporates a ventricular phantom of known stiffness properties.

The aims of this study were: (1) to develop 3D-printed heart phantoms with myocardium-mimicking materials of known mechanical and MRI properties; and (2) to demonstrate the feasibility of an MRI compatible *in vitro* diastolic filling setup for estimating phantom ventricular mechanics and stiffness.

METHODS

Tissue-Mimicking Material Selection: Uniaxial tensile testing samples of Silicone elastomer (Sylgard) were developed and mechanically characterized according to the ASTM D412 standard [3] using an Instron 5848 Microtester (100N load cell). MRI relaxation properties were measured using T1-mapping (MOLLI 5-3-3, spatial resolution $1.00\times1.00\times5.0\text{mm}^3$) and T2-mapping (T2-prep FLASH; flip angle 12º; spatial resolution, $1.00\times1.00\times5.0\text{mm}^3$).

Heart Phantom Development: High-resolution images from a healthy *ex vivo* porcine heart (geometrically restored to its *in vivo* mid-diastasis geometry) [4] were used to generate a 3D geometric mesh model of the heart. The geometric model was modified (Fusion 360, Autodesk) to incorporate ventricular ports and an apical anchor. The LV and right ventricular (RV) blood pools were segmented and converted into sterolithography (STL) files, then 3D printed (Ultimaker 3 Extended) with water-soluble polyvinyl acid (PVA). An STL negative for casting was created from the whole heart segmentation, then 3D printed using polylactic acid (PLA). A heart phantom was then cast using a blend of 20% Sylgard 184 and 80% Sylgard 527.

Inflation Flow Loop: The final model was embedded within a flow loop (Figure 1) controlled by a programmable MRI-compatible linear motion stage (MR-1A-XRV2, Vital Biomedical Technologies). The loop was designed to reproduce *in vivo* diastolic LV filling. MRI-compatible pressure transducers (Micro-Tip SPR 350S, Millar) in the ventricular cavities enable acquisition of filling pressures.

Imaging Methods: All *in vitro* images were acquired on a 3T (Skyra, Siemens). First, a static reference imaging volume of the entire phantom was acquired (3D SPGR; TE/TR = 2.17/5.5ms; FA = 20º; isotropic 1.00mm^3), then a cardiac-like late-diastolic filling cycle (sinusoidal flow: 13 mL/cycle mean, 1s period) was induced. Phantom motion was imaged with an externally triggered cardiac tagging

sequence (TE/Tres=3.1/53.0ms; FA=10º; spatial resolution, 1.0×1.0×8.0mm^3; 17 phases per cardiac cycle, 5mm grid tags) with slices spanning the whole phantom.

Geometric Accuracy: Phantom geometric accuracy was assessed qualitatively using landmark-based rigid registration of *in vivo* MR images (bSSFP; TE/TRes=1.6/17.9ms; flip angle, 38º; spatial resolution, 1.2×1.2×8.0mm3; mid-diastasis cardiac phase) to *in vitro* 3D SPGR images at their native voxel resolution (MITK, German Cancer Research Center). Landmarks used for registration consisted of four points in the most basal slice (septal wall center, anterior papillary muscle, free wall center, posterior papillary muscle) and four similar points at a slice near the apex.

Quantitative Strain Analysis: Tag lines were tracked with a neural-net based algorithm, which produced displacement curves for tag line intersections [5]. Circumferential strain (Ecc) was calculated from displacements with a radial basis function interpolant [6].

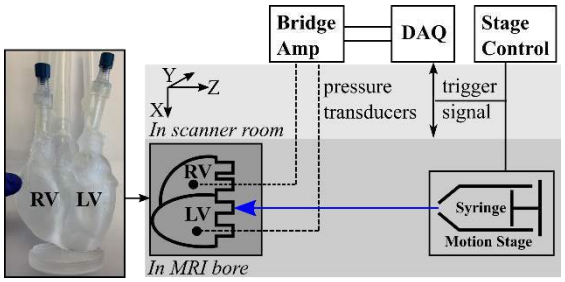

Figure 1: MRI compatible experimental setup

RESULTS

Mechanical and MRI properties of Sylgard blends are reported in Figure 2 and Table 1. Reference values for healthy myocardium are shown. Blends with 10% and 20% Sylgard184 exhibit comparable mechanical and MRI properties to myocardium. The 20% Sylgard184 blend was chosen as heart phantom material for easier workability.

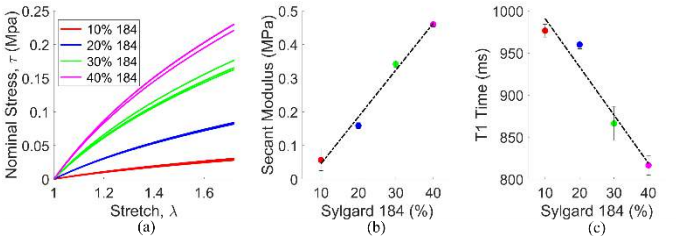

Figure 2: (a) Stress-Stretch curves for Sylgard 184 and 527 blends (b) Secant modulus at stretch of 1.05 (c) T1 relaxation time

Table 1: Sylgard material properties (chosen blend highlighted). Reference values for Myocardium shown in last row

Sylgard 184	Sylgard 527	Secant Modulus (MPa)	T1 time	T2 time
10 %	90 %	0.057±0.032	976.5±7.7	434.8±18.0
20 %	80 %	0.159±0.009	959.9±5.0	313.8±12.3
30 %	70 %	0.342±0.010	866.2±20.3	232.7±10.7
40 %	60 %	0.460±0.007	816.5±11.5	214.7±14.1
Myocardium		0.06 to 0.412 [7]	1158.7 [8]	45.1 [8]

Heart phantom development procedure adequately reproduces the *in vivo* and *ex vivo* geometry as shown by the comparison of registered *in vitro* (phantom), *in vivo* and *ex vivo* (porcine) images (Figure 3).

Tagged image acquisition and analysis demonstrate the feasibility of obtaining quantitative strain measures during late diastolic inflation. Recorded pressures were sinusoidal (peak 28mmHg; mean 14 mmHg) (Figure 4). Strain also followed a sinusoidal pattern (like the filling flow pattern) with peak global LV E_{cc} of 0.0076 (Figure 5) and 1.05mm of peak displacement which accords with magnitude expected *in vivo*.

DISCUSSION

This work demonstrates that subject-specific heart phantoms with diastolic myocardium-mimicking properties can be developed and incorporated within an MRI-compatible diastolic filling setup for estimating phantom material stiffness. Though phantom properties are comparable to myocardium, *in vivo* heart anisotropy was not replicated.

Tensile testing of samples allows for ground-truth phantom material stiffness estimates. Future work will use this system to estimate the phantom's material stiffness as proof-of-principle that material stiffness estimation is feasible *in vivo*. Different subject-specific heart phantoms based on *in vivo* images can be manufactured, with phantom stiffness tuned to a known value. This enables characterizing the accuracy and precision of the stiffness estimation framework.

INTRODUCTION

10 in 1000 babies are born with a clinically significant congenital heart defect each year in the US and 8 in 1000 in the world [1]. Univentricular heart defects are among the most serious pathologies which lead to death without neonatal treatment. A series of palliative surgical courses including the Fontan procedure is typically performed for these patients to utilize the single ventricle solely for pumping the oxygenated blood to the systemic and pulmonary circulation arranged serially. Despite the efficacious lifesaving feature of Fontan for the patients undergoing the operation, there is a growing rate of patients with failed Fontan physiology in a long-term postoperative run. For example, pulmonary arteriovenous malformations (PAVMs) can occur after the Fontan procedure and lead to decreased systemic oxygenation.

Transporting pulmonary growth factors, the uneven distribution of hepatic flow from inferior venous return to both lungs in total cavopulmonary connection (TCPC) is believed to play a key role in the cause of PAVMs [2]. While hepatic flow distribution can only be predicted by computational fluid dynamics (CFD), to our knowledge no experimental validation has been performed in the literature. Therefore the primary aim of the present study is to provide an experimental protocol and series of *in-vitro* data to validate patient-specific simulations performed in pre-surgical planning with complex vascular connections. The validation approach is demonstrated in a very complex patient-specific model as well as in two standard idealized TCPC geometries with different caval offsets. Three key performance parameters including power loss (PL), hepatic flow distribution (HFD) and total pulmonary flow split (TPFS) are experimentally quantified at different SVC/IVC (Superior/Inferior Vena Cava) flow ratios (FR). Furthermore, CFD simulations employing different turbulence and solver settings are performed for the proposed models and the final results are compared with the obtained experimental values.

METHODS

Two ideal TCPC geometries having half-diameter and one-diameter offset (DO) for inlets (IVC and SVC) were designed using SolidWorks (Dassault systemes, Waltham, Massachusetts, USA). The inner diameter was considered to be 7 mm with a 10D extension from each inlet/outlet to eliminate the entrance effects on the impingement zone as depicted in Figure 1.a and 1.b. For the patient-specific anatomy, the IRB approved image and PC-MRI data for a complex single ventricle patient having interrupted IVC and azygous (AZY) vein continuation was obtained by 1.5-Tesla scanner (SignaHDx; GE Medical Systems, Milwaukee, WI, US). The average velocity values were calculated to be used as boundary conditions inputs for CFD analysis. The final patient geometry was scaled with a factor of 0.58 to fit the 3D printer platform (Figure 1.c). The inlet boundary condition values were accordingly scaled to keep the Reynolds number identical to the clinical conditions.

The models were 3D printed using Formlabs (Somerville, Massachusetts, US) followed by a post-curing process to enhance model rigidity and reduce water absorbability. Figure 2 represents the schematic of the *in vitro* setup for the patient-specific prototype. Distilled water was used as the working fluid and loaded with tracer fluid for IVC inlet. The tracer fluid (Pelikan 4001 Royal blue ink) concentration measurements were performed using Multiscan FC microplate reader (ThermoFisher, Waltham, Massachusetts, US). A calibration process was carried out to identify the linear regression relation between the absorbance data obtained from the microplate reader and the tracer fluid concentration. The boundary condition for right and left pulmonary arteries (RPA and LPA) was considered zero

gauge outlet pressure. IVC and SVC inlet flowrates were 40 and (20,30,40) L/hr respectively in ideal model. IVC, RSVC,LSVC and AZY flowrates were 60, 15, 24 and 40 L/hr respectively in patient-specific model.

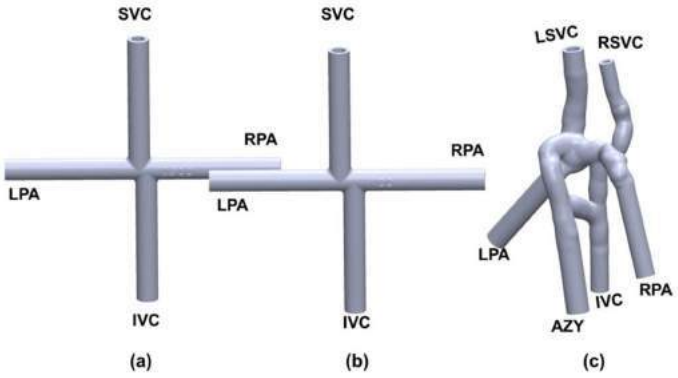

Figure 1: Geometrical representation of experimental prototypes. a: 0.5DO ideal TCPC, b: 1DO ideal TCPC and c: real patient-specific TCPC model

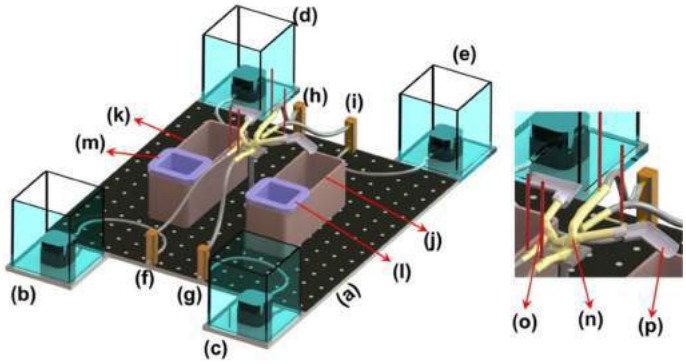

Figure 2: Schematic representation of the *in vitro* experimental setup. (a) Anti-vibration optical table. (b)-(e) RSVC, LSVC, AZY IVC reservoirs respectively. (f)-(i) LSVC, AZY IVC flowmeters respectively. (j)-(k) LPA and RPA waste reservoirs. (l)-(m), LPA and RPA sample collectors. (n) Model prototype, (o) pitot tube pressure probes and (p) flow guidance extension.

For each case, experiment was repeated three times to account for repeatability and the averaged values were considered for the final report. Outlet samples from RPA and LPA were collected for duration of 180 secs and the flowrates were calculated by measuring the collected sample volume with a resolution of 10 mL. The static pressure measurements were accomplished by the pre-integrated pitot tubes at each inlet wall. PL was calculated based on total pressure which was obtained by adding the dynamic part using the averaged inlet/outlet velocities. The CFD simulations were carried out in Star ccm+ (Siemens, Melville, NY, USA). Four different CFD solvers were considered as: CFD1: second order implicit unsteady laminar, CFD2: RANS Standard k-ε two-layer, CFD3: RANS Realizable k-ε and CFD4: RANS Realizable k-ε two-layer.

RESULTS

Discretization error for CFD simulations was analyzed by performing a mesh independent study at three different grid resolutions of 153K, 455K and 830K elements. The absolute difference for domain averaged velocity and concentration was found to be less than 1% for all grid levels. In addition to the residual reduction of 10^{-5} as the convergence criterion, we monitored the integral quantities such as mass flowrate at the outlets and continued the iteration until a steady state is achieved in RANS simulations. In transient simulations, the temporal iteration was continued until a convergence in ensemble average is achieved for all quantities. Table 1 summarizes a part of experimental and computational data for both ideal and patient-specific TCPCs. The flowrate and concentration values are presented for LPA. HFD and TPFS present the LPA's share. HFD was calculated using the continuity equation for the tracer fluid. The error for the tracer fluid continuity equation in experimental data was found to be less than 2% for all cases which shows the reliability of the data.

DISCUSSION

Flow dynamics and mixing inside a TCPC have been mostly considered laminar for computational simulations throughout literature; however, impingement of jet flow streams inside TCPC can create turbulent behaviors. Our earlier studies [3,4] on jet flow in cardiovascular cannulae revealed that a RANS simulation can excellently capture the flow features in line with PIV experiments at transitional flow regimes. Our results in the present study showed that turbulent models can predict the three key parameters (HFD, TPFS and PL) in TCPC anatomies with more than 100 times faster performance and a better level of accuracy as compared to unsteady laminar solver. This is of paramount importance in Fontan pre-surgical planning with different surgery scenarios where a fast decision needs to be made. More importantly, our proposed ideal TCPC geometries can be reliably used for a thorough validation of computational solvers trying to simulate the flow dynamics in real patient complex vascular anatomies since they delivered the same level of accuracy in both cases.

INTRODUCTION

Epithelial morphogenesis is a crucial aspect in the development of three-dimensional (3D) membrane-like tissue structures, such as tubes or cysts. In the case of normal organ development, these 3D structures are polarized monolayers surrounding an open lumen. Tight regulation of the mechanical force balance involved in controlling lumen size and shape is necessary to obtain well-functioning tissues *in vivo*.

The mechanical forces that play a role in lumen growth and its potential stabilization are displayed in Figure 1. The inflation of the lumen can be imposed by an increase in intraluminal hydrostatic pressure. Water passively follows the created osmotic pressure by the secretion of ions in the opening aperture [1]. Tension by the cytoskeleton is able to restrict the expansion created by hydrostatic pressure. Proliferation of the cells can relieve the cytoskeletal forces and thus favors lumen growth [2]. Lastly, the properties of the extracellular matrix surrounding the tube or cyst define the resistance the expanding structure experiences [3]. While the lumens of 3D epithelial structures *in vivo* grow until the appropriate diameter to fulfill their physiological functions is reached, 3D structures *in vitro* have not shown any stabilization of the lumen in time [4].

To understand the individual and combined contributions of these forces in lumen expansion and stabilization, we designed *in vitro* experiments where the hydrostatic pressure, cellular tension, and extracellular matrix resistance are systematically varied. The insights gained could then help mechanically control this process for regenerative or tissue engineering purposes. Madin Darby Canine Kidney cells (MDCKs) serve as an excellent *in vitro* cell model to study lumen formation and growth in the context of kidney morphogenesis, as these cells spontaneously form cysts with a single lumen when cultured in a 3D environment. Here, we varied the extracellular environment composition to possibly increase its resistance to the growth of the central lumen formed in MDCK cysts. Furthermore, preliminary efforts were undertaken to quantify cyst geometry over time.

METHODS

To change ECM resistance to luminal growth, 3D collagen-I gels created with different concentrations of collagen (1, 2 and 3 mg/ml) were fabricated from rat-tail collagen (Corning). The collagen solution was first mixed with culture medium and neutralized with 1M NaOH solution (Sigma-Aldrich). The gel mixture was then placed at 37°C for

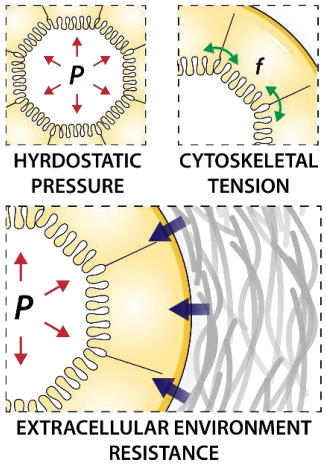

Figure 1: Illustration of the three mechanical forces that influence lumen development: (i) the intraluminal hydrostatic pressure (ii) the cytoskeletal tension on the apical surface of the membrane and (iii) the resistance provided by the extracellular matrix.

45 minutes. After full gelation, culture medium was added on top. Cell-free gels were characterized with SEM to quantify fiber density and orientation, and with micro-indentation to determine pristine gel stiffness.

MDCKs were incorporated in the gel mixture with a density of approximately $2 \cdot 10^5$ cells/ml. The cell-gel constructs were fixed at either a fixed time point (10 days) or monitored over time using fixation times of 2, 4, 7, 10, 14 and 21 days. Immunofluorescent (IF) staining was used to characterize the formed cellular aggregates. Cyst diameter, lumen diameter, circularity and cell number were obtained from the IF images using a custom-built Python script. Using micro-indentation, the gel stiffness of the cell-gel constructs was also measured at the given time points.

RESULTS

The fabricated gels consistently contained dense collagen fiber networks, where fiber density increased with increasing collagen concentration (Fig. 2 - SEM). Cysts were formed in the lower collagen concentrations of 1 and 2 mg/ml (Fig. 2). These cysts were heterogeneous in terms of size and cell number. The circularity however was concurrent in both concentrations. Interestingly, the 1 mg/ml collagen gels seemed to stiffen when comparing the stiffness of cell-free gels with cell-laden gels after 10 day of culture. The 2 mg/ml on the other hand showed no change. The 3 mg/ml concentration collagen gel contained essentially no cysts after 10 days of culture and were excluded from further analysis.

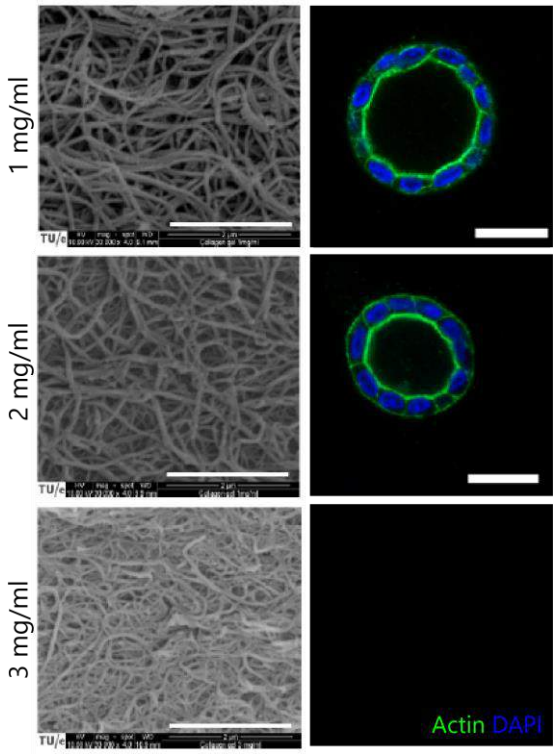

Figure 2: MDCKs grown in different concentrations of collagen gels (1, 2 and 3 mg/ml). The SEM images (left) display the formed fiber networks. Scale bars represent 2 µm. In the IF images, cells stained for DAPI and actin visualize the cyst formation in the different conditions. Scale bars represent 25 µm.

Cyst growth did not stabilize in 21 days, when cultured in a 2 mg/ml collagen gel (Fig 3a). The cyst growth was accompanied by both lumen growth (Fig 3a) as well as cell proliferation (Fig 3b). The results exhibit a high inter- and intra-sample variability.

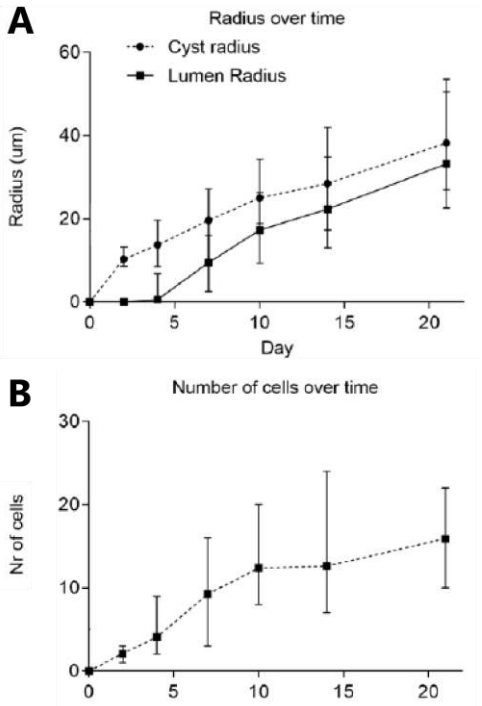

Figure 3: Characterization of MDCK cysts grown in a 2 mg/ml collagen gel concentration over time. (A) Quantification of the cyst and lumen radius over time and (B) the number of cells per cyst over time.

DISCUSSION

Our initial results suggest that the composition of the environment could be one of the mechanical forces that play a role in lumen growth and possible stabilization. Quantitative measurements of cyst geometry over time for the other two collagen concentrations are necessary to investigate to what extent the resistance posed by the environment composition is able to control lumen growth. The found heterogeneity in the experiments could be explained by local differences in matrix composition. In the future, the influence of the other morphogenetic processes should be investigated to obtain a full understanding of their interplay and identify conditions that could enable the stabilization of lumen growth. Furthermore, implementation of these processes in a computational model could further help to explain the individual as well as combined mechanical effects these processes have on lumen growth.

INTRODUCTION

Mechanoregulation in blood vessels tends to maintain homeostasis of mechanical stresses. As a result, given a change of the stress state in the arterial wall, growth and remodeling (G&R) will induce mass changes at the tissue scale to recover its homeostasis. If a localized lesion appears, the artery may not always recover homeostasis and have a degenerative expansion. A number of authors have developed computational models of aneurysm progression using the G&R theory. However, they usually considered straight tubes [1,2]. In this work, we developed a G&R computational model to study aneurysm progression in patient-specific curved arteries, like ascending thoracic aortic aneurysms (ATAA) in the aortic arch (Figure 1).

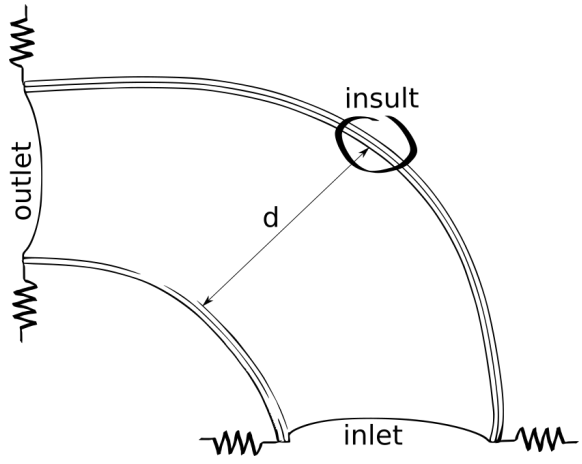

Figure 1: Scheme of simulation conditions.

METHODS

Our G&R framework is based on the homogenized Constrained Mixture Models (hCMM) [1]. The aorta is modeled as a bilayer. The material is composed of three constituents (elastin, collagen, smooth muscle cells) giving a mixture where each constituent has an individual elastic and inelastic deformation such as

$$F = F^j_e F^j_{gr} \tag{1}$$

with F as the deformation gradient of the mixture, F^j_e is the elastic deformation gradient and F^j_{gr} is the inelastic deformation gradient for the jth constituent, ($j = e, c_i, m$).

The strain energy function (SEF) per unit volume for each layer is written such as

$$W = \varrho^e_R \Psi^e + \varrho^m_R(\Psi^m_{pas} + \Psi^m_{act}) + \varrho^{c_i}_R \Psi^{c_i} \tag{2}$$

where Ψ^j and ϱ^j_R are the SEF per unit mass and the density (in reference volume) for each constituent, respectively. The elastin is modeled as an isotropic neo-Hookean material, the collagen and passive smooth muscle cells with anisotropic Fung quadratic material. Moreover, the smooth muscle cells have an active model as presented in [2]. Different mass densities are assigned for every single constituent of the mixture.

The G&R scenario considered for ATAA progression is a localized insult with a loss of elastin inducing a ballooning around the lesion, running up to 5500 days. In these simulations we assessed the sensitivity to the gain parameter, which is the parameter relating the rate of collagen mass change to the deviation of stress homeostasis.

This parameter translates into how fast mechanoregulation is achieved in the tissue.

The simulations were performed over three geometries: cylinder (straight tube), half arch and patient-specific arch. The cylinder is the benchmark case published in [2] with the same material properties and elastin loss. The half arch has a similar shape (lumen diameter and arch radius) as the patient geometry. Then, mechanical properties for arch and patient-specific were calibrated against data obtained on human aortic tissue [3]. In Figure 1, we show how the lumen diameter is measured throughout the aneurysm progression, following deformations induced by G&R. The insult point is located at the right hand side of the diameter arrow. The conditions at the inlet and outlet boundary only allow radial displacements with some stiffness modeled with springs (penalization of the radial displacements). Moreover, for the half-arch and the patient-specific geometries, spatially variable deposition stretches were assigned to elastin as initial conditions to ensure homeostasis.

RESULTS

We first verified that our model was in good agreement with previously existing studies on straight tubes [2]. The effect of the gain parameter is significant as the diameter change varies from 13% to 153% just by varying the gain parameter of a factor 3 (Table 1).

Table 1: Growth under localized elastin loss.

Gain	Straight tube	Arch	Patient
0.05/T	153.8%	292.5%	77.7%
0.09/T	45.8%	103.1%	22.3%
0.11/T	27.0%	55.4%	13.6%
0.15/T	13.0%	20.9%	7.2%

For the same gain parameters, the half-arch shows larger diameter increase than the straight tube. The diameter increase becomes very large for gains from 0.05/T to 0.11/T. The deformation of the arch with a gain of 0.05/T is extrapolated to 5500 days from the simulation until 3860 days.

The patient specific case showed lower diameter changes. Actually, with a gain of 0.15/T, the diameter change is almost half of the deformation obtained on the straight tube. Moreover, a 77.7% growth in the diameter was obtained for 0.05/T (extrapolated from a simulation stopped at 4220 days). Figure 2 shows the von Mises stress distribution of the patient at 4220 days where in some regions the stress reaches 350[kPa] in the adventitia at the left side of the picture. This shows a transfer of stress from the media to the adventitia that occurred during aneurysm progression.

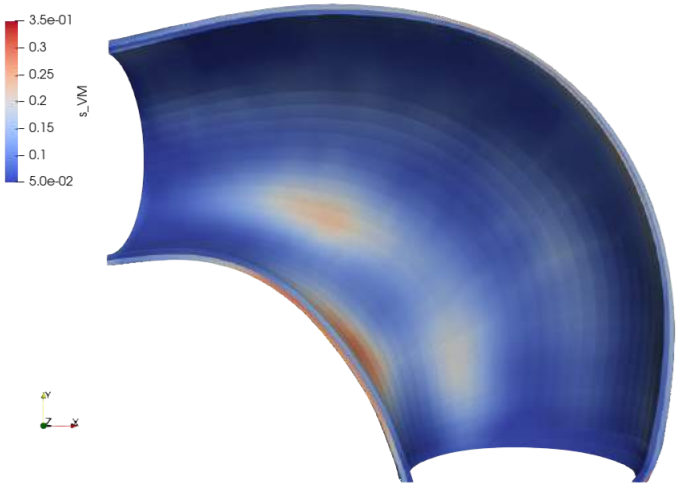

Figure 2: Patient ascending thoracic aorta with von Mises stress.

DISCUSSION

We successfully implemented the hCMM approach into a 3D G&R model of ATAA progression.

After a localized insult, geometries showed a diameter increase above 50% with low gain parameters. Usually the condition to declare an aneurysm is a diameter 50% bigger than the initial one. This shows that the initial insult that we considered can effectively lead to an aneurysm.

The development of the numerical models for the arch and for the patient-specific geometry had to overcome several convergence issues, which were related to the initial deposition stretches and the boundary conditions at the inlet and outlet of the artery. The initial deposition stretch is needed to ensure a homeostatic stress state in the initial geometry. The boundary conditions at the inlet and outlet were set to penalize radial displacements. The spring stiffness can induce stress concentrations which were avoided here by tuning the stiffness appropriately.

Future work will focus on comparing the model predictions to real ATAA geometries on a cohort of patients. The long-term goal is to enable patient-specific predictions of ATAA progression during clinical assessment.

INTRODUCTION

Metastatic spread requires the biomechanical adjustment of cell volume and hence, altered biochemical cascades and cell mechanical properties [1]. It is known that melanoma cells have a predilection for distant metastasis, such as the lung, liver, brain, and bone [2]. However, little is known about why melanoma cells may favor specific distant organs over others. Even less is known about melanoma cell's inherent biomechanical and biochemical properties that coordinate tumor formation in changing 3D environments. Recently, cell stiffness and the oncogenic factor TBX3 have been identified as potential mechanical and molecular biomarkers of metastasis, respectively [3, 4]. Therefore, this study sought to determine how cell stiffness and TBX3 levels change in melanoma cells before tumor formation compared to after tumor formation in 3D *in vitro* collagen matrices of varying rigidity.

METHODS

ME1402 vertical growth phase (VGP) and WM1158 metastatic (MET) human melanoma cells were embedded in Type I rat tail collagen matrices at final collagen concentrations of 2 and 4 mg/ml. Isolated cells and cell clusters were assessed after 1 day (24 hrs) and 7 days. Cells were stained with Mitotracker Green. Mitochondrial fluctuations were captured using time-lapse confocal microscopy (100 s), mitochondrial trajectories constructed using TrackMate, and the ensemble-averaged mean-square displacement (MSD) $\langle \Delta r^2(\tau)_{xy} \rangle$ determined, where the delay time τ is the time between first and last image frame used for the analysis. The MSD-dependent diffusivity α was calculated as a measure of intracellular fluidity (deformability) as:

$$\alpha = \frac{\partial \ln\langle \Delta r^2(\tau) \rangle}{\partial \ln(\tau)} \quad (1)$$

TBX3 content was assessed with immunofluorescence techniques. Data were assessed with multi-factorial ANOVA, with $p < .05$ indicating statistical significance.

RESULTS

The MSD and deformability α of isolated cells were larger for VGP than for MET in 2 mg/ml (MSD: $p < .001$, α: $p = .002$) and 4 mg/ml collagen matrices (MSD and α: $p < .001$), see Fig. 1.

Cluster formation in 2 mg/ml collagen did not affect the intracellular mechanics of VGP cells (MSD and α: $p > .05$) and α of MET cells ($p = .154$) but increased MSD of MET cells ($p < .001$). In 4 mg/ml collagen, cluster formation increased the MSD of VGP and MET cells ($p < .001$ for both cases) whereas α decreased for VGP ($p = .001$) but increased for MET cells ($p = .045$).

TBX3 was equally overexpressed in isolated VGP and MET cells in 2 mg/ml collagen ($p = .987$), see Table 1. In 4 mg/ml collagen, the TBX3 level decreased by 57% ($p = .007$) in VGP and by 87% ($p < .001$) in MET cells compared to 2 mg/ml collagen. TBX3 was still present in VGP but nearly depleted in MET cells.

Cluster formation of VGP cells did not alter TBX3 levels for 2 mg/ml collagen ($p = .731$) but increased the TBX3 content for 4 mg/ml collagen ($p = .028$). TBX3 was overexpressed in VGP clusters. For MET, cluster formation slightly decreased TBX3 levels in 2 mg/ml collagen ($p = .201$) but increased TBX levels in 4 mg/ml collagen ($p = .032$).

DISCUSSION

Mitochondrial fluctuations decreased and cell stiffness increased as VGP progressed to MET stages in 2 mg/ml (soft) and 4 mg/ml (stiff) collagen matrices. The increase in cellular stiffness contrasts with several studies that reported decreased stiffness [3, 5] whereas reports of increased stiffness with increased metastatic potential in melanoma are limited [6]. The Warburg effect may explain smaller mitochondrial fluctuations. Mitochondria of cancer cells produce insufficient ATP;

hence cells switch to a glycolytic metabolic pathway, which has strongly been associated with the metastatic potential, to meet the energy demands [7].

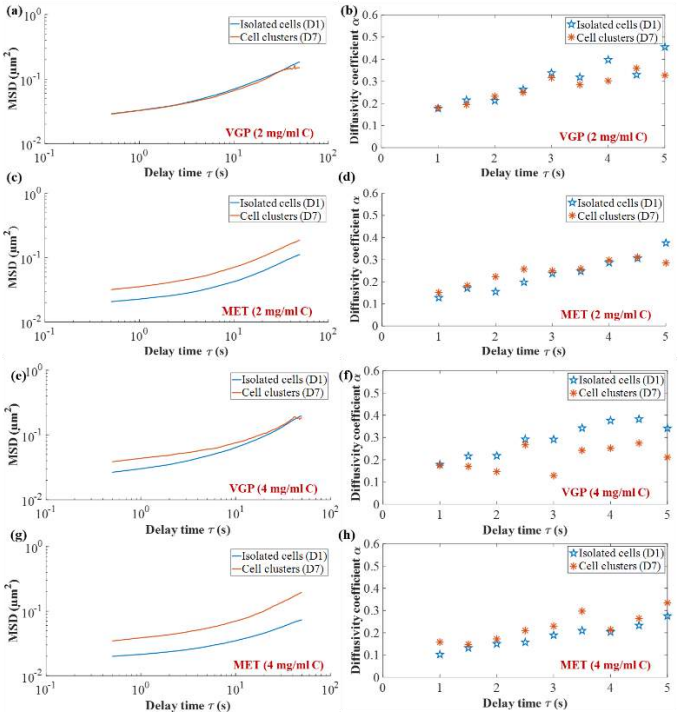

Figure 1: Mean square displacement (MSD) and diffusivity of isolated cells (at day 1: D1) and cell clusters (at day 7: D7) for VGP and MET disease stage in 2 and 4 mg/ml collagen (C) matrices.

Table 1: TBX3 expression in nuclei of isolated cells (at day 1) and cell clusters (at day 7) for VGP and MET disease stage in 2 and 4 mg/ml collagen matrices.

	Collagen concentration (mg/ml)	VGP	MET
Isolated cells	2	0.60 ± 0.41	0.61 ± 0.44
	4	0.26 ± 0.21	0.54 ± 0.35
Cell clusters	2	0.51 ± 0.16	0.32 ± 0.13
	4	0.07 ± 0.07	0.10 ± 0.06

Values are given as mean ± standard deviation

Glycolysis is primarily mediated and enhanced by the PI3K/AKT biochemical cascade [7]. Interestingly, PI3K/AKT signaling has been implicated in melanoma formation and invasion [4]. Further, TBX3 has emerged as a substrate of AKT3, an isoform of AKT, and therefore plays prominent roles in the PI3K/AKT pathway [8]. TBX3 has been reported to promote tumor formation and metastasis [9]. TBX3 was overexpressed in isolated VGP and MET cells in soft matrices, but TBX3 content decreased in stiff matrices. Considering that VGP cells quickly formed cell clusters whereas MET cells remained mainly isolated, it is suggested that overexpressed TBX3 promotes tumor formation in VGP cells and migration but not tumor formation in MET cells.

Decreased TBX3 expression in stiff matrices indicates that TBX3 expression is partially governed by the cells' mechanical interaction with the environment in addition to TBX3 upregulation by signaling molecules [9]. It is proposed that increased matrix rigidity increases actomyosin contractility, which in turn stimulates signaling molecules that have overlapping functions in cytoskeletal remodeling and the PI3K/AKT signaling pathway, such as activation of Cdc42. Cdc42 activity was shown to decrease with increased 3D collagen rigidity [10], and decreased Cdc42 levels were associated with increased PI3K/AKT signaling [11].

Mitochondrial bioenergetics are crucial for tumorigenesis [7]. However, for VGP cells, cluster formation led to an adjustment of intracellular mechanical properties in stiff but not soft matrices. It is proposed that VGP cluster formation in soft matrices do not require increased mechanical or bioenergetic fortification. Instead, isolated VGP cells are innately endowed with suitable mechanical properties to form clusters. This is supported by the findings that TBX3 expression was similar in VGP isolated cells and VGP cell clusters.

VGP cluster formation in stiff matrices was associated with increased mitochondrial fluctuations and cell stiffness. Increased proliferation is common in stiff matrices [12] and associated with increased mitochondrial bioenergetics [13]. The increased mitochondrial fluctuations observed here may result directly from the increased mitochondrial metabolism required for proliferation during VGP cluster formation in stiff matrices. Furthermore, cluster growth through proliferation amplifies the compressive conditions that VGP cells experience, thereby stiffening them.

For MET cluster formation, mitochondrial fluctuations increased in soft and stiff matrices. Conceivably, the formation of MET clusters is an energy-exhaustive process, regardless of matrix rigidity. Noting that mitochondria are regarded as dysfunctional in isolated metastatic cells, cluster formation was not automatic. Instead, cells remained isolated to invade 3D matrices.

Increased mitochondrial dynamics downregulates the PI3K/AKT pathway, thereby limiting glycolytic-mediated metabolism [7]. Although overexpressed in isolated cells, TBX3 decreased during MET cluster formation in soft matrices, alluding to increased mitochondria-mediated metabolism. Furthermore, VGP and MET cell clusters exhibited higher TBX3 levels than isolated cells in stiff matrices, demonstrating that TBX3 is indispensable during cluster formation in 3D cellular environments.

INTRODUCTION

To evaluate the mild traumatic brain injury (mTBI) risk associated with a head impact, multiple brain injury criteria (BIC) have been developed [1-6]. Physiologically, the brain's mechanical strain is often considered the key parameter of brain injury [7]. To evaluate the accuracy of predicting brain injury risks of the BIC, typically Pearson correlation between the BIC and the brain strain (particularly 95% MPS), as well as the coefficient of determination of the linear regression of brain strain on the BIC, have been used [1-3].

Although the BIC are typically designed for specific types of head impacts, many BIC are widely used, regardless of their development background [8]. However, when applied to different impact subtypes, even for the same values of MPS some BIC give different values. That the different BIC may indicate potentially similar brain strain across impact subtypes, poses a risk to using the BIC across the mTBI field.

To better understand the risk of using one BIC for a general metric across impacts subtypes, 5 datasets from various head impact subtypes are used for analysis. Linear regression models were built with 18 BIC as predictors for 95% MPS (MPS95), 95% MPS at corpus callosum (MPSCC95) and cumulative strain damage (CSDM 15%, the volume fraction of brain with MPS exceeding the threshold of 0.15), to analyze the regression slopes and the brain strain prediction generalizability.

METHODS

Data from 6 sources were used to construct 5 datasets: dataset 1 contained 2183 football-type lab head impacts: 2130 were simulated by a validated finite element analysis (FEA) model of hybrid III anthropomorphic test dummy (ATD) headform [9] and 53 were reconstructed impacts in National Football League [10]; dataset 2 contained 302 on-site college football impacts [11, 12]; dataset 3 contained 457 on-site mixed martial arts (MMA) impacts [7,13]; dataset 4 contained 48 impacts in automobile crashworthiness tests from the National Highway Traffic Safety Administration (NHTSA) [14]; dataset 5 contained 272 numerically reconstructed head impacts in National Association for Stock Car Auto Racing (NASCAR) by hybrid III ATD headform. Finite element (FE) modeling based on the KTH model [15] was used to calculate the MPS95, MPSCC95, CSDM. The accuracy in predicting the MPS95/MPSCC95/CSDM was used to evaluate the brain strain predictability of the BIC.

The 18 BIC studied included Severity Index (SI), Head Injury Criterion (HIC), Generalized Acceleration Model for Brain Injury Threshold (GAMBIT), Head Impact Power (HIP), Principal Component Score (PCS), Kinematic rotational Brain Injury Criterion (BRIC), Power Rotation Head Injury Criterion (PRHIC), Kleiven's Linear Combination (KLC), Rotational Injury Criterion (RIC), Brain Injury Criterion (BrIC), Combined Probability of Concussion (CP) [6], Rotational Velocity Change Index (RVCI), Damage [2], Convolution of impulse response for Brain Injury Criterion (CIBIC) [4], Brain Angle Metric (BAM) [3], the peak values of the magnitudes of the linear acceleration at the brain center of gravity (lin_acc_CG_max), angular velocity (ang_vel_max) and angular acceleration (ang_acc_max).

Linear regression models were built with each BIC as the predictor and the MPS95/MPSCC95/CSDM as the outcomes. The regression slopes were analyzed to investigate the relationship between BIC and brain strain on different datasets. 1000 bootstrapping experiments were done. One-way ANOVA and Wilcoxon signed rank tests were used to test the statistical significance of the regression slopes across datasets. Additionally, the predictability was tested on the single-dataset (80% of a dataset to train the model and predict the MPS95/MPSCC95/CSDM of the remaining 20% data) and across-dataset (a dataset used to fit the model and predict the brain strain of another dataset) with the R^2 as the regression metric. To ensure robust results, the mean R^2 was calculated in 100 iterations of bootstrapping resampling on the training data.

RESULTS

Firstly, the regression slopes were analyzed. One-way ANOVA shows statistical significance of the different slopes across datasets on all three outcomes ($p<0.001$). **Fig. 1** show the pairwise comparison Wilcoxon test p-values of regression slopes across datasets (MPS95, with similar results for MPSCC95/CSDM). The results show 535 out of the 540 pairwise comparisons manifested statistical significance ($p<0.05$), and 527 out of the 540 pairwise comparisons manifested statistical ($p<0.001$), which indicates that the exact relationship between the BIC and the brain strain vary with different types of head impacts.

Then, the accuracy of predicting MPS95/MPSCC95/CSDM on the single-dataset or across datasets was analyzed. The MPS95 prediction accuracy is shown in **Fig. 2**. The diagonal elements generally showed higher R^2 in single-dataset prediction tasks than the off-diagonal elements representing the cross-dataset prediction. Similar results were found on MPSCC95/CSDM regressions.

DISCUSSION

Different BIC have been developed on different head impact subtypes, but the predictability of the BIC across head impact subtypes has not been investigated. To study the BIC predictability across different head impact subtypes, this study investigated the regression slopes in linear regressions of MPS95/MPSCCC95/CSDM on 18 BIC and the generalizability of brain strain prediction if the regression models fitted on an impact subtype, with five datasets of different head impact subtypes (lab impacts, college football impacts, MMA impacts, NHTSA impacts, NASCAR impacts). This study found statistically significantly different slopes in most regression models across datasets in **Fig. 1**, indicating that the underlying relationship between BIC and brain strain varies with head impact subtypes. A potential explanation is that the characteristics of the kinematics used by BIC to predict brain strain are different. The differences in the relationship between BIC and brain strain suggest that the risks of brain injury even predicted by the same BIC value vary with head impact subtypes.

The influence of the datasets on the accuracy of the brain strain prediction were shown in **Fig. 2**. The bars were generally higher on the diagonal than off diagonal, indicating the single-dataset predictions generally showed higher mean R^2 than those in the cross-dataset predictions. In other words, the model was more accurate in the prediction of MPS95/MPSCC95/CSDM if it was fit on the same head impact subtype. Exceptions did exist when the off-diagonal prediction accuracy was higher, and the potential reasons may be the insignificant slope difference in the regression between datasets and the randomness in a small dataset. This finding suggests that the accuracy of the BIC should be evaluated according to head impact subtypes. In previous BIC studies, the evaluation of the accuracy in brain strain prediction has been mainly done on the same dataset. Although different head impact subtypes have been combined to develop BIC, it was until recently that researchers started to study the declining accuracy of the brain strain prediction models when applied to a different head impact subtype. Zhan et al [16] developed a deep learning head model for predicting whole-brain strain and showed that the model accuracy deteriorates when the model was trained on a dataset with mainly simulated impacts and applied to MMA. According to this study, concerns arise when a BIC is used to evaluate brain strain if the BIC regression model is fit on a different head impact subtype. The BIC and any other computational head model for predicting brain injury risks need validation across head impact subtypes if they are ever intended to be used in that way.

INTRODUCTION

Peripheral pulmonary artery stenosis (PPAS) is a congenital heart disease found in isolation or in association with Williams and Alagille syndromes. PPAS is characterized by stenoses in the central and peripheral pulmonary arteries (PAs) and results in lung perfusion disparity, right ventricular (RV) hypertension, RV hypertrophy, and ultimately RV failure [1]. No clinical consensus exists regarding the optimal treatment strategy for Williams and Alagille patients with PPAS. Hanley et al. at Lucile Packard Children's Hospital (LPCH) demonstrated that surgical PA reconstruction (PAR), involving comprehensive homograft patch augmentation of all stenoses from the central to lobar and segmental PAs, effectively normalizes RV pressures and provides excellent long-term outcomes with low rates of morbidity, mortality, and reintervention [1-3]. However, patch augmentation of lobar and segmental stenoses is a challenging surgical procedure requiring long hours in the operating room and specialized expertise. Transcatheter interventions thus remain the standard of care for PPAS at most centers despite evidence of unfavorable outcomes, including persistent RV hypertension, pulmonary hemorrhage, vessel dissection, aneurysm formation, rupture, in-stent restenosis, and even death [4-6].

To our knowledge, no prior studies have investigated hemodynamic conditions following transcatheter interventions in Alagille or Williams patients. While previous computational fluid dynamics (CFD) studies modeled the post-operative hemodynamics following surgical PAR in Alagille patients [7-8], these models were not validated against post-operative PA pressures, the primary indicators of success in PPAS repair. Autoregulation of blood flow was considered in response to perturbations in wall shear stress (WSS), yet did not include other factors of known importance to pulmonary vascular adaptation, such as intraluminal pressure and metabolite concentrations [9-11]. Furthermore, adaptation of pulmonary inflow was not considered in response to changes in pulmonary vascular resistance (PVR) [12]. In this study, we aim to predict post-stent PA hemodynamics for Williams and Alagille patients with PPAS using physiologically sound methods to adapt both the cardiac output and downstream PVR. We validate our methods on two patients who underwent stent placement, and subsequently assess the hemodynamic consequences of virtual stenting in four patients who underwent surgical PAR. We further develop the foundations of a virtual treatment planning platform by identifying lesions most responsible for the elevated PVR.

METHODS

The open-source software SimVascular (simvascular.org) was used to construct patient-specific pre- and post-stenting 3D anatomical finite element PA models for n=2 patients who underwent PA stent placement at outside institutions and n=4 patients who underwent surgical PAR at LPCH. Under the guidance of interventional cardiologists, virtual stenting was performed by modifying the lumen segmentations of stented vessels. **Figure 1** shows catheter angiograms most representative of the disease burdens, the CTA/MRA-based pre-stent models, and the modified segmentations for the post-stent models. Hemodynamic simulations were performed with a backflow-stabilized 3D Navier-Stokes solver, and fluid-structure interaction was incorporated via the coupled momentum method [13] with prescribed elastic moduli of 2.5×10^6 dyn/cm^2 for the unstented PAs and 2.5×10^8 dyn/cm^2 for the stented regions. The MPA inlet and PA outlets were coupled to lumped parameter networks (LPNs) representing the upstream right heart and downstream vasculature, respectively (**Figure 2A**). An automated tuning framework was developed to iteratively identify boundary conditions (BCs) that best achieve patient-specific pre-stent systolic, diastolic, and mean pressures at the main PA (MPA), proximal left PA (LPA), and proximal right PA (RPA) measured via cardiac catheterization. To leverage numerical optimization, we designed a high-fidelity nonlinear 0D surrogate of the 3D PA domain (**Figure 2B**). In progressing from the pre- to post-stent simulation for

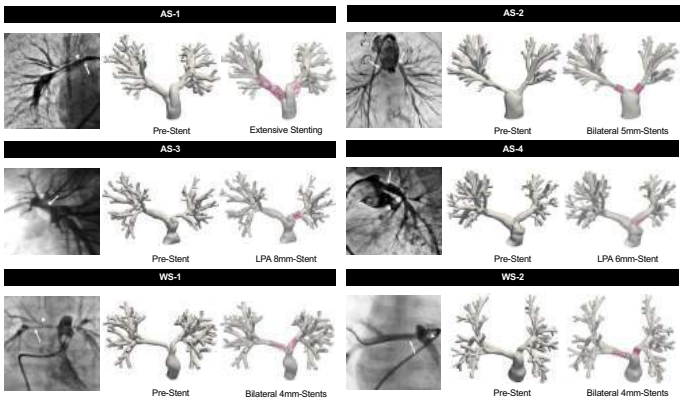

Figure 1: Catheterization angiograms, pre-stent models, and virtual stenting for Williams (WS) and Alagille (AS) patients.

each patient, parameters in the right heart LPN were maintained, as the governing equations offer an automatic approach for adapting the cardiac output in response to altered PA pressures and PVR. To capture vascular adaptation in response to changing hemodynamics, arterial resistances downstream of the PA outlets were adapted with an empirical model for stable autoregulation in response to perturbations in WSS, intraluminal pressure and metabolite concentrations [10-11]. Specifically, the pre-stent arterial network downstream of each PA outlet was modeled with a structured tree [14]; vessel diameters in the structured tree were subsequently adapted. Post-stent predictions of PA pressures were validated on the stenting cohort (n=2) prior to application to the surgical cohort (n=4). To facilitate treatment planning, pre-stent vessel segment resistances were computed to identify the most critical lesions for repair.

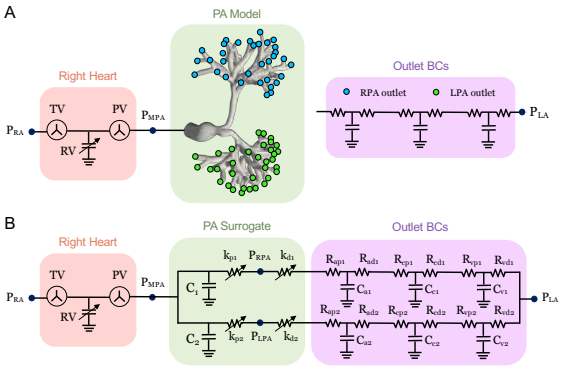

Figure 2: (A) LPNs coupled to the 3D PA model as inlet and outlet BCs and (B) the LPN used for automated BC tuning.

RESULTS

For all six patients, the automated tuning framework successfully identified parameters in the coupled inlet and outlet LPNs that achieved all pre-stent target pressures within 5 mm Hg. Correspondingly, the severe pre-stent pressure drops across the proximal stenoses were accurately captured. While PA flow distributions were not available for all patients and thus were not included as tuning targets, the simulated RPA flow fractions fell within 4% for the 3 patients with available data. Furthermore, we successfully validated our predictions of post-stent pressures for the stenting cohort (within 5 mm Hg of catheterization measurements), suggesting that our numerical methods offer physiological means for adapting the cardiac output and downstream PVR. While most patients were virtually stented only in the proximal PAs to reflect the standard of care, patient AS-1 underwent extensive stenting into the lobar PAs as a bridge therapy to liver transplantation.

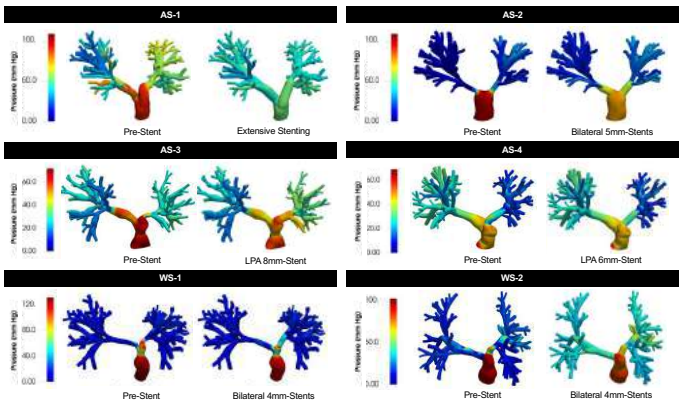

Figure 3: Pre- and post-stent systolic PA pressures.

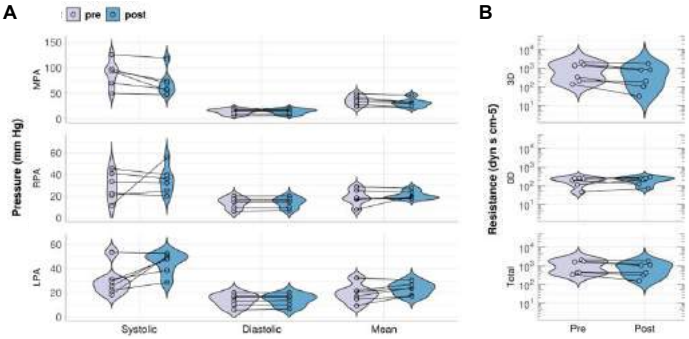

Figure 4: Pre- and post-stent PA pressures and PVR.

Stent placement did not sufficiently normalize PA pressures in any patient but yielded the largest improvement in AS-1, with decreases in systolic and mean MPA pressures by 41% and 26%, respectively. In addition, our pre-stent vessel segment resistance maps effectively identified lesions contributing the most to the elevated PA pressures. We therefore plan to perform additional virtual stenting procedures informed by these segment resistance maps, such that both proximal and extensive stenting are assessed per patient.

DISCUSSION

While surgical PAR has been found to normalize long-term PA pressures at LPCH, transcatheter interventions remain the standard of care for PPAS repair despite its associated complications in Williams and Alagille patients. CFD simulations provide a unique platform for virtual patient-specific treatment planning, in which anatomical models are altered to represent different interventions. Accurate predictions of post-interventional hemodynamics are critical to the success of such a platform, and we have indeed incorporated the relevant autoregulatory physiology and successfully validated our predictions for post-stent hemodynamics. Our results suggest that while lobar stenting reduces pressures beyond the limits of proximal stenting, stenting remains ineffective for normalizing PA pressures in Williams and Alagille patients with PPAS. We note that our methods are broadly applicable to CFD investigations of other cardiovascular interventions.

INTRODUCTION

Post-traumatic joint contracture in the elbow results in reduced range of motion (ROM), primarily due to thickening, stiffening and contracture of the joint capsule. When nonsurgical interventions, such as physical therapy and splinting, are ineffective, surgical capsular release is performed. However, capsular release generally only improves ROM but does not restore it to its normal range. In addition, the surgical procedure itself often initiates additional fibrosis and contraction that reduces ROM gains. Consequently, better treatment methods are needed.

A common feature of fibrotic tissue is the chronic presence of activated myofibroblasts. Myofibroblasts are a fibroblast phenotype distinguished by the expression of alpha smooth muscle actin (α-SMA) in the cytoskeleton and their ability to generate large traction forces and deposit collagen and other extracellular matrix (ECM) proteins. These cells are also highly responsive to their mechanical environment and the presence of biochemical factors, such as TGF-β1. These components interact dynamically and reciprocally with the myofibroblasts in a mechano-chemical feedback loop that can resolve with either normal or pathological healing. We hypothesize that one can control this feedback loop so that myofibroblast activity is reduced, healing proceeds normally, and ROM is improved/restored. One strategy we are exploring is to temporarily block non-muscle myosin II (NMMII)-actin engagement in myofibroblasts with the drug blebbistatin (or one its derivatives). Previously, we demonstrated that blebbistatin-loaded poly(lactide-co-gylcolide) (PLGA) particles could safely inhibit myofibroblast contractile forces and reduce collagen synthesis *in vitro* [1]. We are now exploring whether the controlled-release of blebbistatin or para-nitro blebbistatin can limit elbow joint contracture in an established Long-Evans rat model [2]. We are also exploring the kinetics of drug release and its activity on cells as a function of drug formulation parameters, such as the use of PLGA microparticles versus pellets, in a force measuring bioreactor. This bioreactor allows quantification of myofibroblast force generation and downstream collagen production, data that are used to help evaluate and inform the complimentary animal studies.

METHODS

Drug Encapsulation and Characterization

6 g of 50:50 PLGA polymer was finely grounded into a powder and well-mixed with 100 mg of blebbistatin. The polymer-drug mix was hot-melt extruded at into a long filament 1 mm in diameter and cut by hand into ~5 mm long pellets. Pre-weighed blebbistatin loaded PLGA pellets were incubated at 37 ºC with 1 mL of PBS and 1% Tween-80. 1 µL samples were drawn regularly to quantify drug release via HPLC-UV. The blebbistatin-loaded PLGA microparticles were fabricated as detailed in [1] and characterized the same way as the pellets.

In Vitro Cell Response

Rabbit joint capsule fibroblasts (RJCFs) obtained from medial synovial tissues were used to evaluate the drug and its action *in vitro*. RJCFs were homogeneously dispersed in 0.5 mL fibrin gels that were detached from the wells of 24-well plates after 24 hours, imaged for an additional 24 to 48 hours, and then analyzed for area reduction. Additionally, rectangular fibrin gels were polymerized within a custom force measuring bioreactor. A rigid glass rod and a calibrated, bendable Nitinol wire were embedded at each end of the gel. Contractile force was calculated from the amount of wire deflection observed over time using an overhead microcontroller-based time-lapse imaging system. Functional relationships between drug release and myofibroblast contractility were evaluated under conditions that included no blebbistatin, 50 µM blebbistatin in DMSO, 50 µM blebbistatin-loaded

PLGA microparticles, and 50 μM blebbistatin-loaded PLGA pellets. After 10 days, the fibrin gels were imaged for collagen visualization and assayed for collagen content.

Long-Evans Rat Contracture Model

Following the contracture model developed by Lake *et al.* [2], Long-Evans rat left elbows will be subjected to an anterior capsulotomy, transection of lateral collateral ligament, and immobilization for 6 weeks to produce a contracted elbow. Injured and non-injured controls will be compared with blebbistatin treatment groups at days 7, 21 and 42. Differences will be assessed with histology and mechanical testing. A flexion-extension device was built to interface with an ElectroForce® Planar Biaxial Test Bench Instrument. It has been used to assess uninjured joint total ROM, neutral zone length, and ROM midpoint from torque-angle curves and will be applied to the other groups soon.

RESULTS AND DISCUSSION

Previously, we characterized the release properties of blebbistatin-loaded PLGA microparticles [1]. However, the encapsulation efficiency of those particles was only ~30%. In addition, ~75% of the drug was released within 120 hours (Fig. 1A). To increase encapsulation efficiency and the reservoir of implanted drug, blebbistatin-loaded PLGA pellets were also made.

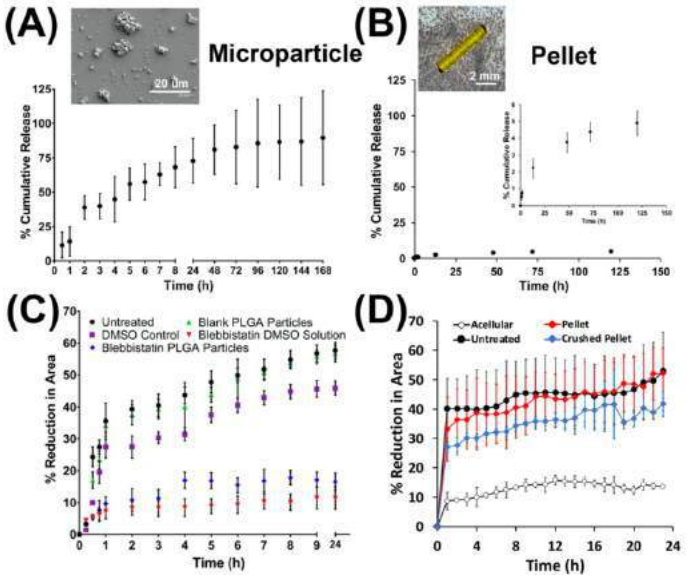

Fig. 1: (A) 75% of the blebbistatin in PLGA microparticles was released after 120 hours [1]. (B) Only 5% of the blebbistatin was released from the pellets over the same period. (C) Microparticles inhibited myofibroblast gel compaction almost to the same degree as blebbistatin in solution [1]. (D) Blebbistatin released from intact pellets did not impact myofibroblast activity. Less compaction was observed when crushed pellets were used due to the increase in available surface area for drug diffusion.

The release of drug from pellets was much slower (~ 5%) after 120 hours compared to microparticles (Fig. 1B). The two formulations variably changed myofibroblast activity. In microparticles (Fig. 1C), the drug activity was similar to adding the drug (dissolved in DMSO) directly to solution. In contrast, the amount of drug released from intact pellets (Fig 1D) was too low to have an impact over the short-term. Crushed pellets, which provided more surface area for drug release, did reduce gel compaction, though not to the same extent as microparticles.

Addition of blebbistatin dissolved in DMSO to the force bioreactor (Fig. 2A) resulted in a 30% reduction in myofibroblast traction forces, which were quantified from wire deflection recovery (Fig. 2B, C)). Additional data for the response to drug delivery via microparticles and pellets is ongoing.

Fig. 2: (A) Schematic showing the main components of the force bioreactor and measurement of the amount of wire deflection, δ. (B) An overhead camera images each of 6 bioreactors every hour. The bioreactors slowly rotate under the camera via a turntable. (C) Gel compaction and wire deflection generally reach equilibrium after 48 hours. Addition of blebbistatin in DMSO temporarily reduced cell traction forces by ~ 30%.

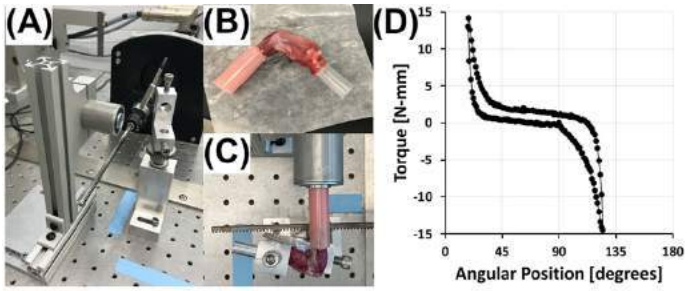

Fig. 3: (A) The fixtures for mechanical testing, (B) an excised Long-Evans rat arm potted for testing, (C) a representative image of the flexion-extension test, and (D) mechanical data for an uninjured rat elbow.

Load-controlled flexion-extension testing on uninjured rat elbows were completed successfully comparable with the results of Lake *et al.* [2]. The total ROM, neutral zone length, and ROM midpoint for the representative sample depicted in Fig. 3D was 107°, 76.4°, and 68.2°, respectively. Additional mechanical testing of injured and injured/treated arms is ongoing.

The combination of detailed *in vitro* studies with an animal model of the elbow contracture is providing complementary and unique data on mechano-chemical components responsible for contracture and on the feasibility of targeting NMMII with small molecules as an alternative/adjunctive treatment for elbow contractures. The knowledge gained here should also have broad applicability to other fibrotic conditions.

INTRODUCTION

Passive elastic modulus of muscles is important for biomechanical functioning of the musculoskeletal system. While most studies assume that the size of a muscle fiber bundle (i.e. a number of muscle fibers ensheathed in their connective tissue) does not influence elastic modulus after normalizing for cross sectional area, elastic modulus of muscle fibers has been shown to be size-dependent [1]. The objectives of this study were to determine the degree to which this size effect was evident in muscle fiber bundles and to examine the validity of the frequent assumption of a circular cross section of muscle fiber bundles.

METHODS

Muscle fibers and fiber bundles were extracted from lumbar spine multifidus and longissimus of three cohorts: group one (G1) and two (G2) included 13 (330±14g) and 6 (452±28g) Sprague-Dawley rats, while Group 3 (G3) comprised 9 human degenerative spine patients. A minimum of six muscle fibers and six muscle fiber bundles from each muscle underwent cumulative stretches, each of 10% strain followed by 4 minutes relaxation. Elastic modulus was calculated as tangent at 30% strain from the resulting stress-strain curve. Linear correlations between the fiber/fiber bundle cross sectional area and elastic moduli in each group were performed. Major and minor axis diameters of fibers and fiber bundles were measured and their ratios were calculated. The results were contrasted against the theoretical median of 1 (for cylindrical shape assumption) using Wilcoxon signed rank test.

RESULTS

In total, 391 fibers (192 in G1, 112 in G2, 87 in G3) and 570 bundles of fibers (262 in G1, 137 in G2, and 171 in G3) were tested. Bundles contained 14±7 fibers. The correlations showed that increasing specimen cross sectional area resulted in lower elastic modulus for both rats and humans, muscle fibers and fiber bundles (all $p<0.05$ except for G2 longissimus bundles with $p=0.21$, Figures 1-2). The median ratio of major to minor axis exceeded 1.0 for all groups, ranging between 1.15 and 1.29 for fibers and 1.27 and 1.44 for fiber bundles (Figure 3).

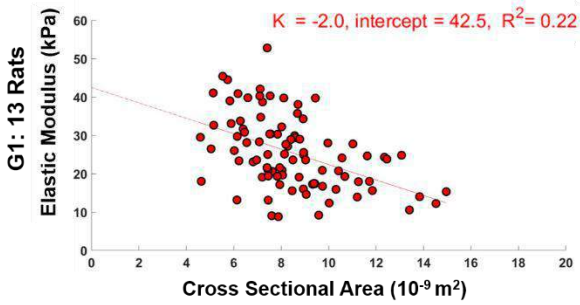

Figure 1: Correlation between elastic modulus and cross sectional area of G1 multifidus single fibers.

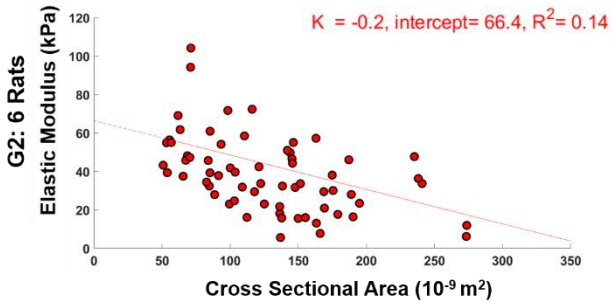

Figure 2: Correlation between elastic modulus and cross sectional area of G2 multifidus fiber bundles.

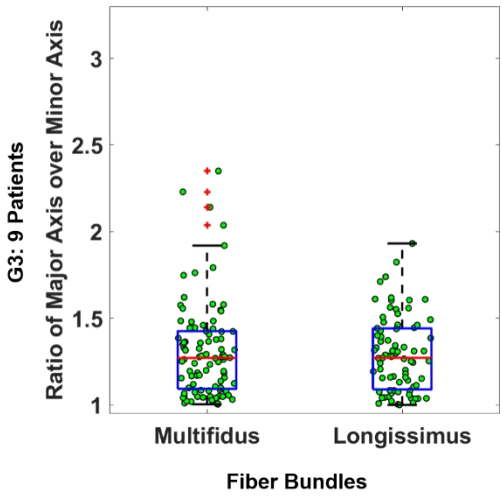

Figure 3: Ratio of major over minor axis diameters of fiber bundles tested in G3.

DISCUSSION

The results of this study demonstrated that the size matters and in general, larger sizes were associated with lower elastic moduli in muscle fibers and bundles of muscle fibers. Therefore, future studies should consider maintaining consistent bundle sizes for measurement of passive properties especially when comparing different groups against each other.

The lower elastic moduli with increasing size can be explained by relatively less collagenous extracellular matrix (ECM) in the large fiber bundles (Figure 4). It is well established that bundles of fibers have a larger elastic modulus than single fibers due to the high stiffness of ECM [2][3][4][5][6]. Assuming that the ECM and fibers within a bundle are both homogenous, the elastic modulus of a bundle can be calculated following the rule of mixture for composites as:

$$E_{Bundle} = f_{ECM}E_{ECM} + (1 - f_{ECM})E_{Fiber} \quad (1)$$

where E_{Bundle}, E_{ECM}, and E_{Fiber} are the elastic moduli of the bundle, the extracellular matrix, and fibers, respectively; and f_{ECM} denotes the percentage of the extra cellular matrix within the bundle. For example, the elastic modulus of a bundle containing 5% ECM (i.e. $f_{ECM} = 0.05$) with a fiber elastic modulus of 20 kPa and ECM elastic modulus of 1MPa [6] is calculated as 69 kPa. The predicted bundle elastic modulus would be 79 kPa or 59 kPa had the ECM percentage been changed to 6% or 4%, respectively.

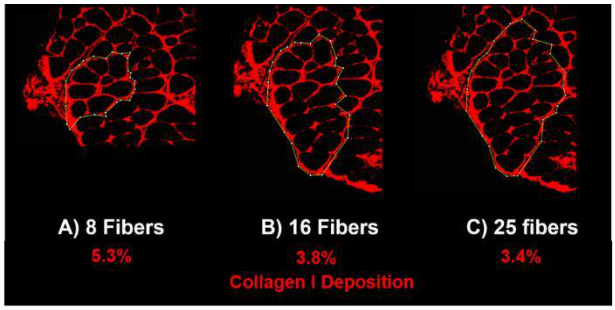

Figure 4: Inverse correlation between collagen I area fraction and size of three bundles of different sizes from multifidus of one rat in G1. Yellow lines represent the borders of selected bundles.

In a recent study, Ward et al. [7] measured the elastic modulus of rabbit muscles at multiple levels, i.e. single fibers, fiber bundles (~20 fibers), fascicles (~300 fibers), and whole muscles. They found that elastic modulus increases nonlinearly with these size scales as does the collagen content. The results of the current study demonstrated that larger bundles were associated with lower elastic moduli. These results are not in conflict, but rather they are complementary. Our results suggest that for fiber bundles of less than ~50 fibers larger sizes will be associated with smaller elastic moduli. However, beyond a certain size (e.g. ~300 fibers), bundles will transition to true fascicles, including the presence of perimysium and higher amounts of collagenous tissue, thereby leading to larger elastic moduli compared to bundles. In conclusion, the findings of our study suggest that future studies of passive property measurement should aim for consistent bundle sizes and measuring diameters of two orthogonal axes of the muscle fibers and fiber bundles.

INTRODUCTION

Hepatocellular carcinoma (HCC), the most common form of primary liver cancer, is one of the leading causes of cancer-related deaths worldwide. In 80-90% of HCC patients, cirrhosis is present [1].

The preferred treatment for unresectable HCC is transarterial chemo- or radioembolization (TACE or TARE). During these therapies, microparticles are injected in the hepatic arteries to selectively damage tumor tissue through a combination of embolization and a secondary chemotherapeutic effect (TACE), or through emission of high-intensity beta radiation (TARE) [2]. The goal of these transarterial therapies is to maximize the dose delivered to tumor tissue and limit the offsite-toxicity delivered to healthy tissue.

However, the impact of clinical parameters (e.g. the injection's location and timing) and microparticle characteristics (e.g. size and density) on the particle distribution is unclear. Therefore, computational fluid dynamics (CFD) may help to understand this impact and potentially use these parameters to improve the clinical outcome [3].

To date, Childress et al. [4] studied the impact of injection timing during the cardiac cycle in two simplified literature-derived hepatic arterial geometries. However, Aramburu et al. [3] noted that the geometry has a significant impact on the particle distribution. Therefore, we previously studied the impact of particle size, density and injection location in two patient-specific hepatic arterial geometries [5].

In this study, the impact of injection timing will be investigated for two axial injection locations in a patient-specific geometry.

METHODS

Geometry & meshing. The liver geometry was obtained by combining vascular corrosion casting and micro-CT imaging of a cirrhotic human liver (see [6] for more details). The hepatic network was segmented and 3D reconstructed using Mimics and 3-matic software (Materialise, Leuven, Belgium). A volume mesh containing $9 \cdot 10^6$ tetrahedral elements and three prism boundary layers was created in ICEM CFD (Ansys Inc., Canonsburg, USA).

CFD. Blood flow (continuous phase) was modeled using a density of 1060 kg/m³ and a modified Quemada model for viscosity. The mass transport of particles (discrete phase) in the fluid phase was calculated in a Lagrangian framework using the Discrete Phase Model (DPM) in Ansys Fluent (Ansys Inc., Canonsburg, USA). The presence of a moderate tumor (565 ml) was modeled in liver segment IV (outlets 1-6, see Fig. 1) using outflow percentage boundary conditions (ranging between 1.25 and 27.75%) based on the arterial perfusion distribution methodology proposed by Aramburu et al. [7]. At the inlet, a transient flow waveform was specified, with a cycle length of 0.8 s and cycle-averaged flow of 481.2 ml/min. The fluid time step was alternated between $1 \cdot 10^{-3}$ and $5 \cdot 10^{-4}$ s depending on convergence conditions. Particles with a diameter of 40 µm and a density of 1600 kg/m³, mimicking SIR-Spheres (Sirtex Medical Australia) used for TARE, were released from the inlet (see '1' in Fig. 1; simulation 1 (Sim1)), and from a second axial injection location near the second bifurcation (see '2' in Fig. 1; Sim2). Seven (Sim1) or six (Sim2) cardiac cycles were run, and particles were released every 0.01 s during the third cycle (1.6 s-2.4 s).

RESULTS

For each injection timing, Particle Release Maps (PRMs) were generated. As shown in Fig. 1, PRMs are visualizations of the injection plane cross-section, showing where particles should be injected to reach certain exit branches (ideally, the tumor-perfusing branches (TPB)). In Composite Particle Release Maps (CPRMs), particles are colored according to their target specificity throughout the cycle, where *e* indicates for which % of the selected injection timings particle fates

corresponded with exit through a TPB (see Fig. 2B & 3B). Here, 16 evenly-spaced injection timings between 1.60s and 2.35s were selected, comparing particle fates from one injection timing to their nearest-neighbor fates at other timings.

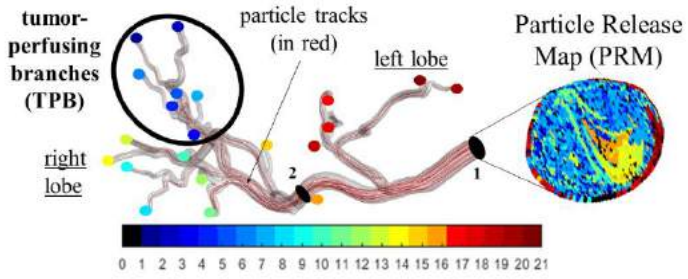

Figure 1: A Particle Release Map (PRM) shows where particles should be injected to reach the tumor.

In Fig. 2A-3A, the PRMs are given for injections at several injection timings (t = 1.60s, 1.80s, 2.00s, 2.20s) at the inlet and at the second bifurcation, respectively. As is clear, the PRM patterns vary significantly between the two axial locations. Moreover, the tumor targeting zone (shown in blue, outlets 1-6 in Fig. 1) varies significantly throughout the cycle. However, injection typically lasts for several cardiac cycles. Therefore, in Fig. 2B-3B, the corresponding CPRMs are given, with the green cells (e > 80%) indicating the cross-sectional injection locations where particles exit through a TPB for >80% of the cycle. These zones can be considered as ideal zones to position the catheter tip throughout the whole cycle.

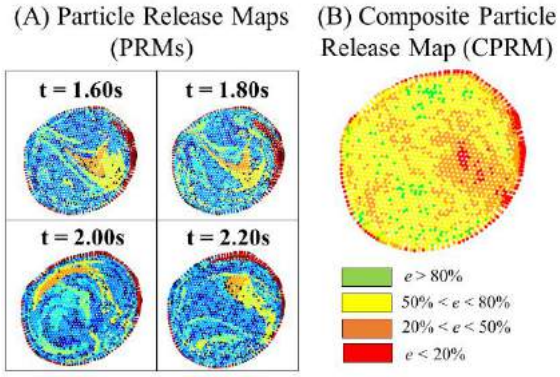

Figure 2: (A) PRMs and (B) CPRM for the inlet injection.

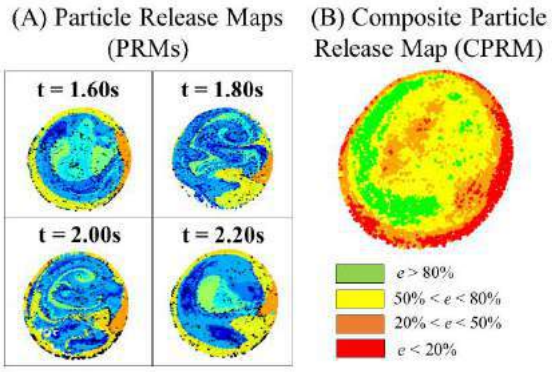

Figure 3: (A) PRMs and (B) CPRM for injection near the second bifurcation.

For the inlet, these ideal locations are distributed over the whole cross-section (4% of total particles displayed). However, for the injection location near the second bifurcation, the ideal cross-sectional injection locations are less spread out and form a much larger, more clearly delineated injection zone (16.8% of total particles).

DISCUSSION

Childress et al. [4] constructed CPRMs for their two idealized hepatic arterial geometries (with only 5 and 3 outlets, no tumors modeled). They noted that for their basic 5-outlet geometry there was little variation between the PRMs for different injection timings, and that clear targeting zones could be distinguished in the CPRM for each exit branch. Interestingly, they noted that the variation was much higher for their 3-outlet geometry, and that there were no clear targeting zones in the CPRM. This implies the importance of the arterial geometry.

In this study, a much more complex, patient-specific arterial geometry was considered (with 21 outlets). As shown in Fig. 2, the variation between the PRMs was large for different injection timings. The CPRMs in Fig.2B & 3B show that for inlet injections there was no clear tumor targeting zone (green), while for injections at the second bifurcation the targeting zone was much clearer. This suggests that the results do not only depend on the arterial geometry, but also on the axial injection location. These results support our hypothesis that injection locations closer to the tumor make it easier to target the tumor.

The strengths of the study lie in (i) the consideration of a complex, patient-specific cirrhotic liver geometry, (ii) the direct comparison of two axial injection locations, and (iii) the modeling of a realistic cancer scenario with increased arterial perfusion in the TPB.

The limitations lie in considering only surface injections. The next step in the workflow includes modeling of the catheter, releasing a targeted injection from the suggested targeting zone (green, Fig. 2B-3B) and investigating the impact of catheter presence on the local hemodynamics and downstream particle distribution. Moreover, a wider range of axial injection locations and particle properties (i.e. size, density) should be studied for their impact on the CPRMs.

Judging from Fig. 2B-3B, there might be a trade-off between the choice of axial and cross-sectional location: far away from the tumor, the ideal targeting zones are minimal, implying that the cross-sectional injection location needs to be very precise; while, closer to the tumor, the ideal targeting zones are larger, and the location of the catheter tip matters less. Since accurate intra-arterial positioning of the catheter tip may prove to be a complex task, the ideal targeting zone should be maximized as much as possible.

In conclusion, the CPRM, studied on a wider scale of injection locations and particle properties, can be a helpful tool in selecting the most optimal injection conditions (i.e. those which maximize the ideal targeting zone) for efficient patient-specific tumor targeting.

EXCESS COLLAGEN DEPOSITION IN DIABETIC KIDNEY DISEASE ENHANCES CELLULAR COMMUNICATION: A MATHEMATICAL MODEL

INTRODUCTION

Diabetes is a significant burden on public health in the U.S. and worldwide. In the year 2015, over 400 million people were diagnosed with diabetes worldwide—a number that is expected to rise to over 600 million in the year 2040 [1]. One-third of these diabetic patients are expected to develop diabetic kidney disease, the leading cause of end stage renal disease [1]. Our lack of understanding of how diabetic kidney disease progresses and affects cellular and tissue function has led to the shortage of effective treatment methods and thus our inability to mitigate the rapidly rising burden of diabetic kidney disease. Diabetic kidney disease, characterized by proteinuria and a loss in glomerular filtration rate, is induced by biochemical perturbations and morphological changes such as excess collagen deposition in the kidney [2,3]. Although excess collagen deposition is a hallmark of diabetic kidney damage, its impact on cellular and tissue function is still not well understood. Thus, our aim is to use a modeling approach to fill this gap in knowledge.

Collagen deposition occurs in the mesangium, a tissue located at the center of the filtration unit of the kidney, the glomerulus. The mesangium is composed of a collagenous matrix and is the region that separates the three key glomerular cells: mesangial, endothelial and podocyte cells. Studies have shown that these three cell types are in constant communication and that interference in this communication can lead to dysfunction within the glomerulus [4-8]. During diabetic kidney damage, the collagen deposition that occurs in the mesangium changes the transport property of the matrix, and, therefore, the ability of signaling molecules to traverse through that medium. The extent to which collagen deposition impacts the ability of glomerular cells to communicate has not been previously investigated. Using established models, we investigate whether collagen deposition impacts glomerular cell communication. We hypothesize that the pathological deposition of collagen decreases the ability of glomerular cells to communicate.

Method

We first mathematically derive a property, the effective signaling distance (ESD), to quantify cell-cell communication in a similar manner to Francis et al. [9] with some changes. In our model, we consider a single mesangial cell that is secreting signaling molecules that diffuse from the cell surface through the extracellular matrix toward podocyte cells. The mass balance for the signaling molecules is

$$\frac{\partial c}{\partial t} = D\frac{1}{r^2}\frac{\partial}{\partial r}\left[r^2\frac{\partial c}{\partial r}\right] \tag{1}$$

where c represents the concentration of the signaling molecules, D is the diffusion coefficient of signaling molecules through the matrix, and r represents the radial distance from the center of the cell. The first boundary condition imposed is

$$-D\frac{\partial c}{\partial r} = F_o \quad \text{at} \quad r = \rho \tag{2}$$

where F_o is a constant secretion rate at the cell surface located at position ρ. The second boundary condition imposed is

$$c \to 0 \quad \text{as} \quad r \to \infty \tag{3}$$

We also postulate that initially there are no signaling molecules present in the matrix, representing the onset of pathological disturbed secretion of signaling molecules. The analytical solution is

$$c = \frac{F_o\rho}{D}\varphi(r,t) \tag{4}$$

where $\varphi(r,t)$ is a function composed of exponential and error functions that depend on r and t [9]. The steady state value of φ is $1/r$. Substituting k_m for c as the minimum concentration required to induce a response in the receiving cell, we can solve for the position for ESD

$$ESD = r = \frac{F_o\rho}{Dk_m} \tag{5}$$

which we define as the steady state propagation distance of k_m.

Secondly, we use an experimentally validated, empirical model to quantify how collagen deposition in the matrix affects the diffusivity of signaling molecules [10]

$$D = D_o \exp\left(-\pi\Phi^b\right) \exp\left(-0.84 f^{1.09}\right) \quad (6)$$

where D is the effective diffusion coefficient, D_o is the free diffusion coefficient, Φ is the volume fraction of collagen in the matrix, and b and f are parameters that depend on the solute radius and the matrix fiber radius. The Stokes-Einstein equation is used to estimate D_o.

RESULTS

The concentration profile of the signaling molecule diffusing through a healthy matrix (Figure 1) shows that over time the signaling molecules accumulate until a steady state concentration of twice the threshold concentration is reached at the cell surface.

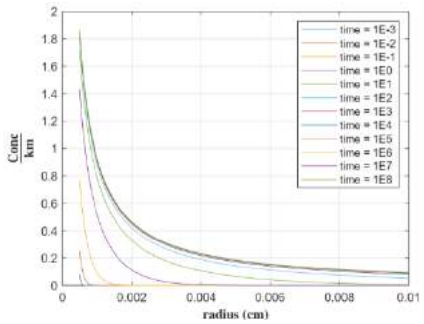

Figure 1. Concentration profile of signaling molecule over time (s)

The propagation of the threshold concentration through the spatial domain clears shows the approach to steady state (Figure 2).

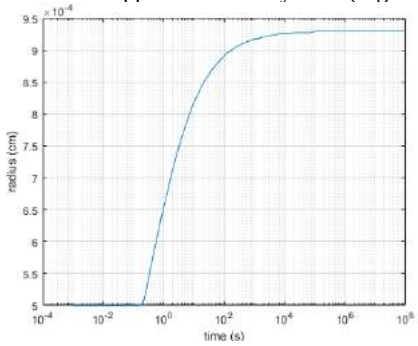

Figure 2. Propagation of the threshold concentration k_m

Unlike Francis et al. [9], we define the ESD at the steady state because steady state is approached much faster in the glomerular anatomy than the generalized infinite domain. The dependence of ESD on the diffusivity of signaling molecules through a diseased matrix is also explored (Figure 3). As the matrix volume fraction increases due to collagen deposition, the effective signaling distance for small signaling molecules increases by over two-fold from an initial signaling distance of 2.5 cell radii. This is surprising, because we had hypothesized that as the matrix becomes diseased, the ability of cells to communicate would decrease; however, we see from these results that a diseased matrix actually enhances the ability of a cell to signal rather than diminishing it if the secretion rate is kept constant. The results also show that larger signaling molecules have greater signaling distances than smaller signaling molecules and that their signaling distance is further increased in diseased conditions with larger volume fraction (Figure 3).

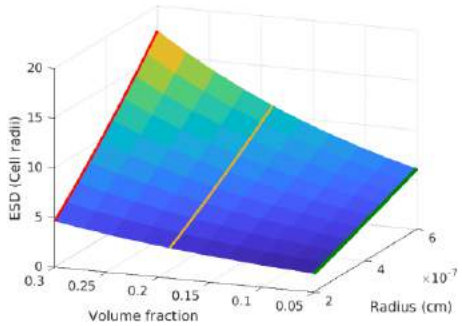

Figure 3. ESD increases with increased collagen deposition

DISCUSSION

As shown in our results, pathological collagen deposition during diabetic kidney disease actually enhances the ability of glomerular cells to communicate, counter to our hypothesis. The unexpected result is due to the counterintuitive nature of diffusion, where a slower diffusivity results in a larger propagation distance. This unusual behavior of diffusion has been observed and documented by others in other contexts [11,12].

Our predicted values for the ESD in the healthy case is within the expected range. Using experimental methods, Bagnall et al. found that the signaling distance for fibroblast cells is on the order of a few cell diameters [13], similar to our model prediction of 2-5 cell radii. Our predictions regarding the changes in ESD due to collagen deposition, however, need experimental validation.

In our model, we assume that there is no breakdown and no self-consumption of the signaling molecules, which leads to an overestimate of ESD, and that no convective transport of signaling molecules occurs, leading to an underestimate of ESD. Although we cannot say the extent to which each assumption impacts the ESD, their opposing influence on ESD could nullify any individual impact. Regardless, this is a potential area for future work. In conclusion, the model provides quantitative insight into the impact of collagen deposition on cellular communication and thus expands our understanding of how diabetic kidney damage affects cellular function.

INTRODUCTION

The myocardium is a mechanically active tissue environment. Following cardiomyocyte death, for instance due to an ischemic insult, the response to injury induces a phenotypical switch from cardiac fibroblast (cFB) to myofibroblast. This will lead to excessive collagen deposition and extracellular matrix (ECM) remodeling, eventually resulting in a stiff fibrotic tissue (E = 35 – 70 kPa), as opposed to undamaged myocardium (E = 5 - 10 kPa) [1]. Presently, it is not well documented how cardiomyocyte progenitor cells (CPCs) perceive alterations in the stiffness of the myocardial microenvironment. Three dimensional (3D) ECM mimicking model systems with tunable stiffness and native-like adhesion sites may shed light on cardiac cell behavior under these circumstances to potentially design strategies to halt adverse remodeling.

Collagen is the most abundant protein in the ECM. It not only provides structural support for cells and tissues, but also mediates many important biological processes through interactions with various binding partners [2]. Up to now, animal-derived collagen and gelatin have often been used to mimic human collagen in 3D scaffolds for disease modeling and tissue engineering purposes. However, increasing concerns associated with animal derived materials in healthcare, batch-to-batch differences, and the inability to tune the stiffness of collagen in a well-controlled manner result in a strong need for an alternative, preferably synthetic, material. Methacrylated Recombinant Collagen Peptide (RCP-MA, Fujifilm) is a collagen mimicking peptide based on human collagen I, produced by a yeast fermentation process, containing no animal-derived components. The peptide is highly reproducible and enriched with arginine-glycine-aspartic acid (RGD) sequences to allow control over its cell-adhesive properties. Moreover, RCP-MA is modified to contain methacrylic groups that enable chemical crosslinking and hydrogel fabrication with a stiffness ranging from 1 kPa to ~300 kPa.

In this study, we explore the usage of RCP-MA as a 3D *in vitro* mechanobiology study platform. With this model, we aim to exploit the tunability of RCP-MA to study how normal and pathology-mimicking myocardial stiffness affects CPC behavior and stiffness perception. To do this, we investigate the expression of cell-specific markers and YAP localization, an important component of the Hippo pathway that conveys mechanical signals from the ECM to intracellular signals that guide cell fate.

METHODS

RCP-MA hydrogels were fabricated by solubilizing RCP-MA (kindly provided by Fujifilm Manufacturing Europe B.V.) with 20% and 50% degrees of methacrylation (%DS) in sterile cell culture medium and chemical crosslinking with UV (Omnicure) at 365 nm in sterile Teflon molds, using lithium phenyl-2,4,6-trimethylbenzoylphosphinate (LAP) as photo-initiator. In this project, RCP-MA was used with 20% DS and 50% DS. Cell-free hydrogel constructs were physicochemically characterized by micro-indentation (Microtester G2, CellScale, Canada) and swelling experiments.

To allow cell encapsulation in separate experiments, pelleted CPCs were resuspended at a concentration of 1×10^6 $cells/ml$ in RCP-MA prepolymer solution before crosslinking. For cell encapsulation experiments, hydrogels were fabricated from prepolymer solutions of a) a 1:1 mixture of 20% DS and 50% DS and 2) 50% DS, and illuminated for 30 s at 2.5 mW/cm^2. Hydrogel biocompatibility was assessed with live/dead staining (calcein AM/propidium iodide) and the phenotype and YAP localization were determined using whole mount immunofluorescence staining.

RESULTS

Micro-indentation experiments were performed to determine whether the different number of photo-crosslinkable methacrylations for RCP-MA had an influence on the final mechanical properties of the crosslinked hydrogels. As expected, a clear difference was observed between the 20%, the 20/50% (1:1), and 50% RCP-MA precursor mixtures (Figure 1A), demonstrating a higher Young's modulus (E-modulus) with increasing number of photo-crosslinkable moieties that can be chemically crosslinked with UV irradiation. A 30s exposure at 2.5 mW/cm^2 of 20/50% (1:1) and 50% RCP-MA resulted in hydrogels that mimic the stiffness of normal and pathological myocardium, respectively (Figure 1B).

Cell viability assays of CPCs encapsulated inside the RCP-MA hydrogel constructs showed viable cells (>70%) up to ten days of culture. Starting from three days of culture inside the hydrogel constructs, live cell imaging (calcein AM) of CPCs displayed an elongated morphology and cellular network formation, allowing cell – cell contact between individual CPCs (Figure 2). After 48 hours of culture on top of the RCP-MA hydrogel constructs, the CPCs produced and deposited fibronectin (data not shown).

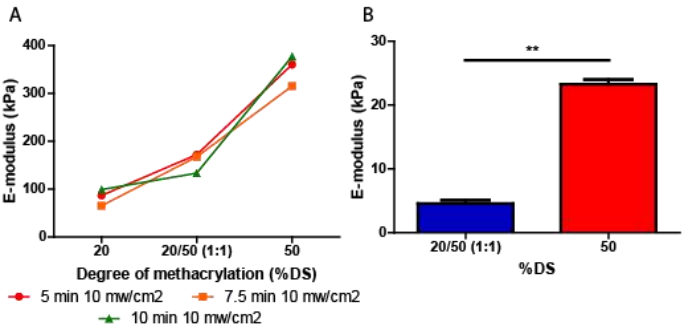

Figure 1: A) Young's modulus (E-modulus) of RCP-MA hydrogels upon varying degree of methacrylation (%DS). B) RCP-MA hydrogels with normal and pathology mimicking stiffness for myocardial disease modelling. $^{**}p < 0.01$.

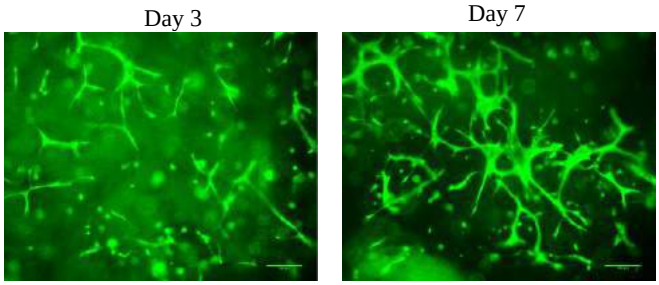

Figure 2: Cardiac progenitor cells (CPCs) demonstrate an elongated morphology and network formation in RCP-MA hydrogels. Calcein AM staining of CPCs (green) after 3 and 7 days of culture inside 20/50% (1:1) RCP-MA. Scale bar indicates 100 µm.

DISCUSSION

The present study reports on the mechanical behaviour of RCP-MA hydrogels as well as the biocompatibility with cardiac cells. The results show that the mechanical behaviour of the RCP-MA hydrogels is affected by the crosslinking of methacrylic functionalities with UV, leading to a range of mechanical properties that can be tuned in a well-controlled manner. Our results indicate that 20/50% (1:1) DS and 50% RCP-MA precursor solutions can be crosslinked into hydrogels that mimic the stiffness of normal and pathological myocardial tissue. *In vitro* biological evaluation demonstrated that RCP-MA is biocompatible towards CPCs, showing elongated cell morphologies and cell – cell contact up to ten days of culture inside the 3D hydrogel constructs. Taken together, these results indicate that RCP-MA is an attractive synthetic alternative to animal-derived collagen or gelatin constructs for cardiac disease modelling. Further studies will focus on the effect of myocardial stiffness on the behaviour and YAP signalling of CPCs. Moreover, the biocompatibility of RCP-MA towards other cardiac cell types, such as cFBs and cardiomyocytes, will be studied.

INTRODUCTION

Despite significant efforts, no tissue engineered construct has successfully replaced a tendon or ligament in a human patient[1]. Clues on how to advance current tissue engineering approaches may lie in understanding how tendons form during embryonic development. In particular, chick tendons undergo rapid changes in macroscale mechanics during late embryonic development that produce a tissue with high tensile load-bearing capabilities[2]. Previous work suggests that this mechanical transformation is due to increases in collagen fibril length[3] and mechanical stimulation via muscle activity[4]. However, no study has investigated the multiscale tensile mechanics of embryonic chick tendons or their dependence on mechanical stimulation. Therefore, **the objective of this study was to measure the changes in multiscale tendon mechanics during late embryonic development and identify the effect of skeletal muscle paralysis**. We hypothesized that the increase in tendon macroscale mechanical properties with development will coincide with an increase in the fibril strains and a reduction in interfibrillar sliding, which is consistent with increasing fibril lengths[5]. Additionally, we hypothesized that skeletal muscle paralysis will prevent the developmental changes in both the fibrillar deformations (i.e., strains and sliding) and the macroscale tissue properties observed during late embryogenesis. This information will provide a deeper understanding of the mechanisms driving tendon development, which will guide the development of tissue engineered constructs that can successfully replicate tendon function.

METHODS

Fertilized chicken eggs obtained with IACUC approval were set within a benchtop egg incubator. At embryonic day 3 (E3), eggs were windowed according to established procedures[6]. At day 15 (E15), eggs were treated to induce rigid or flaccid skeletal paralysis via injection with either 100 µl of 0.02% decamethonium bromide (DMB) or pancuronium bromide (PB), respectively. Control samples were injected with 100 µl of saline. Subsequent injections of 50 µl were then administered daily from E16 – E19. Embryonic motility (events/2 min) was examined daily from E15 – E19 following established protocols[6]. Embryos were sacrificed at E16, E18, and E20 for testing.

Mechanical testing was conducted using a custom uniaxial microtensile device mounted atop a confocal microscope[7]. For each test, the flexor digitorum longus tendon was dissected and stained with 5 µg/ml DTAF. Samples were loaded within custom grips at a gauge length of 10 mm and preloaded to 0.1 g. The tendon major/minor diameters were measured from z-stack images and the cross-sectional area was quantified assuming an elliptical cross-section. Three sets of photobleached lines (PBL) (4 lines, 80 µm apart) were bleached at the sample center and ± 1.5 mm from the center. Samples were loaded to failure in 2% grip-to-grip strain increments. At each strain increment, z-stack images were acquired at all PBL locations. The stage positions of the two peripheral PBL sets were used to calculate the macroscale tissue strain. Fibril strains and sliding were calculated at each PBL site by measuring the displacement between the photobleached lines and their tortuosity, respectively[5]. The fibril:tissue strain ratio was calculated by dividing the mean fibril strain by the tissue strain at each increment.

A two-way ANOVA was used to test for differences in motility with regards to age and paralysis. A one-way ANOVA with a Dunnett's or Tukey's correction was used to measure differences in modulus due to paralysis or development, respectively. An ANCOVA with Bonferroni post-hoc tests was used to determine if the fibril:tissue strain ratio or fibril sliding was dependent on age or paralysis. Linear regressions determined the correlation between the fibril:tissue strain ratio and the applied tissue strain, and t-tests determined if the average fibril:tissue strain ratio was significantly less than 1. Significance was set at $p < 0.05$.

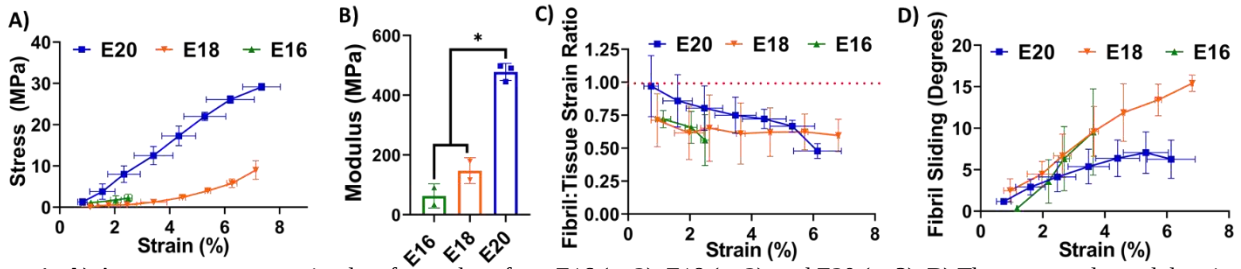

Figure 1: A) Average stress vs. strain plots for tendons from E16 (n=2), E18 (n=2), and E20 (n=3). **B)** The macroscale modulus significantly increased with developmental age. **C)** The fibril:tissue strain ratio in only the E20 samples was negatively correlated with the applied tissue strain but was significantly different from one for all ages. D) There was a significant decrease in fibril sliding with increasing developmental age.

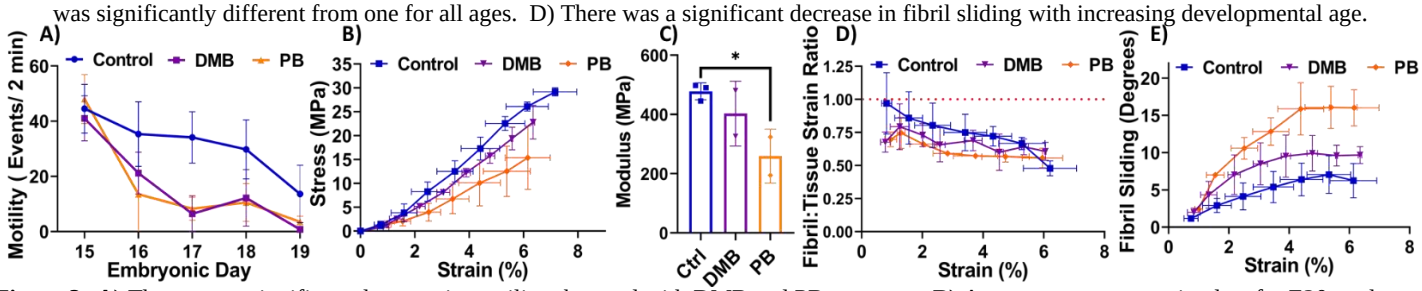

Figure 2: A) There was a significant decrease in motility observed with DMB and PB treatment. **B)** Average stress vs. strain plots for E20 tendons with vehicle control (n=3), rigid paralysis (DMB, n=2), and flaccid paralysis (PB, n=2). **C)** There was a significant decrease in modulus with PB treatment. **D)** The fibril:tissue strain ratio was significantly different from one in all samples and was negatively correlated with applied tissue strain for control and PB tendons. **E)** There was a significant increase in fibril sliding with PB treatment but not with DMB.

RESULTS

Tendons at E20 had a significantly greater macroscale modulus compared to earlier developmental ages ($p < 0.05$) (**Fig. 1A-B**). While the average fibril:tissue strain ratio was less than one for all ages ($p < 0.05$) (**Fig. 1C**), ANCOVA analysis indicated a significant effect due to age ($p < 0.05$) and only the E20 samples displayed a negative correlation with applied tissue strain ($p < 0.001$). Furthermore, there was a significant decrease in fibril sliding comparing E16 versus E20 ($p < 0.01$) and E18 versus E20 ($p < 0.001$) (**Fig. 1D**).

While both DMB and PB significantly reduced motility during development ($p < 0.05$) (**Fig. 2A**), a significant drop in modulus was only observed with PB treatment ($p < 0.05$) (**Fig. 2B-C**). The average fibril:tissue strain ratio was significantly less than one for all samples ($p< 0.01$) (**Fig. 2D**) and no treatment effects were observed from ANCOVA analysis. However, only the control and PB treated samples were negatively correlated with the applied strain ($p < 0.01$). Compared to control tendons, there was a significant increase in fibril sliding with PB treatment ($p < 0.001$) but not DMB ($p = 0.07$) (**Fig. 2E**).

DISCUSSION

This study demonstrated that there is a shift in tendon multiscale mechanics during late embryonic development that is consistent with increasing fibril lengths. Specifically, the increase in the macroscale modulus observed with development (**Fig. 1B**) is accompanied by an increase in the fibril:tissue strain ratio at low applied tissue strains leading to a negative correlation with increasing strain (**Fig. 1C**). Additionally, there was a decrease in fibril sliding with increasing developmental age (**Fig. 1D**). Together, these data suggest that more of the applied tissue strain is being transmitted to the collagen fibrils at later embryonic ages, which is consistent with our hypothesis and previous work suggesting that collagen fibrils fuse and rapidly elongate during late embryonic development[3,5]. While further work involving multiscale modeling and direct measurement of fibril lengths through ultrastructural imaging is necessary to confirm this interpretation, our findings suggest that collagen fibril elongation is the key structural change driving late embryonic tendon development.

Our findings additionally found that mechanical stimulation was necessary to induce the multiscale mechanical changes observed during tendon development. Flaccid paralysis reduced the increase in macroscale modulus seen during normal development (**Fig. 2C**). Furthermore, while not statistically significant due to a low sample size, there appeared to be a small drop in the fibril:strain ratio at low applied tissue strains for the PB samples (**Fig. 2D**). This suggests that flaccid paralysis retards tendon development by preventing fibril elongation and inhibiting strain transmission to the fibrils, which is supported by the increased fibril sliding with PB treatment (**Fig. 2E**). Interestingly, there was a similar but muted effect on the multiscale tendon mechanics with rigid paralysis (i.e., DMB treatment). Since previous work demonstrated that DMB reduces the compressive modulus of embryonic chick tendons[4], the lack of statistical significance in our DMB data may be due to a small sample size. Still, the smaller effect size of DMB compared to PB treatment suggests that while rigid paralysis prevents dynamic muscle activity, it still produces static tension (and hence some mechanical stimulation). This suggests that cyclic mechanical stimulation is critical for proper tendon development.

Altogether, our multiscale tensile testing of embryonic tendons supports the hypothesis that fibril elongation is essential for producing a robust tensile load-bearing tissue and that this structural change is mediated by cyclic rather than static mechanical stimulation. Future work will investigate whether these findings translate into improved approaches to produce tissue-engineered constructs that can successfully replicate tendon and ligament function.

INTRODUCTION

In recent years, large advancements have been made in the development of patient-specific cardiovascular models for blood flow simulations. In these simulations, the choice of appropriate boundary conditions is a crucial step, since they have a large influence on the resulting flow rates and hemodynamic parameters of clinical relevance, such as wall shear stress (WSS). In-vivo measurements, if available, can be used to guide the selection of boundary conditions, such that simulation results better match clinical data. A common approach is to split a given inlet flow rate among all outlets according to their area by means of Murray's law [1]. From the obtained flows and an estimate of pressure, the resistance to be placed at each outlet is obtained. However, manual tuning is required to match in-vivo data, which is time consuming and operator dependent. More systematic methods have been proposed based on optimal control [2], Bayesian estimation [3], and Kalman filtering [4].

With optimal control, a rigorous Lagrangian approach [5] is used to determine the optimal value of resistance boundary conditions that match the given in-vivo measurements. Optimal control was applied to a glass replica of cardiovascular models [6] and to coronary artery bypass grafts [2], but using less realistic Neumann-type boundary conditions. In this work, we propose an optimal control framework for determining resistance-type boundary conditions in patient-specific aortic models, starting from flow measurements obtained with 4D-Flow MRI. We show the validity of the proposed framework on a real clinical case, and investigate the influence of the obtained boundary conditions on WSS and oscillatory shear index (OSI).

METHODS

We present the proposed method by considering the aortic arch represented in Fig. 1, with the goal of determining the values of the resistance R_i imposed at each outlet. The anatomy of the vessels was derived from the computed tomography (CT) images acquired with a 320 multidetector scanner (Aquilion ONE, Canon Medical Systems). From the CT images, the vessels surface was reconstructed using SimVascular (www.simvascular.org). A computational mesh was generated with Tetgen. After CT imaging, blood velocity was acquired in-vivo with 4D-Flow magnetic resonance imaging (MRI) with a 3T MRI scanner (MAGNETOM Aera, Siemens Healthineers).
Blood flow in the vessels is modelled with the steady Stokes equations

$$\begin{cases} -\eta\Delta v + \nabla p = f\,, & in\ \Omega \\ \nabla \cdot v = 0, & in\ \Omega \end{cases} \tag{1}$$

At the ascending aorta inlet Γ_{in}, a Poiseuille flow was imposed, whose average value was extracted from the 4D-Flow MRI data of the patient.

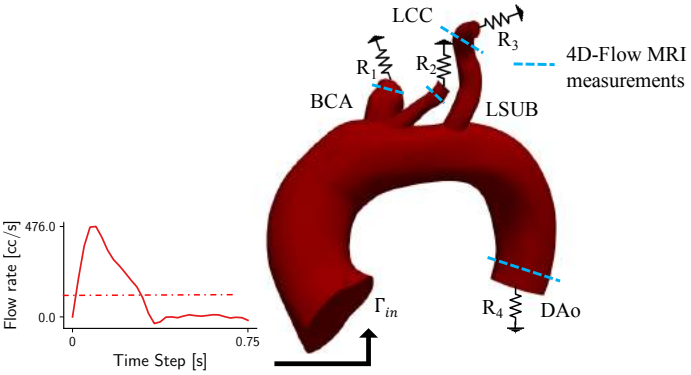

Figure 1: General setting of the proposed framework on a patient's aortic arch.

A no-slip condition was imposed at the vessel walls, assumed to be rigid. At the four outlets, corresponding to descending aorta (DAo), brachiocephalic artery (BCA), left common carotid artery (LCC) and left subclavian artery (LSUB), a resistive-type boundary condition was imposed following the coupled multidomain method proposed in [7]. The unknown resistance values R_i were then determined solving an optimal control problem. Optimal control estimates unknown parameters by minimizing a cost functional constrained by the governing equations of the system.

We defined a cost functional J with the following form:

$$J = \alpha_p \frac{\int_\Omega ||p - p_d||^2 d\Omega}{2\int_\Omega ||p_d||^2 d\Omega} + \sum_{i=1}^{4} \alpha_i \frac{\int_{\Gamma_i} ||v - v_i||^2 d\Gamma_i}{2\int_{\Gamma_i} ||v_i||^2 d\Gamma_i} + \sum_{i=1}^{4} \beta_i \frac{\int_{\Gamma_i} ||R_i||^2 d\Gamma_i}{2\int_{\Gamma_i} ||R_{i,M}||^2 d\Gamma_i} \quad (2)$$

where α_p is set to 100, α_i and β_i to 1, and $R_{i,M}$ is the resistance value at the outlet Γ_i obtained with Murray's law. The first term in (2) represents the difference between the pressure p obtained from (1) and the patient's average aortic pressure p_d derived from clinical data. The second term relates to the difference between the velocity v from (1) and the average velocity v_i measured at each outlet Γ_i. The third term consists of the norm of the control variables R_i, and acts as a regularization term. For solving the optimal control problem, we adopted an adjoint-based Lagrangian approach [5], first deriving the optimality system containing the first-order optimality conditions, and then recasting it to saddle-point form to obtain a monolithic algebraic system for easier computations. The obtained system was then solved with the open-source libraries FEniCS [8] and multiphenics [9].

RESULTS

The results obtained for the case of Fig. 1 are detailed in Table 1. On the first row, Table 1 reports the patient's average pressure measured non-invasively after MRI, and flow rates measured in-vivo with 4D flow MRI. The second and third row of the table report the values obtained with the boundary conditions estimated with Murray's law and with the proposed method. The pressure and flow values obtained with optimal control match the patient measurements quite closely, indicating a proper assimilation of in-vivo information. While a perfect match would be ideal, this is often not possible in practice, due to the noise and uncertainty affecting in-vivo measurements, and due to the assumptions of the adopted mathematical model (1). By minimizing (2), the proposed approach finds the set of boundary conditions that comes as close as possible to the given in-vivo information.

We also observe that the solution from the proposed method is not too far from the one obtained with Murray's law, where boundary conditions are set on the basis of purely anatomical information [1]. This observation further confirms the physiological validity of the boundary conditions selected by the proposed method. Table 2 reports the resistance values obtained with the two methods, Murray's law and optimal control. The values are similar, except for the LSUB resistance, which differs substantially (23%). To investigate how this difference may affect clinically-relevant hemodynamic parameters, we used the two sets of boundary conditions reported in Table 2 to run two unsteady high-fidelity Navier-Stokes simulations, using SimVascular. Resistance values were used to set three-element Windkessel models at each outlet, assuming a total capacitance of 0.001 cm^5/dyne, distributed among the various outlets with an area-based criterion. Fig. 2 depicts the absolute difference between the OSI computed with the two sets of boundary conditions. While the difference is negligible for the most part of the geometry, the difference reaches 40% of the OSI range (0÷0.5) in the region past the left subclavian artery.

Table 1: Comparison of average aortic pressure and outlet flow rates obtained with Murray's law and with the proposed method.

	Pressure (mmHg)	Flow rates (cm^3/s)			
		BCA	LCC	LSUB	DAo
Patient measurements	98.7	15.9	5.98	8.48	73.1
Murray's law	98.8	19.2	6.19	7.48	86.2
Proposed	95.2	19.8	6.10	9.41	83.9

Table 2: Resistance values obtained with Murray's law and with the proposed method (all values in dyn·s·cm^{-5}).

	DAo	BCA	LCC	LSUB
Murray's law	1,526	6,837	21,241	17,591
Proposed	1,513	6,409	20,801	13,467

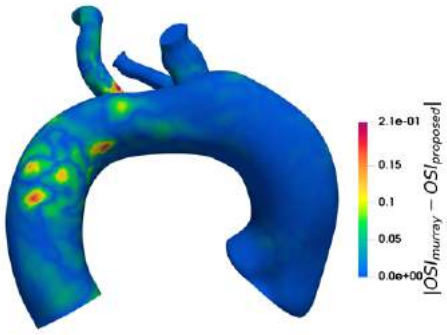

Figure 2: Absolute difference of OSI between Murray's law and the proposed method (back view of the aorta).

DISCUSSION

We proposed a computational framework for the determination of resistance-type outlet boundary conditions based on the assimilation of 4D-Flow MRI measurements by means of optimal control. Our study documents the application of such framework to a real clinical case and shows the influence that the choice of outlet boundary conditions has on OSI, one of the hemodynamic quantities of potential clinical interest. The presence of regions with a considerable difference from Murray's law-based results confirms the crucial role of boundary conditions in hemodynamic modeling, and suggests the need for further research on determining appropriate boundary conditions for computational hemodynamics.

INTRODUCTION

Formed by the endothelial tight junction (TJ) and adherent junction complexes, the blood-brain barrier (BBB) plays a crucial role in protecting the brain parenchyma from the toxic effects of plasma proteins but also poses a formidable challenge to the delivery of therapeutics[1]. High osmotic mannitol to increase BBB permeability has mostly been abandoned due to procedure-related neurotoxicity[2]. While the use of focused ultrasound to increase BBB permeability have progressed to early-phase clinical trial, safety issues such as sterile inflammation[3] and loss of vasoreactivity[4] have been raised.

There is increasing evidence that a dysfunctional BBB is an integral component of many primary neurological brain diseases (e.g., Alzheimer's disease). Therefore, it is critical that the strategies used to disrupt the BBB in at-risk brains do so in a highly selective manner to minimize the risk of unintended injury. To address these challenges, we present a novel method that modulates the BBB with picosecond (ps) laser excitation of TJ-targeted plasmonic gold nanoparticles (**Fig. 1A**). This method increases permeability through the TJ without compromising its structural integrity or inducing any discernable neuronal injury. The increase in BBB permeability allows immunoglobulins (IgG), adeno-associated viral (AAV) vectors, and liposomes to enter the brain parenchyma.

METHODS

Nanoparticle synthesis and functionalization: Gold nanoparticles (AuNPs) were synthesized by previous reported method[5]. Then, the AuNPs were functionalized with antibody (BV11: anti-mouse JAM-A) for targeting JAM-A[6], one of the TJ proteins (**Fig. 1B**).

In vivo experiments: C57BL/6 mice were injected 18.5 μg/g AuNPs functionalized with BV11. We then applied ps laser pulse (532 nm, full width half maximum = 28 ps), through mouse skulls to excite the AuNPs on blood vessels. To mearsure BBB permeability, we intravenously (I.V.) inject tracer (980 Da Evans blue, or 660 Da EZ-link biotin and 70 kDa fluorescein isothiocyanate (FITC) labeled dextran) at different time points post laser stimulation. After 0.5 hr circulation, the mice were transcardially perfused with 25 ml PBS and 25 ml 4% PFA for tracer leakage study, or with 25 ml 2% lanthanum nitrate and 25 ml 2% PFA mixed with 2% glutaraldehyde for electron microscopy (EM) imaging. The brain tissue was extracted for tracer extravasation imaging and analysis.

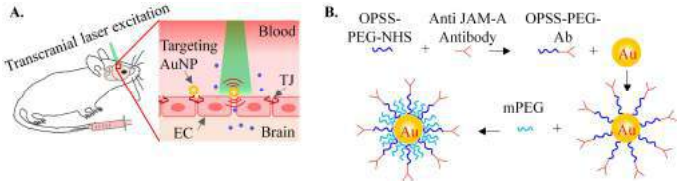

Fig.1. Methods of BBB modulation *in vivo*. (A) Schematic for laser excitation of TJ-targeted AuNP. (B) Synthesis of TJ-targeting AuNPs[7]. Ab: Antibody, EC: endothelial cell.

RESULTS AND DISCUSSION

Nanoparticle targeting and light modulation of the BBB by paracellular diffusion

We examined the targeting of AuNP-BV11 with intravenous injections. Silver enhancement staining of AuNP along brain capillaries was only seen in the case of AuNP-BV11, but not for non-targeting AuNP-PEG (PEG: polyethylene glycol) (**Fig. 2A**). EM imaging showed that AuNP-BV11 co-localizes with the TJ (**Fig. 2B**), indicating that AuNP-BV11 recognizes and targets TJ *in vivo*. Ps laser excitation of the TJ-targeted AuNP-BV11 temporarily increases BBB permeability, as indicated by Evans blue (albumin-bound, 66 kDa in total, **Fig. 2C**). Next, we co-administered tracers of different molecular weights. Leakage of the 660 Da EZ-link biotin was detected up to 6 hr, while 70 kDa FITC-dextran was only detected up to 1 hr after laser excitation (**Fig. 2D**). A size-selective temporal pattern of tracer entry into the brain parenchyma would be consistent with a gradual closing of a paracellular route. No leakage of the two tracers was observed 24 hr after laser excitation, suggesting that the BBB recovers within this time period.

To study the BBB modulation route, we performed transcardial perfusion with 2% lanthanum (La) nitrate after ps-laser stimulation. EM imaging reveals that BBB modulation leads to complete La filling in half of the TJ cleft (51%), while 49% showed partial filling (**Fig. 2E top**). In contrast, in control tissue near 100% of the TJ clefts showed La partial lining the luminal portion of the TJ cleft. Most strikingly, in the former, La was seen to line the basement membrane and diffuse into the interstitial space of the brain parenchyma (**Fig. 2E bottom**).

These results provide clear evidence to suggest that the increased BBB permeability involves the paracellular pathway to allow the passage of luminal tracers through the TJ cleft and into the brain interstitial space.

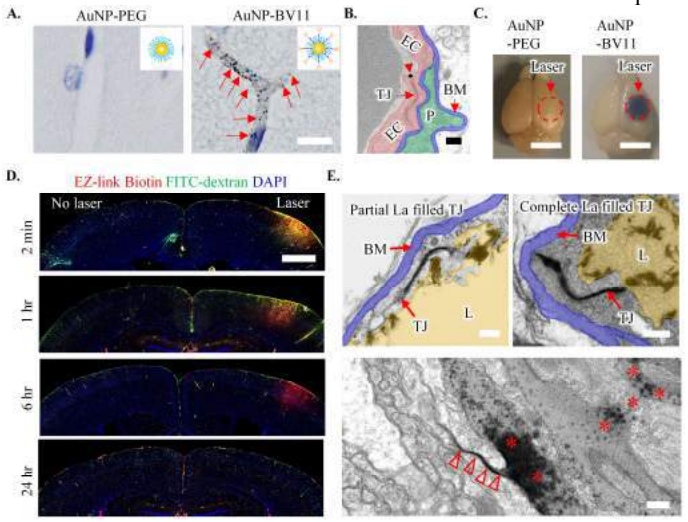

Fig. 2. Picosecond laser stimulation of TJ-targeted nanoparticles reversibly modulates BBB permeability by paracellular route. (A) AuNPs are visualized by silver enhancement staining. (B) AuNP-BV11 (arrow head) co-localizes with TJ detected by EM. (C) BBB modulation visualized by the leakage of albumin-binding Evans blue (25 mJ/cm^2, 1 pulse). (D) BBB permeability probed by molecular tracers (660 Da EZ-link biotin and 70 kDa FITC-dextran, 5 mJ/cm^2, 1 pulse). (E) EM imaging of La infused TJ of brain capillaries, and diffused into basement membrane (*) and interstitial space (empty arrow head). Pseudocolours: endothelial cell (EC: red), basement membrane (BM: blue), pericyte (P: green), Lumen (L: yellow). Scale bar: 10 µm (A), 200 nm [(B), (E)], 4 mm (C), 1 mm (D).

Impact of BBB modulation on brain parenchyma

To investigate the effect of BBB modulation on brain parenchyma post laser excitation (25 mJ/cm^2, 1 pulse, 72 hr post laser stimulation), we performed inmunohistochemry (IHC) staining. The change was not observed in neurons and their axonal processes (NeuN, Ankyrin-G) (**Fig. 3A**), nor in astrocyte end-foot process (AQP4), and pericyte (NG2) as mural support of the BBB (**Fig. 3B and C**). This suggests the BBB modulation doesn't affect the cellular architecture of the brain parenchyma.

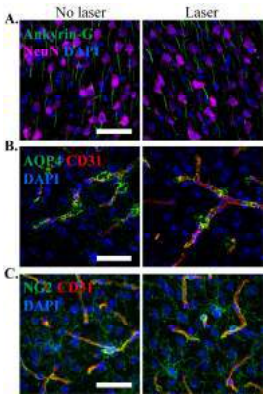

Fig. 3. BBB modulation preserves the cellular architecture. The IHC stianing of neuronal nucleus and axon indicated by NeuN and Ankyrin-G (A), water transporter of astrocyte endfeet indicated by AQP4 (B) and pericyte indicated by NG2 (C). Scael bar: 40 µm.

Antibody, gene, and nanoparticle delivery to the brain

Lastly, we demonstrate that the temporary BBB modulation allows successful delivery of functional molecules and particles, including IgG (**Fig. 4A**), gene therapy vector AAV (**Fig. 4B**) and liposome (**Fig.4C**), which indicates significant therapeutic potential.

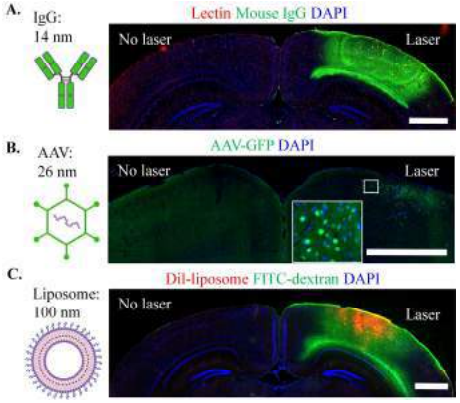

Fig. 4. BBB modulation enables delivery of functional molecules and particles. Delivery of mouse IgG antibody (A, 25 mJ/cm^2, 1 pulse), AAV-CamKII-GFP (B, 10 mJ/cm^2, 1 pulse), and liposome (C, 25 mJ/cm^2, 1 pulse) into the brain. Scale bar: 1 mm.

CONCLUSION

Picosecond-laser stimulation of TJ-targeted AuNPs temporarily increases the BBB paracellular permeability allowing macromolecules to diffuse through the TJ cleft into the interstitial space, including immunoglobulins, AAV particles and liposomes. The ps-laser induced increase in BBB permeability doesn't affect the brain parenchyma. Focal brain delivery of therapeutic agents through the BBB following systemic administration has important translational implications.

INTRODUCTION

Although percutaneous transluminal angioplasty with stenting is widely used for treatment of peripheral artery disease, in-stent restenosis (ISR) is still a serious drawback, compromising the long-term success of the procedure. ISR consists in a maladaptive arterial response to the intervention, which leads to lumen re-narrowing through an abnormal increase of cellular proliferative and synthetic activities [1].

There are different factors contributing to ISR and, among them, the inflammatory response activated by the damage due to the angioplasty, and the abnormal hemodynamics, induced by the stent presence, are thought to play a major role [2]. Specifically, monocyte gene expression data were used as the marker of the inflammatory cues triggered by vascular interventions and were found to correlate with an unfavorable post-surgical outcome [3],[4]. In addition, the low wall shear stress (WSS) was identified as an indicator of disturbed local hemodynamics that contributes to ISR by delaying the endothelial recovery and modulating smooth muscle cell (SMC) activity [5].

Given the complex multifactorial and multiscale nature of ISR, computational modeling, based on a systems biology approach, is deemed to provide a better understanding of the mechanobiological processes. Moreover, patient-specific in-silico models are being established as means that can support the biomedical research and guide towards new therapeutic solutions in the context of personalized medicine.

Accordingly, in the present work we propose an innovative patient-specific multiscale model of ISR that integrates the effects of the local hemodynamics and monocyte gene expression on the cellular dynamics. To do this, computational fluid dynamics (CFD) simulations are coupled with an agent-based model (ABM) of cellular dynamics, replicating arterial wall remodeling in response to local WSS and gene expression inputs.

METHODS

The CFD-ABM computational framework simulated the arterial response following stenting procedure in patient-specific stented superficial femoral artery (SFA) models through the four steps schematized in the central panel in Fig.1. The framework and the ABM scheme were based on our previous work on atherosclerosis [6].

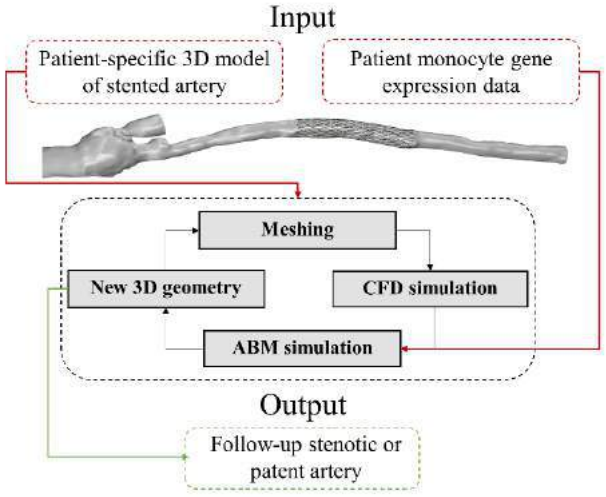

Figure 1: CFD-ABM computational framework of ISR.

The 3D patient-specific stented SFA, reconstructed from CT images, was meshed using polyhedral elements with five layers of prism elements near the wall. A steady-state CFD simulation was performed to compute the average hemodynamics in the stented area and the WSS

was extracted in 9 cross-sectional planes (one every two stent rings). Both the meshing step and the CFD simulations were performed in Fluent (Ansys Inc., Canonsburg, PA, USA). For each cross-section, a 2D ABM was implemented in Matlab (MathWorks, Natick, MA, USA) and, being initialized with the CFD-derived WSS profile and the gene expression data, it simulated the arterial wall remodeling by replicating cell and extracellular matrix (ECM) dynamics. Patient monocyte gene expression was measured at 1 hour before, and 2 hours, 1, 7 and 28 days after the intervention. Only those genes that were found to significantly correlate with the intervention outcome were used as input of the ABM [3],[4].

The 2D ABM of arterial cross-section was generated on a hexagonal grid and filled with SMC and fibroblasts, ECM and stent strut agents. While the patient geometry was used to define the arterial lumen, a circular external border and literature derived wall thickness were set, due to the lack of patient-specific information [7],[8].

The behavior of each cell and ECM agent was simulated by assigning probabilistic rules to the events of interest, namely cell mitosis/apoptosis and ECM production/degradation. While constant activities in the media and adventitia layers were set to preserve homeostasis [6], cell mitosis and ECM production in the intima depended on the local WSS and patient gene expression.

After one simulated month, the ABM simulations were stopped in order to update the fluid dynamics in the modified vessel geometry. Thus, a new geometry was reconstructed from the ABM outputs and the cycle was repeated for a specified follow-up period.

Due to the stochasticity of the model, 5 ABM simulations were run for each plane and the lumen configuration closest to the average of the 5 simulations was selected to reconstruct the new vessel geometry.

As preliminary evaluation of the framework, the lumen area of the stented portion obtained at one month was computed and compared with that measured from patient's CT images at one-month follow-up. The individual distributions were examined through the Mann-Whitney U test and statistical significance was assumed for p-value < 0.05.

RESULTS

Figure 2 shows the ability of the framework to capture the process of intimal growth in the stented region at one-month follow-up. Specifically, after one month all planes showed an increased intima thickness with coverage of the stent struts, due to perturbed cell and ECM activities, while media and adventitia preserved their initial areas. Moreover, the results obtained by the multiple runs were consistent between each other and a good reproducibility of the outputs was confirmed by the small interquartile range of the one-month lumen area (Fig. 2). Finally, no significant differences were observed between the patient's lumen area of the stented portion at one month and the model prediction (Fig. 3). In both cases, a significant lumen area reduction was found with respect to the condition immediately after stenting intervention.

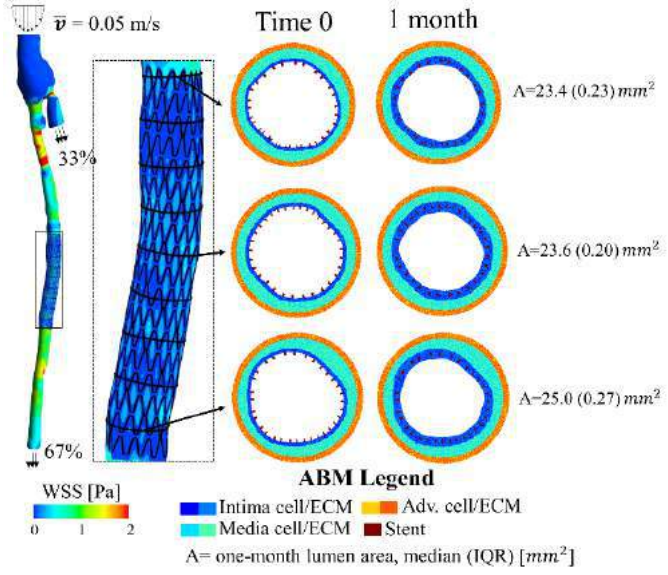

Figure 2: one-month results of the ISR framework for three explanatory planes.

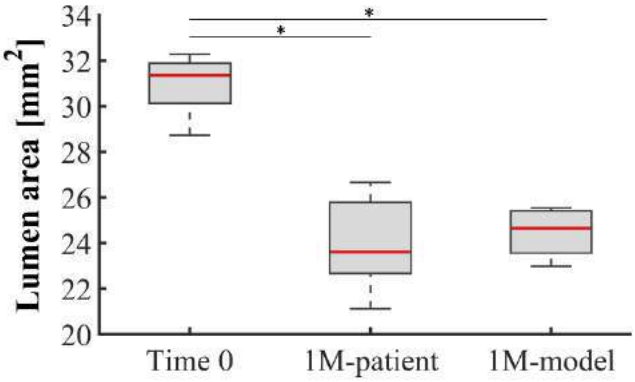

Figure 3: Comparison of the lumen area of the stented portion at one-month follow-up between the patient data (1M-patient) and the model (1M-model). *: p-value < 0.05.

DISCUSSION

In this work, a novel multiscale CFD-ABM framework of ISR was developed and applied to a patient-specific case of stented SFA. The important innovation was the integration of patient's monocyte gene expression as the driver of the cell and ECM dynamics. Accordingly, herein ISR was modeled at cell scale as the arterial response to the gene-weighted systemic inflammation and the stent-induced hemodynamic alteration, through the replication of the ABM cellular and ECM dynamics.

In the near future, a proper calibration of the ABM parameters will be performed based on the available follow-up data. Furthermore, the CFD-ABM framework will be applied to other patient-specific cases to elucidate the role and the interdependence of the different factors promoting ISR, with the ultimate goal to build a multiscale model being able to predict ISR in human SFAs.

INTRODUCTION

Self-expandable stents are commonly implanted to treat atherosclerotic superficial femoral arteries (SFAs). Though, this minimally-invasive treatment is widely affected by in-stent restenosis (ISR), one of the major drawbacks usually requiring a new revascularization [1]. Despite the incidence of this pathology, little is known about its initiation and progression. A combination of clinical (diabetes, smoking) and biomechanical factors (arterial wall injury provoked by the endovascular procedure and the altered hemodynamics due to stent presence) is deemed to promote ISR. In particular, the altered hemodynamics seems to play an important, but still not fully understood, role [2, 3].

In the present work, the progression of ISR over time is studied in human stented SFAs by detailing the morphological lumen remodeling in vessel models. Furthermore, the impact of altered hemodynamics on ISR initiation and progression is analyzed by performing computational fluid dynamics (CFD) simulations at multiple follow-ups within the first post-interventional year.

METHODS

Ten lesions of seven patients presenting with stenotic SFAs were considered (with the written consent). The lesions were treated with stents of different length (range [40÷300] mm) and in some cases in multiple overlapping configurations. The SFA models were obtained from computed tomography (CT) images using a validated reconstruction method [4]. To investigate the ISR progression, the data at four follow-ups (i.e. 1-week (1W), 1-month (1M), 6-months (6M) and 1-year (1Y)) were analyzed.

Transient CFD simulations were carried out for the first three follow-ups, employing the patients' Doppler ultrasound data to impose patient-specific boundary conditions [4].

The morphological remodeling was described by quantifying the lumen area change (ΔA) every 1 mm along the vessel length at each follow-up, and by analyzing the trajectory over time in the whole stented region. As regards the hemodynamics, several wall shear stress (WSS)-based descriptors, including those accounting for the WSS multi-directionality, were quantified. In particular, the time-averaged WSS (TAWSS), oscillatory shear index (OSI), relative residence time (RRT), the axial and secondary components of WSS averaged in time (TAWSSax and TAWSSsc), the transverse WSS (transWSS), the cross-flow index (CFI), and the ratio of the secondary and axial WSS components (WSSratio) were calculated [5]. Hemodynamic data were averaged circumferentially and every 1 mm axially to match the morphological data.

To obtain spatial independent data, the computed local morphological and hemodynamic results were preliminarily processed by calculating a decorrelation length based on surrogate data analysis, as previously described [3, 6]. The most conservative, patient-specific decorrelation length (range [2÷10] mm) was determined.

Following the normality test, the morphological data were examined by comparing the groups at consecutive follow-ups and time intervals (1W-1M, 1M-6M and 6M-1Y) using Kruskal Wallis test. The individual distributions were examined through the Mann-Whitney U test. Moreover, the linear regression between the lumen area change occurring in each time interval and the lumen area at the beginning of that time interval was quantified. The Spearman's correlation was computed between the WSS-based descriptors and the lumen area change. The results were analyzed at a global (i.e. considering one point per lesion) and local level (i.e. collecting all the results together). Statistical significance was assumed for $p\text{-value} < 0.05$.

RESULTS

As emerges from the trends of lumen area over time (Fig. 1-A,B), the first time interval (1W-1M) was the most dynamic in terms of lumen remodeling and was characterized by the largest lumen area change. Overall, in the intermediate time interval (1M-6M), the lumen area reduction was smaller as compared to the first time interval In the last time interval (6M-1Y), short portions of the lesions were characterized by severe, focal lumen re-narrowing, as also observable from the SFA reconstructed anatomies at 1Y (Fig. 1-C).

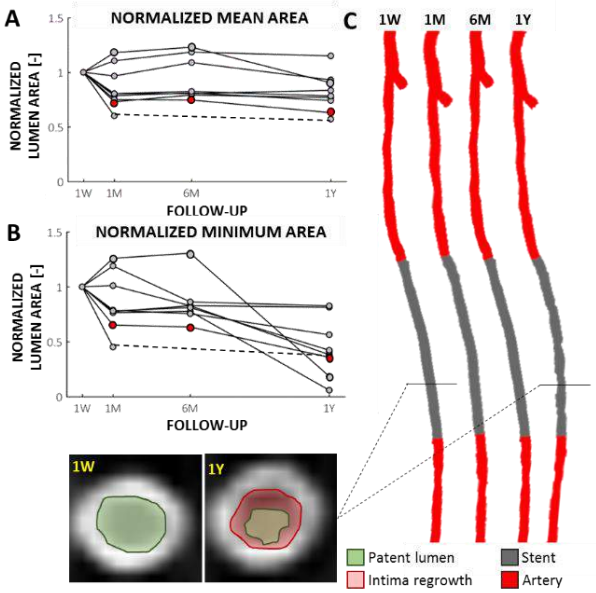

Fig. 1: Remodeling trajectory over time of all cases, reported as A) mean and B) minimum lumen area normalized with respect to the 1W lumen area. C) Reconstructed SFA models and CT images of one explanatory case.

Differences between the lumen area distributions at 1W and 1M ($p=0.0539$) and between those at 1W and 1Y ($p=0.0140$) were present (Fig. 2A). The fractional rate of lumen area change, computed as the lumen area change normalized by the time interval length, was largely different between the first (1W-1M) and the last time interval (6M-1Y, $p=0.0434$) (Fig. 2B). Moreover, a strong positive linear association emerged between the lumen area change in the first time interval (1W-1M) and the lumen area at 1W, indicating that for larger initial lumen area, a larger immediate lumen reduction occurs ($R^2=0.501$, $p<0.0001$).

Regarding the analysis of the association between hemodynamics at the beginning of the time interval and the lumen area change in that time interval, a strong positive correlation was found at the global level between CFI_{1W} and lumen area change $\Delta A_{1W:1M}$ ($\rho=0.6970$, $p=0.0311$), and between $WSSratio_{1W}$ and lumen area change $\Delta A_{1W:1M}$ ($\rho=0.6606$, $p=0.0440$). Moreover, for low TAWSS, high OSI and high RRT, high remodeling occurred in the subsequent time intervals (even if the global results were not significant). The previous global results were confirmed by the local level of analysis (Fig. 3). All the WSS-based descriptors at 1W but the TAWSSsc were correlated with the lumen area change $\Delta A_{1W:1M}$. No significant associations were found in the second time interval (1M-6M). OSI_{6M}, RRT_{6M} and CFI_{6M} were positively correlated to $\Delta A_{6M:1Y}$ ($\rho=0.2233$ with $p=0.0004$, $\rho=0.2277$ with $p=0.0006$, $\rho=0.2019$ with $p=0.0024$, respectively), while the $TAWSSax_{6M}$ was negatively associated with $\Delta A_{6M:1Y}$ ($\rho=-0.1573$, $p=0.0185$).

DISCUSSION

To the best of authors' knowledge, this is the first study quantifying the morphological remodeling occurring in human SFAs after stenting over 1Y follow-up period. The findings of this study showed that in this vascular region the lumen remodeling is a dynamic process characterized by high lumen area change during the first post-interventional month and possible focal re-narrowing in the time interval 6M-1Y. The lumen remodeling was similar along the lesion length, with only slight regional-specific differences (results not shown).

Furthermore, the hypothesis that ISR progression is promoted by abnormal hemodynamics seems to be confirmed. Interestingly, the direction of the correlations between morphological remodeling and WSS-based descriptors was aligned with previous works [2, 3]. Thanks to the longitudinal nature of this study, more quantitative results were here presented, suggesting that the multidirectional WSS is an important biomechanical factor involved in the ISR process, especially in the time interval 6M-1Y, subjected to focal re-narrowing.

In conclusion, despite the limited number of investigated lesions, the methodology adopted in this study enabled to widen the knowledge of ISR progression in human stented SFAs, showing the importance of considering long-term follow-ups in the investigation of ISR and giving insights on the role of hemodynamics.

MYOSIN-INDEPENDENT MECHANOTRANSMISSION FOR SENSING STIFFNESS OF EXTRACELLULAR MATRIX

Nikhil Mittal (1), Sangyoon Han (1)

(1) Department of Biomedical Engineering
Michigan Technological University
Houghton, MI 49931, USA

INTRODUCTION

Mechanical stiffness of the extracellular matrix (ECM) plays a critical role in proliferation, differentiation and migration of adherent cells (1). While it is well-known that stiffness sensing is mainly mediated by integrin-based focal adhesions (2), its exact mechanism has been still unclear. In order for different stiffness to be sensed differently, different 'force' should be transmitted through the focal adhesions in which the force triggers conformational opening of mechanosensitive proteins such as talin and vinculin (2). Indeed, a substantial number of studies have shown an increasing traction force in response to increasing substrate stiffness (3-5). To explain the relationship between the stiffness and the traction, a 'molecular clutch' model has been successfully implemented and used (6). In the clutch model, F-actin's retrograde flow dynamically 'clutches' with the cell-ECM adhesion that results in the transmission of the force to the substrate. Myosin II contractility has been the only source of the retrograde flow where myosin's muscle-like behavior of force-velocity could nearly explain the observed traction in response to stiffness (7, 8). However, evidence shows that cells are able to transmit small but significant traction force even in the absence of myosin activity with also increasing trend with increasing substrate stiffness (9). Given myosin as a 'result' of mechano-signaling, identifying how cells transmit differential force without myosin would shed light on the very initial stiffness sensing event by a cell without complication by myosin's effect. As an alternative power source, actin assembly at the barbed end of F-actin can contribute to the retrograde flow by pushing the membrane and being pushed by the membrane (10). Actin Related Protein 2/3 complex (arp2/3) and formin homology protein are the two main actin nucleators (11, 12). Here, we hypothesize that myosin-independent traction comes from the actin-polymerization-driven retrograde flow and its two main mediators regulates the force transmission in a distinct manner.

METHODS

TFM experiments were performed on a high refractive index silicone gel (Q-gel, Quantum Silicones) substrate of different stiffnesses (0.3, 0.8, 1.5, 5 and 12 kPa) coated with 40nm diameter, far-red carboxylated beads as fiducial markers (13). The stiffness of gels with different mixing ratio was measured with parallel disk-based rheometry. 3T3 fibroblast cells stably expressing paxillin-mRuby (gift from Ginsberg lab) were treated with 1) blebbistatin, a myosin inhibitor, only, 2) blebbistatin with smifh2, a formin inhibitor or 3) blebbistatin with CK666, an arp2/3 inhibitor. In addition, cells without treatment were used as a control. Cells and beads on the gel, 4 hours after seeding, were imaged under a total internal reflection fluorescence (TIRF) microscope, after which another bead image, a reference image, was collected after lysing cells using 10% bleach. Traction reconstruction was done using our own MATLAB-based TFM software (13). Briefly, the displacement field was calculated by particle tracking velocimetry and corrected using the outlier filtering. A regularized-Fourier Transform Traction Cytometry (regFTTC) was used for the inverse problem solution. The regularization parameter was chosen by an L-curve, L-optimal method using FastBEM (13).

RESULTS

First, we assessed how the traction of control 3T3s behaves in response to a range of gel stiffness. We quantified the total force at the cell perimeter, which is an integration of traction over a 2 um-thick inner-band along each cell perimeter, as our metric. As expected, the total force increased with the gel stiffness (Fig. 1a-e). Specifically, a linear increase was observed up to 5 kPa, after which the total force plateaued at stiffer regime (Fig. 1u). When treated with myosin inhibitor, blebbistatin, the overall magnitude of the traction force reduced (Fig. 1f-j, note the reduced color limit), but there was still non-zero,

concentrated traction located mostly near cell edges. Furthermore, the differential transmission was still observed, i.e., a linear increase in traction with increasing stiffness (Fig. 1u, v). This result suggests that the differential traction against varying stiffness is myosin-independent. To investigate the role of actin polymerization in stiffness sensing, in addition to myosin inhibition, either of two actin nucleators, formin or arp2/3, was inhibited with smifh2 or CK666, respectively. Cells treated with these double-inhibitions exhibited a reduced traction overall (Fig. 1k-t). However, the traction trends were observed to be no longer increasing. First, cells treated with blebbistatin and smifh2 showed a sharp increase in force at the soft stiffness regime (up to 0.8 kPa) but plateaued at intermediate regime then slightly reduced at stiff regime (Fig. 1k-o, v). Second, cells treated with blebbistatin and CK666 showed a biphasic behavior in traction with a peak at intermediate (1.5 KPa) stiffness after which traction dropped with the higher stiffness (Fig. 1p-t, v). The force transmission was hampered at stiffer (5-12 kPa) regime by both formin and arp2/3 inhibitions. While the arp2/3 inhibition frustrates the force transmission further than formin inhibition but the cells experience 'frustration point' in formin-inhibited cells earlier at soft regimes (Fig. 1v).

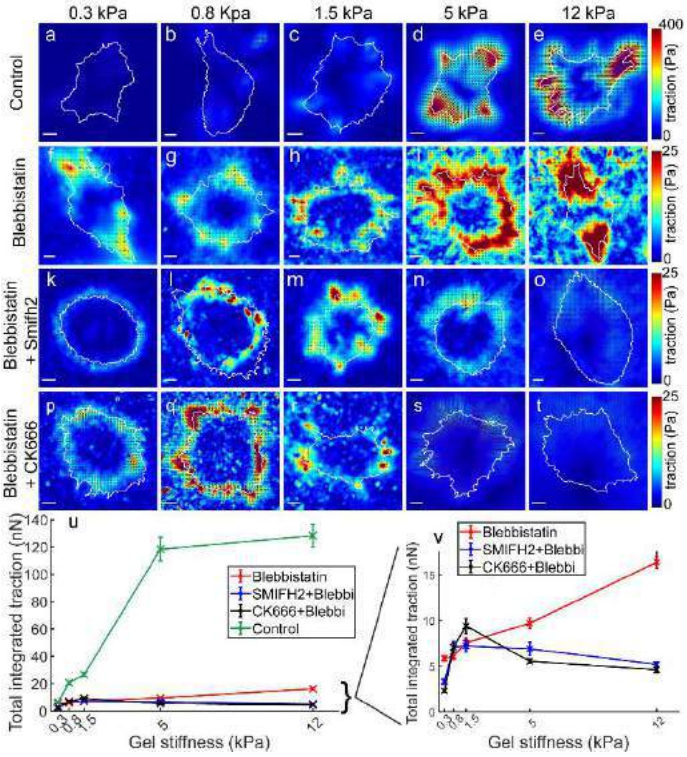

Figure 1: Myosin-independent traction transmission is hampered by further inhibition of actin nucleators. (a-t) High-resolution traction maps with traction vectors of 3T3s in control, blebbistatin, blebbistatin with smifh2, blebbistatin with CK666 conditions on a gel with 0.3 kPa (a,f,k,p), 0.8 kPa (b,g,l,q), 1.5 kPa (c,h,m,r), 5 kPa (d,i,n,s) and 12 kPa (e,j,o,t) as Young's modulus, respectively. (u) Total traction integrated over cell perimeter in all four conditions. Scale bar: 10 µm. (v) Total traction integrated over cell perimeter in all conditions except for control condition. Here, n= 45 (0.3 kPa), 33 (0.8 kPa), 57 (1.5 kPa), 57 (5 kPa), 70 (12 kPa) for control; n= 72 (0.3 kPa), 69 (0.8 kPa), 31 (1.5 kPa), 53 (5 kPa), 60 (12 kPa) for blebbistatin; n= 32 (0.3 kPa), 40 (0.8 kPa), 33 (1.5 kPa), 32 (5 kPa), 35 (12 kPa) for blebbistatin with smifh2; n= 39 (0.3 kPa), 37 (0.8 kPa), 40 (1.5 kPa), 42 (5 kPa), 28 (12 kPa) for blebbistatin with CK666 are the number of independently imaged cells.

DISCUSSION

In this work, we have shown using high-resolution TFM that cells in the absence of myosin activity can still transmit more traction when they are on a stiffer matrix. This trend is abolished upon further inhibition of the two actin-binding proteins that facilitate actin polymerization (Fig. 1v), demonstrating the importance of actin polymerization's active role in stiffness sensing.

The traction trend of the control cells as a function of the stiffness (Fig. 1a-e) is consistent with previously reported data (4, 6). The increase in traction in response to increasing stiffness can be explained by a molecular clutch model where more adhesion proteins are engaged in the complex via fast force development (6). In both formin- and arp2/3-inhibited conditions, cells show a plateauing trend in traction at intermediate-to-high stiffness, but at low stiffness regime, cells exhibit a linear increase in the traction. We speculate that this traction behavior is due to small but significant 'clutching' actin flow by the actin polymerization promoted by the other actin nucleator. Indeed, a work by Pollard group has shown that upon arp2/3 inhibition only, the actin flow becomes even faster, but with additional inhibition of myosin, the flow speed was significantly reduced but still non-zero (14). As actin is linearly polymerized by formin, formin-mediated actin assembly can confer fast-enough actin flow speed, but it can be 'slipped' when not assisted by Arp2/3. Thus, the slowed actin flow might not be enough to effectively clutch against, and unfold, mechanosensitive molecules such as talin, resulting in less force transmission. In contrast, arp2/3-mediated actin retrograde flow might be slower than one by formin, but it can be 'stickier', i.e., interacting better with adhesion molecules and clutch better for traction transmission. Our immediate next plan is to develop an actin polymerization-powered molecular clutch model, by which we will recapitulate the experimental results in Fig. 1. To validate our control cell experiment, we will perform make-up experiment on cells treated with DMSO. We will also quantify the actin flow speed using actin speckle microscopy with qFSM at each condition. We anticipate these experiments/simulations will deepen our understanding on myosin-free mechanotransmission. Together, our results suggest that both arp2/3 and formin synergistically modulate stiffness sensing, possibly by contributing to retrograde actin flow.

INTRODUCTION

Hypertrophic cardiomyopathy (HCM), affecting 1 in 200 people [1], is a genetic disease impacting key sarcomeric proteins in the myocyte. The histological phenotypes for HCM include hypertrophied and disarrayed myocytes, interstitial fibrosis, and cardiac hypertrophy. On a macroscale, the clinical phenotype includes regional growth despite no obvious change of the loading conditions in the heart. HCM growth patterns are heterogeneous, but around 1/3 of patients experience growth in the basal interventricular septum region [2]. In addition to tissue hypertrophy, an HCM patient's heart is at higher risk for cardiac arrhythmias, sudden cardiac death, and heart failure [3].

The following study aims to identify essential factors for regional growth patterns in HCM with the help of modelling. This abstract will investigate two theories for growth drivers in HCM. The first test accounts for the histological change of the fiber orientation in the hypertrophic area of HCM due to disarray. In contrast, the second test investigates the influence of inflammation and the tissue's resulting isotropic swelling in the region of HCM. Inflammation is common in severe HCM cases, particularly those with regional and diffuse fibrosis [4].

METHODS

The general setup for the growth problem is described through a mechanical problem, by solving for the linear momentum balance and the mass conservation equation, such that

$$\int_{\Omega_X} \mathbf{P}(\mathbf{F}, p) : \boldsymbol{\nabla}_X \mathbf{w} + \left(\rho J \ddot{\mathbf{U}} - J\mathbf{b}\right) \cdot \mathbf{w} + q(J-1)dX = 0, \qquad (1)$$

where $\mathbf{w} \in \mathcal{U}_0$ and $q \in \mathcal{P}$ represent the arbitrary test functions of the system for the displacement and the pressure, respectively. Ω_X defines the domain over which the growth problem is solved; ρ is the mass density in the stress-free reference configuration; **P** represents the first Piola-Kirchhoff stress tensor, which is dependent on the overall deformation gradient **F** of the continuum body. The subscript X of $\boldsymbol{\nabla}$ indicates that the derivatives of the gradient are defined with respect to the material coordinates. **b** refers to the body forces acting on the continuum body and was neglected for the below shown simulations. J denotes the determinant of the deformation gradient **F** and gives information about the volume change during the growth process. The system solves the problem with respect to the physical displacement **U** and the initial pressure p.

The theory of kinematic growth is one of two common approaches to model growth, the other being the constrained mixture theory [5,6]. The main advantage and disadvantage of the kinematic growth method is that the whole domain is assumed to be one continuum, which allows for easy parameterization of the material and the use of a phenomenological rate equation for the growth process. The existence of an intermediate configuration as a grown reference state is accepted by researchers in this field [7]. This assumption justifies a multiplicative decomposition (Fig. 1) of the overall deformation gradient into an elastic and an inelastic deformation gradient, such that

$$\mathbf{F} = \mathbf{F}_e \cdot \mathbf{F}_g, \qquad (2)$$

where $\mathbf{F}_g$ describes the growth from an initial stress-free reference configuration, $\Omega_X \subset R^3$ to a new intermediate locally stress-free state $\Omega_Y \subset R^3$. This new state may vary from the intact physically grown configuration $\Omega_t \subset R^3$. The elastic part ($\mathbf{F}_e$) of the deformation gradient maps the intermediate state to the physical configuration and ensures continuity of the body. By doing so, residual stress may be introduced into the body.

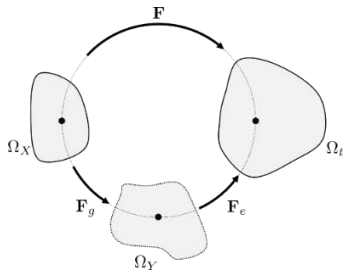

Figure 1: Schematic overview of the multiplicative decomposition of F into an inelastic deformation gradient $\mathbf{F}_g$ and an elastic deformation gradient $\mathbf{F}_e$ (adapted from [8]).

From this assumption, it is possible to map the integral from Eq. 1, which was defined on the reference domain, to the intermediate state. This is done by substituting the overall deformation gradient in this formulation with its multiplicatively-decomposed parts.

In this study, growth was modelled in a patient-specific biventricular geometry. Simulations utilized a Neo-Hookean material law and a boundary condition was applied to constrain the center of mass, ensuring no rotation nor translation of the body in space. As a global growth trigger, an arbitrary spatial constant growth stimulus was introduced that induced an increase in the wall thickness (concentric growth), which is a typical response to an elevated afterload in the heart. The implementation of this type of growth was achieved by using an orthotropic growth tensor $\mathbf{F}_g$, such as

$$\mathbf{F}_g = \mathbf{f}_0 \otimes \mathbf{f}_0 + \vartheta^{\perp}\mathbf{s}_0 \otimes \mathbf{s}_0 + \vartheta^{\perp}\mathbf{n}_0 \otimes \mathbf{n}_0. \quad (3)$$

Here $\mathbf{f_0}$ specified the cell's long axis and was defined using a rule-based method [9]. $\mathbf{s_0}$ described the sheet vector of the cell bundles, and $\mathbf{n_0}$ was the sheet plane normal direction. $\vartheta^{\perp}$ reflects as a growth factor for the change of fiber thickness. Remodeling, however, results in a reorientation of the microstructure.

Two tests were used to try to recreate growth patters observed in HCM. In the first, concentric growth was applied with and without disarray in the basal interventricular septal region. Fiber disarray was introduced by adding stochasticity to the mean fiber and sheet direction in the predefined HCM region. Applying a spatial constant concentric growth tensor $\mathbf{F}_g$ (Eq. 3) that causes the fiber to grow in thickness might result in the typical HCM growth pattern. In the second test, isotropic growth, such as occurs during inflammation, in addition to concentric growth, was introduced in the septal region. Applying equal amounts of growth in all microstructural directions of the myocytes allows a reformulation of Eq. 3, such that

$$\mathbf{F}_g{}^{\mathrm{iso}} = \vartheta^{\mathrm{iso}}\mathbf{f}_0 \otimes \mathbf{f}_0 + \vartheta^{\mathrm{iso}}\mathbf{s}_0 \otimes \mathbf{s}_0 + \vartheta^{\mathrm{iso}}\mathbf{n}_0 \otimes \mathbf{n}_0, \quad (4)$$

where ϑ^{iso} the growth multiplier for isotropic growth is. In this specific test, the overall growth tensor is a weighted function of the concentric growth tensor (Eq. 3) applied on the entire geometry except for the HCM region and the isotropic growth tensor (Eq. 4) solely in the predefined septal area prescribed.

RESULTS

Both geometries in Fig. 2 show the same displacement magnitude over the entire body with no clear manifestation of a typical HCM growth pattern. Therefore, fiber disarray in the basal interventricular septal region did not result in regional hypertrophy as seen in HCM. In comparison, the addition of a regional isotropic growth term exhibited growth patterns typical of HCM, as illustrated in Fig. 3. The right panel with regional isotropic growth shows an extensive amount of growth in the septal region (as indicated by the yellow arrow), leading to an extrusion of the wall while the left image shows more homogeneous growth throughout.

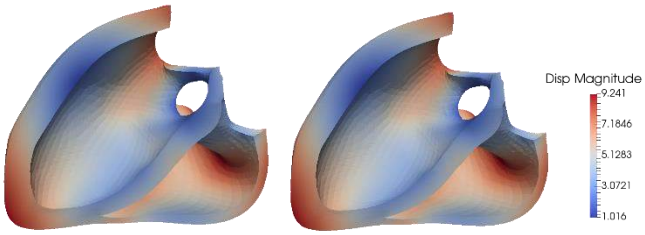

Figure 2: Comparison of the displacement magnitude in concentric growth applied to a bi-ventricular geometry with (right) and without (left) a fiber disarray in the basal interventricular septal region (dimensions in mm).

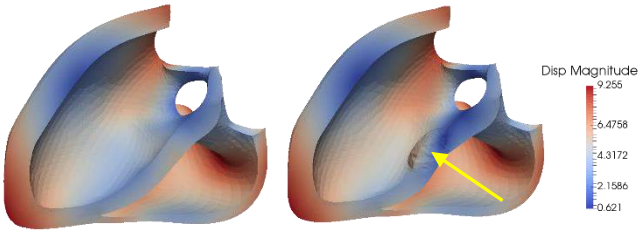

Figure 3: Comparison of the displacement magnitude in concentric growth applied to a bi-ventricular geometry with (right) and without (left) regional isotropic growth in the basal interventricular septal region (dimensions in mm).

DISCUSSION

Under constant growth scenarios, local myofiber disarray does not yield the heart's phenotypical response, while regional isotropic growth does. This supports the idea that septal hypertrophy is not driven by disruption of the fiber structure but could be a consequence of fibrosis and inflammatory responses.

Future work will focus on implementing physiological growth law, with a growth rate dependent on local stress and strain values in the tissue to identify the individual impact on HCM growth pattern. As an alternative approach, we will additionally investigate the effect of constant heterogeneous growth in the heart. In this case, the theory is that myocytes in the septum's hypertrophic region experience higher growth stimuli than the surrounding tissue while the entire geometry experiences the same growth type. By reproducing HCM in the heart, it is possible to study residual stresses in the grown area and further develop patient-specific models for HCM patients.

INTRODUCTION

Schizophrenia (SZ) is a chronic brain disorder that affects ≈1% of the population. Clinical symptoms include delusions, hallucinations, disorganized thought process, and neurocognitive impairments [1]. Antipsychiatric medications have many side effects, are not curative, and only minimally affect the core neurocognitive deficits [1]. Precise understanding of pathophysiology in SZ – such as brain network dysconnectivity – would help in designing more efficacious treatments. The structural covariance network (SCN), constructed from regional morphometric measures from structural MRI data [2], offers a method to quantify connectivity between brain regions. We examined SCNs built using the Human Connectome Project (HCP) parcellation atlas which includes 358 regions based on functional and structural connectivity, on 81 SZ in comparison with 76 healthy controls. Prior studies used atlases have <100 regions and are based on anatomical landmarks or structural data.

METHODS

Using the volume, surface area, and cortical thickness MRI data, the SCN was constructed using the Pearson correlation coefficients between each of the 358 atlas regions. We examined thickness and surface area because volume is the product of these measures. This creates a 358x358 matrix which holds values for strength of the edge (correlation coefficients between two regions), producing one SCN for each group along with a random graph for each of these groups. A random graph is constructed from the group data, but after 100 permutations of randomization. These graphs were used to compare SZ and HC SCNs. First, we examined the distribution of graph measures with threshold sweep using both an intensity threshold and a density threshold. An intensity threshold is computed by choosing a strength and eliminating any of the edges below that value. A density threshold uses a proportion of edges and eliminates in the order of the lowest valued edge. The density threshold keeps the number of edges consistent across groups. Intensities from 0 (includes all edges) to 1 (excludes all edges) are examined at intervals of 0.025. Densities are examined across 0.025-0.95 at intervals of 0.025. At each threshold value, the graph measures modularity, characteristic pathlength, clustering coefficient, and betweenness centrality were calculated using the Brain Connectivity Toolbox [3]. These measures were chosen to evaluate community structure, efficiency, and centrality of the SCN. Additionally, the strength of the network was calculated at three different thresholds for each thresholding method and using all three morphometrics. For the intensity threshold, 0.3, 0.5, and 0.7 were chosen based on the intensity threshold sweep as the approximate location of the maximum values of the SZ measures for modularity (≈0.7), pathlength (≈0.3), and betweenness centrality (≈0.5). The three density thresholds chosen were 0.15, 0.2, and 0.25 based on the small worldness of the networks. Small worldness (σ) is calculated by comparing the clustering coefficient and the pathlength of the SCN with the random SCN [4]:

$$\sigma = \frac{C/C_R}{L/L_R} \qquad (1)$$

where C is the clustering coefficient and L is the pathlength. When calculating pathlength, the connection distance was estimated by using the Euclidian distance. Using the small worldness calculation, a range of thresholds was chosen for the analyses. The minimum (0.15) was chosen when the graphs were fully connected and the maximum (0.25) was chosen when σ asymptotically approached 1. For further investigation into the biological meaning, the hubs, or highly connected regions, was calculated for each group. A region was defined as a hub if the regional degree, betweenness centrality, or

eigenvector centrality was > 2 standard deviations from the network average [4]. The hubs were calculated over the threshold range stated above and if the hubs were found in over 50% of the threshold values, it was considered a network hub.

RESULTS

The threshold sweep for the intensity shows the same shape of the curve for both groups but the SZ tends to be show lower threshold values and the HC is more resilient (Fig 1). The density threshold sweep shows more similar values between the SZ and HC, but at later thresholds, the SZ begins to deviate from the HC curve. In figure 3, Volume, cortical thickness, and surface area are the x labels 1, 2, and 3 respectively. The strength of the FEAP network drops significantly as the intensity threshold increases when compared to the healthy control. The strength using the density threshold showed no significant difference between FEAP and HC. SZ SCN shows smaller number of hubs than the HC (table 1). The two networks share one common hub, Left Area 9 Middle.

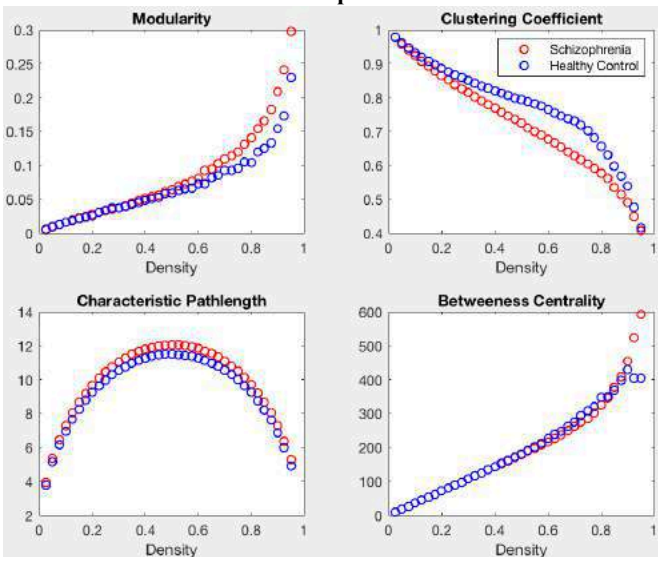

Figure 2: Threshold sweep using a density threshold and volume morphometric.

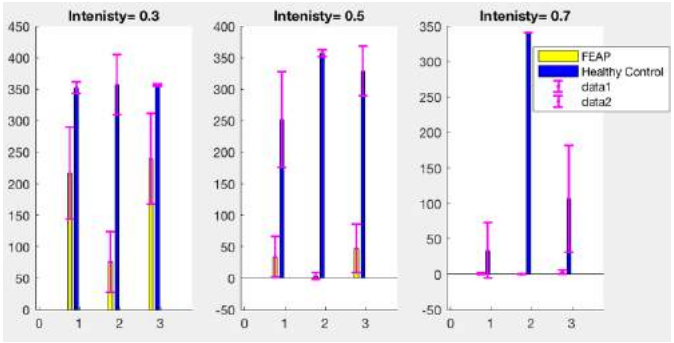

Figure 3: Strength of the SCN at intensity thresholds of 0.3, 0.5, 0.7.

Schizophrenia	Healthy Control
Left Area 9 Middle	Left Area 9 Middle
Left Area 47s	Left Area TG Dorsal
Right Area TF	Left Area PHT
Right Anterior Agranular Insula Complex	Right Area 7 Middle
	Right Area 23 Center
	Right Area 47 Lateral
	Right Area TG Dorsal
	Right Area Posterior Insula 1
	Right Auditory 5 Complex

Table 1: Regional hubs for Schizophrenic and healthy control groups.

DISCUSSION

The intensity threshold sweep shows that the SZ SCN is not as resilient as the HC because it deviates from fully connected network before the HC. Similar results for the SZ and HC SCN strength is shown in Figure 3. The HC SCN has a higher strength throughout all thresholds while the regional connection strength for SZ were not as strong because they were eliminated at lower thresholds. The density threshold for SZ deviated more from HC suggesting that the SZ SCN may be less resilient. A lower number of hubs in the SZ SCN supporting network disarray of SZ SCN. The higher spatial resolution of the HCP atlas allows for a better understanding of the precise circuitry involved in the SZ SCN. Since some of the hub regions are connected either functionally or structurally, it further supports that the schizophrenia network may be disrupted, adding more evidence to suggest schizophrenia is a network disconnection disease.

INTRODUCTION

The mechanics and material anisotropy of soft collagenous tissues are often facilitated by the underlying collagen fiber architecture (CFA). Specific to the atrioventricular heart valve (AHV) leaflets, the unloaded collagen fibers were found in a crimped state, with a preferential alignment along the circumferential tissue direction of the tissue [1]. When loads are applied to the tissue, the collagen fibers tend to reorient towards the primary loading direction, which manifests as a low-stress "toe-region" in the tissue-level nonlinear stress-stretch behaviors. After reorientation, the fibers are recruited and elongated that contribute to the mechanical behaviors in the asymptotic high-stress regime. Collagen fiber kinematics forms the basis of constitutive models to represent the mechanics of tissues; however, some researchers assume that the *affine fiber kinematics* (AFK) is sufficient for accurately modeling the AHV leaflet biomechanics, while others claim that the *non-affine fiber kinematics* is necessary. Herein, the AFK describes elastic elongations of collagen fibers in conjunction with rigid-body rotations, whereas the non-AFK considers the fiber uncrimping process together with elastic elongations of collagen fibers. In the previous work by Lee *et al*. (2015), they performed biaxial testing of the mitral valve anterior leaflet together with small angle X-ray scattering and found that the AFK theory requires correction by including the fiber crimp into the model formulation [2]. While that study provides insight into the mechanics of the mitral valve leaflets, there has not yet been any work to verify the AFK assumption for the tricuspid valve (TV) leaflets, which are subjected to a lower pressure gradient and a distinct functional and mechanical environment and may have different tissue microstructures compared to their mitral valve counterparts.

The goal of this study is to evaluate the AFK assumption for the TV leaflets using an integrated biaxial testing-polarized spatial frequency domain imaging (pSFDI) system to analyze the load-dependent CFA of the tissues. Our approach is advantageous, as the pSFDI device does not require tissue fixation, allowing for the observation of more accurate collagen fiber kinematics. Findings from this study will be useful for TV leaflet *in-silico* modeling that will eventually lead to improved TV simulations with future applications in therapeutic refinements.

METHODS

Porcine hearts were obtained from a commercial vendor (Animal Technologies, TX) and dissected to retrieve the three TV leaflets: anterior leaflet (AL, n=11), posterior leaflet (PL, n=14), and septal leaflet (SL, n=12). The belly region of the TV leaflets were sectioned into a 10x10 mm specimen and mounted to a biaxial testing device (CellScale, Canada) combined with an in-house pSFDI device (**Fig. 1a**) [3]. Tissues were mounted with the circumferential (Circ) and radial (Rad) directions aligned with the X- and Y-directions of biaxial testing, respectively. After mounting, a 2x2 fiducial marker array was glued on the tissue surface using glass beads for determination of tissue strains. Then, tissues were submerged in the phosphate-buffered saline solution at 32 °C. Submerged tissues were preconditioned to a physiologically emulating membrane tension (T) of 50 N/m in both directions, and then tested with 4 displacement-controlled cycles at various ratios of the targeted tension: T_{Circ}:T_{rad}=1:1, 1:0.66, 1:0.33, 0.66:1, and 0.33:1.

After mechanical testing, the pSFDI device was used to capture the tissue CFA of the tissues at the post-preconditioned (PPC) and different peak loading states, based on the birefringent and diattenuating properties of the tissue [3]. Briefly, the procedure consists of: (i) a DLP projector shining light through a polarizer; (ii) the polarized light cast on the specimen at an angle, $\theta_{\text{polarizer}}$; (iii) the light reflected from the tissue with an intensity, I; (iv) the reflected light passing through the polarizer and captured by a CCD camera. The above sequence is

repeated for $\theta_{polarizer}$=0°-180° at 5° increments. The measured fiber orientation angle, θ_{fiber}, at each pixel location is determined as the polarizer angle $\theta_{polarizer}$ corresponding to the maximum reflected *I*. Further details, regarding the pSFDI theory, can be found in [3].

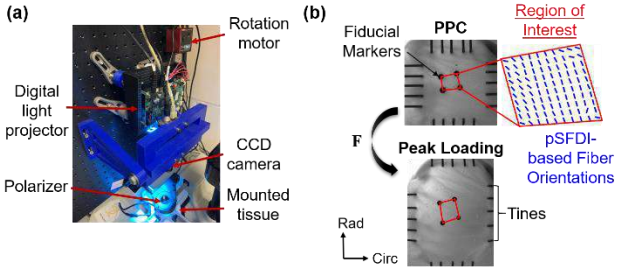

Figure 1: (a) Biaxial testing-pSFDI device. (b) Fiducial marker region of interest for the 100x100 parametric grid.

Based on the pSFDI-derived CFA, the AFK theory was employed to predict the collagen fiber reorientations for a 100x100 parametric grid constructed within the fiducial marker domain (**Fig. 1b**). In brief, the deformation gradient **F** was determined using the locations of the four fiducial markers. Then, the orientation vector at the PPC configuration, $\mathbf{N}=[\cos(\theta_{PPC,j}), \sin(\theta_{PPC,j})]^T$, was determined from the pSFDI-measured fiber orientation at the PPC state, where *j* denotes each query point in the 100x100 grid. The AFK-predicted fiber orientation $\mathbf{n}=[\cos(\theta_{pred.,j}), \sin(\theta_{pred.,j})]^T$ associated with different loading states was computed via $\mathbf{n}=\mathbf{F}\cdot\mathbf{N}/|\mathbf{F}\cdot\mathbf{N}|$. The error between the predicted and the experimentally measured fiber angles was calculated as $\theta_{error}=|\theta_{pred.}-\theta_{exp.}|$. Pearson correlation coefficients (*r*) were calculated to discern trends between metrics. Values are reported as mean ± standard error of the mean.

RESULTS

Results of a representative TVPL specimen are shown in **Figure 2**, including the biaxial stress-stretch responses (**Fig. 2a**) and comparisons of the pSFDI-measured and AFK-predicted CFA (**Fig. 2b-g**).

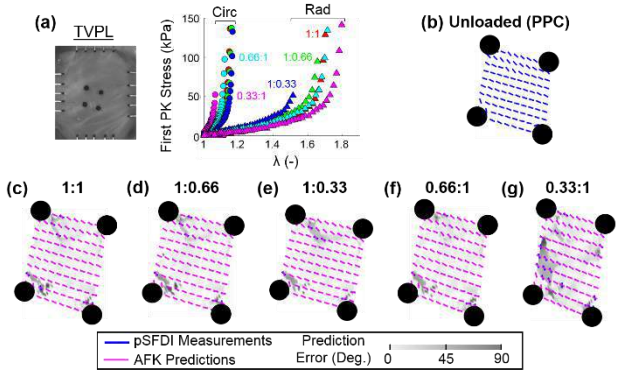

Figure 2: (a) Biaxial testing results for a TVPL specimen. (b) PPC CFA, as measured from pSFDI. (c-g) pSFDI- and AFK-derived CFAs from the five loading states, with vector lines denoting the orientations for selected points, and the color map denoting θ_{error}.

Tissue mechanics-wise, the PPC stretches (λ_{PPC}) were similar for all three leaflets: circumferential direction, 1.17±0.03 (TVAL), 1.17±0.03 (TVPL), and 1.17±0.03 (TVSL); radial direction, 1.31±0.05 (TVAL), 1.36±0.04 (TVPL), and 1.32±0.04 (TVSL). Meanwhile, the TVAL was found to be the least extensible leaflet under *equibiaxial* loading: TVAL, λ_{Circ}=1.31±0.04, λ_{Rad}=1.48±0.06; TVPL, λ_{Circ}=1.38±0.07, λ_{Rad}=1.62±0.07, and TVSL, λ_{Circ}=1.49±0.07, λ_{Rad}=1.72±0.08, whereas the TVPL was found to be the most anisotropic leaflet, as quantified by the anisotropic index (AI)=$\lambda_{Rad}/\lambda_{Circ}$: TVAL, 1.13±0.04; TVPL, 1.21±0.07; TVSL, 1.16±0.05.

In general, we observed that the AFK theory under-predicts the collagen fiber reorientations for the investigated TV leaflet specimens, especially with larger errors in the *non-equibiaxial* loading protocols. Specifically, the average θ_{error} was determined as follows: 10.5°±1.3° (TVAL), 13.3°±2.3° (TVPL), and 17.4°±2.5° (TVSL). Meanwhile, in loading protocol T_{Circ}:T_{Rad}=1:0.33, θ_{error} was found to be: TVAL, 14.6°±1.8°; TVPL, 17.4°±3.4°; TVSL, 23.0°±3.6°.

DISCUSSION

In this study, we have a performed a *first-of-its-kind* evaluation of the AFK theory for the TV leaflets using the pSFDI technique. We found that the AFK theory tended to under-predict the rotations of the collagen fibers, especially in non-equibiaxial loading scenarios. To elaborate, in equibiaxial loading we observed θ_{error} increased with increasing fiber reorientations, suggesting that the AFK theory may be better suited for smaller changes in θ_{fiber} (r=0.66). We also noted the tissue anisotropy, denoted by AI, was weakly, negatively correlated with the collagen fiber reorientations (r=-0.22); however, it was not correlated with θ_{error} (r=-0.01). This observation may be counterintuitive, as more isotropic tissues should exhibit smaller fiber reorientations due to a more disperse fiber network. Our pSFDI device can directly quantify the *optical anisotropy*, however this imaging modality requires more research to quantify the *structural* fiber dispersion. Nevertheless, it is possible the preferential alignment of the fiber network may affect the accuracy of the AFK theory, as noted in a previous tendon study in which more disperse fiber networks correlated to increased AFK errors [4]. The trends in our study may also be explained by the influence of fiber crimp, as reported in Lee *et al*. (2015) [2]. Additionally, we found a weak correlation between λ and θ_{error} (Circ, r=0.16; Rad, r=0.20) under equibiaxial loading, suggesting that larger stretches may attribute to larger errors from the AFK theory, which was also noted in a previous vasculature testing study [5].

The implications of our results suggest the necessity for cautious use of or making adjustment to the AFK theory, such as by including fiber crimping, and/or the incorporation of the non-AFK into the TV leaflet constitutive model forms. The AFK corrections made in the prior studies result in a more robust and computationally inexpensive modeling method; however, the morphological differences in the CFA (fibrillar density, dispersion, etc.) of the TV leaflets may render this option inviable. Thus, our results necessitate an in-depth investigation of the appropriate computational implementation of the TV leaflet collagen fiber kinematics. The refinement of TV leaflet model forms will result in enhanced valve simulations, which will lay the foundation for patient-specific cardiac modeling and guidance for clinical diagnostics and disease treatment.

INTRODUCTION

Atherosclerosis, the leading cause of cardiovascular disease, is characterized by the thickening and hardening of arterial walls due to chronic plaque accumulation. The initial step of the atherogenic process is the adhesion of circulating monocytes and lymphocytes to the endothelial surface followed by their subsequent transmigration into the intimal layer. Endothelial dysfunction and the upregulated surface expression of adhesion molecules, including E-selectin, intercellular adhesion molecule-1 (ICAM-1), and vascular cell adhesion molecule-1 (VCAM-1), predominantly mediate these early processes [1]. Atherosclerotic development has been correlated to regions within the native vasculature exposed to disturbed flow, which primarily occurs at bifurcations and curves [2]. As fluid shear stress acts on the vessel wall, endothelial cells (ECs) alter their morphology, cytoskeletal alignment, and phenotype in response. It has been shown that ECs exposed to low, oscillatory shear stress maintain a rounded cobblestone morphology with an unaligned cytoskeleton, upregulate adhesion molecules, thus, induce a pro-atherosclerotic phenotype. In contrast, ECs exposed to high laminar shear stress maintain an elongated morphology, alignment of the cytoskeleton, and downregulation of adhesion molecules resulting in an athero-protective phenotype [2].

The differential response of ECs to various flow regimes has been extensively studied within literature, but it is still largely unclear exactly how ECs convert mechanical stimuli into biochemical responses. Various mechanotransduction pathways have been proposed, and the cytoskeleton has been implicated to play a significant role in the decentralized model of endothelial mechanotransduction. This theory proposes that the cytoskeleton is able to transmit signals from the luminal surface of ECs via spatial stress distribution throughout the cell, suggesting that cell shape and cytoskeletal structure may regulate EC function and phenotype [2]. Previous studies have suggested the effects of endothelial shape and cytoskeletal alignment on population-based VCAM-1 gene expression [3]. However, a majority of these studies were performed in the absence of a confluent monolayer and lacked the single cell analysis needed to isolate the effect of cytoskeletal alignment on EC phenotype, resulting in the need for further investigation. In this study, we investigated the effects of endothelial shape and cytoskeletal alignment on VCAM-1 regulation independent of fluid shear stress. Topographic micropatterning techniques were used to generate a distribution of EC elongation in a confluent monolayer. Single cell image analysis techniques were employed to correlate EC morphology with VCAM-1 protein expression. We hypothesized that an elongated morphology and cytoskeletal alignment would downregulate VCAM-1 expression, resulting in an athero-protective phenotype.

METHODS

Substrate Fabrication: Topographical micropatterned culture substrates were fabricated as previously described [4]. Briefly, PDMS submasters with both planar and parallel ridge and groove areas with a pitch of 6 μm were fabricated using soft lithography. Polyurethane was then dispensed on top of the PDMS patterns and covered with glass coverslips. Culture substrates were cured with 2 J of long-wave UV light, demolded, and sterilized.

Cell Culture: Human umbilical vein endothelial cells (HUVECs) were cultured in complete endothelial growth medium (Lifeline) and were used in experiments at passage 6. HUVECs were seeded on substrates for 24 hrs and then stimulated with TNF-α (100 U/mL) for 24 hrs to upregulate adhesion molecules. Cells stained for VE-cadherin, VCAM-1, and nuclei. Samples were imaged on a Zeiss 880 inverted confocal microscope (20X, NA = 0.8). Three images per pattern per replicate were collected for quantitative image analyses.

Single Cell Analyses: Images were loaded into FIJI (SciJava) and color channels were automatically split. A 4x4 grid overlaying the VE-cadherin color channel was used to randomly select individual cells to be traced (n=6-12 per image). Cells closest to grid points were measured for cell area (A_S), perimeter (P), and major and minor axis lengths. Whole cell morphology was determined by calculating the shape index (SI, with 0 equal to a straight line and 1 to a circle):

$$SI = \frac{4\pi(A_S)}{P^2} \quad (1)$$

Deviance angle of the cell relative to the pattern was determined as the absolute value of the major axis of the cell minus the angle of the pattern. The deviance of planar cells was calculated using the pattern angle on the same substrate. Cell deviance angles of 0° is reported as perfectly aligned to the pattern and 90° as perpendicular to the pattern. VCAM-1 protein expression was determined using the VCAM-1 color channel only. Mean intensities within previously traced regions of interest were measured. Values were then corrected for background noise and normalized by individual cell area.

Statistics: Correlations were performed by linear regression between SI, cell deviance, and VCAM-1 expression and confirmed with QQ plots. Data was analyzed using one-way ANOVA and Tukey's HSD post hoc test against substrate type. Data is presented as mean ± SD.

RESULTS

Micropatterned HUVECs showed a significant downregulation of VCAM-1 protein expression compared to planar cells (Fig. 1). Normalized VCAM-1 expression on micropatterns and planar regions was 1.20 ± 1.12 ABUs and 2.10 ± 2.51 ABUs, respectively ($p = 0.01$).

Topographical micropatterning induced significant elongation for micropatterned cells with SIs of 0.52 ± 0.15 compared to or planar regions with SIs of 0.69 ± 0.15 ($p < 0.001$). Cells were also significantly aligned to the pattern compared to planar cells with whole cell deviances of 12.87 ± 9.64° and 40.25 ± 24.25° ($p < 0.001$), respectively (Fig. 2).

Single cell VCAM-1 protein expression was significantly correlated to SI for micropatterned cells ($p = 0.02$, Pearson's Coefficient = 0.294) but was not significant for planar cells (Fig. 3). Similarly, single cell VCAM-1 protein expression was significantly correlated to cell alignment for micropattemed cells only (data not shown, $p = 0.03$, Pearson's Coefficient = 0.297).

DISCUSSION

Topographical micropatteming techniques were shown to align and elongate an endothelial monolayer compared to planar substrate regions. Cellular alignment was shown to downregulate the protein expression of VCAM-1, as shown in other studies [3,5-6]. By using single cell image analysis techniques, the correlation between elongation and VCAM-1 expression was found to be significant. This quantitative data suggests that cytoskeletal alignment has a role in the mechanotransduction of VCAM-1, an inflammatory surface marker, independent of shear stress and supports the cytoskeleton is an active regulator of EC phenotype and function.

INTRODUCTION

Many pre-term newborns have airway or lung defects due to prematurity. Tracheomalacia is the narrowing of the largest airway, most often with dynamic collapse during breathing. Newborns with tracheomalacia have breathing difficulties and often require positive-pressure support for breathing. We have previously shown that with tracheomalacia require more energy to move air through the trachea compared to the subjects without tracheomalacia, due to the dynamic tracheal motion [1]. However, the effect of tracheomalacia on airflow in the upper airway (nasopharynx to glottis) during breathing in this patient population has not been studied.

Ultrashort echo time (UTE) magnetic resonance imaging (MRI) is a non-invasive, non-ionizing, and free-breathing imaging technique that can capture the 3D dynamic motion of the airway [2]. This imaging method also allows the reconstruction of high-resolution, respiratory-gated images at different phases of breathing, which can be used to model airway motion via registration [3,4]. Computational Fluid Dynamics (CFD) is a well-known method to model respiratory airflow via medical imaging and it can quantify airway parameters such as work of breathing, pressure loss, and airway resistance that cannot currently be derived clinically. In this study we performed patient-specific CFD simulations with airway motion and investigated the effect of neonatal tracheomalacia on airflow parameters elsewhere in the upper airway.

METHODS

This study included 10 non-intubated newborns (5 non-tracheomalacia, 5 tracheomalacia) from the neonatal intensive care unit of Cincinnati Children's Hospital. Eight subjects were clinically diagnosed with lung disease of prematurity (i.e. bronchopulmonary dysplasia), and 2 term subjects had no respiratory defects. All subjects were imaged using a neonatal sized MRI scanner (1.5 T) while on clinically-indicated respiratory support (room air, high flow nasal cannula, and non-invasive pressure ventilation) [2]. The k_0 waveform obtained from the center of the MRI raw k-space data was used to monitor breathing and to reconstruct 4 MR images, which represent different phases during breathing (end expiration, peak inspiration, end inspiration, and peak expiration) [1,4,5].

All airway surfaces were semi-automatically segmented and registered to obtain airway motion during a breath [3,6]. The k_0 waveform and the segmented lung volumes were used to generate airflow waveforms for the left and right bronchi [1]. Airway motion and airflow waveforms of each subject were used as boundary conditions to perform patient-specific CFD simulations to model airflow from the nasopharynx to the main bronchi.

The commercial CFD package, STAR-CCM+ 14.04.011-R8 was used to run CFD simulations. The CFD mesh consisted of two million cells with polyhedral cells in the interior and nine prism layers on the wall [7]. The Large-Eddy Simulation (LES) turbulence model and the no-slip condition were applied. The pressure at the nasopharynx was assumed to be at atmospheric pressure. An unsteady CFD simulation was performed for each subject for the breathing cycle with a temporal resolution of 0.8 ms [7].

The regional daily work of breathing, the total pressure loss at peak inspiration and peak expiration during breathing, and airway resistance integrated with respect to time across one breathing cycle were calculated for the upper airway (nasopharynx to glottis), (Figure 1). A two-tailed, unpaired, and unequal variance t-test was used to compare results between subjects with tracheomalacia and without tracheomalacia.

RESULTS

On average, the daily work of breathing of the upper airway of the subjects without tracheomalacia (yellow) was 29.9 ± 16.7 J and with tracheomalacia (blue) was 382.4 ± 242.3 J (p = 0.03, Figure 1A). The average total pressure loss of the upper airway at peak inspiration in the subjects without tracheomalacia was 6.5 ± 3.4 Pa; in contrast, subjects with tracheomalacia showed 100.1 ± 77.8 Pa (p = 0.05, Figure 1B). Similar results were also observed at peak expiration. On average, the total pressure loss at peak expiration in the subjects without tracheomalacia was 23.7 ± 14.1 Pa and 247.3 ± 151.4 Pa in the subjects with tracheomalacia in the upper airway (p = 0.03, Figure 1C). The integrated upper airway resistance with respect to time over the breathing cycle also showed a significant difference between the two study groups (p = 0.02, Figure 1D); the average upper airway resistance was 0.2 ± 0.1 Pa.s^2/ml and 2.0 ± 1.1 Pa.s^2/ml in the subjects without tracheomalacia and with tracheomalacia, respectively. Similar results were found after normalizing results based on weight, height, and body surface area of each subject.

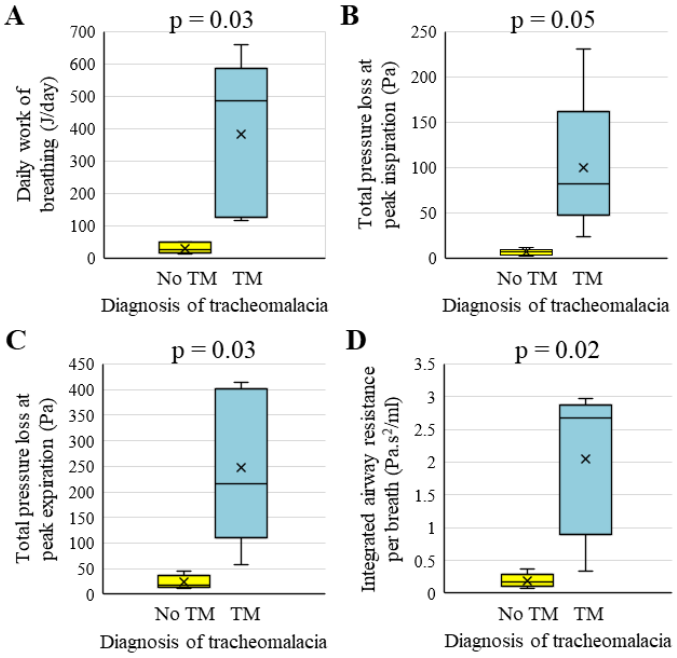

Figure 1: Daily work of breathing (A), total pressure loss at peak inspiration during the breathing cycle (B), total pressure loss at peak expiration during the breathing cycle (C), and integrated airway resistance with respect to time over a breath (D) in the upper airway of the subjects with tracheomalacia (TM) and without TM.

In order to understand the significant differences of the respiratory airflow parameters among the two groups, Figure 2 illustrates the airflow velocity during peak expiration in a subject without tracheomalacia (A) and with tracheomalacia (B). There is a strong jet at the glottis in the subject with tracheomalacia. However, the jet at the glottis in the subject without tracheomalacia is much weaker compared to the subject with tracheomalacia. As a result, the daily work of breathing was 115 J per day for the subject with tracheomalacia and 48 J per day for the subject without tracheomalacia.

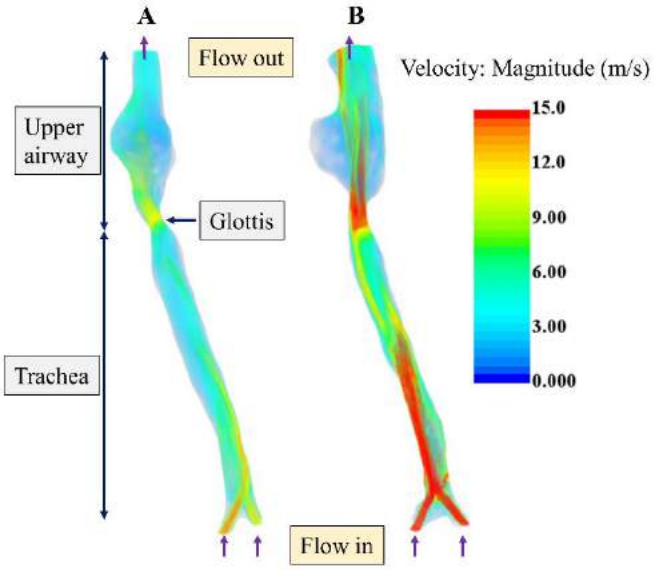

Figure 2: The velocity distribution at peak expiration of a subject without tracheomalacia (A) and a subject with tracheomalacia (B).

DISCUSSION

Tracheomalacia is known to affect the flow specifically in the tracheal region. However, this is the first study to demonstrate that tracheomalacia also significantly affects the flow in the upper airway in neonates (Figure 1). Figure 2 indicates that the laryngeal jet at the glottis affects airflow parameters by creating flow instability in the upper airway, and that neonates with tracheomalacia lose 10 times more pressure in the upper airway than the subjects without tracheomalacia. It is noted that subjects with tracheomalacia were receiving respiratory support at the time of MRI. Without this support, the values would likely be even higher. This study included only non-intubated subjects, since the endotracheal tube can bypass the motion.

The patient-specific CFD simulations with prescribed MRI-based wall motion have shown clinically important information, which may be used in the future to improve patient care and growth. One of the limitations of this study was the image coverage. MR images covered the lungs and the central airway and did not include the upper region of the nasopharynx and through to the nostrils. Another limitation was the CFD run time. Each simulation took approximately 1000 core-hours to complete. The techniques used in this study can also be applied to other airway diseases such as sleep apnea and can be used for older patient populations. Future work will be focused on quantifying regional effects through the entire airway.

INTRODUCTION

Orofacial clefts are the third most common congenital anomaly, with cleft palate having an incidence rate of 1 in 800 births [1]. Currently, surgery remains the definitive treatment for orofacial clefts, however, revision operations from infection, fistulas, or abscess formation are common thereby increasing cost and overall risk [2]. Surgeries to repair large clefts may result in tension across the sutured soft tissue which impairs wound healing [3]. Hence, a method of producing additional graft tissue is needed to reduce the rate of complications and other morbidities.

Inflatable tissue expanders have previously been used in large skin defects, such as severe burns and congenital nevi, to produce additional grafted tissue [4]. Studies have experimented with the use of anisotropic hydrogel expanders in palatal tissue expansion with porcine animal models. An important limitation of tissue expanders are deformities in the underlying bone [5].

The purpose of our study was to formulate a mucosa growth and bone resorption finite element model to examine whether tissue expanders, with the limitations of boney defects, may assist in cleft palate repair procedures. If tissue expanders can produce sufficient mucosal growth for tension-free repair without excessive bone loss, then overall costs for cleft palate repair and risks from primary and revision surgeries may be significantly reduced.

METHODS

Mucosa growth and bone resorption algorithms were developed to model tissue expansion with FEBio. Tissue growth was based on a phenomenological growth model with a multiplicative decomposition of the deformation gradient as shown in Eq. (1) [6].

$$\boldsymbol{F} = \boldsymbol{F}^{(e)} \cdot \boldsymbol{F}^{(g)} \tag{1}$$

The elastic component, $\boldsymbol{F}^{(e)}$, was reversible whereas the growth component, $\boldsymbol{F}^{(g)}$, was not [6]. Ateshian and Ricken proposed a multigenerational material composed of a collection of constrained porous bodies [7]. Here, the multigenerational framework was used to generate a new body when the criteria for growth were satisfied. Our model's rate of mucosa generation was based on a literature value of 4.2 days [8]. In addition to time, an elastic area stretch ratio, $\vartheta^{(e)}$, greater than a critical threshold of 1.10 was required for growth which has been suggested to activate mechanoreceptors and amplify growth factors [6]. Each (fully grown) generation was assigned the same constitutive parameters as the initial body. The mucosa's area stretch ratio, ϑ, was computed with two orthonormal basis vectors, $\overrightarrow{e_0}^{(1)}$ and $\overrightarrow{e_0}^{(2)}$, that were parallel to the tissue surface. The orthonormal stretch ratios, $\lambda^{(1)}$ and $\lambda^{(2)}$, were calculated with Eq. (2) from the corresponding orthonormal basis vector.

$$\lambda^{(k)} = \sqrt{\overrightarrow{e_0}^{(k)} \cdot \boldsymbol{C} \cdot \overrightarrow{e_0}^{(k)}} \tag{2}$$

Where $\boldsymbol{C}$ is the right Cauchy Green tensor. Then, the orthonormal stretch ratios were used to determine the area stretch ratio.

$$\vartheta = \lambda^{(1)}\lambda^{(2)} \tag{3}$$

It is noteworthy that Eq. (1) allows area stretch ratios to be calculated as total, $\vartheta^{(t)}$, elastic, $\vartheta^{(e)}$, and growth, $\vartheta^{(g)}$ quantities.

Boundary conditions included a biphasic contact between the expander, bone, and mucosa surfaces. Mucosal and bone outer edges were fixed. Expander nodes were fixed in the contact plane but allowed to move in the direction normal to the bone surface. To simulate expansion, mucosa was initially placed above the expander, and then translated against the bone. Bone was modeled as a mesh free thin shell with nodes fixed in the contact plane directions, but freely moving (resorption) in the direction normal to the surface. The growth configuration was calculated after generating a new body in the affected elements by translating the mucosa away from the bone thereby isolating the growth deformation component.

Bone resorption was modeled as a pressure-threshold phenomenon initiated above a critical pressure of 1.96 kPa [9]. The rate of bone resorption was assumed to be proportional to pressure in the time period examined here as suggested by previous studies [9]. To quantify the pressure-resorption relationship, our model was fit to a recent *in-vivo* study conducted by Swan *et al.* for bone loss. Swan *et al.* reported about 450 mm^3 of bone resorption [10]. Our fit determined an approximate linear constant of 1.61 µm per kPa-day.

To our knowledge, previous studies have not provided mechanical properties for palatal mucosa under tension. We performed strip biaxial testing of porcine mucosa specimens in the anterior-posterior and medial-lateral directions. Fresh mucosa specimens (12x 5 x 2 mm) were stretched to ~1.25 at a rate of 1 mm per minute (n = 4). Negligible differences in stress were found in each direction. Thus, the tissue was assigned isotropic properties. A least-squares method was used to fit a Holmes-Mow constitutive model to the data (Table 1).

Table 1: Palatal mucosa and expander mechanical properties [11].

Material	Model	E (kPa)	ν	β
Palate Mucosa	Holmes-Mow	386	0.30	9.97
Hydrogel Expander	Neo-Hookean	5800	0.30	N/A

For the purposes of soft tissue expansion, the geometric and mechanical properties have a significant impact on mucosal growth and bone loss. A set of 45 expanders with varying heights, bone-contact areas, and expansion angles were examined. A multiple regression analysis of geometric parameters was used to guide the patient-specific expander design that we applied to a 1-year-old male cleft palate case.

RESULTS

In a patient-specific finite element model, expansion over a 42-day duration resulted in a mucosal area gain of 40 mm^2, or mean growth area stretch ratio of $\langle \vartheta^{(g)} \rangle = 1.18$ as shown in Fig. 1.

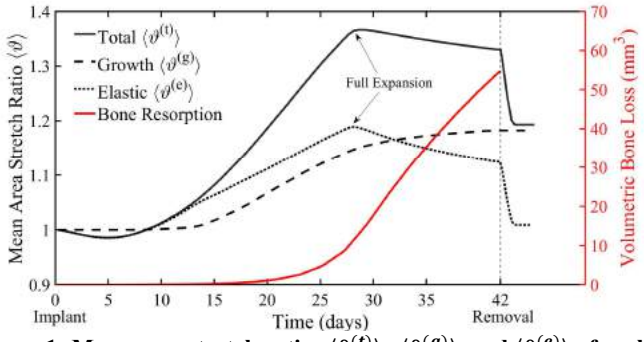

Figure 1: Mean area stretch ratios $\langle \vartheta^{(t)} \rangle$, $\langle \vartheta^{(g)} \rangle$, and $\langle \vartheta^{(e)} \rangle$ of oral surface mucosal elements and volumetric bone loss during tissue expansion.

Full expansion occurred at day 28 which was accompanied by the maximum total and elastic mean area stretch ratios. The volumetric bone loss was approximately 55 mm^3 (Fig. 1) with a depth, demonstrated in Fig. 2, that peaked at 0.70 mm.

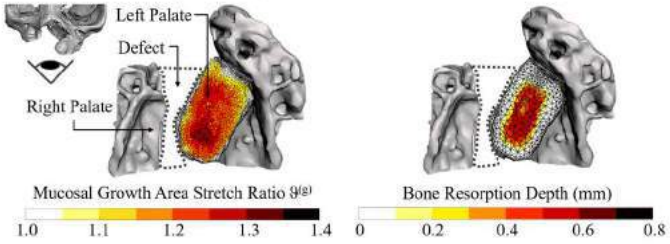

Figure 2: Mucosa growth area stretch ratio and bone resorption depth varied across the palate surface after expander removal.

The model suggested that bone perforation will not occur as greater than 20% of the bone thickness was preserved upon device removal (0.90 mm initial thickness). With a defect area of approximately 70 mm^2 (Fig. 2 dashed lines), the model provided evidence that the amount of tissue growth, visualized in Fig. 3, would aid in a tension-free closure.

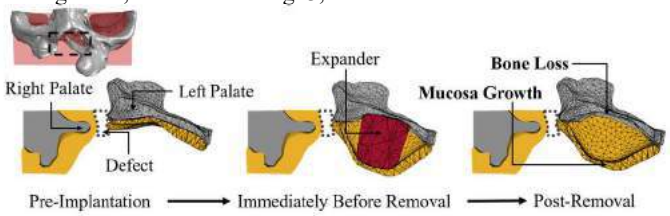

Figure 3: Frontal cross-section view showing bone resorption and mucosa gain that can be grafted to close large defects.

DISCUSSION

Swan *et al.* demonstrated anisotropic hydrogel expanders may improve cleft palate repairs in an animal study. Our patient-specific model suggested that with careful design considerations, significant mucosal tissue from expanders can aid in closing a cleft defect without perforating the underlying bone. Hence, the use of tissue expanders could be a promising adjunct to large cleft palate repair surgeries that may result in less complications than surgeries performed without tissue expansion.

Bone resorption and possible perforation remain a major limitation of tissue expanders for cleft palate repair. Our bone resorption constant that was fit to data from Swan *et al.* used a linear relationship with pressure. Nonetheless, the relationship between load and bone resorption is complex and may be non-linear in other time regimes or dependent on biological factors. For simplicity, the bone resorption process was calculated with contact-pressure rather than stress through the bone. We recognize that bone mechanotransduction has been examined with respect to density and stress, but for the purposes of our simulation's limited time period, we considered a linear assumption to be applicable. Recent literature pertaining to skull bone demonstrated that bone deformities from expanders or other load-inducing devices were reversible within 3 to 9 months post-removal [5]. Additional studies will be required; however, this may indicate an absence of long-term consequences from expander induced bone resorption.

Considering the drastic cost and quality-of-life concerns with cleft palate defects, our results indicated palatal expansion devices can aid surgeons in improving surgical outcomes for large or complex cleft defects.

INTRODUCTION

Lumped Parameter Network (LPN) models are one of several mathematical modelling techniques used to simulate the hemodynamics of the human cardiovascular system. These models are capable of simulating cardiovascular physiology with closed-loop cardiac feedback at minimal computational expense. Their applications in surgical planning, medical device design, education, and training are well documented. However, the inverse problem, i.e., the determination of appropriate LPN input parameters, remains a challenge. Investigators often resort to manual tuning procedures where reasonable ranges for LPN inputs are established, and then different combinations of LPN inputs are tested until the LPN output matches the desired response. Such a process is not only time-intensive, but also requires invasive clinical measurements that are not always available. To our best knowledge, there exists no protocol that can automatically provide appropriate LPN parameter values based on subject characteristics such as age, height, and weight (henceforth collectively referred to as "attributes").

In this work, we address this gap by describing our protocol which provides suitable parameter values for an LPN model that reflects typical, hemodynamics of a healthy subject at rest with specific attributes. Furthermore, the tuned LPN can serve a basis with which minor adjustments can be tuned to match patient-specific characteristics.

METHODS

Our proposed protocol is a procedure which derives a full set of input parameters for an existing closed-loop LPN model (Ref [1] - Figure 1.1) that is derived from previous work modeling uni-ventricular resting and exercise hemodynamics. We will refer to the full set of input parameters, which are necessary to execute the LPN model, as the "LPN inputs" henceforth. For this LPN, we start with a set of inputs which produce a nominally realistic simulation of resting hemodynamics; this particular set of inputs will be referred to as the "reference LPN inputs". For a detailed explanation of the LPN, the circuit diagram, and the reference LPN inputs, please refer [1]. We will refer to hemodynamic quantities such as aortic pressures, pulmonary artery pressures, ventricular volumes, etc., which are the LPN simulation results as "LPN outputs".

We obtain physiologically realistic target values of critical LPN outputs from literature that correspond to a generic subject with the particular set of attributes to be simulated[1]. These attribute-specific critical LPN outputs include hemodynamic parameters such as the systolic and diastolic values of aortic pressure, pulmonary artery pressure, ventricular volumes, mean atrial pressures, etc. Next, we calculate the target Systemic Vascular Resistance (SVR) and Pulmonary Vascular Resistance (PVR) based on these critical LPN outputs.

We have divided the LPN inputs into three categories based on how these values are arrived at. The values of the LPN inputs in the first category are constants, equal to the reference values. We use an Artificial Neural Network (ANN) to estimate the LPN inputs in second category, while the values of the LPN inputs of the third category are arrived at using a scaling procedure.

The LPN inputs in the second category consist of parameters which model the ventricles, i.e., the maximum and minimum elastances for both ventricles, as well as the capacitance of the aorta, and a factor by which all the initial pressures and volumes in the circuit are scaled. The neural network architecture we have employed has been specifically designed for non-linear regression [2]. The neural network operates as a limited inverse model of the LPN. When target values of critical LPN outputs as well as the SVR and PVR are provided to the ANN, it

estimates the values of the LPN inputs in the second category. To generate the data for training the neural network, we used a Uniform Latin Hypercube sampling algorithm to generate 500,000 combinations of the LPN inputs in the second category, within specified limits. The LPN outputs generated by executing the LPN with the 500,000 combinations of the LPN inputs, and the corresponding LPN inputs were used to train the ANN.

The LPN inputs in category 3 are determined by the scaling procedure. These LPN inputs include all of the systemic and pulmonary resistors and capacitors, excluding the thoracic aortic capacitance. Using the values of SVR, and PVR determined from the attribute-specific critical LPN outputs mentioned previously, we can calculate SVR and PVR scaling factors. To account for body size, all capacitors in the third category are scaled using an allometric scaling factor in a manner similar to previous work [3]. Using the ANN's predictions of ventricular elastance values, estimates for the end systolic pressure, and trigonometric relations, we determine the ventricular reference volumes. Finally, the heart rate is prescribed based on Ref [1].

For validation purposes, we have tested the protocol 100 realistic combinations of ages (range: 20 - 70 years), heights (range: 155 – 188 cm) and weights (range: 56 – 100 kg), and have compared the protocol output against literature predictions from Ref [1].

RESULTS

Comparisons of the hemodynamic parameters simulated by the protocol and the corresponding literature predictions are shown in Figure 1. The mean bias, maximum absolute deviation of the protocol test results from the literature predictions, and the corresponding 95% confidence intervals[1], are described in Table 1. In the protocol test results, the mean pulmonary artery (PA) pressure in 96 cases ranged between 14.5 and 19mmHg, with 4 outliers greater than 20 mmHg. Mean right atrial pressures ranged between 3.9 and 5.7 mmHg, whereas mean left atrial pressures ranged between 6.3 mmHg and 17 mmHg.

DISCUSSION

All the simulated hemodynamic parameters in the protocol test set, when compared against literature predictions, exhibit non-zero bias on average (Table 1). However, other than the systolic aortic pressure, and the systolic right ventricular volume, the magnitude of the mean bias is small when compared to their corresponding nominal values. In the case of the systolic aortic pressure and the systolic right ventricular volume the deviation grows near the low end of the range (Figure 1). Despite this, all hemodynamic parameters exhibit deviations within the 95% confidence intervals of literature predictions. In 96 of 100 test cases, the mean PA pressure is below the clinically accepted threshold of 20mmHg for pulmonary hypertension. In all test cases, both mean atrial pressures lie within clinically normal ranges.

Therefore, we conclude that given the attribute information, our proposed protocol can provide the full set of input parameters for the LPN such that it reflects a realistic hemodynamic response under resting conditions for healthy adults across a range of age, height, and weight. In future work, we will expand the scope of this protocol to include exercise hemodynamics, given the same attribute information and the exercise intensity.

INTRODUCTION

Over 110,000 people are currently on the waitlist to receive a life-saving organ transplant, and only 36,000 organs were successfully transplanted in 2020 [1]. A leading cause for the organ shortage is a lack of adequate preservation methods, evidenced by the fact that thousands of organs are discarded every year after being harvested and preserved [2]. The current gold standard for organ preservation is static cold storage, where the organ is bathed in a preservation solution maintained at hypothermic temperatures. However, research has shown that hypothermic and normothermic machine perfusion are superior to static cold storage, as they increase both preservation quality and preservation time [3, 4]. This improved preservation capability allows organs to be transported over longer distances, which ultimately increases the number of organs available to waitlisted patients.

Currently, there are preservation devices specifically designed to maintain individual organs, including kidneys, livers, hearts, pancreases, and lungs [5]. Unfortunately, these devices are typically expensive, bulky, and difficult to operate without proper training. Additionally, the current devices are focused on single organs, which severely limits their utility and, in the event of a donor capable of donating multiple organs, would necessitate multiple devices from multiple companies. Thus, our objective is to develop a frugal, compact, and easy-to-use device that can provide machine perfusion for a variety of organs.

A prototype device was designed and fabricated with the storage capacity needed to preserve a human kidney, liver, heart, or pancreas. Utilizing a modified diaphragm pump, the device is designed to deliver oxygenated and pulsatile perfusion to the organ being preserved. The device is also designed to be compatible with preservation solutions and preservation temperatures that are commonly used for preserving various organs. An image of the device can be seen in Figure 1.

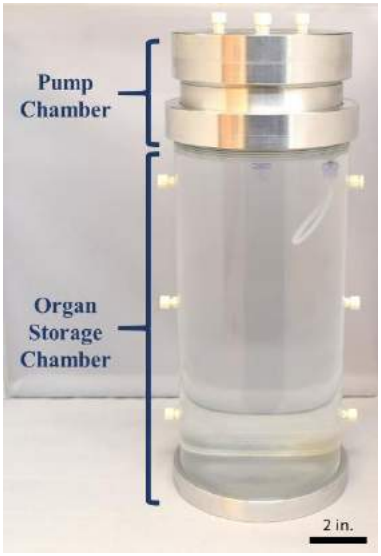

Figure 1: Fabricated preservation device prototype

Two of the most critical machine perfusion parameters for any preservation device are the perfusion pressure and the perfusate flow rate, both of which depend on the organ being preserved. The focus of this work was to validate and optimize the device's perfusion capabilities within the ranges necessary for multiple organs. Specifically, we hypothesized that our device would supply a perfusion pressure and flow rate that would satisfy the perfusion requirements of a human kidney (<30 mmHg, ~140 mL/min) and a human pancreas (<30 mmHg, ~30 mL/min).

METHODS

The device is approximately 6 inches in diameter and 15 inches tall and weighs approximately 16 lbs. when operating. The diaphragm-style pump within the prototype device was driven by pulsed compressed oxygen. Thus, the variables dictating the pump's performance include the size of the diaphragm, the pressure of the oxygen, the frequency of oxygen pulses, and the duty cycle of oxygen pulses. While the size of the diaphragm was kept constant throughout all tests, the oxygen pressure was varied from 2 – 20 psi at increments of 2 psi. Unlike previous work focused on nonelectronic oxygen regulation [6], the compressed oxygen was regulated by a three-way pinch valve (Masterflex®, Cole-Parmer Instrument Company, LLC) programmed to operate at a frequency of 0.25 Hz and a 50% duty cycle. Pressure transducers (U5244-000005-005PG, Measurement Specialties, Inc.) and a flow rate sensor (2PXL-TS410, Transonic Systems Inc.) were used to measure the perfusion pressure and flow rate of the perfusion solution in real time. The perfusion solution (deionized water) was diverted from its normal path into a flow loop so that it could be measured with the flow sensor. The hydraulic resistance created by the flow loop was tuned to 0.5 mmHg/mL/min, which is roughly analogous to the vascular resistance of a kidney and pancreas [7, 8].

The data was collected with a custom LabVIEW virtual interface (NI 9221, NI USB-9162, National Instruments) and exported to MATLAB for processing. The pulsatile flow rate profiles were averaged together (for each individual pressure) and the area under their curves at each progressive time step (0.001 s) was calculated to determine the frequency and duty cycle that would maximize the cumulative flow rate.

RESULTS

Any data from a trial whose peak perfusion pressure exceeded 60 mmHg was discarded, as that perfusion pressure would damage the vasculature of a kidney or pancreas. The average perfusion pressure for the remaining trials varied between 5 – 15 mmHg. Pulsatile flow rate data was averaged (n=30) at various oxygen pressures, and Figure 2 shows the flow profiles of single pulses (with the shaded areas representing the standard deviation). It can be observed that the pulsatile flow rate increased as the oxygen pressure increased.

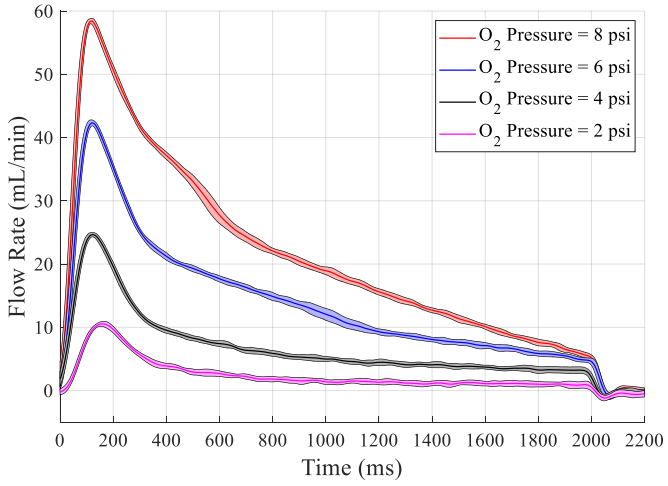

Figure 2: Raw pulsatile flow rate data

The data presented in Figure 2 was used to tune the pulse frequency and duty cycle of the pulsed oxygen and those results can be seen in Figure 3, which displays the experimentally measured cumulative flow rate and the estimated maximized cumulative flow rate. The error bars on the optimized flow rates stem from the deviations of the pulsatile flow profiles shown in Figure 2. The best identified pulse frequency ranged from 1.5 – 2.5 Hz and the best identified duty cycle ranged from 70 – 80%. As oxygen pressure increased, the best identified pulse frequency decreased, and the best identified duty cycle increased.

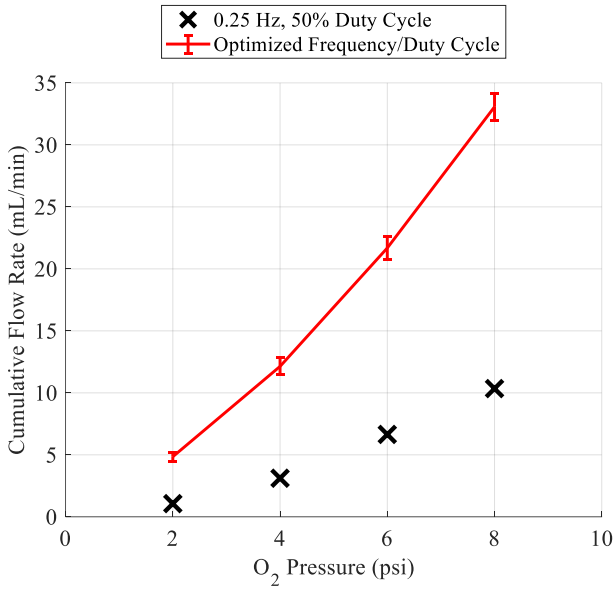

Figure 3: Cumulative flow rates of perfusate

DISCUSSION

The analysis of the diaphragm pump conducted in this study demonstrates that the device can provide adequate perfusion for a human pancreas. However, the device does not provide the cumulative flow rate required by a human kidney. Future work will include altering the size of the diaphragm pump, which will directly influence the response time of the pump. A faster response time will allow for higher pulse frequencies and lower peak perfusion pressures, which will ultimately increase the cumulative flow rate. The device also needs to be evaluated against alternative vascular resistances, preservation solutions, and preservation temperatures. Once the device's performance has been fully characterized, *ex vivo* human organ preservation studies will be conducted to validate the device's ability to preserve a variety of organs.

INTRODUCTION

Articular cartilage and other collagenous soft tissues rely heavily on their internal networks of collagen for mechanical strength. When placed in tension, e.g. due to external loading or osmotic swelling, collagen fibers contribute to the mechanical response and stiffness of these tissues. Collagen networks also provide a foundation for many applications in tissue engineering. We seek to establish a robust methodology and platform for testing isolated collagen networks to aid researchers in investigating the effects of mechanical loading (e.g. repeated, damage-inducing, rate-dependence) and biochemical modifications (e.g. temperature, +/- crosslinking, cell products) on this essential mechanical constituent within tissues and biomaterials. Such understanding may aid in the development and testing of therapeutics aiming to heal damaged tissues, specifically those developed to treat diseases of articular cartilage, i.e. osteoarthritis. Furthermore, isolating collagen networks from the tensile forces generated by osmotically induced pretension may aid in understanding intra-constituent interactions and their roles in tissue biomechanics. Testing of isolated networks of collagen fibers may lead to understanding of the mechanics of individual fibers that can inform multiscale mechanical models.

METHODS

We sequentially focused on sourcing, preparing, and testing networks of type II collagen and sought to optimize each step. We first established a method for isolating collagen networks from bovine articular cartilage. Additionally, cartilage contains a collagen network with through-thickness heterogeneity, a factor that we can include as a variable or control for with specific protocols. We extracted full-thickness cartilage from the patellofemoral groove and femoral condyles attached to the subchondral bone in 1×2 cm pieces. We then sliced the cartilage pieces into 200 μm thick sheets (the thickness of the well-aligned superficial zone of cartilage [1]) using a microtome, before digesting out the proteoglycan (PG) constituents using trypsin [2]. We used the most superficial two or three sheets of cartilage to control for variability in the fiber alignment through the thickness of cartilage [3].

We determined the appropriate trypsin concentration and the duration of digestion using another set of specimens extracted from the tibial plateau and patella for 24 or 48 hours in 0.25, 0.5, 1.0, or 2.0 mg/mL enzyme in phosphate buffered saline (PBS). We quantified the PG remaining and the collagen loss using glycosaminoglycan and hydroxyproline assays. We chose the enzyme concentration and duration that removed the most PG with minimal loss of and damage to collagen, also aiming to minimize the digestion time and the amount of enzyme required. We also investigated the volumetric effects of digestion by imaging specimens before and after digestion and computed the deformation gradients associated with the digestion.

We then established the appropriate specimen dimensions. We used the ASTM D1708 standard dimensions for microtensile testing as a baseline and scaled these down to reduce the amount of tissue required for each test [4]. We performed finite element analyses to ensure that the geometry of the specimen we selected did not create problematic stress concentrations and that the stress distribution in the gauge region remained homogenous. We then varied the specimen thicknesses starting at a maximum of 200 μm, aiming to create sheets of collagen as thin as possible, but thick enough to manipulate during testing and while minimizing undesirable edge effects from damage sustained during specimen preparation. We selected the thinnest specimens that did not present obvious loss of stiffness in the bulk network.

We next determined the displacement rate for tensile testing to eliminate strain-rate dependence while still achieving a reasonable test duration. We started at 75 μm/min (previously determined to be quasi-static [5]) and increased the rate until we noted rate dependence in the

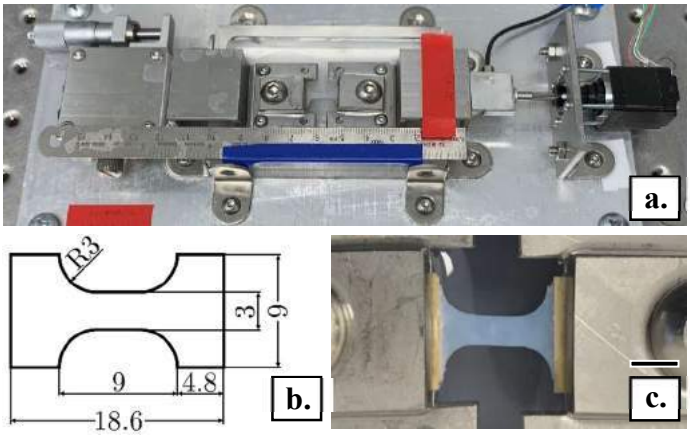

Figure 1. Mechanical testing of collagen networks: a. microtensile testing device; b. dimensions of our tensile specimen in mm; c. specimen mounted within the microtensile device, bar = 5 mm.

mechanical results. Aiming to create a test platform for efficient research, we chose the highest displacement rate that did not increase the apparent stiffness of the collagen network.

We performed all tensile tests on a custom-built microtensile device (**Fig. 1a**) with a displacement range of 12.5 mm (resolution: 2.5 µm) and force capacity of 20 N (resolution: 0.3 mN). We kept tissues hydrated in a PBS bath at 25°C and aligned specimens with the principal fiber orientation, but designed the device to fulfill requirements and constraints of future studies on collagen networks (e.g. visualizing fiber structures, quantifying damage during loading, studying temperature effects). We secured the specimens using cyanoacrylate glue and sandpaper (**Fig. 1c**) and monitored testing to ensure tissue failure occurred within the gauge region.

RESULTS

Table 1 shows the preliminary results of testing our protocols for enzymatic digestion. We will finalize a digestion protocol to reduce the PG in the tissue to less than 2% of the original PG mass with less than 1% collagen mass lost or damaged, while still aiming to reduce the cost and time needed for the specimen preparation. **Fig. 1b** shows the dimensions of our specimens that reduce the required tissue but still maintain a gauge region with homogenous stresses to simplify subsequent mathematical analyses of fiber networks under loading. Preliminary tests also show this level of digestion and PG removal does not cause considerable changes in specimen geometry, i.e. deformation that should be included in interpreting the resulting mechanical data.

Table 1. Mass Percent PG Remaining Post Digestion (Mean ± Standard Deviation, n = 6 per test group)

	Trypsin Concentration (mg/mL)				
Duration	0	0.25	0.5	1	2
24 hr	87.4 ± 4.8	2.2 ± 0.4	1.3 ± 0.8	1.1 ± 1.3	1.6 ± 0.5
48 hr	84.2 ± 4.9	1.2 ± 0.8	1.3 ± 0.6	1.5 ± 0.4	1.1 ± 0.4

Preliminary tests show that digested specimens have a stiffness less than that of intact specimens and that extreme digestion can over soften tissue by damaging the collagen network during removal of PG (**Fig. 2**). Preliminary results show loss of collagen (and thus network damage) at the higher concentrations shown in **Table 1**. Additionally, increasing the strain rate stiffens the tissue response due to the viscoelastic response of collagen fibers [6]. Finally, preliminary tests show that there is a minimum thickness (threshold) below which the stiffness of the tissue decreases due to edge effects from damage.

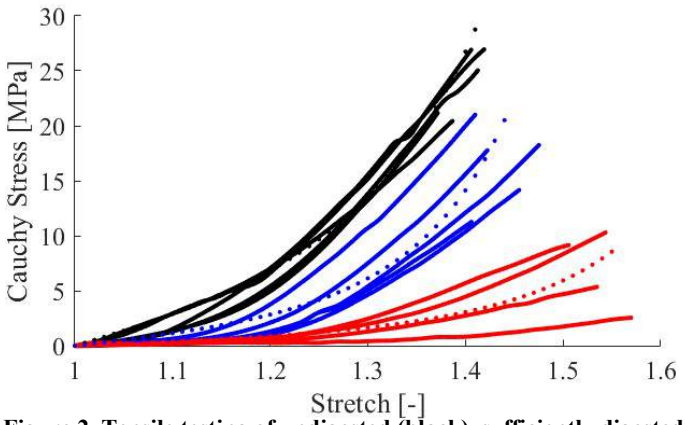

Figure 2. Tensile testing of undigested (black), sufficiently digested (blue), and overly digested (red) cartilage specimens as a source of type II collagen networks. The dashed lines show the prediction based on the average parameters fit from each test type (n = 5).

DISCUSSION

Variability within cartilage and collagen networks arises from many factors. With this protocol, we aim to create a process that is repeatable so that effects presenting in future tests reflect the independent variable of interest and not the innate variability between tissue specimens. We also aim to quantify intra-specimen variability to inform future research.

Preliminary results show that the test parameters we are investigating are relevant in altering the apparent mechanics of collagen networks, speaking to the effects of chemical and mechanical damage as well as the strain-dependent response of collagen networks and possibly fibers, yet we will also evaluate our testing protocol further. We plan to visualize potential damage to the collagen network using collagen hybridizing peptide (CHP) to ensure internal damage without loss of collagen is not present. We also plan on using digital image correlation (DIC) to confirm that strain is homogeneous within the gauge region and investigate the mechanism of failure.

While establishing a testing platform, we needed to make decisions to transform a theoretical test into a practical experiment. Conflicting constraints and aims limit the optimization of these methods, e.g. an ideally thin (<200 nm) sheet of a single layer of collagen fibers would be nearly impossible to handle and mount for tensile testing. We also established arbitrary (but practical) cutoffs for acceptable levels of remaining PG and lost/damaged collagen since we cannot reasonably perform a complete digestion of PG with no effect on the collagen.

Future work using this test platform will characterize the mechanical response of individual type II fibers by analyzing the network structure using a host of tools including second harmonic generation microscopy, transmission electron microscopy, and micro-digital image correlation. Mechanical characterization of individual collagen fibers and isolated collagen networks will also inform models aiming to include micro-mechanics into models of bulk tissues.

COMPUTATIONAL ASSESSMENT OF A NOVEL DESIGN OF TRILEAFLET MECHANICAL HEART VALVE IMPLANTED IN AORTIC POSITION

Syed Samar Abbas (1) and Iman Borazjani (1)

(1) J. Mike Walker ’66 Department of Mechanical Engineering
Texas A&M University
College Station, Texas, USA.

INTRODUCTION

The native aortic valve is characterized by three cusps (or leaflets) and regulates the unidirectional flow of blood from the left ventricle into the aorta. It may malfunction in children and young adults due to congenital heart defects or rheumatic diseases. In such case, it is widely replaced by a Bileaflet Mechanical Heart Valve (BMHV), having two prosthetic leaflets. The commercially available BMHVs are albeit durable, however, they are known to generate non-physiological blood flow patterns [1-4] which can result in thrombus formation [5]. Consequently, recipients of these valves should take anticoagulant drugs for the rest of their lives, which can have fatal consequences if not monitored properly. For this reason, novel mechanical heart valves are required to be designed, tested, and implanted to ascertain physiological blood flow inside the human aorta. This study numerically investigates the hemodynamics of a novel Trileaflet Mechanical Heart Valve (TMHV), designed with three leaflets to replicate the flow field generated by a native aortic valve.

METHODS

The computational simulations were carried out by using Curvilinear Immersed Boundary (CURVIB) method for solving the blood flow field, governed by 3D Navier Stokes equations [6]. The employed CURVIB solver has been well-validated in the past research [6, 7]. The excursion of the TMHV leaflets in response to the cardiac flow is determined by coupling the leaflet equations with the flow through a strong-coupling fluid-structure interaction (FSI) algorithm [6]. The boundary conditions included the incorporation of a physiological flow curve at the inlet of the computational domain and a ‘no-slip’ condition at the leaflet/blood interface. Triangular mesh elements were used to discretize the three leaflets and housing of the TMHV as required by the CURVIB for the classification of the background domain into fluid, boundary, and solid nodes by using an efficient ray-tracing algorithm [6]. To provide high spatio-temporal resolution, the computational fluid domain was discretized with around 10 million cells. The hemodynamics of the TMHV was the output of the numerical solver and have been visualized in Paraview. The scalar viscous shear stresses were evaluated as the major hemodynamic load on the blood constituents, and were calculated by using the formulation proposed by Apel et al. [8].

RESULTS

The leaflet kinematics, velocity field, and the viscous shear stresses have been analyzed to evaluate the hemodynamic performance of the TMHV, as done in the past research [1-4]. Figure 1 shows the leaflet kinematics in response to the prescribed flow curve (also illustrated).

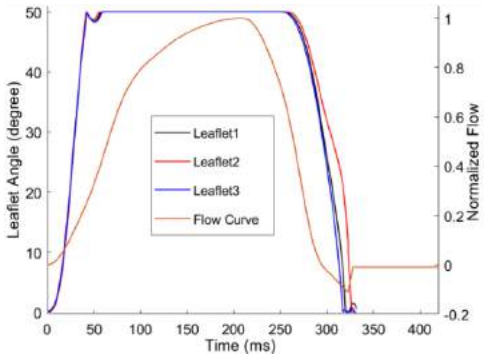

Figure 1: Leaflet kinematics and imposed flow curve

The three leaflets opened synchronously and did not noticeably keep fluttering after having reached to their fully opened position. They

started to close slightly asynchronously during the late forward deceleration phase of the cardiac cycle and fully closed, contrary to BMHVs that start to close by the backward flow [6], without any pronounced rebound. The early closure and absence of leaflet rebound are desirable characteristics that might aid in reducing the regurgitation flow volume.

Figure 2 presents the velocity profile at the peak systolic phase of the cardiac cycle, where the leaflets are fully opened, and the flow is dominantly characterized by a strong 'central-jet' with a triangular cross-section. The central jet could be observed to be void of eddies and vortical structures, in contrast to the flow field observed in conventional BMHVs [5, 7, 9, 10]. Three narrow 'side-jets', one from each leaflet, were also observed with a crescent-shaped structure and a similar maximum velocity as that in the central jet. In the same figure, weak flow recirculation zones with low velocity magnitudes could also be observed in the bulbous sinus region of the aorta.

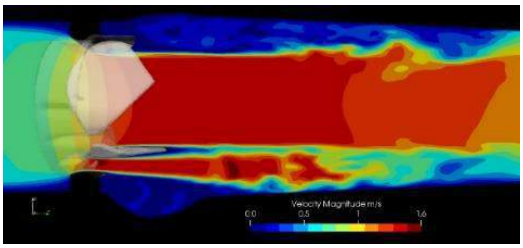

Figure 2: Velocity profiles at peak systolic phase

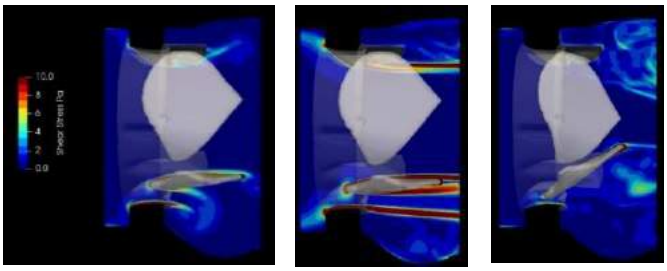
Figure 3(a-c) presents the scalar viscous shear stresses during three cardiac instants of early, peak and late systole, respectively, in the region located in the vicinity of the TMHV leaflets. Figure 3(a) shows the development of shear layers near the leaflet surfaces, which strengthen as the peak systolic phase of the cardiac cycle is reached as shown in Figure 3(b). At peak systole, the maximum viscous shear stresses in the shear layers around the leaflets exceed a magnitude of 10 Pa, however, the blood constituents will be advected with the high-velocity flow, as previously illustrated by the velocity profile in Figure 2, thereby washing out the mentioned regions. For other regions of the domain, the shear stresses are within the threshold magnitude reported to initiate platelet activation [2, 3, 11] but considerably lower than those previously observed for BMHVs [1, 3, 7]. Additionally, there are no large regions of high shear stresses in the bulbous sinuses. During the valve closure phase, the maximum shear stresses only occur in the shear layers formed around the leading edges of the closing leaflets, as illustrated in Figure 3(c).



(a) (b) (c)

Figure 3: Viscous shear stresses at various cardiac instants

DISCUSSION

The current numerical study provides insights into the unprecedented details of TMHV hemodynamics with high spatial and temporal resolution. The TMHV demonstrates a physiological opening and closing kinematics of the leaflets, being contrary to that reported for BMHVs [3, 7]. The central jet generated by the TMHV during the peak systolic phase of the cardiac cycle has a triangular cross-section, which replicates the native aortic flow field. The maximum viscous shear stresses are significantly low in magnitude and do not occupy large regions in sinuses, which contingent with the fact that there exists weak flow recirculation in this region, can drastically reduce the possibility of platelet activation [3]. It could be concluded that the novel design of TMHV analyzed in this study has great potential of circumventing the hemodynamic problems associated with the use of BMHVs.

INTRODUCTION

The organization and composition of the tissue constituents, i.e., tissue structure, dictate the mechanical behavior and function of the tissue. A range of diseases, such as tendinosis and osteoporosis, and conditions, such as pregnancy, influence the tissue structure and mechanical behavior [1]. To diagnose and treat the diseases and understand the influence of biological processes on tissue condition, it is necessary to evaluate the structure and mechanical function of healthy, diseased, abnormal, and damaged tissue.

The characterization of the tissue structural and mechanical properties, and the relationship between them, is experimentally challenging. Many tissues are small, spatially heterogeneous, and elastically anisotropic, and traditional mechanical tests are unsuitable for such samples. Analysis of the tissue structure through the use of optical microscopy and exogenous stains is time-consuming and limited to 2D. Therefore, the 3D structural heterogeneity of the tissue cannot be directly measured from these methods, yet it is important to understanding function.

The measurement limitations are particularly important for complex tissues like the cervix. The cervical tissue is of interest because it has an important biomechanical role during pregnancy; it should stay firm to retain the fetus yet undergo dramatic changes through pregnancy and birth. Both cervix microstructure and micromechanical properties change during this remodeling process.

Advanced imaging technologies and mechanical property testing methods, such as second-harmonic generation (SHG) microscopy and nanoindentation (NI), respectively, can help to overcome these challenges. NI can quantify the local elastic, viscoelastic, and poroelastic mechanical properties of tissues. SHG imaging is suitable for quantifying the microstructural organization of biological materials due to its specificity to collagen and high spatial resolution in 3D.

Previous studies provided valuable insights on the microstructural and micromechanical properties of soft tissues, but the correlation between these properties on the microscale is still poorly understood. We used the combined approaches of NI and quantitative SHG (qSHG) microscopy [1] to evaluate the spatially heterogeneous mechanical properties and 3D microstructure of the cervix, as a model system. We observed a strong correlation between the indentation modulus (E) measured from NI and the qSHG parameters related to the 3D collagen organization. The results contribute to understanding the relationship between the 3D collagen microstructure and mechanical function of the cervix as well as other collagenous tissues.

METHODS

Sample preparation: Non-pregnant (n=5) and 21-days pregnant (n=3) rat cervices (Sprague Dawley's) were harvested and stored at −80°C. Thawed samples were embedded in optimal cutting temperature (OCT) compound, then cryosectioned (−20°C) at mid-cervix, perpendicular to the cervical canals. OCT was washed out after sectioning. Samples were indented and imaged immediately.

SHG microscopy: A custom SHG microscope was used for imaging the non-pregnant cervices. A 10x objective lens imaged the entire cross-section of the samples. Higher resolution images were obtained on selected regions using a 60x water immersion objective lens. The pregnant cervices were imaged with a commercial confocal microscope (Zeiss LSM 710, Oberkochen, Germany) using a 40x objective lens. Two parameters collectively quantified the 3D organization of collagen fibers: average out-of-plane fiber angle (φ) relative to the imaging plane and spherical variance (SV). SV is a measure of the fiber dispersion in 3D.

NI: A Piuma nanoindenter (Optics11, Amsterdam, Netherlands) with a spherical probe indented samples submerged in PBS along a

continuous medial-lateral line every 25 µm. Indentation modulus, E, was calculated using the Hertz model [2]. The tip radius and stiffness were 41.75 ± 22.98 µm and 0.26 ± 0.33 N/m, respectively. The protocol for co-registering the NI and SHG data is in [3].

Statistical analysis: A one-way ANOVA with a post hoc Tukey test compared the data from different cervical regions. A student's t-test compared the pregnant and non-pregnant data. Pearson's r assessed correlation between E and SHG parameters.

Modified SV for fibers: A set of vectors, $\hat{X}_i$, representing collagen fibers, can be equally represented by another set of vectors with the opposite directions, i.e., $-\hat{X}_i$. The following modified SV definition was introduced to take this into account.

$$\hat{R}_1 = \hat{X}_m\,,\ m = \underset{i}{argmax}\,\frac{1}{n}\sum_{j=1}^{n} cos\,(A_{ij}) \quad (1)$$

$$\hat{R}_{i+1} = \hat{R}_i + \hat{X}_m\,,\ m = \underset{i}{argmax}\left(cos\,(tan^{-1}\frac{\|\hat{R}_i \times \hat{X}_j\|}{\hat{R}_i.\hat{X}_j})\right) \quad (2)$$

$$SV = 1 - \|\hat{R}_n\| \quad (3)$$

where A_{ij} is the angle between the i^{th} and j^{th} input vectors.

RESULTS

SHG microscopy: Figure 1 compares the qSHG parameters of three regions in the non-pregnant cervix samples (ring, septum, near septum). The fibers in the near-septum had a significantly larger φ ($p<0.02$) compared to the two other regions, which were statistically similar. The 3D dispersion of collagen fibers, reflected in SV, was also significantly higher in the near-septum, but the ring and septum were again statistically similar.

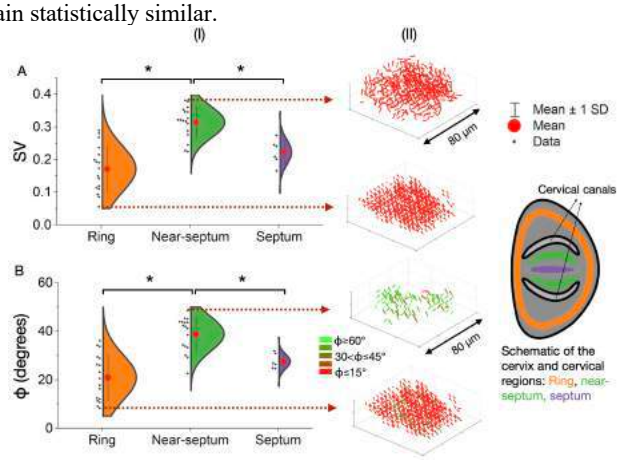

Figure 1: qSHG parameters in the ring, near-septum and septum (I). Representative results illustrate the physical meaning of the parameters (II).

Correlation of E and SHG parameters for non-pregnant cervix: Pearson's r showed a significant correlation ($p<0.02$) between E and both SV (Figure 2-A) and φ (Figure 2-B).

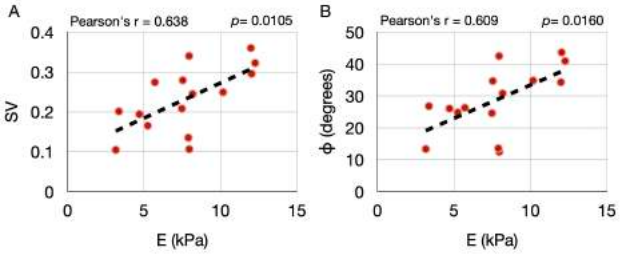

Figure 2: Correlation between qSHG parameters A: SV and B: φ and indentation modulus, E, from NI for non-pregnant cervix.

Comparison between pregnant and non-pregnant rat cervices: Figure 3 compares preliminary results of the 2D microstructural and micromechanical properties of day 21 pregnant cervices to those obtained from the non-pregnant samples. The circular variance (CV), a measure of in-plane fiber dispersion, was significantly higher in the pregnant samples ($p<0.001$), indicating more disorganized fibers. E was significantly higher in the non-pregnant samples, compared to the pregnant ones ($p<<0.001$). Both the quantitative microstructural measures and E differentiated the pregnant vs non-pregnant tissues.

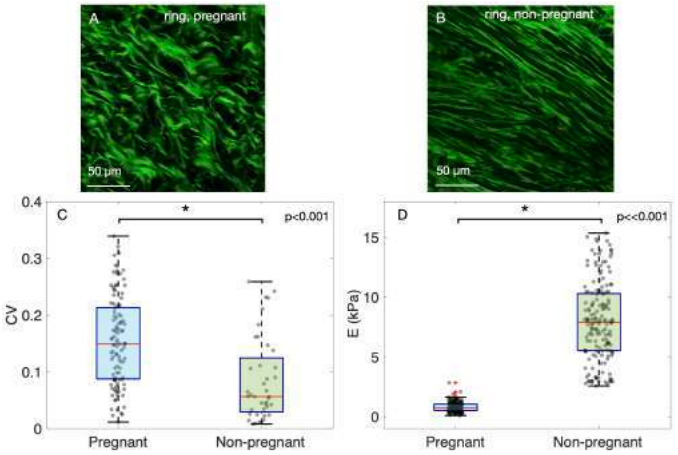

Figure 3 Comparison between the pregnant and non-pregnant cervices. A and B: representative images of ring, C: CV, D: E

DISCUSSION

Physiological changes, such as hormonal changes during pregnancy, alter the tissue microstructure and mechanical properties and affect the tissue function. We co-registered the microstructural and micromechanical properties of rat cervix using SHG microscopy and NI, respectively, and found significant correlations between the measurements. Such correlations can help to explain the underlying principles of biological processes such as cervical remodeling.

An accurate quantitative description of tissue microstructure is a prerequisite for the investigation of structure-mechanical properties relationships. The qSHG parameters used in this study successfully described the collagen fiber organization of the cervix and revealed a link between tissue micromechanical properties and microstructure. The modified definition of SV provides a more accurate description of the 3D dispersion of collagen fibers (data not shown).

There were several limitations to this study. We measured E, but not other properties such as poroelasticity. Further, we did not yet quantify the region-specific 3D structural properties of the pregnant samples. Future work includes a comprehensive 3D microstructural analysis at multiple gestational ages.

To our knowledge, this is the first work that co-registers and identifies a direct correlation between the 3D microstructural and micromechanical properties of the pregnant and non-pregnant cervix. The results contribute to understanding the 3D collagen microstructure and its relation to the mechanical function of the cervix tissue. While we focused on cervix, the findings are useful for understanding the underlying mechanobiology of other collagenous tissues.

INTRODUCTION

Osteoarthritis (OA) is a multifactorial disease, which includes mechanical failure of cartilage in the form of fracture and fibrillation. Cartilage is poro-viscoelastic (PVE), with intrinsic viscoelastic responses from the collagen, glycosaminoglycans (GAGs), and proteoglycans (PGs) solid matrix, and poro-elastic responses from the fluid phase moving through the solid [1–6]. Because energy dissipation is central to fracture initiation, PVE relaxations are important in delaying fracture [7-8]. Because PGs and GAGs are responsible for maintaining tissue hydration by balancing the charge concentration with the surrounding fluid, changing the osmolarity of the surrounding fluid will induce cartilage swelling or shrinking, thereby affecting mechanical properties [9-10]. Therefore, the objectives of this study were to determine the influence of osmolarity on fracture initiation under micro-indentation under extremely slow and extremely fast loading rates, then to estimate where cartilage transitions failure regimes from stress-governed fracture to pressure-induced fragmentation.

METHODS

Experimental Methods

Micro-indentation fracture tests were conducted. Eighty-seven full-thickness cartilage samples from 16 patellae of 5-6 months old pigs were obtained from a local abattoir (sex unknown and assumed random). Patellae were stored at -20° C prior to testing. Cylindrical cartilage cores of 6 mm diameter were obtained using a biopsy punch and scalpel blade. Three different osmolarity sodium chloride solutions were made: 0.0015 M NaCl (hypo-osmolarity), 0.15 M NaCl (normal-osmolarity), and 2 M NaCl (hyper-osmolarity). All solutions contained protease inhibitor (Protease Inhibitor, EDTA-Free, Thermo Scientific, Waltham, MA). Three groups of 29 cylindrical core samples were immersed in each of the above sodium chloride solutions for 1 hour before testing. The equilibrium time was selected to achieve constant thickness based on our preliminary studies. Cartilage thickness was measured using digital calipers at three to four locations per sample, and average cartilage thickness was calculated. Samples were fixed to a custom loading well using cyanoacrylate (Loctite 495, Henkel, Germany).). Fluid was added to the well up to the top of the sample.

Analysis of Experimental Measures

Micro-indentation tests were performed using a diamond sphero-conical indenter with tip radius of R = 100 μm and tip angle of θ_{tip} = 90° (Anton Parr, Austria) on tabletop test machine equipped with a 1000 g load cell (3230-AT series III test ElectroForce, TA Instruments, New castle, DE). Tests were conducted at two loading rates to capture pre- and post-relaxation regimes: slow loading rate (SLR, 0.005 mm/s, n = 16 per osmolarity) and fast loading rate (FLR, 5 mm/s, n = 13 per osmolarity). Critical work, W_c, critical load, L_c, and critical displacement, D_c, were evaluated at the first decrease in load of more than 29.4 mN, which was identified as the point of fracture initiation (Fig. 1). Optical crack images were studied at SLR and FLR (Fig. 1 Insets). W_c was calculated as the area under the load-displacement curve using trapezoidal integration in Origin 2019 (OriginLab, MA).

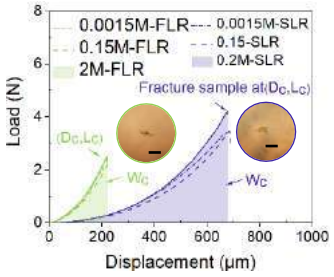

Figure 1: Cylindrical samples were tested using micro-indentation in three osmolarity groups at two loading rates to induce cracks (bar = 400 μm).

Strain Energy Density and Contact Pressure Calculations

Contact pressure (CP) and strain energy density (SED) were calculated to evaluate different failure regimes [12]. First, the contact radius a was determined for the sphero-conical indenter [13]. CP was approximated as the critical load divided by a circular projection of the contact radius

($CP \approx \frac{L_c}{\pi a^2}$). SED was approximated as the critical work divided by a spherical effected volume under the indentation tip ($SED \approx \frac{W_c}{a^3}$). Here, πa^2 is the projected contact area; L_c, and W_c were calculated from the fracture experiments. The normalized thickness (a/t), ratio of the contact radius to the sample thickness, was calculated to evaluate the CP and SED variation zone on the cartilage sample during indentation to eliminate any thickness bias because of large variation in cartilage's thickness in animal studies. The approximations helped in estimating a linear relationship between the CP beneath the indenter tip and the SED responsible for fracture.

Statistical Analysis

Differences between response variable with different osmolarities and loading rate were evaluated statistically. The Shapiro test was conducted to confirm the normality of the data for each loading rate and osmolarity. An ANOVA was used to determine the dependence of CP, SED, W_c, L_c, and D_c on osmolarity for each loading rate. Post-hoc pairwise comparisons were made using Tukey's test. Significance was set at $p \leq 0.05$, and $0.05 < p \leq 0.10$ indicated a trend.

RESULTS

The effect of osmolarity on critical displacement, critical load and critical work trended towards significance at the SLR but not at the FLR (Fig. 2). While not tested statistically, rate-dependent results were consistent with the findings of previous study [18]. CP and SED were not significantly different by osmolarity.

A greater difference in the magnitude of CP and SED vs normalized thickness (a/t) (Fig. 2D, and E) between FLR and SLR was observed, stratifying the cause of fracture into two failure regimes shown by a vertical stratification line drawn at a location where the transition is evident (Fig. 2D, E, and F). On the left side of the line, CP and SED have values that vary with normalized thickness, suggesting a region where neither CP nor SED provides a failure criterion and failure is instead governed by pressurization. On the right side of the line, CP and SED remain roughly constant across normalized thickness, suggesting a regime where failure is stress-governed. Overall, the CP at FLR was 4.87 times larger than at SLR, whereas SED was 4.83 times larger demonstrating a transition from stress-governed failure regime to pressure-induced failure regime (Fig. 2D, E, and F).

DISCUSSION

This study examined the effect of osmolarity on the fracture behavior of articular cartilage and estimated the transition between stress governed fracture and pressure induced fragmentation. Energy dissipation decreased with decrease in Na^+/ NaCl concentration (hypo-molarity) because of increased electrostatic repulsion between charged PGs and tensed collagen fibrils due to Donnan osmotic pressure [13-17] resulted in lower L_c, W_c, and D_c under SLR. On the contrary, we did not observe any noticeable trend in L_c, W_c, and D_c under FLR, thereby demonstrating possible dominance of pre-relaxation time scale over the osmolarity effect. The current set of indentation experiments were consistent with our previous results, which showed a dramatic difference between FLR, in the pre-relaxation regime, and SLR, in the post-relaxation regime [17]. As per Hertz's contact solution [19], CP could be determined by $CP \approx \frac{L_c}{\pi a^2}$. Numerically, a, L_c, W_c, and D_c were higher at SLR than FLR consistent with our previous study [18], hence the CP and SED at FLR were higher than CP and SED at SLR. CP versus normalized thickness (a/t) (Fig. 2D), SED versus normalized thickness (a/t) (Fig. 2E), and CP versus SED (Fig. 2F) showed a transition depicted by a vertical line, from lower values at SLR indicating dissipation of energy via fractures with multiple branches (post-relaxation regime) to higher values at FLR because of localized.

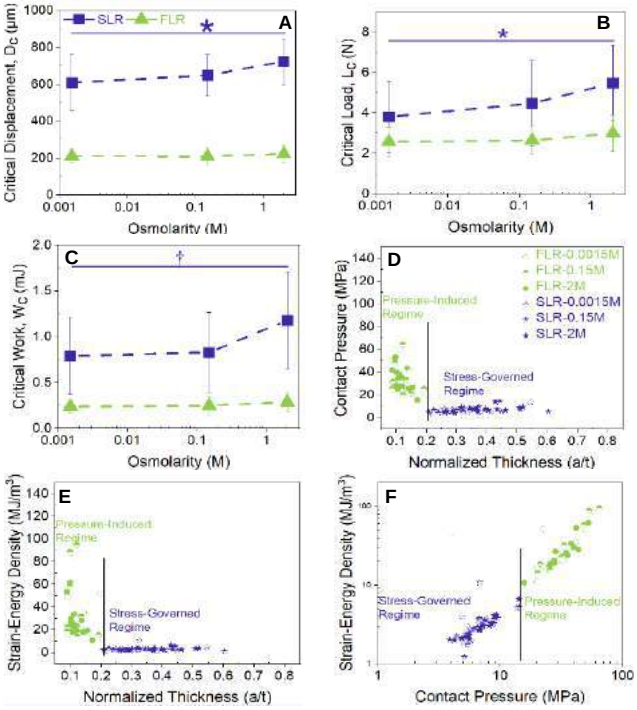

Figure 2: Experimental results: critical displacement, Dc (A), critical load, Lc (B), critical work, Wc (C) (n =13-16), and CP vs normalized thickness (a/t) (D), SED vs normalized thickness (a/t) (E), and CP vs SED scatter plot (F) * = significant, † = trend, and vertical line in (D), (E), and (F) depicts the stratification line for two failure regimes.

envelope near the indenter tip (pre-relaxation regime). The crack morphology studied with optical images during the experiments (Fig. 1 insets), details not reported here, showed line-shaped cracks at FLR and multiple cracks at SLR like the studies performed on balloons [20] and fragmentation aggregation process [21]. Overall, these findings provided new insight into the effects of osmolarity and loading rate, and thereby PG concentration and collagen fiber configuration on fracture nucleation in articular cartilage.

SPATIAL HETEROGENEITY OF THE WHITE MATTER STIFFNESS IN THE CORPUS CALLOSUM OF THE MOUSE BRAIN

INTRODUCTION

Multiple sclerosis (MS) is one of the primary non-traumatic neurological disabilities in young adults. MS is a demyelinating disease that causes a neuroinflammatory response which leads to the demyelination of axons, neuronal and axonal degeneration, and ultimately death. Breakdown of healthy axon functions leads to deficient nutrient transport around white matter lesions and defunct ion homeostasis, which eventually results in cell death. White matter axon fibers are wrapped by myelin sheaths that provide not only structural integrity to the fiber but also leads to a 10-fold increase in signaling speed along the fiber. Beirowski et al. reported that myelin sheaths can significantly increase the conduction speed of electric impulses [1]. In addition to the electrical importance of myelin in CNS, myelin has been suggested as an important factor causing change of mechanical environment which can further influence neuronal growth and development [2]. For example, Garbern et al. reported that a lack of myelin results in axonal degeneration in CNS [3]. Moreover, Weickenmeier et al. studied white and gray matter of fresh bovine brain and found a proportional relation between myelin density and tissue stiffness [4].

Previous work used experimental methods to quantify white matter stiffness. Koser et al. studied white and gray matter stiffness in fresh tissue using atomic force microscopy (AFM) and concluded that the stiffness of gray matter (159±26Pa) is much higher than white matter (60±7Pa) [5]. Melendez et al. conducted studies on 4% paraformaldehyde (PFA) fixed mice brains and reported that demyelinated corpus callosum (CC) shows a lower stiffness in comparison to control mice [6]. While both studies provided an average stiffness value for local CC subregions, the spatial heterogeneity of white matter stiffness across the entire CC remains unclear. The objective of this study is to address this knowledge gap using nanoindentation experiments in coronal brain slices from healthy mice.

METHODS

Sample Preparation. A total of six female 8-week-old C57BL/6 mice were obtained from Jackson Laboratory and fed with normal chow for six weeks. As outlined in Figure 1A, all mice were sacrificed by cervical dislocation and the brain was harvested. We submerged all brains in 4°C phosphate-buffered saline solution and used a vibratome (VT-1200S, Leica Co.) to cut a 500µm thick coronal slice 0.7mm from Bregma. We subsequently glue the resulting slice into a petri dish and submerge the sample in contact lens solution (Opti-free, Alcon) for measurements. All experiments are completed within 4 hours of death.

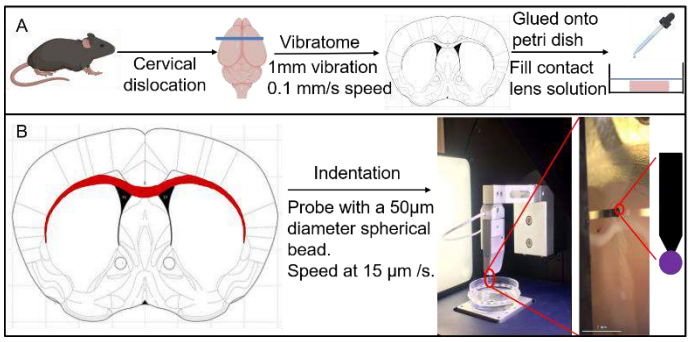

Figure 1. Graphical illustration of the methods. (A) Sample preparation. (B) Indentation measurements.

Indentation Measurements. All indentation measurements were conducted using our FT-MTA03 Micromechanical Testing System (FemtoTools AG). An FT-S200 (FemtoTools AG) microforce sensing probe with a ±200µN force range and a resolution of 0.0005µN at 10HZ. As shown in Figure 1B, we glue a 50µm-diameter polystyrene microsphere (Alpha Nanotech) to the tip of the sensor probe. Our indentation protocol works as follows: we move the probe towards the sample surface at a speed of 100µm/s; when we detect a contact force of 0.3µN, the sensor is automatically moved back to a distance of 40µm in preparation of the actual indentation test. A single indentation measurement is conducted at a constant speed of 10µm/s until we reach an indentation depth of 15µm. To map tissue stiffness of the whole CC section, we repeat individual measurements and move the probe head in

horizontal and vertical increments of 75μm in-between from the left bottom corner along the CC to the right bottom corner, as outlined in Figure 1B. Single force-displacement data at each location is automatically recorded by the testing system.

Data Analysis. All measurement data was processed with customized algorithms. Specifically, each force-displacement curve is fitted to Hertz's model to obtain Young's modulus as following:

$$F = \frac{4}{3}\left(\frac{E}{1-\nu^2}\right)^2 \sqrt{R}\delta^{3/2}, \quad (1)$$

where F is the indentation force, E is Young's modulus, R is the radius of the bead, δ is the indentation depth, and ν is Poisson's ratio which we set to 0.5. To compare the result from each brain, we implement a registration algorithm that maps each brain onto a reference CC shape. Once registered, we interpolate in the reference grid and determine mean and standard deviation (std) at each grid point. A Student's T-test was used to determine the statistical significance between groups, where * means $p < 0.05$, ** means $p<0.01$, and *** means $p<0.001$.

RESULTS

The resulting mouse CC stiffness was plotted as a heatmap in Figure 2, where the relative X is the horizontal position of the tested location to the symmetry line, and the relative Y is the vertical position of the tested location to the lowest location. It is clear the stiffness is heterogeneous in CC. Specifically, the closer the X position to the symmetry line, the softer the tissue.

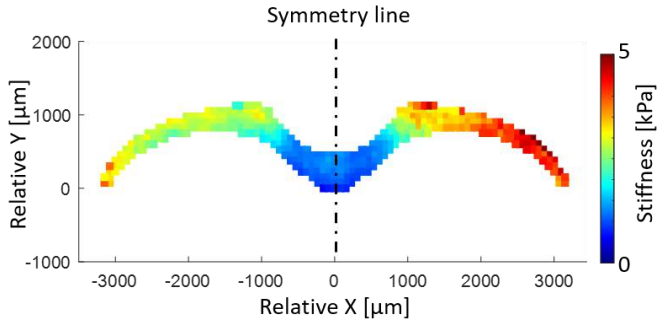

Figure 2 Stiffness heatmap of mouse corpus callosum. We registered all brains onto a reference geometry and report the mean stiffness value at each grid point.

To further study the spatial dependence of white matter stiffness, we calculated mean and std with respect to the same horizontal position, as shown in Figure 3A. We observe that stiffness is lowest at the center and increases as we move outwards, which results in a 'U'-shaped stiffness profile. Moreover, we differentiate between three distinct regions of interest (ROIs) and analyze the center (ROI 2) and two wings (ROI 1 and 3), separately. In Figure 3B, we show the boxplot of each ROI. Mean±std stiffness of ROI 2 is 1.52±0.6 kPa which is significantly lower than ROI 1 (2.80±0.31 kPa) and ROI 3 (3.77±0.62 kPa). Interestingly, ROI 3 is consistently stiffer than ROI 1, as well.

DISCUSSION

The stiffness variation pattern in mouse CC has been investigated in this study. The results suggest a spatial heterogeneity of mouse CC stiffness, which provide significant new insight following previous reports of more localized arrays [5,6]. The spatial heterogeneity in white matter stiffness is likely caused by heterogenous distribution of myelin, cell density, and fiber orientation, and is subject to further analysis. In view of work by Min et al. local variation of fiber orientation and their corresponding angle map in the CC are strong indicators for a structurally motivated reason for stiffness variations [7].

Future works will show whether and how these parameters can be linked to the spatial heterogeneity of mouse CC stiffness. Also, the idea of combining mechanical characterization and immunohistology, as shown in Figure 3C, could serve as a robust method in other soft tissue studies, including tumor, tissue regeneration, and other diseases.

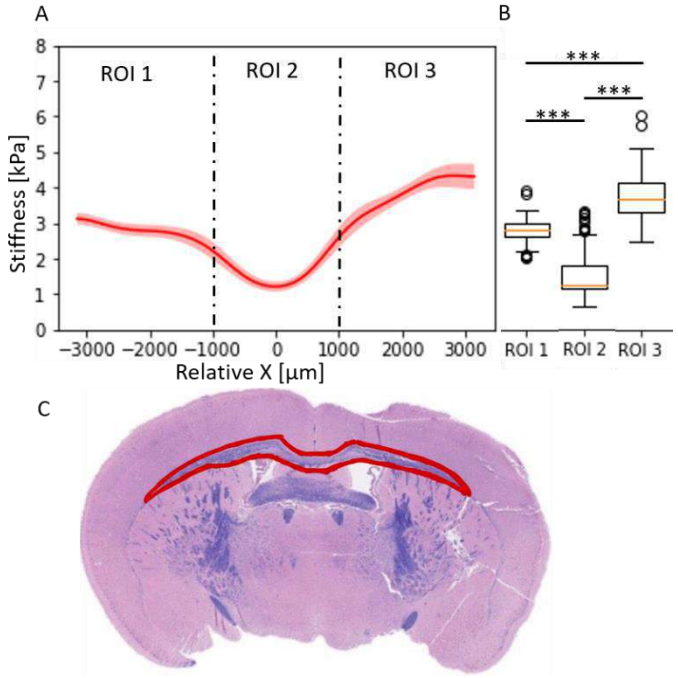

Figure 3 Stiffness variation pattern with respect to relative X. (A) Mean±std stiffness from all measurements with respect to relative X. (B) Boxplot of our three ROIs showing. (C) Combined H&E and Luxol Fast Blue histology image of a coronal mouse brain slice; we outline the blue-appearing corpus callosum which is indicates the presence of myelin sheaths wrapped around axons (* p < 0.05, ** p<0.01), *** p<0.001).

In summary, we demonstrate spatial heterogeneity of white matter stiffness in the corpus collosum of the mouse brain. Our results have significant implications for brain injury mechanisms in traumatic brain injury and multiple sclerosis in terms of tissue regeneration following inflammation.

INTRODUCTION

Due to the rising demand for acquiring comprehensive hemodynamic flow information for the diagnosis of cardiovascular diseases, image-based Computational Fluid Dynamics (CFD) has been widely employed to enable the derivation of functional information that is not accessible by medical images alone (e.g., pressure distribution, shear stress contour, velocity vector field), facilitating quantitative analysis and risk assessment in clinical therapy [1-2]. However, such modeling requires solving mesh-based discretization of partial differential equations numerically, which is computationally expensive, particularly for complex flow or when considering fluid-structure interaction. This has largely limited the translation of image-based CFD to clinical treatments that require timely feedback for further therapeutic assessment and treatment planning [3-4]. Moreover, it has posed a significant challenge to many-query applications, including uncertainty quantification, parameter estimation, and optimization problems arising in cardiovascular modeling. To enable efficient cardiovascular hemodynamic simulations, reduced-order or surrogate models have received increased attention and been developed as an alternative to predict functional information with a significantly less computational cost. For example, Lumped Parameter or 1-D reduced-order models are widely used to rapidly predict volumetric flow rate and have been an area of intense investigation [5-7]. However, those approaches only focus on global information and are incapable of providing local flow information such as spatiotemporal fields of velocity or wall shear stresses, which is more crucial to advancing cardiovascular research/healthcare. Deep neural network (DNN) is renowned for its capability of approximating complex nonlinear functions and fast online inference speed. As a result, trained DNN shows a great potential of serving as a surrogate model for high-dimensional CFD simulations. Recently, Liang *et al*. [8] developed an innovative DNN-based surrogate model that substitutes traditional structural finite-element analysis (FEA) by mapping the shape of the aorta to the corresponding stress contour. The results show good agreement between the original FEA and the DNN-surrogate model, which shows the promise of developing machine learning-based surrogate models for cardiovascular systems. In this work, we propose a novel deep learning surrogate modeling framework for image-based computational fluid simulations, enabling fast predictions of hemodynamics given complex 3-D patient-specific geometries.

METHODS

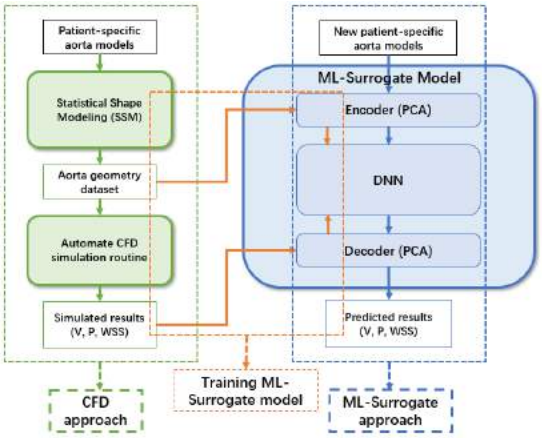

Figure 1: Diagram of the CFD approach and ML-Surrogate model approach

As shown in figure 1, our workflow consists of three steps: (i) build a stochastic shape model (SSM) that generates a synthetic aorta geometry dataset as training data; (ii) establish an automatic CFD

routine that takes in an arbitrary aorta geometry and outputs simulated results including velocity field, pressure distribution, and wall shear stress contours; (iii) feed the aorta geometry and corresponding simulated results as training pairs into the ML-surrogate model and train it. Once our ML-surrogate model is trained, test samples will be fed into the ML-surrogate model for validation.

1). The SSM that generates a synthetic aorta geometry dataset is constructed based on the LDDMM algorithm [9], where the "mean shape" of a set of shapes and the "best" deformation from the mean shape to each shape in the dataset are estimated. The detailed procedure of building the SSM is summarized as follows:

1. Firstly, the correspondence between the different aorta shapes is identified. With the input of N shapes referred to as $\{X_i\}_{i=1,\dots,N}$ where $X_i \in R^{n\times 3}$, the template X_{mean} and approximate shapes $\{\hat{X}_i\}_{i=1,\dots,N}$ deformed from the template can be computed.
2. Each approximate shape $\hat{X}_i$ is flattened into a vector $\tilde{X}_i$ and then squeezed into a data matrix $X = (\tilde{X}^T{}_1, \dots, \tilde{X}^T{}_N)^T$. Subsequently, Principal Component Analysis (PCA) is applied to X, from which one can obtain $\{W_k\}$ and $\{\lambda_k\}$ that represent eigenvectors and eigenvalues of covariance matrix respectively.
3. Each surface can be approximated as follow:

$$X^* \approx X_{mean} + \sum_{k=1}^{K} \alpha_k \sqrt{\lambda_k} W_k \quad (1)$$

where $\alpha_k$is the projection of the variance to the k[th] eigenvector.

2). The CFD routine that produces the simulated flow is built using python which incorporates meshing, setting up models, executing simulations, and extracting results of interest. The meshing step utilizes the Vascular Modeling Toolkit (VMTK) [10] which generates volumetric triangular mesh for each aorta. Next, OpenFOAM simulations are automatically set up and solved using the pimpleFoam solver. For each simulation, a periodic flow is assumed at the inlet and a pre-tunned Windkessel model is applied at the outlet such that the aorta pressure range is within 80~120 mmHg. Every simulation runs for 4~7 cardiac cycles to reach convergence. Finally, the flow vector field, pressure, and wall shear stress distribution of the aorta at systolic pressure are extracted as labeled training data for the ML-surrogate model.

3). The ML-surrogate model that yields the predicted flow includes three components: an encoder, a deep neural network, and a decoder. The encoder and decoder are constructed based on PCA or proper orthogonal decomposition (POD). For example, by reformatting equation 1 the shape encoder is obtained that encodes the nodes for the geometry to principal component values α_k:

$$\alpha_k = \frac{W_k{}^T (X^* - X_{mean})}{\sqrt{\lambda_k}} \quad (2)$$

The velocity vector fields, pressure, and wall shear stress are encoded separately using their POD modes, which can be decoded as full-field solutions in the backward direction. The vascular shapes and simulated flow solutions are encoded and the mappings in-between are captured by a DNN. Eventually, three decoupled sub-DNNs are trained and serve as the surrogate model that maps the input geometry to the corresponding velocity, pressure, and wall shear stress, respectively.

RESULTS

In this work, the initial dataset contains ten samples. The upper branches of the aorta are trimmed off for simplicity. Only the first three principal components are kept, representing over 90% of the variance. Since $X_{mean}, \{W_k\}$ and $\{\lambda_k\}$ are provided by the SSM, one only need to sample $\{\alpha_k\}$ to generate an aorta surface. Thus, A synthetic aorta geometry dataset with 200 aorta shapes is generated by sampling α_k from a normal distribution $\alpha_k \sim N(0,1)$. Figure 2 shows five selected samples, where one can see that the deformation of the showed samples fully occupies the variance of 3D space, hence the synthetic dataset can be considered as a good representation of the input space.

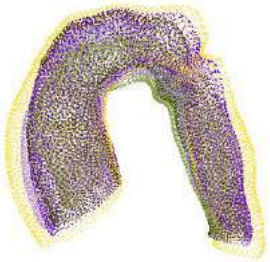

Figure 2: Synthetic geometry created by SSM using LDDMM.

Currently, we are still in the progress of generating CFD simulated training data using the geometry collection sampled by SSM. Once it's done, a cross-validation process will be performed to train and test the ML-surrogate model. We expect close agreement between the ground truth and predicted especially for pressure and shear stress distribution since both of the results are located at the same vertices as the input geometry. For the velocity, the flow pattern in the descending aorta is more likely to have a large discrepancy because the current surrogate model has limitations in capturing local features due to the linear nature of the PCA algorithm.

DISCUSSION

In this work, a synthetic aorta geometry dataset is created by SSM that represents the input space very well. Later, a Machine Learning based Surrogate model is developed to predict hemodynamic flow information within the aorta given its geometry. The author expects the ML-surrogate model can rapidly predict flow solutions close to those generated by CFD simulation. Among the flow information, the author infers that the velocity vector field will have a certain discrepancy due to the current surrogate model's incapability of capturing local details. Local-preserved learning such as geometric DNN will be explored in the future work.

ACKNOWLEDGEMENTS

I would like to express my gratitude to my advisor Prof. Jianxun Wang for providing insights and guidance in building up the workflow. I am also grateful to Xiaozhi Zhu's help in developing the SSM model and building the PCA algorithm for geometry parameterization. I would also like to thank all my colleagues including Han Gao, Luning Sun, and Xinyang Liu who shared their thoughts and suggestions with me.

FINITE ELEMENT ANALYSIS FOR CARPAL ARCH UNDER VARYING THENAR MUSCLE FORCE MAGNITUDES AND DIRECTIONS

Hui Zhang (1,2), Zong-Ming Li (1)

INTRODUCTION

The transverse carpal ligament not only constitutes the palmer boundary of the carpal tunnel but also serves as the primary origin for the thenar muscles (abductor pollicis brevis, flexor pollicis brevis, opponens pollicis). The thenar muscles biomechanically interact with the ligament during manual activities involving the thumb. Shen and Li (2013) demonstrated that thenar muscle contraction during pinching increased the area in the ligament-formed carpal arch [1]. The muscle's biomechanical effects exerted on the carpal arch are dependent on several factors including magnitude, direction, and location of the muscle force. Thenar muscle contraction level can be voluntarily changed from low to high force magnitude (e.g., picking up a small object vs. forceful grasping). And the direction of force application of the thenar muscles on the ligament is also adjustable by changing thumb positions (e.g., key pinch vs. tip pinch). The purpose of this computational study was to examine the effects of various force magnitudes and directions of the thenar muscles on the carpal arch. We hypothesized that the carpal arch area would (1) enlarge with increasing force magnitude, and (2) increase as force rotated from radial to volar directions.

METHODS

A validated finite element model of the distal carpal arch previously developed in our laboratory [2] was utilized (Figure 1). A cadaveric hand (male; left; age 74 years; BMI 30.3 kg/m^2) was imaged by ultrasonography at the distal carpal tunnel to obtain a cross section at the hook of hamate level. The image was segmented to obtain the geometrical information of the hamate, trapezium, thenar muscles, skin, fat, and transverse carpal ligament. The cross section was extruded with 1-mm thickness for a pseudo three-dimensional model. Material properties of these structural components were based on and shown in literature [2]. In particular, the ligament's anisotropic modulus was implemented by adding tension-only nonlinear springs to strengthen the transverse modulus. Structural stiffness parameters of carpal arch were defined according to a previous study [3]. A tie constraint was set for interfaces with an assumption of ''no-slip" contact. All components had displacement boundary condition free in-plane but fixed out-of-plane. The hamate was rigidly fixed.

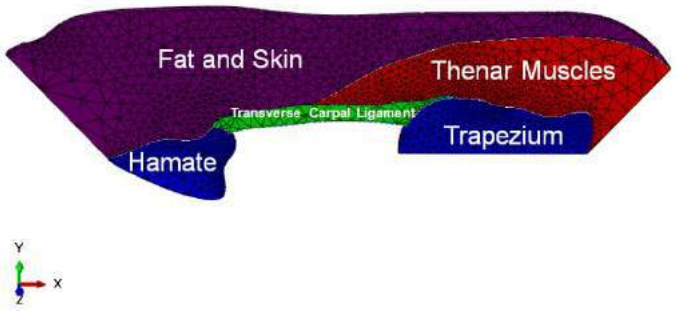

Figure 1: Finite element model of the distal carpal tunnel with components of the hamate, trapezium, thenar muscles, skin and fat, and transverse carpal ligament.

Thenar muscle contraction was simulated by applying force on the muscle-ligament interface. Only the abductor pollicis brevis and opponens pollicis were included in this study as the flexor pollicis brevis has negligible attachment to the ligament [4]. The maximal force by the combined two muscles at distal tunnel cross section was set as 9.09 N according to their force generation capabilities [5]. Three force levels (15%, 30%, and 45%) were simulated, and each force level was evenly distributed on the 95 nodes at the muscle-ligament

interface. The force directions were varied from 0 to 90 degrees (i.e., radial to volar) with an increment of 15 degrees.

RESULTS

The initial arch area without thenar muscle force was 12.1 mm^2. Force applications at any direction and magnitude led to increases of the arch area (Figure 2). The greatest arch area (48.4 mm^2) occurred at the 45% force and 90 degrees. For a given force direction, the area increased as force magnitude increased; for a given force magnitude, the area increased as force rotated from radial to palmar direction. For example, at the force direction of 0 degrees, the areas were 14.0, 16.7, and 20.2 mm^2 under 15%, 30%, and 45% of force, respectively; at 90 degrees, the areas were 29.6, 40.0, and 48.4 mm^2 under 15%, 30%, and 45% of force, respectively. At the 45% force, areas were 20.2, 43.2, 48.4 mm^2 with force directions at 0, 45, 90 degrees, respectively.

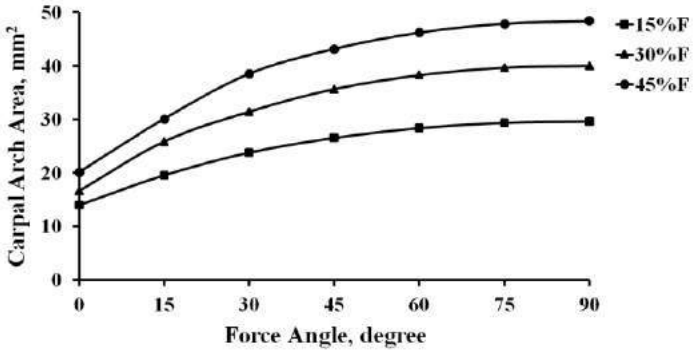

Figure 2: Carpal arch area under various force magnitudes and directions

DISCUSSION

This simulation study demonstrated carpal arch enlargement by thenar muscle forces—the larger the force magnitude, the greater the carpal arch space. The findings are consistent with previous studies involving *in vivo* thenar muscle contractions or *in vitro* force application [1,6]. The amount of carpal arch area increase was also dependent on muscle force direction. The muscle force exerted by the thenar muscles on the transverse carpal ligament can be decomposed into radial and volar directions. The volar component plays the role in decreasing the arch width and/or ligament elongation leading to palmar bowing and increased arch area. In the model, as the force angle changed from radial (0 degree) to volar (90 degrees) directions, the volar component increased from 0 N to full force magnitude, which explains the results in Figure 2 showing the increased arch area with direction change for any given force magnitude.

For *in vivo* condition, direction of force applied on the transverse carpal ligament by thenar muscle contraction is associated with thumb position. As the thumb moves from extension/supination to flexion/pronation positions, the thenar muscle orientation changes from radial to more volar directions, which make the muscle forces more effective in enlarging the carpal arch. On the other hand, thumb positioning may also change the relative distance between muscle origins and insertions, which may affect force generating capabilities of the thenar muscles. Further studies are needed to understand the interactive effects of thumb position, voluntary muscle contraction, and carpal arch changes. Our findings suggest thenar muscle contraction can be considered as means to increase carpal arch space which could be potentially applied to increase carpal tunnel space for median nerve decompression.

PREVALENCE and RISK FACTORS for BLEBS in INTRACRANIAL ANEURYSMS

Seyedeh Fatemeh Salimi Ashkezari (1), Fernando Mut (1), Juan R. Cebral (1)

(1) Bioengineering Department
George Mason University
Fairfax, VA, USA

INTRODUCTION

Intracranial aneurysmal blebs are focal bulges that are commonly observed on the surface of original aneurysm walls. Several clinical studies have identified aneurysm blebs as a risk factor for future rupture, probably because bleb walls are usually weaker than the original aneurysm walls [1-5]. The presence of blebs has been included as a risk factor in scoring scales to assess the risk of rupture of intracranial aneurysms (IAs) [6, 7], and recently has been studied independently from aneurysm size and location [8].

Despite few studies about prevalence of blebs in IAs [9, 10], strong statistical associations between presence of blebs and clinical, morphological, and hemodynamic factors have not yet been established. The purpose of this study was to statistically confirm previous results about prevalence of blebs and factors associated to their development. Another objective of this study was to validate trends relating aneurysm hemodynamic and geometric characteristics to the formation of blebs by using image-based CFD analysis in a large database of IAs.

METHODS

A total of 1704 patients with 2515 intracranial aneurysms and imaged with 3D rotational angiography (3DRA) or computed tomographic angiography (CTA) were studied. Patients ranged from 12 to 100 years of age, with a mean of 57.1 years. There were 1090 females and 423 males (information was unavailable for a subset of patients), and the mean aneurysm size was 6.7mm (range=1.1 – 39.3mm).

Using previously described methods [11], patient-specific vascular models were constructed from 3DRA or CTA images. In these aneurysms, blebs were identified by visual inspection of corresponding volume rendered 3D images, reconstructed vascular models, and aneurysm Gaussian curvature maps, and interactively marked on the vascular models, using a tool called ChePen3D, as detailed in [9].

In order to characterize the local hemodynamic conditions at bleb sites prior to their formation, the bleb regions were first projected to the model with virtually removed blebs and then hemodynamic variables were calculated over these regions.

A total of 13 hemodynamic variables were computed that measure different properties of the intra-aneurysmal flow, including strength and concentration of the inflow jet, speed, viscous dissipation, complexity and stability of the flow pattern, and strength, concentration and spread, and oscillation of the wall shear stress (WSS). In addition, the mean number of critical points were calculated.

Similarly, the geometry of the aneurysm was characterized by computing 10 variables that capture different aspects of the aneurysm geometry, including aneurysm sac size, aneurysm neck size, aneurysm elongation, and aneurysm shape distortion relative to a spherical shape and surface irregularity.

Associations between categorical variables and presence of blebs were analyzed using contingency tables and the Pearson's Chi-squared test. The mean values of continuous variables (hemodynamic and geometric characteristics) were compared between the group of aneurysms with and without blebs using the two-sample unpaired Wilcoxon (Mann-Whitney) test.

The p-values were adjusted for multiple testing using the Benjamini & Hochberg (BH) method available in R. All statistical analyses were performed in R and associations were considered statistically significant if $p<0.05$ after adjustment.

RESULTS

A total of 1176 blebs were identified in 765 (30%) aneurysms in of the 2515 aneurysms studied. The remaining 1750 (70%) aneurysms were classified as having no blebs. The mean bleb size was 2.85 ± 1.40

mm. Of the 765 aneurysms with blebs 450 had a single bleb, while 315 had multiple blebs (two or more).

No significant associations were observed between bleb presence and patient sex (p=0.8988) and age (p=0.5983). The presence of blebs was significantly associated with aneurysm rupture status (p<0.0001), in agreement with several previous studies. Also, significant associations were observed between bleb presence and aneurysm multiplicity (p<0.0001), aneurysm type (p<0.0001), and aneurysm location (p<0.0001).

Hemodynamic and geometric differences between aneurysms with blebs (virtually removed) and aneurysms without blebs are presented in Table 1. As presented in this table, most of the hemodynamic and geometric variables were significantly different between the two groups of aneurysms, even after adjustment for multiple testing.

Table 1: Hemodynamic and geometric characteristics of aneurysms with blebs and aneurysms without blebs. Statistically significant differences are indicated with a "*".

Characteristic	Variable	Aneurysms with deleted blebs	Aneurysms without blebs	Adjusted p-value

	CR	0.81 ± 0.11	0.76 ± 0.13	<0.0001*
Irregularity	UI	0.19 ± 0.11	0.24 ± 0.13	<0.0001*

To illustrate these differences, examples of flow visualizations in two aneurysms at the middle cerebral artery (MCA) bifurcation are presented in figure 1, one without a bleb (left) and another with a bleb (right, in this case flow simulation corresponds to the aneurysm prior to bleb formation—that is, with the bleb virtually deleted).

DISCUSSION

Consistently with one previous study [9], it was found that blebs are relatively common and happen in about 30% of all aneurysms.

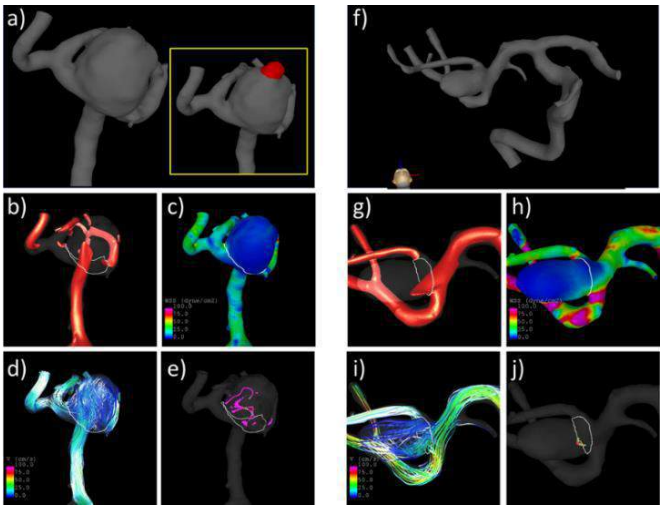

Figure 1. Examples of hemodynamics (at peak systole) for MCA-bifurcation aneurysms with and without blebs. Left panel – aneurysm with bleb removed: a) geometry of aneurysm after removal of one bleb (marked in red), b) inflow jet (iso-velocity surface), c) WSS magnitude, d) flow pattern (streamlines), e) vortex corelines. Right panel – aneurysm without bleb: f) geometry of aneurysm without bleb, g) inflow jet, h) WSS magnitude, i) flow pattern, and j) vortex corelines.

We verified and validated the results associating the presence of blebs in aneurysms, presented in previous studies [9, 10] with more cases and using a different data selection.

New associations between presence of blebs in aneurysms and aneurysm location, type, and multiplicity were found. Blebs are more likely to form in large, elongated, and irregularly shaped aneurysms, and in aneurysms at certain locations such as the ACoA and PCoA.

Hemodynamic conditions characterized by strong and concentrated inflow jets, high speed, complex and unstable flow patterns, and concentrated, oscillatory and heterogeneous wall shear stress patterns favor the formation of blebs in intracranial aneurysms.

Bleb formation seems to be a highly localized phenomenon, and the flow conditions identified here as favorable for bleb formation are characterized by strong and concentrated flow characteristics. Therefore, it seems reasonable to propose that these adverse flow and geometric characteristics may be signs of aneurysm instability and could be used to better understand which aneurysms are more likely to develop blebs and progress to a more fragile and rupture-prone status.

EXTRACELLULAR MATRIX REGULATION OF BREAST CANCER CELL INVASION IN A 3D TUMOR MODEL

Jacob Heiss (1), Hossein Tavana (2)

(1) Department of Biomedical Engineering
The University of Akron
Akron, OH, USA

INTRODUCTION

The extracellular matrix (ECM) is a key regulator of tumorigenesis.[1] ECM provides structural support for tumors and signaling cues to cancer cells through various binding sites. Despite important roles of ECM in cancer, many tumor models do not incorporate the ECM and its compositional complexity. Animal models that are also frequently used in cancer research are not suitable to mechanistically study the ECM roles in tumors. The lack of a physiologic tumor model has been a roadblock in understanding interactions of cancer cells with the tumor stroma, including the ECM, and developing drugs against tumor-stromal interactions.[2] The goal of this study is to use our recently-developed 3D breast tumor model and examine the role of ECM in regulating invasiveness of cancer cells.

METHODS

Tumor spheroids were made in 384-well plates using a cell micropatterning technology based on an aqueous two-phase system of polyethylene glycol and dextran.[3] Two different triple negative breast cancer cell lines, MDA-MD-231 and SUM159, were used to form spheroids with 7.5×10^3 cells in four days. Both cell lines stably expressed a green fluorescent protein. After spheroids formed, they were encapsulated in a hydrogel of human-derived type I collagen alone, or also containing fibronectin (FN) or hyaluronic acid (HA) at 10% by weight, or both. Four days after encapsulation, the spheroids were imaged using confocal microscopy and the invasion pixel area in each image was measured. Using a Prestoblue assay, the metabolic activity of spheroids was measured across all four different ECM conditions as a surrogate for cell proliferation.

RESULTS

Breast tumors have a complex ECM with type I collagen being the predominant component followed by FN and HA, and few other proteins. These proteins interact with cancer cells through specific binding sites. We aimed to evaluate effects of these ECM proteins on breast cancer invasiveness. Both TNBC cells significantly invaded from the spheroids into the collagen ECM (Fig 1A&2A), with MDA-MB-231 cells showing higher invasiveness than SUM159 cells. Addition of FN to the ECM further and significantly promoted invasion of both cell lines (Fig 1B&2B). The largest invasion occurred in the system where the ECM comprised of collagen and HA (Fig 1C&2C), which resulted in 1.7-fold and 3.5-fold increase in matrix invasion of MDA-MB-231 and SUM159 cells (Fig 3), respectively, compared to collagen only. Nevertheless, when both FN and HA were incorporated, the invasion of both cell lines significantly decreased almost to the level of the base system that only had collagen as the ECM (Fig 1D&2D). The quantified invasion data for both TNBC cells are shown in Fig 3. Our measurements of metabolic activities of cells in the tumor models showed small changes across different ECM conditions (Fig 4). Although some of these changes were significant, e.g., MDA-MB-231 cells in collagen only or in collagen and FN, the changes are relatively small.

DISCUSSION

Our study demonstrates that addition of FN or HA to the collagen matrix significantly promotes cancer cell invasion. The TNBC cells have high expression of integrin $\alpha_5\beta_1$ that enables them interact with FN in the ECM. This interaction is known to activate kinase pathways that regulate cell invasion.[4] Similarly, expression of CD44 receptors on the TNBC cells enables them to interact with HA in the ECM. This interaction axis also converges on pathways that promote cell motility and invasion. Inhibiting $\alpha_5\beta_1$, a primary biding site for FN, and CD44 receptor, a primary binding site for HA, is necessary to confirm these data. Paradoxically, addition of both FN and HA to the collagen matrix generated an antagonistic effect and led to a significant decrease in cancer cell invasion. We are currently conducting morphological imaging of the different ECM compositions to study whether this effect is caused by disruption of assembly of collagen fibers and also conducting a Western blot analysis to understand the underlying mechanisms. Small changes in proliferation of cells in different ECMs is also likely because invading cancer cells do not actively proliferate. A more direct analysis of cell proliferation is needed to complement this result.

CHARACTERIZING THE LOCAL RESISTANCE AND INERTANCE OF ANEURYSM SEGMENT TO STUDY THE CHANGES INDUCED BY FLOW DIVERTERS IN 0D BRAIN MODEL

Sara Hadad (1), Fernando Mut (1), Juan R. Cebral (1)

(1) Department of Bioengineering
George Mason University
Fairfax, VA, USA

INTRODUCTION

Flow diverters (FDs) are one of the most popular cerebral aneurysm (CA) treatments, especially for complex aneurysms [1]. Although many aneurysms have been treated successfully with FDs, several studies have reported delayed aneurysm rupture and intraparenchymal hemorrhage (DIPH) after treatment with FDs [2]–[4]. These complications are often life-threatening. The rate of occurrence of delayed rupture aneurysm is about 1% [5] and the rate of DIPH is up to 3% [4]. Many studies [6]–[8] have tried to find a mechanism or explanation for DIPH; however, they could not explain some clinical observations or have been rejected by future research.

A promising method to inspect the reason of DIPH can be studying the effect of local changes after FD deployment in the entire brain circulation. However, modeling the fluid dynamics of blood in the entire brain circulation is complicated. Lumped parameter model, which is based on electrical circuit analogy, can provide a simple model for the entire circulation. Characterizing the local changes of aneurysm segment after FD implantation and using these local changes in the 0D model of brain circulation can help researchers study the effect of those changes on the entire brain blood circulation and the mechanism of DIPH. This study characterizes the resistance and inertance of aneurysm segment to simulate the changes due to FD device deployment.

METHODS

In this study, a total of 27 patient-specific aneurysm models constructed from the 3D images were used to perform CFD simulations. Navier-Stokes equations were numerically solved while assuming rigid vessel walls. Two cardiac cycles with a timestep of 0.01 second were performed and the results of the second cycle were used to calculate the pressure difference.

Local Resistance Changes Two models were made for each aneurysm to calculate the local resistance of the aneurysm segment. In each case, the first model was the original model with aneurysm and the second one without aneurysm. In the second model, the aneurysm was removed virtually to simulate the condition of flow divertor implantation when aneurysm occludes completely.

To calculate the pressure drop due to aneurysm, the skeleton of the parent artery was created where two groups of points were defined (Figure 1): one group before the aneurysm (proximal points) and the other one after the aneurysm (distal points). Then three steady state CFD simulations were performed with three different inflow rates as the inflow boundary conditions. The pressure drop for each inflow rate for both models (the original model and the model without the aneurysm) were calculated between the proximal and distal points (Equation (1)).

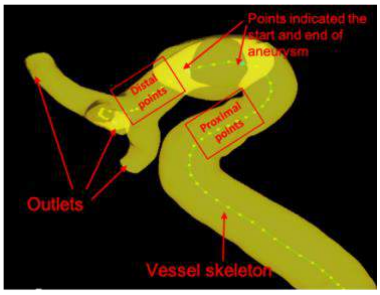

Figure 1: Skeleton made along the parent artery for calculating the local resistance and inertance of aneurysm segment.

The pressure drop along the aneurysm segment was plotted against the inflow rate for both models, and the slope of the linear regression fitted to both curves was calculated — Figure 2 shows the process for the original model. This slope shows the resistance, as Equation (2) indicates.

$$\Delta P = P_{proximal} - P_{distal} \quad (1)$$

$$\frac{\Delta P}{Q} = R \quad (2)$$

The change in the resistance of the aneurysm segment between the two models was calculated based on Equation (3).

$$\Delta R = \frac{R_{without\ CA} - R_{original}}{R_{original}} \times 100 \quad (3)$$

where $R_{original}$ is the resistance of the original model and $R_{without\ CA}$ is the resistance of the model with removed aneurysm. All these steps were repeated for the 27 patient-specific aneurysm geometries among which the maximum change in resistance (ΔR in Equation (3)) was found.

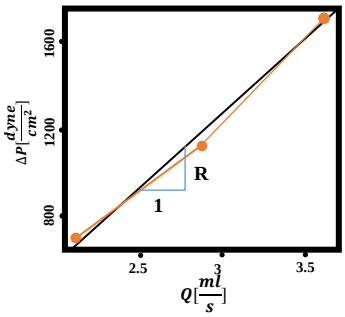

Figure 2: Pressure drop vs. inflow rate for the original model, the slope equals the resistance.

Local Inertance Changes To calculate the local inertance change of aneurysm segment, unsteady CFD simulations were performed. A sinusoidal flow rate (Equation (4)) was considered as the inflow boundary condition.

$$Q(t) = Q_0 + q\, e^{i\omega t} \quad (4)$$

where q is the amplitude of the flow wave, Q_0 is the mean steady state flow rate, ω is the angular frequency of the wave, and t is the time. The pressure drop also was broken into steady and unsteady parts as Equation (5) shows.

$$\Delta P(t) = \Delta P_0 + p\, e^{i\omega t} \quad (5)$$

where p is the magnitude of the pressure wave, and ΔP_0 is the mean steady state pressure drop.

Equation (6) shows the lumped parameter equation.

$$\Delta P = R\,.\,Q + L\frac{dQ}{dt} \quad (6)$$

After inserting Equations (4) and (5) into Equation (6), the result can be broken into two parts: the mean steady state pressure (Equation (7)) and the unsteady contribution of pressure (Equation (8)).

$$\Delta P_0 = R.\,Q_0 \quad (7)$$

$$p\, e^{i\omega t} = R\,.q\, e^{i\omega t} + L\,.\,i\omega q e^{i\omega t} \quad (8)$$

by simplifying Equation (8), Equation (9) was derived. Then $p - R.\,q$ was renamed as ΔP_l (Equation (10)).

$$p = R\,.q + L\,.\,i\omega q \quad (9)$$

$$\Delta P_l = p - R\,.\,q \quad (10)$$

Three CFD simulations with different flow amplitudes (q) and with resistances calculated in the previous part were performed. Then, ΔP_l vs. ωq was plotted for both models. The slope of the linear regression fitted to the plots gave the inertance of the aneurysm segment.

Equation (11) was used to calculate the inertance change between the two models.

$$\Delta L = \frac{L_{without\ CA} - L_{original}}{L_{original}} \times 100 \quad (11)$$

where $L_{original}$ is the inertance of the original model and $L_{without\ CA}$ is the inertance of the model without the aneurysm. This process was repeated for 27 patient-specific geometries among which the maximum inertance change was found.

RESULTS

Analysis of 27 patient-specific aneurysm geometries showed that removal of aneurysm because of FD devices leads to 15.6% and 19% maximum changes in, respectively, the resistance (ΔR) and inertance (ΔL) of the aneurysm segment.

The results also showed that ΔR and ΔL are linearly correlated with an R^2 of 0.91 and a p-value less than 0.001. This study also showed that ΔR and ΔL have no clear relationship with aneurysm size and shape. However, R and L seem to be related to flow domination in shear-driven or inertia-driven flows [9].

DISCUSSION

In this study, the change in pressure due to aneurysm removal (i.e. aneurysm occlusion after FD treatment) was consistent with the previous studies [10][11] that showed the pressure changes after FD deployment. The magnitude of ΔR and ΔL were calculated here from 27 patient-specific aneurysm geometry. There seemed to be an association between these changes and intra-aneurysmal flow as also reported by previous studies [12][13]. The maximum changes of local resistance and inertance of aneurysm were 15.6% and 19%, respectively. These results can be used in the 0D model of the entire brain circulation to study the effect of local hemodynamic changes – because of the FD – and to study the mechanisms of DIPH. The flow condition before and after FD treatment can be modeled by changing the local resistance and inertance. The maximum changes of the resistance and inertance calculated in this study can show the maximum possible change in these parameters in other parts of the brain circulation model.

A limitation of this study comes from assuming Poiseuille flow in the parent artery segment. This is the basic assumption of the lumped parameter model. Future studies can use more realistic methods to calculate the local changes.

In summary, this study calculated the magnitude of maximum changes of the resistance and inertance of aneurysm segment. These changes were up to 15.6% and 19%, respectively, for the local resistance and inertance.

ROLE OF SUBSTRATE STIFFNESS ON PLURIPOTENCY AND DIFFERENTIATION OF HUMAN EMBRYONIC STEM CELLS

INTRODUCTION

Pluripotent stem cells (PSCs) have the potential to differentiate into any cell types but, to differentiate them into specific lineage continues to be a challenge for researchers. While signaling molecules are well known to initiate lineage specific differentiation, recent studies using various biomaterials have shown that the stem cells respond to the biophysical cues from extracellular matrix which in turn modulates specific differentiation [1-3]. Substrate stiffness alone has been shown to regulate cellular adhesion, cell spreading, proliferation and differentiation [4,5]. Specifically, substrates with the stiffness mimicking that of biological tissue induces differentiation in adult and pluripotent stem cells towards the corresponding lineage. MSCs when cultured on soft and stiff substrates differentiate into adipogenic and osteoblastic lineage respectively [6-9].

Hippo pathway regulated transcriptional co-activators YAP and TAZ mediates substrate-dependent stem cells behavior via cytoskeletal tension [10]. YAP is known to integrate several signals from soluble biomolecules as well as insoluble cues from microenvironment (such as substrate stiffness, topology, cell polarity etc.) [11,12]. Numerous studies in mesenchymal stem cells (MSCs) have shown YAP activation and nuclear localization on stiff substrate depends on reorganization of F-actin bundles. Conversely on soft substrate, since there is less tension created on cytoskeleton, YAP remains in the cytoplasm in phosphorylated and inactive state [6,13-14]. However, the role of biochemical cues in stiffness-dependent YAP/TAZ regulation still remains unclear. Whether the differentiation is triggered by YAP/TAZ or by the varying the substrate stiffness alone still remains a question. Comparatively to MSCs, the effect of mechanical cues on human PSCs have received less attention.

The above considerations and the fact that embryonic stem cells in the early embryo development experiences soft environment a contrast to the stiff environment of *in vitro* culture conditions, motivated us to investigate whether the change in the substrate stiffness induces differentiation of human embryonic stem cells (hESCs).

To achieve this, we cultured hESCs on varying substrate stiffness with pluripotency maintaining media and with differentiation inducing media. Since the response of human MSCs to substrate stiffness is well established were used them as control. The expression of pluripotency markers OCT4 and NANOG, and lineage specific markers *SOX17* (endoderm), *PAX6* (ectoderm) and *BRACHYURY* (mesoderm) was checked by western blot and qRT PCR respectively. We also looked at the expression of Hippo pathways proteins YAP, TAZ, MST1, MOB1, LATS and SAV1 by western blot.

METHODS

Cell culture

KIND1 (hESCs cell line) and hMSCs were cultured on tissue culture treated plates (TCP) and CytoSoft® (CS) substrates having stiffness of 0.2kPa (kilopascal), 0.5kPa, 2kPa, 8kPa, 16kPa, 32kPa and 64kPa for four days over three passages. 0.2kPa-8kPa is considered as soft substrate and 16-64kPa as stiff substrate for the study. For maintaining pluripotency KIND1 cells were maintained in Essential 8 (E8) media. For differentiating conditions KIND1 cells were maintained in Advanced DMEM media with 2% FBS. hMSCs were cultured in IMDM media with 10% FBS and 1% GlutaMax.

mRNA expression analysis

Gene expression studies were carried out by qRT PCR. For each sample, normalized threshold cycle (ΔCt) was calculated by subtracting Ct values of each gene with the corresponding Ct value of the sample of 18S rRNA (housekeeping gene). The relative fold change in global expression was obtained by $2^{-\Delta\Delta Ct}$ method. Each PCR was carried out in

duplicates by samples from three biological replicates, with 3 technical replicates each.

Protein expression analysis

Protein expression was studied by western blot. An equal concentration of protein was loaded on SDS-PAGE. Primary antibodies were labelled to target proteins, then HRP-conjugated secondary antibody was added for visualization. Each fold change was plotted against cells cultured on different substrate with respect to the cells on TCP after normalizing with GAPDH.

Statistical analysis

All statistics were performed using ImageJ software (National Institute of Health, USA) and GraphPad Prism software. Multiple comparisons were assessed using two-way ANOVA variance analysis and Turkey's Multiple Comparison Test.

RESULTS

To investigate the matrix-induced changes in stem cells we cultured hESCs and hMSCs on CS substrates of different stiffness. We observed that hESCs on CS substrates did not show any morphological difference compared to cells on TCP in Essential 8 and Advanced DMEM medium. hESCs were in compact colonies with proper cell spreading. hMSCs showed less cell spreading and less number of cells on soft substrates compared to stiff substrate and TCP. hMSCs on stiff substrates showed elongated fibroblast like morphology similar to hMSCs on TCP. Other than visual observation, the proliferation was also checked by the Cyclin D1 protein expression in hESCs on all the substrate.

Pluripotency and Differentiation study

We investigated the expression of pluripotency markers OCT4 and NANOG in hESCs cultured in E8 and Advanced DMEM media on all the substrates. Surprisingly, hESCs cultured on soft as well as stiff substrates did not show any change in the expression of pluripotency markers OCT4 and NANOG as seen by the western blot (Figure 1,2). No expression of lineage specific markers *SOX17*, *PAX6* and *BRACHYURY* was seen by qRT PCR in hESCs cultured in E8 media, however, when cultured in Advanced DMEM, *BRACHYURY* expression was seen in more in soft substrate than stiff substrates. This suggests that the hESCs maintained their pluripotency despite the stiffness change but differentiated into mesoderm lineage on soft substrate due to differentiating media.

Relationship between Hippo pathway and substrate stiffness

Since Hippo pathway is the main regulator of YAP/TAZ we wanted to study the effect of substrate stiffness on Hippo pathway proteins. First, we studied the expression of MST1, SAV1, LATS, MOB1, YAP, pYAP and TAZ in hESCs cultured in E8 media by western blot. MST1 and SAV1 expression was drastically reduced on soft and stiff substrate when compared to TCP. No expression of LATS was seen in any of the substrates except TCP, MOB1 expression did not change significantly in either of the substrates when compared with TCP. YAP expression was lower on soft substrate, however stiff substrate showed high expression of YAP than TCP. Alternatively, pYAP showed high expression on soft substrates whereas almost no expression was seen on stiff substrates as compared to TCP (Figure 1,2). This suggests that substrate does affect the Hippo signaling pathway. Other than F-actin, Hippo pathway might be involved in regulating the expression of YAP on soft substrate. However, this needs to be explored further. Next, we changed the media to Advanced DMEM to check whether adding differentiation media change the expression of YAP and pYAP. YAP expression was less in all the other substrates however the expressions were high than E8 media. pYAP expression increased gradually from soft substrate to stiff substrate.

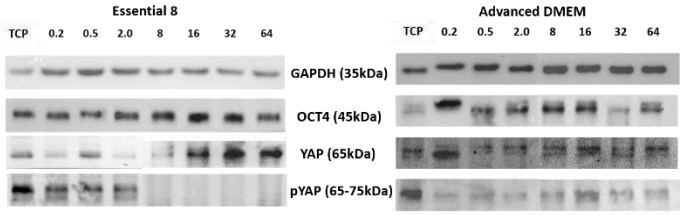

Figure 1: Protein expression in hESCs when cultured with (A) Essential 8 media and (B) Advanced DMEM.

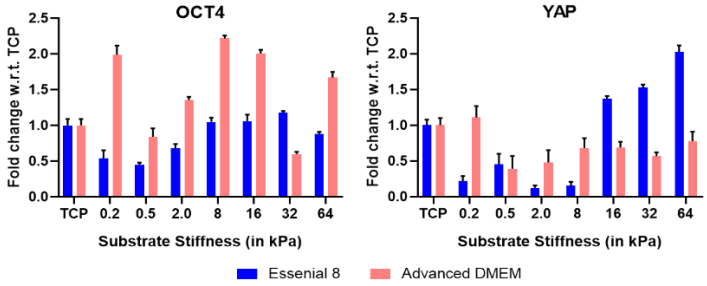

Figure 2: Western bot analysis of OCT4 and YAP shows no statistical difference between each stiffness.

DISCUSSION

Most of the published literature has shown that mouse ESCs and hMSCs differentiate in response to substrate stiffness. However, our findings suggest that substrate stiffness alone does not induce differentiation in hESCs. This suggests that there is some fundamental difference between these stem cells and the way they respond to changes in their environment. hESCs did not differentiate in response to stiffness exclusively, however, once differentiation inducing media was added it led to differentiation, thus it implies that biochemical cues play an important role in cell differentiation that substrate stiffness. It has been previously reported that decrease in YAP expression causes loss of pluripotency in stem cells however, our findings suggests that hESCs maintain a basal level of YAP expression and did not corelate directly with pluripotency. Thus, we show that the correlation of the YAP and pluripotency in hESCs on varying substrate stiffness needs to be explored further.

EFFECTS OF MARATHON TRAINING ON MALE AND FEMALE FEMORAL STRESS FRACTURE RISK

Clara Lin, Scott J. Hazelwood

Department of Biomedical Engineering
California Polytechnic State University
San Luis Obispo, CA, USA

INTRODUCTION

Marathon runners are prone to femoral stress fractures due to high magnitudes and frequencies of loads during training. Stress fractures result from bone fatigue and insufficient bone toughness caused by microcracks in bone tissue [1]. Bone has a cellular remodeling response to remove damaged tissue, but accumulation of microcracks may propagate into stress fractures if the rate of removal cannot keep up with damage accretion. In addition, bone remodeling temporarily reduces bone density and load-bearing ability as damaged bone tissue is removed by osteoclasts creating resorption cavities.

Femoral fractures are common in runners yet difficult to diagnose and treat [1]. Understanding the mechanisms behind this injury and preventing fracture is ideal. Females runners tend to have a higher incidence of stress fractures compared to males [2]. This discrepancy in injury rate may be influenced by sex-specific differences in hip geometry, joint pressure, and muscle activation patterns that affect bone remodeling. Prior studies have found that females have a proportionally wider pelvis, higher hip joint pressure, and greater gluteal muscle activation during running with respect to body weight [3]-[8].

The purpose of this study was to develop a 3D finite element model of the male and female femur during marathon training. This model builds upon prior bone remodeling and finite element studies by focusing on how sex-specific differences observed in female athletes affect bone remodeling during marathon training [9], [10]. This model tested the hypothesis that female marathon runners have lower density and more bone damage at sites of interest after marathon training, which may contribute to greater stress fracture risk compared to males.

METHODS

Finite Element Model Development

A 3D femur finite element model integrated with a mechanistic bone remodeling algorithm [10] was used for the analysis. The finite element mesh was derived from a CT-scan of a male cadaveric femur and consisted of 29,175 quadratic tetrahedral elements. Briefly, the bone remodeling algorithm simulated bone adaptation by cellular activity responding to the level of loading and fatigue microdamage. Bone was assumed to have evolving elastic moduli for cortical (Eq. 1) and trabecular (Eq. 2) bone dependent on porosity, *p*.

Elastic Modulus for Cortical Bone (for $p < 9.7\%$)

$$E_{cortical}\ (MPa) = 23440(1-p)^{5.74} \quad (1)$$

Elastic Modulus for Trabecular Bone (for $p \geq 9.7\%$)

$$\mathrm{E_{trabecular}}(MPa) = 14927(1-p)^{1.33} \quad (2)$$

Microdamage formation in bone was assumed to be proportional to strain and the number of load cycles. Damage removal was a function of the osteoclast activity and the area resorbed. A remodeling period of 24 days for bone resorption followed by 64 days for formation was used. All finite element analyses were performed in Abaqus 2020 (Dassault Systems, Rhode Island, United States).

Baseline Model and Validation

First, a baseline model with properties representative of a mature, active adult femur was established. Hip joint contact and muscle forces for the gluteus medius, gluteus minimus, adductor longus, adductor brevis, psoas, vastus lateralis, and vastus medialis muscles were incorporated based on a 725 N body weight male and 556 N body weight female. To model sex differences in hip structure, the angle of the abductor muscle forces (Male: 24.2°, Female: 19.4°) and magnitude of the hip joint contact pressure (Male: 250% body weight, Female: 313% body weight) were modified for the male and female models respectively [5]-[8]. 5,000 cycles per day (per leg) of heel-strike and toe-off loading conditions were applied to model daily activity.

The baseline model was run to achieve steady state values of porosity, damage, and cell activity and then validated by comparing axial strain at four femoral locations in the model to experimental strain gauge results from a previous study [11].

Marathon Training Simulation

After the validated baseline model was achieved, a 16-week marathon training schedule with mileage ranging from 28-45 miles and two rest days per week was simulated. The training schedule culminated with running a 26-mile marathon. Daily running mileage was converted to cycles per day by assuming 85 cycles per minute at a 7.5-minute mile pace. To simulate running conditions, joint pressure was increased to 520% body weight for males and 651% body weight for females [12]. Gluteus medius and minimus muscle forces increased to 180% of baseline in the male model [12]. Increased muscle activation was modeled in the female gluteus medius (240% of baseline) and vastus lateralis (125% of baseline) [6]. Axial strain, bone mineral density (based on porosity), and damage were analyzed at regions of interest (superior femoral neck, inferior femoral neck, proximal diaphysis, and trochanter) at the end of the training/marathon period.

RESULTS

Increased damage and strain, and decreased bone mineral density, were predicted at all regions of interest after marathon training except for the male trochanter (Table 1). The inferior neck had the highest strain in all models, the greatest increase in strain after marathon training, and the most damage (Table 1, Fig 1a).

Females were predicted to have weaker bone at the superior neck, trochanter, and proximal diaphysis after marathon training compared to males. A greater increase in damage was predicted at these regions, as well as 53% more superior neck damage (Fig 1b) in the female compared to the male model. Strain at the superior neck and trochanter were predicted higher for females, despite their lower body weight.

Table 1: Predicted changes in femur parameters of interest following marathon training

	Superior Neck	Inferior Neck	Proximal Diaphysis	Trochanter
Strain				
Male:	↑ 45%	↑ 92%	↑ 32%	↓ 2.4%
Female:	↑ 44%	↑ 85%	↑ 39%	↑ 30%
Density				
Male:	↓ 0.23%	↓ 23%	↓ 5.7%	↑ 0.2%
Female:	↓ 0.7%	↓ 21%	↓ 4.4%	↓ 0.1%
Damage				
Male:	↑ 97%	↑ 97%	↑ 43%	↑ 29%
Female:	↑136%	↑ 91%	↑ 50%	↑ 43%

DISCUSSION

Weaker baseline bone and increased gluteal muscle activation may have increased strain and damage more in the female model. Since the female model had baseline muscle and joint pressure loads scaled to a lower body weight, the femur may have been less able to bear the higher volume and magnitude of marathon training loads. Closer analysis at the trochanter and superior neck show that females have lower bone mineral density than males at these regions (Fig 2). A scaled-up gluteus medius muscle force was applied to the female model, but this increase may not have been large enough to counterbalance high loads from running, causing more load to be transferred to bone. The gluteus medius insertion point is also located at the trochanter, which was predicted to have greater strain and damage in females.

Stress fracture risk depends on interactions among microdamage, the remodeling response, and resulting bone strength. A small increase in microdamage may significantly impact strength if bone has already reached a level of reduced bone mineral density [13]. While it is not clear if the greater strain and damage predicted for females is significant enough to increase fracture risk compared to males, these predicted model trends suggest that bone becomes weaker, which could potentially increase likelihood of stress fracture for females over time.

MECHANICAL STIFFNESS REGULATES CHROMATIN REMODELING IN MESENCHYMAL STEM CELLS

INTRODUCTION

Multipotent mesenchymal stem/stromal cells (MSC) from different sources such as bone marrow and adipose tissue are highly promising candidates for tissue engineering and regenerative medicine. Despite having multi-differentiation ability, immunomodulatory and trophic properties, scalable application of MSC at the clinical endpoint is limited. To achieve a clinically relevant number of MSC, a small amount of autologous MSC must be expanded to millions of MSC. During the *in vitro* expansion process, MSC gradually lose their stemness and regenerative capability. Mechanics of the culture substrate is a potential candidate among several factors that might promote loss of the MSC phenotype [1,2]. Recently, we and other groups found that the mechanics of the cellular environment can define the tissue specific cellular phenotype through the modulation of intranuclear mechanics and chromatin architecture via epigenetic mechanisms [3,4]. Our objective in this work is to understand how the mechanics affects the MSC phenotype, specifically the deviation from the MSC-like characteristics in culture through chromatin remodeling and epigenetic mechanisms. We investigated how the substrate mechanical stiffness affects the nuclear morphology, intranuclear chromatin architecture and the epigenetic hallmarks using bone marrow derived human MSC.

METHODS

Cell culture: Primary human MSC derived from bone marrow were cultured (PT-2501, Lonza). Passage 3 cells were cultured on either a soft PDMS substrate (Sylgard 527, Dow) with a type I collagen coating or a stiff substrate, which was standard tissue culture plastic. Imaging of the soft substrate required a thin PDMS gel to be made using our optimized protocol.

Imaging and analysis of nuclear and cell morphology: Cells were fixed with 4% PFA, washed in 1X PBS, and stained with DAPI and phalloidin (Thermo Fisher) then imaged using a confocal microscope (Zeiss LSM 980). ImageJ was used to compute the nuclear aspect ratio and roundness.

Imaging and analysis of chromatin architecture: DAPI stained fixed cell nuclei were imaged using a confocal microscope (Olympus IX83). Chromatin segregation index was calculated using a previously published code [5].

Imaging and analysis of epigenetic marker H3K27me3: Cells were fixed in 4% PFA and immunostained to visualize H3K27me3 (CST). Imaging was performed using a laser scanning confocal microscope (Zeiss LSM 980). For high resolution immunofluorescence imaging with a 63× oil objective, the Airyscan 2 modality was used. Low magnification images were used to quantify the relative intensity of the H3K27me3 normalized to the DAPI channel fluorescence intensity, where all imaging parameters were the same for the different groups. ImageJ was used to apply a FFT filter and subsequent thresholding using the same parameters on each image for spatial characterization of H3K27me3 from high magnification nuclei images.

Gene expression study: Total RNA was extracted from cells (Qiagen), reverse transcribed into cDNA and subsequently real time quantitative PCR was performed using QuantStudio 3 (Thermo Fisher). GAPDH was the control gene and primers were custom designed.

Statistics: Student's t-test was used to compare different groups. *p value of < 0.01 represents statistically significant difference.

RESULTS

As reported in numerous previous studies, the cells better maintained their MSC phenotype on the soft substrate, indicated by the spindle-like shape (Figure 1) and diffuse actin in the cytoskeleton. Cells showed relatively more flattened, fibroblast-like phenotype with actin stress fiber formation when cultured on the stiff substrate.

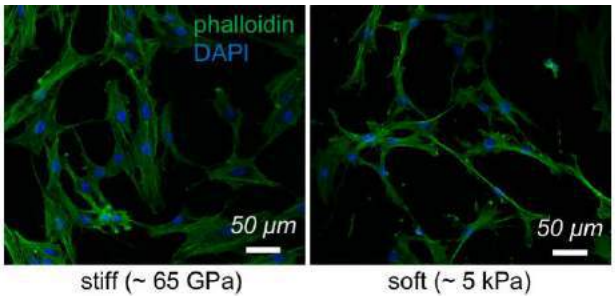

Figure 1. MSC cultured on stiff and soft substrates show different cellular and nuclear shape. Soft substrate promotes a spindle like cell phenotype and elongated nuclear phenotype, along with lower amount of cytoskeletal stress fiber formation.

Cells cultured on soft substrate promoted an elongated nucleus in the subsequent subculture (passage 4) as characterized by the higher aspect ratio and lower roundness values (Figure 2). However, subculture on the soft substrate better preserved the MSC specific chromatin architecture even though they were previously cultured (primed) on a stiff substrate. Open chromatin architecture and therefore, a higher value of chromatin segregation is a hallmark of stem cells.

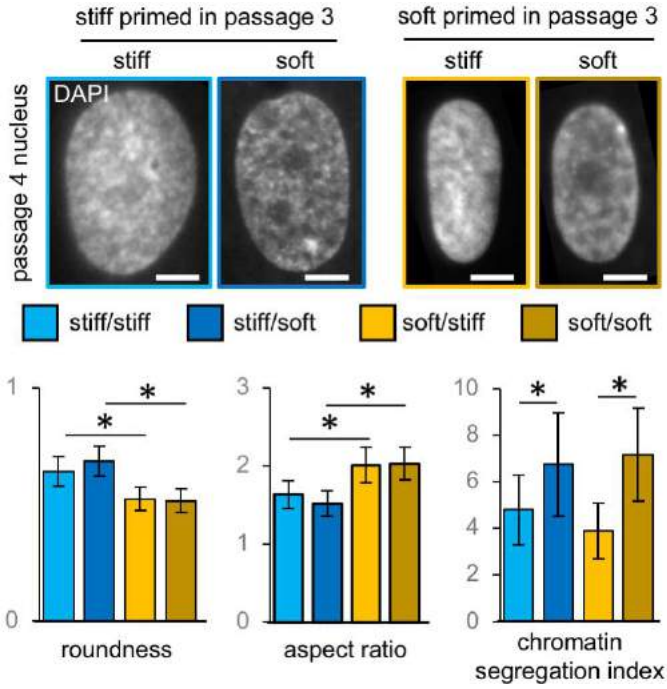

Figure 2. Nuclear morphology and chromatin architecture are different for MSC cultured on substrate with different stiffness. Soft priming of cells promotes more elongated nuclei. Subculture on soft substrates promote chromatin segregation and open chromatin, a hallmark of MSC. Scale bar: 10 μm. Error bar: SD.

To understand whether the chromatin architecture might be potentially associated with the transcriptional status of the genes, we quantified the expression of the transcriptionally repressive histone modification marker H3K27me3. We found that the expression of H3K27me3 is lower in cells cultured on soft substrates (Figure 3), in line with the previous finding that epithelial cells showed lower intensity of H3K27me3 in mechanically strained cells [4]. To further understand how the epigenetic marker is related with the MSC chromatin architecture, we visualized the spatial distribution of H3K27me3 in the nuclei at high resolution. We found that for MSC on soft substrate H3K27me3 is mostly localized near the nuclear periphery thus opening the nuclear interior, whereas on the stiff substrates they are homogeneously distributed in the nucleus, in accordance with a diffuse chromatin architecture (Figure 4a). Interestingly, the gene ARID1A which makes the BAF250A protein (a key component of chromatin remodeling mechanism) was highly expressed in cells cultured on stiff substrates (Figure 4b).

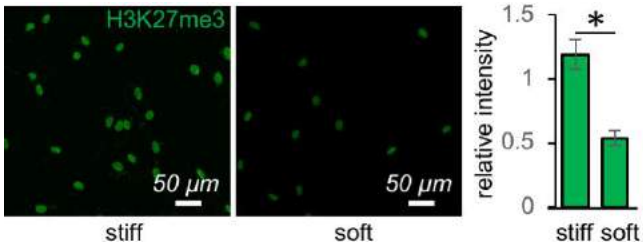

Figure 3. Soft substrate promotes lower amount of H3K27me3, an epigenetic marker for transcriptional repression. Error bar: SD.

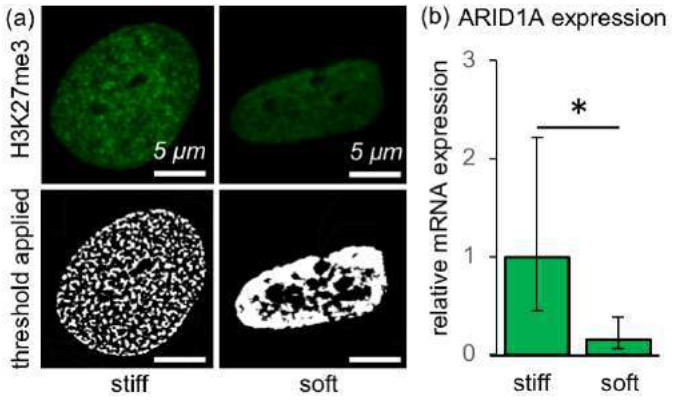

Figure 4. (a) Stiff substrate is associated with a homogeneous distribution of H3K27me3. Soft substrate is associated with a more distinct localization of H3K27me3 clusters at the nuclear periphery. (b) Gene related to chromatin remodeling protein BAF250A is more expressed in cells cultured on stiff substrates (error bars are based on maximum and minimum values, not standard deviation).

DISCUSSION

Our findings suggest that mechanics affects the chromatin architecture and the distribution of the epigenetic marker through possible mechanosensitive mechanism associated with chromatin remodeling. It has been recently found that in response to mechanical strain, the emerin-actin-non muscle myosin IIA complex functions as a nuclear force sensor that controls H3K27me3 occupancy [4]. Stiffer substrates, resulting in higher strain, promote a diffuse chromatin architecture, higher transcriptional repression and more homogenous distribution of the transcriptionally repressive histone modifier. These chromatin remodeling patterns are possibly aided by the chromatin remodeler BAF250A. Further mechanistic studies will reveal how the mechanics functionally alters the MSC resulting into the loss of MSC phenotype, opening novel possibilities to intervene such mechanism.

INTRODUCTION

Right ventricular (RV) strain measurements from speckle tracking echocardiography (STE) are being used more frequently as a non-invasive diagnostic tool for cardiopulmonary pathologies, including pulmonary embolism, heart failure, acute respiratory distress syndrome, pulmonary hypertension, and even SARS CoV-2 [1-7]. Despite the clinical utility of RV STE, previous attempts to quantify RV strain in rodent models have been limited due to ultrasound-based artifacts and non-standardized imaging procedures [8-11]

Here we present a simple method for *in vivo* estimations of RV strain using high frequency ultrasound and automated speckle tracking. We demonstrate that reliable RV strain values can be obtained in rodents with modified imaging and analysis techniques that optimize the echocardiographic view of the RV free wall while limiting lung and rib artifacts. A small number of groups have successfully estimated RV strain in rats using STE [8, 10], yet this is the first time to our knowledge that a method for the estimation of RV strain in mice has been described.

METHODS

Twenty-five-week-old female wild-type CD-1 mice (n=5; Charles River, Wilmington, MA), ten-week-old female C57BL/6J (B6) mice (n=5; Jackson Laboratories, Bar Harbor, ME) , eleven-week-old male B6 mice (n=5; Jackson Laboratories, Bar Harbor, ME), and six-week-old male Sprague Dawley wild-type rats (n=5; Charles River, Wilmington, MA) were used for RV imaging and analysis.

For ultrasound imaging, we used the Vevo3100 system (FUJIFILM VisualSonics Inc., Toronto, Ontario Canada) with a 21 MHz center frequency linear array ultrasound transducer probe (15-30 MHz bandwidth; MX250) for rats and a 40 MHz center frequency linear array ultrasound transducer (25-55 MHz bandwidth; MX550D) for mice. The probes for both mouse and rats were positioned just lateral to the sternum at approximately a 30° angle from the midline in order to obtain a modified parasternal long axis view of the right ventricle (Figure 1). By adjusting the ultrasound probe angle, we optimized our view of the RV free wall and limited anatomical image artifact. We then used a speckle tracking algorithm (VevoStrain, FUJIFILM VisualSonics Inc.) to quantify wall motion and calculate mechanical parameters such as longitudinal strain, strain rate, displacement, and wall velocity for both the endocardial and epicardial borders.

Additionally, we estimated the 2D Green-Lagrange full strain tensor using the endocardial and epicardial boundaries and displacement information provided by the speckle tracking algorithm. For each time point, the 2D version of the deformation gradient tensor ($\boldsymbol{F}$) was calculated [12, 13]. The deformation gradient tensor was then used to estimate the Green-Lagrange strain tensor ($\boldsymbol{E_{2D}}$; eq.1) using the following equation where $\boldsymbol{I}$ is the identity matrix, E_{zz} is the component of the strain tensor that corresponds to the longitudinal strain, E_{rr} is the component that corresponds to the radial strain, and the E_{zr} and E_{rz} components correspond to the shear strain.

$$\boldsymbol{E_{2D}} = \frac{1}{2}(\boldsymbol{F^T F} - \boldsymbol{I}), \quad \boldsymbol{E_{2D}} = \begin{bmatrix} E_{zz} & E_{zr} \\ E_{rz} & E_{rr} \end{bmatrix} \tag{1}$$

RESULTS

We estimated peak RV free wall endocardial longitudinal strain values in female CD-1 (-10.7±0.1%), female C57BL/6J (-10.1±1.0%), and male C57BL/6J (-10.4±0.8%) mice (mean±SEM; n=5/group). As there was no statistical difference between the strain measurements from each mouse group (ANOVA, p=0.85) a combined analysis was also performed with estimated peak RV free wall endocardial longitudinal strain of -10.4±0.4% in mice (n=15, Figure 1). Another group of male Sprague Dawley rats had an average peak RV free wall strain of -4.85±0.42% (n=5). We further demonstrated a full-wall strain analysis approach by estimating the longitudinal component of the Green-Lagrange strain tensor to be -5.7±0.48% in mice and -2.1±0.28% in rats. Finally, we found that the RV estimated parameters were not significantly different in mouse groups when stratifying by age (10-25 weeks), sex, or genetic strain (CD-1 vs. B6).

DISCUSSION

From these results we found that it is possible to estimate RV free wall strain in rodents. Additionally, we found that our RV estimated parameters were not significantly different between mouse groups with different age (10-25 weeks), sex, or genetic strain (CD-1 vs. B6).

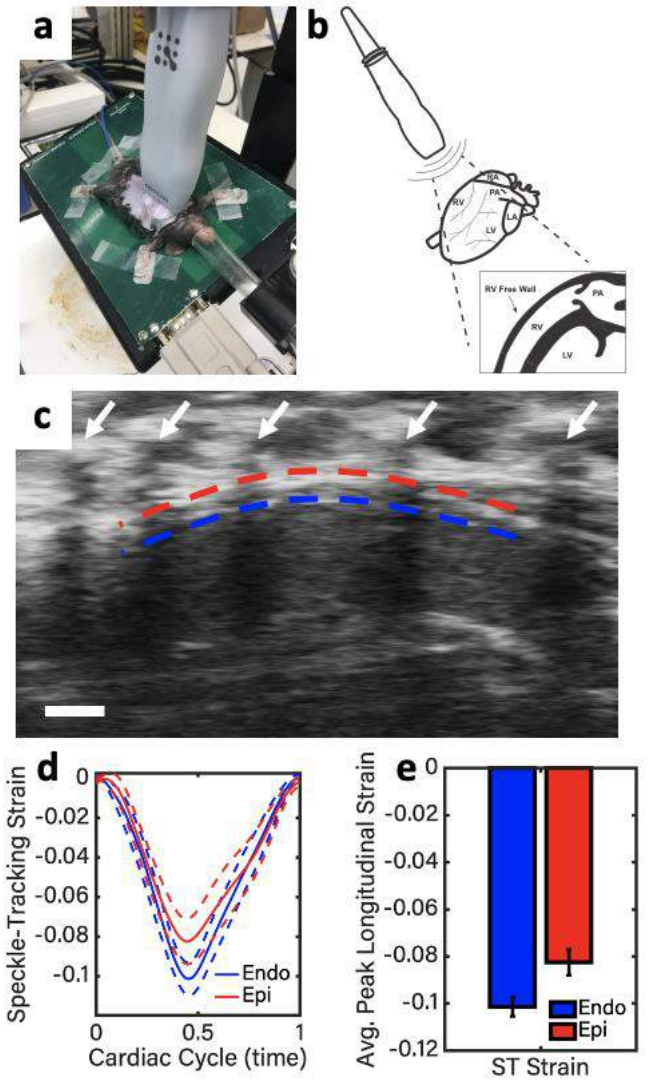

Figure 1: Right ventricular strain estimation in wild-type mice (n=15) (a) A 40 MHz center frequency linear array transducer was used to acquire right ventricular images. (b) A depiction of the unique parasternal long-axis imaging window used to maximize RV free wall visualization. (c) Representative ultrasound image where the red dotted line indicates RV free wall epicardial border, the blue dotted line indicates RV free wall endocardial border used in the analysis, white arrows indicate rib shadow artifacts. Scale bar = 1mm. (d) Average RV endocardial (blue) and epicardial (red) free wall longitudinal strain with 95% CI (solid and dashed lines) over a normalized cardiac cycle. (e) Average peak longitudinal strain for RV endocardial (blue) and epicardial (red) free wall longitudinal strain with error bars (mean±SEM).

While the absolute values of RV wall motion parameters presented in this work may need additional validation, the ability to estimate *in vivo* strain consistently in a non-invasive manner is a strength of this approach. This method of strain estimation allows for longitudinal assessments in the same animal, allowing for the characterization of strain differences over time or between control and diseased models. This non-invasive method also allows for a reduction in total animals used in longitudinal studies of RV function as each animal can be imaged at multiple time points without necessitating terminal procedures for data collection. Additional benefits include cost-savings compared to other non-invasive imaging modalities such as magnetic resonance or computed tomography. As with any method, consideration of these limitations and benefits in the context of study design will be important for optimal results.

Measurement of RV strain in a mouse model is of particular interest as mice are so ubiquitously used and studied in the field of translational medicine. For example, genetic, chemical, and surgical models of RV pathology already exist in mice [14-16]. Studying these pathologies in a small animal preclinical model can be helpful to save costs, evaluate novel treatments, and improve translational potential before moving to large animal and human studies. This may be of particular interest or importance in disease models such as pulmonary hypertension or the cardiopulmonary sequela of SARS-CoV-2.

Murine models of heart disease have been and continue to be of paramount importance to the development of our understanding and treatment of cardiopulmonary disease. While ultrasound analysis of the RV has been limited with these models in the past, continued improvements in technology and methods may allow us to utilize these models to their full potential by improving image quality and reproducibility. Additionally, a standardized approach such as the one presented in this work will help with reproducibility and provide valuable metrics for non-invasive longitudinal assessment of diseased models.

ACKNOWLEDGEMENTS

INTRODUCTION

Arteries undergo multiscale growth and remodeling (G&R), including morphological changes and apoptosis of cells during cerebral aneurysm (CA) formation. Despite such changes, vascular smooth muscle cells (VMSCs) contribute to G&R via mechanoadaptation, either remedying or exacerbating the disease state. A commonly used framework to model the mechanics of vascular tissues during G&R is the constrained mixture model (CMM), which captures the mechanisms of microscale constituents responsible for tissue-scale behavior (**Fig. 1A**) (1). In our models, VSMC stress drives cell-mediated G&R, where VSMCs internally remodel, deposit, or degrade surrounding matrix to return to a homeostatic target stress (3). In a cell-sparse tissue, we hypothesize that the CMM assumption that constituents strain equally is less likely to represent the tissue appropriately and the calculated cell stress governing G&R is subsequently less accurate (**Fig. 1B-C**). Here, we simulate cell-sparse systems using finite element (FE) modeling to explore thresholds of cell loss and density where CMM may require modifications to more precisely characterize microscale behavior in disease states.

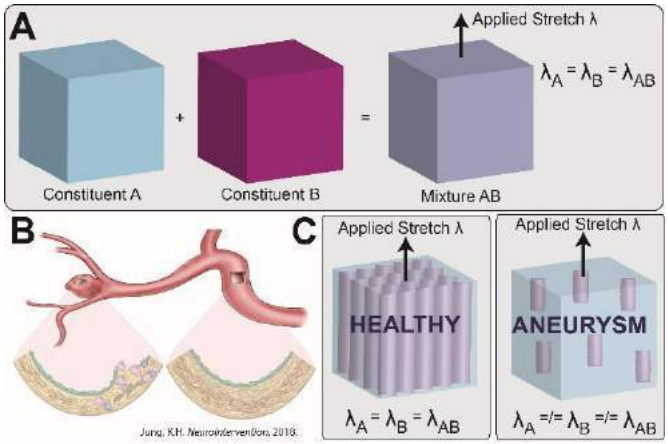

Figure 1. A. Behaviors of constituents undergo the same deformation and are summed to estimate mixture behavior. B. Illustration of CA versus healthy arterial structure (2). C. Presumed deformations of VSMCs in healthy arteries and CAs.

METHODS

Model Geometry. A cubic geometry was created in FEBio with a cell modeled in the center of a box, representative of matrix (4). Eighth symmetry was imposed for simplification (**Fig. 2A**). Multiple geometries, including various volume fractions, aspect ratios, and shapes were created to simulate a wide variety of cellular configurations and morphologies. The model was meshed with hexahedron elements.

Boundary Conditions and Constraints. A uniaxial stretch up to a stretch ratio of 1.33 was applied to the model on the top surface on axis 1 (**Fig. 2A**). The inner faces of the matrix were fixed in their normal directions, while the outer faces on axes 2 and 3 were set to deform inwards, reflective of the Poisson effect in incompressible materials.

Variables and Controls. In the first set of simulations, the cell and the matrix were modeled as incompressible Neo-Hookean (NH) materials with the cell as a cylinder. Different cell volume fractions (VFs) from 0.03 to 0.275 were investigated with changing cylinder heights, influencing a height fraction (HF) varying from 0.1 to 1. The latter HF corresponds to a control cell at its maximum height, completely percolating through the system, thus deforming the same amount as the matrix under applied stretch. Additionally, different ratios of the effective stiffnesses of the cell and the matrix (C/M) were modeled. The second set of simulations investigated the same VFs, HFs, and C/M ratios, but the matrix was modeled as an incompressible

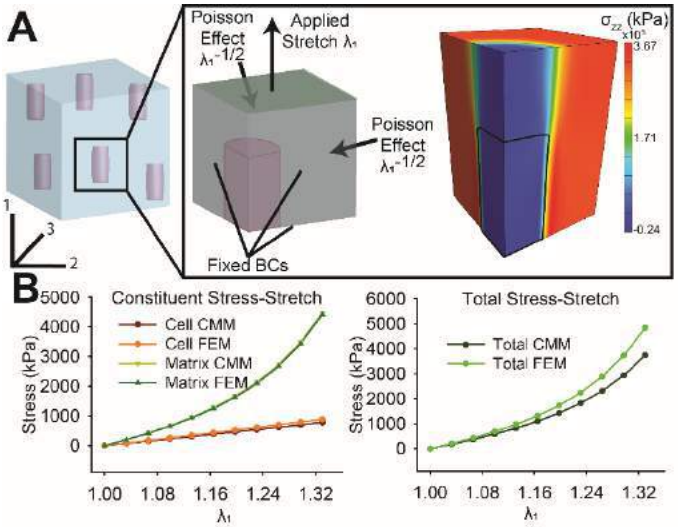

Figure 2. A. Schematic of cell in a box model, with boundary conditions and constraints. Example FE modeled Cauchy stress in 1-direction of deformed configuration. B. Example FE and CMM stress-stretch curves of linear cell in a nonlinear matrix.

Holzapfel-Gasser-Ogden (HGO) material with fibers in the 1-direction (5). The cell was modified to a sphere in the third set of simulations.

Error Analysis. Total, cell, and matrix Cauchy stresses in the 1-direction were calculated at each time step (**Fig. 2B**). A corresponding analytical CMM solution was calculated at each step by

$$\sigma_{tot} = VF_{cell}\sigma_{cell} + (1 - VF_{cell})\sigma_{mat} \quad (1)$$

where σ_{cell} and σ_{mat} are the derived Cauchy stresses of the cell and matrix from their respective material models. The error was defined as the absolute value percent difference of the FE solution from the CMM solution. The percent errors at each step were averaged to obtain single error values for the cell, matrix, and system for all simulations.

RESULTS

The cell stress is the primary value in question for G&R of cell-sparse tissues and is investigated here. Average percent errors against the CMM solution for the simulated cell are plotted across HFs for the first two sets of simulations at different VFs (**Fig. 3A-B**). Additionally, the cylindrical cells at different VFs, fixed at a HF of 0.6, were modeled across different C/M stiffness ratios (**Fig. 3C-D**). Percent errors were plotted across VFs for the third set of simulations at different C/M stiffness ratios (**Fig. 3E**).

NH Cylindrical Cell in NH Matrix. In the first set of simulations, the cell stress error was minimized for HF=1, where the cell fully percolated through the system, undergoing the same deformation as the matrix. As HF decreased, reflective of shortening cells, errors increased, reaching maxima at different HFs for each VF. As C/M ratios were altered, the simulated cell had minimum errors at ratios (~1) where both constituents had similar material properties. Errors increased between the simulated cell and the CMM solution as VFs decreased, indicative of smaller, less dense cells.

NH Cylindrical Cell in HGO Matrix. In the second set of simulations where the matrix was modeled as an incompressible HGO material with fibers in the 1 direction, similar trends as seen in the first set were observed, but with higher percent errors.

Neo-Hookean Spherical Cell in HGO Matrix. In the third set of simulations in which the cell was modeled as a sphere, different C/M stiffness ratios were modeled across increasing cell VFs. Like the former sets, cell error increased as VF decreased. Errors also decreased as C/M stiffness ratios increased, reflective of increasing similarity between the apparent stiffnesses of the cell and matrix, though it must

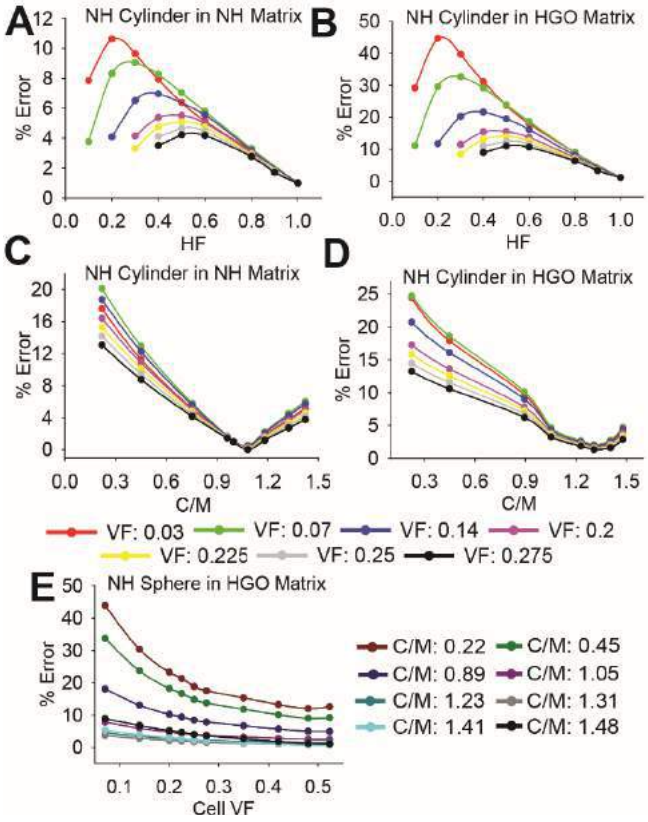

Figure 3. A. NH cylindrical cell in NH matrix (set 1) over cell HFs. B. NH cylindrical cell in HGO matrix (set 2) over cell HFs. C. NH cylindrical cell in NH matrix (set 1) over C/M ratios. D. NH cylindrical cell in HGO matrix (set 2), over C/M ratios. E. NH spherical cell in HGO matrix (set 3), over various cell VFs.

be noted that towards the highest C/M ratios (1.23 and up), the errors start to slowly increase as the cell becomes stiffer than the matrix.

DISCUSSION

The results show that in denser systems with higher cell VFs, simulated cell stresses closely match those of the CMM solution. Additionally, CMM is accurate in sparse systems, but only where cells percolate through their matrix at higher cell heights. Such findings demonstrate that cell shape alongside cell sparsity influence cell behavior to deviate from the assumptions followed in CMM (1). This is consistent with our proposition that increased system heterogeneity in diseased arteries may warrant a different or modified mixture law.

We will modify CMM to capture distributions in constituent deformations as a function of their geometries and the applied deformation. However, continued simulations are required to thoroughly elucidate the efficacy of the existing form on sparse systems. Our future work will include modeling systems where the fiber distribution is localized around the vicinity of the cell and is a function of the distance from the cell. This will recapitulate phenomena in which cells deposit and remodel surrounding matrix, contributing to increased system heterogeneity that may further affect the robustness of CMM.

INTRODUCTION

Aneurysm wall enhancement (AWE) measured by high-resolution vessel wall imaging (HR-VWI) has been used to assess wall inflammation and insatiability of cerebral aneurysm (CA) in recent years [1]. Physicians can manage patient treatment strategies based on AWE assessment. Stable aneurysms based on evaluation of AWE may be monitored over time without considering an immediate surgical or endovascular treatment with their life-threatening complications [2].

However, the mechanisms of AWE are still unknown. A study indicated an association between AWE and intramural thrombus of ruptured aneurysms and suggested that rapture points could be identified by AWE [3]. Other studies have studied relationships between AWE and known rupture risk factors such as size, aneurysms location, and shape irregularity [4,5,6]. Recently, another study showed that aneurysms with AWE had lower wall shear stress (WSS), lower velocity, and larger size compared to the aneurysms without AWE [7].

This study aims to investigate the association between local flow conditions and AWE regions of aneurysm to better understand AWE mechanisms. Here, 7T-MRI is used to segment AWE and then to calculate the local flow conditions in different regions of CA by computational fluid dynamics (CFD) simulations.

METHODS

In this research, twenty patients with 23 unruptured cerebral aneurysms were studied. The CAs imaged by 7T-MR included a TOF-MRA and a 3D T1-weighted MRI before and after gadolinium (Gd) injection.

Patient-specific aneurysm models constructed from the 3D images were used in this work to perform CFD simulations. Navier-Stokes equations with pulsatile inflow conditions were numerically solved. Outflow boundary conditions were defined based on Murray's law and the vessel walls were assumed rigid. Two cardiac cycles with a timestep of 0.01 second were performed and the results of the second were used to calculate the local hemodynamics parameters of aneurysms and AWE regions.

To map the segmented AWE regions to CFD models of aneurysms, we followed a specific methodology. First, 3D models were constructed from available 3D images. Second, the image processing software Amira was used to align a rough segmentation of TOF-MRA to the 3D model. Third, AWE regions were segmented from the subtraction of pre- and post-Gd T1-weighted images. The AWE regions were determined based on the consensus of two experienced teams of investigators (Samaniego and Roa, and Hadad and Cebral, the authors). The high resolution of 7T-MRI allows us to determine the AWE regions visually. The surfaces of segmented AWE region were projected onto the 3D model and were labeled "enhanced'' regions and the rest of the aneurysm area was labeled "non-enhanced".

We computed the region-average of some hemodynamics parameters such as mean (average over time) and peak systole of wall shear stress magnitude (pWSS, mWSS), mean gradient oscillatory number (GON), mean WSS divergence and gradient (WSSDIV, WSSGRAD), and oscillatory shear index (OSI).

We divided the aneurysm sac – based on the geodesic distance to the defined neck line [8,9] –into three regions: neck, body, and dome (Figure 1). Then the locations of AWE regions were determined based on the maximum percentage of overlap between the AWE regions and one of the aneurysm regions (neck, body, and dome). We also classified the location of AWE regions into two groups, "close" and "far", based on their distance to the aneurysm inflow (details in Ashkezari et al. paper [10] in the 'Bleb Location' section).

To analyze our data statistically, we considered three approaches. In the first approach, the means of hemodynamics parameters of

enhanced regions were compared with non-enhanced regions. All parameters were normalized by the corresponding values of the entire aneurysm. Also, all the AWE regions of each aneurysm were considered as a single region (some aneurysms had more than one AWE region). In the second approach, each AWE region located at the neck, body, or dome of the aneurysm was compared with the non-enhanced regions of the aneurysm. In the final approach, hemodynamic parameters of AWE regions at different locations (neck, body, and dome) and their distance to the inflow (far, close) were compared.

In all statistical tests — Wilcoxon tests — differences with $p<0.05$ were considered significant for two-sided test and marginally significant for one-sided tests.

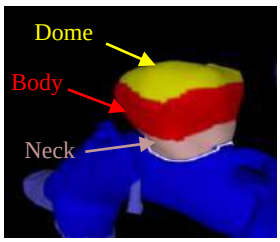

Figure 1: Aneurysm regions: neck (pink), body (red), and dome (yellow).

RESULTS

A total of 72 AWE regions were defined in the 23 aneurysms. Most of the AWEs were at the body of the aneurysms (n=40, 56%) and the rest of them were distributed almost equally at the dome (m=18, 25%) and neck (n=14, 19%).

Results of the first approach showed that on average the mWSS of enhanced regions was lower than non-enhanced regions (p=0.0493). The WSSDIV was larger negative in enhanced regions (p=0.0255). Results of the second approach indicated that AWE regions at neck had higher WSSDIV (p=0.0494), smaller GON (p=0.494), and higher WSSGRAD (p=0.0494) in comparison to the non-enhanced regions. AWE regions located at the body had lower mWSS (p=0.0120), pWSS (p=0.0159), and WSSGRAD (p=0.0086) than non-enhanced regions. Additionally, AWE regions that were far from the inflow had lower mWSS (p=0.006) and pWSS (p=0.037) than non-enhanced regions. Finally, the results of the third approach demonstrated that the AWE regions close to the inflow had larger pWSS (p=0.0147) and mWSS (p=0.0799) compared to AWE regions far from the inflow. Also, the AWE regions located at the neck had larger WSSGRAD than the regions at the body (p=0.0018) and dome (p=0.0070).

DISCUSSION

In our study, the normalized mWSS of AWE region was lower than the non-enhanced regions which was consistent with the previous studies [3,11]. Khan et al. [3] and Xiao et al. [11] and have also reported lower WSS in AWE regions. In our work, most of AWE regions were seen at the body of the aneurysm and fewer were at the dome and neck. Further, different local flow conditions were observed at AWE regions located at different locations. These different flow conditions show the different microenvironments of the aneurysm. These microenvironments have different stages of histological reaction to the blood flow, and thus AWE can indicate the different stages of them. Based on our observations, we hypothesized that hemodynamic conditions are different in AWE regions at different locations. To test this hypothesis, AWE regions were classified according to their locations (neck, body, and dome) and their distance from the inflow (far or close). The results indicate that AWE regions at the neck and close to the inflow have higher WSS, larger negative WSSDIV, and higher and less oscillatory WSSGRAD than the non-enhanced regions. However, AWE regions far from the inflow have lower WSS and WSSGRAD. These results suggest that different mechanisms can be responsible for the AWE regions at different locations.

Despite many studies on the topic, the mechanism responsible for AWE is still unclear. One of the possible mechanisms is the infiltration of Gd through the wall because of increased endothelial permeability. This increased permeability can lead to wall inflammation [1,11,12]. The correlation between circumferential AWE and contrast enhancement in the parent artery [13] shows this inflammation can lead to aneurysm formation. Endothelial dysfunction, caused by abnormally low WSS or high WSS, may also lead to wall inflammation [14] and the leakage of Gd to the wall. Further research needs to understand the AWE mechanisms completely and their potential use as biomarkers for aneurysm inflammation.

The small sample size and lack of follow-up data limited the scope of this work. The small sample size did not allow us to have a specific threshold to identify AWE regions objectively. Further studies with a larger sample size should be done to approve our findings.

Our results showed that AWE regions have lower WSS than non-enhanced regions, and AWEs at the neck and near the inflow have higher WSS and WSSGRAD. These results suggest different mechanisms for AWE at different locations.

ACKNOWLEDGEMENTS

INTRODUCTION

Standing surface acoustic wave-based (SSAW-based) acoustic tweezers are widely integrated with microfluidics for this purpose [1], and 3D (three-dimensional) SSAW acoustic tweezers have been proposed [2]. Theoretical analysis of acoustic manipulation with SSAW is crucial for understanding the underlying mechanisms of acoustic tweezers and for refining the technique.

However, a theoretical study to establish a foundation for developing this technology has not yet been undertaken. We therefore undertook such a study with the aim of improving SSAW technologies by revealing the mechanisms underlying acoustic tweezer manipulation of heterogeneous bodies like cells. Conventional theories for estimating ARF are based upon planar standing waves, and therefore fail to consider the transmission of energy from solid to fluid, and the associated influence of the Rayleigh angle, as is needed for the study of surface standing waves [3]. Moreover, theories for planar standing waves cannot predict the component of ARF acting perpendicular to substrate, as is needed for modeling and controlling particles or cells (Fig. 1a).

We therefore developed a spherically symmetric, three-layered model and calculated the ARF vector induced by a SSAW incident on a three-layered cell using the partial wave expansion method (Fig. 1). Results revealed significant effects of the Rayleigh angle and of the geometrical and acoustic parameters of the nucleus.

METHODS

SSAWs can be generated by two identical interdigital transducers (IDTs), fabricated on a piezoelectric substrate, that generate two progressive surface acoustic waves traveling towards one other with phase velocity c_s (Fig. 1a). When surface acoustic waves travel along the substrate-fluid boundary, part of the vibrational energy transports into the fluid medium, yielding two compressional waves. Each wave travels with velocity c_f at a Rayleigh angle θ_R with respect to the *x*-axis:

$$\theta_R = \arcsin(c_f/c_s) \quad (1)$$

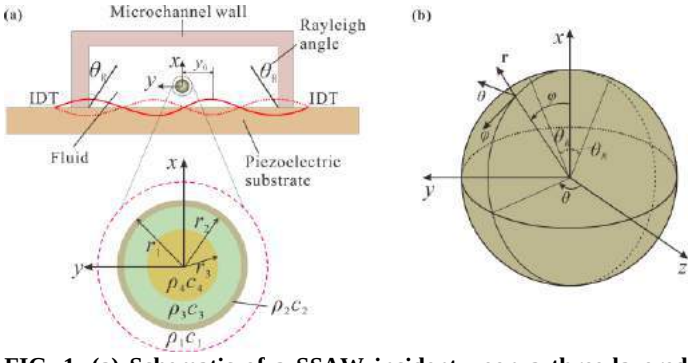

FIG. 1. (a) Schematic of a SSAW incident upon a three-layered model of a eukaryotic cell. (b) The origin of the local spherical coordinate system $(\boldsymbol{r}, \boldsymbol{\theta}, \boldsymbol{\varphi})$ resides at the instantaneous center of the eukaryotic cell.

For a continuous SSAW travelling in an ideal fluid, the total ARF, $\boldsymbol{F}$, can be determined by integrating the excess of pressure $(p - p_0)$ generated by the sound field over the instantaneous surface $S(t)$ of the eukaryotic cell, as:

$$\boldsymbol{F} = -\int\int_{S(t)} (p - p_0)\boldsymbol{n}dS \quad (2)$$

where $\boldsymbol{n}$ is the outward normal to $S(t)$. For proper evaluation of the ARF, the excess of pressure should be taken up to second-order terms in the velocity potential [4]. For a periodic wave, the ARF is defined as a time-averaged quantity over period T of the sound field. The time-

averaged force acting on a sphere immersed in an infinite ideal fluid is given by:

$$\langle \boldsymbol{F} \rangle = -\left\langle \int\int_{S_0} \rho \langle (u_n \boldsymbol{n} + u_t \boldsymbol{t}) u_n \rangle \boldsymbol{n} dS \right\rangle + \int\int_{S_0} \left[\frac{1}{2}\frac{\rho}{c^2} \left\langle \left(\mathrm{Re}\left[\frac{\partial \phi_1}{\partial t} \right] \right)^2 \right\rangle - \frac{1}{2}\rho \langle |\nabla \mathrm{Re}[\phi_1]|^2 \rangle \right] \boldsymbol{n} dS \quad (3)$$

where $\langle \cdot \rangle$ is represents the time average, $\boldsymbol{t}$ is the outward-pointing unit tangential vector of S, S_0 is the surface of the target at its equilibrium position, $dS = rdrd\theta$, and the parameters $u_n \boldsymbol{n}$ and $u_t \boldsymbol{t}$ are the radial and tangential components of the velocity at the surface, respectively. In the following study, we will mainly focused on the normalized ARF in x-direction, Y_{px}, which has been ignored by previous studies.

RESULTS

For illustration, with reference to Fig. 3(a), we consider the effect of the acoustic impedances of the cortical layer and cell nucleus while keeping the position parameter set to $y_0 = \lambda_s/2$, so that the cell is centered at the pressure antinodes; the Rayleigh angle was set to $\theta_R = 20°$. The theoretical and the finite element predictions of the dimensionless ARF Y_{px} were within a few percent for all cases and for acoustic excitation frequencies studied. As the SSAW frequency increases, the curve describing the dimensionless ARF Y_{px} exhibits a series of prominent peaks and dips, due mainly to resonant vibrations of the cell, and the magnitude of the peaks decreases. The presence of either a nucleus or a cortical layer can significantly affect the ARF on the cell, with an especially strong effect of the nucleus. This is due to the strong mismatch in acoustic impedance of the nucleus relative to other components, which results in significantly effect on the scattering field.

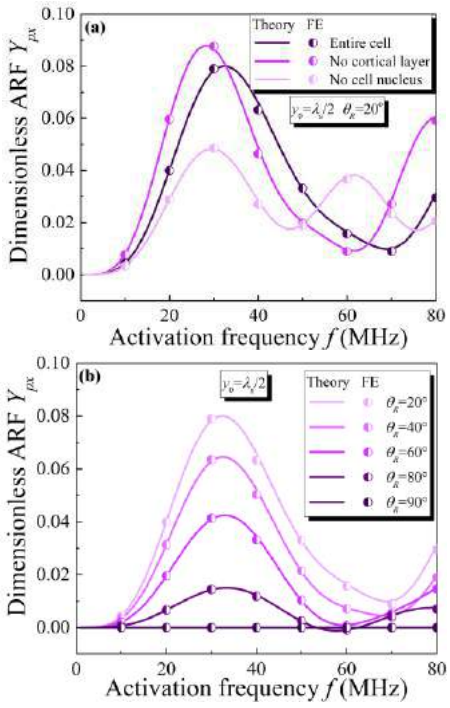

FIG. 3 (a) Dimensionless acoustic radiation force, Y_{px}, versus frequency for an entire cell, a cell lacking a cortical layer, and a cell lacking a nucleus. For the case shown, the cell position parameter is $y_0 = \lambda_s/2$ so that the cell is centered at the pressure antinodes, and the Rayleigh angle is $\theta_R = 20°$. (b) Dimensionless ARF, Y_{px}, versus frequency for an entire cell with several different Rayleigh angles. For the case shown, the position parameter is $y_0 = \lambda_s/2$ so that the cell is centered at the pressure antinodes. For certain frequency ranges at higher Rayleigh angles, the cell is drawn back towards the substrate.

We next consider the effect of the Rayleigh angle (Fig. 3b), with the cell position again fixed at $y_0 = \lambda_s/2$. The dimensionless ARF Y_{px} is largest at around 32 MHz for all values of the Rayleigh angle below 90° with the magnitude of the peak at 32 MHz increasing with decreasing Rayleigh angle. This is expected because more energy will emerge in the *x*-direction with decreasing Rayleigh angle. This suggests a preferred frequency for manipulating eukaryotic cells when a large ARF is needed. Further inspection of Fig. 3b reveals that Y_{px} can become negative for certain frequencies at larger Rayleigh angles, indicating that the ARF in the *x*-direction points back towards the substrate.

DISCUSSION

We have shown that the design of SSAW microfluidic devices to manipulate cells is strongly dependent upon the Rayleigh angle of the system and the heterogeneous mechanics of the cells, neither of which had previously been explored theoretically. Our results extend the state of the art analysis to include waves other than plane standing waves, and to assess the effects of the Rayleigh angle and of cell mechanics. The theoretical model we derived reduced to earlier, simpler solutions for planar standing and planar traveling waves. It provided exact solutions for scattering coefficients, and a near-field approximation for the ARF.

These exact solutions have some limitations that bear mention. For example, the mechanical properties of cells depend strongly upon the way that they are loaded. The numbers used in the studies here are all derived from experiments that involve large perturbations of cells, but the application of ultrasound involves minimal deformation and relatively low stresses. The results presented may enable the estimation of mechanical properties at very low levels of cell deformation based upon motion in response to ARF.

INTRODUCTION

Physiological loading of knee articular cartilage is highly dynamic. Excessive strains occurring with cyclic compression are mitigated by cartilage's dynamic mechanical properties. Without this protective behavior, mechanical fatigue often results in the onset of osteoarthritis [1]. Therefore, measurement of cartilage's dynamic mechanical properties is critical for functional assessment of native tissue and is strongly recommended by the Food and Drug Administration (FDA) for any knee cartilage repair or replacement product [2].

Mechanical testing of cartilage tissue is common, but dynamic measurements are infrequently performed compared to quasi-static methods. This may be partly due to the destructive nature of these tests, thus preventing researchers from performing more comprehensive investigations. The possibility of a nondestructive form of dynamic mechanical testing would be a boon to cartilage research, enabling the field to further explore cartilage tissue dynamics.

Vibrometry, a nondestructive measurement modality, has been extensively used to determine dynamic properties of engineering materials. We hypothesized that vibrometer-based measurements of cartilage dynamic mechanical properties would correlate with quasi-static mechanical properties and biochemical composition. We also hypothesized that the vibrometer would detect differences in the dynamic and viscoelastic properties among various knee cartilages. The results from this work will enable nondestructive dynamic characterization of native, repaired, and replacement cartilage to determine their ability to withstand physiological mechanical demands.

METHODS

Cartilage punches (5mm dia.) were obtained from the tibiofemoral condyle, trochlear groove, patella, and meniscus of juvenile bovine knees. Each punch was placed on a piezoelectric actuator which excited the bottom surface of the tissue. Two forms of excitation were used: a frequency sweep ranging from 10Hz to 100kHz and a 500Hz sinusoidal. Deformation of the tissue's top surface was measured by a PSV-500-B Xtra Laser Scanning Vibrometer (Polytec). Each sample's first and second resonant frequencies were identified in response to the frequency sweep. ASTM guidelines were used to calculate the dynamic modulus (G*) based on these resonant frequencies [3]. Additionally, phase shifts between the tissue response and applied sinusoidal were then used to calculate storage (G') and loss (G'') moduli. Linear perturbation frequency analysis in ABAQUS was used to predict and compare to the resonant frequencies and bending modes of the cartilage samples. Modeled and experimentally observed frequencies were correlated using a Pearson's test.

Following vibrometry, the punches were divided into portions to be used for stress relaxation tests (at 10% and 20% strains), creep indentation, and biochemical assays. Biochemical assays measured collagen, pyridinoline, and GAG content per wet weight and dry weight. Quasi-static mechanical and biochemical parameters were correlated to vibrometry-based measures (G*, G', and G'') using Spearman's ρ test. Statistical differences between cartilage groups were determined using a one-way ANOVA and Tukey's post hoc test.

RESULTS

Distinct bending mode shapes were identified for each group's first and second resonant frequencies and were closely matched with model predictions (Fig. 1). First resonant frequencies ranged between 2kHz and 9kHz, while the second resonant frequencies ranged between 5kHz and 15kHz. Measured and modeled resonant frequencies significantly and strongly correlated across all cartilage groups (R^2=0.93). Dynamic moduli (Fig. 2) were not significantly different among the condyle, patella, and trochlear groove groups, but the meniscus dynamic modulus

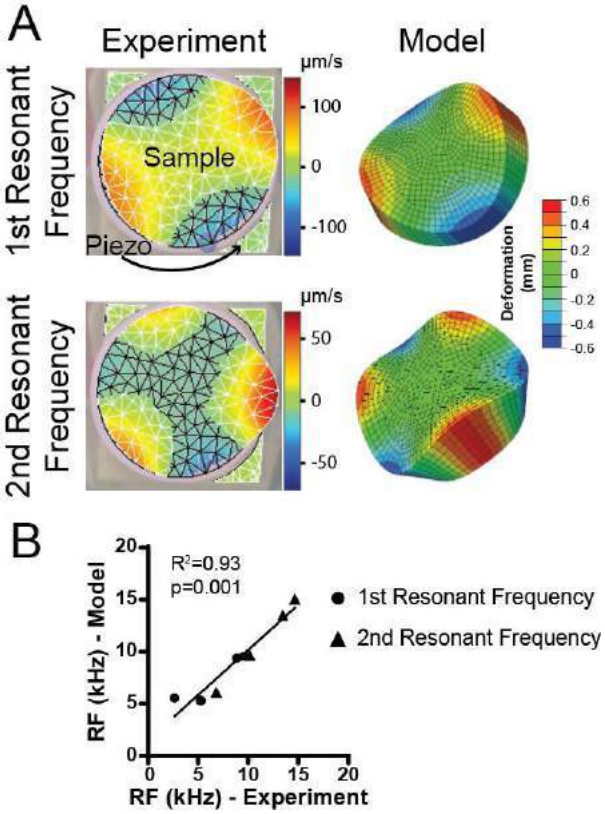

Figure 1: (A) Velocity plotted over the tissue and piezo platform (left) with corresponding modeled bending modes (right) at the first and second resonant frequencies. (B) There is a strong correlation between measured and predicted frequencies (R^2=0.93).

(6.1±0.5MPa) was significantly lower than that of the patella (46.7±11.0MPa) and trochlear groove (56.4±29.9MPa).

The storage modulus, G', mirrored the pattern observed in the dynamic modulus and significantly correlated with the instantaneous moduli from stress relaxation tests (Fig. 3). There were significant differences in the loss modulus, G'', even among the hyaline cartilage groups. The meniscus values were significantly lower than that of the condyle group (78% decrease). G'' was most strongly correlated with the aggregate and shear moduli from creep indentation tests. A similar correlation between G'' and GAG content was also observed (not shown).

DISCUSSION

The dynamic mechanical properties of cartilage are critical for the daily function of the knee joint. However, the destructive nature of most dynamic testing and tissue scarcity often preclude this form of characterization. We found that vibrometry was a novel, nondestructive alternative. Cartilage deformation at resonance was well represented by finite element modeling. Our high frequency vibrometer-based results were not only comparable to previously reported dynamic properties using other methods [1,4], but also correlated with various mechanical properties obtained through quasi-static methods. This is further reinforced by similar correlations to biochemical composition.

Vibrometry is well poised to make significant contributions to cartilage research. For example, the present data show that the meniscus has a significantly lower loss modulus than condylar cartilage, which supports recent calls to reconsider meniscus function as energy absorbing [5]. Future work includes the development of a fluid-filled sample chamber amenable to vibrometry to reduce drying effects and enable time-course measurements. These efforts may present new opportunities for studying the mechanical maturation of engineered cartilage.

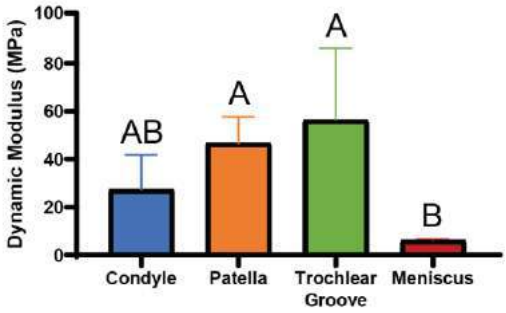

Figure 2: Dynamic moduli are determined from the resonant frequencies. The values significantly differ among the cartilages of the knee. Capitalized letters not shared between groups denote significant differences. Error bars represent standard deviation.

INTRODUCTION

Articular cartilage, a soft tissue covering the bone ends in joints, provides support for bearing load and movement by the virtue of unique structural composition and very low coefficient of friction at the surface. Osteoarthritis (OA) is a disease of the synovial joint, with degeneration and loss of articular cartilage as one hallmark change. Despite the multifactorial nature of OA, mechanical stresses, e.g., tension, compression, shear, hydrostatic pressure, play a key role in the destructive evolution of the disease [1-4]. Both overloading (e.g. trauma) and reduced loading (e.g. immobilization) of cartilage induce molecular and microstructural changes that lead to mechanical softening, fibrillation, and erosion.

In response to mechanical and chemical stimuli, chondrocytes (the cells within cartilage) express and degrade components of extra-cellular matrix (ECM) including structural constituents such as collagen, proteoglycan, and other proteins. To facilitate better understanding of the mechanobiology of cartilage and chondrocytes we seek functional relations between the type and magnitude of mechanical stimuli and the resulting cell-driven mass/density changes within cartilage, which affects the subsequent mechanics.

Here we established a novel framework to incorporate the evolution of constituents generating volumetric changes in cartilage, i.e., volumetric growth and remodeling (VG&R), by leveraging our established constitutive model of cartilage [5-6]. Experimental evidence indicates that application of strain at varying physiological frequencies facilitates chondrocytes expressing PG and collagen at different rates and total quantities [7-10]. We curated the available literature and established functional relations between the loading conditions and normalized expression of constituents. To validate our proposed VG&R framework for cartilage we reproduced the experiment of Kraft et al. [11] and predicted the production of collagen and PG.

METHODS

Constitutive Model. We modeled articular cartilage as a biphasic (swelling) continuum $\phi = \phi^{\mathrm{S}} + \phi^{\mathrm{F}}$ consisting of a porous solid phase ϕ^{S} saturated with an interstitial fluid phase ϕ^{F}. We defined the Helmholtz free-energy function of the solid ψ^{S} as [5-6]

$$\psi^{\mathrm{S}} = \psi^{\mathrm{S}}_{\mathrm{OP}}(J_{\mathrm{S}}) + (1-\nu)\psi^{\mathrm{S}}_{\mathrm{IM}}(J_{\mathrm{S}}, I_1) + \nu\psi^{\mathrm{S}}_{\mathrm{FN}}(\mathbf{C}_{\mathrm{S}}, \mathbf{M}), \quad (1)$$

where $\psi^{\mathrm{S}}_{\mathrm{OP}}$, $\psi^{\mathrm{S}}_{\mathrm{IM}}$, and $\psi^{\mathrm{S}}_{\mathrm{FN}}$ are the contributions of the osmotic pressure, isotropic matrix, and network of collagen fibers, respectively; ν is the volume fraction of collagen to total solid; J_{S}, $\mathbf{C}_{\mathrm{S}}$, and $\mathbf{M}$ are Jacobian, the right Cauchy-Green tensor, and the reference fiber orientation, respectively; and $I_1 = \mathrm{tr}(\mathbf{C}_{\mathrm{S}})$. We modeled the contribution from osmotic pressure as [6]

$$\psi^{\mathrm{S}}_{\mathrm{OP}} = \frac{1}{\rho^{\mathrm{S}}_{0\mathrm{S}}} R\theta c^{\mathrm{fc}}_{0\mathrm{S}} n^{\mathrm{F}}_{0\mathrm{S}} \left[\frac{2\bar{c}_{\mathrm{m}}}{c^{\mathrm{fc}}_{\mathrm{m}}} - \frac{\sqrt{4(\bar{c}_{\mathrm{m}})^2 + (c^{\mathrm{fc}}_{\mathrm{m}})^2}}{c^{\mathrm{fc}}_{\mathrm{m}}} + \sinh^{-1}\left(\frac{c^{\mathrm{fc}}_{\mathrm{m}}}{2\bar{c}_{\mathrm{m}}}\right) \right], \quad (2)$$

where $R = 8.314$ MPa mm^3/mmol K, $\theta = 310.2$ K, $\rho^{\mathrm{S}}_{0\mathrm{S}}, c^{\mathrm{fc}}_{0\mathrm{S}}, n^{\mathrm{F}}_{0\mathrm{S}}, c^{\mathrm{fc}}_{\mathrm{m}}, \bar{c}_{\mathrm{m}}$ are the initial solid partial density, initial concentration of fixed charges, the initial fluid volume fraction, initial concentration of fixed charge and the ion concentration of the external solution, respectively. We modeled the contribution from densely packed proteoglycan as [2,3]

$$\psi^{\mathrm{S}}_{\mathrm{IM}} = \frac{1}{\rho^{\mathrm{S}}_{0\mathrm{S}}} \left[U(J_{\mathrm{S}}) + \frac{1}{2}\mu^{\mathrm{S}}(I_1 - 3) \right], \quad (3)$$

including compaction effects via $U(J_{\mathrm{S}})$ and with shear modulus μ^{S}. We modeled the contribution from the network of collagen fibers as [5-6]

$$\psi^{\mathrm{S}}_{\mathrm{FN}} = \frac{1}{\rho^{\mathrm{S}}_{0\mathrm{S}}} \int_{\Omega} \rho(\mathbf{M}) \frac{k_1}{2k_2} \left\{ e^{[k_2(I_4-1)]^2 - 1} \right\} \mathcal{H}(I_4 - 1)\, \mathrm{d}\Omega, \quad (4)$$

where $\rho(\mathbf{M}), k_1, k_2$ are a voxel-wise orientation distribution function, a stress like parameter and dimensionless parameter, respectively, $I_4 = \mathbf{M} \cdot \mathbf{C}_{\mathrm{S}}\mathbf{M}$, and $\mathcal{H}$ is a Heaviside function.

We modeled the corresponding permeability of cartilage matrix as [5-6]

$$\mathbf{K}_{\mathrm{F}} = k_{0\mathrm{S}} \left(\frac{n^{\mathrm{F}}}{1 - n_{0\mathrm{S}}^{\mathrm{S}}} \right)^{m} \frac{1}{4\pi} \int_{\Omega} \frac{\rho(\mathbf{M})}{I_4} \mathbf{m} \otimes \mathbf{m} \, \mathrm{d}\Omega \,, \tag{5}$$

where $\mathbf{m}$ is the current fiber orientation, n^{F} and $n_{0\mathrm{S}}^{\mathrm{S}}$ are the volume fractions of fluid and solid, and $k_{0\mathrm{S}}$ is the initial Darcy permeability.

Volumetric Growth and Remodeling Framework. We defined the target volume change due to VG&R as $\hat{v} = \sum_{i=\mathrm{PG,CO}} \hat{m}_i \phi_i$, where $\hat{m}_i$ and ϕ_i are the individual normalized mass productions and volume fractions, respectively. We defined the modified Jacobian, and right and left Cauchy-Green tensors as $\hat{J} = \hat{v}^{-1} \det(\mathbf{F}) = J/\hat{v}$, $\hat{\mathbf{C}} = \hat{v}^{-2/3}\mathbf{C}$ and $\hat{\mathbf{b}} = \hat{v}^{-2/3}\mathbf{b}$, respectively. We also defined the modified invariants as $\hat{I}_1 = \hat{v}^{-2/3} I_1$, $\hat{I}_2 = \hat{v}^{-4/3} I_2$, $\hat{I}_3 = \hat{v}^{-2} I_3$, and $\hat{I}_4 = \hat{v}^{-2/3} I_4$. The density changes of the individual constituents are $\hat{\rho}_i = \hat{m}_i / \phi_i$. Finally, we express the total Cauchy stress of the solid constituents as,

$$\boldsymbol{\sigma}^{\mathrm{S}} = \boldsymbol{\sigma}_{\mathrm{OP}}^{\mathrm{S}} + (1 - \nu) \hat{\rho}_{\mathrm{PG}} \boldsymbol{\sigma}_{\mathrm{IM}}^{\mathrm{S}} + \nu \hat{\rho}_{\mathrm{CO}} \boldsymbol{\sigma}_{\mathrm{FN}}^{\mathrm{S}} \,, \tag{6}$$

Normalized PG and Collagen Production. Experiments confirm that chondrocytes synthesize components of PG and collagen at different rates under different treatments with cyclic compression [7-10]. Therefore, we proposed a generalized function of normalized production of PG and collagen dependent on applied stretch (λ) within the tissue, loading rate or frequency (f), and the time (τ), i.e for the duration of loading. We proposed a linear relation,

$$\hat{m}_i = \alpha_i \lambda + \beta_i f + \gamma_i \tau + \omega_i \,, \tag{7}$$

where α_i, β_i, γ_i, and ω_i are fitting parameters for $i \in \{\mathrm{PG}, \mathrm{CO}\}$.
To facilitate general loading we converted the frequency to strain rate and stretch to principal stretches and maximum shear stretches, and implemented these within our VG&R framework.

Cartilage under Hydrostatic Pressure. To validate our established numerical framework, we simulated cartilage undergoing cyclic hydrostatic pressure [11] and predicted both proteoglycan and collagen production. We created a quarter-symmetry model of a cylindrical specimen of cartilage (10 mm Ø, 182 µm thickness) with 582 linear hexahedral elements. We first allowed the model to swell and achieve equilibrium. We then applied cyclic hydrostatic pressure from 0.5 MPa to 5 MPa at 0.1 Hz frequency following the experiment [11]. Exploiting the very different time scales between daily activities, e.g. walking (sec), and progression of OA (days to years), we used iterative rather than simultaneous solutions. We simulated the loading conditions for 21 days. We present the model properties for our analyses in **Table 1**. We performed our simulations using FEBio (University of Utah, USA).

Table 1: Model parameters for cartilage

Parameter			
$\boldsymbol{\mu^{\mathrm{S}}}$	0.25 MPa	$\boldsymbol{k_{0\mathrm{S}}}$	9.6×10^{-4} mm^4/Ns
$\boldsymbol{k_1, k_2}$	0.43 MPa, 8.0 [-]	$\boldsymbol{m}$	3.3 [-]
$\boldsymbol{n_{0\mathrm{S}}^{\mathrm{S}}}$	0.15 [-]	$\boldsymbol{c_{0\mathrm{S}}^{\mathrm{fc}}}$	0.50×10^{-6} mol/mm^3
$\boldsymbol{\nu}$	0.82 [-]	$\boldsymbol{\bar{c}_{\mathrm{m}}}$	0.15×10^{-6} mol/mm^3
$\boldsymbol{J_{\mathrm{cp}}^{\mathrm{S}}}$	0.37 [-]		

RESULTS

The fitted parameters for our normalized PG and collagen production, i.e. (7), are $\alpha_{\mathrm{PG}} = 0.0850, \beta_{\mathrm{PG}} = 0.0294, \gamma_{\mathrm{PG}} = 0.0206,$ and $\omega_{\mathrm{PG}} = 0.852$ for PG, and $\alpha_{\mathrm{CO}} = -5.03, \beta_{\mathrm{CO}} = 0.0215, \gamma_{\mathrm{CO}} = 0.0531,$ and $\omega_{\mathrm{PG}} = 5.53,$ for collagen. We present the fitted multilinear equations as contour surfaces with the experiment data used for fitting in **Fig. 1**.

We predicted the normalized production of cartilage constituents for each day of the experiment, see **Fig. 2**. **Fig. 2(a)** shows a comparison between the predicted (normalized) production of PG vs. the corresponding experiment from Kraft et al. [11], while **Fig. 2(b)** illustrates the same comparison for collagen type II.

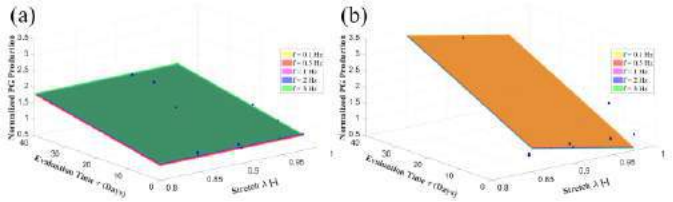

Figure 1: Normalized production of (a) proteoglycan (PG) and (b) collagen type II under general loading conditions.

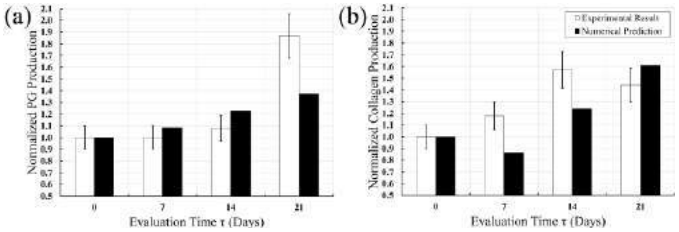

Figure 2: Normalized production of (a) proteoglycan (PG) and (b) collagen type II predicted versus experiment [11].

DISCUSSION

We introduced a VG&R framework considering the mechanobiologically induced turnover of constituents in articular cartilage resulting from mechanical loading. Our simulations of the cartilage successfully predict the production proteoglycan and collagen determined experimentally [11]. In predicting the evolution of PG, our simulation reasonably approximates the experimental results except for day 21. Our prediction of collagen follows the trend determined in the experiment; but the numerical values differ. Nevertheless, the difference between the prediction and experiment is in a narrow range of the normalized scale.

Unfortunately, the experimental data available for calibrating our framework i.e., formulate and fit (7), are quite sparse. In this light we selected the most simple (linear, not nonlinear) relationship among stretch, frequency, and time. Moreover, we formulated (7) based on experiments under uniaxial cyclic loading, while we predicted the evolution of constituents under cyclic hydrostatic pressure. Despite of the difference in loadings, we successfully predicted the evolution of constituents to test our novel VG&R framework for articular cartilage.

Limitations and outlook. We must improve the correspondence between predictions and experiments [11]. By leveraging more experimental data we could extent (7) to include nonlinearity and likely improve the fitting. In our simulations, we considered the number of chondrocytes as constant, while this may evolve with cell death or proliferation. Our framework is the first step towards a new class of computational tools that will facilitate, for the first time, patient-specific modeling of OA progression considering the biomechanics and kinetics of cell ECM turnover and production, both *in vitro* and *in vivo*.

LUNG LOBAR SLIDING HELPS REDUCE PARENCHYMAL DISTORTION DURING BREATHING

Adam E. Galloy (1), Ryan Amelon (1), Joseph M. Reinhardt (1), Madhavan L. Raghavan (1)

(1) Roy J Carver Department of Biomedical Engineering

Iowa City, Iowa, United States of America

INTRODUCTION

Many lung diseases, such as chronic obstructive pulmonary disease, initially affect only a small region of the lung tissue. However, these diseases are diagnosed and characterized based on pulmonary function tests that only capture the total function of the lungs. When only the total function of the lungs is considered, healthy tissue can obscure the effects of small regions of unhealthy tissue that need medical attention. Patients may receive better diagnoses and treatment plans if regional lung mechanics metrics are used to characterize lung health. However, regional mechanics information is difficult to interpret because of a poor understanding of its role in breathing and because of variability within and between patients.

One source of both inter and intra patient variability arises from the sliding motion of the lung lobes. Lung lobes slide against each other along lobar fissures throughout the respiratory cycle [1]. However, some patients have missing or incomplete lobar fissures which can limit or prevent lobar sliding and change how the lung deforms [2]. In addition, patients can have different fissure orientations and lobe geometries [3].

We previously reported on a method for quantifying lobar sliding [1]. The objective of this study is to test the hypothesis that lobar sliding helps reduce directional distortion in the lung tissue during breathing using finite element analysis (FEA). Understanding how lobar sliding, or the lack thereof, affects regional lung deformation will improve our understanding of lung physiology and help us account for some of the variability between patients.

METHODS

Image Acquisition and Segmentation We acquired 4DCT scans from eight subjects with lung cancer using a protocol approved by the institutional review board. Patients were scanned in the supine position during gaited tidal breathing using a 40-slice CT scanner (Siemens Biograph, Hoffman Estate, IL) operating in helical mode.

The chest wall boundary and lung lobes were segmented for each subject from CT images at end of inhalation using Slicer4 and converted to smooth surface geometries using Mimics (Materialise). From the chest wall boundary, a 3-node triangular shell mesh was generated for each subject using Gambit (Ansys). Also using Gambit, 4-node tetrahedral solid meshes were generated for each lung lobe. Only the left lung was considered for this study.

Finite Element Analysis We used FEBio (University of Utah) for the FEA simulation. For both lung lobes of the left lung, we assigned a neo-Hookean material model with the parameters $E = 3$ kPa and $\nu = 0.30$. We applied nodal displacements to the chest wall shell to simulate the motion of the chest wall as it moves from end of inhalation to end of exhalation. These displacements were derived from deformable image registration of the end inhalation and end exhalation segmentations of the lung/chest wall boundary. We also applied contact boundary conditions between the chest wall shell and lobes as well as contact boundary conditions between lobes. These boundary conditions ensured that the lung tissue deformed with the chest wall. Contact between each interface was enforced using FEBio's sliding elastic formulation with augmented Lagrangian constraint enforcement. To compare lung deformation with lobar sliding to lung deformation without lobar sliding, we generated two models for each subject: one model with a friction coefficient of 1.5 between lobes to prevent lobar sliding, and one model with no friction between the lobes to allow for lobar sliding (Figure 1).

Post-Processing In order to quantify the directional distortion at a point in the lung tissue we used the anisotropic deformation index (ADI) [4]:

$$ADI = \sqrt{\left(\frac{\lambda_1 - \lambda_2}{\lambda_2}\right)^2 + \left(\frac{\lambda_2 - \lambda_3}{\lambda_3}\right)^2} \quad (1)$$

Where λ_i^2 are the eigenvalues of the right Cauchy-Green tensor. For each left lung model, ADI was calculated at each element and a volume-weighted average of ADI was calculated for the entire lung, the lower lobe, and the upper lobe. To determine if the differences in mean ADI between sliding and non-sliding models for the left lung as a whole and in each of the lobes were significant, we performed a Wilcoxon signed-rank test with $p<0.05$ as the criteria for significance.

In addition, the FEA mesh and displacements were interpolated onto a voxel grid. To quantify the amount of sliding that occurred at a voxel element, we used our sliding metric [1]:

$$\gamma_{max} = \frac{\lambda_1 - \lambda_3}{2} \quad (2)$$

The mean sliding metric of all fissure elements was calculated to quantify the amount of sliding on the entire fissure for each subject.

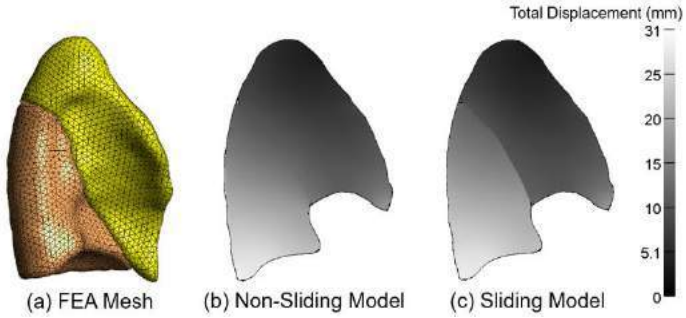

Figure 1: Finite element mesh of a lobe-specific CT segmentation from a representative subject (a). Displacement map on sagittal slice for FE simulation when lobar sliding was disallowed (b) and when friction-free lobar sliding was allowed (c). Note the displacement discontinuity at the lobar fissure in the latter, and the smooth transition in the former.

RESULTS

Using the ADI within the lung tissue calculated from the FEA results as a measure of directional distortion, we compared the mean ADI between the left lung models that restricted sliding to the models that allowed sliding (Figure 2). Mean ADI was calculated in the whole lung and within each lobe. We found that mean ADI significantly decreased in the lungs (5.3% average difference, $p < 0.01$). This supported our hypothesis that the additional degrees of freedom provided by lobar sliding allow the lungs to inflate with less directional distortion. A more pronounced mean ADI decrease between sliding and non-sliding models was observed when only the lower lobe was examined (9.4% average difference, $p < 0.01$); however, in the upper lobe there was no significant difference (2.0% average difference, $p = 0.11$). The lower lobe is closer to the diaphragm which is one of the largest sources of directional distortion in the lungs. This could be why the lower lobe is better positioned to decrease directional distortion with lobar sliding.

In addition to looking at differences between models from the same subject, we also looked at trends between subjects. In Figure 3 we plotted the reduction in ADI between the non-sliding models and the sliding models against the mean sliding metric along the lobar fissure for each subject. We found a positive correlation between the mean sliding metric and the mean ADI drop, further indicating that lobar sliding decreases directional distortion in the lungs. The five-fold difference in the smallest and largest mean sliding metric demonstrates the degree of variability in different subjects' sliding motion.

DISCUSSION

The inter and intra subject trends of this study are consistent with the hypothesis that lobar sliding allows the lungs to deform with less directional distortion. Lobar sliding is an often neglected cause of mechanical variation within and between subjects. Many FEA studies model the lungs as continuous solids, but this could lead to inaccurate deformation results such as larger directional distortions. Future work will consider the right lung and explore the relationship between fissure geometry and the amount of sliding that occurs to help us better account for inter-subject variability in lung mechanics.

One limitation to our study is that we only simulated scenarios where each lobe was free to slide frictionlessly or where sliding was almost completely prevented by a large friction coefficient. However, the lobes may be coupled to each other at certain locations, or a moderate friction coefficient may govern the sliding behavior. Future work comparing model predicted displacement fields to displacement fields computed from image registration of the original CT images can test these assumptions.

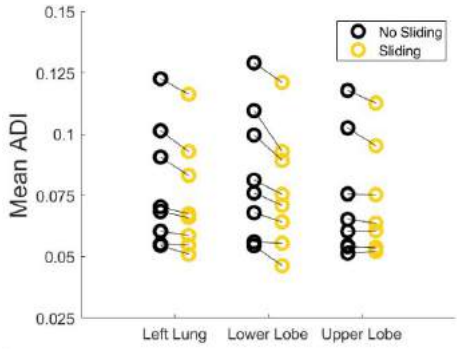

Figure 2: Change in spatial mean ADI in each subject's lung and in lobes when sliding was allowed. Models that allowed lobar sliding had significantly less directional distortion. This difference was more pronounced in the lower lobe of the lung.

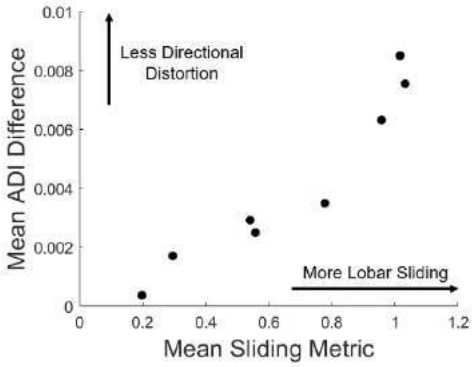

Figure 3: Subjects that had more sliding along the lobar fissure had a greater decrease in directional distortion.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is responsible for over 90% of pancreatic cancer cases and is the seventh leading cause of cancer-related deaths in the United States[1]. New treatments for pancreatic cancer are urgently needed as it is highly resistant to all forms of chemotherapy and radiotherapy. Complete surgical resection is currently the only curative treatment, however, patients with advanced or metastatic pancreatic cancer are ineligible for surgical removal, and even following resection, the tumor usually relapses a year after surgery[1]. Current studies focus on targeting or restoring the microenvironment of PDACs that exhibit biomechanical abnormalities. These abnormalities include a dense tumor-associated stroma composed of extracellular proteins such as collagen I and hyaluronan that are remodeled to create a stiffer Extracellular Matrix (ECM), a condition known as desmoplasia. Increased matrix stiffness serves as a diagnostic marker and is associated with poor prognosis. These altered mechanical properties of the ECM, trigger signaling cascades resulting in increased cell motility, migration and invasion[2]. Moreover, tumor growth within a physically-restricted environment, surrounded by dense stroma, leads to the development of compressive forces in the tumor interior, generating intracellular *solid stress* that can reach up to 75mmHg (10kPa)[2]. This type of stress has been shown to activate signaling pathways that promote tumorigenesis and invasiveness. *However, the molecular mechanisms that enhance metastatic potential via mechanical stress remain elusive.* We hypothesize that mechanical compression, and hence solid stress, overstimulates several signaling pathways that have been shown to be consistently activated in pancreatic tumors. These pathways include the PI3K/Akt and Ras/MAPK signaling cascades that are involved in the regulation of cell survival and motility [2]. Specifically, Ras genes (*K-Ras, N-Ras, H-Ras*) are frequently mutated in several tumor types, including pancreatic tumors, whereas K-Ras is found to be the most frequently mutated gene in invasive pancreatic tumors with a rate of 95%[3]. One of the main targets of the K-Ras pathway is the MAPK signaling cascade, that includes the Jun N-terminal kinase (JNK) and p38 MAPK. These kinases are known to be activated by environmental and genotoxic stresses and have key roles in the regulation of cell proliferation, survival and migration and could possibly be implicated in solid stress-induced signal transduction[3]. In our previous studies, we showed that mechanical stress promotes GDF15-induced cancer cell migration through activation of PI3K/Akt and MEK1/Erk1 signaling cascades in pancreatic and brain cancer cell lines, respectively [4, 5]. Based on these findings, we comprehensively profiled mechanical stress-induced signaling cascades that drive the motility of pancreatic cancer cells using a large-scale proteomic assay. Our results elucidate mechanical stress-induced signaling mechanisms and provide novel information to prioritize therapeutic targets for pancreatic cancer metastasis.

METHODS

Cell Lines*:* MIA PaCa-2 cells were purchased from the American Type Culture Collection (ATCC, Manassas, VA, USA) and cultured according to manufacturer's guidelines.

Application of mechanical compression: The application of a defined and controlled compressive solid stress on cancer cells was achieved using a piston with adjustable weight, which was placed on the top of a cell monolayer that was covered with an agarose cushion and placed in a transwell insert. 4.0 mmHg of compressive stress was applied to the cell monolayer. Control cells were covered with an agarose cushion only.

Wound Healing: To characterize migration, a wound healing assay was performed on cancer cells growing in 2% FBS-containing medium by introducing a scratch wound on a cell monolayer[4]. Images were taken at 0 hours and 16 hours post-compression. The cell-free area was quantified using the ImageJ software. Quantification was performed for each condition using the following formula: (Width of the wound at 0 hours – Width of the wound at 24 hours) / (Width of the wound at 0 hours).

Protein Extraction for Reverse Phase Protein Array (RPPA): Pancreatic cancer cells were compressed by 0.0 or 4.0 mmHg in 2%-FBS containing medium for 16 hours and then were washed twice with cold PBS. Cells were then lysed using 150µl of cold lysis buffer. Proteomic analysis using reverse-phase protein arrays (RPPA) was performed at the RPPA core facility (MD Anderson Cancer Center, Houston, TX). For pathway analysis, scores were used to evaluate the activity of the pathways after compression. RPPA data was normalized and grouped by compression (n=3). Pathway scores were calculated as the average sum of expression level of all protein members in each pathway, and then normalized to the uncompressed expression level. Heatmaps for pathways were generated to show the alteration of each protein member. Proteins and cell samples were grouped with a two-way hierarchical clustering based on the column-normalized z-scores. (Only Ras/MAPK heatmap is shown in this submission).

RESULTS

To examine the effect of compression on the migration of pancreatic cancer cells, we performed a scratch wound assay and found that compressed MIA PaCa-2 exhibited increased migratory ability as compared to the uncompressed cells (**Figure 1A**). To also determine whether mechanical compression impacts cell shape after compression, we performed a phalloidin staining and we observed increased stress fibres, filopodia and lamellipodia formation in compressed compared to the uncompressed cells (indicated with white arrows in **Figure 1B**).

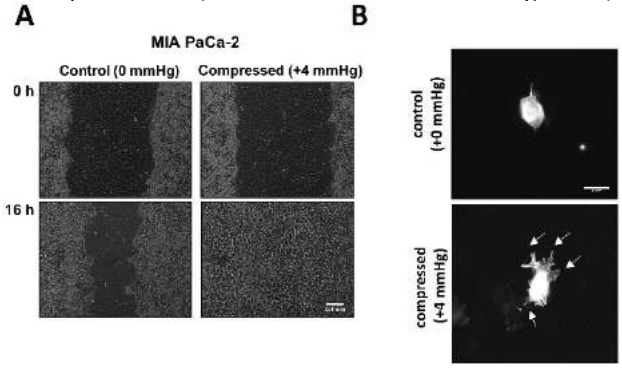

Figure 1. Mechanical stress induced the migration of pancreatic cancer cells. A, Wound healing assay of compressed MIA PaCa-2 cells[4]. Scale bar: 0.1 mm. B, Phalloidin staining of compressed MIA PaCa-2 cancer cells. Scale bar 0.1 mm.

Next, to tease out the signaling pathways that are associated with increased migratory ability of cells caused by mechanical compression, we further analysed MIA PaCa-2 protein extracts using a Reverse Phase Protein Array (RPPA). Pathway score analysis of the RPPA data, that incorporates both positive and negative regulators of signaling pathways, revealed that proteins implicated in cell cycle progression and TSC/mTOR pathway were decreased upon compression. Contrary to that, the PI3K/Akt and Ras/MAPK signaling cascades were activated (**Figure 2A and Figure 2B**). By validating selected RPPA hits in MIA PaCa-2 and PANC-1 pancreatic cancer cells using Western Blotting and by modulating expression levels using inhibitors and siRNAs, we revealed that mechanical stress can activate JNK/ c-Jun and p38 MAPK signaling. We showed that c-Jun and p38 MAPK regulated cell survival and the expression of genes implicated in epithelial-to-mesenchymal transition (EMT), including Slug, Twist and Snail. Moreover, compression can activate HSP27, a stress response element that is downstream of p38 MAPK, and Rac1 and cdc42 that altogether regulate actin cytoskeleton remodeling for the formation of cell protrusions necessary for cell motility. Rac1 and cdc42 can also activate PAK1 to stabilize actin filaments and mediate actomyosin contractility, resulting in enhanced pancreatic cancer cell migration under compression.

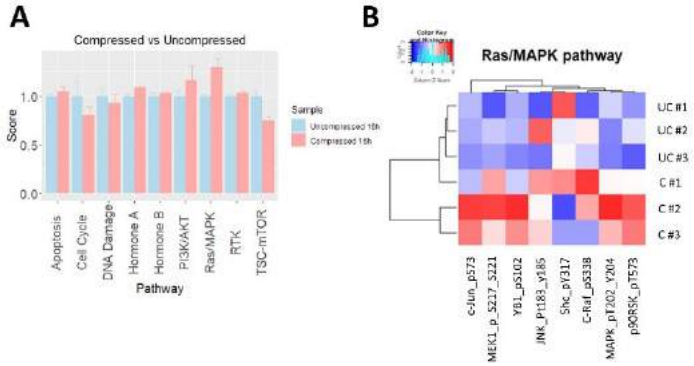

Figure 2. A, Pathway score analysis of proteomic data in MIA PACA-2 cells 16 hours after exposure to 4 mmHg (n=3). B, Heatmap of Ras/MAPK pathway shows the alteration of each pathway member in uncompressed (marked as "UC") and compressed (marked as "C") cells derived from 3 independent experiments. Red shows high protein expression compared to the median and blue shows low protein expression.

DISCUSSION

Although mechanical stress has already been associated with pancreatic tumor progression, little is known about the molecular mechanisms involved. Here, we used for the first-time proteomic profiling to examine signaling pathway adaptation of compressed pancreatic cancer cells and monitor multiple signaling pathways, regulating processes including cell cycle progression, actin cytoskeleton remodelling and migration. Specifically, we revealed that mechanical compression reduced TSC/mTOR pathway activity, while activating the RAS/MAPK signaling pathway to regulate cell motility. The high expression of these pathways in pancreatic tumors could eventually be used as a novel marker for the presence of mechanical forces in the tumor interior. Furthermore, these mechanical stress-induced signaling pathways could be targeted, in combination with conventional treatments, to improve treatment responses in pancreatic tumor patients.

INTRODUCTION

The left atrial appendage (LAA) is an anatomical structure in the left atrium that influences the blood pressure and flow in the left atrium (LA). Its function was long unknown, but recent research suggests that its active contraction and high concentration of atrial natriuretic peptide are important for cardiovascular hemodynamics, thrombogenesis and arrhythmogenesis [1]. The contraction pattern of the LAA seems to vary largely between individuals and is challenging to investigate.

Clinically, the contraction is commonly assessed by measuring the peak velocities of the blood in the LAA orifice with doppler ultrasound, but this method is limited to the measurement of the velocity components along the ultrasound beam and does not provide high quality 3-dimensional information. Alternatively, the blood velocity in the LA can be measured with 4D-flow MRI. Markl et al. measured the blood flow in LA of patients with atrial fibrillation and found lower velocities in patients compared to healthy controls [2].Though they analyzed the general flow in the LA, it is challenging to identify the LAA in 4D flow MRI images.

In recent years, assessment of the cardiac structure and function with time resolved computed tomography (CT) has become more common. Using iodine-based contrast agents, the blood pool in the heart can be distinguishable in CT images. Using modern CT systems, 3D images can be obtained over the cardiac cycle at a relatively low radiation dose. Tracking the motion of the LA and the LAA in CT is challenging. Commonly in time resolved CT, the cardiac motion is reconstructed to 10-20 frames per cardiac cycle. The LAA contracts very quickly and its motion might not be fully captured with this temporal resolution. A few tracking algorithms have been proposed[3], [4],but these have not been evaluated against other measurement modalities.

We aimed to develop and validate a motion tracking algorithm that can capture the quick motion of the LAA, facilitating clinical assessment of LAA motion from CT and possibly LA and LAA hemodynamics using Computational Fluid Dynamics (CFD) simulations, similar to [5]. To validate our algorithm, we compared the motion tracked in time resolved CT images with velocities measured in 4D flow MRI of the same individual.

METHODS

Study Population In this study we included 9 patients that received a clinical coronary CT angiography examination for diagnosis of chest pain. The participants agreed to take part in an additional 4D flow MRI examination. The study was approved by the local ethics board and written informed consent was obtained by all patients.

CT and MRI acquisition The CT images were acquired on a third-generation Siemens dual-source CT scanner (Somatom Force, Siemens Healthineers, Forchheim, Germany) during sinus rhythm and inspiration. The images were reconstructed to 20 temporal phases, equivalent to 0% to 95% of the R-R interval. The in-plane resolution was 0.353×0.353 mm ± 0.035 mm and the slice thickness was 0.5 mm with a 0.25 mm increment.

After the CT examination, 4D flow MRI images were acquired on a clinical 3.0-T Philips Ingenia MRI unit (Phillips Healthcare, Best, the Netherlands) during sinus rhythm and free breathing. The cardiac cycle was reconstructed to 40 phases and the spatial resolution was 2.9×2.9×2.9 mm.

Wall tracking The blood bool was segmented in the 4D CT data using ITK-SNAP (www.itksnap.org) and MeVisLab (www.mevislab.de). Thereafter, motion of the endocardium was tracked from the blood pool surfaces using an algorithm based on the optimal step nonrigid iterative closed point algorithm developed by Amberg et al. [6]. This algorithm deforms a source surface onto a target surface by reducing the distance between the surfaces while keeping the topology of the source. To obtain more accurate tracking of the LA and LAA, these regions were tracked separately, allowing for different tracking settings.

Evaluation To validate this approach, the flows though the LAA orifice and thought the mitral valve (MV) were derived from the registration and from 4D flow MRI measurements. To calculate the mitral valve flow based on the wall tracking, the volume of the ventricle was calculated for each of the 20 phases and then differentiated with

respect to time. Negative volume changes equate to the flow through the mitral valve. The flow thought the LAA orifice was measured similarly, by deriving the volume of the LAA over time.

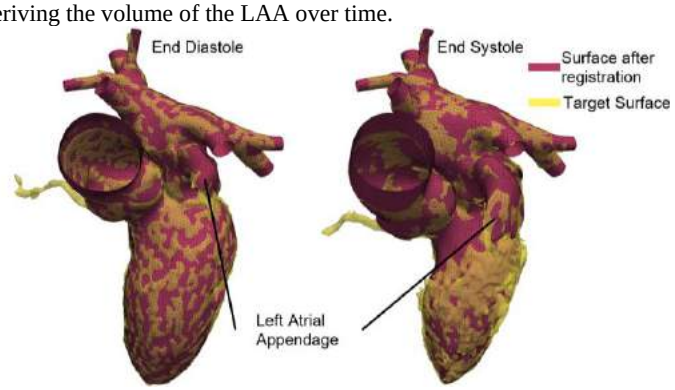

Figure 1: Surface of endocardium after registration and target surface at end diastole and end systole

In the 4D flow MRI images, the mitral valve flow was quantified by tracking the valve over the cardiac cycle and integrating the flow over the mitral valve orifice. Measuring LAA flow from 4D flow MRI was challenging, as the LAA cannot be clearly defined over the whole cardiac cycle. Therefore, the flow rate was measured in three parallel planes, that were set during LAA peak outflow phase and kept at the same position though the cardiac cycle. In every plane the flow over the cardiac cycle was obtained by integrating the flow in a manually drawn region of interest. The flow curves in the LAA orifice were defined by averaging the volume flow from the three planes.

RESULTS

Visual inspection showed a good agreement between the surface of the endocardium after the wall tracking and the target surface, as shown for a typical patient at end diastole and end systole in Figure 1. The average distance between the tracked surface and the target surface for all patients over all time steps was 0.62 mm with a standard deviation of 0.49 mm.

The flow through the mitral valve is characterized by two flow peaks, the first one during early ventricular filling and the second one during the late filling. Both peaks are clearly visible in Figure 2 a). The timing of the peaks is similar in both imaging modalities. The average early diastolic mitral flow was 494.4 ±183.1 ml/s and 283.1 ±67.7 ml/s for CT and MRI, respectively. The average late diastolic mitral flow was 309 ±66.9 ml/s and 283.1 ±67.7 ml/s for CT and MRI, respectively, see Figure 2 b). While the magnitude of the peak flow during late filling was similar, the average peak flow during early filling was 1.74 times higher for CT.

The flow though the LAA orifice calculated from time-resolved CT followed a similar pattern as the mitral valve flow, but with a lower magnitude. This bi-phasic characteristic was less obvious in the in 4D flow MRI, in which the early diastolic peak often not could be recognized. The average late diastolic LAA flow was 40.2 ±17.9 ml/s and 60.8 ±30.2 ml/s for CT and MRI, respectively, see Figure 2 d).

DISCUSSION

We developed a surface-based algorithm to track the LA motion including the LAA from CT data. The results are in good agreement with automatically segmented geometries and results from 4D flow MRI data.

Previous studies [3], [4] have assessed the motion of the LA in CT images, but these have not been validated against other measurements in the same individual. Our algorithm could successfully track the motion even with noisy target surfaces that contained holes.

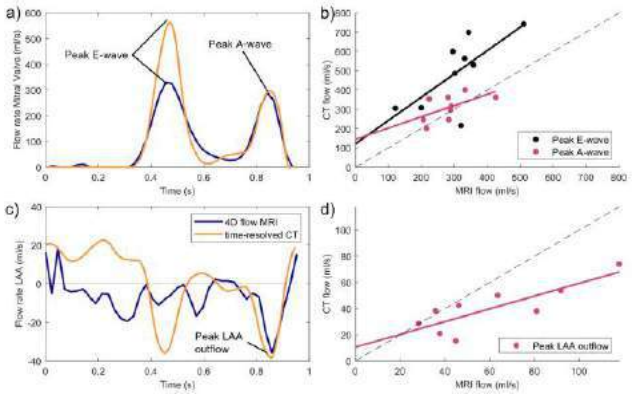

Figure 2 a),c): Flow through Mitral Valve and LAA measured with CT and 4D flow MRI over time for 1 example patient. b),d): linear regression of peak flow for all 9 patients.

The blood flow though the mitral valve showed a similar pattern in both measurements. However, the magnitude of the early wave was higher in the CT measurement than in 4D flow MRI. This could be due to that the MRI data are averaged over many cardiac cycles and synchronized at end-diastole. Fluctuations in the length of the cardiac cycle could lead to less accurate results during early diastole

Similar to Al-Issa et al. [4], there are two peaks in the flow through the LAA orifice measured in CT. The late peak agrees well between CT and MRI, while the early peak is only apparent in the CT measurement. Besides the temporal averaging of the MRI data, another reason for the difference could be that the signal-to-noise ratio for MRI is relatively low in the range of LAA outflow velocities and therefore the early wave might not be apparent in the MRI data.

Our study is limited by the relatively small group of 9 individuals. In the future, it would be beneficial to include more individuals and analyze the blood flow with respect to different cardiac pathologies such as atrial fibrillation and heart failure. Additionally, we noted a trend for individuals with high LAA contraction at late diastole, in which the velocities in MRI where slightly higher than in CT. This might indicate that the temporal resolution of the time-resolved CT is not fully sufficient to capture the complete motion of the LAA, leading to an overestimation of the minimal LAA volume and an underestimation of peak outflow rates. Future developments in CT technology leading to higher temporal resolutions could improve this disagreement. However, from a clinical perspective, accurate assessment of LAA in patients with moderate and weak LAA contraction is most interesting, since this might promote thrombus formation.

In conclusion, our surface-based algorithm could successfully track the endocardium and the wall of the LAA. The resulting LAA outflow was in good agreement to flow rates measured in the same individual with 4D flow MRI.

INTRODUCTION

Thoracic aortic aneurysms (TAAs) are bulging enlargements of the aorta. They affect approximately 15,000 people in the US per year and can be fatal in 80% of the cases when ruptured[1]. Surgical intervention criteria are defined primarily in terms of the maximum diameter and growth rate, but it has been shown that about 60% of the patients present complications before the intervention criteria are reached[2].

Formation and growth of TAAs are often associated with genetic connective tissue disorders (CTDs), which are mutations that affect extracellular matrix (ECM) proteins[3]. Similarly, blood flow dynamics features, such as altered luminal pressure, wall shear stress, and intramural stress, have also been linked to the disease[4]. Further, it has been found recently that the aortic tortuosity index (ATI) correlates with the disease outcome[5]. The long life cycle of the human and the need to protect patients place limits on our ability to study aneurysm growth and failure mechanisms in humans. Mouse models of CTD provide an opportunity to explore the in-vivo progression of aneurysms.

In this study, we used blood flow dynamics features to explore better predictive indicators of aneurysm outcomes. To perform the study, we used a combination of mouse-specific fluid-structure interaction (FSI) models and aortic shape measurements to characterize aortic aneurysms in a CTD mouse model, and we compared the various measurements and calculations with the lifespan of the individual mice.

METHODS

Mouse models: Mouse models with TAA caused by deletion of the ECM fibulin-4 gene in smooth muscle cells (Fbln4^{SMKO}) were used. TAA growth in each animal was monitored throughout the early disease stages by magnetic resonance angiography (MRA). The scans were collected at two, four, and six months of age. After the mice died naturally or were sacrificed at least 24 months of age, biaxial mechanical testing was performed to obtain the material properties of the aortic tissues. Table 1 shows the results of the biaxial measurements, as well as wall thickness, lifespan, and ATI for each mouse.

Table 1. Mouse-specific parameters.

Mouse	Elastic modulus [MPa]	Wall thickness [mm]	Lifespan [months]	ATI
1	2.23	0.129	17.8	45.34
2	1.16	0.122	18.2	59.53
3	1.22	0.109	22.4	37.87
4	0.88	0.112	21.9	53.57
5	1.59	0.110	25.1*	39.86
6	0.93	0.123	24.9*	38.78
7	0.64	0.119	24.9*	22.80

* Sacrificed after reaching at least 24 months of age

FSI simulations: MRA images of mice at 6 months of age were used to generate mouse-specific models for the FSI simulation. Wall thickness was treated as constant over the length of the aorta and based on experimental measurement as shown in Table 1. The aortic wall was described as neo-Hookean and incompressible, with each mouse specified based on the elastic modulus measured post mortem.

Blood was treated as Newtonian with a viscosity of 3.5 cP. A waveform from an earlier mouse study[6] was used as the inlet boundary condition and assumed to be the same for all mice. For the outlet arteries, windkessel models with values based on literature[6] were used as boundary conditions for all mice. Simulations were performed for five cardiac cycles using SimVascular[7] at the Minnesota Supercomputer Institute (MSI).

Data Analysis and Statistics: A Tobit model[8] was used to analyze the data assuming linear effects with lifespan data censored to a maximum value of 25 months (i.e., the three mice that were sacrificed were specified to have a lifespan of at least 25 months). A pseudo-r^2 estimate[9] was used to assess goodness-of-fit for each Tobit model fit.

RESULTS

We performed FSI simulation for seven Fbln4^{SMKO} mice all at 6-months of age, and at different stages of aneurysm formation. Figure 1 shows the geometry and von Mises stress distribution at peak systole for each aortic model. High-stress regions are concentrated in the ascending aorta, close to the branches for all the models.

Using the results obtained from the simulations, we investigated the correlation between mouse lifespan and the features of the blood flow dynamics. Figure 2 shows the pseudo-r^2 correlation matrix for results from the FSI simulation and experimental measurements. Red circles highlight the parameters that have the highest correlation with mice lifespan (LS). Among those, oscillatory shear index (OSI) shows a very high value (r^2=0.95), suggesting it is the best parameter to be used as a predictor of the outcome of an aortic aneurysm in these mice. Surprisingly, the calculated OSI correlated *positively* with lifespan.

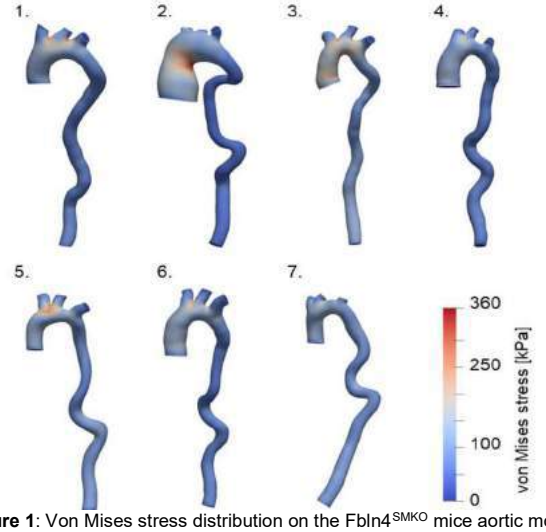

Figure 1: Von Mises stress distribution on the Fbln4^{SMKO} mice aortic models.

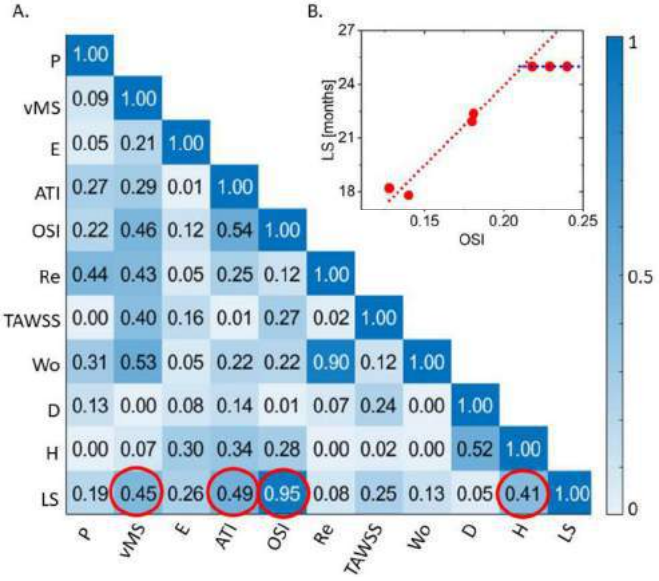

Figure 2: A) Correlation matrix for maximum luminal pressure (P), maximum von Mises stress (vMS), maximum velocity (V), elastic modulus (E), aortic tortuosity index (ATI), oscillatory shear index (OSI), Reynolds number (Re), time averaged wall shear stress (TAWSS), Womersley number (Wo), maximum aortic diameter (D), maximum aortic thickness (H), and lifespan (LS). Red circles highlight the parameters with high correlation with LS. B) Correlation plot between LS and OSI from Tobit model. Blue line represents the maximum value of the censored data.

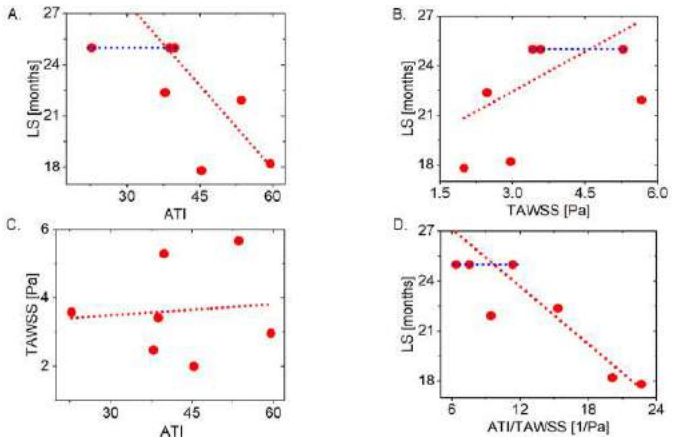

Figure 3: Correlation plots for **A)** LS and ATI, **B)** LS and TAWSS, **C)** TAWSS and ATI and **D)** LS and the ratio of ATI and TAWSS. Solid circles are the measurements for each one of models, the dashed line is the linear fitting from Tobit model, and blue line represents the maximum value the censored data.

Additionally, we notice that extra information could be collected by combining ATI and TAWSS: both have a fair correlation ($r^2 \geq 0.25$) with LS, as shown in Figs. 3A and 3B, but are largely uncorrelated with each other ($r^2 \leq 0.01$, Fig. 3C), suggesting that a combination of the two could provide additional information. The ratio ATI/TAWSS shows a high negative correlation with LS ($r^2 = 0.79$, Fig. 3D).

DISCUSSION

We created seven aortic models for Fbln4^{SMKO} mice at the age of 6 months. The mice were at different stages of the aneurysm formation and exhibited different degrees of aortic tortuosity. Mouse-specific material properties and wall thickness were combined with generic boundary conditions for blood flow in the FSI simulations. Results for von Mises stress distribution along the wall show a high-stress region concentrated at the ascending aorta for all the models.

Mouse lifespan was correlated to vMS, ATI, H, and especially OSI, suggesting that OSI estimated from patient-specific flow simulations could serve as a biomarker for aneurysm outcome. The combination of ATI (a geometric measure) and TAWSS (a biofluids measure) also showed a high r^2, suggesting that a hybrid measurement may be used to improve the prediction of aneurysm outcome.

This was a small study (n = 7) of only one mouse model. Further study is needed to determine which, if any, of the effects observed here are general, how those effects change with different CTDs, and how the ideas suggested can be extrapolated to humans. Nevertheless, as it becomes more and more possible to acquire geometric and mechanical data from patients[10], multi-physics, multi-information models will provide new insight into aneurysm disease and its outcomes.

INTRODUCTION

Discrete subaortic stenosis (DSS) is an obstructive cardiac disease characterized by the formation of a thin fibromuscular ring of tissue in the left ventricular (LV) outflow tract (LVOT). Risk factors promoting DSS include morphological LVOT abnormalities such as a steep aortoseptal angle (angle between the long-axis of the aorta and the septal wall), subphysiologic aortic annulus diameter, and large aortic valve-mitral valve separation distance [1]. Without intervention, the lesion can lead to an array of secondary pathologies including aortic regurgitation, LV hypertrophy, infective endocarditis, and death [2]. Treatment consists of invasive membrane resection, but many patients require additional surgeries due to the lesion's high recurrence rate (8-34%) [2].

Although the etiology of DSS is unknown, the strong association between DSS and morphological LVOT abnormalities suggests that the lesion could result from a biological cascade initiated by endocardial cells and triggered by flow alterations in the LVOT [2]. The assessment of this hypothetical pathway requires elucidating the LV wall shear stress (WSS) abnormalities caused by the aberrant LVOT anatomy. Therefore, the aim of this study was to utilize 3D computational fluid dynamics to quantify the LVOT WSS environment in representative LV models reconstructed from patient data.

METHODS

LV images were obtained from a healthy 21-year-old adult female volunteer using a 3T MRI scanner (GE Medical Systems MR 750w). 20 total temporal phases per cardiac cycle were acquired within the short-axis plane with a slice thickness of 8 mm. Manual segmentation and 3D reconstruction were done using Segment v3.0 R7568 [3] to generate a template LV geometry (Fig. 1), and intermediate displacements between frames were generated using cubic spline interpolation.

Echocardiographic data taken from recent DSS resection patients (DSS-prone; n=40) and healthy individuals (control; n=40) between May 1997 and June 2020 at Texas Children's Hospital were used to generate additional LV geometries. Variations in LV and LVOT anatomy were parametrized by segregating the patient data into four age ranges (1-2 yrs., 3-5 yrs., 6-8 yrs., and >9 yrs.; n=8 total cases), from which representative LV geometries were generated (Fig. 1). Briefly, the LV template was first globally scaled to match patient-averaged blood volumes, and the LVOT anatomy was recreated using patient-averaged aortic/mitral annuli dimensions and aortoseptal angles. Finally, the averaged location of DSS development was identified and

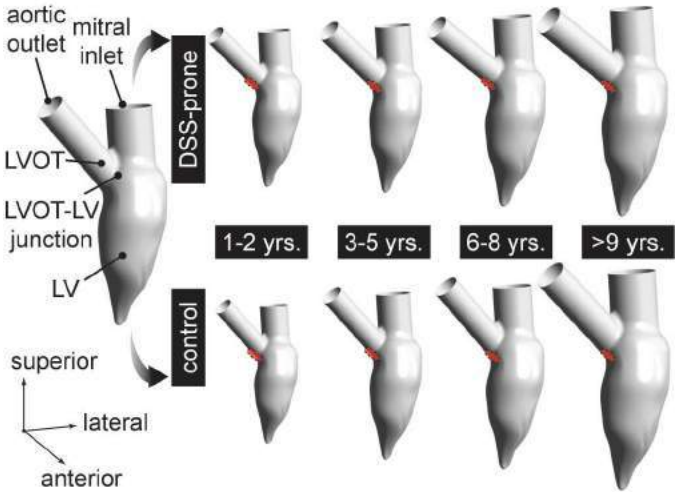

Figure 1. Age-matched representative LV geometrical models with averaged location of DSS development (highlighted in red).

specified as a region of interest in both study groups (Fig. 1).

LV motion was implemented via a one-way fluid-structure interaction (FSI) technique in ANSYS 2019 R3 [2]. Following a mesh sensitivity analysis, each fluid domain was meshed with a characteristic cell length of 0.8 mm and a near-wall resolution of 10 μm. The cycle-averaged LV WSS environments were characterized in terms of the temporal shear magnitude (TSM, cycle-averaged WSS magnitude) and oscillatory shear index (OSI, quantifies WSS oscillatory nature; 0: unidirectional, 0.5: bidirectional). The WSS topological skeleton was also computed to map the complex features of the WSS vector field [4].

RESULTS

Global blood flow characteristics between the DSS-prone and control groups were similar despite differences in local LVOT geometry and global hemodynamic parameters across the age groups. Interventricular filling generated an asymmetric vortex ring during diastole, which redirected blood flow towards the LVOT and out the LV during systolep. Systolic volume-averaged velocity and vorticity magnitudes, averaged among all age ranges, indicated no substantial differences between the DSS-prone and control groups (8.4% and 1.7% difference, respectively).

Cycle-Averaged Hemodynamic Stress Characteristics

Pair-wise comparisons of the global cycle-averaged hemodynamic stress spatial distributions did not substantially vary between the DSS-prone and control groups; however, local value differences were detected primarily in the LVOT. Regions of high TSM were observed at the LVOT-LV junction, which were augmented on the LVOT anterior-inferior area in the DSS-prone anatomies (Fig. 2). Conversely, OSI values captured at the LVOT-LV junction were uniformly low, highlighting strong unidirectional flow behavior leading into the outflow tract. A region of high OSI value, indicating flow recirculation, was detected downstream on the anterior LVOT surface, which trailed further into the LVOT in the DSS-prone models.

The cycle-averaged WSS topological skeleton was computed by taking the divergence of the normalized cycle-averaged WSS vector field (WSSdiv_{Norm}) to characterize fixed points (i.e., locations where the WSS vector field disappears) and the WSS contraction/expansion regions that connect them (contraction: $\mathrm{WSSdiv}_{Norm} < 0$; expansion: $\mathrm{WSSdiv}_{Norm} > 0$) [4]. All models exhibited fixed points primarily on the superior LVOT-LV junction, with the DSS-prone group revealing additional points lining the anterior-inferior areas of the junction (Fig. 2). Both groups predicted concentric regions of WSS expansion with similar normalized magnitudes upstream the LVOT-LV junction. Though all models displayed similar concentric regions of WSS contraction at the LVOT-LV junction, the DSS-prone LVs predicted stronger WSS contraction on the anterior-inferior region of the junction, which colocalized with areas of high TSM (> 80th percentile).

WSS Characteristics in Regions Prone to DSS

The averaged site of lesion development showed substantial differences in WSS characteristics between the study groups. When compared against the age-matched controls, a threshold was observed in the DSS-prone LVs in which patients younger than 5 years exhibited lower WSS magnitudes (up to 6.5 % decrease in TSM vs. control) and older than 6 years exhibited WSS overloads (>30% increase in TSM vs. control). Although no such threshold was identified when evaluating WSSdiv_{Norm} , increased age was associated with stronger WSS contraction in both DSS-prone and control LVs. Further, age-matched comparison indicated that DSS-prone LVs generated substantial decreases in WSSdiv_{Norm} especially in the youngest age range (up to 11.2-fold decrease vs. age-matched control), suggesting strong WSS luminal contraction. Despite this, multidirectionality characteristics between both study groups were similar (less than 0.05-point difference in OSI between age-matched LVs), and indicated strong pulsatile/unidirectional flow overall (OSI <0.2).

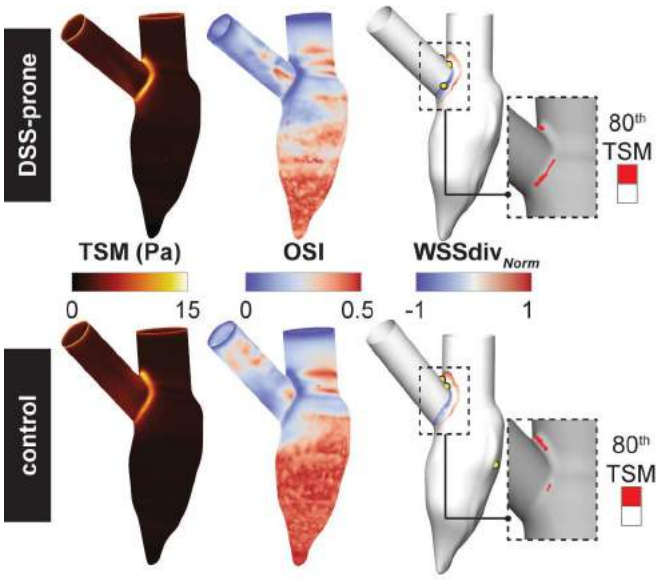

Figure 2. 3D contour mapping on the > 9 yrs. LV model (yellow dots: saddle points). Insets denote colocalized regions of high TSM (> 80th percentile) and WSS contraction ($\mathrm{WSSdiv}_{Norm} < 0$).

DISCUSSION

3D simulations of representative LV models with realistic wall motion were performed to assess the effects of anatomic variation on blood flow patterns and hemodynamic stresses. Though predicted hemodynamics did not substantially vary between the study groups, small changes in LVOT morphology heavily impacted the WSS environment and resulted in WSS overloads and increased local contraction action in regions susceptible to DSS development. Consistent with the literature which suggests such mechanistic impacts could promote lesion formation, the results, therefore, provide compelling evidence for (1) the existence of a mechano-etiology for DSS, and (2) the potential role played by abnormal WSS colocalizations in DSS lesion development.

Although exclusion of the cardiac valves is a limitation, this study demonstrates the existence of significant WSS abnormalities in LVs prone to DSS formation, which may play a key role in the pathogenesis of the lesion. Further biological studies are needed to assess the effects of such abnormalities at the tissue and cellular levels.

AN EVALUATION OF INTERFACE PRESSURE AND SHEAR FORCE PATTERNS IN INJURY PRONE REGIONS WHILE SEATED IN AN ARTICULATING CHAIR

Justin Scott and Tamara Reid Bush PhD

Department of Mechanical Engineering
Michigan State University
East Lansing, MI, USA

INTRODUCTION

Pressure Injuries (PIs) are soft tissue wounds that affect an enormous number of wheelchair users, especially those with spinal cord injuries (SCIs). This population has an 80% lifetime incidence [1]. Not only are PIs prevalent, but treatment costs $35,000 on average [2]. As such, the United States spends $11 billion annually to treat them [3]. It is imperative to reduce PI occurrence to improve quality of life and decrease the societal financial burden.

The buttocks and lower back are regions of the body that are especially prone to PIs. This is due to large interface loads, both normal and shear, while seated. Around half of PIs occur in the buttocks or lower back, and thus, prevention efforts have focused on these regions [4]. In particular, wheelchairs include back recline and whole-body tilt to reduce pressure on the buttocks and lower back. Unfortunately, results are inconclusive regarding the effectiveness of these approaches, despite being the most used pressure relief positions [5]. PIs in the buttocks and lower back have persisted to be a common medical issue.

Determining effective PI prevention strategies often includes modeling of PI prone regions. Finite element models connect external loads to tissue stresses, and ultimately to PI formation. However, many finite element models used to study PI formation in wheelchair users relied on inputs from able-bodied individuals [6]. As wheelchair users experience larger external loads while seated relative to able-bodied individuals, load data from wheelchair users are needed to create more representative models [7].

Therefore, the goals of this work were to design an accessible articulating chair and to collect data from both able-bodied individuals and wheelchair users that 1) evaluate back recline and seat pan tilt for their effectiveness in reducing normal interface pressure in the buttocks and lower back, and 2) evaluate a custom nylon cushion cover for its ability to reduce shear interface load on the buttocks while seated.

METHODS

30 individuals volunteered for this study (IRB #15-889). 20 able-bodied individuals (10 male, 10 female) and 10 male wheelchair users participated. An articulating chair was built with independently rotating seat pan and chair back. Thorax and pelvis supports were mounted on the back (Fig. 1). The seat pan, pelvis, and thorax surfaces were mounted on six-axis load cells and covered by pressure mats.

Force and interface pressure data were obtained in 9 seated positions for all participants. Positions were described by **all the combinations** of back recline angles and seat pan tilt angles described in Table 1. Recline and seat pan tilt were the chair back's and seat pan's angles from the vertical and horizontal, respectively. Whole-body tilt positions were those with both nonzero back recline and seat pan tilt. Interface pressure and force data were collected in each position with two cushion covers on the seat pan. One was a standard vinyl cover, while the second was a custom cover constructed from two layers of nylon fabric designed to reduce shear.

Pressure data were then segmented by region of the body. The inferior third of the back pressure mat was considered the lower back, and the posterior half of the seat pan pressure mat was considered the buttocks (Fig. 1). The maximum pressure recorded in each of these regions is reported in the results.

A three-way repeated measures ANOVA and subsequent Tukey tests were used to determine the effects of back recline and seat pan tilt, and group differences on the buttocks and lower back on maximum pressures of able-bodied individuals and wheelchair users. A two-way repeated measures ANOVA and subsequent Tukey tests were used to determine the effects of back recline and inter-group differences in shear force on the buttocks.

Table 1. Angles of rotation for chair supports in all positions, given in degrees

Back Recline	Seat Pan Tilt
0°	0°
10°	15°
20°	30°

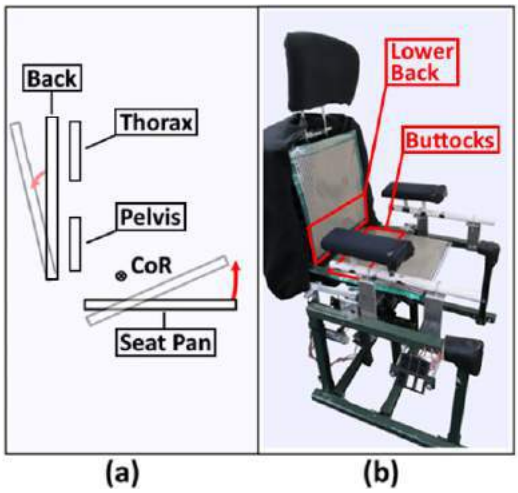

Figure 1. a) Articulating chair schematic, where seat pan and chair back rotate about point 'CoR' b) pressure mats attached to chair with regions of interest in red boxes

RESULTS

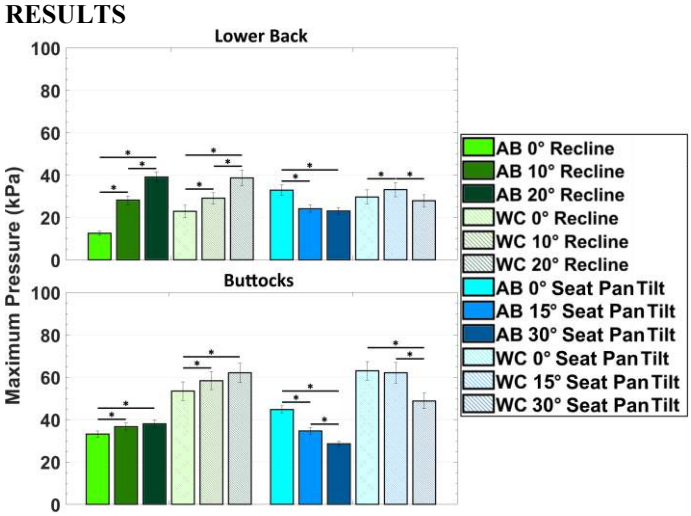

Figure 2. Average maximum interface pressure in the lower back (top) and buttocks (bottom) regions for each level of each articulation. Able-bodied (AB) participants are darker bars, and wheelchair users (WC) are light bars. In general, pressures on both regions increased with increased recline and decreased with seat pan tilt. Significant differences are indicated by asterisks (*)

Normal interface pressure data in the lower back and buttocks are presented in Figure 2 for both able-bodied participants and wheelchair users. Data are shown for every level of recline and seat pan tilt. Both chair articulations and wheelchair use were found to affect maximum normal pressures. The normal pressure data indicated that recline increased the maximum normal pressure in the lower back and buttocks of both groups, while seat pan tilt decreased it. The maximum pressures in the buttocks of the wheelchair users were significantly larger than the maximum pressures of the able-bodied group, but there were no significant inter-group differences in the lower back.

A majority of the effects of recline angle, cushion cover, and group on shear force were significant. Shear force on the seat pan increased with recline angle in both groups regardless of cover. Overall, the custom nylon cover reduced shear force on the seat pan relative to the vinyl cover. The nylon cover reduced the shear force on the seat pan by approximately 10% for all back recline angles for both groups, except for the 0° recline position for wheelchair users. Lastly, wheelchair users tended to have higher shear forces than able-bodied individuals, but there were no significant differences between groups ($p = .069$).

DISCUSSION

This project characterized normal pressure and shear force patterns in PI prone regions of seated individuals across several seated positions and with two cushion covers. Both wheelchair users and able-bodied participants were included, and common pressure relieving positions, recline and whole-body tilt, were tested as well as isolated seat pan tilt.

The primary goal of this work was to assess the efficacy of different seated positions at reducing interface pressure in PI prone regions. Changes in seated position affected the normal pressure and shear force patterns in all participants. Of particular importance was the finding that increasing recline angle increased both the normal pressure and shear force in the buttocks region of the seat pan. This is important because recline is the most common pressure reducing position in wheelchair users, but our results do not support its use [5]. Both normal pressure and shear force are associated with the formation of PIs; and therefore, another chair articulation could be more effective at PI prevention. As whole-body tilt was a combination of back recline and seat pan tilt, it did not have a definitive effect on the maximum pressure in the lower back or buttocks. Instead, seat pan tilt alone was actually found to decrease the maximum normal pressure on the buttocks and lower back and thus shows potential as a PI prevention strategy. Though trends in shear force relative to seat pan tilt have yet to be established, it has shown promise as a pressure reducing articulation that can help prevent PIs.

The custom nylon cushion cover reduced shear force on the seat pan, providing a non-repositioning based option for reducing factors associate with PI risk. The nylon cover may be used in conjunction with other PI prevention strategies, such as seated repositioning or specialized cushions, to further reduce the risk of PI formation.

The data and trends observed in this study can be used to inform processes, such as design of components and model development, in the future. Wheelchairs can be designed with an isolated seat pan rotation to allow individuals to relieve the pressure on their buttocks and lower backs. Cushion covers can be designed to minimize shear force on the buttocks. Moreover, since these data include interface pressure data from wheelchair users, they can be used to model how seated repositioning affects the tissue stresses in wheelchair users in more representative models.

Turin, Italy

INTRODUCTION

Coronary stents are tube-shaped devices expanded inside an atherosclerotic coronary artery aiming to restore the correct blood flow to the heart. In studying the hemodynamics in stented coronary arteries, a large body of literature has highlighted that local blood flow disturbances may play a key role in the pathophysiological trajectories leading to stent failure, e.g., in-stent restenosis [1,2]. Notwithstanding the growing research interest in stented artery hemodynamic features as predictors of stent failure, how local hemodynamics influence flow-related processes leading to in-stent restenosis is still not completely understood.

In this context, to improve and extent the current understanding of the association between local hemodynamics and vascular diseases, a marked interest recently has emerged on Wall Shear Stress (WSS) vector field topological skeleton, composed by fixed points and their connections, called stable/unstable manifolds [3,4]. A fixed point is a focal point where the WSS vanishes, and unstable/stable manifolds are contraction/expansion regions linking fixed points [4]. Such an interest arises from the ability of WSS topological skeleton features to reflect cardiovascular complexity, with direct links to near-wall flow stagnation, separation, and recirculation, flow features associated with in-stent restenosis in coronary arteries [3].

The present study explores the WSS topological skeleton features in image-based computational fluid dynamics (CFD) stented coronary artery models replicating the complete clinical procedure of stent implantation performed in clinical practice [2]. The final aim is to investigate the possible involvement of WSS topological skeleton features in the processes leading to stent failure. To do that, a recently proposed Eulerian-based method for the analysis of the topological skeleton of the WSS vector field [4] is applied.

METHODS

Computational hemodynamics. The two cases (i.e., CASE A and B) of pathologic Left Anterior Descending (LAD) artery with bifurcations treated with the provisional stenting technique considered here have been already partially presented elsewhere [2]. In CASE A, a Xience Prime stent by Abbott Vascular (nominal diameter of 3 mm, length of 28 mm and strut thickness of 81 μm), was implanted. In CASE B, two Endeavor Resolute stents by Medtronic (nominal diameter of 2.75 mm, length of 15 mm and strut thickness of 91 μm) were implanted. Pre-operative vessels were reconstructed combining conventional angiography and computed tomography angiography data [2], and structural finite element analyses replicating the clinical stenting procedures were used to obtain the post-operative, stented fluid domains [2]. A hybrid discretization strategy using both tetrahedral and hexahedral elements was adopted [2]. Transient CFD simulations were performed using a finite-volume based code, applying a pulsatile flow waveform representative of the human LAD as inflow boundary condition. Additionally, two transient simulations in the two non-stented geometries were performed. Exhaustive details on the computational settings are provided elsewhere [2].

WSS topological skeleton. The WSS topological skeleton analysis was performed by considering a recently proposed Eulerian-based method [4]. Briefly, based on Volume Contraction theory, it has been demonstrated that the divergence of the normalized WSS vector field can be used to easily identify the connections between WSS fixed points, i.e., WSS manifolds [4]:

$$DIV_W = \nabla \cdot \left(\frac{\boldsymbol{\tau}}{\|\boldsymbol{\tau}\|_2}\right) = \nabla \cdot (\boldsymbol{\tau}_u) \quad (1)$$

where $\boldsymbol{\tau}_u$ is the WSS unit vector. Technically, DIV_W negative values identify *contraction regions* approximating *attracting manifolds*, while positive values identify *expansion regions* approximating *repelling*

manifolds. To complete the WSS topological skeleton analysis, WSS fixed points were identified and classified by computing Poincaré index and eigenvalues of the Jacobian matrix respectively, according to the scheme proposed in [4].

In addition, a quantity based on WSS divergence, named Topological Shear Variation Index (*TSVI*) [5], i.e., the root mean square deviation of the divergence of the normalized WSS with respect to its average over the cardiac cycle:

$$TSVI = \left\{\frac{1}{\mathrm{T}}\int_0^{\mathrm{T}}\left[\nabla\cdot(\boldsymbol{\tau}_u) - \overline{\nabla\cdot(\boldsymbol{\tau}_u)}\right]^2\ dt\right\}^{1/2} \qquad (2)$$

where T is the cardiac cycle duration, was here adopted. Roughly speaking, $TSVI$ measures the local amount of variation in WSS contraction/expansion action exerted along the cardiac cycle on Endothelial Cells (ECs) lining the luminal surface of a vessel.

RESULTS

The cycle-average WSS topological skeleton and the $TSVI$ distribution along the luminal surface for stented CASE A and B are displayed in Figures 1 and 2, respectively. In both cases, WSS fixed points were mostly located at the luminal surface in correspondence with stent peaks. Moreover, WSS fixed points were located at the luminal surface close to all strut connectors in CASE A (Figure 1) and in the overlapping region between the two stents in CASE B (Figure 2). Both stented cases were characterized by WSS contraction regions, identified by negative DIV_W values, located at immediately upstream struts regions and WSS expansions regions, identified by positive DIV_W values, located at immediately downstream struts regions. Interestingly, a completely reverse DIV_W distribution can be observed in the stent malapposition region for CASE A (Figure 1) and in the overlapping zone between two stents for CASE B (Figure 2).

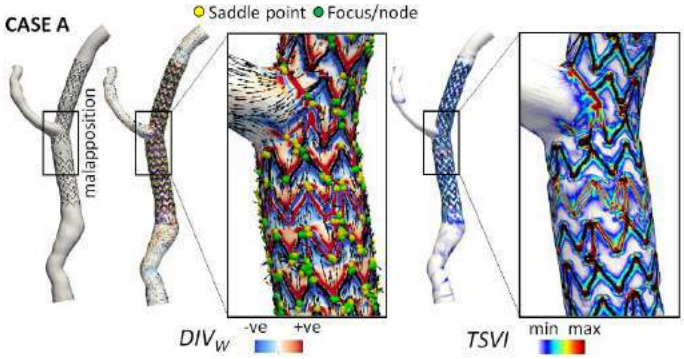

Figure 1: Cycle-average WSS topological skeleton and *TSVI* distribution on the luminal surface for CASE A with stent. Regions where the stent struts are in contact with the wall are black colored.

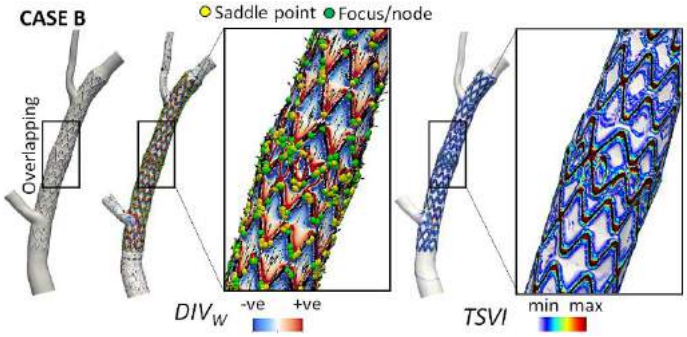

Figure 2: Cycle-average WSS topological skeleton and *TSVI* distribution on the luminal surface for CASE B with stent. Regions where the stent struts are in contact with the wall are black colored.

TSVI maps highlighted that marked variations in the WSS contraction/expansion action exerted on the endothelium along the cardiac cycle were mainly located at the luminal surface in correspondence with stent peaks and close to all the struts in both models. The highest *TSVI* values were located at the bifurcation, in the stent malapposition region and close to stent connectors for CASE A (Figure 1), and at the stents overlapping region for CASE B (Figure 2).

To appreciate the hemodynamic impact of the stenting procedures, the cycle-average WSS topological skeleton and the *TSVI* distribution along the luminal surface of the non-stented models are displayed in Figure 3. In non-stented models WSS saddle points, WSS contraction/expansion regions and high *TSVI* values were located only at the bifurcation regions, and in the proximal region CASE A, where the vessel presents marked curvature and tortuosity.

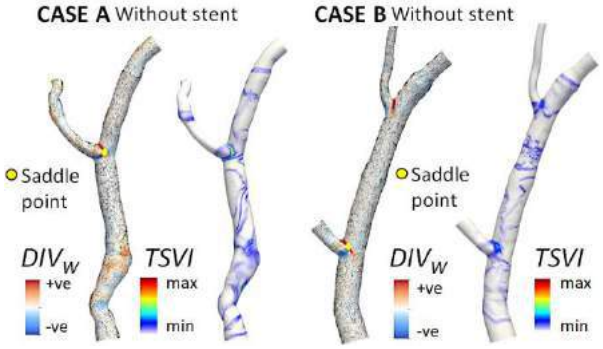

Figure 3: Cycle-average WSS topological skeleton and *TSVI* distribution on the luminal surface for CASE A and for CASE B without the presence of stent.

DISCUSSION

The present study investigated for the first time the role of the WSS topological skeleton features in processes leading to in-stent restenosis in coronary arteries by applying a Eulerian-based WSS topological analysis on two image-based stented coronary artery models. The findings of this analysis suggest that WSS topological skeleton features could represent a hemodynamic cue promoting coronary in-stent restenosis, in addition to the well-established low WSS. In detail, the luminal exposure to the high variability in the contraction and expansion action exerted by WSS (biomechanically described by *TSVI*) could induce a recurring variation in intracellular tension (acting e.g., on cell roundness) [6] and intercellular tension (e.g., increasing propagation of tension acting on junctions directionality) [7], with consequences on the endothelium permeability. Moreover, WSS contraction and expansion regions surrounding the stent struts could be linked to the EC migration and accumulation process observed in experimental studies [8], with WSS contraction action co-localized with ECs migration upstream from stent struts and WSS expansion action co-localized with ECs accumulation immediately downstream from stent struts [8].

In conclusion, the presented approach might contribute to a deeper understanding of the hemodynamics-driven processes underlying in-stent restenosis in coronary arteries.

INTRODUCTION

Ascending aorta (AAo) aneurysm is a common aortic disease which consists of a localized dilation of the AAo and which carries a considerable risk of life-threatening events, such as aortic dissection. Since a dilation of the AAo usually presents with altered hemodynamics and aortic insufficiency, an accurate knowledge of the aortic blood flow is required to reveal possible links between hemodynamic features, dilation progression and related risks. In this exploratory study, the Complex Networks (CNs) theory was applied for the first time to an *in vivo* dataset of 4D flow MRI acquisitions of human aorta, aiming at exploring the spatiotemporal heterogeneity of large scale/dominant aortic flow features, as well as its association with AAo dilation. A total of ten patients, five presenting with no AAo dilation and five with dilated AAo, underwent 4D flow MRI [1], covering the thoracic aorta with a spatial resolution of 2.5x2.5x2.5 mm. The time-resolved phase velocity data were used to build a correlation-based CN for each subject [2]. The persistence length of the correlation of velocity data along the cardiac cycle was quantified and its association with AAo dilation, kinetic energy, flow jet angle, and pulse wave velocity was explored.

METHODS

The study population comprises five patients presenting with AAo dilation (one of them with bicuspid aortic valve, BAV), and five with no AAo dilation (one with BAV). All the enrolled patients also present with mild-to-severe aortic valve dysfunction. Full details on 4D flow MRI acquisition protocol and data processing are exhaustively reported elsewhere [1,3]. The study was approved by the ethics committee of the Vall d'Hebron Hospital and informed consent was obtained from all participants. The lumen of each thoracic aorta was semi-automatically segmented from an angiography derived from 4D flow MRI data using ITK-Snap and its centerline was computed using VMTK (www.vmtk.org). Anatomical landmarks were identified from co-registered 2D cine images and used to ensure a consistent spatial extent across all cases. For each patient and each voxel pertaining to the aorta, time-resolved velocity magnitude waveforms were obtained, as reported elsewhere [1]. 3D velocity data were exported using in-house Matlab code (MathWorks Inc, USA) and used to build a CN.

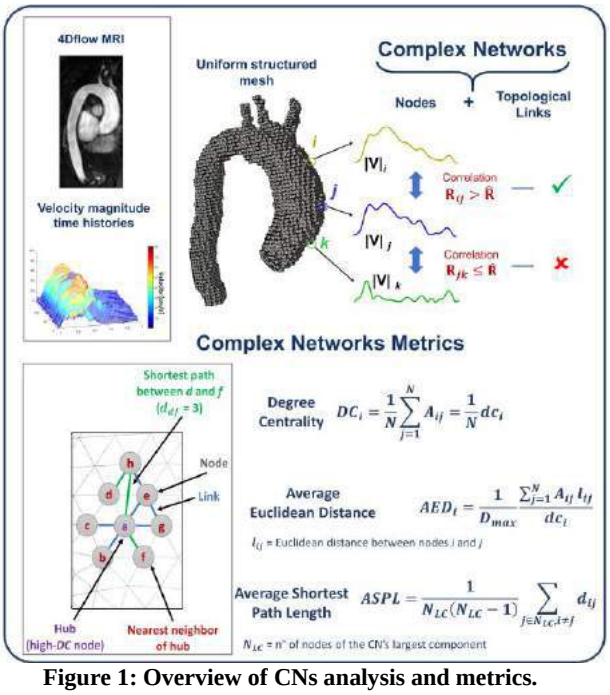

Figure 1: Overview of CNs analysis and metrics.

In detail, each node of the CNs is defined by the voxel where the velocity magnitude |**V**| time history along the cardiac cycle is acquired and two nodes are connected by a topological link $\{i, j\}$ if the Pearson correlation coefficient R_{ij} between the time histories at nodes *i* and *j* is greater than a threshold value $\hat{R}$ (**Fig. 1**) [2]. In this study, the median value of the correlation coefficients between |**V**| time histories derived from patient-specific CFD simulations carried out on a dataset of healthy aorta models was adopted as threshold value ($\hat{R}$=0.87). Each patient's network was characterized by its adjacency matrix A_{ij} containing the information on each node connections [2]. The topological structure of the networks built from *in vivo* data was characterized by three CNs metrics [2] (**Fig. 1**): (1) the *degree centrality* (DC_i) of node *i*, defined as the number of nodes of the CN connected to node *i* expressed as a percentage of the number of voxels in the model; (2) the *normalized average Euclidean distance* (AED_i) between node *i* and all its nearest neighbors, expressed in terms of number of maximum patient-specific AAo diameters D_{max}; (3) the *average shortest path length* ($ASPL$) of the network, defined as the average length of the shortest path d_{ij} connecting two generic nodes *i* and *j* in the CN (**Fig. 1**). DC is a measure of the homogeneity/heterogeneity of |**V**| time history acquired at each voxel with respect to the whole fluid domain, whereas AED and $ASPL$ quantify for each patient the anatomical and topological persistence length of the correlation between |**V**| time histories in the aorta, respectively [2]. The impact of clinically-relevant features on the heterogeneity of the aortic hemodynamics was evaluated by exploring the existence of associations between CNs metrics and kinetic energy (KE), flow jet angle (FJA) [4], pulse wave velocity (PWV) [5] and AAo maximum diameter (D_{max}).

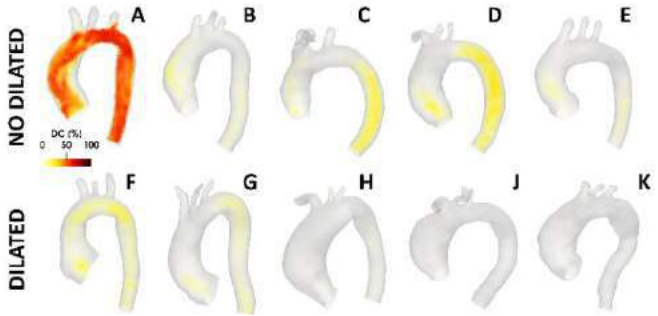

Figure 2: DC volumetric maps.

RESULTS

The volumetric maps of DC in **Fig. 2** clearly highlight a large interindividual variability in the heterogeneity of |**V**| time history shapes. The CN built on patient A is characterized by a dense pattern of connections between nodes in the entire aortic domain, confirmed by the DC values around 50%. The other patients present sparse, scarcely connected networks, reflecting from very poor (as in dilated patients H, J and K, **Fig. 2**) to moderate homogeneity (in particular no dilated patients C and D). The AED maps (data not shown) highlight that, in general, the anatomical length of the correlation of |**V**| time histories is higher in the descending aorta, whereas it reaches a minimum the ascending aorta, especially in patients with dilated AAo. A significant, negative correlation emerges between AED median values and D_{max} (**Fig. 3a**), suggesting that AAo dilation can play a major role in disrupting hemodynamic similarity in velocity magnitude waveforms not only in the AAo, but involving the entire thoracic aorta. In parallel, a near significant positive trend (p_{value}=0.06) emerges between KE and AED, suggesting that high peak kinetic energy values might contribute to increase the anatomical length of the correlation persistence (**Fig. 3b**).

The opposite effects of aortic dilation and blood flow kinetic energy also emerge in the moderate but significant associations with the topological correlation persistence length, expressed by $ASPL$ (**Fig. 3c** and **3d)**. Finally, CNs metrics were not significatively correlated with FJA and PWV at this stage of the investigation, probably because of the scarcely stratified dataset.

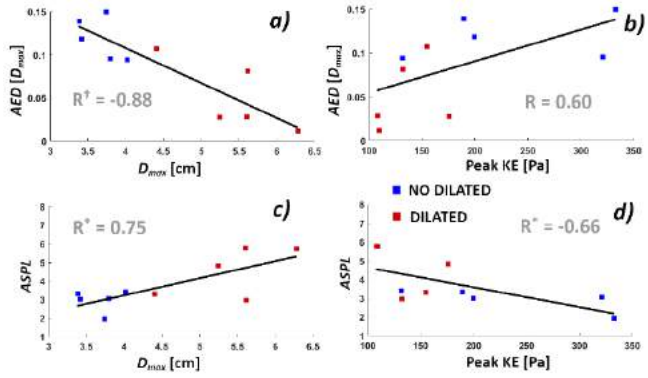

Figure 3: Associations between CNs metrics and clinically-relevant features. For each CN, AED is expressed as the median value of all nodes. (*p_{value} < 0.05; †p_{value} < 0.001)

DISCUSSION

In this study, the CNs theory is applied to *in vivo* 4D flow MRI velocity data to investigate the spatiotemporal heterogeneity of aortic velocity magnitude waveforms shape along the cardiac cycle, and the existence of possible associations between CNs metrics and quantities of clinical interest is explored. The main findings suggest that the physiological Euclidean and topological length of persistence, which are supposed to characterize the physiological aortic intravascular hemodynamics, might be more markedly disrupted in patients with larger maximum AAo diameter (high D_{max} values reduce the anatomical extension of the correlations, AED, and increase the topological separation between nodes, $ASPL$). This is consistent with a recent study on CFD models of ascending thoracic aorta aneurysms, highlighting how the aortic dilation disrupts the correlation persistence of velocity-based waveforms, breaking the topological connections between nodes, especially in the region where a marked change in the mechanical properties of the aortic wall occurs [6]. Conversely, it is suggested that the amount of fluid kinetic energy, representative of the large scale flow features, might play a beneficial role in preserving physiological homogeneity in blood velocity magnitude waveforms shape. In conclusion, this first *in vivo* application of CNs theory to cardiovascular flows looks promising in disentangling the complex 4D aortic hemodynamics. The combined use of D_{max} and CNs distance metrics may allow a finer risk stratification for AAo disease in future applications on larger datasets.

INTRODUCTION

Tendons are highly organized and fibrous tissues that transmit the mechanical load from muscle onto bone.[1–3] Common measurements of tendon quality are the quantification of collagen fibril size, shape, and organization.[4,5] Often mutants with compromised tendons have smaller and irregularly shaped collagen fibrils.[6]

As fibril diameters are measured in nm, observation requires highly sophisticated imaging techniques. Transmission electron microscopy (TEM), which is a high magnification and high resolution imaging technique which generates a greyscale image that assigns pixel value based on scattered electrons. However, TEM is limited by the noise associated with high magnification images and can be difficult to quantify automatically. That is why there is a need for quick, accurate, and repeatable technique for TEM analysis. Dragonfly (Object Research Systems, Montreal, Quebec, Canada) high performance software is a great for analysis of data based on pixel value. Here, we designed a protocol for the quantification of TEM image date using Dragonfly and compared the repeatability and time-requirements of our methodology to ImageJ[7], which is commonly used for tendon. We hypothesized that our Dragonfly technique would be quicker and yield similar results to ImageJ quantification.

METHODS

For TEM, right Achilles tendons of adult wild type mice (6-8 months of age; n = 2) were dissected and fixed for 2 weeks in a 2% glutaraldehyde, 2% paraformaldehyde (PFA) solution buffered to PH 7.4 with 0.1M sodium cacodylate. Tendons were cut in the transverse plane from the proximal tendon and imaged to visualize collagen fiber diameters and tendon ultrastructure (Zeiss Libra 120 Transmission Electron Microscope; 120kV, 0.34nm point to point resolution, and Gatan Ultrascan 1000 CCD camera, Pleasanton, CA).

From a single 10 x 10 µm TEM image, five separate 2 x 2 µm regions of interest (ROIs) were extracted. Partial fibrils that were cut off by the perimeter of the ROI were omitted from the study. Two separate rounds of quantification were completed to test for repeatability. To avoid bias, data was not reviewed until both rounds were completed. Minimal fibril size in the second round was larger than the first round. During the round 2, a timer was run during quantification to see how long each method took. The timer began after file was uploaded and the timer ended once data was exported. On the second round of Dragonfly quantification, window leveling was adjusted for sake the figure 1 to make fibrils stand out better.

Files were first uploaded into ImageJ[7]. Using the freehand selection tool, fibrils were outlined, measured, and saved. Per ROI, average fibril area and fibril number were calculated.

Original ROIs were uploaded into Dragonfly. A histogram of pixel values was generated, dark fibrils were highlighted while the light space around the fibrils were omitted. These highlighted fibrils were separated into a sperate ROI. Using a combination of morphological operations and the ROI painter tool, fibrils were filled in and non-connected pixels were removed (Fibril ROI). The highlighted ROI was duplicated and inverted to select the surrounding space (NonFibril ROI). From the NonFibril ROI a distance map was generated which assigned a pixel value based on the distance from the ROI. Thus, the center of the fibrils was the brightest, and the fibril edges were the darkest. The distance map was then inverted so dark represented the center of the fibrils. The same define range tool was used on the inverted distance map. A range of pixel values was selected that separated each fibril (New ROI). Using the painter tool on New ROI, we removed highlighting between fibrils and filled in small fibrils that might have been lost. The result was each fibril having a separate highlight. On the New ROI channel, we generated a new multi-ROI which gives each fibril highlight a unique

color. We then did a watershed transform based on multi-ROI, inverted distance map, and Fibril ROI to expand the ROI highlight to the full area of the fibril. The filled multiROI was then exported into a file which listed each fibril and corresponding area. Per ROI, average fibril area and fibril number were calculated.

Statistical analyses were performed using Prism 8.0 (GraphPad, LaJolla, CA). Student's t-tests were used to compare time and measurement rate. Two-way ANOVAs were used to compare fibril area and fibril count repeatability. Z score was calculated per method, based on average and standard deviation of separate rounds.

RESULTS

Both ImageJ and Dragonfly come with their advantages and disadvantages for fibril analysis (Table 1). Both provide easily identifiable and reviewable data. Qualitatively, these techniques provided very similar results between separate rounds of quantification (Figure 1).

Table 1: Comparisons by fibril quantification techniques

	ImageJ	VS	Dragonfly
Learning Curve	Mild	<	Steep
Fibrils/ min	8.68	<	15.80
Area StDev	3.00E-04	≈	6.00E-04
Area Repeatability (Z test)	0.30	≈	0.81
Count StDev	8.26	≈	5.87
Count Repeatability (Z test)	0.12	≈	0.90
RAM requirement	≈ 150 MB	<	≈ 300 MB
File size relative to original	≈1X	<	≈10x

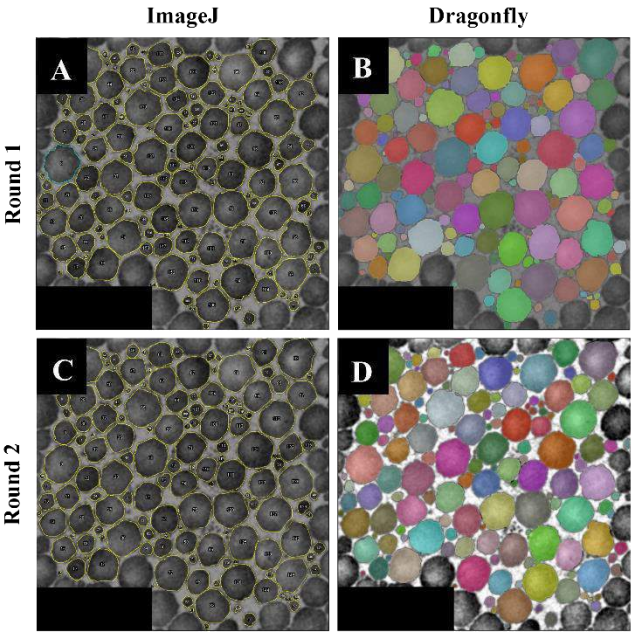

Figure 1: Both ImageJ and Dragonfly allow quantification and observation of collagen fibrils. Each ROI = 4μm^2.

Data was expected to be similar between technical replicates since all technical replicates came from the same TEM image. A larger minimal fibril size was set during the second round of quantification. For quantifying fibril area and fibril count, both ImageJ and Dragonfly similar data between two separate rounds (Figure 2A,B). However, Dragonfly data better reflected the changes to minimal fibril size as average fibril area increased (Figure 2A) and fibril count decreased (Figure 2B) from round 1 to round 2. Between the two techniques, ImageJ was more repeatable (Figure 2B). Dragonfly took less time to quantify each image (Figure 2C), with more fibrils counted per minute (Figure 2D).

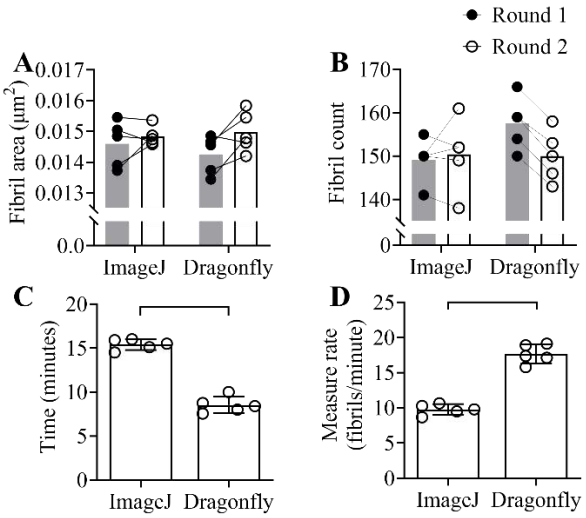

Figure 2: Dragonfly offers a quicker alternative to manual measurements in ImageJ. Both ImageJ and Dragonfly quantification shows an insignificant difference in repeatability of (A) fibril area measurement and (B) fibril count measurement. (C) Dragonfly is the faster method for fibril quantification with (D) more fibrils counted per minute. Data are technical replicates, mean ± SD. Lines in C and D indicate significance ($p < 0.05$).

DISCUSSION

Here, we have established a repeatable, reliable, and fast method for quantifying collagen fibril properties from TEM. When compared with manual ImageJ methods, our Dragonfly method is quicker with similar repeatability in fibril area measurements. Since our ROIs are 4 μm^2 pieces of a 100 μm^2 image, this difference in time would be immensely different in a TEM analysis with multiple technical and biological replicates. Although ImageJ is the "ground truth" method for counting, Dragonfly is better as handling differences in methods as seen between round 1 and 2 where different minimal fibral size was set. This may be attributed to the automatic nature of Dragonfly which eases any user bias. Though quicker, this Dragonfly method comes with a slower learning curve and a higher computational demand. This technique remains promising as it does not take full advantage of the power of Dragonfly, and we hope to advance these steps soon.

HYPERTROPHIC CARDIOMYOPATHY PROGRESSION CHARACTERIZED VIA SPATIOTEMPORAL STRAIN MAPPING FROM 4D ULTRASOUND

Frederick W. Damen (1), Daniel P. Gramling (1), Craig J. Goergen (1)

INTRODUCTION

Murine models play a critical role in uncovering the underlying mechanisms of cardiac disease and progression[1, 2]. Complementary to these mouse models, high-frequency ultrasound has become an integral tool for noninvasively quantifying cardiac function (ejection fraction, stroke volume, etc.)[3], thus helping to characterize disease stage. Here we demonstrate how we can leverage recently developed high-frequency four-dimensional ultrasound (4DUS) techniques[4, 5] to provide comprehensive characterizations of left ventricular (LV) function. Using mice with pathological cardiac hypertrophy and litter-mate controls, we quantify spatiotemporal maps of regional circumferential and longitudinal strain, and demonstrate how those maps change due to both normal aging and disease progression.

METHODS

Animal Models: 4DUS data was collected on 24 male mice with genetically induced cardiac hypertrophy (n=12; *Nkx2-5*$^{183P/+}$)[6] and control littermates (n=12; wild-type). Six mice from each cohort were euthanized at week 8 and had hearts excised for proteomic analysis. Remaining animals were subsequently imaged at week 12 and 16, after which they were similarly euthanized for proteomics analysis.

Ultrasound Imaging: All data was collected using a Vevo2100 high-frequency ultrasound system (FUJIFILM VisualSonics Inc.) with a 40 MHz center frequency transducer (MS550D). 4DUS data was created by collecting cardiac- and respiratory-gated planar images from serial short-axis views across the LV and then spatiotemporally sorting images in MATLAB (MathWorks Inc.).

4DUS Left Ventricle Kinematics: 4DUS data were loaded into an in-house MATLAB GUI and analyzed using a standardized procedure (Figure 1), resulting in a structured point cloud that tracked regional kinematics of the endocardial boundary across a representative cardiac cycle. A 4D mesh was then interpolated from the analysis-derived point cloud with a set number of interpolation points around (60) and down (60) the LV, as well as across the cardiac cycle (60).

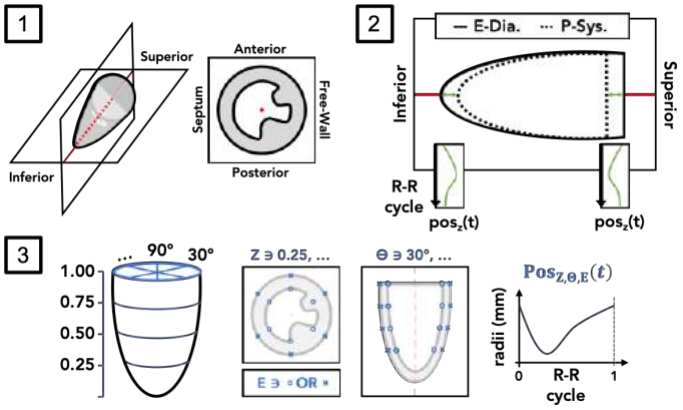

Figure 1. Schematic of 4DUS analysis procedure demonstrating: (A) standardization of orientation, (B) definition of LV base and apex displacement, and (C) tracking of regional wall kinematics.

Spatiotemporal maps of circumferential strain were then compiled from strain curves computed at each slice down the 4D LV mesh, using the Green-Lagrange strain tensor definition[7]:

$$E_{\theta\theta}(z,t) = \frac{1}{2}\left(\left(\frac{C(z,t)}{C_D(z)}\right)^2 - 1\right) \quad [1]$$

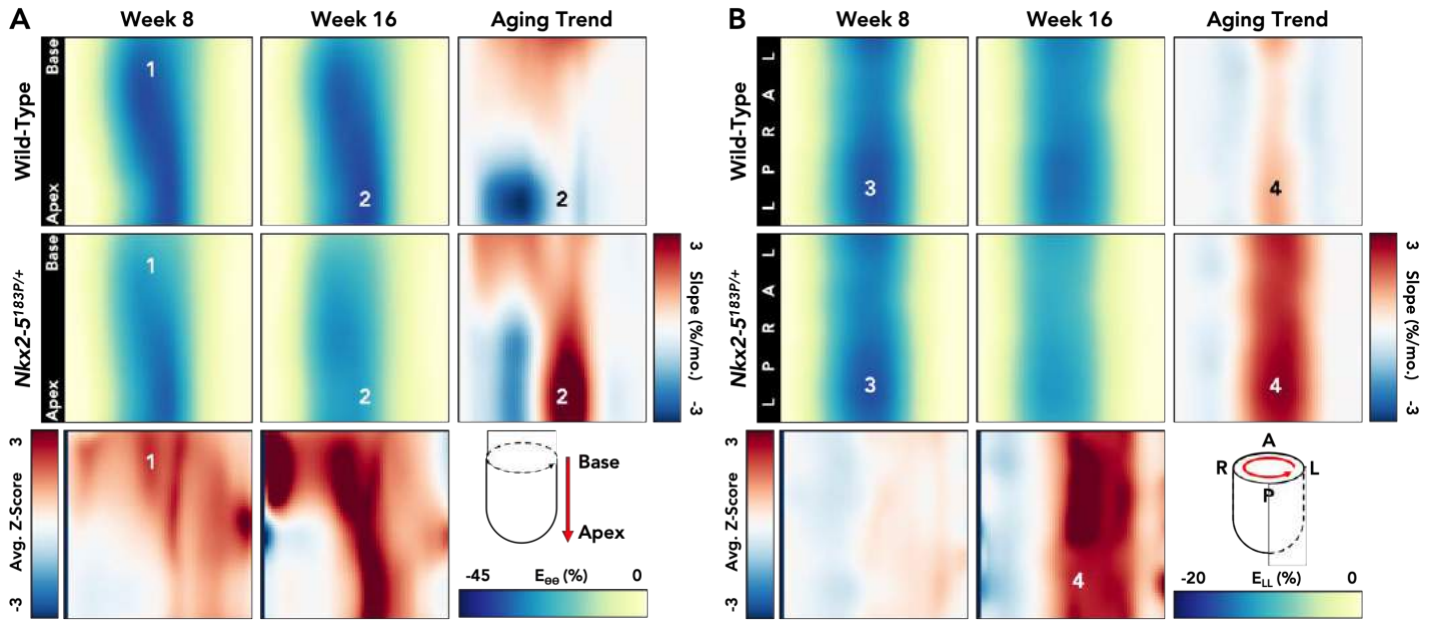

Figure 2. Spatiotemporal colormaps of circumferential (A) and longitudinal (B) strain across a representative cardiac cycle (x-axis = R-peak to R-peak; y-axis relative spatial position). Cohort averaged maps are shown for week 8 and 16. Z-score maps (bottom row) visualize how the mean *Nkx2-5*$^{183P/+}$ maps compare pixelwise to the wild-type distribution (i.e., standard deviations from the wild-type mean) at weeks 8 and 16. Additionally, trend maps (right column) visualize pixelwise per-month changes in strain for each cohort.

where C represents the relative circumference at slice z and time position t in the cardiac cycle; C_D is the circumference at end-diastole (t=0). Comparable spatiotemporal maps of longitudinal strain were derived using the linear small strain approximation (i.e., proportional length change from end-diastole) at each rotation around the center axis.

RESULTS

Since spatiotemporal strain map matrix sizes were standardized during analysis (60 locations x 60 time-points), resultant maps could be overlaid by cohort and age, allowing for pixelwise averaging and comparisons. Figure 2 highlights averaged strain maps at weeks 8 and 16, cross-sectional comparisons using pixelwise z-scores, and trend maps showing strain changes per month of aging. Week 12 data was excluded for clarity. The primary observations from Figure 2, marked 1-4 in the figure, are provided below:

1. At the earliest age imaged, circumferential strain magnitude deficits in the *Nkx2-5*$^{183P/+}$ cohort were primarily observed at the base of the heart during systole, suggesting weakened contractility near the mitral and aortic valves.
2. As both cohorts aged to week 16, a disproportionately lower magnitude circumferential strain was observed apically for the *Nkx2-5*$^{183P/+}$ cohort. Interestingly, both cohorts showed a decrease in strain magnitude in the basal region through aging, suggesting a natural shift of systolic contractility towards the apex over time.
3. In both cohorts, the posterior free-wall observes higher magnitude longitudinal strain throughout systole. Although unlike circumferential strain, negligible differences were observed at week 8, suggesting that circumferential systolic contractility may be more sensitive to the early development of hypertrophy.
4. By week 16, the distribution of longitudinal strain in the *Nkx2-5*$^{183P/+}$ cohort became more uniform around the ventricle and the duration of the systolic contraction wave shortened. Interestingly, both cohorts show a trend of increased early systolic longitudinal strain, suggesting a more rapid response to the cardiac conduction system with aging.

DISCUSSION

We demonstrate here the ability to use 4DUS imaging to produce spatiotemporal maps of both circumferential and longitudinal strain, from which we can quantify changes in cardiac kinematics that correlate with age and phenotype. In this study, we identified when and where kinematic patterns deviate in a genetic model of cardiac hypertrophy (*Nkx2-5*$^{183P/+}$). Our findings suggest that inhibited cardiomyocyte energy handling induced by the *Nkx2-5*$^{183P/+}$ mutation not only induces a hypertrophic myocardium[8], but also alters the systolic contraction kinematics. As research exploring regionally specific strain in mice using 4DUS technology remains limited[9], these findings may provide a framework for how 4DUS can be leveraged to provide more comprehensive characterizations of cardiac function and disease.

THE SKELETAL RESPONSE TO VARIED MODELS OF METABOLIC ACIDOSIS

INTRODUCTION

Metabolic acidosis (**MA**), a disease affecting millions annually, is clinically characterized by a decrease in blood pH and bicarbonate ($\mathbf{HCO_3^-}$) [1-3]. MA can lead to bone loss, fueled by a dissolution of bone mineral that can restore pH homeostasis by yielding the required buffering alkali from bone mineral [1-4]. MA is most commonly observed in chronic kidney disease, diabetes, and critically ill patients; however, western diets may also cause onset acute MA [5-7]. MA is known to increase the risk of bone fractures since acidic environments denature collagen and affect the structure and composition of bone mineral, reducing bone strength, bone volume, and mineral stiffness [8-10].

Despite the prevalence and establishment of the negative effects of MA on the skeletal system, there are limited studies of murine models that recapitulate the clinical blood chemistry and bone phenotype of MA. Previously established methods induced MA in adult mice by administering 0.28M ammonium chloride (NH_4Cl) into their diet. However, these methods do not mimic the MA bone phenotype observed clinically nor maintain long-term acidemia [11-13]. We previously established a method to induce MA in adult mice by administering NH_4Cl into their diet, providing a higher graded dosage every three days. This graded diet mimicked the MA bone phenotype observed clinically and maintained MA over the course of two weeks [14]. To better understand the skeletal response to MA temporally and determine a dosage-dependent response to acid-loading in murine bones, we characterized the bone phenotype resulting from two models of MA over the course of two weeks and characterized the blood gas and bone responses.

Here, we propose a murine MA model with a graded NH_4Cl diet as an alternative to the conventional flat-dose models. We hypothesized that the use of graded acid-loading for MA induction will inhibit excessive compensatory buffering from the kidneys and lungs to exceed dietary acid loading, resulting in a bone phenotype similar to that observed in clinical MA.

METHODS

Induction of MA: All animal experimental procedures were approved by the Institutional Animal Care and Use Committee at UConn Health Center and Columbia University, and comply with the National Institutes of Health guide for the care and use of laboratory animals (NIH Publications No. 8023, revised 1978). Metabolic acidosis was induced in 4-6-month old CD-1 mice by replacing their drinking water with an aqueous solution of ammonium chloride and 5% sucrose. For the flat-dose group, the NH_4Cl dose remained constant at 0.28M for 14 days [11,13]. For the graded group, the NH_4Cl dosing began at 0.2M NH_4Cl and was increased by 0.1M every 3 days for 14 days, with the highest dose at 0.6M [14]. Mice were sacrificed following the time of blood-gas analysis indicated for each group. *Blood chemistries analysis*: For each time period assessed, 200-300 µl of blood was extracted from non-anesthetized mice through submandibular puncture procedures [15]. Blood samples were analyzed using a Heska PoC Epoch blood-gas analyzer (Loveland) to obtain values of blood chemistries. *Whole-bone mechanics:* 3-point bend tests were used to evaluate the mechanical properties of the femurs. Load vs. displacement curves were analyzed using custom programs in MATLAB (MATLAB, R2020a, MathWorks) to determine structural and material mechanical properties. Stress vs. strain curves were calculated by normalizing the force and displacement using the beam span length, the bone centroid distance, and area moment of inertia as determined from micro-computed tomography (µCT). *Structural analysis:* After mechanical testing, the femoral samples were evaluated by µCT to obtain morphological information for the distal trabecular bone. The images were analyzed using the

BoneJ toolbox of ImageJ (U.S. NIH) and the Bruker CTAn software. *Statistical analysis:* Statistical analysis was done using one-way ANOVA on Minitab software. A significance level of 0.05 was used for all tests. Comparisons between time periods were made using post-hoc tests. Both the flat-dose and graded models were compared to independent and concurrently run control groups. Data are mean ± standard deviation.

RESULTS

At day 1 of NH_4Cl administration, the flat-dose model exhibited a significant decrease in blood pH and subsequent increase in Ca^{2+} compared to the control mice (**Figure 1**). However, following this time point, the pH and Ca^{2+} returned to baseline, with Ca^{2+} levels again increased on day 14. HCO_3^- in the flat-dose group was not significantly altered at any time point evaluated. The flat-dose group also did not exhibit any changes in mechanical properties nor the structural metrics. Our graded model of MA showed continuously decreased blood pH and HCO_3^- and increased Ca^{2+} as observed in clinical MA, with the exception of day 3. For the graded group, the femurs exhibited a significant decrease in bone volume (%) for days 1 and 3 compared to the control (**Figure 2**). Additionally, there was a significant increase in toughness from day 1 to day 14 (**Figure 3**). Resilience also increased significantly from days 1 and 3 to day 14 (data not shown). The other structural and material mechanical properties were not altered in the graded model.

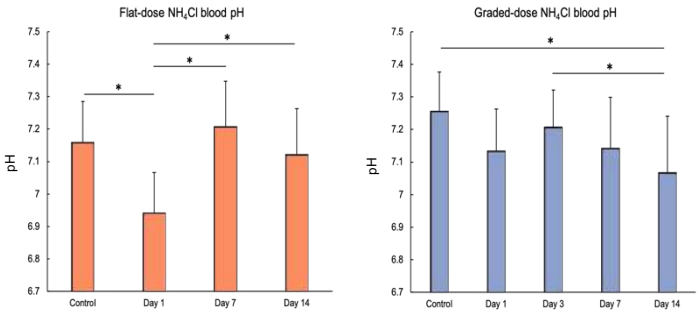

Figure 1. Blood pH data for MA across 14 days. N=16-25/day for flat and N=18-24/day for graded.

DISCUSSION

The flat-dose model of diet-induced MA showed unreliable utility as a model of MA in mice as it did not meet the clinical criteria for MA of low pH and low HCO_3^- but instead only induced "acute" acidemia at day 1. The increase in blood Ca^{2+} at this time point suggests that the onset of acidemia may generate bone dissolution, but phenotypic MA-induced bone loss or altered bone mechanics were not reflected in any metrics from our analysis. This suggests that compensatory buffering mechanisms, likely via the kidneys, were successfully engaged in the flat-dose model. Despite being well-established in the literature, the clinical chemistry and lack of bone phenotype renders this model of MA in adult mice unsuitable beyond an "acute" timepoint.

The graded-dose model effectively induced "chronic" MA across all time points, except on day 3, based on blood pH and HCO_3^-. The return to normal blood-gas pH, Ca^{2+}, and HCO_3^- values at this timepoint implies the onset of the clinically observed phenomena of "eubicarbonatemic MA", whereby bone dissolution reestablishes blood pH and ion homeostasis [7]. Furthermore, a decrease in the percent bone volume at days 1 and 3 illustrates this dissolution. At day 14, an increased toughness and resilience suggests a greater contribution of collagen to the total bone mechanics due to bone mineral dissolution in an acidic environment. Continued bone dissolution due to acidosis could contribute to further compromised mechanics as seen clinically [16]. Future and ongoing studies aim to concretely determine whether bone composition and bone remodeling dynamics are altered in these models of MA independently. We conclude that there is both a dosage-dependent response to acid-loading in bone, and the temporal response to MA in bone drives the clinically observed phenotype. Ultimately, our model of graded MA is characteristic of the bone phenotype observed clinically and can maintain onset of MA for the course of 14 days.

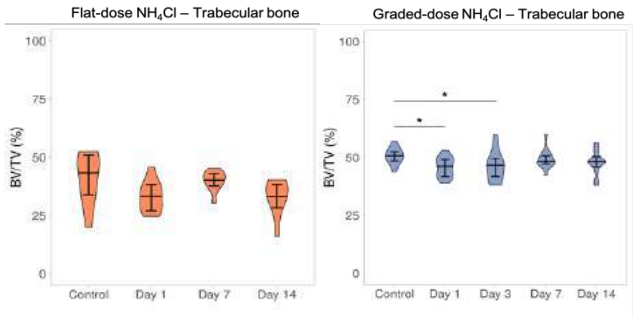

Figure 2. Bone volume (%) for MA across 14 days (N=12-14 /day).

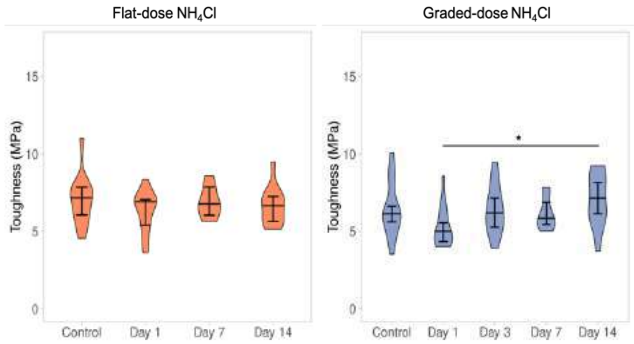

Figure 3. Toughness (MPa) for MA across 14 days (N=10-15/day).

SENSITIVITY OF THE SHEAR WAVE SPEED-STRESS RELATIONSHIP TO LIGAMENT FIBER ALIGNMENT – A PROBABILISTIC FINITE ELEMENT STUDY

INTRODUCTION

Shear wave tensiometry is an emerging measurement technique used to determine the tension in tendon [1] and ligament [2] noninvasively. Fundamentally, this technique measures the speed of a shear wave propagating along the length of the tissue. Based on an analytical relationship for a shear wave propagating in a tensioned beam, we can determine the axial tissue stress and tension from the measured shear wave speed. In previous ex vivo experiments, we have observed that shear wave speeds measured in axially loaded collateral ligaments [2] are greater than those measured in axially loaded tendon [3] by up to 45% at a similar axial stress level.

While tendons and ligaments both exhibit transversely isotropic material properties, they differ in factors relating to their structure that might affect their loading behavior. For example, ligaments have less well-aligned fibers than tendon [4]. Further, the gradual recruitment of substructural features, such as fiber-fiber bonds, in ligaments can cause nonlinear material behavior to occur during loading, which could be in part due to an increase in shear modulus [5]. Concerning tensiometry, it is well understood that the unloaded shear modulus is the driving factor for changes in shear wave speed at low loads in tendon [1]. However, the interaction between the substructure-dependent shear modulus and shear wave speed remains uninvestigated in ligament.

The purpose of this study was to investigate whether the substructure-dependent shear modulus could alter shear wave speeds. Our hypothesis was that less well-aligned fibers would increase the tissue's unloaded shear modulus, and thus shear wave speed, during axial loading.

METHODS

We modeled a ligament (FEBio v3.0) as a rectangular prism with an aspect ratio of 8 with a similar cross-sectional area as a human MCL. In the static portion of the simulation, we axially loaded the tissue to a constant axial strain and allowed it to settle. During the dynamic portion of the simulation, we applied a transverse ramp displacement to nodes through the depth of the tissue to excite a shear wave and measured the shear wave speed using the time delay in wave arrival at two points downstream from the excitation. We modeled the tissue's material behavior using a Mooney-Rivlin transversely isotropic constitutive model [5,6]. The variation in the tissue's intrinsic fiber alignment was governed by a 2D semi-circular von Mises distribution [7].

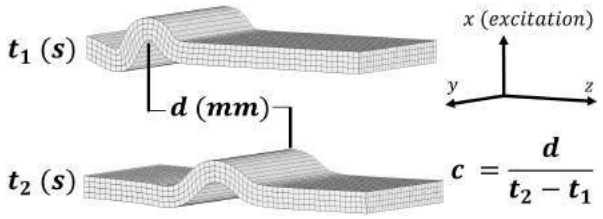

Figure 1: Fiber alignment was modeled in 2D planes parallel (xz) and perpendicular (yz) to the excitation direction (x-direction). Shear wave speed (c) was measured as distance divided by time. For visualization, displacement in the figure was amplified 100x.

We used Monte Carlo probabilistic modeling to determine sensitivities of the shear wave speed-stress relationship to variations in fiber alignment in 2D planes parallel (Figure 2a) and perpendicular (Figure 2b) to the excitation. A fiber concentration factor, k_f, was prescribed to scale the semi-circular von Mises distribution. We varied k_f according to a one-sided normal distribution, with a value of 0 corresponding to an isotropic fiber distribution. As k_f increases, the fibers become more aligned along the preferred fiber orientation (axial loading direction). We varied the axial strain according to a random uniform distribution between 0% and 10%. Using a high-throughput computing grid, we performed 10,000 simulations per analysis.

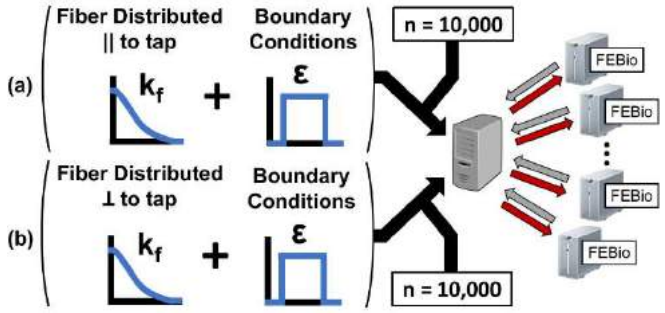

Figure 2: We used Monte Carlo probabilistic modeling in two cohorts of simulations with randomly applied fiber alignment factors (one-sided normal distribution, mean ± standard deviation = 0 ± 25) and axial strains (uniform distribution between 0-10%).

To assess the shear wave speed-stress relationship, we used an analytical relationship (Equation 1) relating the shear wave speed, c, to the axial stress, σ_z, in terms of the shear modulus in the plane of the shear wave (μ_{xz}, scaled by a shear correction factor k') and the tissue density (ρ) [1]:

$$c^2 = \frac{k'\mu_{xz}+\sigma_z}{\rho} \qquad (1)$$

We determined the sensitivity of this analytical relationship to ligament fiber alignment using a linear regression between the squared shear wave speed and axial stress for fiber concentration factors from 0-50+ in increments of 1. The shear modulus of interest (in plane with the shear wave) was determined using the corresponding term in the underlying spatial elasticity tensor.

RESULTS

The shear wave speeds measured using the finite element model agreed closely with predictions using the analytical model ($R^2 > 0.99$). When varying only the fiber alignment, there was a notable difference in shear wave speed for less well-aligned fibers for the cohort of simulations with fibers distributed parallel to the excitation (Figure 3).

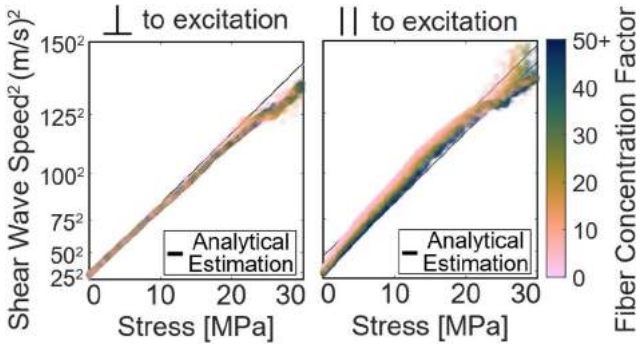

Figure 3: Shear wave speed measured for each cohort of simulations (n=10,000 each). Overall, the shear wave speed was well predicted by the analytical relationship.

Less well-aligned fibers parallel to the excitation resulted in shear wave speeds that were 9.6% higher than the analytical estimation of the shear wave speed for a transversely isotropic material at a given stress level. Despite this, they remained well predicted by the upper and lower bounds (corresponding to the lowest and highest μ_{xz} observed in the entire cohort, see Figure 4b) of the analytical estimation. Overall, there was an average predictive error of 2.68 ± 1.92 and 4.07 ± 2.88 m/s using the analytical model and unloaded shear modulus for fibers distributed perpendicular and parallel to the excitation direction, respectively.

The shear wave speed-stress relationship demonstrated a higher sensitivity for models that had less well-aligned fibers, and this sensitivity was higher for models with fibers distributed parallel to the excitation (Figure 4a). This is likely a result of a higher shear modulus for low fiber distribution factors (Figure 4b), since the shear modulus is a component of the analytical relationship governing the squared shear wave speed-stress relationship (Equation 1).

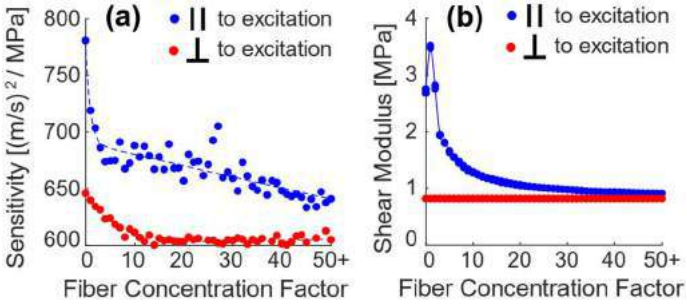

Figure 4: (a) The model was more sensitive to fibers distributed in the direction of the excitation, and the sensitivity to fiber alignment generally decreased as fibers became more aligned. (b) The resulting differences in shear wave speed could be due to the higher unloaded shear modulus in the excitation direction.

DISCUSSION

Our study shows that our dynamic finite element model can predict shear wave speeds in ligaments with distributed fibers that are in the same range as previous studies [1-3]. Further, the analytical relationship between the shear wave speed and axial stress holds for ligament models with different degrees of fiber alignment. The sensitivity between the squared shear wave speed and axial stress decreases as fibers become more highly aligned, and there is a nonlinear trend with low fiber alignment for both cohorts of models (Figure 4a). This is likely due to the nonlinear effect of fiber concentration on the unloaded shear modulus of the tissue (Figure 4b).

This study provides useful insights into how the unloaded shear modulus may affect shear wave propagation. However, the shear modulus for less well-aligned fibers can increase with loading (e.g., 10x and 3x increase in shear modulus for $k_f = 0$ and $k_f = 10$, respectively, at 10% strain, based on pilot simulations). This may be exacerbated in intact ligaments, where the gradual recruitment of microstructural features, such as fiber-fiber bonds, can change material shear behavior during loading [5]. The exact effect that loading may have had on the shear modulus-dependent shear wave speeds and whether the loaded shear modulus may provide a better analytical estimate of the shear wave speed is a focus of our on-going investigation.

The model-based findings of this study suggest that the degree of fiber alignment can affect the shear modulus and measured shear wave speeds in axially loaded ligaments. Practically, these effects should be accounted for when making shear wave speed measurements experimentally. Moving forward, insights from this model will be used to inform and develop methods for the noninvasive characterization of collateral ligament stress using shear wave tensiometry.

INTRODUCTION

Arteries have the ability to grow and remodel in response to alterations in their mechanical environment induced by injury or pathology. It is thought that arteries adapt to these perturbations in an effort to restore levels of stress and/or strain to preferred values, hence maintaining a so-called mechanobiological homeostasis [1]. Multiple computational models have been developed that aim to understand this arterial response to mechanical perturbations and predict the corresponding adaptive growth and remodeling (G&R) [2,3]. These models are often phenomenological and do not consider the biochemical and cellular mechanisms underlying arterial G&R. To better understand arterial G&R and uncover ways to control it, there is therefore a need for more mechanistic models that consider mechano-mediated cellular processes driving tissue G&R across length scales.

It is known that arterial G&R is modulated, in part, by vascular smooth muscle cells (VSMCs) populating the arterial wall. These can switch between a contractile phenotype, characterized by quiescence and muscular tone, and a synthetic one, characterized by increased proliferation and matrix synthesis. This phenotypic switch is regulated by Notch signaling, a mechanosensitive, cell-cell signaling pathway that involves interactions between membrane-bound receptors and ligands of neighboring VSMCs and plays a crucial role in arterial development, homeostasis, and adaptation [4,5]. It has been shown that the Notch pathway in VSMCs is sensitive to strain [6,7] and this has recently been incorporated into a computational model that simulates Notch signaling interactions and predicts the phenotype of VSMCs [6]. However, this model does not include arterial G&R and does not feature a full coupling between events at the tissue and cell scale.

Here, we have developed a multiscale computational model integrating cell-scale Notch signaling, mechanobiology and phenotypic switching with tissue-scale arterial G&R and mechanics. This framework provides a systematic tool to gain a deeper understanding of the role of Notch signaling in arterial G&R. This could ultimately be used to explore methods to control arterial G&R via interventions in the Notch pathway.

METHOD

A computational model was developed that combines a tissue-scale description of arterial G&R with a cell-scale description of Notch signaling in VSMCs (Fig.1). The tissue-scale part is based on the widely adopted constrained mixture theory [8], and describes arterial tissue with constituents collagen, elastin, and smooth muscle, whose production and removal are captured with constitutive equations to simulate the tissue G&R. In addition, biaxial stresses and strains are computed based on arterial geometry and hemodynamic loading conditions using Laplace's law.

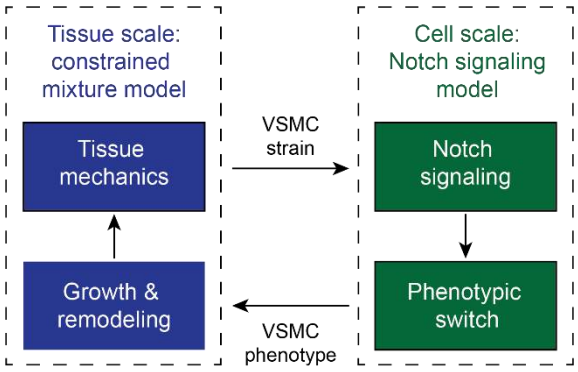

Fig. 1. Schematic overview of the multiscale computational model.

Cell-cell Notch signaling dynamics in the arterial wall are simulated using a recent model [6] in which Notch receptors and ligands of adjacent cells interact, resulting in the release of the Notch IntraCellular Domain (NICD) and, consequently, Notch activation and gene transcription. The production of Notch receptors and ligands decreases with increasing VSMC strain and, for each cell, changes in Notch protein content are described using a system of ordinary differential equations. The NICD content in each cell is used to predict whether that cell adopts a contractile or synthetic phenotype.

Fig.1 illustrates how the two models are coupled. In classic constrained mixture models, the mass production and removal terms of the constituents are governed by phenomenological stimulus functions whose values are based on perturbations from a mechanobiological homeostasis [2,3]. Here, we adapt this method by introducing a Notch stimulus function, which similarly acts as a regulator of the production and removal of tissue constituents and is itself a function of the NICD content and, thus, phenotype of the VSMCs. In particular, we assume that a contractile phenotype causes normal turnover, while a synthetic phenotype leads to increased proliferation and matrix synthesis.

RESULTS

Figure 2 shows the response of the model to a mechanical perturbation, such as a sustained increase in blood pressure, which results in increased inner radius and associated VSMC stretch (Fig.2A). This causes an initial decrease in the expression of Notch pathway proteins and, consequently, a decrease in NICD molecules, representing reduced Notch activation (Fig. 2B), leading to a switch from contractile to synthetic cells. As a result, tissue production is increased and the artery grows, shown by an increase in mass density (Fig. 2C) and wall thickness (Fig. 2D). Over time, thickening of the wall and a decrease in inner radius (not shown) in turn decrease the stretch and, thus, compensate for the initial perturbation leading to the tissue re-establishing its mechanobiological homeostasis as the stretch returns to its original value.

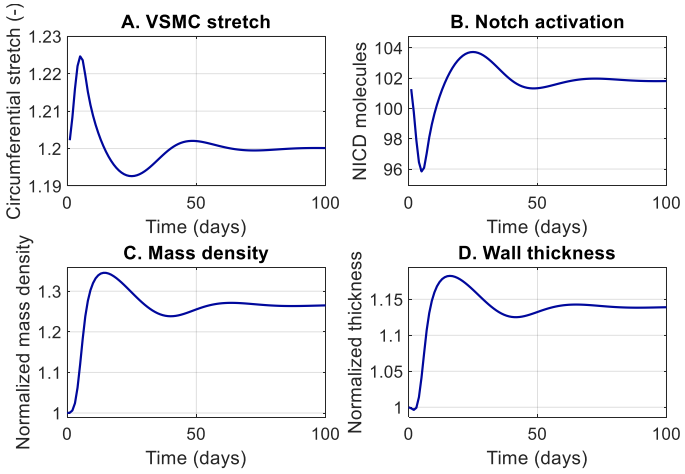

Fig. 2. Predicted adaptation of an artery to a sustained mechanical perturbation starting at day 0.

The model can also be adopted to investigate interventions in the Notch pathway, as shown in Fig. 3, where both over- and under-expression of Notch ligands in VSMCs are simulated. This leads to the phenotypic switch between synthetic and contractile cells occurring at a higher or lower stretch, respectively. As a result, the tissue will reach an altered homeostatic state, accompanied by a different mass density and wall thickness, corresponding to the new homeostatic stretch value.

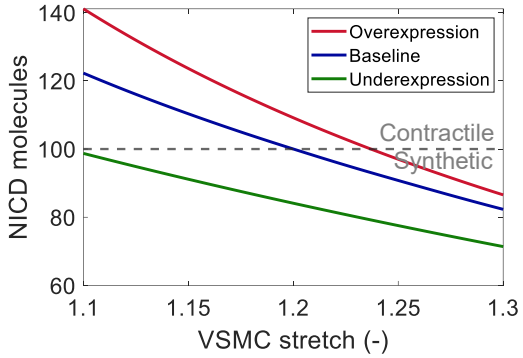

Fig. 3: Over- or underexpression of Notch ligands alters the stretch at which VSMCs reach a contractile phenotype.

DISCUSSION

An increase in arterial wall thickness (Fig. 2D) following increased strain induced by some mechanical perturbation is consistent with previous findings from both computational [2,3] and experimental studies [9]. The underlying changes in Notch activity seen in the model are also in accordance with previous experiments [7,10].

Interestingly, the model results are quite sensitive to interventions in the Notch pathway such as over- or underexpression of ligands (Fig. 3), which leads to the prediction of different homeostatic states. This is in line with experimental findings in which Notch interventions were successful in altering the adaptation of arteries after injury [5] and shows the model's potential to simulate how arterial G&R may be manipulated or controlled using Notch signaling. This potential could be adopted to explore new treatment options or be applied to the field of tissue engineering to examine methods of improving the G&R potential of engineered tissues by manipulating the Notch pathway, for example by functionalizing scaffold biomaterials with Notch ligands, which has recently been shown to be feasible [11].

Taken together, our multiscale model provides a computational framework that integrates mechano-mediated cell-cell Notch signaling with arterial G&R to predict the adaptation of arteries to mechanical perturbations. Our model demonstrates how Notch signaling can act as a key mechanistic player in G&R models, which have previously been mainly phenomenological, and has shown its potential in predicting ways to control tissue G&R via interventions in the Notch pathway. Ultimately, our model may be utilized to gain a better understanding of cell-mediated arterial G&R, explore new therapeutic strategies and aid in the rational design of scaffolds for vascular tissue engineering.

INTRODUCTION

Type II Diabetes (T2D) affects up to 21 million people in the United States and continues to increase each year[1]. Patients with T2D have a decreased ability to heal after a bone fracture or reconstructive surgery[2]. Delayed healing or non-union can be attributed to several factors, such as reactive oxygen species (ROS) like hydrogen peroxide, that promote osteoclastic activity over osteoblastic[3].

The current standard of care for at-risk patients is to use more hardware to increase fixation to achieve boney fusion. Unfortunately, these methods have not demonstrated clinical success and in the case of extremities, failed fixation in T2D patients often leads to amputation.

The ideal bone graft can be characterized by the ability to promote bone fusion despite the native environment, degrade at a rate complementary to neotissue formation, and maintain mechanical integrity throughout the remodeling process. Specific to T2D, modulation of the biological response to decrease inflammation and oxidative stress could return tissue back to homeostasis. By fabricating a synthetic bone graft with the antioxidant moieties, the shortcomings of current solutions may be addressed.

In this study, we report the preliminary findings on the chemical and oxidative degradation properties of a class of thiol-ene based thermoset polymers for use as bone grafts. Additionally, the thiol-ene polymer networks were assessed in terms of their oxidative responsiveness and ability to scavenge hydrogen peroxide at pathophysiologic levels.

METHODS

Fabrication of Thiol-ene Photopolymers (TPP). Polymer disks approximately 12.0 mm in diameter and 2.5 mm thick or thin films approximately 10.0 mm x 5.0 mm x 2.5 mm (l x w x h) were fabricated by mixing methacrylate macromers, butanediol dimethacrylate (BDMA) and diurethane dimethacrylate (DUDMA), with thiol macromers, pentaerythritol tetrakis3-mercptopropionate (PTMP), PCL4MP, and Glycol Dimercaptoacetate (GMA). The methacrylate and thiol ratio were varied from 50:50 to 70:30. Control compositions without thiol groups were fabricated in the same manner. Resin compositions were made in accordance with Table 1 with 0.5 wt% photoinitiator and cured using UV light at 425 nm for 5 minutes. The disks were then washed with isopropyl alcohol and dried under vacuum (32 mmHg) at 50ºC until a constant weight was achieved.

Table 1: Formula weights of resin composition used to make antioxidant thiol-ene networks.

Formulation Name	Weight Percent (wt %)				
	BDMA	PTMP	PCL4MP	DUDMA	GMA
TPP1a	43.3	21.6	13.0	21.6	-
TPP1b	33.3	16.6	33.3	16.6	-
TPP1c	24.4	12.2	51.1	12.2	-
TPP2	66.3	-	-	33.2	-
TPP3	45.2	22.6	-	22.6	9.0
TPP4	58.5	-	29.3	-	11.7

Chemical Characterization. The chemical structure of the thiol-ene networks was characterized by Attenuated Total Reflectance Fourier Transform Infrared Spectroscopy (ATR-FTIR) using a Bruker Alpha (Bruker).

Thermomechanical Characterization. Dynamic Thermal Mechanical Analysis (DMTA) was conducted with a Q800 DMA (TA Instruments) on neat films approximately 10.0 mm x 5.0 mm x 2.5 mm (l x w x h). Specimens were subject to a temperature ramp from -20°C to 120°C at

a rate of 5°C/min while under a 0.1% cyclic strain at 1 Hz frequency. The storage modulus and glass transition temperature were recorded.

Accelerated Oxidative Degradation. A 20% H_2O_2 solution was used for the accelerated oxidative solution. Disks were submerged in 25 mL of solution in a sealed vial. The vials were placed in a 37 °C oven (± 0.5 °C, measured continually with a thermocouple). Samples were incubated for 7 days before replenishing the solution, checked daily to monitor solution levels, and were weighed every week. At each time point, samples were removed, rinsed thoroughly in RO water, and dried in a 50 °C oven. Vacuum was pulled for 24 hours at 32 mm Hg. After removal from the oven, samples were weighed and returned to the vials, with freshly replenished solution. The mass was converted to remaining mass percentage, and the average change and standard deviation was recorded and plotted.

Hydrogen Peroxide Consumption. A 6.8 ppm (200 µM) H_2O_2 solution was used to simulate pathologic levels of hydrogen peroxide. Polymer disks were submerged in a 25 mL of solution in a sealed vial. The vials were placed in a 37 °C oven (± 0.5 °C, measured continually with a thermocouple). Hydrogen peroxide levels were evaluated using a colorimetric Hydrogen Peroxide Assay Kit (CHEMetrics) upon initial insertion (t=0) and after 72 hours (t=72). A blank vial filled with solution was used as a control. The concentrations were recorded and the average value with the standard deviation was plotted.

RESULTS

All formulations produced optically clear disks or neat films. The structures were confirmed with ATR-FTIR and show a reduction in the free thiol and the (CH2=CH2) bond of methacrylates, indicating successful incorporation of thiols into the network.

DMTA of the thin films for TPP1a, TPP2, and TPP3 displayed a storage modulus at 25˚C in the GPa range, with TPP3 being the highest. Additionally, TPP3 demonstrated a sharp transition likely attributed to the ideal network formation and the influence of hydrogen bonding from the urethane groups. All compositions demonstrated a decrease in storage modulus at 37˚C except for TTP1c because the network was in the rubbery phase. Although the glass transition temperature of TPP3 is near 37˚C, the storage modulus is consistent with the reported values of trabecular bone[4].

Table 2: Summary of mechanical and thermal properties of polymerized thiol-ene networks.

Formulation Name	Modulus at 25˚C	Modulus at 37˚C	Tg
TPP1a	1420 MPa	674 MPa	47°C
TPP1b	50 MPa	28 MPa	11°C
TPP1c	7 MPa	7 MPa	-19°C
TPP2	3015 MPa	2772 MPa	51°C
TPP3	1318 MPa	315 MPa	38°C
TPP4	349 MPa	199 MPa	28°C

In vitro accelerated degradation was performed in an oxidative environment to characterize the oxidative response of the polymer. All thiol containing resins was characterized by rapid changes in mass followed by a plateau for scaffolds that contained sulfide groups (Figure 2). This phenomenon may be attributed to the oxidation of sulfide functional groups, which increases the network's susceptibility to hydrolysis.

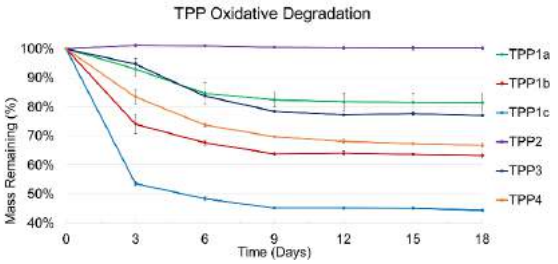

Figure 2: Mass loss of thiol-ene networks in accelerated oxidative media.

Increasing thiol content from 70:30 (methacrylate:thiol) to 50:50, correlated to a decrease in hydrogen peroxide concentration as represented by TPP1, TPP2, and TPP3. Additionally, hydrogen peroxide consumption increases in resin compositions that contain shorter chain thiols such as TPP3 and TPP4. Hydrogen peroxide concentration did not decrease with the thiol free resin, TPP2. The control blank demonstrated that there was slight degradation with the initial hydrogen peroxide which is expected as hydrogen peroxide naturally degrades over time.

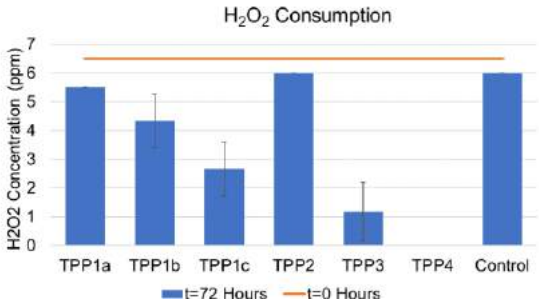

Figure 3: Consumption of hydrogen peroxide at pathophysiologic concentrations.

DISCUSSION

The work presented in this study demonstrates that polymer networks containing sulfide groups successfully sequester hydrogen peroxide at pathologic levels. Hydrogen peroxide responsiveness can be tailored by changing the methacrylate to thiol ratio as well as the molecular weight of the thiol moieties used. The oxidative media converts the sulfide groups to sulfoxides and sulfones. This oxidation increases the hydrophilicity near ester moieties allowing for increased degradation via hydrolysis. The oxidative degradation of the resin composition did not directly correlate with the ability to react with ROS species, indicating that the processes may not be directly related.

This preliminary work shows that thiol-ene polymer networks can reduce the ROS species that contribute to delayed bone healing in T2D. Additionally, the storage modulus of the resin compositions was comparable to native bone. Future work will focus on optimizing the ROS sequestering in addition to biocompatibility assessment and mechanical testing relevant to bone grafting applications.

MOTOR EVOKED POTENTIAL RECRUITMENT CURVES INDICATE NEUROPLASTICITY OF THE BICEPS BRACHII IN CERVICAL SPINAL CORD INJURY.

Thibault Roumengous (1), Yasmina Zeineddine (1), Carrie L. Peterson (1)

INTRODUCTION

Chronic spinal cord injury (SCI) is a condition that involves motor impairment through partial or complete paralysis, reducing the quality of life for individuals with SCI [1]. Understanding injury-induced neuroplasticity following SCI has implications for the development of rehabilitation programs aimed at recovering motor function [2]. Reliable tools and models are needed to provide accurate indicators of neuroplasticity over time in these populations to further aid recovery.

Non-invasive brain stimulation is a promising approach for measuring neuroplasticity. Resulting motor evoked potentials (MEPs) from the different transcranial magnetic stimulation (TMS) intensities represent responses from a variety of neural populations, and demonstrate a graded response with increasing intensities, offering comprehensive insights into the condition of a neuromuscular circuit through metrics such as the slope of the curve [3]. Thus, RCs could enhance our understanding of injury-induced neuroplasticity and recovery when analyzing these changes over time [4]. If RCs are to be used as a metric of neuroplasticity in individuals with SCI, an understanding of RC reproducibility is needed. In particular, proximal arm muscles such as the biceps brachii (BIC), which may be targeted in rehabilitation to grant individuals with SCI greater functional independence, have not been studied with respect to their ability to produce reproducible RCs at a given time point.

This study aims to compare RC slopes between SCI and nonimpaired (NI) individuals and determine the reproducibility of RC slopes across three assessments. Additionally, linear regression and the Boltzmann equation were compared as methods of modeling the MEP RCs. We hypothesized a steeper slope in SCI patients relative to NI subjects, which would correlate to increased excitability in the BIC and imply adaptive neuroplasticity after injury.

METHODS

Experimental Set-up: Eight nonimpaired (F=4, mean age 22.7 ± 2.5 years) and five SCI (F=3, mean age 46.6 ± 7.8 years, levels of injury: C5-C6, ASIA scores: A-D, at least 3 years post injury) participants consented to participate in the study and completed two or three sessions separated by at least a day, a week at most. EMG surface electrodes were placed on the BIC before determining the cortical hotspot and resting motor threshold (RMT) using a double cone TMS coil. To collect RCs, TMS pulses were randomly administered between 80%-160% of a participant's RMT in 10% increments with a 10s inter-stimulus interval. MEPs were excluded if they exceeded ±3 standard deviations of the mean response per intensity to eliminate MEPs that may have been facilitated by low levels of muscle activation.

$$Y = minEMG + \frac{(maxEMG - minEMG)}{1 + e^{\frac{(V50 - X)}{Slope}}} \quad (1)$$

Equation (1), the Boltzmann equation, was used to model the RC data [5]. The variable *minEMG* and *maxEMG* represent the minimal and maximal MEP size, respectively. *V50* represents the stimulus intensity (% MSO) value when the MEP size is half of its maximal size. Simple linear regression was also utilized for curve fitting, and their respective accuracies of prediction (R^2) were calculated for comparison.

Data and Statistical Analysis: Statistical analyses were performed using R (R Core Team (2013)) and GraphPad Prism. Slopes obtained between 110% and 160% RMT from the recruitment curves of SCI and NI participants were compared using an unpaired t test with

Welch's correction to account for unequal standard deviations between the SCI and NI groups.

Inter-session reproducibility was determined by calculating intraclass correlation coefficients (ICCs) of the slope parameter. ICCs were calculated using a two-way random-model with consistency agreement. ICC values > 0.75 were defined to represent good to excellent agreement between sessions [6].

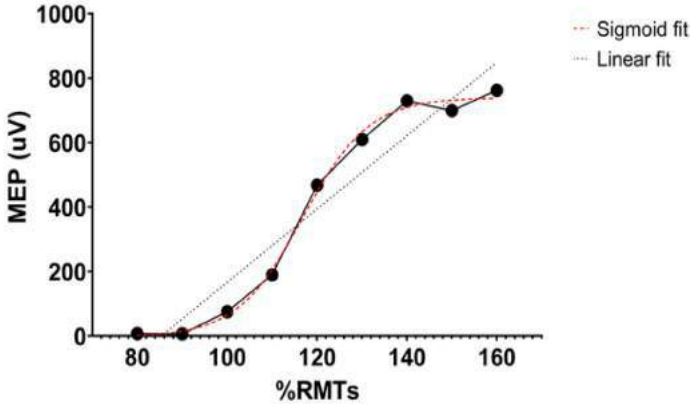

Figure 1: MEP recruitment curve from an individual with SCI. Both curve fitting methods are shown superimposed onto the recorded MEP data (black).

RESULTS

The RC's slopes obtained using linear regression from the SCI group (6.12 mV/%RMT ± 6.82) were significantly higher than the slopes obtained from the NI group (1.34 mV/%RMT ± 1.32) ($p = 0.008$ $t = 2.505$, $df = 13.52$). No significant differences in RMTs were found between the SCI and NI group ($p = 0.557$, $t = 0.5919$, $df = 44$) (Figure 2). Accuracy of prediction (R^2) and inter-session reproducibility data are presented in Table 1.

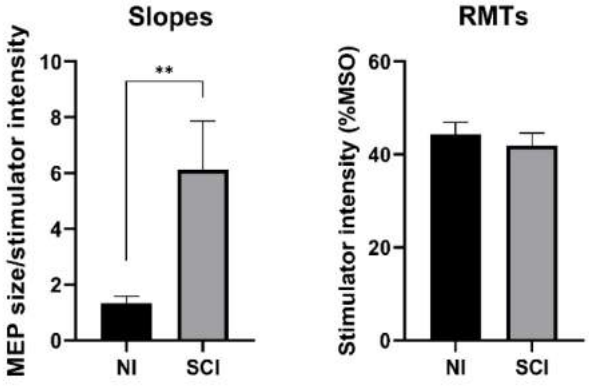

Figure 2: Left: Slopes obtained from linear regression are significantly greater in the SCI group compared to NI. Right: Mean RMTs are not different between SCI and NI. Asterisks represent statistical difference ($p < 0.05$) and error bars represent standard the error of the mean (SEM).

Table 1: Inter-session reproducibility and accuracy of prediction of curve fitting methods (mean ± SEM).

Parameters	NI	SCI
Mean ICC (3, k)	0.83	0.78
Sigmoid fit mean R^2	0.73 ± 0.04	0.95 ± 0.05
Linear fit mean R^2	0.71 ± 0.04	0.82 ± 0.05

DISCUSSION

Our primary aim was to compare MEP RCs of the BIC between nonimpaired participants and participants with chronic cervical SCI and determine the reproducibility of biceps RCs. A secondary aim was to investigate curve fitting methods (linear regression versus sigmoidal function).

Our study results demonstrate that MEP recruitment curves of the BIC analyzed using linear regression revealed significantly higher slopes in the chronic SCI group compared to the nonimpaired group. An increased RC slope indicates greater excitability in the neuromuscular circuit between the motor cortex and the BIC, suggesting a degree of cortical reorganization occurred post-injury in the group with SCI [7]. Potential mechanisms of reorganization include the enlargement of the motor representation of the BIC in the motor cortex, enhanced synaptic transmission, or reduced inhibition [8, 9]. No significant differences in RMTs were found between groups. This suggests that the alteration in excitability after SCI (demonstrated by the RC differences) may be prominently occurring at sub-cortical or spinal levels since RMTs are thought to be related to the membrane excitability of a central core of cortical neurons [10].

The sigmoidal function models the shape of the curve more precisely compared to the linear regression approach, although no differences in accuracy of prediction (R^2) were found in both NI and SCI groups. Linear regression was found to accurately represent the slope of the modeled data. Finally, parameters extracted from the MEP recruitment curves were found to be reproducible across sessions, lending credibility to the utility of RCs in monitoring neuroplasticity in populations undergoing neuromuscular rehabilitation.

Limitations of this work include small sample sizes and heterogeneities in remaining motor function among SCI participants. Additionally, most SCI participants only completed two sessions, limiting the reproducibility analysis across two days.

Future research should determine whether RCs are a sensitive biomarker for the effect of recovery or interventions during acute and chronic stages of SCI.

INTRODUCTION

Branch pulmonary artery stenosis (bPAS) commonly occurs in congenital heart disease (CHD) [1]. The presence of localized, anatomical bPAS disrupts global distribution of blood flow to the lungs due to obstruction to the lung distal to the bPAS, and an increase in relative flow into the 'unaffected' lung. At many centers catheter based interventions are used to manage patients with bPAS. While catheter interventions successfully relieve the anatomical bPAS with long term favorable outcomes [2], a recent study showed that 1/3 of patients do not improve their pulmonary blood flow (PBF) distributions following interventions [3]. The reasons for the failure of some patients to normalize their PBF distributions, despite catheter-relief of the anatomical bPAS, remains unknown. Failure to improve PBF distributions was associated with lack of improvement of exercise capacity and could be especially problematic in young patients, for whom normal PBF is believed to be essential for lung and PA growth.

There is a clinical need for a non-invasive tool to predict which patients are most likely to benefit from bPAS intervention. The development of such a tool should improve treatment planning for patients and may also suggest novel research directions to better understand the pathophysiology of this disease. Hemodynamic simulations based on patient specific anatomies extracted from non-invasive medical imaging are a promising technology with expanding applications in the clinical management of coronary artery disease and an active area of research in other vascular territories, including bPAS [4]. The goal of this study was to develop a predictive tool leveraging non-invasive MRI measurements to generate hemodynamic simulations using 3D vascular anatomy reconstructions and flow dynamics followed by direct experimental measures and outcomes in a validated swine PAS model.

METHODS

Discrete proximal left PA stenosis (LPAS) was surgically created as in ten 2-week old male swine. Five swine had stent intervention at 5 weeks of age with stent dilation at 10 weeks of age. Five swine had stent intervention at 10 weeks of age. Right heart catheterization and MRI were performed to measure hemodynamics and pulmonary blood flow (PBF) distributions immediately pre- and post- intervention. Further details on the imaging and catheterization techniques can be found in our previous publications [5]. The University of Wisconsin IACUC reviewed and approved this protocol.

We had 13 cases to perform virtual intervention predictions. A recently developed lumped parameter modeling technique was implemented and used for hemodynamic simulations that retains accuracy while significantly improving efficiency compared to traditional computational fluid dynamics [6]. First pre-intervention pulmonary artery anatomies were segmented from medical imaging datasets. The resistance and compliance of the distal right and left pulmonary vasculature were tuned to match measured pre-intervention PBF distributions to within 10% accuracy. The diameter of the proximal LPA was then virtually increased to match the maximum distal LPA diameter. Predictive hemodynamic simulations were then performed, either PBF based simulations or RHC based simulations.

The agreement of simulation predictions with experiments was assessed with standard statistical techniques such as Bland-Altman analysis and ICC. The accuracy and diagnostic value of simulations was evaluated by their capability to predict physiologic intervention success based on whether interventions met three previously defined criteria: 1. an increase in total LPA blood flow greater than 20%, 2. a decrease in the stenotic pressure gradient greater than 50%, and 3. a decrease in systolic MPA pressure greater than 25%.

RESULTS

The variability of the physiological responses to an intervention was large. For further information of the physiological consequences of LPAS and stent interventions in swine the reader is referred to our previous publication [5].

Representative results of pre-to-post intervention changes from a simulation of a 5-week stent intervention are shown in Figure 1. It can be observed that the simulation predicted a decreased MPA pressure, decreased stenotic pressure gradient, and increased PBF to the left lung.

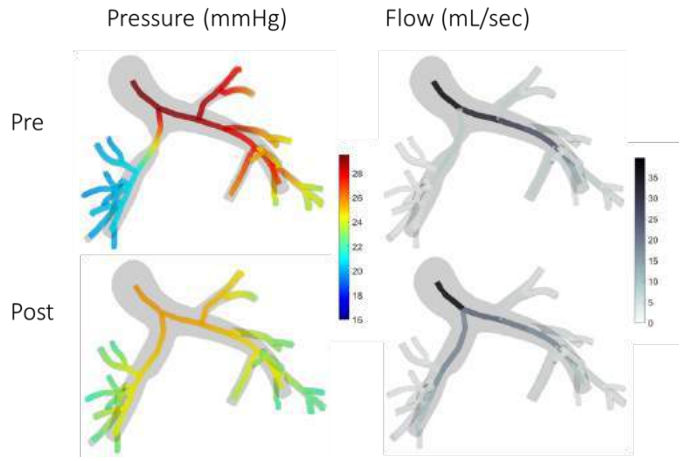

Figure 1: Representative intervention prediction results

Results from Bland-Altman analysis and ICC are presented in Table 2. Simulations predicted a decrease in MPA systolic pressure that was not observed experimentally. Simulations systematically predicted smaller changes to the stenotic pressure gradient compared to experiments. There was a negligible bias between experimentally measured changes in left PBF distribution and simulations. Simulations had moderate agreement and correlation with experimentally measured changes in left PBF %.

Table 1: Statistical comparison of simulations and experiments

	Δ Experiment	Bias	ICC	r
MPA Systolic Pressure (mmHg)	0.5±3.5	-2.9±3.6	0.00	0.29
Stenotic Pressure Gradient (mmHg)	-12.5±4.7	4.5±4.2	0.28	0.57
Left PBF (%)	11.4±15.6	3.4±11.1	0.69	0.71

Predictions of >20% LPA flow increase had excellent accuracy and diagnostic value. Predictions of >50% decrease in pressure gradient were also excellent but diagnostic value could not be calculated as 100% of our experimental interventions successfully decreased the pressure gradient. Predictions of >25% MPA systolic pressure decrease has excellent accuracy but weak diagnostic value.

Table 2: Accuracy and Diagnostic Value

Success Marker		Simulation
>20% Flow Increase to LPA	Accuracy	92%
	Area Under Curve	0.96
>50% Decrease Pressure Gradient	Accuracy	90.9%
	Area Under Curve	--
>25% Decrease MPA Pressure	Accuracy	92%
	Area Under Curve	0.58

DISCUSSION

We investigated the feasibility of hemodynamic models to predict the success of catheter based interventions for branch pulmonary artery stenosis. These predictions were then validated with experimental measurements in a swine model of left PAS with catheter interventions. Overall, there was only weak to moderate agreement between predicted and measured changes in stenotic pressure gradient and pulmonary blood flow distributions. However, simulations showed good diagnostic value for predicting successful vs. unsuccessful bPAS interventions. We believe the results of this proof of concept study are promising and should encourage future development for using hemodynamic models in planning interventions for patients with bPAS.

Catheter interventions to relieve bPAS in patients with CHD have shown long term favorable results [2] and in several centers catheter techniques are first line therapy for bPAS. However, research on catheter based interventions for bPAS has typically focused on immediate procedural technical success measured by the increase in the stenotic diameter rather than physiologic changes in PBF distributions, exercise capacity, or patients' clinical symptoms. A recent study found that for catheter interventions in patients with bPAS immediate technical success was achieved in 100% of patients, but PBF distribution improved in only 67% of patients [3]. Importantly, the patients who did not improve PBF distribution also did not improve their exercise parameters or symptoms.

While we consider the results of the current study promising, improvements could be made to enhance the simulations predicative capabilities. A key area for improvement would be to include changes in distal vascular resistance following interventions. Our simulations predicted that MPA pressures would decrease following intervention which experimentally does not occur in swine or humans [3,5]. Previous simulations of surgical repair for bPAS have assumed that the distal vasculature will vasodilate to maintain wall shear stress homeostasis [4] but this would further decrease MPA pressures. Instead, our results and the cited literature suggest that in patients without significantly elevated PA or RV pressures, the distal pulmonary vascular will vasoconstrict to maintain pre-intervention MPA pressures following an intervention. The hemodynamic and anatomical response of the distal pulmonary vasculature to changes in flow and pressure (both before and after relief of stenosis) is clearly complex. There is potential for these simulations and subsequent direct measures of PBF to support a better understanding of this disease, which should lead to more effective therapies, particularly for the 1/3 non-responder group.

Limitations include a relatively small sample size of only male swine, and that surgically created discrete PAS lesions are likely simpler than the complex lesions often seen in human patients.

In conclusion, this study investigated the feasibility of hemodynamic models to predict the success of catheter based interventions to relieve branch pulmonary artery stenosis. We believe the results of this proof of concept study are promising and should encourage future development for using hemodynamic models in planning interventions for patients with bPAS.

A DEEP-LEARNING APPROACH FOR DIRECT WHOLE-HEART MESH RECONSTRUCTION

Fanwei Kong and Shawn C. Shadden

Department of Mechanical Engineering
University of California, Berkeley
Berkeley, California, USA

INTRODUCTION

Computer models of anatomical structures reconstructed from volumetric medical images are increasingly used for a number of clinical applications. In particular, computer models of the heart, if combined with biophysical simulations, can assist understanding, diagnosis and treatment of cardiac diseases [1-2]. Creating accurate patient-specific models of the heart from image data requires significant time and human efforts; this is arguably the #1 factor limiting clinical applications. Deep learning methods can train neural networks from existing data to automatically process medical images and generate whole heart reconstructions. Such methods may accelerate the model generation process to enable high-throughput, large-cohort analyses of patient-specific cardiac function.

Most deep learning methods have focused on segmentation of the cardiac structures by pixel classification [3-4]. This results in an implicit representation of cardiac structures, however simulation and even some visualization methods require explicit representations—typically as unstructured meshes. Besides requiring additional surface processing techniques to generate meshes from the segmentation, these prior approaches suffer from a number of limitations including disconnected regions or incorrect surface topology due to erroneous segmentation and stair-case artifacts from limited image resolution [3].

We propose a novel approach that directly predicts whole heart surface meshes from volumetric images by predicting deformation on mesh vertices from a pre-defined mesh template using a graph convolutional neural network. We demonstrate promising performance of generating high-resolution and high-quality heart reconstructions from both CT and MR data. Furthermore, our method shows improved robustness to limited data, and can more efficiently produce temporally-consistent and feature-corresponding predictions of heart motion from CT or MR cine sequences, and therefore can potentially be applied for efficiently constructing 4D whole heart dynamics.

METHODS

Dataset Information: Contrast-enhanced CT images or MR images that cover the whole heart were obtained from four existing public datasets: multi-modality whole heart segmentation challenge (MMWHS), orCalScore challenge, left atrial wall thickness challenge and left atrial segmentation challenge. From these data, we used a total of 87 CT images and 41 MR images to train our model, and 15 CT images and 6 MR images to validate the model. The final performance of our model was evaluated on the MMWHS held-out test dataset that contains 40 CT images and 40 MR images. Furthermore, additional time-series CT images were collected to evaluate the performance of our approach on time-series image data.

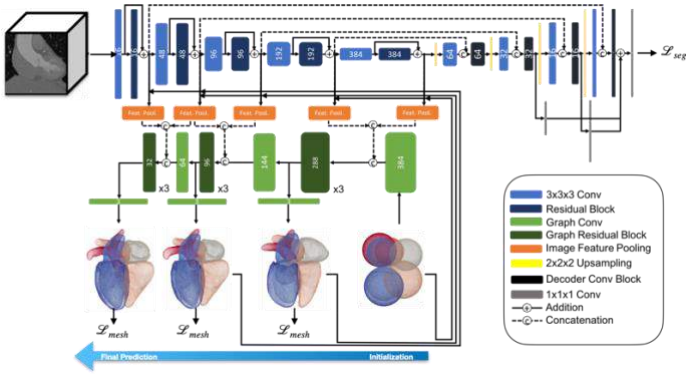

Figure 1: Proposed automatic whole heart reconstruction approach.

Neural Network Architecture: As shown in Fig 2, our framework consists of three components to predict the whole heart meshes from a volumetric input image. For an 3D image volume, our framework uses an image encoding module that extracts and encodes image features. From these image features, we use a mesh deformation module that combines features from images and meshes to predict deformation of mesh vertices from sphere mesh templates. The mesh deformation module consists of three deformation blocks with graph convolutional layers that progressively deform mesh templates to match with the corresponding tissue boundaries. Furthermore, our framework uses a segmentation module that predict a binary segmentation map to enable additional supervision using ground truth annotations.

Neural Network Optimization: The training of the neural network model was supervised by 3D ground truth meshes of the whole heart as well as a binary segmentation representing the occupancy of the heart in the input image. The ground truth whole heart meshes were extracted from the segmentation of cardiac structures using a marching cube algorithm. We considered two categories of loss functions for the mesh predictions, geometry consistency losses and regularization losses in the training process. The geometry consistency losses include point and normal consistency losses while the regularization losses include edge length and Laplacian losses. The parameters in the neural network models were optimized by minimizing the loss functions using the Adam stochastic gradient descent algorithm.

RESULTS

Our method is able to automatically generate high-resolution whole-heart reconstructions (10k surface vertices for each cardiac structure) from an input image within half a second on a modern GPU. We compare the performance of whole-heart reconstructions from our method against two baselines: 2D UNet [5] and a modified 3D UNet [6]. Table 1 shows the average Dice score (a similarity index) of the reconstruction results of both the whole heart and individual cardiac structures for the MMWHS test dataset. For both CT and MR data, our method consistently outperformed our baselines in terms of Dice scores for both whole heart and all individual cardiac structures.

Table 1: A comparison of prediction accuracy on MMWHS MR and CT test datasets from different methods.

	3D UNet	0.761	0.852	0.879	0.866	0.828	0.742	0.764	0.840

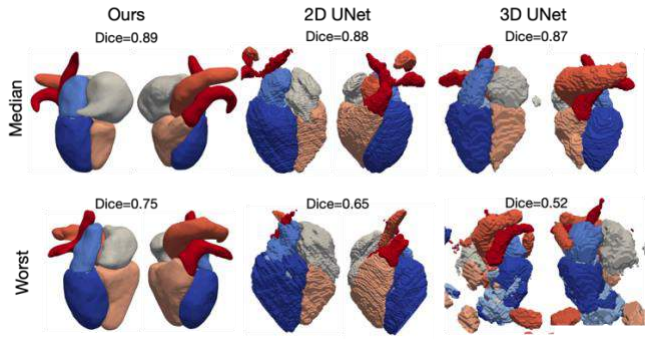

Figure 2: Visualizations of the median and worst reconstruction results among the test dataset in terms of whole-heart Dice scores.

Figure 2 visualize the median and worst results from the different methods for MR images, respectively, from the MMWHS test dataset. As shown, our method is able to construct smooth geometries while segmentation-based methods, such as the 2D UNet or 3D UNet, produced surfaces with staircase artifacts or disconnected regions that would require post-processing to remove or connect.

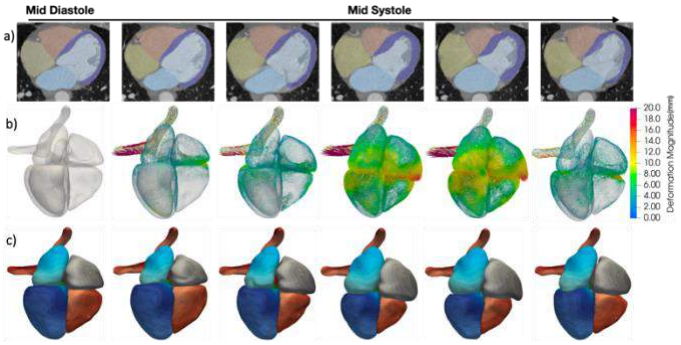

Figure 3: Whole-heart reconstruction results for time-series CT data. A) predicted segmentation b) mesh deformation vectors since late diastole and c) the feature correspondence maps of meshes.

Figure 3 displays example whole-heart reconstructions from our methods on time-series CT data. Although our model predicts mesh reconstructions independently from each time frame, it is able to consistently deform the template meshes so that the same mesh vertices on the template are generally mapped to the same region of the reconstructed geometries across different time frames, as shown by the color maps of vertex IDs in Figure 3. Moreover, as shown, our method is able to capture the minor changes between time frames whereas 2D and 3D UNet results (not shown) often had significant segmentation discrepancies between time frames. Therefore, our method can potentially be applied to efficiently construct 4D dynamic whole-heart models to capture the motion of a beating heart by computing the deformation field on each mesh vertex, as displayed in Figure 3.

DISCUSSION

Automated image-based reconstruction of cardiac anatomy and the concomitant geometric representation using unstructured meshes is important to a number of applications, including visualization of patient-specific heart morphology and computational simulations of cardiac function. We have demonstrated the advantages of this method over prior segmentation-based approaches in terms of both precision and surface quality [4-6]. Namely, the use of a template mesh can introduce topological constraints so that predicted cardiac structure are diffeomorphic to the template. Thus, our template-based approach enables one to eliminated disconnected regions and greatly reduce erroneous topological artifacts often encountered with prior methods. Furthermore, the method produced temporally consistent and feature-corresponding predictions by consistently mapping mesh vertices on the templates to similar structural regions of the heart. While the cardiac structures of interest were diffeomorphic to spheres, the presented method has the potential to be generalized to anatomical structures with a different topology, by using a different template mesh with the required topology.

INTRODUCTION

As we move toward personalized precision medicine, understanding the influence of sex on cellular phenotype and disease is becoming increasingly important. Most research on sex-specific effects focuses on lifelong exposure to sex hormones in primary adult cell lines. Human umbilical vein endothelial cells (HUVEC) provide unique insight into innate differences between male and female endothelial cells. Prior studies found that female HUVEC express a more proliferative and migratory phenotype than male [1], and a proteomic analysis of twin pairs demonstrated 88 differentially expressed proteins between male and female HUVEC [2]. Sexual dimorphisms in HUVEC may help parse out hormonal vs. innate effects of sex on endothelial function, and thereby provide novel insight into vascular pathologies and subsequent cardiovascular disease. The goal of this study was to determine the influence of cell sex on endothelial gene expression.

METHODS

Cell culture: Pooled HUVEC (passages 4-9) from 3 male and 3 female donors were cultured in Endothelial Growth Medium-2 supplemented with 10% fetal bovine serum, 1% penicillin-streptomycin, and 1% L-glutamine.

RNA Isolation: Total RNA for RNA sequencing were isolated using TRIzol phenol/chloroform. RNA quantity and quality were assessed using a NanoDrop 2000c. RNA was sequenced by Novogene using the NovaSeq 6000 with 150-bp paired end reads. Data were cleaned and assessed in Galaxy and visualized in Advaita iPathway.

Western Blotting: Protein O-linked β-N-Acetylglucosamine (O-GlcNAc) and endothelial nitric oxide synthase (eNOS) were assessed by Western blot. Cells were scraped and lysed in ice-cold RIPA buffer. Lysates were normalized to protein content, separated using SDS-PAGE in a 4-12% Bis-Tris Gel, and transferred to a nitrocellulose membrane using the iBlot 2 system. Membranes were incubated overnight at 4°C with an O-GlcNAc (CTD110.6) or eNOS (D9A5L) primary antibody diluted 1:1000, and then incubated for 2 hours at room temperature with a horseradish peroxidase-conjugated secondary antibody at 1:2000. Proteins were visualized using an Enhanced Chemiluminescence Substrate in a Fluorchem digital imager. Band intensities were quantified using AlphaView Software.

Statistical analysis: Differential expression of sequenced RNA was assessed using the EdgeR function in Galaxy with a Benjamini-Hochberg p-value correction. Genes with an adjusted p-value of less than 0.05 and a log fold change of at least 0.5 were identified as being significant. Western blots were analyzed using an unpaired two-tailed t-test in Prism (GraphPad).

RESULTS

2,140 of the 37,747 genes identified through RNA sequencing were differentially expressed in male and female HUVEC (Fig. 1A). Pathway analysis in iPathway revealed extracellular matrix (ECM) interactions, vascular function, and inflammation to be among the pathways with the highest degree of differential gene expression between male and female HUVEC. 13 of these genes were related to ECM proteins and adhesion (Fig. 1B). Of the six collagen-encoding genes that were differentially expressed, genes for Collagen I Alpha I, Collagen 4 Alpha 6, and Collagen 6 Alpha 2 and 3 (COL1A1, COL4A6, COL6A2, COL6A3), were downregulated in male, while Collagen I Alpha 2 and Collagen 9 Alpha 3 (COL1A2, COL9A3) were upregulated. Genes coding for integrin subunits Alpha 1, Alpha 10, Alpha 7, and Beta 4 (ITGA1, ITGA10, ITGA7, ITGB4) were upregulated in male cells. Laminin genes encoding for laminin subunits beta 3 and gamma 2 (LAMB3, LAMC2) were downregulated in male cells.

Seven differentially expressed genes were associated with vascular dysfunction and inflammation (Fig. 1C). NOS3, which encodes eNOS, was downregulated in male compared to female HUVEC, confirming previous findings [1]. SDC1, which encodes glycocalyx proteoglycan syndecan-1, was also downregulated in male HUVEC. Genes encoding for ICAM-1, VCAM-1, and E-Selectin (ICAM1, VCAM1, SELE) were all upregulated in male HUVEC. Finally, IL1R1, which encodes for an IL-1 receptor, was upregulated in male HUVEC, while IL1A, which encodes for IL-1α was downregulated in male cells.

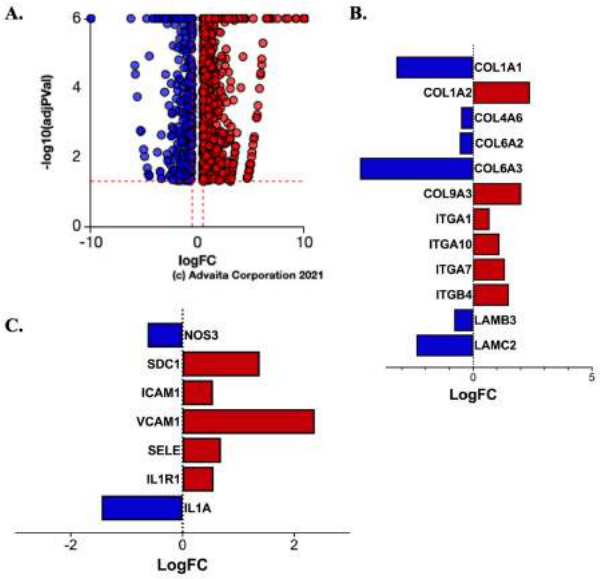

Figure 1. Differential gene expression in male vs. female HUVECs. A. Volcano plot showing significantly up- or down-regulated genes. Genes were categorized as significant for adjusted p<0.05, and a log fold change >0.5. B. Log fold changes of ECM associated genes. C. Log fold change of vascular function associated genes. Red: genes upregulated in male cells compared to female cells. Blue: genes downregulated in male cells compared to female cells.

We confirmed that NOS3 gene upregulation correlated with increased eNOS protein (Fig 2). eNOS O-GlcNAcylation, which is thought to inhibit NO production, is higher in female HUVEC. However, there were no differences in the glycolytic enzymes regulating O-GlcNAc production (glutamine-fructose-6-phosphate aminotransferase; GFAT), attachment (O-Linked N-Acetylglucosamine Transferase; OGT), or removal (O-GlcNAcase; OGA).

DISCUSSION

Sexual dimorphisms identified through RNA sequencing in this project confirm previous findings [1][3] and support innate sex differences in ECM and vascular function and inflammation pathways. Differential ECM gene expression may indicate differences in cell adhesion between male and female cells. Collagen I increases focal adhesion complexes, while laminin decreases endothelial cell doubling and adhesion time and increases adhesion force compared to uncoated glass [4]. ECM composition is also closely linked with vessel stiffening, with collagen, a stiff protein, dominating ECM composition in hypertension [5]. Further examination of ECM sex differences in HUVEC are valuable in determining the influence of cell sex on angiogenesis, response to shear stress, and arterial stiffening.

Increased SDC1 expression in female cells may increase syndecan-1 release from endothelial cells. Syndecan-1 increased angiogenesis and invasion in human dermal microvascular endothelial cells through association with $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins [6]. Thus syndecan-1 may be a mechanism by which female HUVEC have increased proliferation and migration compared to male HUVEC [1]. Upregulation of ICAM1, VCAM1, and SELE, all associated with leukocyte adhesion and transendothelial migration, indicate male HUVEC may have a more pro-inflammatory phenotype than female cells. Additionally, IL1R1, upregulated in male cells, binds proinflammatory cytokines IL-1α and IL-1β, and anti-inflammatory IL-1 receptor antagonist (IL-1Ra). Increased binding of proinflammatory cytokines and leukocyte extravasation may make the male endothelium more prone to atherosclerotic lesion development and growth, and arterial stiffening.

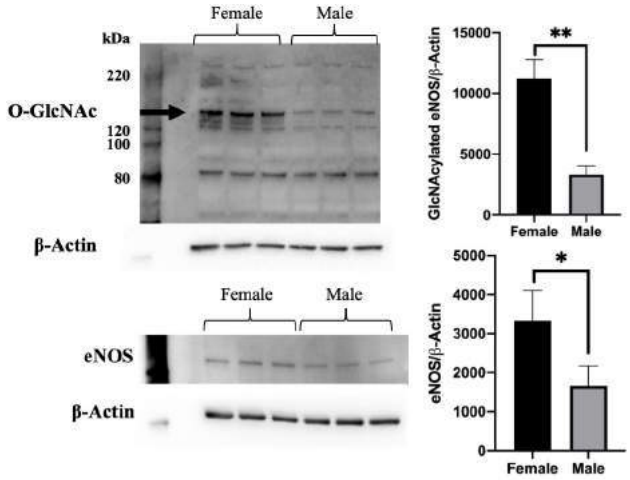

Figure 2. HUVEC O-GlcNAcylated eNOS (~140 kDa) and eNOS (140 kDa), normalized to β-actin, are both higher in female cells than in male cells. *p<0.05, **p<0.01.

eNOS O-GlcNAcylation was found to be increased in female HUVEC, yet others have shown female HUVEC produce more NO in static culture, as measured through eNOS phosphorylation and the citrulline:arginine ratio [7]. Thus, it is possible that female HUVEC have other adaptations that enable them to produce more NO despite eNOS O-GlcNAcylation. Further research is needed to determine why female cells have increased protein O-GlcNAcylation, since we did not observe changes in the related enzymes.

Overall, these data call for further analysis of the influence of sex on endothelial cell-ECM interactions and vascular function. Specifically, the influence of sex on endothelial cell-mediated angiogenesis and vascular stiffening should be examined in greater detail through sex specific *in vitro* and *in vivo* modeling. A greater understanding of the influence of cell sex on the vasculature will improve individualized treatment of cardiovascular disease and other vascular pathologies.

INTRODUCTION

Bicuspid aortic valve (BAV) is the most common congenital cardiac anomaly with an incidence of 0.4 – 2.25% in general population [1]. Unlike tri-leaflet aortic valves, BAV is marked by the fusion of two aortic leaflets with a thick, fibrous raphe present at the location of fusion in most cases. In addition to the anomalous valve morphology, BAV is also associated with other structural complications including aortic root dilatation and dissection [2]. The structural malformation and altered hemodynamics result in an early onset of calcific aortic valve disease (CAVD) in most BAV patients, eventually leading to aortic stenosis (AS) and regurgitation, which may require replacement of the valves. A minimally invasive, alternative to surgical aortic valve replacement, transcatheter aortic valve replacement (TAVR) is designed for tricuspid calcific aortic valve and recently adapted for off-label use to treat BAV patients with severe AS due to the presence of CAVD. Despite showing promising performances, TAVR is reported to be associated with various clinical complications including atrioventricular and left bundle branch blockage (LBBB) [3]. Post-TAVR cardiac conduction abnormality (CCA) can occur due to any mechanical damage sustained by the atrioventricular conduction system located near the inter-leaflet triangle region between the non-coronary and the right-coronary leaflet. Conduction disturbances may eventually lead to permanent pacemaker implantation, abnormal cardiac function, and therefore to increased mortality [4]. This is of particular concern among the BAV population since many of them who require aortic valve replacement are young and low risk patients. The structural anomaly of the BAV patients make them susceptible to conduction abnormalities and exacerbates other post-TAVR complications, which prevents the establishment of TAVR as a standard care for BAV patients. In addition, BAV patients had systematically been excluded from TAVR clinical trials due to inherent structural asymmetry, severe leaflet calcification and resulting distorted stent profile. Finite element (FE) modeling is a common research computational method for performing patient-specific simulation of the TAVR procedure, studying post-procedural outcomes and aiding in pre-surgical planning. The number of computational work focusing on modeling conduction disturbances in BAV patients is minimal. This motivates us to perform computational study on 2 BAV patient groups – 1) Control patients and 2) Patients who developed post-TAVR LBBB. The goal of this work is to simulate TAVR procedure in patient-specific BAV models, investigate post-procedural strain development near the atrioventricular conduction region, and analyze for possible strain value threshold that may predict the risk of post-TAVR CCA development in BAV patients.

METHODS

Anonymized cardiac CT scans of 6 type I BAV patients who underwent TAVR, were obtained from Rabin Medical Center, Israel, with IRB approval. Patient- specific surface meshes were reconstructed from DICOM images and optimized for FE analysis using ANSYS SpaceClaim and Fluent Meshing while maintaining their features. Native tissue was modeled using isotropic Ogden hyper elastic material model. Calcium deposits were modeled using linear elastic homogenous isotropic material (E = 12.6 MPa, ν = 0.3) [5]. Self-expandable TAVR stents were modeled using super-elastic nitinol alloy. A cylindrical catheter with cone shaped tip was modeled in order to crimp the self-expandable stent as well as to help the leaflets open during device delivery. A 4-step FE simulation (crimping, insertion, deployment, and relaxation) was performed using Abaqus Explicit 2019, and the implantation depth was chosen based on the clinical data. Clinical data also includes membranous septum (MS) length, which is obtained from the cardiac CT scans, marked by the distance between the hinge point of the non-coronary cusp and the vertex of the muscular septum (Figure 1 A and B) as described by Hamdan et al. [6]. This information along

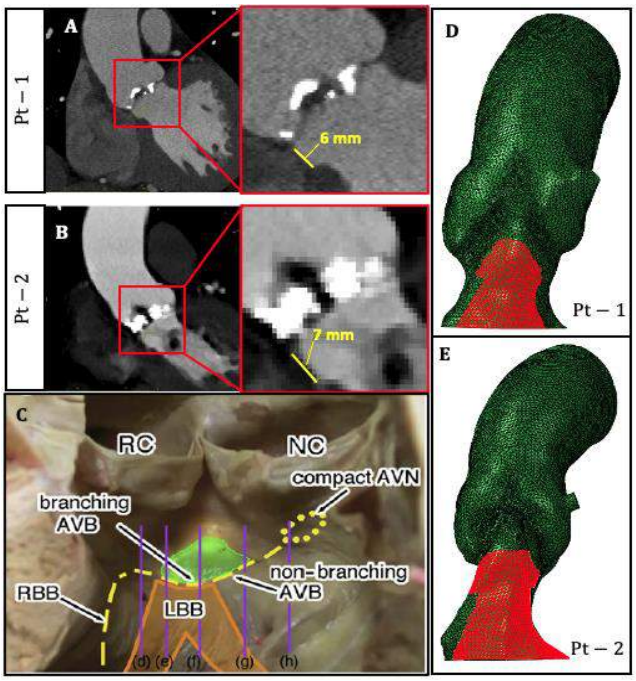

Figure 1: A,B - Measurements of the MS length, obtained from the coronal view of the cardiac CT scans; Patient 1 MS length = 6mm, Patient 2 MS length = 7mm; C - Morphology and location of atrioventricular bundle and left bundle branch (LBB) [7]; D, E – Estimated MS and LBB region in 2 patient specific models (highlighted in red); Patient 1 – control and Patient 2 - LBBB

with a previous report on the anatomical detail and variation of MS and LBB location (Figure 1 C) were then used as a guide to define the MS and LBB region in the patient models (Figure 1 D - E). The area-weighted average logarithmic (LE) strain (%) in the LBB region was calculated in all implantation steps.

RESULTS

A highly eccentric stent deployment was observed in two patient cases (Figure 2 A-B; Patient 1 – control patient, Patient 2 – developed post-procedural LBBB). The distribution of maximum principal LE strain values on the left ventricular outflow tract (LVOT) near the MS and LBB regions was analyzed (Figure 2 C-D). The difference in strain contour between these patients was marked by a region of very high strain located between the non-coronary and the right coronary cusp in patient 2. In addition, the distal end of the LVOT region in patient 1

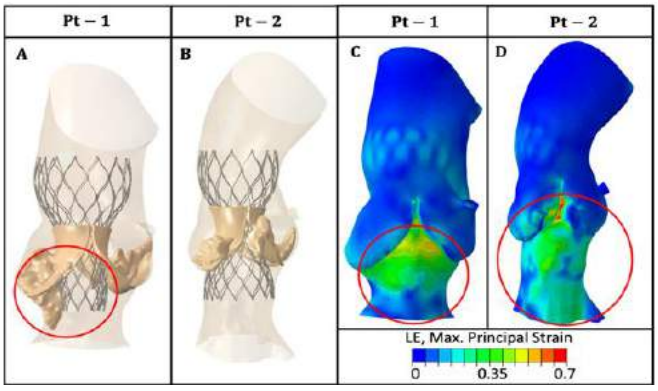

Figure 2: A, B - Post-deployment eccentric stent profile with heavily annular calcification in patient 1 (circled); C, D - Maximum LE strain on ascending aorta and LVOT (circled).

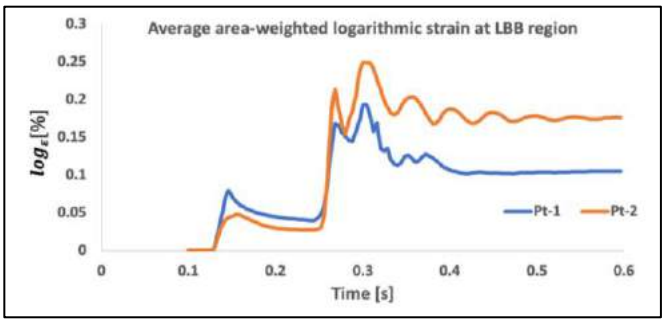

Figure 3: Mean area-weighted average strain at LBB region

exhibited an overall lower strain value. In both patients, the area-weighted average LE strain values at the LBB region (Figure 3) increased until the middle of the deployment phase (0.3 s) and reached a stable value by the end of relaxation phase (0.6 s). The strain value of LBB in patient 1 reached ~ 10 %, whereas in patient 2, it reached a higher value, ~ 17%.

DISCUSSION

The higher strain in the LBB region predisposes patient 2 to the risk of LBBB, which one of the most common post-TAVR complications, especially in BAV patients. This data agrees with the clinical data as patient 2 was reported to have new post-TAVR LBBB. Multiple factors including MS length and calcification are important predictors of post-TAVR conduction disturbances [6]. Non-coronary leaflet calcification that extended downward toward the LVOT along the ventricular wall (Figure 2 A), interrupts the interaction between the distal end of the stent and the part of the lumen that is adjacent to MS and LBB region (Figure 1 A), resulting in an overall lower strain value at the distal end of the LVOT, which is adjacent to LBB. Whereas in patient 2, the distal end of the stent was completely in contact with the LVOT lumen. This trend was also reflected by the area-weighted average LE strain values calculated at the LBB region in both patients. Our current work is focusing on the patients receiving self-expandable valves because self-expandable valves are more likely to cause conduction disturbances due to the constant radial force applied by the nitinol frame, and having a large portion of the device located at the LVOT region increases the risk of mechanical damage to the atrioventricular conduction region. However, we are currently working on extending our study to the balloon-expandable patient group in order to analyze the difference in strain value between self-expandable and balloon-expandable patient populations. As a part of our ongoing study, we are working on additional BAV patient models with a possibility of establishing a strain threshold that could differentiate between the patients who does and the patients who does not develop CCA. By establishing this computational framework, we could strengthen the role of patient-specific modeling as a predictive tool in pre-TAVR planning, which can help identify BAV patients who are at increased risk of developing post-TAVR CCA.

EFFECTS OF PIA-ARACHNOID COMPLEX CONSTITUTIVE FORMULATIONS ON PREDICTIONS OF CONCUSSION

Nikolaus A. Benko (1) and Brittany Coats (1)

INTRODUCTION

It has been hypothesized that the mechanics of the pia-arachnoid complex (PAC) contribute substantially to the dynamic strain response of the brain during traumatic injury. However, the paucity of experimental data to characterize the human PAC has prevented detailed investigations into the role of the PAC during traumatic brain injury. In this study, we use recent *in situ* measurements of the human PAC modulus in traction to investigate the importance of PAC heterogeneity and anisotropy in computational predictions of brain strain, as well as the relative contribution of PAC constitutive formulations to the prediction accuracy of concussion.

METHODS

To test the effect of PAC constitutive formulations on strain prediction in computational models of traumatic brain injury, a simplified finite element model of the human head was constructed. Four PAC formulations were created and used in a 2-factor 2-level design to isolate the effects of PAC heterogeneity and constitutive model isotropy.

Model geometry was based off of a segmented T1-weighted MRI of a 24-year-old male with no neurological dysfunction, available from the public OASIS dataset [1]. Scan IP (Synopsys, Mountain View, CA) was used to create surface meshes of gross brain parenchyma, meningeal layers, falx cerebri, tentorium cerebelli, and the skull. Surface meshes were loaded into TrueGrid (XYZ Scientific, Pleasant Hill, CA) and used to define the boundaries of a multi-block hexahedral mesh (Figure 1A). The falx cerebri and tentorium cerebelli were represented with 2D shell elements (Figure 1B). 3D elements representing brain matter were roughly divided into seven regions representing the frontal lobe, corpus callosum, brainstem, parietal lobe, temporal lobe, occipital lobe, and cerebellum. All elements used a reduced integration formulation.

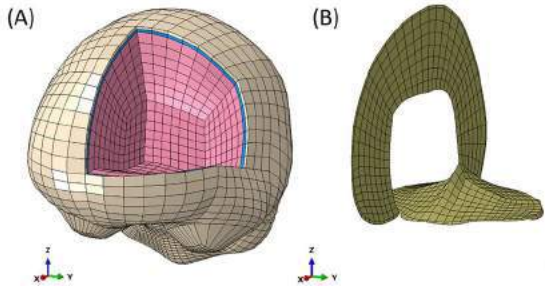

Figure 1: (A) Hexahedral mesh of skull, CSF, and brain matter. (B) Shell elements representing falx and tentorium.

Four versions of the FE model were created with different constitutive formulations for the PAC elements. First, a baseline model, *Model I*, was created representing the PAC as a linear elastic isotropic material that is homogeneous across the surface of the brain. The modulus for the baseline model is defined as the average PAC traction stiffness from previous studies by our lab [2]. The second model, *Model H*, is also a linear elastic isotropic material model, but the PAC modulus is heterogenous across the brain. This model defines a unique modulus for each PAC region (Figure 2) from the average of the regional material properties. All isotropic PAC elements had a Poisson's ratio of 0.4999 corresponding to an average bulk modulus of 21.1 MPa. The final two models were homogeneous (*Model T*) and heterogeneous (*Model HT*) as defined above, but implemented using a transversely isotropic linear elastic formulation for the PAC instead of an isotropic formulation. The

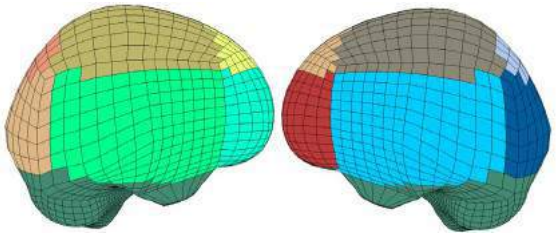

Figure 2: PAC regions assigned unique material properties based on experimental measurements of PAC traction stiffness.

transversely isotropic material models were formulated using the methods described in Scott et al [3].

For injury prediction, we simulated 53 recreated impacts from the National Football League (20 with concussion, and 33 without) [4]. Three-dimensional accelerations from the reconstructions were used as the inputs for the simulations. Strain data were recorded for each element in time increments of 0.0001 seconds for the duration of each simulation. Average 90th percentile peak maximum principal strain (ε_{90}) was calculated for each brain region, as well as the brain as a whole. The 90th percentile value of peak strain taken from each anatomical region were fit to concussion outcomes using multivariate regression. A leave-one-out cross validation scheme was adopted to account for potential overfitting with the limited training dataset. The injury prediction performance of different PAC formulations was compared using area under the curve (AUC), sensitivity, and specificity extracted from ROC curves.

RESULTS

Across the 53 impacts, ε_{90} throughout the whole brain for the homogeneous isotropic model was 32.56%. For the heterogeneous isotropic model, homogeneous transversely isotropic model, and heterogeneous transversely isotropic model, ε_{90} values were 32.60%, 29.32%, and 29.31% respectively. Two-way analysis of variance (ANOVA) showed that PAC heterogeneity had no significant effect on ε_{90} when averaged across the entire brain (p=0.9506) while transversely isotropic models predicted significantly lower ε_{90} than isotropic models (p<0.0001, Figure 3). These trends were persistent within individual anatomical regions of the brain.

Of the four PAC formulations, the Model H performed best in the testing dataset (AUC=0.870, sensitivity=0.85, specificity=0.91). *Model I* performed very similarly to *Model H* (AUC=0.870, sensitivity=0.80, specificity=0.91), while *Model T* and *Model HT* both had a much lower specificity of 0.76 (Figure 4).

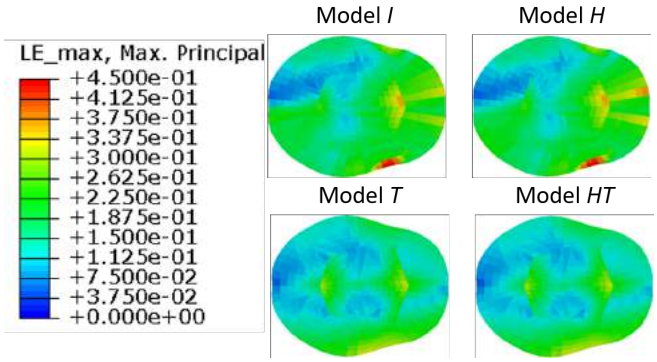

Figure 3: Fringe plots comparing peak maximum principal strain distributions in Case 038HD01 from the impact dataset with each of the PAC constitutive formulations.

DISCUSSION

Simulations of recreated collisions between football players revealed that PAC heterogeneity had no discernible effect on strain estimates. This is likely due to the relatively small regional variability in PAC modulus (12.8±3.2kPa). Transversely isotropic models of the PAC yielded lower estimates of brain strain than isotropic models. The increased stiffness of the transversely isotropic formulations was mostly due to the explicit inclusion of the in-plane tensile modulus which was much greater than the out-of-plane traction modulus.

Isotropic PAC formulations produced better injury predictions than transversely isotropic formulations with increased specificity. The heterogeneous formulation produced marginally higher injury prediction sensitivity, however given the limited size of the injury prediction dataset, this finding should not be considered definitive. The relatively lower performance of transversely isotropic PAC formulations is interesting as the anatomical structure of the space, with trabecular fibers predominantly oriented radially outward from the surface of the brain, would suggest that the PAC would have a directionally dependent strain response. For this study, we relied on our previous measurements of the out-of-plane traction response of the human PAC and derived the in-plane behavior from previous studies of bovine PAC [5]. The findings presented here suggest the importance of further experiments to quantify the in-plane tensile and shear behavior of the human PAC.

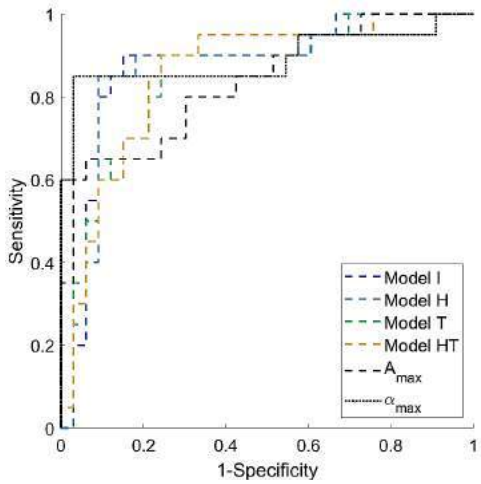

Figure 4: ROC curves for the multivariate injury predictions for *in situ*-based PAC formulations. Univariate injury predictions based off of peak linear (A_{max}) and angular (α_{max}) accelerations have been added for reference. Homogeneous and heterogeneous variations of PAC formulations performed similarly for both isotropic and transversely isotropic variations. Isotropic formulations had higher AUC and specificity compared to transversely isotropic formulations.

INTRODUCTION

The talus bone in the human ankle joint has a limited blood supply with only 40% being supplied by blood vessels and the rest enclosed with cartilage [1]. When the talus is injured or fractured, this limited blood supply makes it vulnerable to osteonecrosis which can cause severe ankle pain [2]. One of the common treatments for talar osteonecrosis is tibiotalocalcaneal arthrodesis, a surgical procedure where the talus bone is fused to the tibia and calcaneus bones [3]. Not only is this procedure technically challenging, but it also inhibits range of motion and function, which significantly impact the quality of life of these patients [4]. Additionally, this procedure may lead to other complications such as nonunion and infection [3,4]. Talar body replacement is an alternative procedure where the talus bone is replaced with an artificial prosthesis, preserving ankle functionality and reducing pain [5]. In this procedure, computed tomography (CT) scan data of the contralateral (uninjured) talus is used to design and create a customized implant [5]. Although this procedure offers good outcomes for patients [5], it is quite expensive and patients are forced to endure delayed treatment as a result of the lengthy surgical planning process. As well, this procedure cannot be used on patients who have injured both tali.

Since the talus bone shape is similar across the population [6], a universal talus implant can be designed and made readily available for surgery. It would be used instead of customized implants and would be manufactured in different sizes to accommodate the various talus sizes within the population. This will enable patients with talar injuries to avoid long wait times and costly procedures while taking advantage of the benefits of talar body replacement surgery.

To design a successful implant, the mechanical effect of the candidate implants on the articular cartilage surrounding the talus bone would need to be examined first. Therefore, the objective of this study is to model the talus bone and surrounding joints and use finite element (FE) simulations to calculate resultant contact pressure and contact area on the articular surfaces.

METHODS

The model geometry is created by taking CT scans of a cadaver ankle in a neutral standing position. These 2D CT scans are imported into Materialise-Mimics® (Materialise, Leuven, Belgium), an image processing software which converts them into a 3D model. The ankle model is then imported into Geomagic® (3D Systems, South Carolina, USA) to isolate all 5 bones in the region: the talus, fibula, tibia, calcaneus, and navicular. Geomagic® is also used to refine the bone models by smoothing and reducing noise. Next, each of the bone models are exported to HyperMesh® (Altair, Troy USA) for meshing and the articular cartilage layers are created by highlighting the contact areas on every bone and extruding the surfaces by 1.5 mm. Adding the cartilage causes adjacent layers to be in an overlapping position. Therefore, all bones and surrounding cartilage are moved slightly away from the talus using HyperMesh®. Finally, the ankle model is exported to ABAQUS® (Dassault Systèmes, Johnston, USA) for conducting the FE simulations.

The talus models included in the simulations are the *biological* model (natural talus with human cortical bone [7] and cartilage [8] mechanical properties to serve as a means of comparison), the *customized* model (same shape as the biological model with no cartilage

layers), the *universal* model (average talus bone shape developed by Trovato et al. [6]) and the *statistical shape* model or SSM (average talus bone shape developed by Liu et al. [9]). For the three implant models, the cartilage thickness is taken into account by scaling the original models using a volume scale factor. The implants are then given mechanical properties of cobalt chrome [10].

The simulations on ABAQUS® occur in three successive time steps: 1) the talus is fixed and initial contact is created by moving the other bones back to their original positions in the CT scans; 2) the talus is unconstrained; 3) the tibia and fibula are given a translational degree of freedom (DOF) in the z-direction and the fibula also a rotational DOF about the z-plane and then a downwards axial load of 2000 N is applied to the tibia (Figure 1) [11]. The simulations are performed on all models and the resulting contact pressure on the talus bone is calculated in the tibiotalar and talocalcaneal cartilage. The contact pressure is displayed in the form of color maps to easily visualize the distribution.

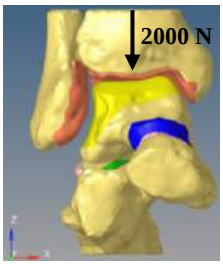

Figure 1: Ankle model with talus implant and cartilage areas colored in yellow, blue, and green. Cartilage layers of surrounding bones are colored in red and pink. The axial load applied is shown.

RESULTS

The contact pressure (MPa) in the tibiotalar region of all four models is displayed in Figure 2a. The maximum contact pressure in each model was also recorded and presented in the figure. Figure 2b includes the contact pressure and maximum values for the talocalcaneal cartilage area. The contact pressure scales were normalized to the maximum values of the biological model in both figures. Therefore, the grey areas represent contact pressure values greater than 10.9 MPa and 13.6 MPa in the tibiotalar and talocalcaneal cartilage areas, respectively.

From the color maps in Figure 2a, it can be deduced that the contact area of the tibiotalar region in all three implant models was less than the biological. The maximum contact pressure was substantially larger in the implant models and there were more areas of stress concentration (red/grey areas). Similar results were found in the talocalcaneal cartilage area. Also, the shape of the contact pattern of the universal and SSM implants were different from the biological model (Figure 2b).

DISCUSSION

The goal of this study was to calculate contact pressure on the articular surfaces of the ankle model when using talus implants and compare the results to that of a natural talus. Results showed that the candidate implants currently result in smaller contact areas and larger values for contact pressure. Areas of stress concentration were identified, as shown in Figure 2. In the future, we will investigate other implant shapes and designs that can reduce the instances and magnitudes of stress concentrations and obtain contact pressure contours similar to the biological model. The customized talus model had the same shape as the biological model and although the contact contours were similar, the maximum contact pressure was considerably higher. This suggests that materials other than cobalt chrome should be investigated and may provide results closer to the biological model.

Future work will focus on including talofibular and talonavicular cartilage areas in the analysis. Two more loading scenarios (dorsiflexion and plantarflexion) will also be simulated along with the neutral standing position. Lastly, more subjects will be included to offer a more definitive conclusion of the impact of these implants on the ankle.

INTRODUCTION

Pressure-volume curves are classical measures of investigating lung mechanics and deviations caused by disease progression [1]. Studies of pressure-volume curves have been limited to using positive-pressure ventilation (PPV), where the air is directly applied to the lung to cause inflation, as in modern artificial ventilators [2]. Conversely, natural lung function is governed by negative-pressure ventilation (NPV), where the lung inflates due to diaphragm distension, reducing the thoracic cavity pressure which the lung expands to fill. However, despite these drastic loading differences, the mechanical characteristics of the lung in physiological NPV settings is vastly underexplored and its pressure-volume response in relation to PPV is unknown. This knowledge void continues to plague understanding how ventilators should be optimized, a need that can no longer be overlooked as highlighted by the demand to ventilate COVID-19 patients.

To address these fundamental scientific needs, we utilize our custom-designed and validated novel volume-controlled, pressure-measuring, and dual-piston apparatus capable of testing the lung in both PPV and NPV under matched loading conditions [2]. We study the effect of various tidal volumes (one of the key variables in ventilator settings) in ex-vivo porcine lungs. Directly comparing the classical pressure-volume curves of PPV and NPV will enable improved ventilation strategies by understanding how to emulate the loading patterns characteristic of physiological lung mechanics, ultimately helping to mitigate fatalities caused by barotrauma, volutrauma, acute respiratory distress syndrome, and ventilator induced lung injury.

METHODS

Lungs from three pigs (200-250lbs) were collected from a local abattoir. The lungs were tested within 24hrs of sacrifice to minimize tissue damage and were stored in 1X PBS [3]. Specimens were inflated with a preload of 5 cmH_2O to implement a fixed reference state for all specimens regardless of trapped air inside the lung. The inflation-deflation rate was set to a normal frequency of 15 breaths per minute. Applied inflation volumes of 675, 900, and 1350 ml, corresponding to clinical tidal volumes of 6, 8, and 12 ml/kg in PPV were used [4]. The compressed air volume of the lung was measured by controlling and equilibrating the piston-actuator positions in real-time, enabling a valid comparison between PPV and NPV loading mechanisms [2]. The induced peak pressures and lung volume changes were recorded from applied loads under positive-pressures and then analogous negative-pressure loading cycles were applied to the lung such that the peak pressure magnitudes and volumes matched within $\pm 10\%$.

Each test was repeated three times to precondition the lung and followed by the matched test inflation-deflation cycle. The area between loading and unloading curve was used to define the hysteresis. Energy loss was described as the hysteresis area normalized by the total work done. Initial and final slopes of pressure-volume curve were calculated using a bilinear model fitted to two linear portions of curve while the difference between fitted line and experimental data was minimized by setting the coefficient of determination R^2 to 0.9 [5].

Statistical comparison of PPV and NPV results was performed using paired t-test and volume group comparison was done by one-way analysis of variance (MATLAB Statistics Toolbox, MathWorks Inc.). The significance level was set at $p< 0.05$, represented by * and ▲ for PPV-NPV and volume comparisons, respectively. Due to COVID-19 there was a shortage of research available pig lungs, limiting our analysis to the statistical minimum of three specimens.

RESULTS

Representative volume-pressure curves for artificial (PPV) and corresponding physiological (NPV) breathing mechanics for different

inflation volumes are shown in Figure 1. Greater inflation volume had similar effect on both PPV and NPV tests, resulting in increasingly disparate inflation and deflation paths.

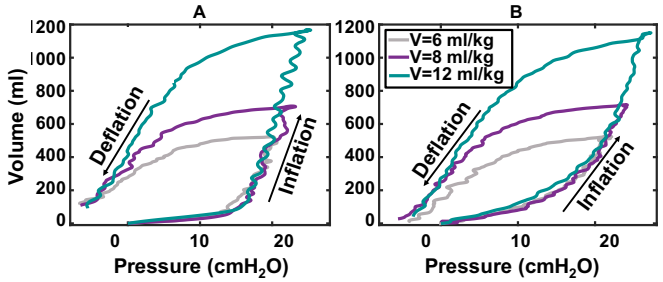

Figure 1: Representative specimen's volume-pressure response for various inflation volumes in PPV (A) and NPV tests (B). Inflation loading response drastically differed while deflation paths were similar between PPV and NPV tests.

Figure 2A illustrates the lung inflation-deflation response in PPV and NPV. Initially, the inflation slope increased incrementally in PPV compared to the greater slope of NPV. The quantitative initial and final slope values obtained from bilinear fitting for three pigs were averaged and represented in Figure 2B and 2C, respectively. Initial slopes were notably higher for NPV compared to PPV, although these differences were found to be statistically significant only in tidal volumes of 6 and 12ml/kg. In contrast, PPV tests inverted the trend for the final slope, surpassing the NPV slope for 6 and 12 ml/kg tidal volumes (Figure 2C). Greater inflation volumes resulted in unidirectionally increasing higher initial slopes in NPV (Figure 2B) which was not observed in PPV; the final slopes of PPV and NPV were instead noted to increase with increasing inflation volumes (Figure 2C).

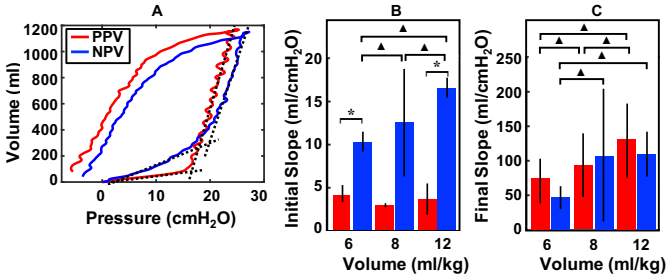

Figure 2: Representative of a volume-pressure response for a tidal volume of 12 ml/kg comparing PPV and NPV tests where dotted lines show bilinear fit (A). Comparison between slopes of fitted lines to initial (B) and final (C) portion of PPV and NPV curves for different inflation volumes.

Lung behavior in PPV and NPV settings, was also examined energetically: hysteresis was noticeably greater in artificial breathing in all inflation volumes although not enough to be statistically significant. Similarly, the lung lost more energy in PPV compared to NPV tests. Variation in maximum inflation volume resulted in an increase in hysteresis in both test settings, however, its effect on energy loss was not unidirectional.

DISCUSSION

This study directly compares the pressure-volume mechanics of the lung in artificial and physiological breathing conditions for the first time and further assesses the comparative response of porcine lung under various tidal volumes. The direct comparison between PPV and NPV shows that despite matching the peak lung pressure and expansion volume, the inflation paths followed to reach each matched tidal load

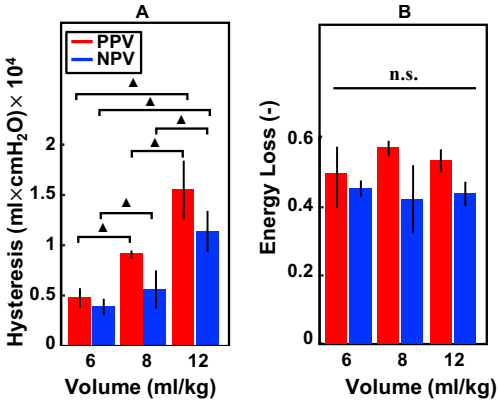

Figure 3: Comparable hysteresis and energy loss for PPV and NPV tests at various tidal volumes where bar graphs represent average and standard deviation for three pigs.

differed significantly in PPV and NPV (Figure 1): during initial inflation, the relative reduced pressure-volume slope in PPV is representative of greater organ stiffness, while lung behaves more compliantly (greater slope) in NPV. This initial part is medically known as the lower inflection point, indicative of airway resistance and the minimum pressure required to recruit alveoli [6]. The notable differences between initial slope of PPV and NPV reveals that the latter the alveoli inflate early on and there is much less airway resistance. This phenomenon can be attributed to the different loading mechanism between PPV and NPV; in PPV, the air must be pushed through each airway before reaching the alveoli whereas in NPV, the lung is inflated by a difference in pressure felt foremost at the distal alveoli pulling air in from the proximal airways. These results are in agreement with previous studies reporting better oxygenation and more homogenous air distribution in NPV tests based on hemodynamics and biochemical responses [7].

In addition to the different loading paths followed in PPV and NPV, the lung exhibits greater hysteresis and energy loss in PPV tests, potentially explaining damages associated with this ventilation method; an increase in hysteresis is associated with an increase in the work of breathing, where the latter phenomena has been reported in chronic obstructive pulmonary disease patients [8].

The effect of lung volume inflation on compliancy and hysteresis has also been examined in this study. Greater inflation volume does not affect initial compliancy in PPV tests (Figure 2B) but results in greater initial compliancy in NPV tests as well as an increase in the final compliancy and hysteresis in both PPV and NPV tests. While these are the first measures for NPV, increase in hysteresis with greater inflation volumes for PPV are in agreement with what has been reported for dog and human lungs [9].

This mechanical study demonstrated that the lung is more energy efficient and compliant in physiological loading compared to artificial breathing conditions. These direct mechanical comparisons between PPV and NPV will inform the improvement of ventilators function and mitigate injury.

INTRODUCTION

Vision loss in glaucoma, the second leading cause of blindness in the world, is due to progressive retinal ganglion cell axon damage. [1] Although it is known that this damage starts in the back of the eye, in a region called the optic nerve head (ONH), the pathogenesis of the disease is still not well understood. Understanding the mechanisms leading to nerve damage will help with early detection and treatment. This is crucial in glaucoma because lost nerve fibers cannot be recovered, and therefore vision is lost forever. One of the leading hypotheses of glaucoma postulates that low blood flow within the ONH may contribute to ischemic death of the retinal ganglion cells. [2] If this is correct, understanding how eye-specific contributes to low blood flow would allow predicting susceptibility to disease.

Our goal in this project was to characterize geometric parameters of the ONH capillaries and determine whether they are associated with blood flow. Specifically, we reconstructed the 3D capillary network of a monkey ONH, and quantified four geometric parameters: capillary length, tortuosity, inclination, and azimuth. We simulated the blood flow throughout the capillary network, and then evaluated the associations between the local flow rate and the four geometric parameters for each capillary segment.

METHODS

3D reconstruction of the ONH capillary network. Serial histological sections (thickness: 16 µm) were obtained from a normal monkey ONH, in which the vasculature had been perfusion-labeled with a fluorescent dye. The sections were imaged with fluorescence microscopy at a resolution of 0.73 µm per pixel. The images were registered to one another as a 3D stack. The capillaries were then identified using a modified 3D Hessian filter and manual segmentation. The result was skeletonized and converted into a graph for simulation of blood flow rate and quantification of vascular geometry.

Simulation of blood flow rate. A fluid mechanics approach was used to predict the blood flow rate within the capillaries. [3] Hemodynamics boundary conditions were defined to simulate blood inflow from the circle of Zinn-Haller in the periphery, drainage through the central retinal vein, and interactions with the pre and retrolaminar regions. Blood was considered as an incompressible Newtonian fluid, and its flow behavior was described by the Hagen-Poiseuille equation.

Quantification of vascular geometry. Each capillary segment was defined as an unbranched vascular tract between two branch points or between a branch point and a terminal point. We quantified four geometric parameters of capillaries: length, tortuosity, inclination, and azimuth. Figure 1 shows the detailed definition of each parameter.

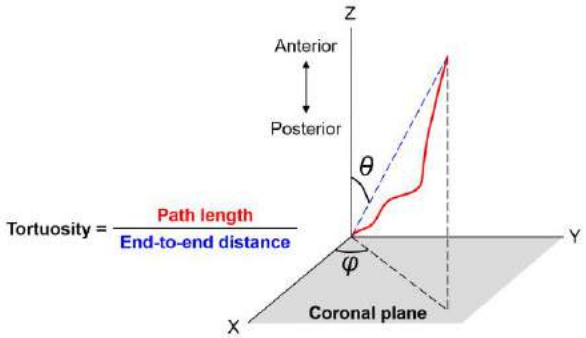

Figure 1: Definition of the capillary geometric parameters. Tortuosity (≥ 1) was the ratio of the path length (red solid line) to the end-to-end distance (blue dashed line). Inclination ($0 \le \theta \le 90^o$) was the angle between the end-to-end line and the z-axis (anterior-posterior axis). θ=90˚ indicates that the capillary is parallel to the x-y plane (coronal plane). Azimuth ($0 \le \varphi < 360^o$) was the angle between the projected end-to-end line and the *x*-axis.

Statistical analysis. As we analyzed the results, we found that neither the blood flow rate nor the four geometric parameters were normally distributed (Figures 2 and 3). To improve the normality of their distributions and residuals, the flow rate, length, tortuosity, and inclination were transformed with a base 10 log. Since the azimuth is circular data, it was transformed with dummy variables. We performed a multivariate linear regression analysis to determine the associations and used $\alpha = 0.001$ to define significance. All statistical analyses were done using R (v4.0.3).

RESULTS

The 3D ONH capillary network architecture and its flow were quite complex. Figure 2 shows the network as reconstructed, and the distributions of the flow rate, capillary length, tortuosity, inclination, and azimuth. Scatterplots of segment flow rate and the four geometric parameters are shown in Figure 3, and the statistical results in Table 1. There was no preferential azimuthal orientation of the capillaries. A majority of the fibers were in the coronal plane.

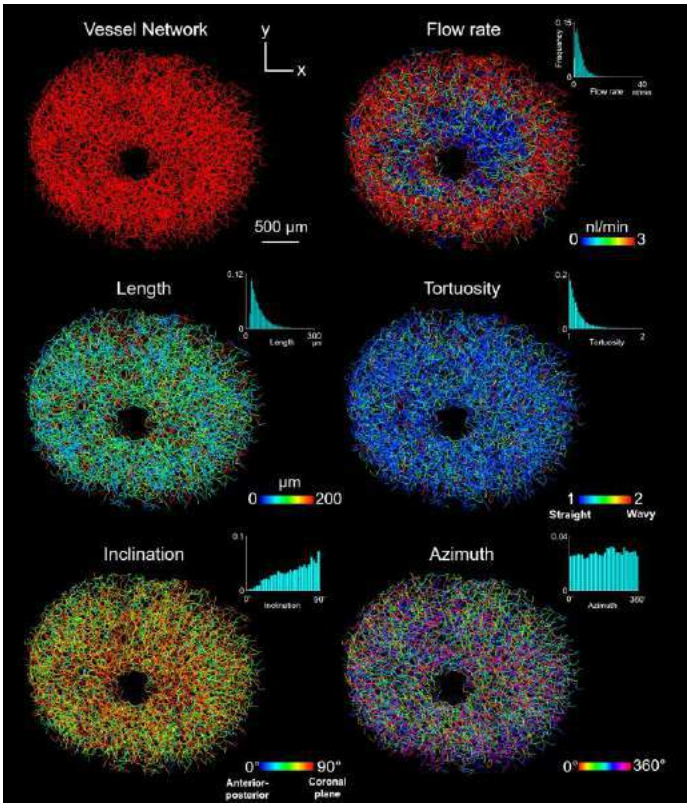

Figure 2: 3D reconstruction of the capillary network of a normal monkey ONH, which included 1100 terminal points, 7989 branching points, and 12966 segments. The network is shown colored by segment flow rate, length, tortuosity, inclination, and azimuth, with histograms showing their distributions.

Table 1: Summary of results from statistical tests.

Parameter	Slope	*P*
Length	-	> 0.01
Tortuosity	-0.06	< 0.0001
Inclination	-0.11	< 0.0001
Azimuth	-	> 0.01

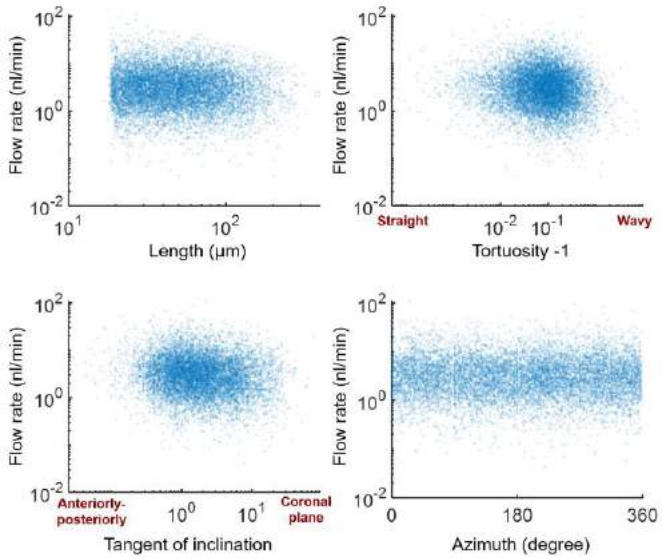

Figure 3: Scatterplots of blood flow rate as a function of the four geometric parameters. Flow rate had a small negative association with tortuosity and inclination (P's < 0.0001). We detected no associations between flow rate and length or azimuth (P's > 0.1).

DISCUSSION

The capillaries in the ONH form an extremely complex interconnected network. Since measuring blood flow experimentally is still not possible, we used computational simulation to estimate blood flow in a specimen-specific ONH capillary network and then determined the associations between the capillary geometric parameters and blood flow.

We found that the flow rate was negatively associated with the capillary inclination. This suggests that the flow rate in capillaries within the coronal plane (θ = 90°) was slightly lower than that in capillaries oriented anteriorly-posteriorly (θ = 0°). Previous models of optic nerve head blood flow used simplified 2D ONH capillary networks, [4] which may reduce the fidelity of the models for representing hemodynamics in the ONH.

We also found that the flow rate was negatively associated with the capillary tortuosity. That is, the flow rate in a tortuous capillary was lower than that in a straight one. However, the slope of the association was very low (*i.e.*, -0.06), indicating that the effects of tortuosity on the flow rate were small. Tortuous capillaries would increase the proximity to tissues and the time the blood is available for nutrient and oxygen exchange, which may be advantageous for the tissues. [5]

In summary, our study revealed associations between the ONH capillary geometric parameters and blood flow rate. The associations, however, were weak. Findings from this study have the potential to be clinically useful in glaucoma management, diagnosis, and risk profiling.

A NOVEL LOCAL TUMOR PROGRESSION PREDICTION METHOD FOR MULTI-MODE THERMAL ABLATION

Xinyi Wang, Jianlong Yang, Aili Zhang*, Lisa X. Xu

School of Biomedical Engineering,
Shanghai Jiao Tong University,
Shanghai, China

INTRODUCTION

Multi-mode ablation [1] is a new minimally invasive therapy that uses thermal energy to destroy tumors. During the therapy consisting of sequential rapid freezing, thawing and radio-frequency heating, tumors undergo significant cell damage and capillaries rapture, resulting in antigen releasing and triggering of immune responses. Since the ablated lesion remains in vivo, a detailed histological analysis is not available. To avoid potential recurrences, post-operative evaluation becomes extremely important.

Continuous and frequent imaging follow-up is the most common way to track progression that has occurred [2], rather than predicting it in advance. Radiomic attempts to find hidden clues beyond structural differences in images before the event, but is rarely reported in thermal treatment [3]. Based on the thermal history experienced, temperature and thermal dose estimate the extent of local ablation [4]. However, the difficulty in predicting complex changes, such as immune effect and indirect death, dramatically limits the use of long-term assessment.

This work establishes a prediction framework for local tumor progression. We leverage the multi-modal information provided by pre- and early post-operative MRI, intra-operative CT, and especially, a novel thermal dose map, implicitly giving the relationship between the applied heat and the necrosis and immunity within tumors. The information is then inputted into the random survival forest model [5]. In addition to returning the risk score, this model shows the temporal evolution of survival probabilities, an important reference for clinical follow-ups. Its exclusion of static and medical priors also benefits the generalization capability of trained models. To validate our framework, a clinical dataset from Shanghai Cancer Center, Fudan University was used, including 17 patients with colorectal liver metastases and hepatocellular carcinoma. We collected the multi-modality informatics mentioned above in this dataset retrospectively.

METHODS

The proposed framework consists of three major steps (Fig. 1): multi-modal preprocessing, model development and model output (with Comsol 5.4, simpleITK, pyradiomics, pysurvival, survcomp).

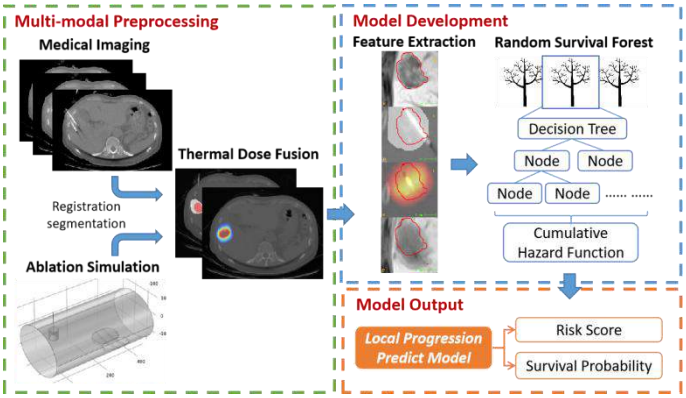

Figure 1: The framework to predict the risk of local progression

Thermal dose mapping was first calculated and only for radio-frequency ablation, since the ice balls in CT scans could characterize the cooling process. We used a numerical simulation model based on the patient's individualized impedance to invert the steady-state temperature field [6]. The initial state and boundary conditions were set according to actual therapeutic parameters. We calculated the equivalent thermal dose during steady state in voxel-scale, the values of which were accumulated if heated more than once. We fused the thermal dose maps with intra-operative images, and registered the pre- and post-operative scans to the same CT series [7]. The segmentation of the region of interest was then implemented.

Table 1: The extraction of radiomic features

Image	Tumor	Ice Ball	Thermal Dose	Ablation Zone
Geometric	√	√		
Grayscale			√	
Texture	√		√	√

We extracted a total of 113 features directly from each sample. The radiomic features were extracted from 2D slices of the region of interest (Table 1), and the texture features consisted of Law features, Tumaru features, and GLCM features in detail. Age, disease type, tumor number and treatment position were added as clinical features. Considering the complex linear and nonlinear relationships in high-throughput features, we applied the group-Lasso and correlation graph to avoid dimensional catastrophes.

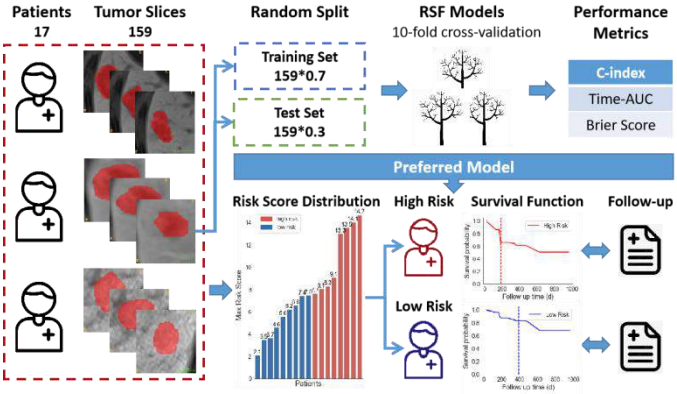

Figure 2: The training and validation of random survival forests

We used the random survival forest to predict the risk of local progression (Fig. 2). A conservation-of-events principle for survival analysis is introduced to define the overall mortality, a interpretable measure used as a predicted risk. We randomly split 159 slices into training and test set by 7:3. Based on the ranked importance of predictors, models with different input combinations were established.

Three performance metrics were measured: the C-index, the Brier Score and the time-dependent AUC, expressed as mean±deviation and confirmed by Wilcoxon rank-sum test. According to the distribution of maximum risk scores, we classified the patients into high- and low-risk groups. Kaplan-Meier curves were used to validate the grouping ability. Randomly selected two patients from each subgroup, we observed the predicted disease-free survival, especially at the event.

RESULTS

Importance ranking was performed for all selected features (Fig. 3a). The clinical (blue), pre-operative (yellow), intra-operative (red) and post-operative (gray) features contributed 18.3%, 29.2%, 34.5% and 18.1%, respectively. Intra-operative features had a higher ranking than post-operative ones, implying an indispensable role in prognostic evaluation. Therefore, the followed two models were compared:

• Model 1: clinical features, pre-operative tumor features, and post-operative ablation zone features.

• Model 2: clinical features, pre-operative tumor features, and intra-operative thermal dose features.

Performance metrics measure the ability of ranking survival times and grouping risk levels, and the error of predicted survival probability (Fig. 3 b-d). The thermal dose in Model 2 improved the C-index by 11% with less deviation, and maintained higher grouping accuracy until the median follow-up (iAUC: P=0.007). It might indicate the reflection for both immediate damage and long-term immunity. Model 2 also reached a lower error for maximum and average (iBS: P=0.004), providing a reliable estimate of individual progression-free survival.

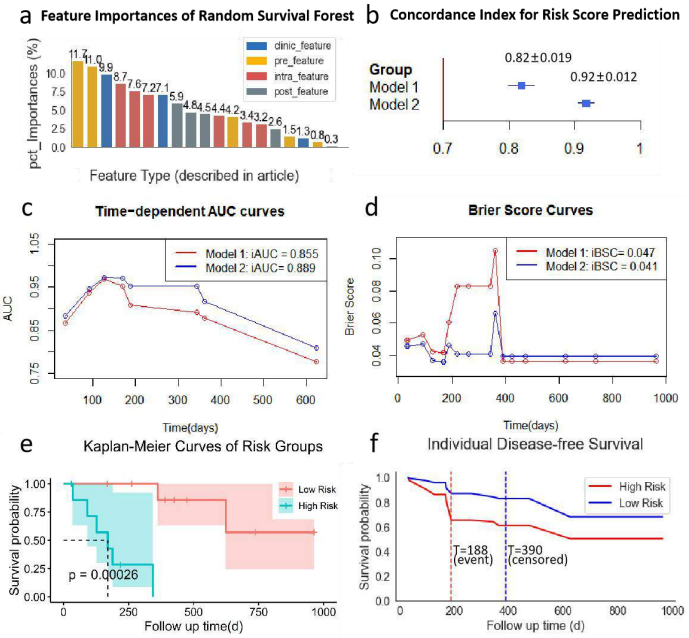

Figure 3: The performance of prediction models

The validation of the preferred Model 2 to clinical data was analyzed (Fig. 3f). The Kaplan-Meier curves for the predicted high-risk and low-risk groups differed significantly. The individual survival probability dropped sharply around the actual event for the high-risk patient, while it kept above 0.8 without progression for the low-risk patient. The predicted risk scores and survival probabilities provide quantitative information to assist early intervention.

DISCUSSION

The purpose of this study is to develop an accurate, timely and instructive prognostic evaluation tool, which allows the immediate evaluation of the progression risk after multi-mode ablation treatment. Our results show the potentiality of thermal dose maps to predict the direct and indirect damage more precisely in long-term, which may be attributed to the high-throughput features rather than a simple specific threshold. The quantitative information, especially individual survival probabilities, advance the potential of this method for clinical applications. In the future, we will explore the associations of immune response with thermal dose and provide personalized treatment for patients. We will also include more patients into our dataset.

INTRODUCTION

Myocardial infarction (MI) is the deadliest complication of coronary artery disease (CAD), with approximately 1 million of cases per year in the United States alone [1]. Coronary atherosclerotic plaques experience a variety of hemodynamic stimuli, such as wall shear stress (WSS) and pressure gradients, linked to plaque progression and destabilization, increasing the risk of an abrupt occlusion [2]. In particular, WSS is purported to play a major role in translating hemodynamic signals to vascular biological phenomena. In this regard, peculiar WSS features obtained from patient-specific computational fluid dynamics (CFD) simulations have been associated with coronary plaque rupture [3]. Therefore, WSS-based quantities may prove to have predictive capability for MI, allowing the identification of lesions prone to rupture improving the medical management of CAD patients.

Accordingly, the present study aims to explore the capability of a comprehensive hemodynamic assessment of coronary lesions to predict MI. To do that, quantitative coronary angiography (QCA), fractional flow reserve derived from angiography (vFFR) and WSS derived from patient-specific CFD simulations were retrospectively tested on a population of patients (N=188 vessels) with future culprit (FC) and non-future culprit (NFC) lesions.

METHODS

Patient population. Patients presenting with acute MI admitted for invasive coronary angiography were retrospectively screened to identify those who had (1) a previous coronary angiography performed between 1 month and 5 years before the event (baseline angiography), (2) a visually identifiable FC mildly stenosed lesion (i.e., $\leq$ 50% diameter stenosis) at the baseline angiography, and (3) at least one additional NFC lesion in the other two major epicardial vessels. This selection resulted in 80 patients and a total of 188 vessels, with 80 FC lesions and 108 NFC lesions.

Computational hemodynamics. The workflow of the study is presented in Figure 1. Three-dimensional QCA vessel reconstructions were performed using two angiographic projections with at least 30 degrees apart, extracting anatomical (percentage area stenosis, %AS) and functional (vFFR) data, using the CAAS Workstation vFFR software (Pie Medical Imaging, Maastricht, the Netherlands). 3D reconstructions were then discretized and transient CFD simulations were performed using a finite element-based code (CAAS Workstation WSS software, Pie Medical Imaging) to obtain the WSS distribution along the luminal surface. Patient-specific mean flow rates were prescribed as inflow boundary conditions scaling a generic Doppler velocity curve, distinctive for the right, left anterior descending, and left circumflex coronary arteries with a diameter-based scaling law [4].

Wall shear stress-based descriptors. The most widely adopted cycle-average descriptors of WSS magnitude, multidirectionality and topological skeleton features were tested. Here, we focused on the two descriptors that emerged as the strongest predictors of MI, as reported in the following. In detail, the cycle-average WSS (TAWSS) was selected as a measure of the WSS magnitude acting on the endothelium. Moreover, the contraction/expansion action exerted by hemodynamic shear forces on the endothelium was quantified according to a recently proposed Eulerian-based method for the analysis of the WSS topological skeleton based on the divergence of the WSS unit vector field (DIV_{WSS}) [5]: negative (positive) DIV_{WSS} values at the luminal surface identify WSS contraction (expansion) regions. Very recent findings demonstrated that the WSS topological skeleton is able to capture hemodynamic features linked to vascular dysfunction [6,7,8]. Here the quantity Topological Shear Variation Index (TSVI) was used as a measure of the variability of the local contraction/expansion action

exerted by the WSS along the cardiac cycle. Technically, the TSVI is defined as [7,8]:

$$TSVI = \left\{\frac{1}{T}\int_0^T [DIV_{WSS} - \overline{DIV_{WSS}}]^2 dt\right\}^{1/2} \quad (1)$$

where T is the cardiac cycle duration.

Statistical analysis. WSS-based descriptors were averaged over the lesion, identified using the standard QCA-based approach. The predictive capacity of WSS-based descriptors was quantified in terms of receiver operating characteristic (ROC) curve and area under the curve (AUC).

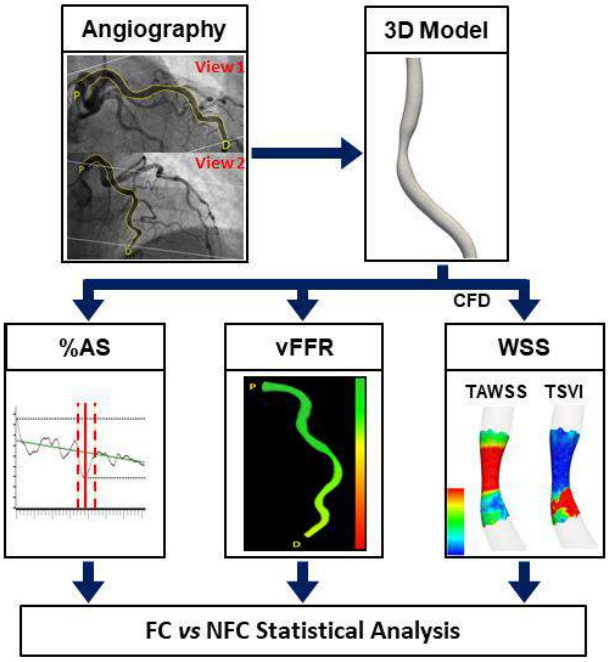

Figure 1: Workflow of the study

RESULTS

The FC and NFC groups were significantly different in terms of both anatomical and functional data ($p<0.001$ and $p=0.009$ for %AS and vFFR, respectively). Significant differences emerged between the FC and NFC distributions of lesion-average values of TAWSS (FC: 3.36 [IQR: 2.51-5.23] Pa; NFC: 2.94 [IQR: 2.36-3.80] Pa, $p=0.011$) and TSVI (FC: 71.08 [IQR: 44.42-116.20] m^{-1}; NFC: 33.21 [IQR: 24.77-60.11] m^{-1}, $p<0.001$), as reported in figure 2. Notably, both TAWSS and TSVI were significantly higher in FC than NFC group, with a more marked statistical significance for TSVI.

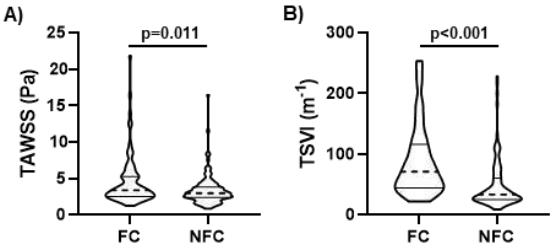

Figure 2: Violin plots of TAWSS (panel A) and TSVI (panel B) averaged over the lesion.

Anatomical and functional data emerged as moderate predictors for MI (AUC=0.65 and AUC=0.63 for %AS and vFFR, respectively). In figure 3, the ROC curves for lesion-average values of TAWSS and TSVI are presented. From the analysis, it emerged that TAWSS was a moderate (AUC=0.61; 95% CI: 0.53 to 0.69, $p=0.011$) but weaker MI predictor than anatomical and functional data. TSVI (AUC=0.77; 95% CI: 0.70 to 0.84, $p<0.001$) emerged as a stronger MI predictor than anatomical and functional data, as well as TAWSS. The best identified threshold values were: (1) 5.01 Pa for TAWSS, resulting in sensitivity equal to 0.34 and specificity equal to 0.89; (2) 40.52 m^{-1} for TSVI, resulting in sensitivity equal to 0.85 and specificity equal to 0.65.

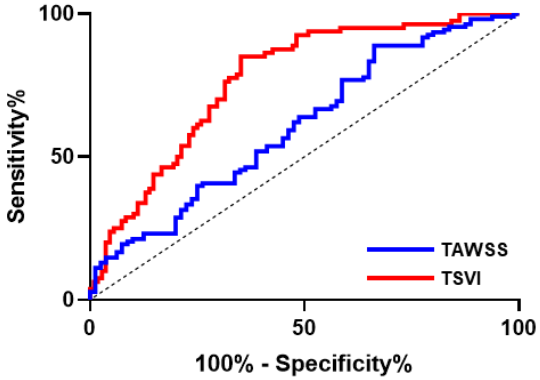

Figure 3: ROC curves based on TAWSS (blue) and TSVI (red) prediction of MI.

DISCUSSION

This study investigated the prediction capability for MI of anatomical, functional, and CFD-derived WSS-based quantities. The main results can be summarized as follows: (1) significantly different anatomical (%AS), functional (vFFR) and hemodynamic quantities (TAWSS and TSVI) characterized FC and NFC groups; (2) vFFR, %AS, and high TAWSS exhibited a moderate MI prediction capability; (3) high TSVI emerged as the strongest MI predictor. The obtained results enforce the hypothesis that (1) endothelial shear stress is a main actor in CAD, and (2) TSVI represents a relevant hemodynamic cue in CAD. The emergent predictive power of TSVI expands its association with long-term restenosis after carotid endarterectomy [7] and ascending aortic aneurysm wall degradation [8]. Physically, TSVI describes the variability of the contraction/expansion action exerted by WSS on the endothelium. Thus, it describes different features of the WSS vector field with respect to TAWSS and it represents a different hemodynamic stimulus to the endothelium. Translating this into mechanistic implications, the variability in the contraction/expansion action exerted by shear forces on endothelial cells reflects on intracellular tension variability that could lead to aggravating biological events [9]. A high temporal variability of WSS contraction/expansion action may result in fibrous cap fragility, accelerated disease progression, plaque fatigue, ending in plaque rupture and subsequent MI. This hypothesis, which needs further investigation, is also supported by the fact that TSVI identifies blood flow stagnation, recirculation and separation regions usually classified as flow disturbances promoting vascular dysfunction.

In conclusion, high TSVI resulted a strong predictor of MI in the analyzed population, encouraging further clinical trials to enforce the presented results and translate this concept into clinical practice.

LYMPHOCYTE NANOMECHANICS IN RESPONSE TO STENT IMPLANTATION

Konstantinos Kapnisis (1), Andreas Stylianou (2, 3), Despoina Kokkinidou (1), Marianna Prokopi (1) and Andreas Anayiotos (1)

INTRODUCTION

Changes in the arterial mechanical environment due to stent implantation are the main causes of the initiation of thrombosis and restenosis [1]. The mechanical properties of live cells can affect their physical interactions with the surrounding extracellular matrix, potentially influencing the process of mechanical signal transduction in living tissues. Previous studies have described the infiltration of inflammatory cells and immunocytes (T-lymphocytes) in restenotic tissue. This inflammatory response is characterized by the activation of circulating leukocytes that express adhesion molecules on the cell surface [2]. In this work we investigate stent-induced alterations in the nanostructure, cytoskeleton and mechanical properties of circulating lymphocytes in an effort to establish mechanical biomarkers to access stent-induced inflammation in the adjacent vascular tissue.

METHODS

Animal stenting: Male atherosclerotic ApoE−/− (30±5 g) and male CD1 (40±5 g) mice were used throughout the study (Project license: CY/EXP/PR.L9/2019). Custom made self-expanding nitinol stents (0.7 x 3.3 mm, closed-cell design with a diamond-shaped pattern; Admedes GmbH, Pforzheim, Germany), were implanted following the experimental protocol reported by Simsekyilmaz et al. 2013 [3] which describes a rapid and accessible procedure of stent implantation in mouse carotid artery.

Lymphocyte isolation: Whole blood (0.5-1 ml per animal) was collected from control (non-stented; n=3 per strain) and stented (12 weeks post implantation; n=3 per strain) mice, by direct cardiac puncture using a heparinized syringe. Mononuclear cells (MNCs) were isolated from whole blood using the SepMate™ procedure and highly purified CD4+ T lymphocyte subsets were enriched via the RosetteSep™ protocol (Stemcell Technologies, Vancouver, BC, CA).

Cell culture: Isolated lymphocytes were cultured in RPMI1640 medium, supplemented with penicillin 100 IU/ml, streptomycin 100 mg/ml, L-glutamine and 10% newborn calf serum at 37 8C in a humidified atmosphere of 5% CO2. The cells were cultured either on 35 petri dishes or glass cover slips, both coated for 5 minutes with Poly-L-lysine hydrobromide (Sigma).

Atomic Force Microscopy (AFM): AFM characterization was performed to probe the mechanical properties of live cells using a Molecular Imaging-Agilent PicoPlus AFM system and V-shaped soft silicon nitride probes (MLCT-Bio, probe C, Bruker). Petri dishes with the cultured cells, either for 2h (same day group) or for 24h (next day group), were directly mounded on AFM sample plates. In an area of 1x1μm near the center of the cells, 8x8 points of force curves were collected and analyzed by the freeware software AtomicJ so as to calculate the sample's Young's modulus using the Hertz model (for cells a 0.5 Poisson ratio was used). All mechanical properties measurements were recorded with a set point of 1nN normal force. For the mechanical characterization at least 30 live cells per condition from 3 independent experiments were studied, while attention was paid to always perform the measurements in less than 40min per experiment. Imaging of fixed cells (20 min with 4% paraformaldehyde-PFA) was performed in tapping mode with silicon probes (ACT-Applied Nanostructures). The AFM image processing was performed by using the PicoView software (Agilent) and the freeware scanning probe microscopy software WSxM.

Cell Immunostaining: Cells were first fixed with 4% PFA for 20 min and then a permeabilization buffer containing phosphate buffered saline, 2mg/ml Bovine Serum Albumin, and 0.1% Triton X-100. Then, cells were incubated with phalloidin for 1 hour at room temperature. Finally, cells were washed again three times with the permeabilization buffer and incubated for 2 min with 4',6-Diamidino-2-Phenylindole

(DAPI, Sigma). All coverslips were then mounted on a slide and observed under an Olympus BX53 fluorescent microscope equipped with an Olympus XM10 Monochrome CCD camera.

Stress fibers: For the characterization of the actin stress fibers, the FilamentSensor tool was used. In the reconstructed images each color corresponds to a different fiber orientation. Stress fiber orientation was assessed using the order parameter S=cos2θ, where he higher the value of S is, the more oriented the fibers become.

Cells' shape: Cell elongation was assessed using optical microscopy images. ImageJ software was used to automatically measure factor E from cells. Factor E equals to the long axis divided by the short axis minus one. Thus, E is zero for a circle, and one for an ellipse with an axis ratio 1:2. The cells that presented E values 0–0.5 were considered as spherical, 0.5–1 as ellipsoid, and E values higher than 1 as elongated. We used the optical microscope images from the cells so as to measure the cells circularity.

RESULTS

Firstly, we studied normal lymphocyte morphology. Our data demonstrated that lymphocytes from non-stented (control) ApoE and CD1 mice present typical spherical shape (Fig.1A), while high resolution AFM images showed cellular microvilli at the cells' surface and pseudopodia at the edge of the cell (Fig.1B). Furthermore, stress fibers where mainly located at the periphery of the cells, without any significant orientation pattern (Fig. 1A).

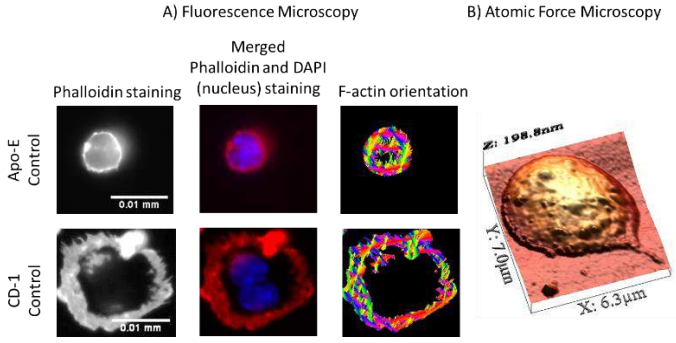

Figure 1: Representative images of lymphocytes (from control ApoE and CD1 mice) via A) fluorescence and B) AFM microscopy.

AFM studies on live cells from stented mice, highlighted that lymphocytes exhibit a significantly higher Young's modulus value. This pattern was observed in cells from both mouse strains, and in lymphocytes that were studied *in vitro* either 2h (same day) or 24h (next day) after isolation (Fig.2).

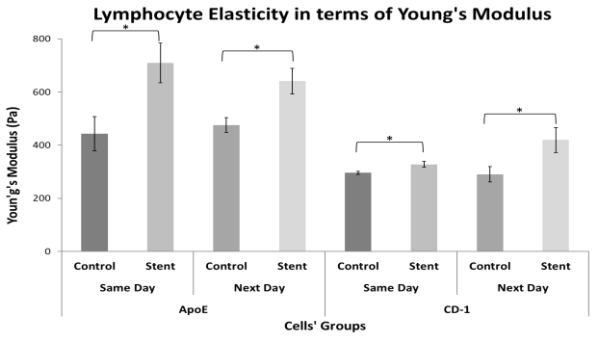

Figure 2: Young's modulus of lymphocytes (2h and 24h after isolation) from control vs stented mice. (* indicates p<0.05)

Subsequently, we used fluorescent microscopy to study whether inflammation alters lymphocytes morphology and F-actin stress fibers characteristics, which are considered to be the major cytoskeleton characteristic responsible for cells' mechanical properties. The results show that lymphocytes morphology was altered, as lymphocytes were becoming more elongated (Fig. 3 A (left) and B). Furthermore, notable cytoskeleton changes were observed, including F-actin stress fibers distribution and orientation (Fig. 3 A (right) and C). Stress fibers were distributed throughout the cell body, and more elongated patterns were formed. We believe that these alterations in F-actin fibers are due to the activation of lymphocytes as a result of the stent-induced inflammatory response. Consequently, cellular remodeling significantly modified the cell's mechanical properties, as assessed with AFM.

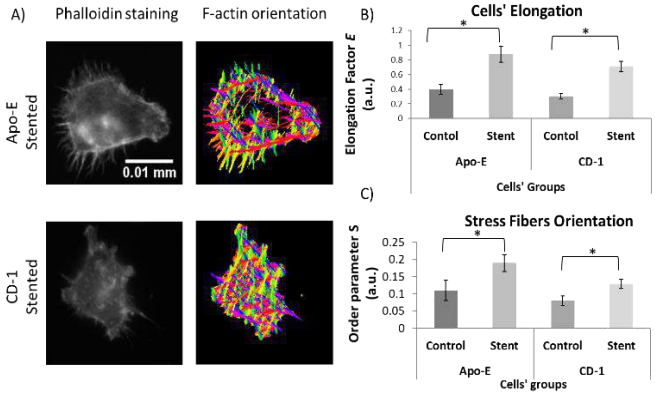

Figure 3: A) Representative images of lymphocytes (from stented ApoE and CD1 mice). Quantification of cell's B) elongation and C) stress fibers orientation. (* indicates p<0.05)

DISCUSSION

Restenosis appears to be associated to inflammatory and immunological activity that persists several months after coronary intervention. AFM has emerged as a powerful tool for studying important dynamic cellular processes in real time and it has been recently demonstrated that it can be used for developing nanomechanical biomarkers from single cells up to tissue samples [4].

Our research results demonstrated that lymphocytes from stented mice present an increase in their stiffness. Cell remodeling was observed in two different mice strains, the most widely used model of atherosclerosis, the ApoE-/- (for which changes due to lymphocyte activation are more profound) and the multipurpose CD1 strain. It is noted that the elevated Young's modulus is accompanied with the cytoskeleton rearrangement. Our findings suggest that the nanomechanical properties of circulating lymphocytes, could potentially be used as a biomarker to access stent-induced inflammation and possibly early stages of in-stent restenosis.

MULTISCALE HEMODYNAMIC PREDICTIONS IN CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

Mitchel J. Colebank (1), Mette S. Olufsen (1)

(1) Department of Mathematics
North Carolina State University
Raleigh, NC, USA

INTRODUCTION

A compromised pulmonary vasculature can lead to pulmonary hypertension (PH), a disease defined by a mean pulmonary arterial blood pressure (mPAP) $>$ 20 mmHg [1]. Though there have been advances in PH treatments, only chronic thromboembolic pulmonary hypertension (CTEPH) is considered curable. CTEPH is characterized by multiple recurrent or unresolved pulmonary emboli that impede flow to the alveoli. Disease confirmation requires elevated mPAP and at least one lobular perfusion deficit verified by a ventilation-perfusion (V/Q) scan. Severe CTEPH leads to small vessel arteriopathy, affecting pulmonary arterioles in both obstructed and unobstructed territories [2]. CTEPH patients typically undergo pulmonary thromboendoarterectomy (PTE); however, those with lesions in the smaller segmental and subsegmental arteries are deemed inoperable, and represent up to 60% of CTEPH patients [3]. An alternative surgical procedure for inoperable patients is balloon pulmonary angioplasty (BPA), which mechanically disrupts thromboembolic material by inflating a catheter balloon. Patients undergoing BPA receive multiple treatments, and the treatment strategy, i.e., the order in which lesions are targeted, vary with lesion severity and location, making it difficult to prioritize lesions for BPA. To address this, we propose a multiscale model of CTEPH hemodynamics that couples a one-dimensional computational fluid dynamics model (1D CFD) of the large arteries to a linearized 1D model of the small arteries and arterioles. We also integrate two pressure-loss models, mimicking typical CTEPH lesions. Our results show that the model framework predicts common phenotypes of CTEPH, including perfusion deficits, small vessel flow imbalances, and elevated mPAP.

METHODS

The pulmonary arteries and lung tissue from a normotensive, control CT image (from SimVascular, http://simvascular.github.io/) are segmented using 3D Slicer [4] (see **Fig. 1**). The segmented geometry is converted to a centerline network using the Vascular Modeling Toolkit (http://www.vmtk.org/), and then post-processed using custom MATLAB (Natick, MA) software [5], providing the network connectivity and individual vessel length and radii. We assume that the small vessels not captured by imaging follow a fractal, binary structured tree [6]. Each small vessel's length and daughter radii are determined as

$$L = \ell_{rr} r_p, \qquad r_{d_\alpha} = \alpha r_p, \qquad r_{d_\beta} = \beta r_p, \tag{1}$$

where α and β are dimensionless radius scaling factors ($\beta \leq \alpha < 1$), and ℓ_{rr} is the length-to-radius ratio. The small vessel network emanates

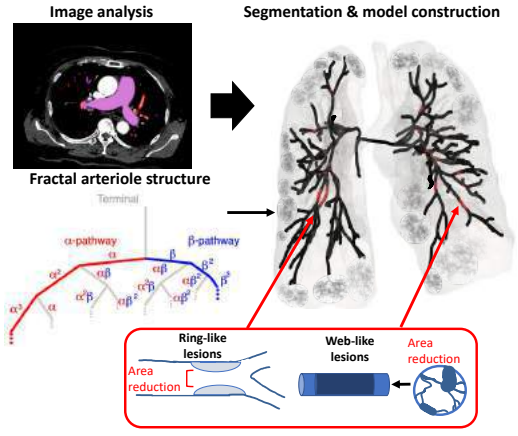

Figure 1: Proposed workflow that integrates medical imaging data, a small vessel fractal network, and two lesion energy loss models to predict multiscale hemodynamics in CTEPH.

from each terminal large artery and ceases after reaching a specified minimum radius, $r_{min} = 75\mu$m.

Large artery hemodynamics are predicted by solving nonlinear 1D CFD equations. Assuming that blood is incompressible, flow is Newtonian and axially dominated with no swirl, and that blood vessels are cylindrical and impermeable, the mass conservation and momentum balance equations are

$$\frac{\partial q}{\partial x} + \frac{\partial A}{\partial t} = 0, \qquad \frac{\partial q}{\partial t} + \frac{\partial}{\partial x}\left(\frac{q^2}{A}\right) + \frac{A}{\rho}\frac{\partial p}{\partial x} = -\frac{2\pi\nu R}{\delta}\frac{q}{A} \tag{2}$$

where x (cm) and t (s) denote space and time, and the dependent variables q (cm^3/s), $A = \pi R^2$ (cm^2), and p (mmHg) are the flow, cross-sectional area, and pressure, respectively. The hemodynamic parameters $\rho = 1.055$ (g/cm^3) and $\nu = 0.032$ (cm^2/s) are the blood density and kinematic viscosity. We assume that the blood velocity profile is flat but linearly decreases from the boundary layer thickness, $r = \delta$ (cm), to the vessel wall, $r = R$, satisfying the no-slip condition [6]. The system of equations is closed under the assumption that vessel walls are linear, elastic, incompressible, and isotropic, giving

$$p = \frac{4}{3}\frac{Eh}{r_0}\left(\sqrt{A/A_0} - 1\right) \tag{3}$$

where E (mmHg), h (cm), and $A_0 = \pi r_0^2$ (cm^2) are the Young's modulus, wall thickness, and reference area, respectively. An inflow profile drives the hyperbolic PDE system, conservation of pressure and flow are enforced at vessel junctions, and a small vessel hemodynamics model provides a terminal boundary condition for the large arteries.

In the small arteries and arterioles, we assume greater viscous forces than inertial, leading to a linearized form of eq. (2). We rewrite pressure and flow as periodic functions, leading to a wave equation with analytical solutions. Here, blood viscosity is modeled as non-Newtonian [6]. We assume pressure and flow conservation at each junction tree and prescribe a terminal impedance Z_{trm} as a resistance boundary condition.

To model CTEPH conditions, we increase both small and large artery stiffness, dilate the proximal arteries, and induce small vessel vasoconstriction. In addition, we employ two pressure loss models to simulate ring- and web-like stenoses common in CTEPH. They are

$$\Delta p_R = \frac{\mu K_v}{2\pi r^3} q + \frac{\rho K_t}{2A^2}\left(\frac{1}{C} - 1\right)^2 |q|q + \frac{\rho K_u L_R}{A}\frac{\partial q}{\partial t} \quad \text{and} \tag{4}$$

$$\Delta p_W = L_W\left(\frac{\mu}{K_p}\frac{q}{A} + \rho K_W\left(\frac{q}{A}\right)^2\right), \tag{5}$$

respectively, where K_v, K_t, and K_u are the viscous, turbulent, and inertial loss coefficients, K_p and K_W are the static and inertial permeability coefficients, L_R and L_W (cm) are the ring- and web-like lesion lengths, and $C \in [0,1]$ is the maximal area reduction of ring-like lesions. Eq. (4) is often used to model coronary artery stenoses [7], whereas eq. (5) is a novel model for web-like lesions. We place 20 lesions throughout the large arteries (see Fig. 1); 9 ring-like lesions ($C = 90\%$) and 11 web-like lesions with ($K_p = 9 \times 10^{-3}$, $K_W = 1.05$).

RESULTS

Fluid dynamic simulations are conducted under normotensive and CTEPH conditions, the latter including large and small vessel stiffening and 20 pulmonary lesions. Systolic pressure predictions in all 226 large arteries are provided in **Fig. 2a**. Results show a pressure increase proximal to CTEPH lesions, while pressure downstream from the lesions is substantially lower. The fractional flow reserve (FFR), defined as the ratio of mean proximal and distal pressure, is 0.37 ± 0.23 and 0.94 ± 0.05 for ring- and web-like lesions, respectively. Hemodynamic predictions in the structured tree are shown in **Fig. 2b** along an obstructed pathway distal to a lesion and an unobstructed pathway. Both mPAP and mean flow decrease in the obstructed pathway in CTEPH,

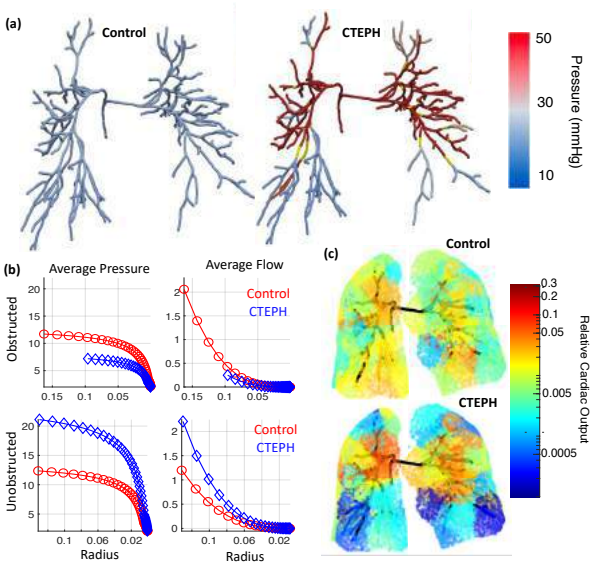

Figure 2: Model simulations in normotensive and CTEPH scenarios. (a) Systolic pressure throughout the large artery network. (b) Mean pressure and flow in the small vessels in both an obstructed and unobstructed pathway. (c) Perfusion map projected from the large vessels to the segmented lung tissue.

while these quantities both increase in the unobstructed pathway. Small vessel vasoconstriction in the obstructed path decreases the radii values in the structured tree relative to control, as shown on the x-axis. Lastly, flow predictions are mapped to the lung tissue in **Fig. 2c** and show increased flow heterogeneity and perfusion deficits in CTEPH.

DISCUSSION

Pulmonary hemodynamics models are underutilized in comparison to their systemic counterparts [7]. However, our model framework provides a useful *in-silico* tool for understanding the progression of CTEPH, and, more broadly, PH. FFR values from the model are consistent with those measured invasively by a catheter wire [8]. CTEPH is known to cause large perfusion deficits, increased mPAP, and small vessel arteriopathy, which is captured in our multiscale results in **Fig 2**. Results show underperfusion in vessels downstream to lesions, while small vessels in unobstructed pathways are overperfused, consistent with clinical hypotheses [2]. This proof of concept study lays the foundation for future investigations into the both the progression of small vessel disease in CTEPH and disease management. Our ultimate goal is to integrate patient specific lesions from CTEPH CT scans, estimate patient biomarkers, and provide an assistive tool in surgical planning, i.e., identifying improved mPAP and perfusion after BPA.

INTRODUCTION

Many medical procedures today require biomaterials which are both versatile and adaptive in order to treat complex conditions. The aim of this project is to combine the versatility of shape memory polymers (SMPs) with the biocompatibility of the electrospinning fabrication technique. SMPs are often beneficial for medical applications as they allow for significant shape change in difficult to access areas. Additionally, electrospinning is an advantageous fabrication technique for tissue contacting devices due to high porosity, flexibility, and ECM like microstructure. Presented in this study is a thermoplastic polyurethane with tunable chemistry which can be crosslinked via thiol-ene click chemistry post fabrication into the desired geometry via electrospinning. The ability to crosslink these materials post-fabrication enables mechanical properties not usually achievable by thermoplastic electrospun materials. Mechanical, morphological, and shape memory properties are presented. These properties are important in determining appropriate potential biomedical applications for this material. Potential applications include self-constricting tubes for improved support and protection in tendon and anastomosis surgeries, a protective wrap for use in bone defect repair, or as a self-closing bandage for wound healing.

METHODS

Fabrication of Crosslinkable Thermoplastic Polyurethane. A thermoplastic polyurethane was synthesized as described previously by Hearon et al.[1] with changes described hereafter. This polymer system includes pendant vinyl groups by incorporating trimethylolpropane allyl ether (TMPAE) into the backbone with allows for tiol-ene crosslinking post fabrication into the desired geometry. Alterations to the polymer backbone were made as shown in Table 1 to tune material properties.

Table 1: Polymer backbone alterations to tune material properties.

Target Alteration	Isocyanate	Diol	AA Concentration

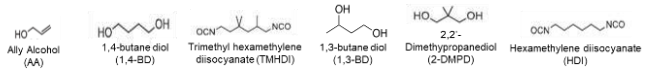
	HDI		



Electrospinning and Crosslinking Process. Electrospinning solutions were prepared by mixing thermoplastic and solvent on a weight basis (g/g) in a glass vial. This solution was then agitated on an orbital shaker until completely dissolved. For crosslinked samples, the desired weight of crosslinker (PETMP) and photoinitiator (DMPA) was then added, vortexed, and allowed to mix of the orbital shaker for 30-40 minutes. The desired volume was then drawn into a syringe which was loaded on the syringe pump and connected to PTFE tubing running into the electrospinning box. The positive end was connected to the dispensing needle via an alligator clip and the ground wire was wound around the rotating collection mandrel. The gap distance was measured as the distance between the end of the dispensing needle and the top of the rotating mandrel. The syringe pump was run until the solution was starting to come out of the dispensing needle and the voltage source was

then started. Samples were allowed to spin for 30 minutes. UV crosslinking of the electrospun mats was performed using a UV floodlight box (Integrated Dispensing Solutions – Intelli Ray 400). Samples were treated for 30 minutes per side at 50% intensity.

Fiber Morphology Characterization. Scanning Electron Microscope (SEM) images of the mats were collected using a JEOL JSM-7500F at magnifications of 100 and 500X for each sample. Prior to imaging, samples where mounted on carbon tape and sputter-coated using an Au target. Fiber diameter was determined using ImageJ software plugin Diameter J.

Mechanical Testing. Tensile testing for both bulk film and electrospun mat samples was performed on an Instron 5965. Samples were tested with a gauge length of 20mm, width of 7.6 mm, and thicknesses between 0.5 and 1 mm. Deformation was applied at a rate of 10 mm/min until sample failure.

Shape Memory Testing. Shape recovery testing was performed on a TA Instruments Q800 Dynamic Mechanical Analyzer (DMA). Samples were heated to 80 °C (well above their Tg's) and elongated to 100% strain. The strain was then locked and the samples were cooled to -10 °C to lock in the elongated shape. The DMA control arm was then allowed to float and the samples were heated to 50 °C and recovery stain was measured.

RESULTS

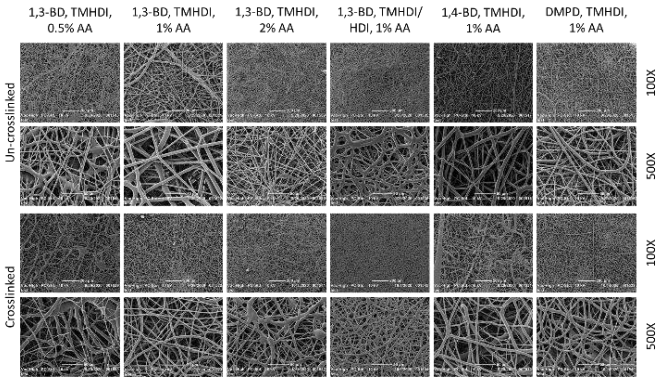


Figure 1: SEM images of electrospun polyurethane. Each column indicates one of each of the formulations presented in Table 1.

With exception of the formulation that used only HDI, all polymer compositions were able to be successfully electrospun into microfibers ranging from 2-20 µm as shown in Figure 1. This includes both un-crosslinked samples, which lacked the addition of crosslinker or photoinitiator, and crosslinked samples which were UV treated.

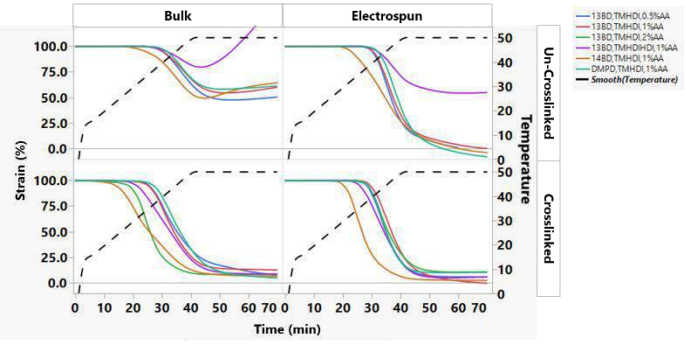

Figure 2: Shape recovery profile for bulk and electrospun samples

Shape recovery data is presented in Figure 2 and demonstrates the shape recovery properties of these materials. When un-crosslinked, bulk samples only achieved about 50% of the applied strain while crosslinked samples achieved 90%+. For electrospun samples, both un-crosslinked and crosslinked samples achieved 90%+ shape recovery with one exception (un-crosslinked 1,3-BD, TMHDI/HDI, 1%AA).

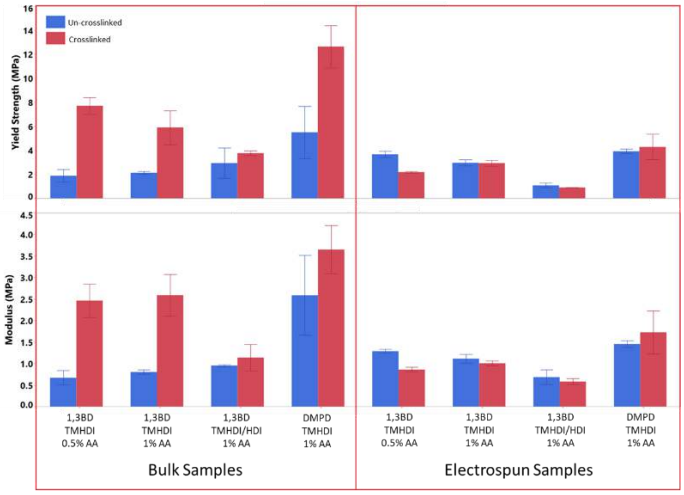

Figure 3: Modulus and yield strength of bulk and electrospun samples when crosslinked and un-crosslinked.

Mechanical testing of both bulk and electrospun materials is presented in Figure 3. Most bulk samples showed marked increases in modulus and yield strength when crosslinked. This indicates the success of the crosslinking process for these samples. The un-crosslinked Electrospun samples had comparable mechanical properties to their un-crosslinked bulk counterparts which is surprising given the inherent porosity and random fiber orientation of the materials. However, the electrospun samples did not show improvement of mechanical properties when crosslinked, indicating either a failure of the crosslinking process for these samples or an inability of this crosslinking to translate into tensile toughness.

DISCUSSION

This study demonstrated the ability to electrospin a shape memory polyurethane with good shape recovery properties and mechanical properties appropriate for biomedical applications. The fibrous nature of this electrospun material makes it an ideal candidate for tissue contacting implants and the shape memory properties enable innovative applications. One such application could be for anastomosis repair applications in which an electrospun SMP sleeve could be used to cover and protect the anastomosis site, helping to prevent dehiscence and leakage which can occur during these procedures [2].

MATERNAL BONE ADAPTATION TO MECHANICAL LOADING DURING PREGNANCY, LACTATION, AND POST-WEANING RECOVERY

Yihan Li[1], Chantal M. J. de Bakker[1], Hongbo Zhao[1], Ashutosh Parajuli[2], Wei-Ju Tseng[1], Shaopeng Pei[1,2], Tan Meng[1], Rebecca Chung[1], Liyun Wang[2], and X. Sherry Liu[1]*

INTRODUCTION

Although the maternal skeleton undergoes dramatic bone loss during pregnancy and lactation, several innate compensatory mechanisms are initiated to maintain the skeletal mechanical integrity [1,2]. Our previous studies suggest that reproduction-induced adaptations in cortical bone structure compensate for trabecular bone loss to maintain whole-bone mechanics [3]. Moreover, the extent of post-weaning bone recovery highly depends on bone's load-bearing capacity [4]. The above findings lead to our next question: does maternal bone also have a greater response to external loading? Recently, it was found that lactation-induced perilacunar/canalicular remodeling (PLR) may alter the osteocyte microenvironment [5,6], thus affecting skeletal mechanosensitivity. The objective of this study is to investigate the effects of pregnancy, lactation and weaning on maternal bone's mechano-responsiveness and osteocyte microenvironment in a rat model. We hypothesized that alterations in the osteocyte microenvironment through PLR activities during lactation would result in greater responsiveness to external loading, thereby indicating a beneficial effect of weight-bearing exercise on bone health postpartum.

METHODS

All animal experiments were approved by IACUC. *In vivo dynamic loading:* Female SD rats (n=8/group; age 26 weeks when loading started) were assigned to Virgin, Pregnancy (loading from day 7 of pregnancy), Lactation (loading from day 1 of lactation), and Post-weaning (loading from day 1 of post-weaning) groups, and subjected to a 2-week dynamic, compressive loading protocol [7]. A peak load of 45N, corresponding to ~1500 με at the tibial midshaft medial surface as determined by strain gauges, was applied to the left tibia at 2 Hz, at 5 min/session for 2 weeks (5 days/week), while the right tibia remained unloaded. *In vivo μCT imaging:* μCT scans of proximal tibia and tibial midshaft were performed on both tibiae before (week 0) and two weeks after loading (week 2) using VivaCT 40 (Scanco, voxel size 10.5μm). Percent changes between week 0 and week 2 for non-loaded and loaded tibiae were calculated, and the corresponding loading-induced differences in cortical microstructural percent changes between loaded *vs.* non-loaded tibiae were further derived. All rats were sacrificed at the age of 28 weeks after μCT scans. *Dynamic histomorphometry:* All rats were injected with calcein green and alizarin red on day 4 and day 13 of loading. Dynamic histomorphometry analyses were performed to evaluate double-labeled bone formation, and the fold change of bone formation parameters between loaded *vs.* non-loaded tibiae for each rat were calculated to determine the loading-induced bone formation. *Histology and IHC:* Paraffin-embedded non-loaded tibial cortex (n=6/group) was immunostained for MMP13 and CtsK to evaluate PLR enzyme expression. Ploton silver staining were performed on the tibial cortex to assess the lacunar-canalicular network. *Statistics:* Student's paired t-test was used to compare parameters between the loaded and non-loaded limbs in the same animal, while one-way ANOVA with Bonferroni corrections was used to compare loading responses and osteocyte-related parameters in rats with different reproductive status. Significant differences were considered when $p<0.05$.

RESULTS

Reproduction and lactation induced dramatic alterations in trabecular microstructure at the proximal tibia, but minimal changes in cortical bone structure at the tibial midshaft. At the proximal tibia, loading significantly reduced lactation-induced loss in trabecular bone volume fraction and thickness (BV/TV and Tb.Th) in Lactation rats, while minimal loading responses were found in other groups (Fig

1AB). At the tibial midshaft, loading led to significantly increased cortical bone area (Ct.Area) and polar moment of inertia (pMOI) compared to unloaded tibiae in all rats (Fig 1CD). However, loading responses in Ct.Area or pMOI did not differ among groups (Fig 1EF). Dynamic histomorphometry suggested that the 2-week dynamic loading led to significant increase in, and bone formation rate (BFR/BS) in the loaded *vs.* non-loaded tibia in all groups (Fig 2AB). Intriguingly, a higher loading-induced fold change in BFR/BS in Lactation rats was detected when compared to other groups (Fig 2C). Similar results were found in mineralizing surface and mineral apposition rate (data not shown).

Histological assessment at the tibial cortex indicated that Lactation rats had greater lacunar perimeter than all other groups (Fig 2AB) while no difference was detected in number and density of canalicular network (data not shown). Moreover, the investigations of PLR enzymatic expression revealed that Lactation rats had 37% and 40% greater percentage of MMP13+ osteocytes than Virgin and Post-weaning rats, respectively (Fig 2CD). Similarly, the percentage osteocytes that stained positive for CtsK was 50% higher in Lactation than Post-weaning rats (Fig 2EF).

DISCUSSION

While weight-bearing exercise during pregnancy and postpartum improve women's physical and psychological well-being, its effect on bone health remains unclear. By applying a dynamic loading protocol in a rat model, we demonstrated that loading reduced lactation-induced trabecular bone loss and improved cortical bone structure regardless of reproductive status, indicating a beneficial effect of weight-bearing exercise on maternal bone health postpartum. Moreover, loading led to greater periosteal bone formation in lactating rats as compared to rats at other reproductive stages or age-matched virgins, indicating a greater mechano-responsiveness of maternal bone during lactation. Consistent with previous studies in mice [5,6], we further confirmed that lactation led to increased lacunar size and osteocytic PLR enzyme activities in rats, and these transient changes were reverted post-weaning. According to the LCS fluid flow model initiated by Weinbaum *et al.* [8] and developed by Wang et al. [7,9], the enlarged lacunae and canaliculi alone could contribute to the pericellular fluid space, leading to marked increase of fluid drag force on osteocyte body and cell processes under a high frequency (4Hz) loading and an enhanced solute transport through LCS. Moreover, degradation of the PCM fibers, which most possibly would occur in matrix lysis, along with high frequency loading, would synergistically promote flow-mediated mechanical stimulations on osteocytes and their cell processes and enhance solute transport in LCS. Taken together, these factors may partially explain the elevated mechano-responsiveness of female skeleton during lactation observed in the current study.

This study was the first investigation on the effects of dynamic loading on bone health during pregnancy, lactation, and post-weaning recovery in an *in vivo* animal model. Our study provides important insight into the relationship between reproduction and lactation-induced skeletal changes and external mechanical loading, emphasizing the importance of weight-bearing exercise on maternal bone health postpartum.

INTRODUCTION

Male bighorn sheep (Ovis canadensis) engage in repeated ramming bouts and do not exhibit major signs of traumatic brain injury. Previous work has shown that the keratin-rich horn may play an important role in mitigating brain injury through energy dissipating horn-tip oscillations [1]. Specifically, removal of the distal half of the horn increased brain cavity accelerations up to 51% in a dynamic finite element model of ramming [1]. However, the extent to which specific horn shapes may reduce accelerations post-impact remains unclear. The goal of this work was to investigate different tapered horn shapes in reducing post-impact accelerations of a simplified impact model. We hypothesized that the specific tapered horn shape found in male bighorn sheep horns [2] would reduce post-impact payload accelerations when compared to a simplified tapered circular shape or a shape rotated by 90°.

METHODS

A representative male bighorn sheep skull and horns were previously scanned using computed tomography, segmented, and smoothed to produce a skull (bone) and horns (keratin) for the work by Drake et al. [1]. The left horn was imported into computer aided design software (Fusion 360, Autodesk Inc.). A loft defined by the mid center spline and seven cross-sections was created that closely approximated the horn shape and was then attached to a half sphere representing the sheep's skull. Two additional horn shapes of the same approximate volume were created by modifying the distal half of the horn – one with circular cross sections and one with cross sections rotated by 90° counterclockwise (Figure 1).

Each geometric model was imported into finite element software (Abaqus, Dassault Systèmes Inc.) for a 0.05 second dynamic analysis of a symmetric impact with an explicit solver (Figure 2). This model was based on the work of Drake et al., which details a symmetric finite element model of bighorn sheep ramming. Horn and half-sphere were assigned linear elastic keratin material properties E = 2 GPa, ν = 0.3, and ρ = 1.3 g/cm^3 [1]. An initial velocity of 4.7 m/s was applied to the horn and half sphere [1] in the z-direction, and all other degrees of freedom of the symmetric surface were restricted (Figure 2). Model outputs include half sphere center point translational z-acceleration 5 ms head injury criterion (HIC_5) [3], mean horn tip velocity for top 1% of nodes, mean horn von Mises stress for top 1% of elements, and kinetic energy to total energy fraction.

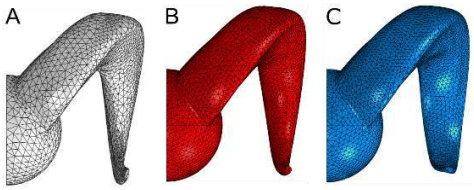

Figure 1. Horn variations A) baseline, B) circular, and C) rotated.

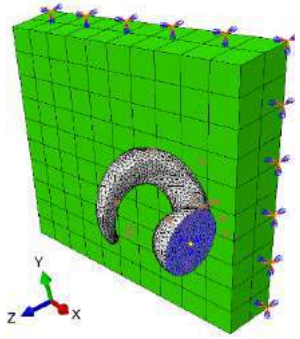

Figure 2. Symmetric finite element model of the baseline shape.

RESULTS

The baseline model exhibited the lowest HIC_5 when compared to the circular model (41% increase) or rotated model (38% increase) (Table 1). This result is mainly attributed to the consistent reduction in after-impact acceleration over the 0.05 sec simulation (Figure 3). The baseline model also exhibited a greater top 1% mean velocity, though this result was less pronounced (Table 1). There were no clear differences between top 1% von Mises stress or kinetic energy to total energy fractions.

Table 1: Simulation results.

Model	HIC_5 [s]	Top 1% Velocity [m/s]	Top 1% VM Stress [MPa]	KE:TE Fraction [-]
Baseline	21,200	28.9	27.4	0.919
Circular	29,900	26.8	26.3	0.903
Rotated	29,300	25.8	28.0	0.892

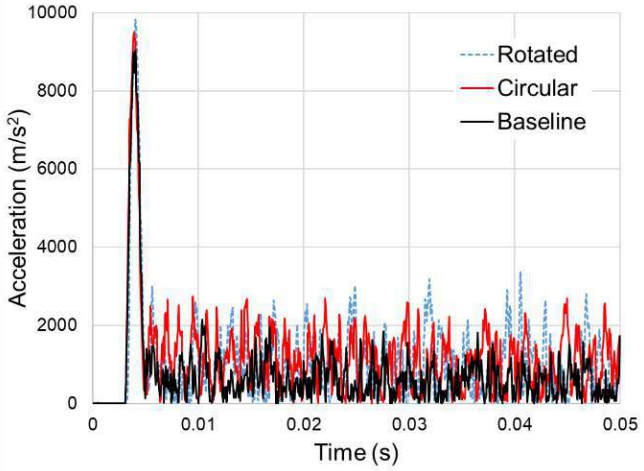

Figure 3. Model center point translational accelerations as a function of time. The center point represents the payload or brain cavity center.

Horn tip velocity vectors showed that the baseline model exhibited the greatest horn tip oscillations in the medial-lateral direction (perpendicular to the direction of impact), while the rotated model exhibited primarily anterior-posterior oscillations (the impact direction) (Figure 4). The circular model exhibited less of a preference in horn tip oscillation direction.

DISCUSSION

This study investigated the effect of bighorn sheep horn tip shape on the mechanics of a simplified impact model. Previous modeling work suggested that oscillations of the horn tip contribute to mitigating brain cavity accelerations during and after impact by directing kinetic energy away from the brain cavity [1]. The goal of this study was to determine the extent to which the cross-sectional shape may play a role in reducing brain cavity accelerations and thus mitigating traumatic brain injury. Such information could be useful in designing a wide range of devices or systems for applications that include automotive impacts, high-impulse athletic events, military applications, or other scenarios where energy dissipation is needed. This study also demonstrated an elastic energy dissipation technique, which could be reusable in comparison to other techniques such as material plasticity or damage.

Our results showed that the anatomically accurate horn model – with a medial-lateral bending preference due to the horn tip shape – exhibited lower center point (payload) accelerations when compared to a circular or rotated cross section. The unique tapered horn shape of adult male bighorn sheep is consistent between animals [2], suggesting that the medial-lateral horn tip oscillations observed after impact [1] (Figure 4) may be observed across animals.

This work showed that medial-lateral horn tip oscillations convert pre-impact kinetic energy into medial-lateral kinetic and strain energy, which has a reduced effect on center point accelerations due to symmetry. The circular and rotated models have less medial-lateral oscillation (Figure 4) and a lower horn tip velocity (Table 1), thus diminishing the mechanism that reduces center point acceleration. Additionally, the ability to reduce payload accelerations did not come at a cost of increased horn von Mises stress (Table 1), thus demonstrating a viable elastic energy dissipation technique.

Previous work has shown that a tapered spiral cylinder exhibits beneficial shockwave reducing properties in comparison to simpler shapes such as a non-tapered spiral cylinder [4]. Comprehensively, our results suggest that carefully designed non-cylindrical tapered structures may provide a further benefit for impact or shockwave applications by employing directed structural oscillations. Future work may explore additional horn shape variations and loading conditions to further explore the properties of these structures and potential applications to human safety systems.

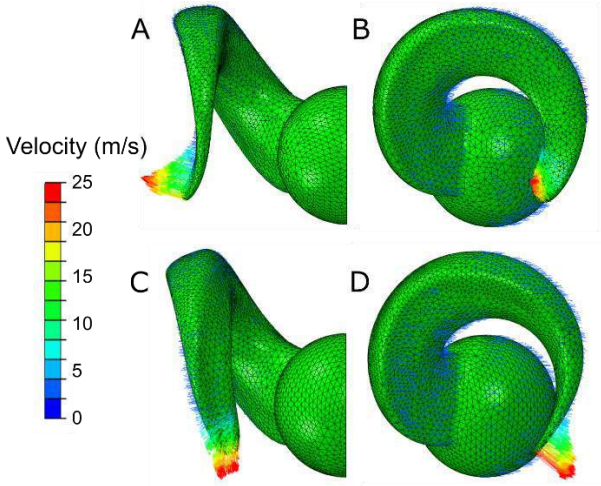

Figure 4. Horn tip velocity vectors after impact, highlighting the differences in oscillation directions between the baseline (A, B) and rotated (C, D) models.

CONCLUSIONS

This study revealed that an anatomically accurate bighorn sheep horn geometry, with a bending preference in the medial-lateral direction, exhibited lower payload acceleration, greater horn tip velocity, and similar material stress in comparison to models with circular or rotated geometries. Thus, horn-like structures could be specifically designed for optimal energy dissipation during and after high-rate impacts through directional oscillations. These findings could help influence the design of structures to prevent injury or damage because of such impacts.

SOLUTION COMPOSITION AFFECTS DISSOLUTION-RECRYSTALLIZATION MECHANISMS OF BIOMIMETIC APATITES

University of Connecticut
Farmington, Connecticut, US

INTRODUCTION

Aging affects bone health and blood chemistry but it is unknown how these are related. As we age, kidney function diminishes, which decreases blood bicarbonate and pH leading to aging-induced metabolic acidosis[1]. In addition, other blood components, such as ionic strength and phosphate levels, change with aging-induced metabolic acidosis[2]. To aid the body in reaching homeostasis, bone mineral dissolution occurs to attempt to increase bicarbonate and pH levels[2]. While it is generally known that acidic pH's can increase bone mineral dissolution[3], it is unknown how these other factors affect bone mineral dissolution. Therefore, the objective of this study is to identify the mechanisms of pH, ionic strength, and phosphate content on the dissolution of biomimetic bone mineral.

METHODS

Biomimetic carbonated apatite (CAP) with either 2, 6, or 12 wt% carbonate was synthesized by an aqueous precipitation. These were exposed to various solutions for 72 hours in order to determine the effects of pH, ionic strength, and phosphate (PO_4^{3-}) content. To evaluate the effect of initial solution pH (pH_i), 6 wt% CAP was exposed to either 0.1M potassium chloride (KCl), water, or 1x phosphate-buffered saline (PBS) all at pH_i 5.5, 7.4, and 8.0. To isolate ionic strength effects, water and 0.1M KCl at pH_i 5.5 was used for 2, 6, and 12 wt% CAP. For PO_4^{3-} content, 0.1M KCl and 0.7x PBS both at pH_i 3.0 was used for 6% CAP in order to have identical ionic strength, pH, and buffering capacity while varying PO_4^{3-} content. After exposure, the powders were weighed, filtered, and dried in a 60°C oven overnight. Then, the powders were analyzed by Raman spectroscopy to identify the change in carbonate to phosphate ratio (ΔCO3/PO4) and X-ray Diffraction (XRD) to analyze the lattice and microstructure. The change in pH (ΔpH) of each solution was measured at 72 hours to obtain buffering information. In addition, calcium (Ca), sodium (Na), phosphorus (P), and potassium (K) levels in the solutions were measured by Inductively Coupled Plasma - Optical Emission Spectroscopy (ICPOES).

RESULTS

pH Effects: In all cases, the ΔpH positively increased as pH_i decreased. Mass loss occurred for all conditions and was not well correlated to pH_i. Generally, PBS and KCl showed a greater loss of carbonate (-ΔCO3/PO4) with decreasing pH_i (Fig. 1). Conversely, water gained carbonate (+ΔCO3/PO4) irrespective of pH_i (Fig. 1). For CAP in PBS, the c-axis decreased and a-axis generally increased as pH_i decreased, however, no trend in pH was observed for the lattice of CAP in KCl and water. Ca in the solution increased for all solutions after exposure with no clear correlation to pH_i. P was increased in water and KCl but decreased in PBS with no relationship to pH_i. Na generally increased as pH_i decreased in water and KCl while PBS exhibited no correlation to pH_i.

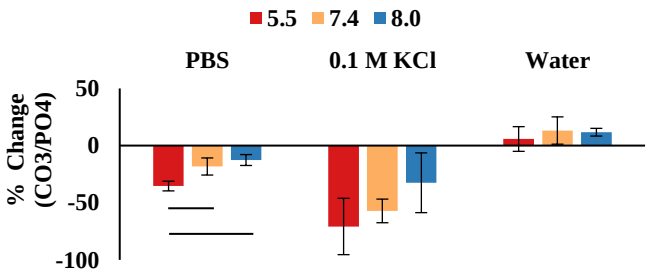

Figure 1: Carbonate decreased in CAP as pH_i decreased after exposure to PBS and KCl.

Ionic Strength Effects: As ionic strength increased, the ΔpH significantly increased while mass loss significantly decreased. ΔCO3/PO4 significantly decreased as ionic strength increased for 2 and 12 wt% CAP with 6% CAP showing similar trends (Fig. 2). The c-axis increased as ionic strength increased for all CAP while there was no trend in the a-axis for ionic strength. Crystallite size increased irrespective to ionic strength as well. Ca, P, and Na in solution decreased as ionic strength increased, while K generally did not change.

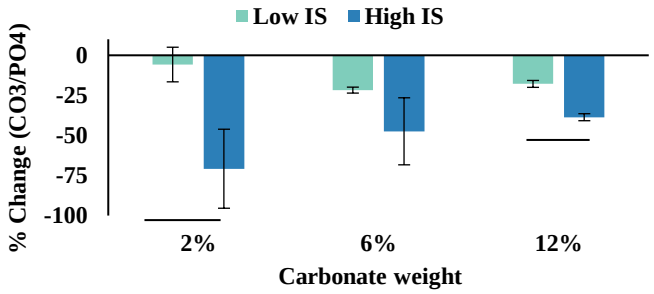

Figure 2: Carbonate decreased in CAP as ionic strength (IS) increased.

PO_4^{3-} Effects: The change in pH and mass loss increased and ΔCO3/PO4 decreased significantly as PO_4^{3-} in the solution decreased (Fig. 3). Ca, K, and Na increased after exposure irrespective of initial PO_4^{3-} content. The c- and a-axis generally do not change with no PO_4^{3-} content in the solution while the c- and a-axis increase with PO_4^{3-} content. Crystallite size increased for both solutions with no association with PO_4^{3-} content. In addition, the amount of P decreased in the solution as initial PO_4^{3-} content increased while P content increased without initial PO4 content.

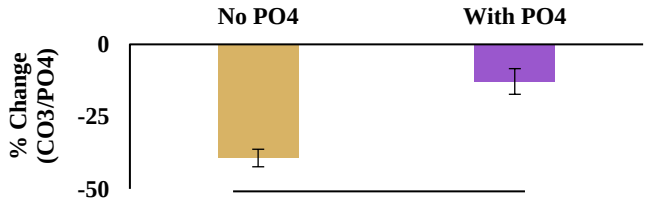

Figure 3: Less carbonate is lost in the presence of PO_4^{3-} in solution.

DISCUSSION

pH Effects: Although decreasing pH is generally believed to increase mineral dissolution, we found that pH effects were solution specific. pH_i was negatively correlated to ΔpH in all solutions indicating that decreased pH promoted the release of buffering ions to raise the pH. The decrease in ΔCO3/PO4 as pH_i decreases for PBS and KCl suggest that low pH's may preferentially release carbonate from CAP for buffering. This is supported by the decrease in c-axis and increase in a-axis for PBS, which are associated with carbonate removal from the lattice[4]. The reduced P in PBS after exposure implies that CAP in PBS experiences a dissolution/recrystallization event where carbonate is released at low pH and then recrystallization of a less carbonated apatite occurs. The inconsistent change in CAP lattice in KCl may indicate the presence of other substitutions, such as K^+ and Cl^-, into the lattice while carbonate is lost during recrystallization[5]. These ionic substitution changes could explain the lack of correlation between pH_i and mass loss as the crystal density may be modified with recrystallization. For CAP in water, the increased ΔCO3/PO4, inconsistent lattice spacing, and increased solution P after exposure suggests the low pH_i in water preferentially releases PO_4^{3-} from CAP or the CAP surface is adsorbing protons due to a lack of proton-accepting ions in solution[6]. Overall, we found that the effects of solution pH_i were highly solution dependent making it necessary to understand the role of other solution factors.

Ionic Strength Effects: Decreased ΔCO3/PO4 with increasing ionic strength suggests that the presence of K^+ and Cl^- increased carbonate removal from CAP into the solution. This is supported by a larger increase in ΔpH in the KCl compared to water. However, both the c- and a-axis increases, which is not reflective of carbonate removal from the apatite lattice[4]. This may again be caused by the substitution of Cl^- for OH^- in CAP. The additional release of OH^- into the solution could further explain the larger ΔpH in KCl. Additionally, Cl^- substitution may explain the smaller mass loss since chlorapatite is denser than carbonated apatite[7]. However, the amount of Cl^- substitutions may be insufficient to induce a phase transition that can be clearly seen on XRD. In conclusion, the increased ionic strength significantly modified the dissolution behavior of CAP; however, this may be specific to the presence of certain ions.

PO_4^{3-} Effects: The presence of PO_4^{3-} significantly decreased ΔpH, mass loss, and increased ΔCO3/PO4 compared to an absence of PO_4^{3-}. This suggests that the presence of PO_4^{3-} in solution is protective against dissolution, reducing mass loss and carbonate loss. To compensate for the carbonate loss, P is up taken for apatite recrystallization, as shown by decreased solution P after exposure. In the process, H^+ may be sequestered to form an HPO4-bearing apatite that may change the lattice spacing as seen in XRD[5,6,8]. Alternatively, in the absence of PO_4^{3-}, the increased ΔpH, mass loss, P in solution and decreased ΔCO3/PO4 in CAP after exposure implies that both carbonate and PO_4^{3-} is being released from CAP into the solution, resulting in heightened dissolution. In general, the presence of PO_4^{3-} may shield CAP from further dissolution.

To fully elucidate the effects of solution type on CAP dissolution, it will be necessary to examine larger variations of ionic strength and phosphate content in solution, ideally with non-substituting ions and controlling for buffer capacity.

This study challenges the notion that pH is a main contributor of apatite dissolution, especially in metabolic acidosis conditions. Acidic pH's generally increase the dissolution of bone mineral. However, in these tested conditions, pH is likely not the sole component affecting apatite dissolution and other factors may take precedence, such as ionic strength and ion substitutions like K^+, Cl^-, and PO_4^{3-}. We found that the presence of PO_4^{3-} was protective against dissolution leading to lower carbonate and mass loss. Conversely, increased ionic strength and the presence of K^+ and Cl^- appear to increase carbonate loss possibly due to substitutions of those ions into the apatite structure. These results will be important in understanding bone dissolution associated with the complex changes in blood chemistry, such as ionic strength and ionic content, as seen in aging-induced metabolic acidosis.

INTRODUCTION

Growth and development studies have defined a critical role for Hedgehog (Hh) signaling in the formation of zonal tendon-to-bone insertions (i.e., entheses). Zonal enthesis formation involves anchoring collagen fibers, synthesizing proteoglycan-rich fibrocartilage, and mineralizing part of this fibrocartilage. Specifically, Hh signaling promotes mineralized fibrocartilage production, leading to the establishment of distinct tissue zones [1]. Despite this important developmental role, it is not known whether the Hh pathway plays a similar function in adult tendon-to-bone repair, representing a significant gap in knowledge. Unfortunately, traditional tendon-to-bone repair surgeries do not recreate a zonal insertion. However, ligament injuries reconstructed with a tendon graft passed through a bone tunnel can result in zonal insertions [2,3]. In this setting, amplifying α-smooth muscle actin (αSMA)-expressing bone marrow stromal cells (bMSCs) contribute to tunnel integration by forming zonal fibrocartilaginous attachments [2]. Our central hypothesis is that the Hh pathway promotes tendon-to-bone integration in the adult, similar to growth and development. Using our established murine anterior cruciate ligament (ACL) reconstruction model, our objective is to modulate the Hh pathway genetically and pharmacologically in these αSMA-expressing cells to determine the effect of Hh signaling on tunnel integration in adult repair.

METHODS

All animals and procedures were approved by UPenn's IACUC. Experimental Design. ACL reconstructions (ACLR) were performed on 93 transgenic mice. *Genetic Hh Inhibition Study*. αSMACreERT2 mice [4] that target the amplifying progenitor pool that gives rise to zonal attachments [2] were crossed with mice containing loxP sites flanking a coding sequence of the central signal transducer of the Hh pathway Smoothened ($Smo^{flox/flox}$) [5] (Smo^{tm2Amc}/J) to yield SMACre;$Smo^{flox/flox}$ (SmoKO) experimental mice to decrease Hh signaling and $Smo^{flox/flox}$ control genotypes. Mice were sacrificed at 28 days post-surgery and assigned to cryohistology (n = 7/group) or biomechanics (n = 9/group). *Genetic Hh Activation Study*: αSMACreERT2 mice were crossed with constitutively active SmoM2 mice [6] ($Gt(ROSA)26Sor^{tm1(Smo/EYFP)Amc}$/J) to yield SMACre;SmoM2 (SmoCA) mice with increased Hh signaling and Cre-negative control genotypes. Mice were sacrificed at 28 days post-surgery and assigned to cryohistology (n = 5-6/group) or biomechanics (n = 5-7/group). Tamoxifen injections (80 mg/kg) were given on the day of surgery then every other day for a total of five injections to ablate Smo or constitutively activate Smo in αSMA-expressing cells. *Pharmacologic Hh Activation Study*: Mice received either Hh agonist (20mg/kg Hh-Ag1.5) or PBS vehicle control injections 5X per week. Mice were assigned to cryohistology (n = 6/group) at 7- or 28-days post-surgery and biomechanics (n = 7/group) at 28 days post-surgery. Demeclocycline and EdU were given 1 day before sacrifice to help define mineralized fibrocartilage (MFC) zones of attachments and label proliferating cells, respectively. ACL Reconstruction. The ACL was excised near the femoral insertion. The tibial and femoral tunnels were drilled with 27G needles. A tail tendon autograft was passed through the tunnels and anchored to outer cortices with stainless steel washers [2,3]. Mineralized Cryohistology. Knees were fixed in formalin, embedded, sectioned undecalcified with cryofilm, and imaged on the Zeiss Axio Scan.Z1 (Fig. 1B-D). Tunnel Pullout Test. Femurs were potted in PMMA and gripped such that the tunnel was parallel to the linear actuator. A suture was passed through the washer and loaded to failure (Fig. 2D). Image Quantification. MFC area/total length was measured to assess the extent of zonal integration (Fig. 2A) while EdU+ cells in expanding marrow were measured to assess amplification of the progenitor pool (Fig. 3A). Statistics. Experimental and control groups

were compared via Student's t-tests ($p < 0.05$). Data presented as Mean ± SD.

RESULTS

SmoKO, SmoCA, and Hh agonist-treated groups did not display any adverse systemic effects throughout the duration of the study. Hh Pathway Positively Regulated Tunnel Integration and Strength. When targeting the αSMA-expressing amplifying progenitor pool, SmoKO mice (53 ± 18μm^2/μm, n = 7) had a 23% decrease in MFC area in the bone tunnels compared to controls (70 ± 32 μm^2/μm, n = 7) at day 28 ($p = 0.2$). SmoCA mice had 36% greater MFC compared to controls at day 28 ($p = 0.07$) (Fig. 2B). Mice that received Hh agonist for four weeks had 35% more MFC at the tunnel interface compared to PBS controls ($p = 0.06$) (Fig. 2C). SmoKO mice (0.9 ± 0.3N, n = 9) possessed comparable pullout strengths with controls (0.8 ± 0.3N, n = 9) at day 28 ($p = 0.4$). SmoCA mice showed a 58% increase in pullout strength compared to controls at day 28 ($p = 0.2$) (Fig. 2E). Mice that received Hh agonist for four weeks had 48% greater pullout strength compared to PBS controls ($p = 0.02$) (Fig. 2F). Hh Pathway Activation Increased Proliferation of the bMSC Progenitor Pool. There were 50% greater EdU+ cells in the expanding bone marrow adjacent to the graft (Fig. 3A) in agonist treated mice after 7 days ($p = 0.1$) (Fig. 3B).

DISCUSSION

Following ACL reconstruction, bMSCs expand and infiltrate the periphery of the tendon graft, then assemble collagen and produce fibrocartilage to anchor the tendon graft to adjacent bone. In the present study, we demonstrated that Hh signaling positively regulated mineralized fibrocartilage formation (Fig. 2A-C) leading to greater pullout strength (Fig. 2D-F), which can partially be explained by increased proliferation of the progenitor pool (Fig. 3). While Hh signaling improves fracture repair via improved osteogenesis and angiogenesis [7], here we found through both genetic and pharmacologic means that Hh signaling improves fibrocartilage formation similar to enthesis development. Since we saw a similar effect with Hh agonist delivery as the SmoCA model where we targeted the αSMA-expressing progenitor pool that gives rise to attachments, it suggests that this cell population is the most important to target. However, it is still unclear if Hedgehog signaling is only important at the progenitor stage of this lineage or if it is also important for the differentiation of these cells into mineralized fibrochondrocytes. Our results indicate that the increased MFC formation may, at least partially, be due to increased proliferation of the bMSCs. A potential mechanism for this increase in MFC could be an increased expansion of the bMSC progenitor pool leading to a higher number of attachments along the tunnel length. However, another mechanism for increased MFC could be that Hh signaling is promoting fibrocartilaginous differentiation and maturation of cells in attachment sites at later stages of the repair process, leading to more MFC per attachment. In future studies, we will deliver the Hh agonist at different stages of the repair process to assess this important proliferation vs. differentiation question.

An improved understanding of the signaling pathways that regulate zonal insertion formation in the adult will be crucial to developing novel therapies to improve repair outcome. If the Hh pathway is harnessed therapeutically, it could result in a paradigm shift in the clinical treatment of these debilitating injuries, especially in more challenging scenarios that require reformation of the enthesis, such as rotator cuff repair.

INTRODUCTION

The mechanical behavior of skin is complex – it is heterogenous, anisotropic, viscoelastic, and non-linear. Furthermore, its properties are dependent on anatomic location, sex, age, health, and ethnicity, primarily due to differences in microstructural composition and organization of the collagen rich dermal layer [1]. To better understand how changes to the microstructure relate to functional changes in the tissue, we submit that a multi-scale perspective of skin is required, as local microstructural changes impact global tissue function. The ability to simultaneously observe both macro-scale tissue deformation and microscale fiber-level restructuring, however, has been technologically challenging until recently [2]. Now that such data exist, we are interested in using multi-scale mechanical models to help interpret and understand the rich mechanical behavior observed in skin. Ultimately, we envision that these models will be useful for understanding and improving skin health in a variety of scenarios, such as aging, wound healing, disease, long-term interactions with wearable technologies, *etc*.

METHODS

Experiments: Dog-bone shape murine skin was gripped in an ADMET bioreactor mounted on a multiphoton microscope (MPM). These skin samples were preconditioned and then stretched at a rate of 0.2 mm/min to 4 mm of displacement while being imaged. At each mm of displacement, MPM image stacks of the collagen microstructure were acquired in the center of the gauge region while the loading was paused. Quantification of tissue kinematics and changes in microscale volume and directional variance (DV) were also made [3].

Simulation: To-scale image-based multiscale models (MSMs) were created based on the geometry of the sample prior to tensile loading akin to previous work [4]. These MSMs link the macroscopic domain of the model to fiber networks representative of the collagen microstructure using volume averaging theory [5]. A FE mesh of 105 linear hexahedral FEs was then generated (one FE through the thickness). At the microscale, the volume fraction of fibers was set to match experimental values (~25%) for three different network cases: nearly aligned (DV = 0.15), experimentally matching (DV = 0.55), and nearly isotropic (DV = 0.90). For each case, five unique fiber network models were created with the same fiber network throughout the model. To represent the skin's non-collagenous matrix an additive stress from a compressible Neo-Hookean material (G = 3.0 kPa, ν = 0.1) was included. Parameters in the fiber-level constitutive equation were chosen to closely match the experimental loading curve in the DV = 0.55 case and were also applied to the nearly isotropic and nearly aligned cases.

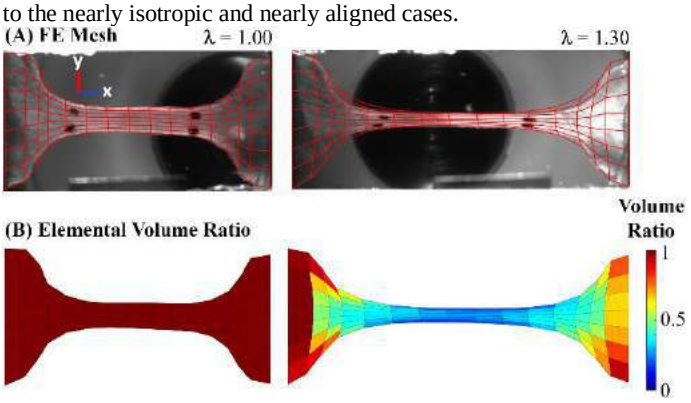

Fig. 1. Macroscale comparison of experiment and simulation. (A) The FE mesh, which initially closely corresponded to the sample geometry, reasonably followed sample stretch (DV = 0.55 model depicted). (B) FE volume decreased substantially with stretch, particularly within the gauge region of the model.

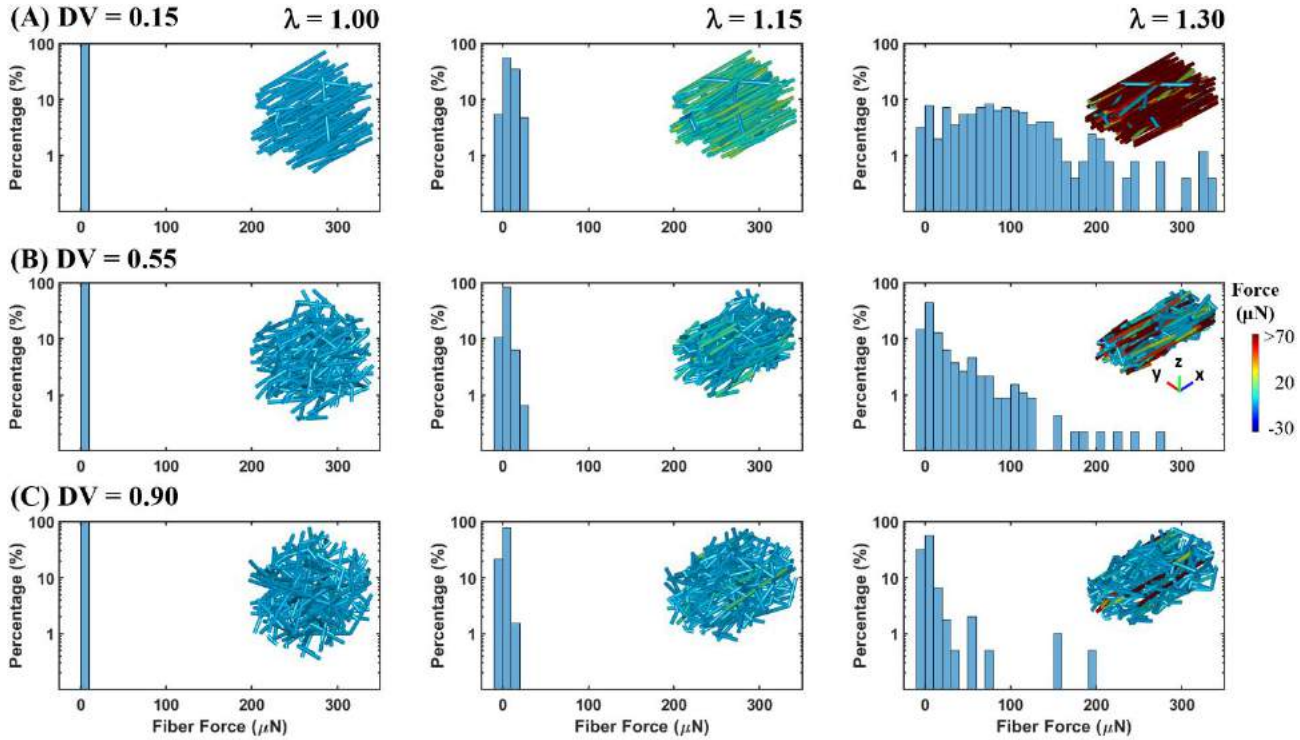

Fig 2. Representative fiber networks from the central element of the gauge region for each DV case. Fiber color corresponds to fiber force. The distribution of force within the network is also indicated in the histograms. In the initial state, λ = 1.0, the forces within each fiber are zero. As stretching progresses, the arrangement and loading of fibers changes to accommodate macroscopic tissue loading.

RESULTS

Macroscopically, the models deformed and decreased in volume similarly to the sample, with the DV = 0.55 case overlapping closest (Fig. 1). Microscopically, a comparison between networks in the central element with MPM volumes indicates that each of the three fiber network models was capable of reproducing the large decrease in skin volume that accompanied stretch observed experimentally (Fig. 3A). However, the network models that were less (DV = 0.90) or more aligned (DV = 0.15) than experimental values did not match changes in DV with stretch ratio as well (Fig. 3B).

An examination of fiber network kinematics in the central part of the gauge region (Fig. 2) highlights the complex restructuring associated with each type of network. Nearly aligned (DV = 0.15) networks remained so and experienced very high forces in comparison to moderately aligned and nearly isotropic cases. In the DV = 0.55 and DV = 0.90 cases, more fibers are able to rotate to accommodate stretch before picking up load, and their volume changes are more substantial, particularly in the directions orthogonal to the direction of tissue stretch. This volume decrease was greatest in the DV = 0.55 case.

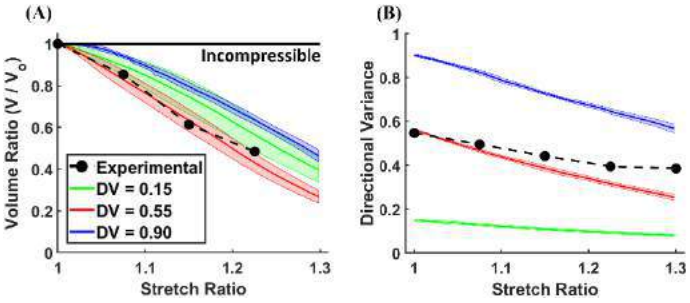

Fig. 3. Comparison of model simulation with experiment. (A) Models including fiber networks decreased in volume with stretch at the MPM imaging and central element location. (B) DV decreased with stretch in the experiment and in all three network models as a function of network capacity for fiber realignment.

DISCUSSION

Our work provides an image-based comparison of the macro- and microscale mechanics of mouse skin using experimental and computational approaches. Our results demonstrate that MSMs consisting of interconnected fiber networks can capture the complex kinematic changes displayed experimentally, such as the large decrease in tissue volume observed under uniaxial tension. Further, the fiber networks presented an increase in fiber level alignment and varied fiber-level force responses due to differences in reorganizational patterns. Future work will investigate how these behaviors change when fiber-level damage is incorporated in addition to analyzing the microstructural changes responsible for the altered mechanics of aged skin.

NUMERICALLY MODELLING SKIN-PPE INTERACTION TO REDUCE INJURY IN HEALTHCARE WORKERS DURING THE COVID-19 PANDEMIC

R. D. Jobanputra, S. Royyuru, J. Hayes, M. A. Masen

Department of Mechanical Engineering
Imperial College London
United Kingdom

INTRODUCTION

Due to the COVID-19 pandemic, medical staff wear personal protective equipment (PPE) for much longer than recommended. The extended duration of use has resulted in a range of skin issues including irritation and injuries such as urticaria, skin tears and pressure injuries, ranging from isolated indentation marks at the locations of contact, to deep tissue level bruising across a larger area (Fig. 1). Such device related pressure injuries are caused by the prolonged shear stresses acting on the skin that result from wearing PPE. These shear stresses in the skin are increased when there is high friction in the skin-PPE interface. The occurrence of injury also correlates with heavy sweating and with the use of higher-grades, thus tighter fitting, PPE[1]. Preventing these injures in healthcare workers is critical, as researchers have also found a dermal pathway to COVID-19 infection.

Figure 1: Skin damage following excessive PPE-skin interaction. Source: www.instagram.com/covid_nurses

MATERIALS & METHOD

In this study we aim to reduce the subsurface stresses in the skin and thus reduce the risk of skin injury developing, by optimizing the interface between the PPE and skin. This information will help improve the design of PPE; for example, by modifying geometric and material parameters. A finite element model describing the contact between respirator masks and facial tissue was developed to calculate the stresses in the skin. As skin bruising and damage typically involves the rupturing of blood vessels in the dermis, this skin layer was the focus of the investigation. In line with observations from Oomens[2], we use the local maximum strain energy density (SED) in the dermis as the critical output parameter that is indicative of skin injury developing.

The seal or skin interface of a respirator masks are typically silicone rubbers or various foams of polypropylene, polyester or polyvinylchloride. To establish the ideal material, a parametric study was performed in which the geometric and interfacial properties of the mask against the skin were varied. Parameters altered include the stiffness and Poisson's ratio, the thickness of the material as well as the size. Finally, the adhesive friction coefficient at the PPE-skin interface was also varied to observe the effect on direct shear stresses on the strain energy density in the dermis.

RESULTS

A SED field developing in the skin as the result of contact with PPE is shown in Figure 2. Two areas of elevated SED can be observed in the upper dermis, just under the edge of the contact with the face mask. A larger central area of high strain energy density develops deeper in the skin. The results of the parametric study show that a significant reduction of the maximum strain energy density in the dermis can be achieved through varying the characteristics of the PPE-skin interaction.

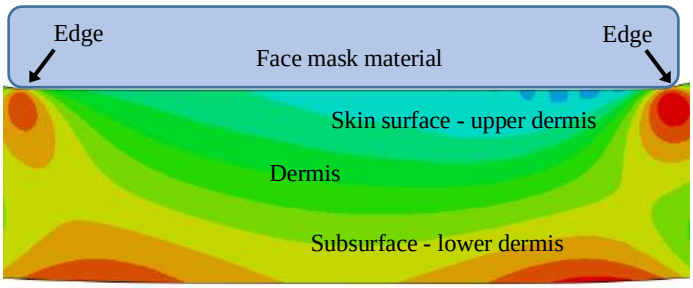

Figure 2: Dermal SED during PPE interaction. Red spots indicate peak SED.

In detail, the following effects were found:

- **Stiffness (E):** The use of softer materials decreases SED in the dermis and results in lower SED peaks in the upper dermis. In contrast, the use of stiffer materials results in the migration of the maximum SED to the upper dermis.
- **Friction (μ):** Reduced interfacial friction in the skin-PPE interface results in lower dermal SED (Fig. 3). Friction directly affects upper dermal SED, whilst having a negligible effect on the lower dermis.

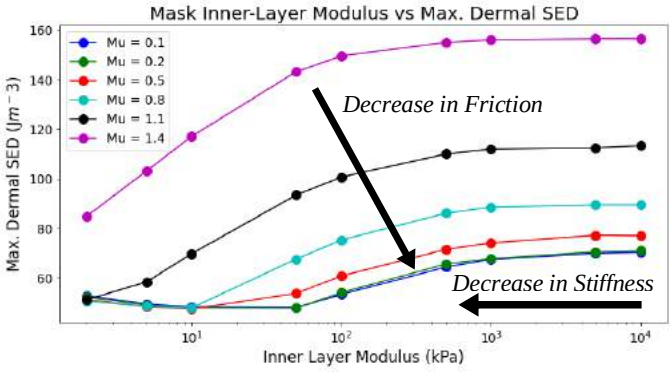

Figure 3: Effect of changing the stiffness and interfacial frictional coefficient of the mask's inner layer on the max. dermal SED.

- **Poisson's ratio (*ν*):** For materials with intermediate levels of stiffness (0.01-1MPa), a lower *ν* results in a significant reduction in maximum SED in the dermis. For soft materials, a lower *ν* results in a lower average SED and a migration SED from the upper dermis to the lower dermis.
- **Thickness (t):** For softer materials, a thicker mask material slightly reduces the average SED in the skin.
- **Size of the contact (S):** By changing the radius of curvature (r) of the edge of the mask, the size of the contact between skin and PPE was altered. Larger sizes resulted in lower dermal SED. However, the effects of changing contact area along with modulus were highly non-linear.

DISCUSSION

In this investigation, dermal shear and deviatoric stresses were found to have similar trends to dermal SED. The locations of the two isolated upper dermal SED peaks and the larger lower dermal central SED peak could respectively represent the indentation and deep tissue bruising marks seen amongst healthcare workers. Soft materials are often used in the interface with skin to reduce the discomfort caused by elevated pressures. In this investigation, reducing the stiffness of the material indeed resulted in a reduction of both the average and maximum SED. However, and possibly counter-intuitively, the use of rubber-like materials may actually result in an increase of the SED in the dermis due to the combination of an intermediate stiffness, high incompressibility (i.e. *ν* approaches 0.5), and high friction against skin that rubber materials show. In addition, mask designs that combine a large interface with skin with the use of soft materials show elevated SED as the increased area results in a reduction of the pressure but also a disproportionally large increase of the friction. Finally, dermal SED increases with increasing friction and this effect is particularly pronounced at elevated levels of friction. Therefore, decreasing the interfacial adhesive frictional coefficient should be a priority. This can be done by material selection or by directly modifying the skin-PPE interface, for instance using creams, lubricants or dressings[3].

The obtained results enable the specification of an ideal material to minimize skin injury. Such a material would have a sufficiently low stiffness (e.g. < 1 MPa) and a Poisson's ratio smaller than 0.45. In addition, the surface of the material should have a frictional coefficient against skin, not exceeding about 0.3. In addition, the material should be breathable and reduce the impact of perspiration, to prevent elevated friction[4]. All this may be achieved by employing foams made from PU, PP or PE. Foam materials are frequently used in a variety of skin-contact based applications, from headphones to prosthetic limbs. An outer skin or coating could be added to the material to benefit from the combination of good bulk material properties of the foam (low stiffness and low Poisson's ratio) and optimum interfacial properties, in terms of friction and moisture uptake.

Finally, it should be noted that the simulations presented in this work focus on the local effects of skin-PPE interaction and presume appropriate use and fit of PPE. The properties of facial soft tissue and craniofacial dimensions differ significantly, for instance between ethnicities and sexes and further work is needed to enable differentiation and further optimization of PPE design.

CONCLUSION

The use of close-fitting PPE is essential to prevent exposure to dispersed airborne particles such as the COVID-19 virus. However, the current pandemic led to many healthcare professionals wearing their PPE for prolonged times, causing skin irritation and injury. These injuries can be prevented by optimizing the design of the PPE with respect to its skin interaction characteristics. This should be done by ensuring the PPE interface is designed with a sufficiently low stiffnesses material that shows low friction. This will help reduce the risk of discomfort, skin injury and skin failure.

ON THE CHARACTERIZATION OF EMBRYONIC CURVATURES USING BEZIER CURVES

Ashok Ramasubramanian

Department of Mechanical Engineering

Schenectady, NY, USA

INTRODUCTION

We study morphogenesis (shape changes) that occur during early embryo development. The shape of the early embryo is characterized by a series of well-defined curves. We study here the dorsal curvature of the early chick embryo, which is characterized by two distinct bends – cervical and thoracic flexures (Fig.1). We study the formation and deepening of these flexures starting at about Hamburger and Hamilton (HH) Stage 14 and following the development 9 or 10 hours of incubation later, when the embryo reaches HH Stage 15 or 16 [1].

The deepening of flexures is a significant morphogenetic event in the early embryo and usually they are described imprecisely and using adjectives. Reference [1], for instance, describes cervical flexure as "a broad curve". We need a mathematically precise way to quantify flexures and precise criteria that can be used to distinguish between normal and abnormal flexures. Prior research indicates that correct flexure formation is important for the development of major organs, including the heart [2]. In that study, we quantified the cervical flexure by fitting a circle and here we expand on those results, by fitting a parametric curve to the entire dorsal wall. We use Bezier curves, which are widely used in computer graphics and to precisely define font shapes, to describe the shape of the dorsal wall in early embryonic development.

METHODS

The dorsal wall was "sampled" by selecting closely-spaced points using ImageJ. We used a total of 7 embryos (n=7). Measurements were taken at t=0 and at t=9h (n=2) or 10h (n=5). The cubic Bezier curve is a parametric curve where $t \in [0,1]$ is a parameter that varies from 0 (start of the curve) to 1 (end of the curve).

$$\mathbf{B}(t) = (1-t)^3\mathbf{a_0} + 3(1-t)^2 t\mathbf{a_1} + 3(1-t)t^2\mathbf{a_2} + t^3\boldsymbol{a_3} \qquad (1)$$

where $\mathbf{a_0}$, $\mathbf{a_1}$, $\mathbf{a_2}$, and $\mathbf{a_3}$ are the Bezier control points in 2D space. The line joining the Bezier control points is called the Bezier Polygon (Fig. 1). Unlike polynomial fits, wherein the coefficients do not convey insight about the shape of the curve, the Bezier control points, which are the curve parameters, are rich in meaning. To begin with, the first (last) control point is simply the first (last) point in the data set. The middle two control points ($\mathbf{a_1}$, $\mathbf{a_2}$) were fit using an optimization procedure in MATLAB. Also, the line joining the first two control points ($\mathbf{a_0}$, & $\mathbf{a_1}$) is tangent to the initial curve direction and the line joining the last two control points ($\mathbf{a_2}$, & $\mathbf{a_3}$) are tangent to the final curve direction. Note also that the movement of the middle control points from t=0 to t=9 or 10h quantifies the deepening of flexures and the movement of the first and last control points shows the increase in curve length (Fig. 1A,B). Bezier curves are also invariant under affine transformations.

The single cubic fit is unable to capture fully the sharpness of the thoracic flexure at the later time point (Fig. 1C). In this case, it is possible to fit a piecewise Bezier curve where the last control point of the first curve becomes the first control point of the second curve, i.e., $\mathbf{a_3} = \mathbf{b_0}$ (Fig. 1C). Also, we impose a constraint for geometric continuity, i.e., $\mathbf{a_2}$, $\mathbf{b_0}$, and $\mathbf{b_1}$ are colinear. The ability to break up larger curves into smaller ones, each with its own control polygon, is a significant advantage to using Bezier curves to characterize complex shapes.

RESULTS

The length of the curve, as measured by a numerical line integral using the selected data points, increases from 3.46±-0.27 mm at t=0 to 5.43±0.42 at t=9 or 10h. These values are similar to the Bezier curve lengths (data not shown).

Once a parametric curve is fit, we can measure the curvature using techniques from Differential Geometry. Fig. 1D shows the curvature for a single embryo (done in MATLAB and verified in Mathematica). Note that the composite curve fit is able to precisely capture the thoracic flexure, enabling us to calculate the curvature more accurately (Fig. 1C,D). For the composite fit, the curvature is very nearly straight for the first half of the curve (arrow in Fig. 1D), indicating that the cervical flexure portion can be approximated by a circle. For the embryo in Fig.1C, the radius for cervical flexure is about 2.5 mm ($\kappa \cong 0.4$, Fig. 1D), which is consistent with the results from our earlier study [2].

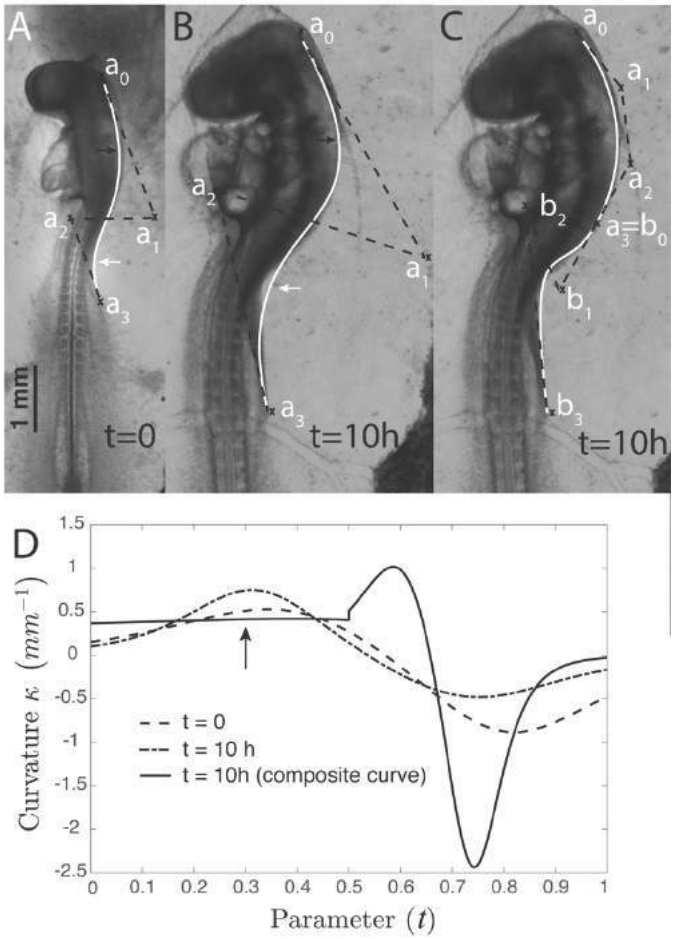

Figure 1: Chick embryo at stage HH 14 (A) and 10 hours later (B, C), along with Bezier curve fits and curvatures (D). Black and white arrows in A & B indicate cervical and thoracic flexures, respectively; note the deepening of flexures at t=10h (B). A—C show the Bezier curve (white) and Bezier polygon (black dashed). In (A) & (B), a_0, a_1, a_2, a_3 are the four control points (marked by "x") of the single cubic Bezier curve. The middle control points move farther from the embryo (compare locations of a_1 & a_2 in B & C), indicating the deepening of flexures. The fit for the thoracic flexure is poor in (B), a situation remedied by the composite Bezier curve fit in (C). Curvatures for the curves shown in (A—C) are reported in (D). The curvature information can be used to develop finite element models (Fig. 2B) that give insight into the mechanisms driving flexure formation. The reader is cautioned not to confuse the parameter *t* (*italic*; used in the horizontal axis in D) with the time stamp t used to denote progression of embryo development.

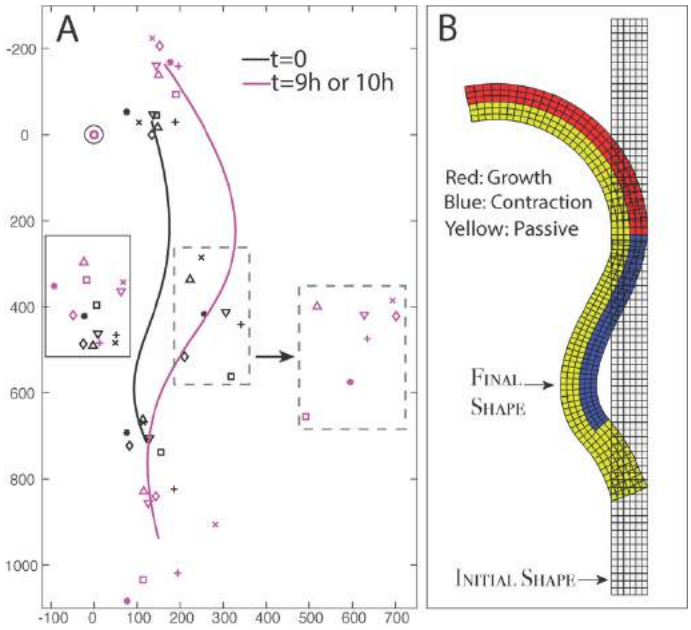

Figure 2: (A) Bezier control points "constellation" from curve fits on 7 embryos, each shown by a different marker (+,* etc.). Pixel dimensions are used (225.696 pixels = 1 mm). An affine transformation (translation) is carried out with the embryo eye as the origin (denoted by the bull's eye symbol at 0,0). Black markers denote t=0 while purple markers denote t=9 or 10h. Solid curves show the average Bezier curve fit based on the Bezier control points presented. Note that the second control points (enclosed in the dashed boxes; again, black and purple symbols denote t=0 and t=9 or 10h respectively) move farther (black arrow), indicating a deepening of cervical flexure. There is not a similarly large shift in the third control point location (solid box), which corresponds to the thoracic flexure; hence we use a composite curve to better capture the thoracic flexure (Fig. 1C). (B) Results from a finite element model (done in ABAQUS) of the dorsal wall with growth (contraction) specified in regions of positive (negative) curvature. Undeformed (black) and deformed (color) shapes are shown.

DISCUSSION

Cubic Bezier curves have a number of elegant properties which make them ideal to quantify shape changes during morphogenesis. We found that a single cubic Bezier curve captures the overall features of the dorsal wall. The control points (Fig. 2) and the control polygon (Fig. 1) are useful tools to broadly characterize shapes. Composite curves can be used to fit cubic curves for smaller sections when more precision is desired (Fig. 2C). Tools from differential geometry such as curvature, arc length, and velocity of curves can be used to develop finite element models and investigate mechanisms driving morphogenesis. Bezier curves can be used to compare curvatures across different time points, control vs. perturbation conditions, and also for comparing embryo shapes from different species at the same developmental period.

INTRODUCTION

The prevalence of myopia (nearsightedness) is rapidly increasing, with predictions of approximately 50% of the global population affected by 2050 [1]. Myopia is a refractive error, *i.e.*, a mismatch between eye geometry and optical power, predominately caused by excessive axial elongation of the eye. Evidence implicates remodeling of the sclera, the outermost white coat of the eye, and the resulting altered biomechanics as obligate to myopic axial elongation. Scleral biomechanics are consistently observed to change with myopia development, and altering scleral biomechanics, e.g., through surgical scleral reinforcement or collagen crosslinking, has been used to combat myopia progression in humans and animal models.

Certain light stimuli can be myopigenic, meaning that retinal sensing and processing of such stimuli result in axial elongation. This implies the existence of signal(s) capable of both traversing the vascular choroid that separates the retina and sclera (**Fig. 1**) and directing scleral remodeling processes. While the specifics of this retinoscleral signaling cascade are still poorly understood, retinoic acid (RA) has emerged as a promising candidate molecule central to the process. RA is found in all tissues between retina and sclera, and in increased concentrations in mammalian eyes developing myopia. Additionally, guinea pigs given exogenous all-trans RA (atRA) developed myopia [3]. Here, we feed mice atRA to test the hypothesis that exogenous atRA treatment will mimic the effects of sustained myopigenic visual stimulation, including alteration of scleral biomechanical properties.

METHODS

Male C57BL/6J mice (n=10) were trained to voluntarily ingest sugar pellets at 4 weeks of age (2.5 g pellet/kg). Mice were fed either sugar pellets with a 25 mg/kg dose of atRA (atRA: n=6) or plain sugar pellets (Ctrl: n=4) once daily for 2 weeks. Groups were chosen to ensure presence of littermate controls. Refractive errors (RE) of eyes were measured weekly until 6 weeks of age using a photorefractor, with baseline measurements made the day prior to starting atRA treatment. Reported refractive errors are the average of both eyes of each animal.

Animals were sacrificed and one eye each was randomly selected for biomechanical testing from a subset of animals (Ctrl: n=4, atRA: n=4). Eyes were enucleated and stored in 4 °C PBS (1X) until mechanical testing. Scleral samples (1 mm diameter) were taken ~0.5 mm from the optic nerve head and coated in graphite powder. Unconfined compression stress-relaxation experiments were performed on samples submerged in a 37 °C PBS bath using the Microsquisher (CellScale, Waterloo, Canada). Samples were compressed to 15% strain in three incremental steps (5% strain each), allowing stress to relax and equilibrate before application of the next step. A compressive modulus was obtained for each strain step as the ratio of equilibrium stress to strain. The conewise linear elastic biphasic model was independently fit to each strain step to determine the tensile modulus and hydraulic conductivity [4,5]. Generalized linear mixed models were used to test statistical significance of differences in biomechanical properties.

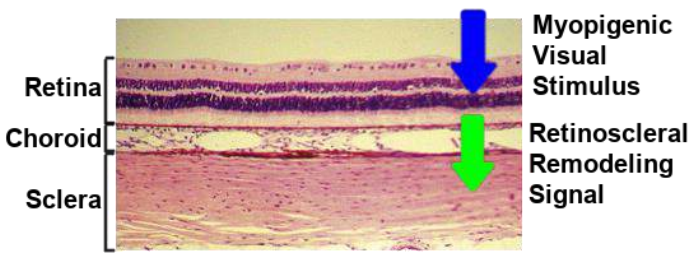

Figure 1: Structure of the posterior eye wall [2]. Signal(s) directing scleral remodeling originate in the retina after exposure to

myopigenic stimulus (blue arrow) and are believed to traverse the choroid (green arrow) to reach the sclera.

RESULTS

All animals voluntarily ingested the pellets with or without atRA. Control mice fed sugar pellets displayed a typical hyperopic refractive development that was significantly disrupted by oral atRA treatment (Interaction: treatment*age, $F(2,16) = 42.9$, $p<0.001$; **Fig. 2**). Relative myopia developed after 1 week of atRA treatment in atRA-fed mice vs controls (mean±STD: 0.3±2.7 vs 4.3±0.4 D, $p=0.024$) with the difference increasing after an additional week of treatment (mean±STD: -1.0±2.6 vs 6.3±0.1 D, $p<0.001$).

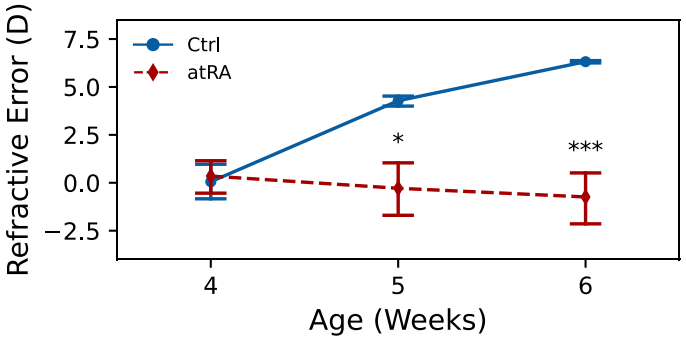

Figure 2: Development of refractive error (in diopters) of mice fed sugar pellets (blue, n=4) and sugar+atRA (red, n=6). Error bars represent 95% confidence interval. Statistical significance is indicated as: * p < 0.05, ** p <0.01, *** p < 0.001.

Changes in RE were accompanied by significantly altered scleral biomechanical properties, indicative of scleral remodeling. In-plane tensile stiffness of sclerae from atRA-fed animals was significantly decreased compared to control sclerae on average (95% CI, atRA: [83.8, 118] kPa, Ctrl: [131.6,186] kPa, Main effect: atRA, $\chi2(3)=13.5$, $p=0.004$; **Fig. 3**). The effect of atRA on in-plane scleral tensile stiffness was more evident at the larger compressive strain steps (Interaction: atRA*Strain, $\chi2(2)=9.9$, $p=0.007$), with sclera from atRA-treated eyes being only about half as stiff as controls at 15% compressive strain (95% CI, atRA: [109.6,168.2] kPa, Ctrl: [224.5,344.5] kPa, $p<0.001$).

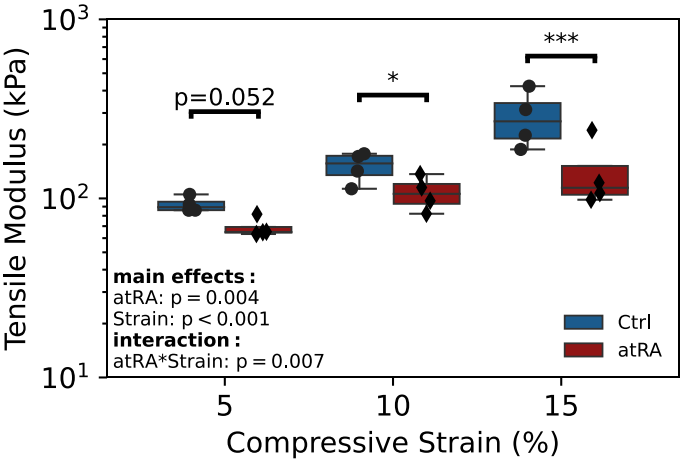

Figure 3: Scleral tensile modulus at 3 strain steps. Sclerae from control animals were stiffer than atRA-fed animals (n=4 each). Statistical significance indicated as: *p<0.05, ***p< 0.001.

Permeability was highly compressive-strain dependent (Main effect: Strain, $\chi2(4)=36.9$, $p<0.001$), with values spanning an order of magnitude over the range of compressive strains used. On average, sclera from atRA-fed animals trended towards being more permeable than the contralateral control sclera (95% CI, atRA: [5.6,10.6] $m^4/Ns*10^{-15}$, Ctrl: [4.1,7.8] $m^4/Ns*10^{-15}$, Main effect: atRA, $\chi2(3)=13.5$, $p=0.36$; **Fig. 4**) with the largest difference observed in the final strain step (95% CI, atRA: [2.6,6.2] $m^4/Ns*10^{-15}$, Ctrl: [1.4,3.3] $m^4/Ns*10^{-15}$, $p=0.05$). There was no significant change in compressive stiffness due to atRA treatment (95% CI, atRA: [5.9,8.2] kPa, Ctrl: [6.7,9.3] kPa, Main effect: atRA, $\chi2(3)=3.4$, $p=0.33$).

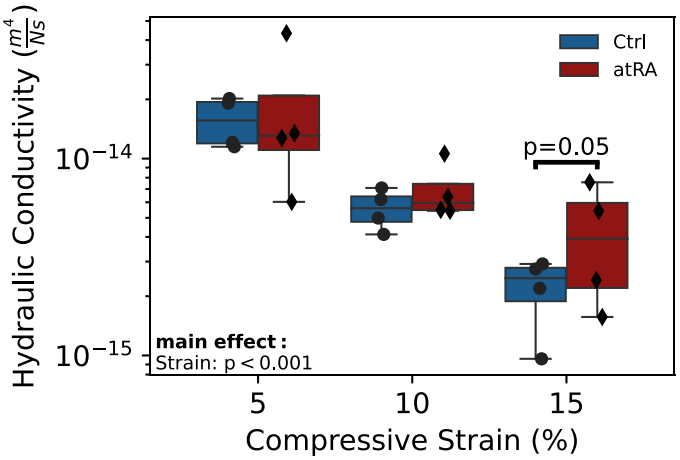

Figure 4: Scleral hydraulic conductivity at 3 strain steps. atRA-fed animals showed a trend towards more permeable sclerae than controls (n=4 each).

DISCUSSION

We have shown that exogenous atRA is highly myopigenic in mice, a novel result that corroborates previous findings in guinea pigs and is consistent with other correlational data in mammalian models of myopia. Further, we show for the first time that oral delivery of atRA affects scleral biomechanics by decreasing in-plane tensile stiffness of the sclera, suggesting that systemic atRA reaches and acts upon the sclera to influence remodeling processes. Scleral proteoglycans and collagen are known to remodel during myopia development, both of which may influence tensile stiffness. Both the rate of the atRA-induced myopia development (~7D of myopia in 2 weeks) and the decrease in scleral tensile stiffness are comparable to that seen in the mouse model of form deprivation myopia [5], consistent with a role for atRA in retinoscleral signaling of myopigenic visual cues.

Future work will study ocular tissue retinoid concentrations and how they compare between exogenous atRA treatment and myopigenic visual cues. Further, with atRA identified as myopigenic in the mouse, the power of transgenic animals can be exploited to elucidate the role of atRA in myopia development, e.g., by knocking out specific retinoid receptors or retinoid binding proteins.

INTRODUCTION

Degradation quantification techniques have been employed for various polymer systems, primarily for *in vitro* degradation kinetics [1]. Gravimetric analysis serves as the gold standard when possible. However, the quantification of *in vivo* degradation for polymer systems requires in-depth images or scans of the material. Image-based techniques offer the ability to combine pathological analysis and degradation quantification, as well as spectroscopic analyses [2,3]. The earliest non-destructive degradation evaluation techniques for implanted polyurethane foams were semi-quantitative [4]. Modern techniques rely on several imaging modalities, including magnetic resonance (MR), computed tomography (CT), optical coherence tomography (OCT), and microscopy (light and electron) [5-7]. However, these modalities often require some modification to the polymer system (e.g. metallic additives) for visibility. Spectroscopy is another common technique but fails to determine an exact quantitative mass loss [8]. The process becomes especially challenging when the polymer system is a porous implant for vascular occlusion applications, where tissue encompasses the material.

A Shape Memory Polyurethane (SMP) foam system has been developed and optimized for vascular occlusion applications [9-11]. From this platform material, two primary devices have been developed for clinical use. The peripheral embolization device (PED) is intended for the treatment of vascular insufficiency and is typically deployed in the designated vessel. The neurovascular embolization device (NED) is intended for the treatment of intracranial aneurysms. Both devices have been tested thoroughly for FDA clearance. Specifically, these devices have been implanted in animals for safety testing. The performance and lifetime of the implants *in vivo* served as the motivating factors for this work.

The porous foams allow blood to perfuse the scaffold, inducing microclots throughout the volume that transition into a complete embolized clot. Via the wound healing response, inflammatory cells remove the clot/foam matrix and scar tissue replaces the clot [9]. These devices are thus intended to rapidly occlude the region of interest, induce wound healing at the site, and gradually degrade to make way for pseudo-neointimal tissue for permanent occlusion. As reported in previous work, the SMP foam system is hydrolytically stable but oxidatively degradable, making the foam susceptible to cellular processes. A unique degradation profile has been identified in the foams, with scalloping events along the edges of struts (Figure 1).

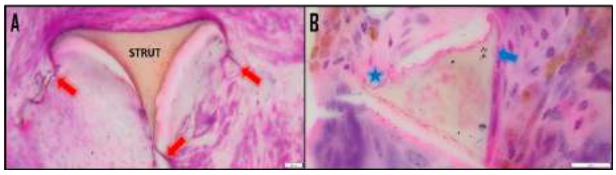

Figure 1: (A) strut of the SMP foam in histological section with membranes attached at vertices (red arrows). (B) strut with visible scalloping along edges (star) and isolated pits (blue arrow).

The SMP foam system is not inherently tuned for live imaging such as OCT, making *in vivo* gravimetric analysis a post-implantation process. Moreover, these implants had already been processed for histological assessment, limiting the method to trans-sectional evaluation. Thus, a method for quantitatively and qualitatively evaluating *in vivo* degradation will be presented in this work. It is critical that the degradation be quantified for the purpose of toxicity assessments and understanding device performance, especially as it relates to regulatory submissions. This paper will report out the degradation rates *in vivo* and the character of the observed degradation.

METHODS

SMP Foam Synthesis and Device Fabrication. PEDs were fabricated as detailed by Jessen et al, and NEDs were fabricated as described by Herting et al. and Boyle et al. [11-13]. Specifically, the PED implants are composed of a SMP foam (HH30/40) pledget attached to a bare nitinol anchor coil. HH30/40 foams range in pore size from 800-1500μm, and are comprised of hexamethylene diisocyanate (HDI), 30/40% N,N',N'-tetrakis(2-hydroxypropyl) ethylenediamine (HPED), and 70/60% 2,2',2"-nitilotriethanol (TEA). NED implants are composed of SMP foams (TH60) threaded over bare Pt-W coils. TH60 foams are comprised of trimethylhexamethylene diiscoyanate (TMHDI), 40% HPED, and 60% TEA.

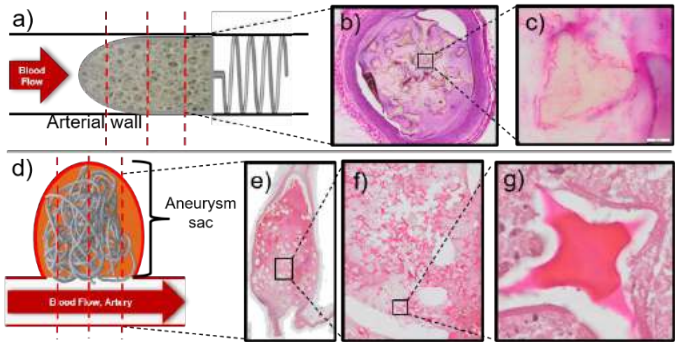

Figure 2: Device implants (a,d) in vivo were processed (b,e) for histology. High magnification and resolution images were used from these sections to evaluate degradation (c,f,g).

Gravimetric and Microscopic Analysis of SMP Foams. The mass ratio between struts and membranes in the SMP foams was determined through gravimetric analysis. Cold plasma reticulation was used to remove membranes from the foams according to the process outlined by Nash et al. [14]. Masses were taken before and after plasma treatment to determine the mass of membranes. All foams were imaged under light microscopy to ensure foam struts were not destroyed in the process.

Device Implantation and Explantation. The devices were implanted in their respective environments, with PEDs implanted in porcine arteries (n=3 animals per timepoint) and NEDs implanted in rabbit right common carotid aneurysms (n=10, 5, and 14 animals per timepoint) [12,13]. PEDs were explanted at 30, 60, and 90 days from different animals. NEDs were explanted at 30, 90, and 180 days. Explanted tissues were then fixed and sectioned according to previously reported methods [12,13].

Quantitative and Qualitative Analysis of Degradation. Histological sections were scanned at high resolution and magnification using OLYVIA Olympus software. Scans were then prepared for degradation analysis through detailed imaging of the remnant foam in the scans. Membranes of the foam were tallied as present, disrupted, or missing to form the relative membrane loss (RML). Visible struts were counted in the sections across the different timepoints to establish a relative strut loss (RSL). Struts that presented quantifiable degradation were imaged at high resolution. The images were imported to FIJI (ImageJ), scaled accordingly, and the regions of pitting and scalloping were measured using the Freeform tracing tool. These measurements formed the second part of the strut analysis: measured strut loss (MSL). Using the mass ratios from the gravimetric analysis of struts (k_s) and membranes (k_m), the following equation was used to determine the estimated mass loss for the section evaluated:

$$Deg_{Section} = RML * k_m + (RSL + MSL * (1 - RSL)) * k_s \quad (1)$$

RESULTS

Gravimetric Analysis of Struts and Membranes. Membranes accounted for 28.6 ± 9.8%; 26.8% ± 4.5%; and 22.9 ± 2.6% mass ratio for HH30, HH40, and TH60 foams, respectively. Struts subsequently accounted for the remaining mass percent. These values were incorporated into the equation for calculating the mass loss per section.

Quantitative and Qualitative Analysis of Device Mass Loss. For the PED studies, degradation was observed to steadily increase with increasing implantation time (Table 1). Relative strut loss was non-existent within the sections for all timepoints. Relative membrane loss dominated the degradation profile. Membranes were steadily disrupted and isolated through cellular activity and tissue ingrowth. Struts presented with increasing volumes of pitting along edges. For NED studies, 30-day timepoints showed near total membrane loss. Struts did not show evidence of dissolution and relative counts were high. 90-day timepoints showed drastic mass loss, with near total strut loss observed. Pockets of foam struts were located near the osteum of the aneurysm. 180-day sections showed a similar progression of degradation with one outlier section.

Table 1: PED/NED Mass Loss Rates per Explant Timepoint

Device	Timepoint (d)	Mass Loss (%)
PED [12]	30 (n=11)	3.22 ± 3.90
	60 (n=12)	6.91 ± 4.97
	90 (n=17)	9.42 ± 7.05
NED [13]	30 (n=10)	13.6 ± 2.75
	90 (n=5)	98.5 ± 0.22
	180 (n=14)	97.3 ± 3.08

DISCUSSION

The method presented expands on previously published image-based degradation quantification techniques by estimating a true polymer mass loss. Additionally, the qualitative assessment, coupled with the known pathological assessment of the devices, adds another dimension to the devices' performance. PEDs in porcine arteries showed a slower mass loss rate than observed *in vitro* and especially slower than NEDs in the rabbit elastase aneurysm models. The marked difference in the device lifetimes (90 days versus 3 years) have initiated an investigation into the wound healing responses of porcine models versus rabbit models. The degradation rates reported here will guide toxicity threshold assessments. The data presented has been used in FDA submissions for device clearance.

INTRODUCTION

The ability to rapidly detect diseases is of paramount importance as evidenced by the current COVID-19 pandemic.[1] Homogeneous assays are simple and rapid detection methods without the need for immobilizing, separating or washing reagents, and are promising for POC diagnostic applications. For example, homogeneous assays utilizing plasmonic gold nanoparticles (AuNPs) have been widely used in chemical and biological detection for proteins, nucleic acids, and virus particles.[2] Due to their localized surface plasmon resonance and coupling, AuNPs in the visible wavelengths provide intense color signals that can be conveniently read out by naked eyes. However, the performance of colorimetric and other ensemble measurements has been largely limited by the high background signal, resulting in poor sensitivity. The limitation makes such assays inadequate to be standalone diagnostic platforms.

In this work, we report a novel strategy, based on digital plasmonic-nanobubble detection (DIAMOND), to achieve the compartment- and label-free homogeneous assay with dramatically enhanced sensitivity. Specifically, the plasmonic-nanobubble (PNB) refers to the transient vapor bubble generated around a plasmonic NP by the laser heating and can be readily detected by the optical scattering (**Figure 1A**). Importantly, the PNBs are highly dependent on the light absorption and heat generation, and thereby are sensitive to the NPs' sizes and concentration. Due to their transient structure, the PNB events have lifetime up to several hundred nanoseconds and allow signal confinement within a detection zone, bypassing the conventional sample partitioning (e.g., microwells or droplets). As a result, the integrated DIAMOND platform measures "on" and "off" signals digitally in a flow channel and has the capability of single-particle enumeration (**Figure 1B**). With its ability to differentiate PNB signals from individual NPs and their clusters, DIAMOND is suitable to implement on homogeneous assay for rapid diagnostic fashion (<2 min). We demonstrated the DIAMOND technique enhanced the sensitivity of homogeneous assay by more than 300 times using respiratory syncytial virus as a model.

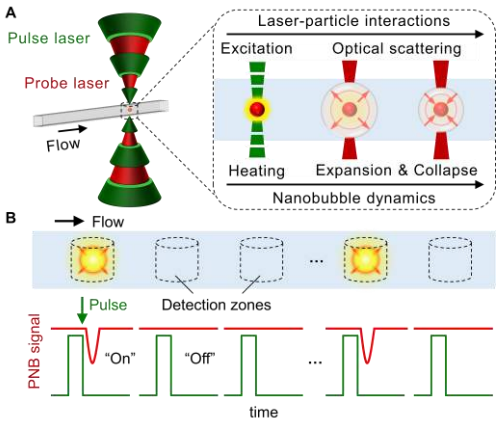

Figure 1. Schematic illustration of DIAMOND platform. (A) The major courses involved during a transient plasmonic-nanobubble (PNB) event. Pump-probe laser configuration allows PNB generation and detection simultaneously. (B) The digital counting of "on" and "off" PNB signals in the presence and absence of target of interest.

METHODS

DIAMOND platform. Briefly, ultrafast 532 nm laser pulses (28 ps, 50 Hz) were applied to activate the NPs and induce PNBs. The continuous probe laser of a 633 nm was used to monitor the PNB signals by a high-

speed photodetector (FPD510-FV, Thorlabs) and an oscilloscope (LeCroy WaveRunner204Xi-A). Data processing and analysis were automatically performed through a MATLAB script.

DIAMOND-based Single-Particle Detection. We prepared AuNPs solutions according to Frens' methods with slight modification.[5] The 70 nm AuNP suspensions were pumped through a micro-capillary (200 μm×200 μm) for the signal generation and data acquisition in DIAMOND system.

DIAMOND-enhanced RSV detection. We conjugated Synagis (RSV specific antibody) to AuNPs using DTSSP as crosslinkers to prepare RSV probes. The AuNP probes were incubated with RSV and other respiratory viruses at room temperature (RT) for 30 minutes before absorbance measurements and DIAMOND test.

RESULTS

DIAMOND-based Single-Particle Enumeration

First, we evaluated the performance of DIAMOND technique in single-particle enumeration. **Figure 2A** shows the typical PNB signal traces recorded from the 70 nm AuNPs suspensions with different concentrations. The concentrations were converted into expected number (λ) of NPs considering the 16 pL detection zone. Apparently, the different number (k=0, 1, 2…) of AuNPs passing through the detection zones caused the signal variations. At high concentration (λ=40), the number of AuNPs being detected was more than 15 in the detection zones, resulting in consecutive "on" signals. Decreasing the concentration led to the increasing probability of NPs in absence (k=0), causing the discrete signal traces and in turn, allowing the digital counting of "on" and "off" signals. Taking the AuNPs of λ=0.4 as an example, **Figure 2B** shows the bivariate plot of amplitude and area-under-curve (AUC) extracted from the signal traces. The as-counted frequencies, f_{off} and f_{on}, were close to the theoretical probabilities (P) of none (k=0) and a number (k>0) of AuNPs being detected, based on Poisson statistics. A close inspection of the data based on a gating algorithm using the theoretical P allowed us to sort the scatters representing for a number (k=0, 1, 2, and >2) of AuNPs being detected (**Figure 2C**). Clearly, the DIAMOND technique detects NPs at single-particle resolution.

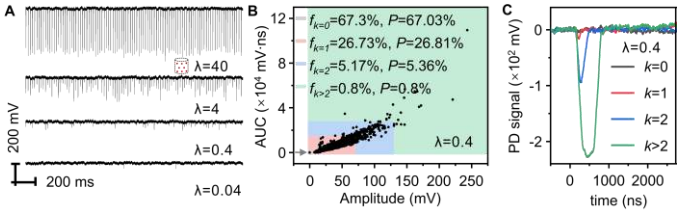

Figure 2. **DIAMOND technique for the single-particle enumeration.** (A) PNB signal traces recording of 100 pulses for 70 nm AuNPs with different particle concentrations at fluence of 8 μJ. Schematics show the expected number (λ) of AuNPs per detection zone correspondingly. (B) Bivariate plot of amplitude and AUC for the case of λ=0.4. f is the counting frequency of specific number (k) of AuNPs in detection zone and P is the corresponding Poisson probability. (C) The representative PNB signals for a number (k=0, 1, 2 and >2) of AuNPs being detected.

DIAMOND-Enhanced Homogeneous Assay

Next, we evaluated the DIAMOND technique for homogeneous assay of respiratory syncytial virus (RSV). RSV is the major respiratory pathogen in infants and children worldwide.[6] AuNPs conjugated with antibodies as probes could specifically target to RSV and were ready for detection (**Figure 3A**). The TEM images in **Figure 3B** confirmed the effective target-probe binding, while the spectra measurements shown in **Figure 3C** revealed the good detection selectivity among different respiratory viruses, including Parainfluenza viruses (PIV), Influenza A (IVA), Human metapneumovirus (hMPV) and sensitivity around 3.6×10^4 PFU/mL. We then carried out the DIAMOND test for the sensitivity enhancement. **Figure 3D** shows the bivariate plot of the detection results at different RSV titers in the borate buffer solution, where the thresholds were determined as five times standard deviation above the mean of control groups and assigned for the "on" signal counting. The calibration curve that plotted the counted frequency (f_{on}) against the RSV titers was shown in **Figure 3E**. In particular, a linear relationship (R^2 = 0.995) in the range of 10^2-10^4 PFU/mL was observed and the limit of detection (*LOD*) was calculated to be 108 PFU/mL (inset of **Figure 3E**). Clearly, DIAMOND improved the detection limit by more than 2 orders of magnitude.

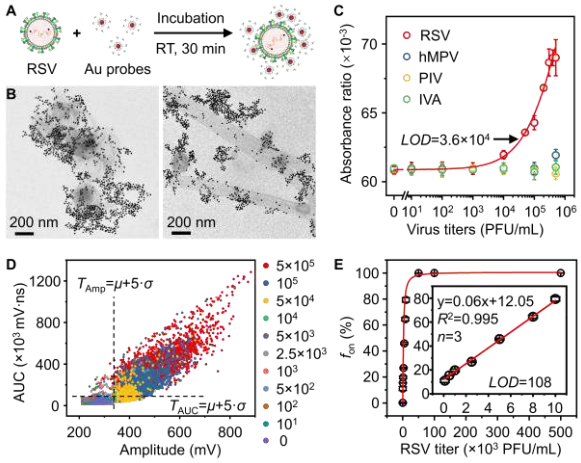

Figure 3. **Applying DIAMOND technique for the homogeneous assay of RSV**. (A) The schematic illustration of homogeneous assay. (B) TEM images of AuNPs targeting RSV of different shapes. (C) Colorimetric analysis of the assay. (D) Bivariate plot extracted from PNB signal traces of assay solutions. The thresholds were highlighted in grey and dash lines. (E) Quantification of RSV titers as a function of frequency counting (f_{on}). Error bars indicate the standard deviations of three independent measurements. The inset shows the linear detection range and *LOD* was calculated as 3 times standard deviation of the control dividing the slope of regression line.

DISCUSSION

In this study, a novel method based on the digital plasmonic nanobubble detection (DIAMOND) was developed to detect NPs and RSV. The results suggested the DIAMOND technique could detect NPs at single-particle level and RSV at 108 PFU/mL. This work will have a broader impact on addressing the technological challenges of conventional digital assays and providing a diagnostic platform for rapid and ultrasensitive tests. Further optimization of the DIAMOND system allows high throughput data acquisition and portable and even handheld POC prototype.

INTRODUCTION

Pulmonary arterial hypertension (PAH) is characterized by elevated pulmonary artery (PA) pressure >25 mmHg, dilation of the proximal PA vessels, distal PA remodeling resulting in occlusion of the PA vasculature, and right heart failure. Although the exact biological mechanisms of PAH initiation are unknown, PAH associated with congenital heart disease (CHD), PAH-CHD, is likely to develop in patients with untreated systemic-to-pulmonary shunts, especially for large shunts with pulmonary to systemic flow ratios (Qp:Qs) >2 [1]. Ventricular septal defects (VSDs) are the most common type of CHD where a hole exists in the interventricular septum between the two ventricles resulting in systemic-to-pulmonary, or left-to-right, shunts which are an indicator of severity and VSD size.

Although previous studies have investigated PA hemodynamics and its effect on cellular function in PAH, most have only focused on the disease progression and on the larger PAs [2, 3]. Few have investigated PA hemodynamics in the small, distal PAs, which are most severely affected by the remodeling process in PAH, and in the context of CHDs. Difficulties in assessing the hemodynamics in the small, distal PAs include the lack of *in vivo* flow and morphometry measurements, specifically in the pediatric population. We hypothesize that unrestricted left-to-right shunts alter PA hemodynamics and mechanical stimuli on vessel walls leading to initiation of dysfunctional cellular pathways in the small PAs contributing to the initiation of PAH.

In this study, we performed computational fluid dynamics (CFD) simulations to study the hemodynamics of the entire PA tree in different VSD conditions to understand the mechanical conditions present at initiation of PAH. We used a patient-specific geometry of the pediatric proximal PA vessels to simulate large PA hemodynamics (>1mm diameter vessels) in a 3D model. To model small PAs (<1mm diameter), we used scaling laws of PA morphometric somatic growth and PA resistance approximations to optimize a distal PA tree geometry and estimate hemodynamics in a 0D model. To our knowledge, this is the first study investigating the hemodynamics at the initiation of VSD-induced PAH that quantifies hemodynamics in the entire PA tree.

METHODS

To model the hemodynamics in the proximal PAs (>1mm diameter) in VSD conditions, we created a 3D geometric model of the healthy PAs of a 1-year-old male subject (BSA=0.49m^2, Ht=75.6cm, Wt=11.3kg) from a CT scan using the open-source software package, SimVascular (simvascular.org). Hemodynamics were simulated using SimVascular's stabilized finite-element solver [4] with backflow stabilization [5] and coupled Windkessel boundary conditions [6]. To model PA wall deformability, we used the coupled momentum method [7] for fluid-solid interaction with external tissue support [8] where PA walls were modeled as deformable linear elastic membranes with variable wall thickness. An elastic modulus of 126 kPa, 163 kPa, and 291 kPa was used for the normal and small VSD, moderate VSD, and large VSD simulations, respectively, based on previous studies showing stiffer PA material properties at higher pressures [9, 10].

To simulate increasing VSD severities, we prescribed a generalized normal PA inflow waveform at the main PA, scaled to mean flows of 2.5, 3.7, 4.9, and 7.4 L/min to represent the left-to-right shunt quantified by the Qp:Qs ratios found in a healthy control (1:1) [11], small VSD (1.5:1), moderate VSD (2:1), and large VSD (3:1). For all simulations (healthy and VSD conditions), we prescribed the same 3-element Windkessel model to all 3D PA outlets to represent a healthy downstream pulmonary vascular resistance and compliance. These Windkessel models were tuned to achieve a healthy target main PA pressure in the control simulation and subsequently used for all VSD simulations to represent conditions before vascular remodeling and the

initiation of PAH. The 3D PA simulation setup is shown in Figure 1a. From the proximal PA simulation, we extracted pressure, velocity, wall shear stress (WSS), oscillatory shear index (OSI), and strain measurements at each PA segment in the 3D PA model.

To model the distal PAs (<1 mm diameter), we used an optimized PA morphometric geometry to extrapolate 3D PA simulated flows to the distal geometry in a 0D model. The distal PA geometry was constructed using scaling laws of the PA morphometry for the 1-year-old BSA [12], the vessel connectivity of previous PA morphometric studies [13, 14], and optimization of the distal PA dimensions to achieve a target PA resistance of 33% of the entire healthy pulmonary vascular resistance [15]. Distal PA hemodynamics were calculated by extrapolating the outlet flows from the proximal PA model to the optimized distal PA morphometric model (Fig 1b). To extrapolate flows down to 50 μm diameter vessels and calculate wall shear stress (WSS), we applied Poiseuille assumptions in a 0D model with a diameter-dependent viscosity exponential function [16] to account for non-Newtonian effects from the Fahreus-Lindqvist effect in the small PAs.

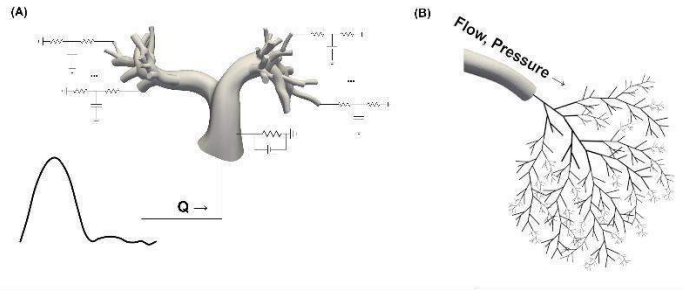

Figure 1: (a) Proximal PA model simulation setup with a prescribed inlet flow waveform, Windkessel outlet boundary conditions, and external tissue support. (b) Distal PA mathematical model setup with extrapolated outlet flows from the proximal 3D PA simulation to an optimized distal 0D PA tree.

RESULTS

In the proximal 3D model, pressure, flow, vessel strain, and WSS increased with increasing VSD size. OSI decreased with increasing VSD size in the larger PA vessels. WSS in the proximal 3D model increased from the main PA to the smaller PA vessels in the model in all conditions. In the distal PA 0D model, WSS increased with increased VSD size and increased in the smaller, distal PA vessels exceeding 100 dyn/cm^2 in the smallest pre-acinar PA vessels. Figure 2 shows WSS increasing from the proximal PAs in the 3D model to the distal PAs in the 0D model and with increasing VSD size. Due to differences in model assumptions between the 3D proximal and 0D distal PA models, WSS varies largely at this transition.

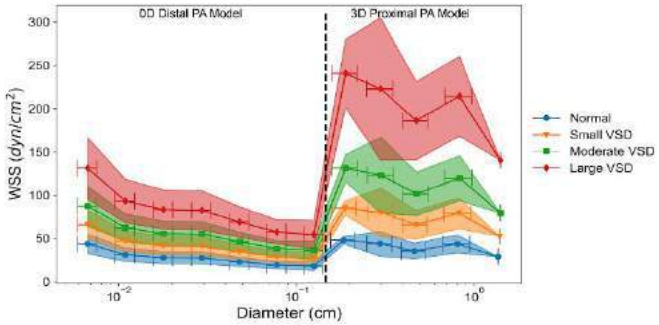

Figure 2: WSS increased from the proximal PAs (~1cm-1mm) to the distal PAs (~1mm-50μm) and increased with VSD size.

DISCUSSION

Knowledge of the hemodynamics in the small, distal PAs is significant in our understanding of the remodeling process that occurs in PAH. We estimated several hemodynamic markers with significant WSS differences between the normal and large VSD conditions with small distal PAs exhibiting >100 dyn/cm^2 WSS values. This is significant in informing mechanotransduction studies investigating the initiation of PAH, specifically as a result of the mechanical stimuli involved in untreated CHD patients who later develop PAH. Previous shear stress related gene expression studies on PAH have used lower WSS values of 5-20 dyn/cm^2 [2, 17], which correspond mostly to the largest PAs where dilation and remodeling usually occur in late stages of PAH, not initiation or early stages.

This is the first study to estimate the hemodynamics of the entire pediatric PA tree with VSD conditions before initiation of PAH, showing much higher WSS estimates in the small PAs than previously believed. These results have implications for the design of future biological studies assessing the effects of mechanical stimuli on endothelial cells as well as vascular wall mechanics that may occur during the initiation of PAH.

INTRODUCTION

The tendon-to-bone attachment (i.e., enthesis) is a functionally graded tissue that translates muscle-generated force from tendon to bone. The enthesis matures during postnatal growth and is susceptible to overuse injuries. Repeated loading of the adult enthesis induces mineralization and causes abnormalities such as bony spur formation and calcification of the distal tendon. Increased activity during periods of rapid growth, such as in children and during adolescence, can lead to micromotion at the enthesis and apophysis, resulting in inflammation and the clinical presentation of Sever Disease [1]. However, the temporal effect of training on the growth and remodeling of the enthesis remains unclear.

The use of small animal models allows for mechanistic exploration of the effect of loading on the growth and structural remodeling of the enthesis. Previously, muscle unloading has been shown to disrupt the structural and mechanical properties of the growing postnatal enthesis [2-4]. In the present study, we aimed to determine the effect of repeated daily bouts of increased muscle loading (using optogenetically-controlled muscle contractions) on the growth and adaptation of the immature and mature enthesis. We hypothesized that the mechanoadaptation differs between the immature and mature enthesis, and we compared the mineralization and structural changes of the enthesis in response to *in vivo* loading-induced remodeling. To do this, we used non-invasive optogenetic control of muscle contraction, which relies on the expression of light-responsive microbial opsins (e.g., Channelrhodopsin-2, ChR2) in activatable cells to translocate ions across the cell membrane for cell-specific, fast optical control of the membrane potential [5]. We and others have previously used optogenetics to control muscle contraction *in vivo* in mice and we have demonstrated the feasibility of eliciting sustained muscle contractions in the triceps surae muscle group [6-8]. In this study, we used optogenetics to induce isometric muscle contraction for non-invasive loading of the Achilles tendon enthesis daily, for three weeks, in Immature (3-week old) and Mature (6-month old) mice. We used microcomputed tomography (microCT) and histology to evaluate the effect of repeated mechanical loading on the mineralization and structural changes of the Achilles enthesis between repeatedly loaded and contralateral entheses.

METHODS

All procedures were approved by our Institutional Animal Care and Use Committee. Doxycycline-inducible ACTA1-rtTA;tetO-cre mice (Acta1-Cre; C57BL6J background) were crossed with Ai32 reporter mice (C57BL6J background) to generate Acta1-Cre; Ai32 offspring that expressed ChR2 blue light-sensitive opsin (455nm sensitivity) in skeletal muscle when treated with tetracycline. Dams were treated with doxycycline chow at the time of mating until weaning. Offspring were genotyped using PCR (Transnetyx), and Acta1-Cre; Ai32 homozygous mice (Immature group: 3-week old, n = 6 ; 2 females and 4 males; Mature group - 6-month old: n = 4; 2 females and 2 males) were used for blue light-induced stimulation. In addition to contralateral within animal controls (right: stimulated, left: control), external age-matched littermates heterozygous and homozygous Ai32 offspring (n = 7; 4 females and 3 males) were used as non-stimulated controls for the Immature group. Mice were anesthetized with isoflurane, hair was removed from their right triceps surae muscles to expose the skin, and animals were placed on a heating pad at 37°C. Right limbs were stabilized at the knee joint and feet were placed on a foot pedal connected to a servomotor shaft (Aurora Scientific) to induce isometric muscle contractions. For light stimulation, a collimated LED light (455 nm, 900 mW, M455L3, Thorlabs) and a high-power LED driver (DC2200, Thorlabs) were used for pulse modulation [6]. Muscles were stimulated using 10Hz pulsed light (70ms on, 30ms off; 10 cycles)

followed by 4 seconds of rest for 20 minutes (240 consecutive loading cycles), for 5 consecutive days per week for (3 weeks). Ankle torque measurements were collected throughout loading bouts. Maximum ankle torque at the start of each bout of stimulation was compared after normalizing to body weight. Contralateral limbs of the Loaded group were used as paired controls for microCT. Knee and ankle placement was also repeated for non-stimulated control immature group for 20 minutes under anesthesia. After 3 weeks of unilateral loading, mice were euthanized using carbon dioxide asphyxiation. Hindlimbs were dissected and fixed overnight in 4% paraformaldehyde and then scanned using microCT (Bruker SkyScan 1276; 59kV, 175µA, 10.58µm voxel size, 930ms exposure, 0.5mm aluminum filter). Digital reconstructions were analyzed using CTAn (Bruker) and Dragonfly (Object Research Systems) for: calcaneal total and bone volume; apophyseal total and bone volume; apophyseal bone mineral density (BMD); and calcaneal length. After microCT, tissues were decalcified in 14% EDTA and paraffin processed for histology. Sagittal plane sections of the Achilles enthesis (6µm) were stained using Toluidine Blue and Hematoxylin and Eosin (for enthesis morphology) and DAB immunohistochemistry (IHC) for markers of enthesis tissue transition (Aggrecan, Collagen Type II, Collagen Type III). *Statistical analysis*: maximum measured torque was normalized to the measured body weight for each bout of loading and repeated measures ANOVA was used to compare the variation of normalized torque for each mouse for the duration of the experiments. Paired Student t-test was used to compare BMD, BV, TV, and BV/TV between contralateral limbs.

RESULTS

All mice tolerated the daily loading bouts well and were included in analyses. Normalized maximum torque did not fluctuate for the duration of the experiment for each mouse and between mice of each group (Immature and Mature) at each bout (data not presented here). After 3 weeks of unilateral loading in the Immature group, the Achilles enthesis showed increased vascular infiltration in the calcaneal apophysis and at the calcified fibrocartilaginous border of the enthesis in stimulated limbs compared to contralateral limbs (Fig. 1A, shown with arrows). In 50% of the Immature mice, repetitive loading resulted in the formation of an enlarged and irregularly shaped apophysis compared to unloaded controls (Fig. 1A). We also saw a smaller fibrocartilage zone, with less Collagen II staining, in the Loaded compared to control entheses of Immature mice and adaptation to compressive loading at the wrapping site of the enthesis (Fig. 1C).

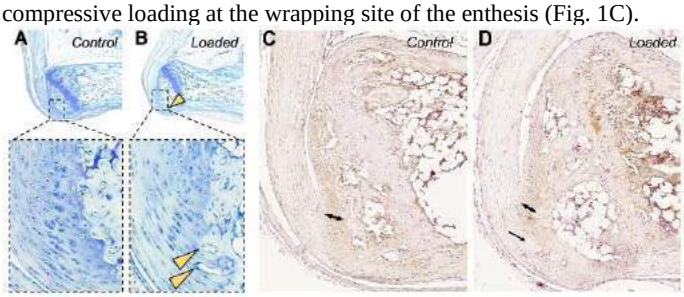

Figure 1: Morphology of the Achilles enthesis of (A) Control and (B) Loaded Immature mice after 3 weeks of daily bouts of optogenetic muscle contraction. Yellow triangles show misshapen apophysis near the enthesis and increased vascularity. (C, D) Loaded Immature mice have thinner entheses, indicated by less Collagen II (black arrow).

Bone loss visualized histologically in the loaded Immature group was confirmed following microCT analysis, both qualitatively and quantitatively. The apophysis was "pulled" in the posterior direction in the Immature group enthesis (dotted line, Fig. 2A), but not in the Mature group. Bone quality, measured as BMD, was lower in Loaded compared to contralateral Control apophyses in the Immature group (Fig. 2B). However, the total apophyseal volume did not differ between loaded and control groups in the Immature group. In the Mature group, the morphology of the Achilles enthesis and apophysis appeared histologically normal and there were no significant differences in BMD or apophysis volume between loaded and control sides (Fig. 2 E, F).

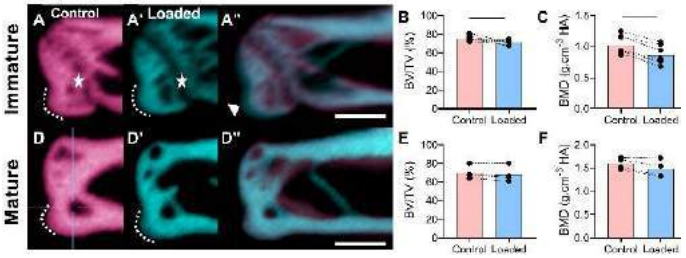

Figure 2: Sagittal microCT view of representative calcanei of Immature (A-A") and Mature (D-D") (Achilles attachment site outlined with dashed line). After 3 weeks of daily loading, Immature mice had posteriorly pulled apophyses (white triangle in A'') with growth plate opening (stars in A, A'). Apophyseal bone volume fraction and BMD (B, C) were reduced in the Loaded Immature group compared to contralateral apophyses. No structural differences were observed in the Mature group (D-F). Scale bar: 500 µm, bars indicate $p < 0.05$.

DISCUSSION

Using high-resolution three-dimensional imaging techniques (microCT) and histology, we found irregular apophyseal bone formation and increased vascularization, with smaller fibrocartilage and decreased bone quality, following repetitive loading in the Immature but not Mature enthesis. Vascular infiltration may be an indicator of bone and fibrocartilage remodeling in the immature entheses [9]. These findings model the structural and mechanical changes similar to those occurring during overuse activities in the young athlete and are generally associated with pediatric apophyseal pathologies [9-12].

Significance/clinical relevance: Pediatric sports-related injuries, such as Sever disease, Little Leaguer's elbow, and Osgood-Schlatter disease, all represent common clinical apophyseal pathologies in the young athlete. Increasing clinical evidence demonstrates the link between prolonged overuse activities and repetitive loading with other diagnostic (e.g., magnetic resonance imaging) and clinical abnormalities in skeletally immature athletes [10-13]. Our non-invasive, repeatable model for *in vivo* muscle loading enables mechanistic investigation of the effect of loading on the structure of developing and mature enthesis in order to improve clinical interventions for overuse injuries in children and adults.

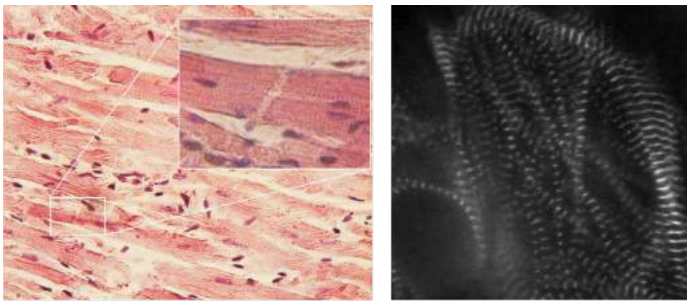
SARCGRAPH: AUTOMATED SEGMENTATION, TRACKING, AND ANALYSIS OF SARCOMERES IN HUMAN INDUCED PLURIPOTENT STEM CELL DERIVED CARDIOMYOCYTES

Bill Zhao (1), Emma Lejeune (1)

(1) Mechanical Engineering
Boston University
Boston, MA, USA

INTRODUCTION

Heart disease is the leading cause of death worldwide [1]. Because of this pressing societal challenge, cardiac drug discovery and cardiac tissue engineering are highly active areas of research. There is not only a pressing need to discover new treatments for cardiac disease, but also a pressing need to understand unintended cardiac-related adverse effects of drugs used for other purposes [2]. Recently, there has been a growing focus on human induced pluripotent stem cell derived cardiomyocytes (hiPSC-CMs). This technology presents a feasible approach to acquiring human cells and future patient-specific treatment plans [3]. However, hiPSC-CMs are both morphologically and functionally distinct from mature cardiac tissue (Fig. 1).



mature cardiac tissue hiPSC-CMs

Figure 1. Contrast between mature tissue and hiPSC-CMs.

The immature and non-linear structure of hiPSC-CMs makes it difficult to extract quantitative information from image-based assays. Recently, there has been significant work in this direction where z-disks in hiPSC-CMs are fluorescently labeled (Fig. 1) and advanced image processing and analysis software is used to segment and track sarcomeres and approximate their length with respect to time [3]. However, these state-of-the-art computational methods have room for improvement in both the efficacy of sarcomere segmentation and tracking under laboratory conditions, and strategies for comprehensive data analysis. Here we present our recent step forward in automated quantitative analysis of beating hiPSC-CMs.

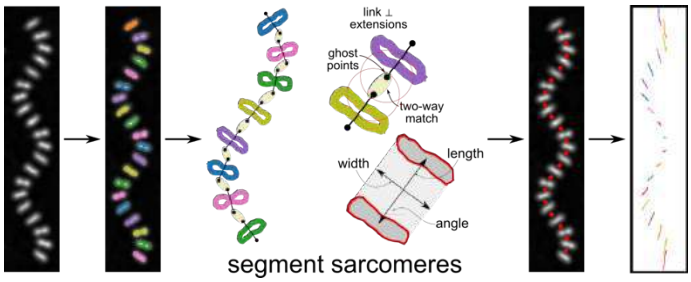


Figure 2: Z-disk and sarcomere segmentation and tracking.

METHODS

Here we introduce "Sarc-Graph," a computational framework to segment, track, and analyze sarcomeres in fluorescently tagged immature and non-linear hiPSC-CMs. Our framework includes functions to segment z-disks and sarcomeres, track z-disks and sarcomeres in movies of beating cells, and perform automated spatiotemporal analysis and data visualization. Here we briefly note a few key features of our framework. First, we created an algorithm to segment z-disks and sarcomeres (Fig. 2). Of note, our algorithm does not require any input parameter tuning, and is able to reliably capture non-linear sarcomeres in the presence of noise. Then, we track z-disks

and sarcomeres independently using the Python package trackpy which is based on the Crocker–Grier algorithm [4]. Finally, we use Gaussian process regression to interpolate data between lost movie frames when necessary and feasible [5]. The segmentation and tracking process takes only a few minutes to run on a laptop computer.

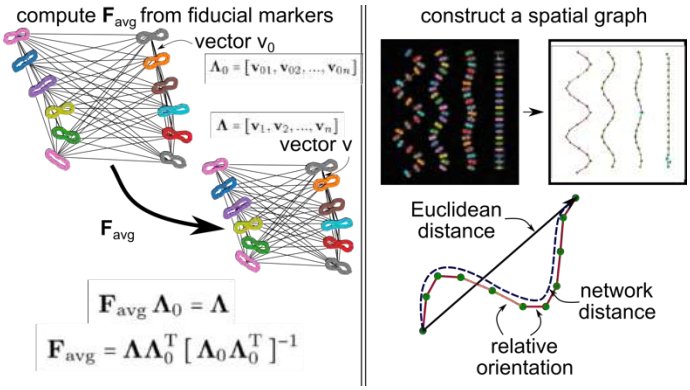

Figure 3: Analyzing average and local sarcomere behavior.

Next, we introduce two novel analysis approaches. First, we treat tracked and segmented components (i.e., sarcomeres and z-disks) as fiducial markers and use them to compute the approximate deformation gradient of the entire tracked population. This represents a new quantitative descriptor of hiPSC-CM function (Fig. 3). Second, we construct spatial graphs where z-disks correspond to nodes and sarcomeres correspond to edges. This makes measuring the network distance between each sarcomere straightforward and makes it possible to compute statistics that include information about the network structure (Fig. 3). We showcase and validate our approach with both synthetic and experimental movies of beating hiPSC-CMs. The Sarc-Graph software can be freely accessed through GitHub: https://github.com/elejeune11/Sarc-Graph. Example data and code to generate and analyze synthetic data with a known ground truth are also included on GitHub. We encourage anyone interested to try it out.

RESULTS

Here we show two examples of Sarc-Graph run on movies of beating hiPSC-CMs (Fig. 4, raw data first published with [3]). For Example E1, we are able to segment ≈500 sarcomeres per frame and successfully track 74 sarcomeres. The time series plot of normalized sarcomere length with respect to frame number shows three distinct contraction events during the movie. Though the individual sarcomeres are clearly not perfectly in sync, there is enough of a unifying pattern for these three peaks to emerge. These three distinct contraction events are also reflected in the average deformation plot. For Example E2, we are able to segment ≈500 sarcomeres per frame and successfully track 60 sarcomeres. The time series plots of absolute sarcomere length change and average deformation with respect to frame number also show three distinct peaks. We also show the spatial graph representation of each example and a plot of normalized cross-correlation between pairs of individual sarcomere time series curves with respect to network distance. We note briefly that additional information, including movies, more experimental data examples, and validation examples on synthetic data, are available both on GitHub and in our forthcoming manuscript.

DISCUSSION

Qualitatively, Examples E1 and E2 are different in that the sarcomeres in Example E1 appear vertically aligned throughout while the sarcomeres in Example E2 appear radially aligned around the edge of the cell and unaligned in the center. By segmenting the sarcomeres and analyzing their individual un-tracked properties, we can quantitatively confirm this morphological description. In addition, we can use our tracking results and our computed average deformation metric to go beyond morphology alone and quantify the function of the observed hiPSC-CMs. For example, we can show that the contraction-driven deformation in Example E1 is quite anisotropic while the contraction-driven deformation in Example E2 is nearly isotropic.

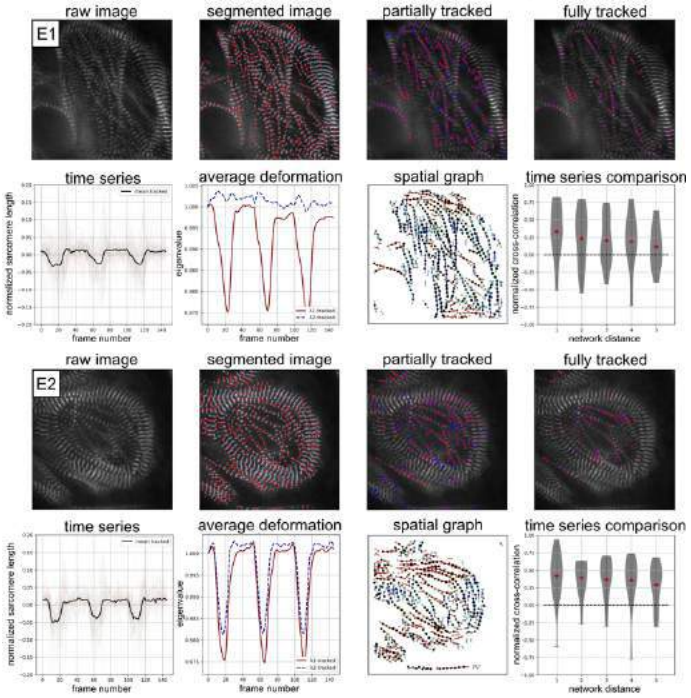

Figure 4: Two example results from running SarcGraph.

The objective of this work was to provide an open source computational framework to quantitatively analyze movies of beating hiPSC-CMs. With our framework, we are able to automatically segment and track a higher number of sarcomeres than other state of the art tools, and we introduce two important new approaches for the analysis of beating hiPSC-CM: a method for computing an average deformation gradient based metric, and a method for treating the hiPSC-CMs as spatial graphs. Looking forward, we see this work as an important tool for substantial future study of hiPSC-CM behavior with applications ranging from drug discovery to tissue engineering.

INTRODUCTION

Traumatic brain injury (TBI) is a major public health problem in the world (Peden *et al.*, 2004; CDC, 2015). It is caused by rapid brain deformation (strain) resulting from sudden head acceleration or deceleration events. Numerous studies attempt to translate impact kinematics to brain injury risk by defining kinematics based injury metrics (Hernandez *et al.*, 2015). Their effectiveness is usually assessed by how well they represent the peak maximum principal strain of the whole brain. However, an important limitation is that these metrics are scalar and do not consider the anatomical location where the peak strain occurs. For example, peak rotational acceleration/velocity do not account for the directionality or the temporal shape of the impact profile, which are important for spatially detailed brain strains.

To overcome this limitation, finite element (FE) models of the head provide valuable insight into the induced brain strain spatial distributions. However, unlike kinematic injury metrics, FE model simulations are slow and resource intensive. They are infeasible for real-time injury risk assessment (Zhao and Ji, 2019). Methods to circumvent the computational cost of FE models include pre-computation (Ji and Zhao, 2015) and more recently, deep learning (Wu *et al.*, 2019; Ghazi *et al.*, 2020b). The former simplifies an arbitrary head impact to an idealized acceleration impulse to interpolate strain, while the latter directly transforms an arbitrary head impact to detailed brain strains.

In this study, we explores a concept of "effective impact kinematics", which inversely determines a set of simple kinematics variables while preserving spatially detailed brain strains.

METHODS

We used an impact database (N=3069) drawn from contact sports, which were previously simulated using the Worcester Head Injury Model (WHIM) V1.0 (Wu *et al.*, 2019). For each simulated impact, a corresponding simplified impact was identified from the previous pre-computed brain response atlas (pcBRA) (Zhao *et al.*, 2017). The pcBRA consists of idealized, acceleration-only impacts about different rotational axes and velocity magnitudes, which allows real-time strain estimation *via* interpolation. For each arbitrary impact, simplified pcBRA impacts that had "similar" brain strains based on elementwise linear regression slope and correlation were first identified. Their rotational axes were weight-averaged to produce a rotational axis to represent that of the arbitrary impact (Fig. 1).

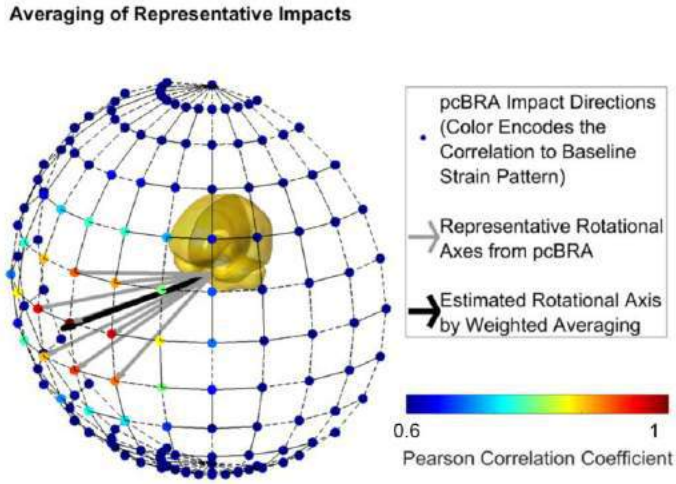

Figure 1: Wireframe and scatter plot illustrating the pcBRA data structure, where each dot represents an impact with a prescribed rotational axis. A cluster of representative impact of similar strain

patterns are identified and weight averaged to produce an effective rotational axis for the arbitrary real-world impact.

The peak rotational velocity magnitude was next determined that would produce a linear regression slope of 1.0 between its corresponding brain strains with respect to those from the arbitrary impact. This process generated three unique scalar values, which were referred to as the "effective kinematic triplets" to describe the impact: peak rotational velocity (v_{rot}), azimuth (θ) and elevation (α) angles.

In order to bypass this "analytical" process, a convolutional neural network (CNN) was further developed to transform an arbitrary head impact profile directly into the effective kinematics triplets. To verify the accuracy of the CNN, the estimated triplets were translated into brain strains *via* the pcBRA and were compared to those directly from the actual impact simulation. The whole process is illustrated in Fig. 2.

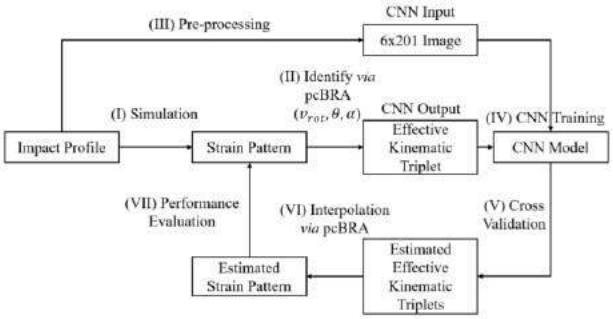

Figure 2: Flowchart of the study. Impact profile is first simulated. The resulting brain strains are used to determine a close representative in pcBRA, from which "effective kinematic triplets" are determined. Then, a CNN is trained to predict the triplets based on arbitrary impact profiles. Its prediction accuracy is evaluated by translating the triplets into brain strains using the pcBRA and to compare strains from the direct simulation.

RESULTS

For the set of arbitrary impacts, 66.1% of the impacts (N=2030) were able to be simplified into a triangulated rotational impulse based on pcBRA. From these, CNN was able to successfully predict effective impact triplets for 74.5% of the impacts (Fig. 3). An example impact is further illustrated in Fig. 4.

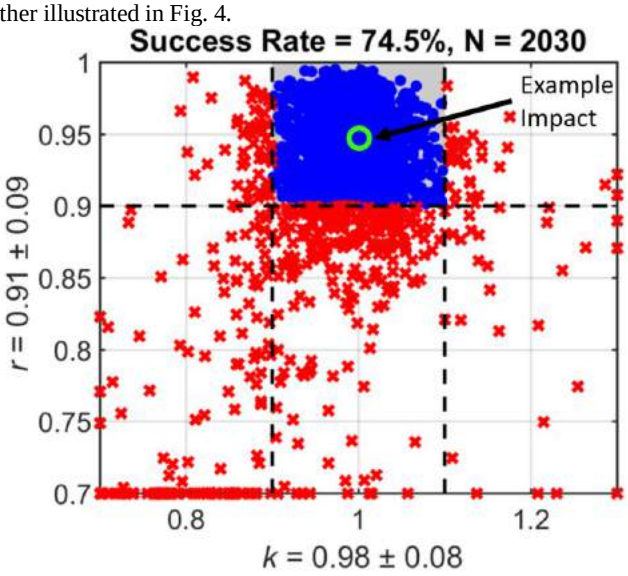

Figure 3: Pearson correlation coefficient (*r*) vs. regression slope (*k*)

of elementwise comparison between brain strains based on CNN-predicted effective kinematic triplets and the baseline simulation.

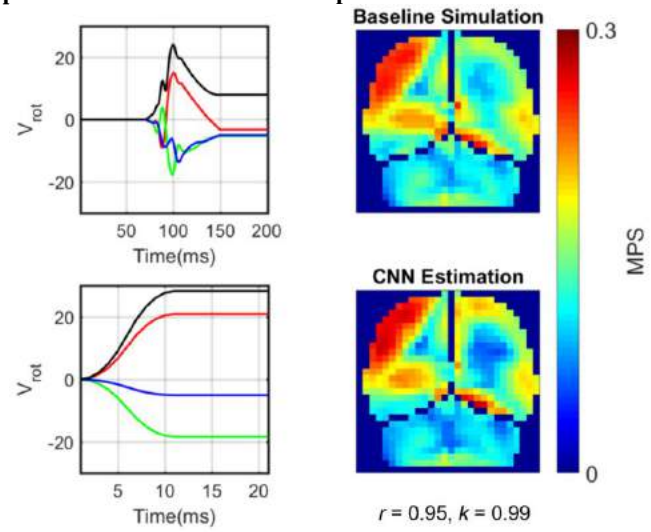

Figure 4: An example of a simplified impact and the corresponding strain distribution.

DISCUSSION

Impact kinematics-based injury metrics are ubiquitously used. In this study, we explore the concept of "effective kinematic triplets" to simplify an arbitrary real-world head impact into an idealized head rotational impulse to preserve spatially detailed brain strains. Essentially, the idea is to inversely map brain strains based on the pcBRA. The triplets consist of peak rotational velocity magnitude and the azimuth and elevation angles that characterize the impact severity and rotation directionality, respectively. The impact simplification may facilitate intuitive understanding and comparison of real-world impacts.

The pcBRA is restricted to acceleration-only impacts. This limits the range of brain strains that can be used to approximate real-world impacts. About two thirds of impacts from the dataset were successfully represented. Using a CNN, effective kinematic triplets for ~75% of the impacts were successfully predicted (Fig. 3). It is worth exploration whether inclusion of more head rotation "modes" could improve the performance, e.g., to include head impacts with both acceleration and deceleration in the pcBRA to expand variations in brain strains.

To conclude, we show that it is possible to use a simplified head impact to represent a complicated, real-world impact while preserving spatially detailed brain strains. The "effective kinematic triplets" repurpose existing kinematic variables, which may facilitate better comparisons among arbitrary real-world head impacts in the future.

EVOLUTION OF THE HEMODYNAMIC PROPERTIES AND ARTERIAL WALL REMODELING IN PULMONARY ARTERIAL HYPERTENSION

H. Mu (1), D. Valdez-Jasso (1)

INTRODUCTION

Pulmonary Arterial Hypertension (PAH) is a progressive vasculopathy characterized by sustained elevation of mean pulmonary arterial pressure. As the disease progresses, the stiffening and thickening of the large pulmonary arteries increases pulse wave velocity and decreases vascular compliance, further exacerbating the pressure overload and adversely impairing perfusion and hemodynamics. [1,2] To understand how the remodeling of the arterial wall alters pulmonary hemodynamics during disease progression, a one-dimensional fluid dynamic model is used to examine *in-vivo* pressure and flow measurements from the main pulmonary artery (MPA) and *ex-vivo* mechanical properties of the left and right pulmonary arteries (L/RPA) measured at different stages of PAH in rats. Herein, we present our work on establishing a baseline of the hemodynamic properties of the pulmonary vasculature in early and advanced PAH stages.

METHODS

Male Sprague-Dawley rats weighing about 200 grams (Charles River Lab) were injected with monocrotaline (MCT) to induce PAH. Timepoints studied were one and four weeks post-disease induction to mimic the early and advanced stages of the disease. Aged-matched rats injected with saline were added as the control group. Rats underwent an open-chest surgery to simultaneously measure pulmonary arterial flow and pressure with a 1.6F dual-pressure sensor catheter and a flow probe (Transonic Science), respectively (Figure 1). The data were collected and pre-processed in LabChart Software (ADInstruments Inc.). After hemodynamic measurements, pulmonary arteries from LPA and RPA were harvested, cannulated, and mounted into the BioDynamic chamber (ElectroForce Systems Group) to perform tubular biaxial mechanical testing. The circumferential forces and displacements were used to calculate the stress and strain, respectively, and thus the elastic modulus of the LPA and RPA at each stage of the disease. [3]

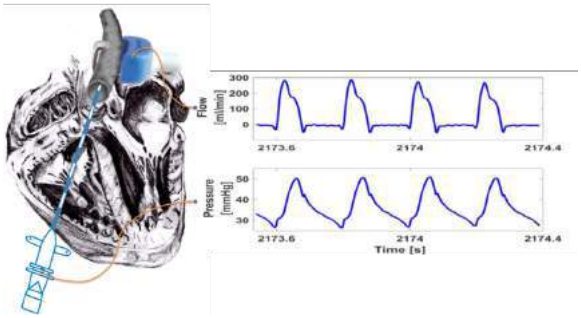

Figure 1: *In-vivo* blood pressure and flow measurements taken from male Sprague-Dawley rats. [5]

Our one-dimensional fluid model spans the first three branches coming out from the right ventricle: MPA, LPA, and RPA. The arteries are assumed to be the tapering right cylinders with no-slip and impermeable walls. We assume blood to be incompressible and Newtonian, and blood flow is described as axisymmetric, inviscid, and laminar. The partial differential equations relating flow Q, pressure P, and cross-sectional area A as function of time t and space x are the Euler equations with conservation of mass (Equation 1) and momentum (Equation 2). A linear thin-wall equation (Equation 3) describes the pressure-area relation of the vessel wall.

$$\frac{\partial A(x,t)}{\partial t} + \frac{\partial Q(x,t)}{\partial x} = 0 \quad (1)$$

$$\frac{\partial Q(x,t)}{\partial t} + \frac{\partial}{\partial x}\left(\frac{Q(x,t)^2}{A(x,t)}\right) + \frac{A(x,t)}{\rho}\frac{\partial P(x,t)}{\partial x} + \frac{2\pi\upsilon}{\delta} r(x,t)\frac{Q(x,t)}{A(x,t)} = 0 \quad (2)$$

$$P = P_0 - \frac{4Eh}{3r_0}\left(1 - \sqrt{\frac{A_0}{A}}\right) \quad (3)$$

In these equations, ν kinematic viscosity, δ boundary layer thickness, r outer radius of the vessel; E circumferential elastic modulus, h the thickness of vessel wall, and A_0 and r_0 are the *ex-vivo* area and radius of the individual arteries.

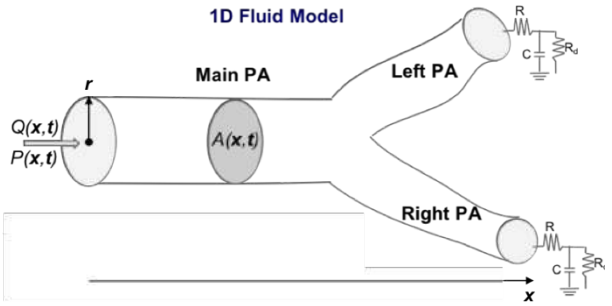

Figure 2: One-dimensional fluid model of the large pulmonary arteries initiated with flow *Q* and pressure *P* measured invasively that simulates flow and pressure propagation along the vasculature.

The model is initialized with the *in-vivo* flow and pressure data measured at the inlet. At the bifurcation, flow exiting MPA equals the sum of flow entering LPA and RPA, and pressure is the same for the three arteries. At the outlet boundary conditions of LPA and RPA, three-element Windkessel models are applied to account for the effect of all downstream vessels (Figure 2), where R is the proximal resistance, R_d is the distal resistance, and C is the compliance. [4,5]. Windkessel model parameters are determined from *in-vivo* flow and pressure measurements offline. The elastic moduli of LPA and RPA are obtained by fitting the stress-strain data from the tubular biaxial testing to a quasi-linear viscoelasticity model of the arterial wall. [3] The MPA elastic modulus is assumed to be the average of LPA and RPA values and is tuned to fit the measured *in-vivo* pressure.

RESULTS

Simulations using data from MCT animals reproduce the shape of measured *in-vivo* pressure, including the ratio of systole and diastole duration, the slope of diastolic pressure decay, and timing of peak pressure (Figure 3). Wave propagation is shown as the delay of systolic peak pressure along the arteries. The difference between the flow and pressure waveforms show the presence of wave reflection, indicating that our model mimics features of the blood waveforms.

The tuned MPA elastic modulus increased from 0.52×10^6 g/(cm•s^2) in the control, to 1.7×10^6 g/(cm•s^2) in the early PAH, and 3.4×10^6 g/(cm•s^2) in the advanced PAH. By inspecting the first cardiac cycle, the peak pressure is about 23 mmHg in the control, 47 mmHg in the early PAH, and 57 mmHg in the advanced PAH, while the *in-vivo* measurements have the peak pressure in the same cycle as about 19 mmHg in the control, 40 mmHg in the early PAH, and 53 mmHg in the advanced PAH. The peak pressure of the simulation results matches with the measurement in the control and advanced PAH. The early and advanced PAH groups have pressure elevation in both diastolic and systolic phases. The PAH groups also have an increased pulse pressure. The peak cross-sectional area of the first cardiac cycle is about 9.5 cm^2 in the control, 11 cm^2 in the early PAH, and 9.5 cm^2 in the advanced PAH.

DISCUSSION

The reflected wave superimposes with the forward-traveling wave, and the wave speed determines the timing of this superposition, given the wave is reflected from the same location. [7] As in shown in our simulations, there was an increase in wave speed due to arterial wall stiffening from the control to the advanced PAH, so the reflected wave returned early at systole, increasing the pulse pressure as we observed in the simulation.

The peak cross-sectional area of MPA increases from the control to the early PAH, and then the value returns to the original in the advanced PAH. This finding does not match with the persistent increase in peak pressure, but it can be explained by the almost 7 folds increase in the MPA stiffness. The different trends of area and pressure changes imply the presence of structural remodeling (stiffening of the arterial wall) in the proximal pulmonary arteries. According to [6], the stiffening and thickening of the arteries reduce the stress and strain experienced by the vessels, thus returning the system to homeostasis.

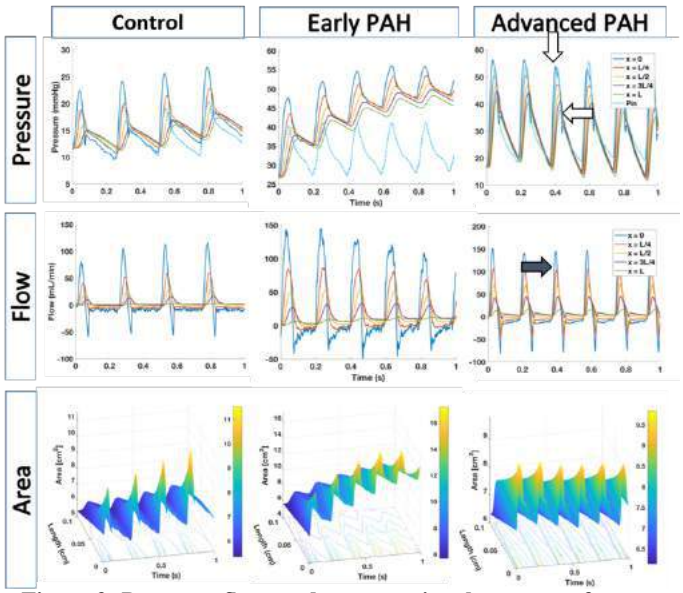

Figure 3: Pressure, flow, and cross-sectional area waveforms simulations across the MPA, where P_{in} is the measured *in-vivo* pressure. The simulated pressure is generally in the same range of measured pressure in the control and the advanced PAH groups. White arrows indicate the delay of peak pressure, and the black arrow indicates the difference in flow and pressure waveforms.

The major advantage of our framework shown here is the animal-specific *in-vivo* flow data along with the mechanical properties of the downstream vessels LPA and RPA. We can run these simulations to test the hypothesis that the stiffening of proximal pulmonary arteries is an important determinant in PAH. Current limitations include the high computational cost due to small step sizes and lack of MPA elastic modulus measurements due to the geometry of the MPA that is short and curved for tubular biaxial testing.

INTRODUCTION

Modeling and simulation are widely used to study scleral biomechanics and the effectiveness of the models depends on the accuracy of the assumed microstructure [1, 2]. However, most models use continuum approaches which do not incorporate some potentially critical characteristics of the fibers, such as fiber-fiber interactions, in-depth fiber distributions and fiber interweaving [3]. Our goal was to build a specimen-specific fiber-based model of sclera and use it to determine the fiber mechanical properties.

METHODS

General strategy: A model was created and optimized to match fiber orientation data obtained using polarized light microscopy (PLM). Fiber mechanical properties were estimated through inverse modeling by matching model's prediction to experimental measurements (stress-strain curves) obtained from biaxial tensile tests of human sclera [4].

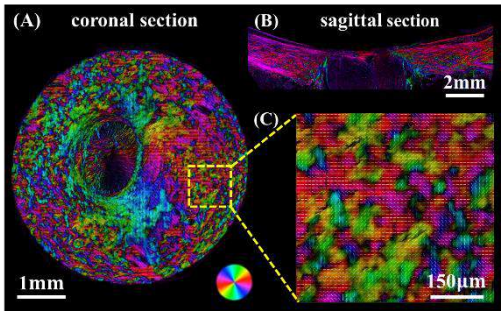

Figure 1. (A) Coronal and (B) sagittal ONH sections were imaged using PLM. The colors indicate the local fiber orientation in the section plane, whereas pixel intensity is proportional to collagen fiber density. (C) Example of selected region of a coronal section.

Image acquisition: Two optic nerve heads (ONH) were sectioned, one coronally and the other one sagittally, both at 30 µm thickness. The sections were imaged using PLM to obtain local collagen fiber density and orientations (Figure 1) [5].

Model construction: Images of 17 consecutive coronal sections were registered to form a volume. A rectangular region (721x691 µm) in the nasal sector was selected to build the fiber model.

To initialize the fiber structure, orientations from the images were sampled in a grid, with grid cell edge length (24 pixels) equal to the average width of small fiber bundles in images (Figure 2). In each grid cell, a straight fiber extending the full span of the volume was traced in the direction of the local PLM orientation. Fibers were thus traced in all images. Fibers were defined in linear truss elements (T3D2) and their locations characterized by Cartesian coordinates X, Y, Z of nodes p_i. Initially, all fibers from an image were in the same plane. To match fiber in-depth positions with PLM data, we first meshed fibers into small elements which were subjected to merge and split in a further step. Then we adjusted Z coordinates of fiber elements based on their visibilities in PLM images. A fiber segment with an orientation that was in good agreement with the PLM orientations (within 45deg) in the images was kept at that level. A fiber segment that disagreed with the local orientation (more than 45deg), was "moved" in Z. This process implies the assumption that fibers are continuous. Fibers were created and processed for each image in the stack.

To resolve fiber overlaps, we used an iterative algorithm that refines and displaces them [6]. Briefly, if the smallest distance between two elements was less than fiber diameter, a collision was detected. All the elements were then moved apart iteratively to resolve collisions. Fiber elements were re-meshed and smoothed to maintain pre-defined average length and fiber radius of curvature.

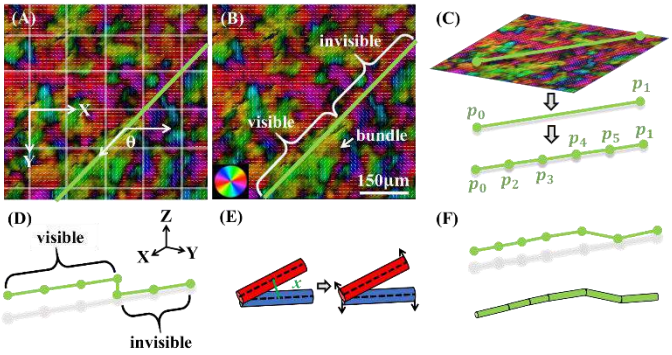

Figure 2. Workflow of creating and processing fibers. (A) grid (shown enlarged) was defined and used to sample orientation θ at a grid cell center, in turn used to trace a straight fiber. (B) In this case, the fiber follows the direction of a yellow-green bundle. Fibers are "visible" or "invisible" if they are in agreement, or not (within 45deg), with the local orientations. (C) (top) Isometric view of the image and the fiber. (middle) The fiber initially had one element and 2 nodes p_1 and p_2 and (bottom) split into five elements and six nodes. (D) The visible elements (p_0-p_2, p_2-p_3, p_3-p_4) were assigned a higher Z coordinate value than invisible elements (p_4-p_5, p_5-p_1), effectively "pushing" the invisible elements to another section. (E) Elements were moved apart if the shortest distance x between them was smaller than fiber diameter, indicating a collision. During the process, elements were combined or split to maintain a pre-defined average length and fiber curvature was adjusted for smoothing. (F) (top) the fiber after processing (bottom) fiber 3D rendering. Fiber diameter was assumed to be 2.98 μm.

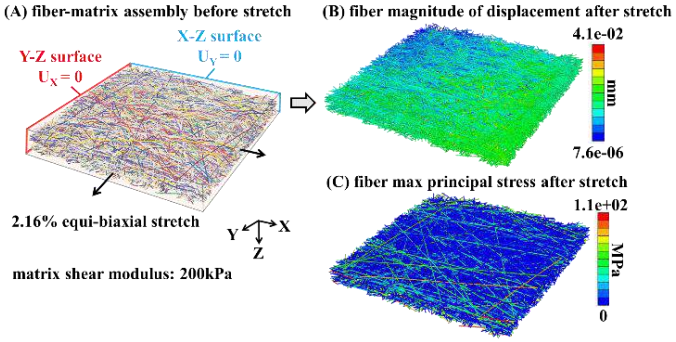

Figure 3. (A) Model as reconstructed, before test. (B, C) After stretch, the fiber mechanics were highly variable.

Model validation and optimization: In-depth fiber orientations of the model were adjusted in an inverse process to match the orientation distribution and anisotropy from the PLM data of the sagittal sections. Wilcoxon rank sum tests were used to compare distributions.

Inverse fitting: Fibers were embedded in a matrix and were assigned a hyperelastic Mooney-Rivlin material property (Figure 3) [7]. The matrix was meshed with linear eight-node, hybrid hexahedral elements (C3D8H) and modeled as a neo-Hookean material. Fiber interactions were approximated by preventing fiber interpenetrations and were defined as general contact with no friction.

Extraction of fiber material properties: To be consistent with the experiment [4], we assigned an equi-biaxial stretch of 2.16% as displacement boundary conditions to the fiber-matrix assembly. The model stress-strain behaviors were calculated, where the stress was computed as the total force along that direction divided by the normal cross-sectional area. The two material constants (C_{10} and C_{01}) of the fiber model were identified which yielded the closest match to the experimental stress-strain curves.

RESULTS

There were no significant differences in fiber orientation distributions between the model and the PLM images, in both coronal ($p>0.7$) and sagittal ($p>0.6$) directions (Figure 4).

The fiber model material constants were C_{10}=5746.9MPa and C_{01}=-5002.6MPa. The resulting model's stress-strain curves fit closely the experimental data in X and Y directions simultaneously (Figure 5).

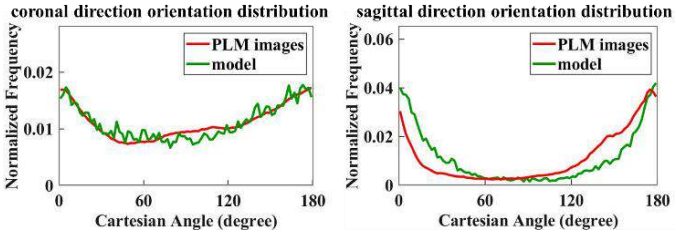

Figure 4. There was excellent agreement between the fiber orientation distributions in the reconstructed model and PLM data in both (left) coronal and (right) sagittal directions.

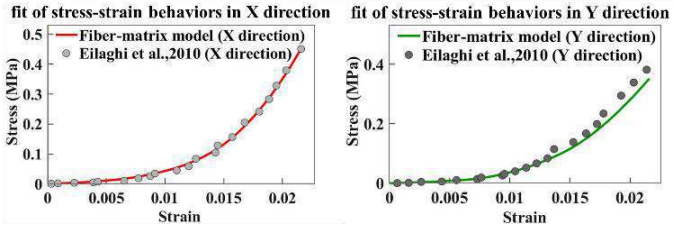

Figure 5. An excellent fit of stress-strain response was achieved between the model and the experiment in both (left) X and (right) Y directions (R^2=0.9978 and R^2=0.9585 for X and Y, respectively).

DISCUSSION

We developed a fiber-based scleral model that explicitly simulated collagen fiber architecture. The fiber orientations of the model matched both in-plane and in-depth high-resolution PLM data. The model accounts for fiber-fiber interactions and long-distance load transfer, previously ignored. The model mechanical behavior fits very well with experimental data. The predicted fiber stiffness is higher than in previous studies [8]. This difference may be due, in part, to the relatively low fiber volume fraction of this model compared with previous ones. The PLM data were from both pig and sheep ONHs, which can be improved in further study. This modeling approach provides unprecedented details of fiber-level tissue behaviors, such as microscale variations in deformations and stresses, which are crucial to understanding tissue remodeling and cell activation.

MEASURING IN SITU LUMBAR FACET CAPSULAR LIGAMENT STRAINS DUE TO JOINT PRESSURE AND RESIDUAL STRESS

INTRODUCTION

The lumbar facet capsular ligament (FCL) plays a potential role in the development of low-back pain (LBP) due to its role of sending proprioceptive and nociceptive signals to the brain[1-2]. LBP affects 70-85% percent of Americans at some point in their lifetime, with almost a quarter of cases resulting in chronic LBP without a clinically identifiable trigger[3-4]. The FCL fully encases the facet joint space between two adjacent articulating vertebrae, with ligament insertion into both the superior and inferior facet joint of the vertebra. The FCL's structural matrix consists of collagen and elastin fibers. The collagen fibers are highly aligned and primarily oriented bone-to-bone, resisting loads parallel to their orientation and preventing painful motions from occurring. The FCL also encapsulates synovial fluid within the joint space that lubricates the articulating joint surfaces as well as pressurizes the FCL *in vivo*. Given the complicated anatomical structure of this joint, mechanical testing of the FCL is limited to planar off-bone samples. Excised, off-bone FCL samples have been well characterized with many previous studies capturing its structural-mechanical relationship via uniaxial[1], biaxial[5] and shear[6] testing.

Little is known, however, about the state of the FCL and its constituent collagen and elastin fibers *in situ*. Two factors to consider are (1) the ligament's residual stress due to its attachment to the vertebrae, and (2) the pressurization of the joint space via the encapsuled synovial fluid. These constraints can cause the FCL to be under strain *in vivo*, even when the joint is unloaded, and cutting the FCL off the bone for planar mechanical testing releases the ligament from these constraints, altering the rest state prior to experimentation. Therefore, both residual strain and inflation of the ligament due to pressurization must be considered when relating the mechanics of planar off bone FCL samples back to its *in situ* state. In this study, we conducted inflation and residual strain tests to capture the *in situ* strain state of the FCL.

METHODS

Sample Preparation

One donor lumbar spine (F, age 41), without a history of spinal pathologies, was obtained through the Anatomy Bequest Program at the University of Minnesota Twin-Cities. The spine was cleared of superficial tissue to expose the posterior region of a left L3L4 FCL. The FCL sample was speckled with dried Verhoeff-Van Geison stain that had been crushed into a fine powder prior to speckling.

Inflation Testing

The cadaveric FCL was injected with roughly 0.55 mL of 1% PBS at a rate of 1 mL/min into the joint space between adjacent facet pairs. The pressure within the joint space was measured using a pressure transducer (Harvard Apparatus), and a baseline pressure drop due to flow through the needle was established prior to insertion into the joint space. At the conclusion of the inflation test, the PBS was withdrawn from the joint space to return the FCL to its original, undeformed state prior to residual strain testing.

Residual Strain Testing

The FCL was released of its residual stress by cutting a rectangular sample from the center of the ligament. Careful consideration was taken to fully release the underside (anterior) of the ligament off the bone.

3D Strain Tracking and Analysis

Over the course of the inflation and residual strain tests, FCL motion was tracked in 3D using a two-camera stereo system. Surface ligament deformations were analyzed using MultiDIC[7], where a region of interest (ROI) was selected to include the released area and the area immediately surrounding it. The residual and elastic deformation, or deformation due solely to inflation of the joint space, were obtained for each discretized element on the tracked ROI. The total deformation gradient tensor was calculated using equation 1:

$$\boldsymbol{F} = \boldsymbol{F}_{\boldsymbol{I}} * \boldsymbol{F}_{\boldsymbol{R}}^{-\boldsymbol{1}} \quad (1)$$

where $\boldsymbol{F}$ is total deformation, $\boldsymbol{F_R}$ is the deformation due to releasing the residual stresses, and $\boldsymbol{F_I}$ is the inflation-induced deformation (Fig 1).

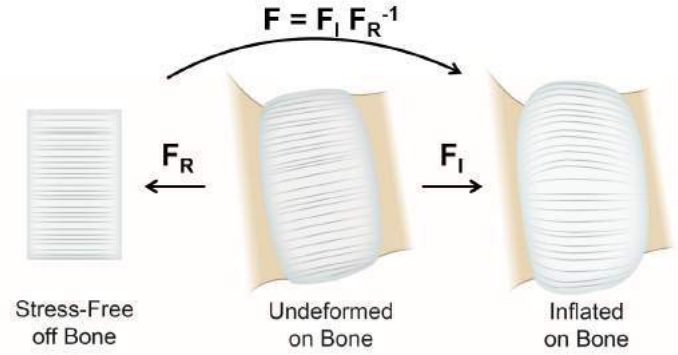

Figure 1: Posterior view and deformation of the FCL in a stress-free (F_R) and inflated state (F_I). The total deformation (F) of the ligament is considered to be the combined deformation of the residual and inflated states.

The maximum first principal strain was calculated as the max eigenvalue of the Green-Lagrangian strain tensor, as calculated from **F** using equation 2:

$$\boldsymbol{E} = \frac{1}{2}(\mathbf{F}^{\boldsymbol{T}}\mathbf{F} - \boldsymbol{I}) \quad (2)$$

where $\boldsymbol{E}$ is the Green-Lagrangian strain tensor, and $\boldsymbol{I}$ is the identity.

RESULTS

A relationship between joint pressure and volume of injected PBS is shown in Fig. 2a. Initially, the pressure increases linearly before a non-linear pressure response is observed, which may suggest that the joint space was initially filling with PBS before the ligament was loaded and contributing to the observed phenomenon. The residual strain is shown in Fig 2b with an average max 1st principal strain of 13.3% across 287 ROI elements.

The inflation strain, as measured from inflation testing, and the total max 1st principal strain was calculated for three points along the pressure-volume curve (Fig. 2c-h). Within the 287 ROI elements tracked during the residual strain test, the average of the inflation max 1st principal strain was 4.1%, 7.7%, and 10.7% for the strain distribution shown in Fig. 2 c, e, and h, respectively. Subsequently, the average of the calculated total max 1st principal strain was 14.7%, 16.1%, and 23.2%, respectively (Fig. 2 d,f,h).

DISCUSSION

In this work, we paired an inflation test with a residual strain test to decouple ligament strains from either inherent residual stresses and inflation stress due to pressurization of the joint space. We obtained ligament strain distributions when the ligament was inflated and then released from its residual strain, which allowed us to calculate the contribution of each to the total observed strain. To our knowledge, this is the first mechanical characterization of the *in situ* state of the FCL.

An accurate characterization of the local mechanics of the FCL is crucial to understanding the influence of the FCL on spinal motions, and the deformations that may result in nerve strain and pain signaling. Overlapping regions of similar tensile or compressive strains in the inflation and residual strain distribution compound to give localized regions of high total strain, indicating that these may be regions capable of triggering a pain signaling cascade (Fig. 2). An average max residual strain of 13.3% would significantly lengthen collagen fibers that become crimped in off bone FCL samples. Due to experimental limitations, there is no known record of pressure within the *in vivo* lumbar FCL joint space, but inner capsular pressure is essential for healthy fluid movement in joints[8] so we can assume the pressure is non-

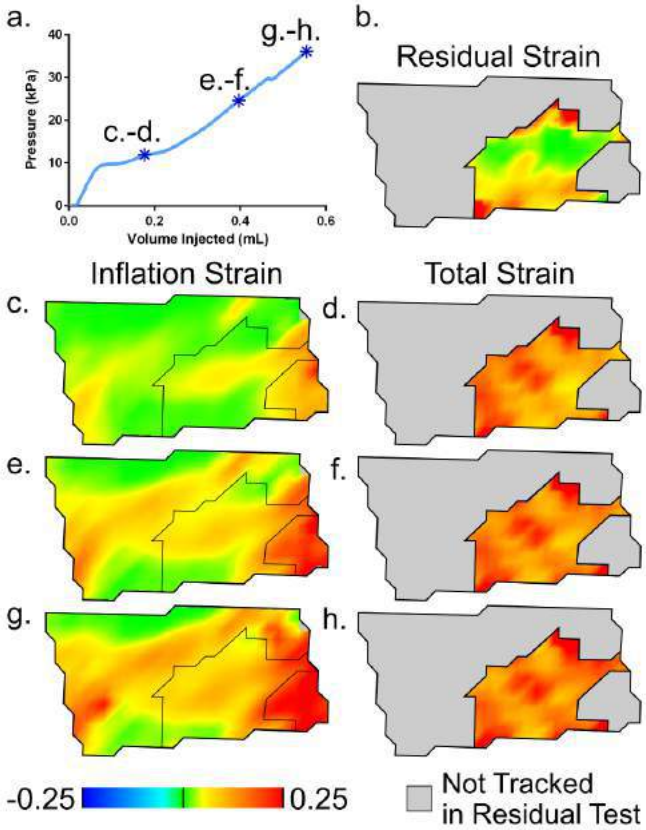

Figure 2: (a.) FCL pressure-volume relationship with three analysis points marked (*). (b.) The max 1st principal strain of the residual as observed when a portion of the ligament was removed from the bone. The max 1st principal strain observed during inflation with low (c.), medium (e.), and (g.) high volume of fluid injection and the corresponding calculated total max 1st principal strain (d.), (f.), and (h.), respectively. Outline in c, e, and g corresponds to tracked area in d, f, and g. A portion of the ROI mesh elements (gray) were not tracked due to either their location outside the portion of the ligament cut during the residual strain test or due to high correlation coefficient between the tracked stereo images.

negligible. Therefore, we can use these experimental results to establish a baseline strain distribution for undeformed, pressurized FCLs and, using residual strains, can relate the mechanics of planar FCL samples back to their on-bone state, furthering our understanding of *in vivo* FCL mechanics.

INTRODUCTION

Aortic stenosis (AS) is a prevalent form of aortic valve disease. In AS, the leaflets become thickened, stiffened, and calcified. In general, calcification and aging contribute to AS. Calcific aortic valve disease (CAVD) is a form of AS where the calcium deposits produced in the valve leaflets accelerate the natural stiffening and thickening process due to aging, and ultimately the valve dynamics is impaired [1]. CAVD is a multistage process. The first phase of CAVD shares similarities with atherosclerosis. However, the major distinction between atherosclerosis and CAVD is in the second phase; in this propagation phase, valvular interstitial cells (VICs) differentiate to a pro-calcific phenotype, and the resulting apoptotic bodies create nucleation sites for calcium deposition. The outcome is a stiffer and thicker valve structure that compromises valve functionality. Calcification is more likely to occur on the aortic side of the leaflets [2], which has been linked to the complex hemodynamic environment in this region.

Conversely, aging has an inevitable effect on biological systems. Aortic valve leaflets are known to become thicker and stiffer due to aging [3]. Consequently, aging affects the dynamic of the valve. Given the large time-scale for CAVD progression, aging also needs to be considered in CAVD growth models.

Modeling CAVD is a multiscale problem. Although the stiffening and thickening of leaflets due to aging and calcification take place over the time-scale of months/years, the valve opening and closing occurs over one cardiac cycle. This demonstrates the temporally multiscale nature of CAVD. In this study, we have developed a multiscale model that can couple the transient dynamics of aortic valve with long-term growth and remodeling (G&R) due to calcification and aging. Specifically, we propose a multiscale continuum growth framework and couple transient aortic valve dynamics with *global* tissue thickness growth and stiffening due to aging, and *local* tissue thickness growth and stiffening due to calcification. Subsequently, we study the transient dynamics of the aortic valve during these processes using measures such as the geometric orifice area (GOA), which are of clinical interest.

METHODS

An idealized 3D aortic valve was the assumed geometry. The model included the valve leaflet, the aortic root, the sinus, and the ascending aorta. To simplify the model, the three leaflets were considered to have the same size, and symmetry was used where only half of one leaflet was considered to reduce the computational cost required in performing several cycles of nonlinear transient structural mechanics simulations. The baseline valve dimensions were collected for a healthy 35 years old subject [4]. The model was discretized into 360K tetrahedral elements with higher resolution in the leaflet. The model was meshed in SimVascular. The aortic wall was assumed as a linear hyperelastic material with a single term Mooney-Rivlin constitutive equation (Eq. 1a). The leaflet was considered as anisotropic hyperelastic material with the strain energy defined in Eq. 1b [5].

$$W_{wall} = c_{wall}(I_1 - 3), \tag{1a}$$

$$W_{valve} = c_1\left(e^{c_2(I_1-3)} - 1\right) + c_3\left(e^{c_4\left(\sqrt{I_4}-1\right)^2} - 1\right), \tag{1b}$$

where I_1 is the first invariant of the right Cauchy-Green strain tensor and I_4 models the anisotropic behavior due to collagen fibers in the circumferential direction. A density of 1100 kg/m^3 was used for all tissues. A transient nonlinear structural mechanics solver was implemented in FEniCS using quadratic elements. Namely, Cauchy's equation of motion was formulated in the reference configuration for a nearly incompressible material

$$\rho_0 \frac{\partial^2 U}{\partial t^2} - \nabla.(\mathrm{F_e} S) = \rho_0 b_0, \quad \text{where } F_e = F_t F_g^{-1}. \tag{2}$$

In Eq. 2, F_t is the total deformation gradient, F_e is the elastic part, and F_g is the growth part of the deformation gradient [6]. Boundary conditions (BCs) include fixing the vessel wall in the circumferential and axial directions at the ends (zero Dirichlet BC) and pulsatile pressure waveforms applied at the vessel wall and leaflet (Neumann BC) driving the tissue dynamics. An algorithm was developed to couple the dynamics of the valve in a cardiac cycle with the local/global growth and stiffening effects due to calcification/aging. Our proposed algorithm

has six components and simulates calcification and aging for a person between 35 to 85 years old. The calcification growth pattern was pre-assumed in this study based on clinical data. In total, we simulated 10 cardiac cycles sampled within 824 growth stages that spanned between the above ages. Our model includes several key mechanisms: *1- Global growth of the aortic valve leaflet due to aging:* Aging-related valve thickness changes were modeled. The direction of the growth was assumed to be normal to the surface of the leaflet. The total leaflet thickness growth over these 50 years (35 to 85 years old) was assumed to be 81 percent. *2- Global stiffening of aortic valve due to aging:* The valve stiffness was globally increased linearly due to aging during these 50 years such that the final stiffness was 2.3 times the baseline. *3- Local growth of aortic valve due to calcification:* The calcification pattern was assumed to be around the coaptation area based on prior clinical studies. The calcification process was assumed to start from 60 years old. The tagged band for local growth was the first two layers of elements in the aortic side of the leaflet. 100 percent local growth for these two layers was prescribed from 60 to 85 years old. *4- Local stiffening of aortic valve due to calcification:* The stiffness of the elements corresponding to local growth (calcification) was increased to the level reported for calcium deposits [7]. *5- Global stiffening of the aortic wall due to aging:* The aortic wall stiffness was increased during the 50 years based on clinical data. *6- Dynamics of the valve:* global and local growth and stiffening were considered to happen in the timescale of years. However, each heartbeat is about one second. In Cauchy's equation of motion (Eq. 2), the first left-hand-side term (acceleration term) was assumed zero when each growth step was first being prescribed. However, during the corresponding transient cardiac cycle simulation, the acceleration term was considered. Finally, the transvalvular pressure gradient was increased with age based on clinical data.

RESULTS

GOA was calculated by projecting the leaflet surface to the plane perpendicular to the aortic root. For the healthy case (35 years old), the intra-cardiac temporal variation of GOA and displacement for a point at the leaflet tip were verified with previous studies [4,8]. Subsequently, GOA results for different ages (35 years old to 85 years old) were computed, which are shown in Fig. 1. The model shows a heterogeneous reduction in GOA during early years where aging is only applied and later years (after 60 years old) where aging and calcification are applied.

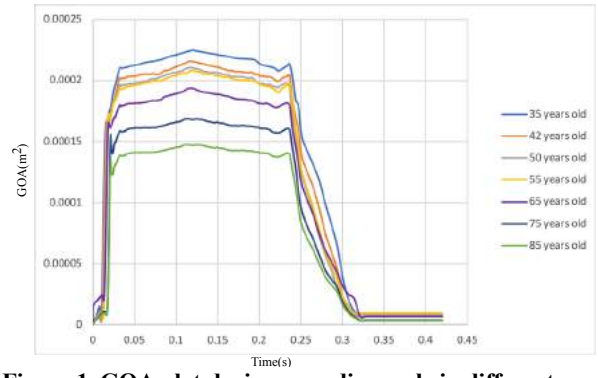

Figure 1. GOA plot during a cardiac cycle in different ages.

In Fig. 2, the displacement patterns for 3 different ages are shown. In the top row, the maximum valve open position in systole is shown for 35, 55, and 75 years. In the bottom row, changes in the valve thickness due to aging/calcification can be observed. Our model simulates the concurrent effect of aging and calcification (prescribed a priori) on the transient valve dynamics throughout 50 years.

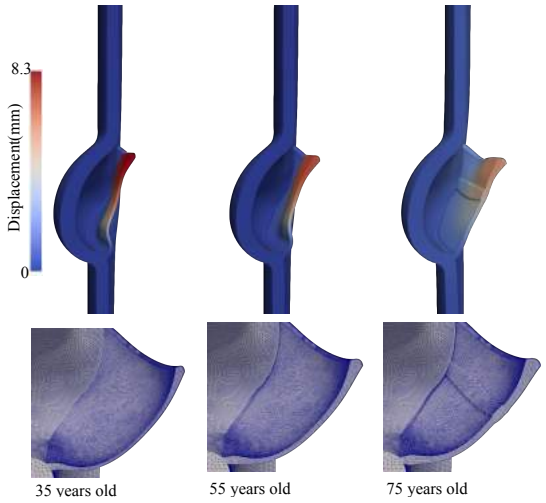

Figure 2. Top row: Peak systolic displacement patterns. Bottom row: Aortic valve thickness growth for different ages.

DISCUSSION

We developed a novel model to investigate how calcification and aging influence the transient dynamics of aortic valves. We simulated global stiffening/growth due to aging (based on population-averaged data) and local stiffening/growth due to calcification (based on a common calcification pattern). Our model demonstrates the substantial effect of calcification on aortic valve dynamics in comparison to aging.

Our study has several limitations. First, we have used an idealized geometry. Second, the calcification and aging patterns were prescribed a priori. Additionally, the thickening in the aortic wall and changes in aortic diameter were deemed negligible. While we validated our baseline model with clinical data (results not shown), validation of long-term results is expected to be challenging and remains to be performed. Nevertheless, our goal was to demonstrate how local (pathological) and global (aging) growth and stiffening could be simulated and coupled to transient nonlinear structural mechanics simulations of valve dynamics.

Our model is an early step towards a comprehensive multiscale continuum model of CAVD. Our model simulated the temporal multiscale process in CAVD based on a "pre-assumed" calcification model. In future work, we plan to extend our model to consider hemodynamics-driven calcification using a mechano-sensitive systems biology model of calcification [9]. The ultimate goal is to develop a spatiotemporally multiscale model that can capture the two-way coupling between aortic valve hemodynamics and calcification.

INTRODUCTION

The assessment of intracranial aneurysm (IA) rupture risk still remains challenging due to its complex nature [1]. Patient-specific remodeling processes, driven by the local hemodynamics and the individual wall properties, might lead to the formation of a stable dilation or a vulnerable, rupture-prone aneurysm shape. Apart from advanced analyses of morphologic and hemodynamic parameters [2], the acquisition of IA wall imaging becomes more and more feasible [3]. Aneurysm wall enhancement on vessel wall MR imaging (VW-MRI) after administration of Gadolinium-based contrast agents has been proposed as a surrogate marker for wall inflammation and aneurysm instability. Thus, advanced quantitative analyses were carried out, e.g., using image-based blood flow simulations, to associate wall enhancement with specific hemodynamic conditions. In the most recent study, Hadad et al. [4] found that IA wall enhancement regions tend to have lower wall shear stress than nonenhanced regions. Similar findings were reported by Larsen et al. [5], demonstrating that focal wall enhancement is colocalized with lower wall shear stress, lower maximum oscillatory shear, and increased low shear areas.

Besides those observations, it must be noted that flow artifacts occurring in the vicinity of the aneurysm wall can additionally contribute to the signal enhancement based on VW-MRI measurements. In this regard, Cornelissen et al. [6] showed in *in vitro* experiments that insufficient slow-flow suppression can result in enhancements similar to those attributed to vessel wall inflammation on VW-MRI sequences.

To further quantify this effect, this study investigates the role of local hemodynamics on the intensity of VW-MRI signal in three patient-specific IA models.

METHODS

To allow for extensive quantitative analysis of the VW-MRI enhancement, three representative, patient-specific IAs were selected. Specifically, one basilar tip aneurysm, one case located at the carotid terminus, and one originated at the middle cerebral artery bifurcation were chosen. The corresponding image datasets, acquired using digital subtraction angiography (Allura XperFD 20/10, Philips, Best, the Netherlands), were processed according to Pravdivtseva et al. [7]. The resulting three precise flow models were used to obtain flow *in vitro*.

VW-MRI and Phase-Contrast Magnetic Resonance Imaging (PC-MRI) were performed for all models to acquire the luminal signal enhancement and the corresponding time-resolved, three-dimensional velocity fields. The measurements were performed on a 3T MR system (Ingenia CX, R5 V6.1, Philips Healthcare, Best, the Netherlands).

In addition to the PC-MRI measurements, image-based blood flow simulations were carried out, enabling analyses at the highest temporal and spatial resolution (Δt=1 ms, Δx=0.1 mm). Here, numerical results were obtained using the fluid dynamics solver STAR-CCM+ 14.04 (Siemens Product Lifecycle Management Software Inc., Plato, TX, USA). Corresponding boundary conditions (time-dependent flow and pressure waveforms, fluid properties) were derived from the measurements to establish an identical flow setup.

RESULTS

As demonstrated in Figure 1, the signal enhancement drastically deviates throughout the different IA models. Higher inflow velocities lead to less signal intensity, while regions of slow flow correspond to intra-luminal enhancement. The highly-resolved blood flow simulations further confirm this observation and are capable of reproducing visible inflow jet phenomena (e.g., Figure 1, Model 3).

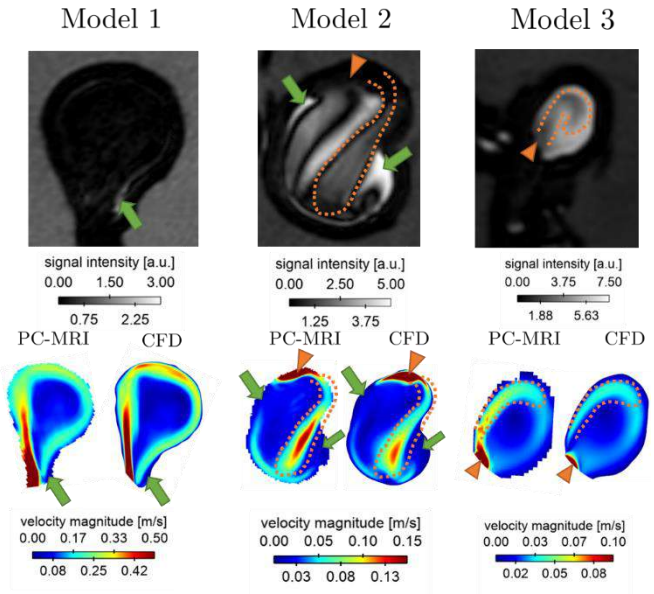

Figure 1: Illustration of the signal enhancement based on VW-MRI measurements (top) and the local hemodynamics (bottom) in the lumen of three IA models. Enhanced regions are marked green (arrows), and signal void zones are represented in orange (triangles, dashed lines)

To further quantify the underlying flow structures, Figure 2 contains the results of a cluster analysis. Here, regions of similar VW-MRI signal intensity values are compared to the corresponding velocity values. It can be noticed that almost identical trends are visible. Specifically, an exponential relationship between the local velocity value and the associated extent of enhancement exists in all cases. Hence, the strongest signal intensity appears in regions where the blood flow is very low (i.e., smaller than 3 cm/s).

DISCUSSION

The role of wall enhancement on VW-MRI as a potential surrogate marker for the assessment of IA rupture risk is a recent research question awakening the interest of many neurointerventionalists [8]. Although its clinical use for IA stage evaluation remains currently uncertain, an increasing number of observations inficate that aneurysms at risk could be identified with these modified MR-sequences [3]. However, in addition to wall enhancement, increased signal intensity attributable to slow flowing blood was observed within the aneurysm lumens [9]. To quantify the luminal enhancement, this study demonstrated the relationship between local flow velocities and the corresponding MR signal intensity. Based on three patient-specific IA models, it was shown that low flow results in strong enhancement.

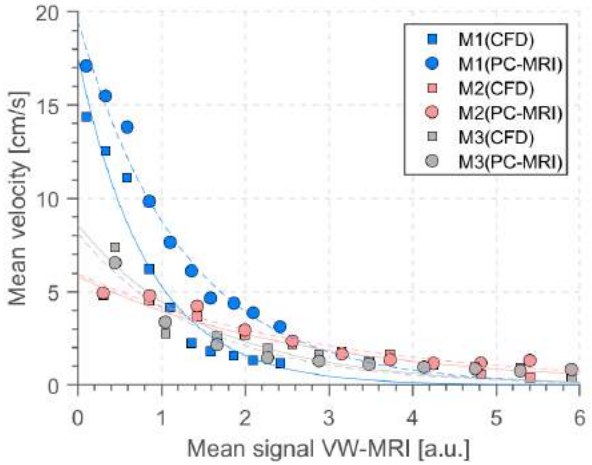

Figure 2: Cycle-averaged velocity values measured using PC-MRI and CFD over mean signal intensity for all IA models.

Therefore, VW-MRI can be used to assess potential inflammatory processes within the aneurysm wall and to detect regions of slow flow inside the lumen. This could be especially of interest for identifying thrombotic regions after endovascular treatment or detecting a recurrence.

Finally, it is important to outline several existing limitations regarding the investigations. First, due to enormous efforts with respect to the measurements and simulations, only three IA cases were considered. For generalizable conclusions, further observations with more aneurysms varying in size and morphology have to be carried out. Second, a blood-mimicking fluid was used instead of real blood, and the fluid-dependency of VW-MRI needs to be further investigated.

INTRODUCTION

Cardiovascular diseases are among the major causes of morbidity and mortality worldwide. Surgical interventions are often needed to replace diseased vessels with autologous tissues or synthetic grafts. However, autologous tissue sources are limited, and synthetic grafts often have complications affecting long-term patency, particularly for small-diameter vascular grafts. *In situ* cardiovascular tissue engineering, which aims to transform biodegradable scaffolds into living tissues at the implantation site, has the potential to overcome these limitations. Currently, there are still many questions related to how the engineered tissues remodel after implantation, and how the native-like organization can be achieved to enable proper functionality. To answer these questions, a mechanistic understanding of the processes regulating functional vessel growth and remodeling is needed.

Vascular growth and remodeling are mediated by vascular smooth muscle cells (VSMCs), in turn influenced by mechanical cues and cell-cell signaling. VSMCs demonstrate a quiescent contractile phenotype in mature vessels, and switch towards a more proliferative and migratory synthetic phenotype when growth and remodeling is needed. These phenotypic changes are regulated by Notch, a juxtacrine signaling pathway [1]. Increasing evidence suggests that Notch signaling is mechanosensitive [2], and computational modeling has recently predicted that this Notch mechanosensitivity can regulate the phenotypic switch in VSMCs and explain the establishment of homeostasis [3]. Nevertheless, these computational findings are scarcely validated and the combined effects of strain and Notch on VSMCs of different phenotype are poorly characterized. Validating this prediction and understanding the complex interaction between mechanical cues and Notch signaling in VSMCs will provide an opportunity to steer this interaction and control vascular growth and remodeling in engineered tissues. The outstanding question is therefore: '*Does Notch signaling regulate strain-mediated changes in VSMC phenotype?'*.

METHODS

Human coronary artery smooth muscle cells (Lonza) were cultured for 7 days in Medium 231 (Gibco) supplemented with either smooth muscle growth supplement (Gibco) to obtain synthetic VSMCs, or smooth muscle differentiation supplement (Gibco) to obtain contractile VSMCs. In addition, the Jagged1 ligand was immobilized on the culture surface in static conditions to investigate if activation of Notch signaling can directly lead to differentiation in synthetic VSMCs.

Bioflex culture plates (Flexcell) were coated with bovine fibronectin (Gibco) in the center of the wells. One day after cell seeding on the Flexcell, cells were either treated with the γ-secretase inhibitor DAPT (Sigma) to inhibit Notch signaling, or with the vehicle DMSO at a similar concentration as a control. Furthermore, cells were either cultured statically or equibiaxially stretched with the Flexcell Tension System at 1 Hz for 48 hours. The membranes of each well were marked and tracked with a camera. The displacement was analyzed, and the corresponding strain was calculated via digital image correlation.

Immunofluorescence (IF) imaging and quantitative polymerase chain reaction (qPCR) were conducted to characterize the changes in cell phenotype, ECM production and Notch signaling upon stretch. In particular, cells were stained for the contractility marker α-smooth muscle actin (αSMA), vinculin, F-actin and collagen. The gene expression of phenotypic markers αSMA, calponin and Ki67; Notch-related genes Notch1, Notch2, Notch3 and Jagged1 were compared in static and stretched conditions, as well as the control and Notch-inhibited cells. One-way ANOVA and post-hoc Tukey HSD were used to determine statistically significant differences between experimental

groups (GraphPad Prism v8). The qPCR data were plotted as boxplot and differences were considered statistically significant for $p<0.05$.

RESULTS

Synthetic and contractile VSMCs showed differences in their morphology and gene expression. Contractile VSMCs were larger in size, had more and elongated focal adhesions, and they expressed more αSMA (Figure 1) and calponin compared to synthetic VSMCs. Moreover, αSMA was organized as fibers in contractile VSMCs, differently than synthetic VSMCs (Figure 2A&C).

The initially synthetic cells cultured on the immobilized Jagged1 coating showed similar trends as the contractile VSMCs, in terms of organized stress fibers and gene expression, confirming a role of Notch in determining VSMC phenotype. In agreement with this, the expression of proliferation marker Ki67 was increased in synthetic VSMCs compared to the contractile and Jag1-stimulated groups.

The contractile phenotype required Notch signaling to be active. In fact, the stress fiber organization observed in contractile VSMCs disappeared when Notch signaling was inhibited (Figure 2C-D). αSMA (Figure 1), calponin, and Jagged1 expressions also decreased in Notch-inhibited contractile VSMCs. On the other hand, Notch inhibition hardly affected synthetic VSMCs (Figure 1&2A-B).

Upon strain application for 48 hours, our results showed that αSMA expression in contractile VSMCs decreased to the level of synthetic VSMCs (Figure 1). In addition, stress fibers were not detected in stretched contractile VSMCs (Figure 2G), and Jagged1 expression was reduced. This suggests a transition of contractile VSMCs towards a more synthetic state mediated by Jagged1 reduction upon stretch. In agreement with this, the expression of αSMA did not change in synthetic VSMCs upon stretch (Figure 1). Moreover, Notch inhibition in stretched contractile VSMCs did not have a synergistic effect on αSMA expression.

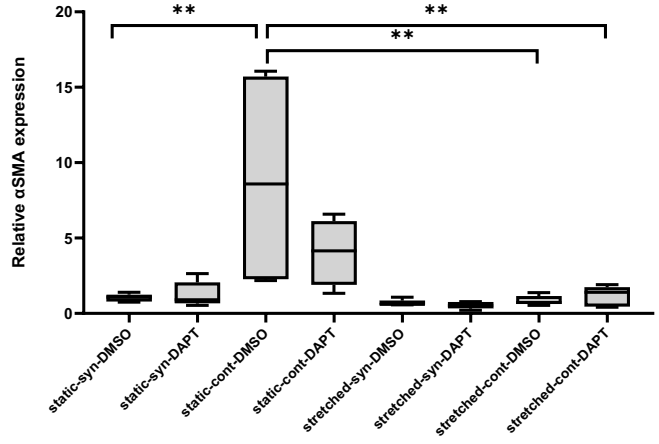

Figure 1: The gene expression of αSMA was compared in static and stretched (10% strain for 48 hours at 1 Hz) VSMCs. DMSO was added as a control to Notch-inhibited (DAPT) groups. All expression values were normalized to static synthetic control group (syn: synthetic VSMCs, cont: contractile VSMCs) ($p<0.01$, $n=5$).**

DISCUSSION

Our results so far indicate that Notch signaling might have a key role in regulating strain-mediated changes in VSMC phenotype. Contractile VSMCs obtain stress fibers (Figure 2C) and increase their Notch activity. Notch induction promotes a contractile-like phenotype, whereas Notch inhibition leads to a synthetic phenotype in VSMCs. Similarly, strain decreases Notch signaling and induces a shift towards a synthetic state in contractile VSMCs. In addition, Notch inhibition in stretched VSMCs has a similar effect. To better understand the role of Notch in strain-mediated changes, future efforts will be directed to analyze Notch-stimulated VSMCs. Unravelling this complex interaction is an important step towards controlling functional growth and remodeling in engineered vessels.

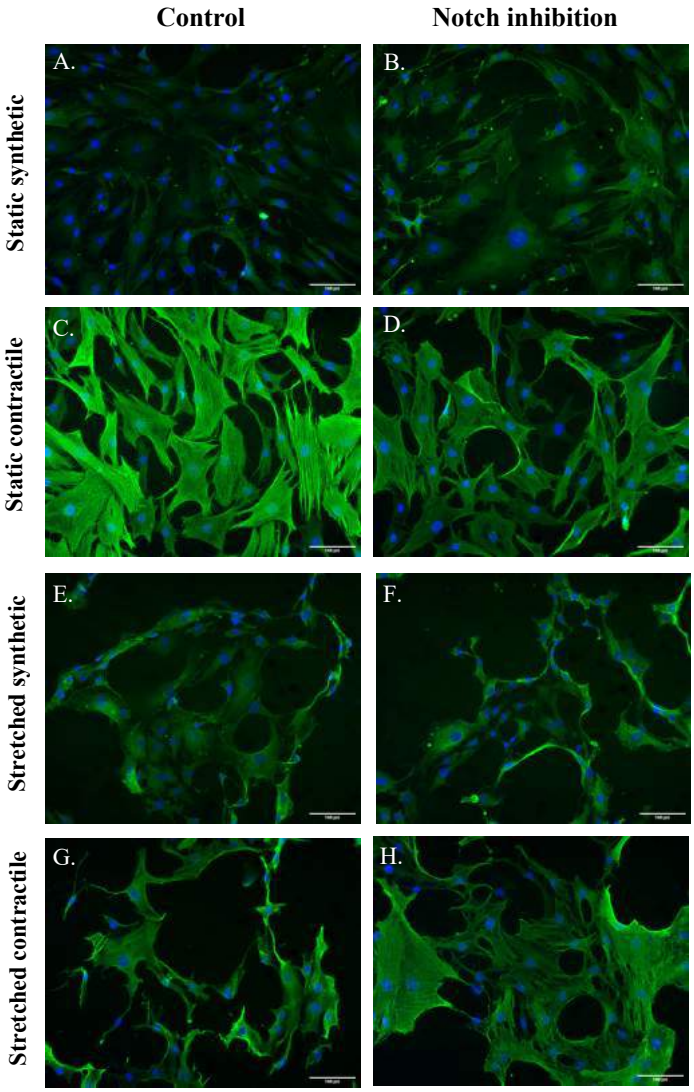

Figure 2: IF staining of αSMA was visualized for synthetic and contractile VSMCs treated with either DMSO as a control or DAPT for Notch inhibition. The cells were radially stretched at 10% strain, 1Hz, for 48 hours (E-H) and compared with the static controls (A-D). (green: αSMA, blue: DAPI. Scale bar: 100 um)

A MULTISCALE COMPUTATIONAL MODEL FOR CELL-SIGNALING DRIVEN GROWTH AND REMODELING OF ARTERIES

New Haven, CT, USA

INTRODUCTION

Soft biological tissues adapt, remodel, and repair in response to diverse mechanical and biochemical stimuli, which are sensed by cell surface receptors. Downstream signaling leads to altered gene expression and gene products, and many such transcriptional changes alter extracellular matrix composition and organization, orchestrating changes in tissue geometry and biomechanical properties, thereby affecting tissue functionality. Cell signaling is mechanosensitive, and tissue-level biomechanical changes induce further changes in cell signaling in the form of a feedback loop. This feedback is crucial to understand, since tissue homeostasis requires negative feedback, whereas positive feedback is considered a potential driver of disease.

Although there has been much progress in modeling cell signaling networks and tissue-level growth and remodeling (G&R) separately, a continuing challenge has been coupling computational models across these disparate scales to enable modeling from transcript to tissue. Coupled models capturing the feedback between cell signaling and tissue mechanics promise to provide improved mechanistic insight into remodeling by allowing studies of the role of specific signaling proteins and pathways. In addition, they uniquely allow for studies of targeted interventions or disrupted signaling and the resulting effects on potential tissue maladaptations. Here, we present our new multiscale modeling framework for cell-signaling driven growth and remodeling of arteries [1]. We have coupled of a logic-based cell signaling model and a constrained mixture model of soft tissue G&R, motivated by the fundamental need to capture changes in cell phenotype and associated changes in deposition and degradation of individual components of the extracellular matrix. We view a mixture-level balance of mass equation as central to coupling outputs of the cell signaling model to inputs in the constrained mixture model. For illustrative purposes, we focus on homeostatic control of arterial G&R in response to sustained changes in blood pressure and flow.

METHODS

We couple two previously developed modeling frameworks to capture associated multiscale interactions: one for vessel-level growth and remodeling and one for cell-level signaling. At the vessel level, we use a constrained mixture model [2] to model evolving wall mechanics, considering three primary load-bearing constituents: elastin-dominated, collagen-dominated (with four families of fibers), and smooth muscle cell-dominated. Such models have proven useful in predicting diverse adaptations as well as disease progression using phenomenological constitutive relations. Nevertheless, we now seek an improved mechanistic understanding of these processes and we replace phenomenological relations for stress-driven production and removal of mass with outputs of a logic-based signaling model [3] which directly predicts changes in collagen synthesis, matrix metalloproteinases, and cell proliferation in response to altered intramural stress, wall shear stress, and exogenous angiotensin II.

The signaling model accounts for activation and inhibition reactions across 52 species of interest, focussing on six main pathways (Smad, p38, ERK, JNK, PI3K/mTOR, RhoA/ROCK), with relations inferred from the literature. Central to the multiscale coupling are the widely separated timescales between G&R (days, weeks, months) and signaling processes (seconds, minutes, hours). Relatively, the stress inputs to the signaling network change slowly, thus it is reasonable, and computationally efficient, to assume steady state cell signaling within G&R timesteps (1 day). Thus, ordinary differential equations (ODEs) for cell signaling reduce to nonlinear algebraic equations.

The coupled model is outlined schematically in Fig 1. Under imposed changes in blood pressure and flow, we calculate tissue-level changes in intramural and wall shear stresses, which depend on material properties, wall geometry, and fold-changes in applied loads. These stresses form inputs to the cell signaling model, outputs of which govern phenotypic modulation of cells and associated turnover of extracellular matrix. The resulting tissue turnover affects the stresses, which feedback to the cell signaling model, and so forth.

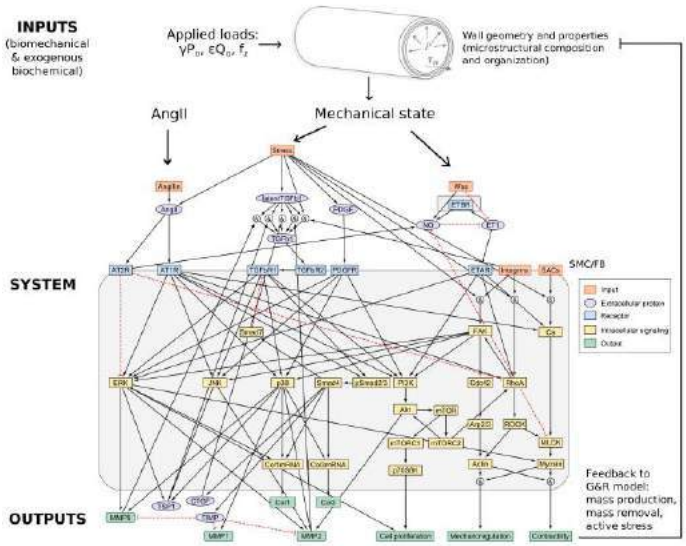

Fig 1. Schematic outline of multiscale coupling. Vessel-level changes in intramural and wall shear stresses feed into the logic-based cell signaling model, the outputs of which govern constituent turnover (collagen, smooth muscle cells) in the vessel-level constrained mixture model. Figure first published in [1] by Springer Nature.

RESULTS

We first verified our model predictions against previously published data from the hypertensive murine infrarenal abdominal aorta in apolipoprotein-E null (ApoE-/-) mice in response to 28 days of AngII infusion [4]. Material parameters were determined previously from pressure-diameter and axial force-length curves from vessels subject to biaxial loading [5], and network parameters were fit to capture the evolved collagen and smooth muscle cell mass densities (calculated from histological data at day 28). Our model then predicted well the evolving vessel geometry, stresses, and composition at intermediate timepoints (0, 4, 7, 14, 21 days).

Next, we verified the model against a broader range of synthetic results generated by a phenomenological model. Such models have long captured diverse experimental datasets, and we aimed to ensure that our model could produce similar behavior over a broad range of pressure and flow perturbations. We considered 15 combinations of pressure and flow perturbations, and fit the coupled model to results for one intermediate combination (a 30% increase in pressure and 5% increase in flow). Using the best-fit parameters for this case, we ran coupled model predictions for the remaining 14 combinations and found the results to be consistent with those from the phenomenological model.

To challenge this new framework, we considered effects of noisy signaling parameters, and replicated the network 100 times to represent heterogeneous cells. Cell signaling networks are inherently noisy, yet robust in function, and we used the coupled framework to investigate the sensitivity of tissue-level outputs to perturbed signaling parameters. We do this in two ways: firstly, with uniformly distributed noise applied identically across each network, and secondly, with uniformly distributed noise applied individually to the 100 networks (simulating cell heterogeneity). We find that higher levels of noise can be withstood when applied heterogeneously, and that the averaged signaling outputs with moderate noise ($\pm$20%) yield robust tissue-level results.

DISCUSSION

Phenomenological models have provided, and continue to provide, considerable insight into the G&R of biological soft tissues. However, given the continually increasing information available on transcriptional changes (e.g. bulk and single-cell RNAseq) and associated cell signaling, there is now an opportunity, and necessity, to incorporate such information into models that predict tissue-level clinical phenotypes. We have now developed a multiscale framework for coupling cell signaling and constrained mixture G&R [1], which will enable myriad future studies in diverse areas. We first verified the implementation and validated tissue-level predictions for the hypertensive murine abdominal aorta, and then for a larger synthetic dataset generated by a previously validated phenomenological model. We also tested the effects of noisy signaling parameters and found tissue-level outputs to be robust to mild signaling perturbations, as must be in the case in real biological systems. To represent cell heterogeneity, we then simulated parallel identical networks with different parameters, and similarly found robust tissue-level responses in the presence of moderate noise. Our results highlight the importance of collective behavior and the protection it offers from the noise, individual fluctuations, and disruptions inherent to cell signaling networks. Within this new modeling framework, the same principles used to simulate heterogenous cells could be extended to support multiple cell types with unique network structures, and be used to better understand associated paracrine signaling. Accordingly, now that the basic framework for coupling is in place, the current tissue-level model can be extended and refined, for example to a bilayered wall model.

INTRODUCTION

The middle cerebral artery (MCA) is one of predilection vessels of aneurysm. In hemodynamics of cerebral aneurysm, a lot of researchers assumed to be rigid wall in CFD. A few numerical approaches were carried out for the cerebral aneurysm with elastic wall in FSI [1]. However, the frequency characteristic of elastic cerebral aneurysm model has not been clarified [2]. In the present study, the effect of wall elasticity on frequency characteristics was experimentally investigated the comparison of deformable with non-deformable models using PIV.

METHODS

Phantom model

The morphology constructed from a patient-specific aneurysm at apex of bifurcation at human middle cerebral artery (MCA) in full-scale is shown in Figure 1. Two outlet vessels M2 and M3 bifurcate from the inlet vessel M1. The left and right morphology show the front (median plane) and the right-side views shown in Figure 1, respectively. The diameter of inlet vessel M1 is d_1= 2.8 mm, and the diameters of each outlet M2 and M3 are d_2 = 2.3 mm and d_3 = 1.8 mm, respectively.

The current phantom model was fabricated in silicone elastomer of Sylgard 184 (Dow Chemical Co.) using a special technique. The wall elasticity is E = 0.67 MPa which was measured in the tensile machine.

Flow circuit

The flow circuit is shown in Figure 2. To reproduce pulsatile flow waveform through human cerebral vessel, the high reproducibility pulsatile pump (Alfa Flow EC-1, FUYO Co.) was employed. The phantom model was immersed in the acrylic bath (40×50×120 mm³). After passing through the phantom model, the flow rates through both outlet vessels were measured by flow meter (Keyence, FD-XS8). The pressure at inlet and two outlets was measured in pressure transducer (Keyence, AP-12S).

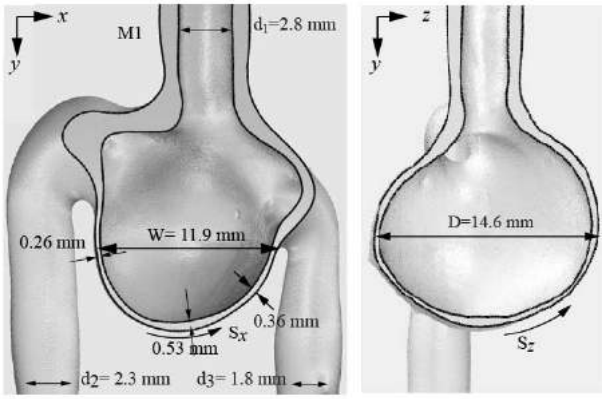

Figure 1: Phantom morphology of front and right side views.

The working fluid is aqueous Glycerol with potassium iodide solution, i.e. Water of 47.38 %, Glycerol of 36.94 %, NaI of 15.68 % [3]. The physical properties are as follows: the density of ρ = 1188 kg/m³, the kinematic viscosity of ν= 3.57×10⁻⁶ m²/s and the refractive index of n=1.412. The maximum and minimum Reynolds numbers are 510 and 255, respectively. The mean Reynolds number of 310 is referred as the flow rate of Q_{mean}= 146 mL/min [4]. One period of pulsatile flow is set to be 1.0 s, the peak flow phase is at t= 0.28 s and the Womersley number is α= 1.86.

RESULTS

At peak systole, the velocity contours in non-deformable and deformable models are shown in Fig. 3. Although both flow patterns are

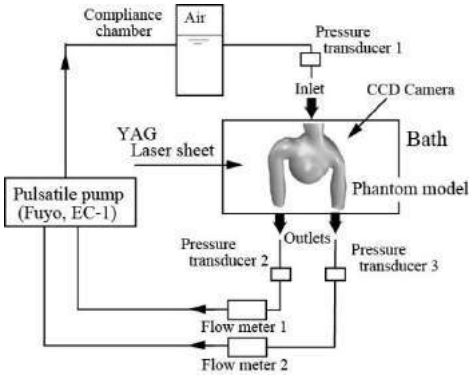

Figure 2: Current flow circuit.

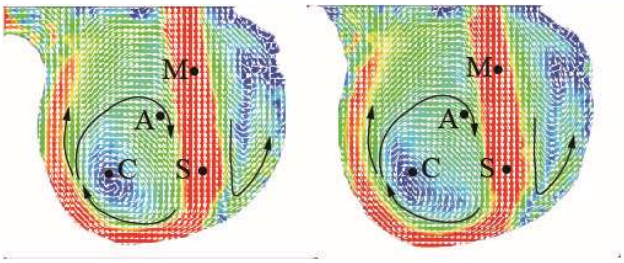

(a) Non-deformable (b) Deformable

Figure 3. Velocity contour at peak systole.

similar and the large clockwise circulating flow appears in left side, the velocity in non-deformable velocity is slightly larger. At typical points C, A, M and S, the frequency characteristic is examined using a SpeedSense M camera (Dantec SYSTEM 8) in PIV. For power spectral density (PSD), velocity data were analyzed over four cardiac cycles at sampling rate of 2000 fps.

Figure 4 depicts PDS at three points C, A & S. At each point at low frequency range, the gradient of PSD decrease in deformable is larger than that in non-deformable models. Furthermore, at high frequency range, PSD reaches constant value for each point and PSDs in deformable are lower than those in non-deformable models.

DISCUSSION

Asymptotical decrease of PSD from 10 to 100 Hz in Fig. 4(a) denotes laminar flow around point C. Also, there was another difference between constant PSD (1×10^{-7}) at >70 Hz in non-deformable and constant PSD (1×10^{-8}) at >100 Hz in deformable models. Furthermore, at low frequency range, the gradient PSD of 2.6 in deformable is larger than that of 1.7 in non-deformable models. Except for point M (not shown here), the gradient PSD in deformable model is larger than that in non-deformable model. In other words, PSD in deformable model steeply decreases. At point M, although there is little gradient of PSD in both models and PSDs are constant over 15-100 Hz because velocity around this point is like uniform flow and there is little velocity gradient. Around points A and S, this trend is similar to that around point C as shown in Figs. 4(b) and (c). Generally, at higher frequency rangePSD in deformable model asymptotically approaches lower constant PSD and it is also by approximately 10-fold lower than that in non-deformable models. So, the small displacement of wall might absorb flow instability.

INTRODUCTION

Healthy articular cartilage withstands complex, repeated loading patterns while maintaining low strains (5-20%) and vanishingly low friction coefficients ($\mu_k < 0.02$).[1] These remarkable capabilities occur primarily through *interstitial lubrication*, whereby pressurized interstitial fluid carries the bulk of applied loads (>95%). How variations in cartilage properties influence these important tribomechanical behaviors remains an unresolved, yet fundamentally important question. While a number of preclinical animal models have been used to study cartilage's compositional and biomechanical variability in health and disease *ex vivo*,[2-4] similar comparative approaches have seen limited application to cartilage lubrication. Moore and Burris showed that improved fluid load support and equilibrium friction behaviors were associated with increased equilibrium contact modulus, increased tensile modulus, and lower permeability in bovine stifle cartilage.[5] To our knowledge, similar studies had not been performed in other model species. Therefore, comparative assessment of healthy cartilage's material properties and tribological performance across model species may serve as a basis for interpreting the functional consequences of disease-related changes in cartilage composition.

We recently performed a comparative analysis of cartilage tribology across five common mammalian models (equine/horse, bovine/cow, porcine/pig, ovine/sheep, and caprine/goat) using our convergent stationary contact area (cSCA) configuration.[6] In the cSCA, hydrodynamic pressurization at the edges of the contact drives, through *tribological rehydration*, the restoration of tissue lubrication, sustaining a sliding environment on the benchtop that is both physiologically consistent and informative. This study revealed incredible consistency in many sliding speed-dependent characteristics of tribological rehydration, despite the presence of noted inter-specimen/species variabilities. In the present study, we sought to uncover predictive correlations that inform critical relationships between tissue geometry, material properties, and tribological behaviors. Importantly, the presence of inherent variability within our study populations allows us to define relationships between tissue properties and biphasic lubrication with bearing on both healthy and diseased tissue function.

METHODS

Osteochondral explants were harvested from the centerline of femoral condyles of five model species.[6] A static loading experiment with optical measurement of *in situ* contact areas was performed for each species to determine the normal loads necessary to generate contact pressures of 0.25 ± 0.05 MPa. Each tribological test began with static compression to drive fluid exudation from the cartilage, enabling the facile observation of tribological rehydration upon initiation of sliding at different speeds. The duration of static compression was calculated from the classical relationship between cartilage's characteristic stress relaxation time and the square of the contact radius.[7] Compression (δ), strain (ε), and kinetic friction coefficients (μ) were measured during bouts of reciprocal sliding at 10-80 mm/s.

A custom microtribometer was used determine cartilage material properties using rate-dependent indentation.[5] Moore and Burris's analytical model based on Hertz biphasic theory was used to calculate compressive modulus (E_{y-}), tensile modulus (E_{y+}), intrinsic permeability (k_0), and the nonlinear flow limiting constant (M).[8]

After tribological and indentation testing, the average cartilage thickness across the center of the bisected cSCA contact and the contact radius-of-curvature were determined.[6] Species-specific explant geometries and material properties were compared using the nonparametric Welch's ANOVA in Prism 9 (significance set at $p <$

0.05). All outcome measures were then correlated using Pearson's method (significance set at $p < 0.01$).

RESULTS

Cartilage thickness increased proportionally with body size (**Fig. 1A**). Equine specimens were the thickest (1.31 ± 0.17 mm), while ovine and caprine samples were the thinnest (0.49 ± 0.09 mm, and 0.40 ± 0.08 mm, respectively). Interestingly, cSCA explant radius of curvature did not vary significantly among species (**Fig. 1B**).

Each species' material properties are shown in **Fig. 1C**. As expected, all specimens exhibited significant tension-compression nonlinearity ($p < 0.0001$, Student's *t*-test; $E_{y+} \approx 10E_{y-}$). Significant differences in compressive moduli were not observed among species ($p = 0.15$). However, tensile moduli of larger species were greater than those of smaller species ($p < 0.05$). Intrinsic (k_0) and strain-dependent (M) permeability values were greatest in smaller species ($p < 0.001$).

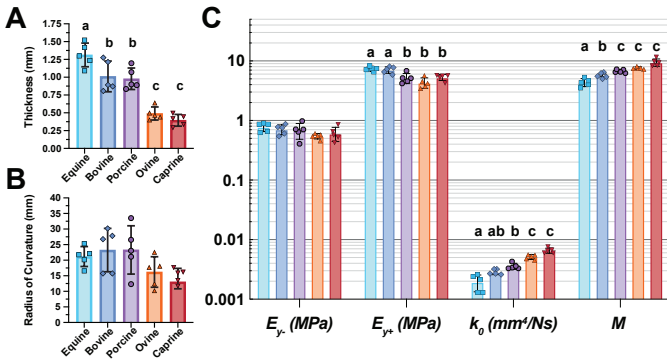

Fig. 1. Geometric (A-B) and material properties (C) of cartilage explants from each model species. Dissimilar letters indicate significant differences ($p < 0.05$, Welch's ANOVA).

The thinnest cartilage explants (ovine and caprine) had the highest intrinsic permeabilities (R = -0.85). Similarly, thicker cartilage had greater compressive moduli (R = 0.63); tensile moduli and intrinsic permeability were inversely correlated with one another (R = -0.61). Correlative analyses also revealed pathlength-dependent characteristics of tribological rehydration: time-averaged compression (δ_{TA}) during static loading (R = 0.62) and compression recovery (δ_{rec}) during high-speed sliding (R = 0.78) were cartilage significantly correlated with tissue thickness. As anticipated from the strong inverse relationship between thickness and permeability, increasing k_0 was associated with decreased ∂_{rec} during high-speed sliding (R = -0.79).

Between static loading and high-speed sliding, δ_{TA} values were strongly correlated (R = 0.97; **Fig. 2A**); as were δ_{TA} between static loading and slow sliding (R = 0.98). Importantly, δ_{TA} under static conditions exceeded δ_{TA} under all sliding conditions ($p < 0.001$, paired *t*-test). **Fig. 2B** shows that slow speed sliding behaviors are predictive of high-speed behaviors, and vice versa; e.g., end-of-sliding compression (δ_{EoS}) at 10 mm/s was strongly correlated with that at 80 mm/s (R = 0.91).

We extrapolated the sliding speeds at which load-induced fluid exudation and sliding-induced fluid recovery matches (i.e., *tribological rehydration threshold speed*, v_{TR}) as well as the minimal speed needed to suppress increases in friction (i.e., *friction recovery threshold speed,* $v_{\mu rec}$) for each specimen. More permeable explants required faster sliding speeds to sustain fluid recovery (R = 0.41, v_{TR} vs. thickness) and lubrication (R = 0.57, $v_{\mu rec}$ vs. thickness). The strong correlation between these parameters highlights the phenomenal and universal lubricating properties of tribological rehydration (R = 0.77; **Fig. 2C**). Similar to the compression behaviors, kinetic friction coefficients under recovery conditions were strongly correlated with those under exudation conditions (R = 0.66; **Fig. 2D**). Importantly, high-speed sliding facilitated a ~50% suppression of time-average friction vs. slow sliding.

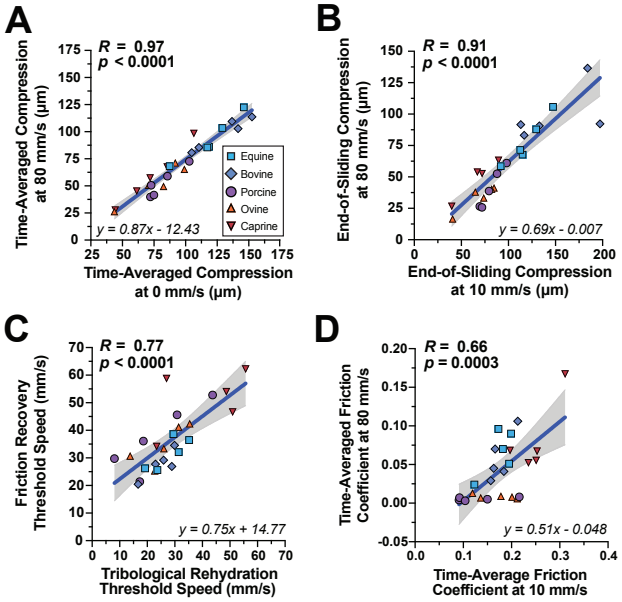

Fig. 2. Compressive behavior under static load was predictive of compression in response to sliding (A-B). Strain and friction showed similar speed dependencies (C), and slow-speed friction behavior was predictive of high-speed friction (D).

DISCUSSION

Our findings demonstrate that cartilage's ability to recover and sustain fluid load support under hydrodynamic sliding conditions are dependent upon tissue material properties, and more importantly, can be extrapolated from their static compression behaviors. More permeable tissues, with lower compressive and tensile moduli, exhibited increased relative exudation and rehydration, but required faster sliding speeds for recovery. Similar predictive relationships were identified among static exudation behaviors and slow cSCA sliding responses, and among slow- and high-speed sliding responses. An imperfect relationship between time-averaged compression under static and slow sliding conditions (i.e., *slope* ≠ 1) indicates the even slow speed sliding (10 mm/s) is capable of partially 'buffering' load-induced fluid exudation. Taken together, these results provide further context for cSCA-based studies of tribological rehydration within the broader cartilage tribology literature, the bulk of which comprises classical SCA tests under slow sliding speeds (0.1-10 mm/s) and show that cartilage's compressive response under hydrodynamic conditions can be surmised from its behavior in other widely used 'non-hydrodynamic' testing regimes. Additional relationships among structural and functional properties have been identified and will be explored in future work. Collectively, these findings provide a framework with which to interpret the effect of disease-associated changes in tissue properties on their subsequent hydration and tribomechanical responses during articulation.

INTRODUCTION

Bio-printing is an emerging tissue engineering technique that has gained prominence in recent times. It's rising prominence is due to its ability to create 3-dimensional (3D) structures that not only help provide embedded cells with the appropriate 3D biological environment, it also recapitulates physiologically relevant structures that capture complex architectural details that could not be re-created using other tissue engineering methods [1]. Bio-printing can be performed using three main techniques, namely extrusion, inkjet and light-assisted printing [2]. Of these, extrusion bio-printing has proven to be the most popular technique, given its versatility in using a wide range of bio-inks affordability and ease of modification [3].

While bio-printing has gained prominence amongst the tissue engineering community, the main challenge is in developing bio-inks that are both printable and bio-functional. These two properties are often conflicting with each other and is adequately captured in the 'biofabrication paradigm' [4]. As such, much effort has been placed in the bio-printing community to develop bio-inks that push the biofabrication paradigm boundary. An exciting bio-ink candidate is silk fibroin (SF) which has garnered the interest of research groups around the world in recent years. Due to its superior mechanical properties, degradability and simple processibility, research groups are looking at using SF bio-inks to push the biofabrication paradigm. However, one major challenge of using SF bio-inks is in its poor viscosity characteristics when the protein is dissolved [5]. The challenge becomes even more prominent in relation to extrusion bio-printing, which requires shear-thinning bio-inks.

This paper describes the development of a silk-based bio-ink, containing an interpenetrating network between its constituents, that allows the bio-ink to be printed using extrusion bio-printing at room temperatures. This is done by functionalizing SF solutions with methacrylate groups (SilMA) and adding gelatin methacryoyl (GelMA) to form SilMA-GelMA (SG) bio-ink. This paper serves as a proof of concept that the SG bio-ink is suitable for extrusion bio-printing at room temperature. Structures can then be thermally stabilized using the appropriate photo-initiator and light exposure to allow bio-printed structures to be incubated at physiological *in vitro* conditions. The SG bio-ink demonstrates a simple way to functionalise SF for extrusion bio-printing, which has the potential to push the biofabrication paradigm, allowing for more detailed structures to be printed with greater bio-functionality.

METHODS

Organic silk fiber yarns were obtained from Chul Thai Co. Ltd., which were then degummed using 0.02M Sodium Carbonate solution to remove the hydrophilic sericin outer coating. The degummed fibers were left to dry in a fume hood overnight, at which point 9.3M Lithium Bromide solutions (LiBr) was used to dissolve the degummed fibers at 60^{o}C. Glycidyl Methacrylate (GMA) was added during the dissolution process to functionalise the SF protein chains with methacrylate groups, to confer photocrosslinkability. After dissolution, the resulting SilMA solution was then dialysed in DI water over 4 days to remove LiBr and unreacted GMA. The solutions were then dialysed in PEG solutions with average molecular weight of 10,000 MW to obtain the appropriate concentration. After dialysis, they were then stored at 4^{o}C until further use. GelMA was synthesized using protocols well established in other papers. Briefly, Type A gelatin was dissolved in DI water to form 10% w/v solutions. Methacrylic Anhydride (MeAH) was added drip-wise to the solution at 50^{o}C, and allowed to react for 3 hours. The resulting solution was then centrifuged, decanted, and dialysed in DI water to remove un-reacted MeAH for one week. The solution was then syringe

filtered under sterile conditions, lyophilized and stored in -20ºC until further use.

The SG bio-inks were made by first syringe filtering the SilMA solutions under sterile conditions. The required lyophilized GelMA was then added to the sterile SilMA solutions and stirred at 50ºC until complete dissolution. Lithium phenyl-2,4,6 trimethylbenzoylphosphinate (LAP) measuring to 0.2% w/v was also added to the solution as the photo-initiator. The resulting bio-ink was then left in 4ºC to form an extrudable hydrogel that can be used for subsequent experiments. Single Sweep Rheology was performed using TA Instruments RH-2 Discovery with 20mm flat disc attachment to obtain the Viscosity against Shear Rate profile. Briefly, the SG bio-inks were loaded onto the rheometer platform and measured between 1/100 to 1000 rotations per second. This was performed under 25ºC with 1 minute of soak time. Viscosity and shear stress against shear rate was then measured accordingly.

Bio-printing was performed using Cellink Inkredible+ Bio-printer, in which porcine Nasal Chondrocytes (pNCs) were mixed in SG bio-inks at a cell density of 1 x 10^7 cells per ml. The cell-laden SG bio-inks were then bio-printed at approximately 50-70kPa, exposed to UV light (of 365nm and 405nm) for 2 minutes and subsequently incubated in either control culture medium or chondrogenic medium. Live/dead viability assays were performed at various timepoints to assess if pNCs could survive within the bio-printed constructs. After 14 days, the constructs were fixed with formalin, and immunohistochemistry (IHC) was performed with anti-rabbit AP-polymer and rabbit Col II antibodies to assess if pNCs could express appropriate phenotype.

RESULTS

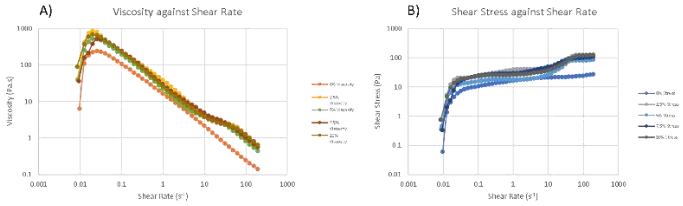

Figure 1: Rheological properties of SG Bio-Ink. A) Viscosity against Shear Rate profile. B) Shear Stress against Shear Rate profile.

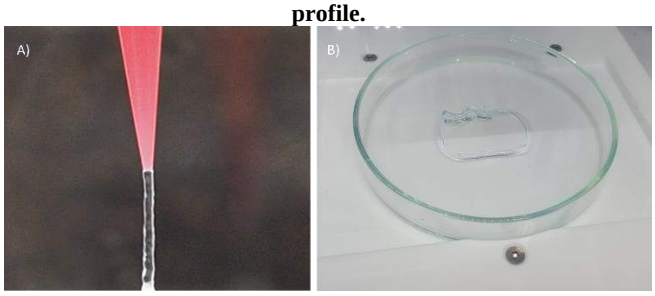

Figure 2: Printability demonstration of SG Bio-ink. A) Close-up photo of extruded filaments. B) Shape retention of bio-printed cat structure using SG Bio-ink.

Single sweep rheology showed that the SG bio-inks possess shear thinning properties as shown by the downward slope of the viscosity against shear rate graphs of all SG bio-ink compositions as seen in figure 1. This indicates that as shear rate increases, viscosity decreases, which is favorable for bio-printing applications. This was also confirmed by the shear stress vs shear rate graph as shown by figure 1B. The printability of the SG bio-ink was also confirmed as shown by figure 2. Figure 2A shows the extrusion of SG bio-inks as a single, continuous filament, with little deviation from the exit nozzle. Figure 2B also shows that the extruded filaments could retain its bio-printed shape.

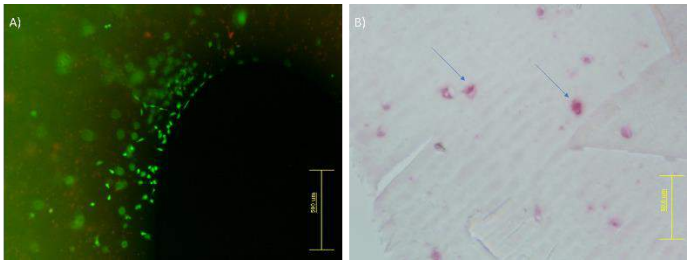

Figure 3: Bio-functional properties of SG Bio-inks. A) Live/Dead image of embedded pNCs. Note that pNCs towards the edge show cell elongation. B) IHC of SG Bio-ink using Col II antibodies. Red indicating positive stain.

The bio-functional properties of SG bio-inks were also demonstrated by the live/dead assay and IHC results as shown in figure 3. Figure 3A shows the live/dead image captured at day 7. The interesting thing to note about figure 3A is the elongation of pNCs at the edge of the SG bio-ink, which indicates that pNCs at the edges are experiencing proliferative activity. Figure 3B shows the IHC images of SG bio-inks that were formalin fixed at 14 days and stained for Col II antigens. Red stains indicate positive Col II antigen expression. One thing to note is that the pericellular area shows some signs of degradation, which indicates that the embedded pNCs could be re-modelling the bio-ink matrix surrounding it.

DISCUSSION

Because extrusion bio-printing is one of the most affordable and versatile bio-printing techniques, it is crucial that novel bio-inks are developed for extrusion methods so that there is greater adoption of bio-printing techniques around the world. The main challenge, however, is in developing bio-inks that also push the boundaries of the biofabrication paradigm, with a balance between the printability and bio-functionality characteristics. SF, being a recent entrant as a bio-ink candidate, also must be functionalized to push the boundaries of the paradigm.

In this paper, we present a simple method of functionalizing SF for extrusion bio-printing. By leveraging on GelMA's ability to form gel-like structures at room temperature [6], the combination of both SilMA and GelMA to form SG bio-inks results in a bio-ink that can be easily used in extrusion bio-printing applications. Furthermore, the methacrylate functional group that exist on both SilMA and GelMA allows both to photocrosslink to form an interpenetrating network, further enhancing the mechanical properties of the final structure.

Further development of the SG bio-ink needs to be done to characterize the mechanical properties of the bio-printed structure, and its degradation profile. Also, more work needs to be done to examine if other cell types can be used in conjunction with the SG bio-ink and whether these cells can still maintain its phenotypic expression.

INTRODUCTION

Soccer is a popular sport in the United States, but the nature of the sport exposes players to repetitive head impacts and increased risk of concussion.[1] Repetitive head impacts in soccer have been associated with deficits in clinical outcomes such as reduced processing speed[2] and neuro-ophthalmological function,[3] which may be the result of microstructural changes occurring in the brain.[4] In response to the growing concern over the potential short- and long-term effects of head impacts in soccer, the United States Soccer Association banned heading for youth athletes age 10 and younger and added restrictions for athletes age 11-12.[5]

Head motion sensors coupled with time-synchronized video have been used to characterize the frequency and magnitude of head impacts in youth soccer.[6–8] Associations between head impact magnitude and frequency and athlete-specific factors such as sex and age have been observed as well as mechanistic factors such as ball delivery method and impact type. Yet, it is unclear how head impact exposure may vary by the activities the athlete engages in during training. In sport, practice sessions are a compilation of unique training activities designed to improve skill and performance that may also affect head impact exposure.[9] Characterizing head impacts across common activities performed in soccer can help to inform meaningful interventions that aim to reduce head impact exposure through changes in training regimens. Therefore, the objective of this study was to compare head impact exposure across common training activities in soccer.

METHODS

Eight youth soccer players (13.5 ± 0.11 yr, 166.8 ± 5.57 cm, 60.1 ± 9.28 kg) from a single U14 soccer team were recruited to participate in this study. To assess head impact exposure, a combination of film review (to assess head impact frequency) and kinematic sensor analysis (to assess head impact magnitude) was utilized. Head kinematic data was collected using a custom mouthpiece instrumented with a tri-axial accelerometer and gyroscope. Players wore the mouthpiece sensor during all practices and games during the study period. Data was collected from the accelerometer and gyroscope at 4,681 Hz and 800 Hz, respectively for 60 ms (15 ms pre-trigger, 45 ms post-trigger) whenever the device recorded linear acceleration above 5 g (season 1) or 3.5 g (season 2) for at least 3 ms. Sensor thresholds were adjusted in the second season to increase the number of video-verified head impacts recorded by the sensor. Kinematic data was processed following the steps of Rich et al.[10] Briefly, the data was calibrated to standard units (g and rad/s), filtered, rotated to align with a conventional coordinate system and zero-offset. Rigid body dynamics were used to transform the measured linear acceleration to the center of gravity of the head. A time-synchronized camera was used to film each practice and game. Events without head contact were excluded from the present analysis. The film collected from each practice and game was reviewed to identify all head contact events that occurred from each player enrolled in the study and to video-verify all sensor recorded events. Reviewers recorded the time and impact type of each head contact event. Possible impact types included: ball-to-head impacts, player-to-player collisions, ground contact, and other impacts (e.g., player's head touches the ground during core conditioning).

During each session, research staff recorded all activities performed by each enrolled player. The start and end time and description of each activity was recorded. If a player was inactive during any part of the activity (i.e. on the bench), the time the player was inactive was subtracted from the total time of the activity to obtain the player-specific exposure time. Each activity was characterized as one of 16 drill types under the advisement of the coach. Each drill was further categorized into one of 5 activity types: technical training, team

interaction, position specific, set pieces, and other (e.g., conditioning). The time of each mouthpiece recorded and film reviewed head contact event was used to pair the event with a corresponding drill/activity type.

Peak resultant linear acceleration, rotational velocity, and rotational acceleration were computed from kinematic data corresponding to a video-verified event. Impact rate was computed from the head impacts observed in the film review. Mixed effects models were used to compare peak kinematic metrics across activity types while controlling for the session date and season. All kinematic metrics were log-transformed prior to analysis and back-transformed to report results. A generalized linear model using a negative binomial link function was used to identify differences in impact rate across activity types. Activities with fewer than 20 total head impacts and/or less than 5 hours of total exposure were excluded from statistical comparisons of kinematics and impact rate, respectively.

RESULTS

The eight players enrolled in the study were monitored over 110 sessions (n=72 practices, n=38 games) across two seasons. Only 6 players were monitored in the second season as two players declined to continue with the study. Each player was exposed to an average of 106.0 hours of soccer activities throughout the two seasons of soccer. This consisted of an average of 31.6 hours of team interaction, 31.3 hours of technical training, 23.8 hours of game play, 16.0 hours of other activities, 0.3 hours of set pieces, and 0.3 hours of position specific activities for each player. A total of 4,329 head impacts (n=2,583 season 1, n=1,746 season 2) were observed from film review of which 2,001 head impacts (46%; n=990 season 1, n=1,001 fall) were recorded by the mouthpiece. Most head impacts (film reviewed [mouthpiece recorded] occurred during technical training activities (86%, n=3,736 [1,737]) followed by other activities (5%, n=225 [96]), game play (4%, n=188 [96]), team interaction activities (4%, n=167 [61]), and position-specific activities (<1%, n=13 [9]). No head impacts occurred during set pieces.

Overall, mean head impact rates were greater during practice (4.09 per player per practice) than games (2.53 per player per game). Technical training activities were associated with the highest head impact rate across activity types. Overall, mean peak kinematic magnitudes were 9.57 g, 4.30 rad/s, 0.69 krad/s^2. For each kinematic variable, a significant main effect was observed for activity type (all $p<0.0001$) and drill type (all $p<0.0001$). Figure 1 compares the mean head impact magnitude and frequency across activity types. Head impacts occurring during game play were associated with the greatest mean peak linear acceleration and mean peak rotational acceleration compared with all activity types. A total of 30 (31%) head impacts >20 g were observed during game play compared with 27 (1.6%) during technical training. Head impacts occurring during team interaction activities resulted in significantly greater peak rotational acceleration than technical training and other activity types (all $p<0.001$). Peak rotational velocity during team interaction and game play activities had significantly greater mean kinematic magnitudes compared with other and technical training activity types (all $p<0.0001$). A total of 1,389 (80%) head impacts occurring during technical training activities were below 10 g. Ball-to-head impacts were the most common type of impact across activity types except position-specific activities where falls and dives were most common. A small number of player-to-player collision related head impacts were reported in technical training (n=4), team interaction (n=7), and game play (n=3) activities.

DISCUSSION

This study compared head impact exposure across common activities in youth soccer. To the best of the researcher's knowledge this is the first study to characterize head impact exposure across common activities in soccer. Technical training activities exposed players to significantly greater impact rates than all other activity types but mean head impact kinematics were significantly lower than other activity types. Moreover, game play and team interaction activities exposed players to the greatest mean peak head impact kinematics but at much lower frequencies than other activity types. Although mean kinematics were greater in game play and team interaction activities, a similar number of head impacts greater than 20 g were experienced in both technical training activities and game play activities. These events may be attributed to increased ball velocity and/or use of poor header technique. Soccer balls with reduced mass and/or ball pressure have been shown to reduce impact forces, and the use of these soccer balls during technical training activities may help to reduce head impact magnitudes[11]. Interventions designed to reduce head impact frequency may benefit from targeting technical training activities, whereas interventions designed to reduce head impact magnitude in soccer may benefit from targeting team interaction and game play activities.

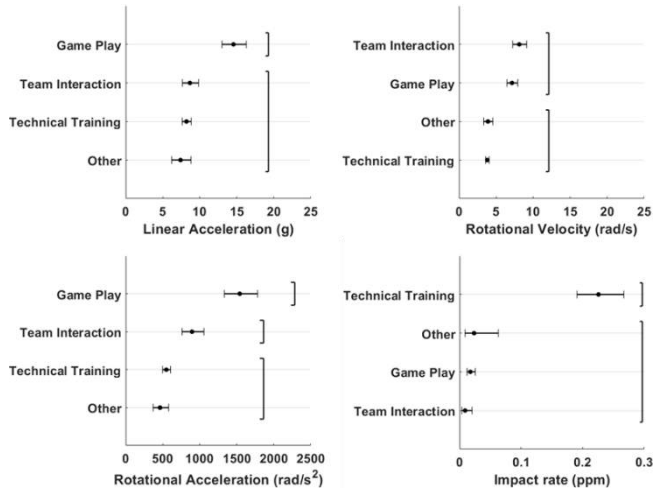

Figure 1. Head impact exposure across activity types in soccer. Markers represent the mean and lines represent the 95th% confidence interval. Mean values of activity types not bounded by the same bracket were significantly different.

ACKNOWLEDGEMENTS

The authors received support from the Childress Institute for Pediatric Trauma at Wake Forest Baptist Medical Center to complete this study. The authors would like to thank the athletes, coaches, and club who participated in this study for their generous support. They would also like to thank Konstantia Strates for her efforts in coordinating the study and Megan Hayden and Kathryn Romano for their efforts in collecting and processing data.

INTRODUCTION

Proper cervical function, acting as a barrier between the fetus and the external environment, is critical to a healthy pregnancy. The tissue must stay closed throughout gestation and remodel sufficiently at the appropriate time to allow for an at-term delivery [1]. Premature remodeling of the cervix is a final common pathway for premature birth (PTB), defined as birth before 37 weeks of gestation, and PTB prediction and prevention remains a significant clinical challenge [2]. Murine models are therefore used to understand the evolution of the gravid cervix. Remodeling of the mouse cervix over the 19 days of gestation has been previously characterized and attributed to changes in the extracellular matrix and collagen turnover [3,4]. This study will explore the role of extracellular proteins in cervical mechanics over pregnancy using genetic knockout mouse models.

Small leucine rich proteins (SLRPs) are one of many components found in the extracellular matrix (ECM) of biological tissues, including cervical tissue [5]. Decorin and biglycan are SLRPs found in the mouse cervix, and their roles have been studied previously in many other tissue types, including tendon and heart [6,7]. Both SLRPs have been implicated in the formation and assembly of ECM structural components, mainly the collagen fibers [8,9]. TEM imaging studies of cervical tissue demonstrated a gestation-dependent effect of decorin loss on the microstructure, in which aberrant collagen fibrils are observed only in early pregnancy [4]. Also, previously unpublished data shows abnormal elastic fibers in cervical tissue with a loss of these proteoglycans. Due to the high homology between the 2 SLRPs, it is of interest to study the two proteoglycans together and their possible compensatory behaviors. Furthermore, mice lacking decorin and bigylcan (DKO) manifest complications in pregnancy, but cervical function has not yet been studied [10]. The goal of this study was to characterize the mechanical behavior of mouse cervices lacking decorin and/or biglycan through pregnancy and understand how they may contribute to cervical dysfunction. With the motivation to observe the hyperviscoelastic behavior typical of hydrated, soft tissue, we develop a mechanical test that would elicit these mechanical behaviors and examine the role of SLRPs in instantaneous and viscoelastic properties, their evolutions being a key feature of tissue softening in pregnancy [11].

METHODS

A viscoelastic testing protocol was developed to assess the role of decorin and biglycan in cervical mechanics. Six mouse genotypes were tested in this study, as shown in Table 1. Cervix samples were collected from non-pregnant (NP) mice and mice at day 18 (d18) of gestation, with 19 days considered term. Five of each genotype was tested, except DKO, for which two were tested. Samples were prepared for whole-specimen ring tensile loading, as previously described [12].

Table 1: 6 genotypes for NP and d18 time points.

Name	Genotype
Wildtype (WT)	Dcn +/+ Bgn +/+
Decorin Knockout (DcnKO)	Dcn -/- Bgn +/+
Biglycan Knockout (BgnKO)	Dcn +/+ Bgn -/-
Decorin Knockout, Biglycan Heterozygous (DB)	Dcn -/- Bgn +/-
Biglycan Knockout, Decorin Heterozygous (BD)	Dcn +/- Bgn -/-
DKO	Dcn -/- Bgn -/-

Samples were first allowed to swell for 2 hours in phosphate-buffered saline with 2 mM ethylenediaminetetraacetic acid. The loading protocol consists of 2 main sections: 1) strain rate sensitivity cyclic load-unloads and 2) stress relaxation ramp- holds (Fig.1). Different load levels were applied for NP and d18 to ensure each sample could sustain a majority of the test without breaking. Between each loading, the sample was held at zero displacement for 20 minutes to recover.

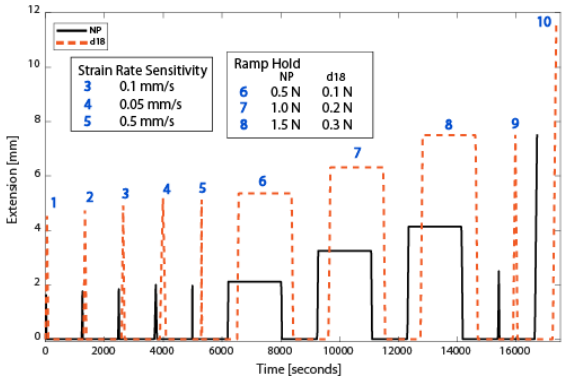

Figure 1: Viscoelastic Loading Regimen for NP and d18 samples.

Sample geometry was tracked and used to generate stress-stretch curves from which structural parameters were determined. A 2-term exponential decay function was fit to each ramp hold to characterize the time-dependent behavior. A microstructurally-inspired material model was fit to the equilibrium behavior of the ramp hold section using inverse finite element methods (IFEA). The model consists of fibers embedded in a compressible ground substance. The fiber component is a free joint chain and, in a configuration, inspired by the Arruda-Boyce 8 chain model [13]. The free energy density is:

$$\psi(I_1,J) = n\theta kN\left[\frac{\sqrt{I_1}}{\sqrt{3N}}\beta + \ln\left(\frac{\beta}{\sinh\beta}\right)\right] - \frac{nk\theta}{3}\sqrt{N}\beta_0 \ln J + \frac{1}{2}\kappa(\ln J)^2 \qquad (1)$$

where N is the locking stretch of the chain, ξ=nkθ is strength coefficient, and κ is the bulk term. A genetic algorithm was applied to optimize the three material parameters for each sample [Under Review]. The force-displacement and final thickness-displacement data were used for fitting. The width-displacement and length-displacement were used for validation. A non-parametric ANOVA with a posthoc t-test (p-value <0.05) was used to assess significance.

RESULTS

The cervix indeed exhibited hyperviscoelastic behavior. The model captured the equilibrium force and thickness data and provided a good match to the width and length data (Fig.2).

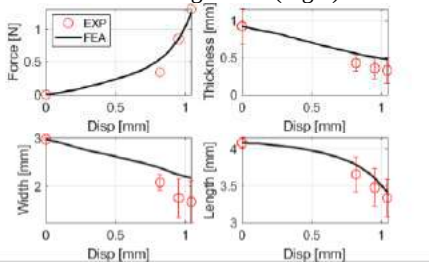

Figure 2: Representative fitting from IFEA. Fit Force-Disp. and final Thickness-Disp. Validate with Width-Disp and Length-Disp.

An increase in N was observed in late pregnancy, indicating an increase in stretchability of d18 samples (Fig3A-B). A decrease in ξ and κ with d18 samples indicates a decrease in stiffness and resistance to compression consistent with softening (Fig3C-F). Surprisingly, for NP, no difference between parameters for genotypes was observed, but after cervical remodeling, this model describes a material difference between knockouts and WT. BgnKO, BD, and DKO exhibited a decreased N compared to WT, indicating a loss of stretchability (Fig3B). Remarkably, DcnKO and DB had a similar N to WT. Although not significant, the knockouts' ξ increased compared to WT, with DKO being the stiffest of the genotypes (Fig3D). In comparing structural parameters of cycles 3-5 (Fig. 1), strain rate dependency was not observed. The time constants of the exponential fit were higher in knockouts than WT, indicating a slower stress dissipation.

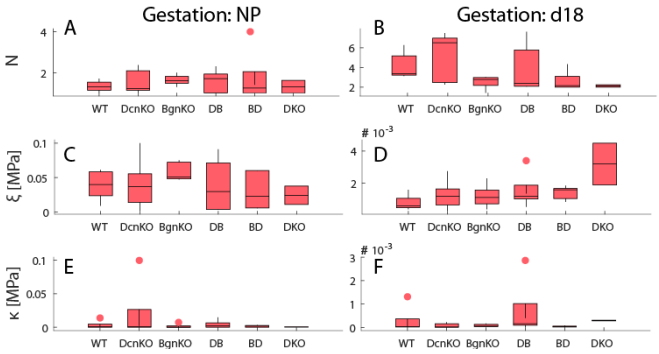

Figure 3: Optimized material parameters by gestation and genotype. A-B) Locking stretch N, C-D) Strength coefficient ξ, E-F) Bulk term κ

Decreased rupture stress and stretch highlight the mechanical insufficiency of the knockout models.

DISCUSSION

The material model captures the equilibrium material behavior of cervical tissue, describing force and 3D tissue deformation. Moving from a phenomenological model, this relatively simple microstructure-based model with three parameters can capture large deformation behavior of both NP and d18 mouse cervices. The change in parameters between NP and late pregnant mouse cervix was also reflected in the human cervix [Shi et al, In Preparation]. The d18 DKO fiber was less stretchable (lower N). An essential characteristic of a correctly remodeled d18 cervix is its high extensibility without breaking, indicating a possible mode of cervix mechanical failure. The material model and changes in rupture and stress relaxation between genotypes indicate the role of decorin and biglycan is gestation dependent as some deficiencies are recovered, while others augmented through cervical remodeling. Ultimately, these modeling efforts are towards our goal of modeling the viscoelastic material response of cervix.

Limitations of this experiment include simplified cervical geometry. The small sample size limited statistical power, but trends are still evident. The data indicates the crucial role of decorin and biglycan in the proper remodeling of cervical tissue during pregnancy and offers insight into how proteoglycans support its proper mechanical function.

SPECTRAL BANDEDNESS IN HIGH FIDELITY CFD PREDICTS RUPTURE STATUS IN INTRACRANIAL BIFURCATION ANEURYSMS

INTRODUCTION

Recent studies using high-fidelity computational fluid dynamics (CFD) in patient-derived cerebrovascular geometries have revealed high-frequency flow instabilities, which have been speculated to contribute to the growth and rupture of intracranial aneurysms (IAs) **[1, 2]**. Various techniques have quantified the power of these instabilities, such as fluctuating kinetic energy and spectral power index (SPI) **[3]**, but these metrics have yet to show association with IA rupture.

In experimental studies, IAs have been observed to emit acoustic *bruits,* which are thought to result from "turbulence"-induced wall vibration **[4]**. These vibrations are difficult to measure in-vivo and have not been a reliable source of diagnostic information, but hint at intriguing associations between acoustic harmonics and IA stability.

Spectrograms of cardiovascular CFD data have been demonstrated as a method for summarizing spectro-temporal hemodynamic trends over a spatial domain. In **[5]**, sac-averaged spectrograms reveal coherent harmonic banding, suggesting the presence of vortex-shedding phenomena in the IA sac, as distinct from more broadband spectra associated with turbulent-like flow. The hemodynamic implications of such narrowband harmonic flow structures, which could preferentially trigger IA wall vibrations **[6]**, have yet to be studied in detail.

Spectrograms are a common audio representation for which a broad array of quantification and decomposition tools exist **[7]**. In this paper, we make novel use of this audio-processing literature to present a method for quantifying narrowband harmonics from CFD spectrograms, and explore them for possible associations with rupture in a cohort of 48 patient-derived IA geometries.

METHODS

We propose a method based on spectral chroma features, which are a cyclical representation of frequency commonly used in musical audio processing for identifying similar pitches across octaves of an equal-tempered scale **[7, 8]**. For example, the consecutive doubling of a given frequency (e.g., 100, 200, 400, 800 Hz) are all considered to have the same pitch class and thus chroma value, c, as given by:

$$c = log_2 f + \lfloor log_2 f \rfloor$$

where f is the frequency and $\lfloor \cdot \rfloor$ indicates the floor function. Each frequency has a unique chroma value $c \in [0, 1)$.

To calculate a chroma power spectrum from a frequency power spectrum, power is integrated over frequency bins with equivalent chroma values. Broadband chroma power may suggest noise, while power concentrated into narrow regions of chroma suggest harmonic structure. A *chromagram* depicts the chroma power as a function of time. To quantify the concentration of chroma power in a chromagram derived from a sac-average spectrogram, we compute the time-varying dynamic range of chroma power and normalize by the range of the final time frame; this ratio is termed the *narrowbandedness ratio* (NBR).

To assess the possible relationship between NBR and rupture status, we used a dataset of 48 high-fidelity *pulsatile* CFD simulations of patient-derived bifurcation IA geometries from the AneuriskWeb project database **[9]**. Simulation details, including meshing strategy and solver settings, are as described in **[10]**. The methodology for generating sac-averaged spectrograms of hemodynamic velocity is detailed in **[5]**. Chromagrams were generated from the sac-averaged spectrograms using the chroma_stft module of the Librosa 0.8.0 audio toolkit in Python **[7]**. From these chromagrams, we calculated NBR.

To assess relationship with rupture status, we performed univariate logistic regression for previously established geometric and hemodynamic factors (IA size; size ratio (SR); time-average wall shear stress (TAWSS); oscillatory shear index (OSI)) **[11]** with time-averaged NBR. For each model, we computed significance tests using Student's t-test for normally distributed data and the Mann-Whitney U test for

non-normally distributed data using a critical value of p=0.05 to reject the null hypothesis of equivalent populations. Standard clinical receiver operating characteristics (ROC) analysis was performed to compare the performance of each regression model, as quantified by the area under each ROC curve (AUC).

RESULTS

Results from three representative high-fidelity CFD cases are shown in Figure 1. The spectrograms of (Aneurisk case IDs) C0029 and C0078 demonstrate narrowband harmonic structures. The respective chromagrams show energy concentrated within narrow chroma bands, and the time-varying histograms of chroma power show periods of high dynamic range. The spectrogram of C0052 demonstrates the presence high-frequency flow instabilities, but exhiibits little banding in the spectrogram or chromagram. The chroma dynamic range contracts near peak systole, suggesting characteristics of broadband noise, i.e. turbulent-like flow.

Figure 2 shows the ROC analysis using all 48 cases, summarizing various performance metrics for the univariate logistic regression models. Only the proposed NBR was found to be a significant predictor of rupture for this dataset (p=0.008); however, owing to the relatively wide CIs, none of the AUCs themselves were significantly different.

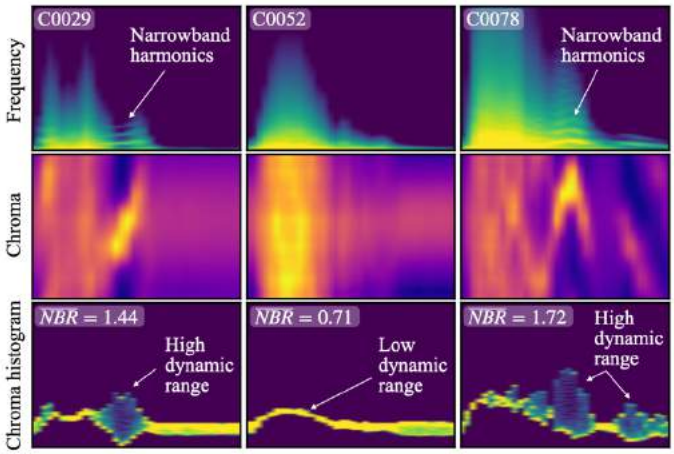

Figure 1: Representative results from 3 of 48 cases, showing: (top) sac-averaged spectrograms (frequency 0-1314 Hz), (middle) chromagrams; (bottom) histograms of chroma power, with corresponding NBR value. X-axis is time (one cardiac cycle).

DISCUSSION

The harmonic quality of blood flow instabilities may be an important feature in the search for predictors of IA rupture. In this cohort of 48 cases, narrowband chroma power of sac-averaged chromagrams was shown to have stronger association with rupture compared to established geometric and hemodynamic predictors. The presence of multiple harmonic bands in a sac-average spectrogram is speculated to result from vortex-shedding in the IA sac, and thus supports further research of IA vibration and its potential mechanobiological effects on aneurysm wall integrity.

The associations of IA size, SR, TAWSS, and OSI with rupture status were weaker than previously reported in **[11]**. This may be due to our use of a smaller cohort (n=48 vs n=204 cases). On the other hand, it might be due to or our focus on bifurcation IAs compared to their cohort of both bifurcation and sidewall IAs, since morphological and hemodynamic predictors of rupture have previously been shown to differ significantly in bifurcation vs. sidewall IAs **[12]**.

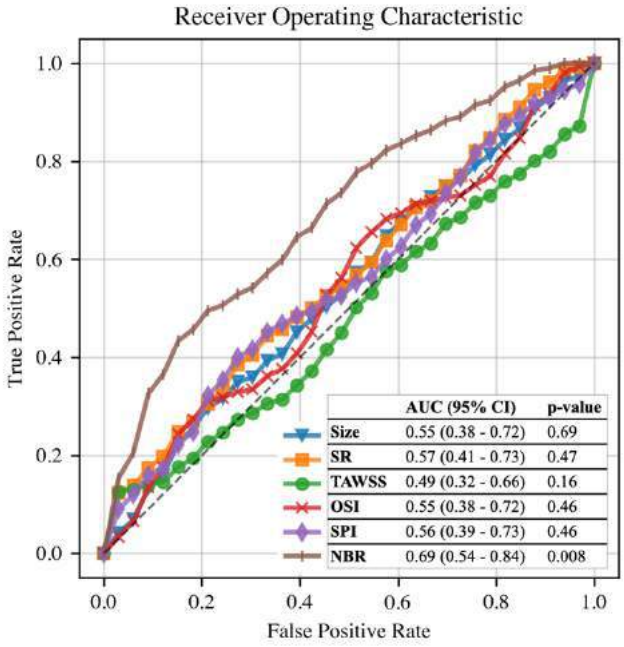

Figure 2: ROC curves of probabilities from each univariate logistic regression. CI = confidence interval

As noted in the Methods, the chroma equation maps frequencies according to a geometric progression given by the consecutive doubling of a fundamental frequency. Flow-induced harmonics may behave more closely to integer multiples of a fundamental frequency, as suggested by the evenly spaced banding in the spectrograms of C0029 and C0078. Nevertheless, since spectral power tends to decay with frequency, we expect the chromagram to be dominated by low-frequency spectral power and, in the presence of integer harmonics, by the low-integer harmonics.

Patient-specific flow rates were not available for the Aneurisk cases, so we used a well-validated power-law **[13]** to estimate pulsatile flow conditions for each case. As flow instabilities are likely more sensitive to inflow rates than other hemodynamic factors [**3**], sensitivity of NBR to such uncertainty must still be explored and quantified. Further work will also focus on better understanding the fluid dynamical phenomena implicated by these narrowband harmonics.

INTRODUCTION

Participating in research as an undergraduate student has been associated with beneficial outcomes such as increased GPA, retention in STEM majors/careers, and the development of a scientific identity[1]. Serving as a mentor to undergraduate researchers is a common feature of graduate training and offers an opportunity for graduate students to gain experience in teaching and research management[1]. In STEM, these mentorships typically occur through face-to-face interactions in the laboratory where both the undergraduate mentee and graduate mentor have access to laboratory equipment, reagents, and other research samples. The onset of the COVID-19 pandemic and associated stay-at-home orders and social distancing measures meant that many research mentorships were required to transition to a work-from-home model and use virtual platforms to accomplish research goals.

Virtual mentoring (also referred to as e-mentoring or digital mentoring) has been used for over two decades and has been shown to promote many of the same benefits as face-to-face interactions, such as social and academic support and professional development[2]. Virtual mentoring has several advantages including increased flexibility in meeting times and locations comparted to in-person mentoring[2]. However, virtual mentoring also has challenges (e.g. technology and privacy) and adjusting to the format can be difficult[2]. When campuses shut down due to COVID-19 and transitioned to online learning, many resources were made available to educators to assist with using synchronous and asynchronous classrooms, setting new guidelines for students, and altering attendance/grading policies. In contrast, at some institutions relatively little guidance was provided to graduate students on how to maintain their own research productivity and how to continue mentoring undergraduate researchers.

The objective of the present study was to understand how undergraduate mentees and graduate mentors at one private R1 institution (Washington University in St. Louis) adjusted research mentorships to the virtual environment at the onset of the COVID-19 pandemic (Spring 2020 semester). Here we seek to determine if there were changes in the mentoring relationships, communication, and productivity when switching to virtual mentoring and to identify the benefits and challenges mentors and mentees experienced.

METHODS

A survey was developed using Qualtrics software (Qualtrics, Provo, UT) that included multiple choice, Likert scale, and short response questions, and asked students to reflect upon their virtual mentorships during the COVID-19 pandemic. In June 2020, an email was sent to undergraduate and graduate students in six departments at Washington University in St. Louis where research is largely conducted in wet laboratories (Biology, Chemistry, Physics, Biomedical Engineering, Mechanical Engineering and Materials Science, and Earth and Planetary Sciences). Undergraduate students who had been mentored by a graduate student ("mentees") or graduate students who had mentored an undergraduate student ("mentors") during the Spring 2020 semester were invited to participate in the survey.

Survey participants were required to state their research role (mentor or mentee) but otherwise were permitted to leave other questions blank. Subsequent questions asked students to rank their overall research experience (occurring from January to May 2020) and to indicate how virtual research (March to May 2020) compared to their face-to-face interactions prior to the onset of the pandemic (January – March 2020). At the end of the survey, students were asked to indicate their academic department and year of study. This research study was conducted with approval from the Washington University in St. Louis Institutional Review Board.

117 total respondents participated in the survey (79 undergraduate mentees and 38 graduate mentors) and these individuals represented all academic years and departments surveyed. Analysis of the qualitative

and quantitative data was considered in aggregate (all responses) and according to mentorship role (mentor or mentee). The multiple choice and Likert scale responses were tabulated and presented as percentage of total responses. The answers from the free-response questions were assessed using an open coding, two-pass, approach to identify emergent themes. First, categories of responses were generated and then answers were assigned to categories which were altered, combined, or generated as necessary.

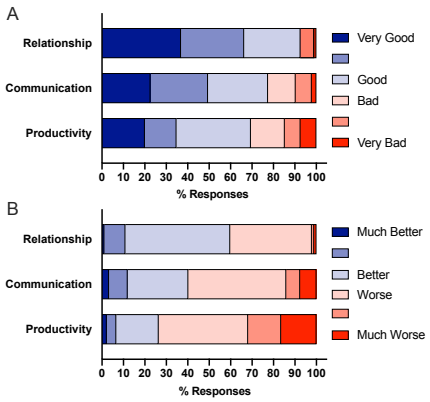

Figure 1: Ratings from undergraduate and graduate students in aggregate showing perceptions of mentoring relationship, communication, and productivity overall (A) or indicating how these measures changed with the shift from face-to-face to virtual mentoring (B).

RESULTS

The responses from undergraduate mentees and graduate mentors revealed that the quality of the mentored research experience during the Spring semester of 2020 was perceived as positive overall. 92% of respondents indicated positive relationships with their mentor/mentee, 77% rated their communication as good to very good, and 69% said their mentorships had above-average productivity (Fig. 1A). 60% of respondents rated their mentoring relationship as improved following the switch to virtual research. However, only 40% and 26% indicated improvements to communication and productivity respectively (Fig. 1B).

Qualitative analysis of the text-based answers corroborated and expanded on trends in the quantitative data. Reponses from both mentors and mentees suggested that the increased informality of virtual mentoring improved the mentoring relationship (““I get to see [pet] photos and learn more about my mentee and her life”). Additionally, this insight into the personal lives of the mentees prompted many mentors to take greater consideration for their mentees’ mental health and wellbeing. However, not all mentoring relationships were improved using the virtual format, and many respondents had challenges with maintaining communication. Mentors utilized a variety of platforms to accomplish research remotely including email and video conferencing which were employed by 40% and 34% of respondents, respectively (Fig. 2). Respondents who indicated their communication improved utilized a combination of communication modalities to achieve distinct goals. Two common trends were observed in responses that indicated worsened communication, 1) response times became much slower or communication halted completely following campus shut downs, or 2) individuals were speaking directly with their mentor but were not communicating with the lab group as a whole. Lastly, decreased ratings of productivity by both mentors and mentees were generally related to an inability to conduct hands on research in the wet lab. Many undergraduates also indicated that that research activities other than data collection were perceived as inherently less productive (e.g. data analysis, data visualization, or literature review). Conversely, there were undergraduates who indicated that, “…the remote work [was good] because it forced me to think about my work more conceptually and engage with the material.”

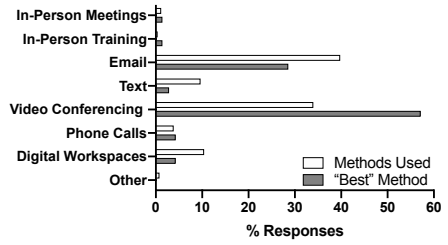

Figure 2: Communication modalities survey respondents indicated they used and those they perceived to be “best.”

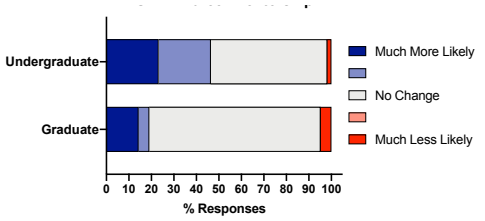

Figure 3: Interest of respondents in future STEM careers (undergraduate students) or mentoring opportunities (graduate students).

Although the data indicate ways in which the benefits of virtual research differed from in-person mentorships, undergraduate respondents indicated that their interest in future STEM careers had either increased (46%) or remained unchanged (52%). Similarly, 19% of graduate student mentors said their interest in serving as a mentor had increased and for 76%, their interest remained unchanged (Fig. 3).

DISCUSSION

The responses of both undergraduate and graduate researchers at Washington University in St. Louis reveal ways in which virtual platforms were able to support research mentorships during the COVID-19 pandemic. The majority of mentors and mentees noted benefits to virtual mentoring such as improved relationships, opportunities to emphasize scientific theory, and increased consideration of the emotional and mental wellbeing of researchers. However, challenges arose when mentors and mentees did not work effectively together to define research and learning objectives or did not communicate with each other efficiently. The finding that neither undergraduate nor graduate students altered their future plans following this experience may speak to the ability of virtual mentoring to support professional/academic development but may also reflect how many students felt this was a temporary situation. Additional studies including those with longitudinal components will be required to determine and assess the efficacy of virtual mentoring in STEM research. These data also demonstrate the necessity of providing researchers with support and training in how to effectively engage in research mentorship remotely as well as face-to-face. Best practices will need to be defined to optimize virtual mentoring as a tool for research mentorships while the COVID-19 pandemic continues and beyond. If implemented well, virtual mentoring can positively supplement in-person mentoring and increase access to STEM research for populations traditionally underrepresented in laboratories.

ACKNOWLEDGEMENTS

The authors wish to express thanks to all the survey participants and the administrations of the Chemistry, Biology, Physics, Biomedical Engineering, Mechanical Engineering and Materials Science, and Earth and Planetary Sciences departments (particularly Dr. Buhro, Dr. Larsen, Dr. Olsen, Dr. Ferrrer, Dr. Setton, Dr. Bayly, Dr. Bradley, and Dr. Skemer) for their assistance in distributing the survey. Additional thanks to the Center for Teaching and Learning for their support. JES has received financial support from the Spencer T. and Ann W. Olin Fellowship for Women in Graduate Study.

INTRODUCTION

Pulmonary hypertension caused by left heart failure (PH-LHF) is a progressive disease that contributes to increased morbidity and mortality in millions of adults in the United States [1]. PH-LHF begins as a passive process called isolated post-capillary PH (Ipc-PH) and is diagnosed by elevated mean pulmonary artery pressure (mPAP) with normal pulmonary vascular resistance (PVR). Mortality in patients increases significantly once Ipc-PH transitions to combined pre-/post-capillary PH (Cpc-PH). Clinical and experimental hypotheses suggest that pathological wall shear stress (WSS) and cyclic stretch (CS) are key regulators of pulmonary vasoconstriction and remodeling, yet the exact mechanical stimuli of PH-LHF are unknown due to the difficulty associated with estimating these quantities.

In this study, we develop a one-dimensional (1D) fluid mechanics model predicting blood pressure, blood flow, area deformation, WSS, and CS in the pulmonary arterial and venous system. This work extends a previous study [2] by adding a capillary model allowing us to compute WSS and CS in the complete network. Our extended model includes large arteries and veins with geometry extracted from computed tomography (CT) data, small pulmonary arteries and veins, modeled as structured trees with fractal dimensions extracted from data, as well capillaries, which are modeled using a sheet model inspired by previous work by Y.C. Fung [4]. Combining these three submodules allows us to capture dynamics at multiple scales ranging from centimeters to nanometers. This multiscale approach allows quantification and exploration of system dynamics and mechanistic relationships at several levels of the pulmonary circulation, and under different hemodynamic conditions of the left heart.

Large vessel hemodynamics are predicted in a reconstructed geometry from CT imaging using 1D Navier-Stokes equations, while small vessel predictions occur in an empirically driven, bifurcating fractal tree using a linearized version of the large vessel equations. The arterial and venous trees are connected by pulmonary capillaries whose network geometry is characterized by a sheet of fluid flowing between two membranes. This approach provides a novel way to investigate hypotheses related to disease progression in PH-LHF.

METHODS

Large Vessels. Vessel-dimensions and network connectivity are extracted from CT chest images from a healthy human adult. We used 3DSlicer to reconstruct three generations of arteries and one generation of veins and subsequently used the vascular modeling toolkit (VMTK) to obtain cartesian loci tracing each vessel's centerlines and measure associated radii. Each large vessel is modeled as an axisymmetric tube with a circular cross-section and impermeable wall. We assume that the blood is Newtonian and the flow is incompressible, irrotational, and laminar. We consider a Stokes velocity profile discussed in [2] and obtain reduced 1D conservation of mass and momentum equations

$$\frac{\partial A}{\partial t}+\frac{\partial q}{\partial x}=0, \qquad \frac{\partial q}{\partial t}+\frac{\partial}{\partial x}\left(\frac{q^2}{A}\right)+\frac{A}{\rho}\frac{\partial p}{\partial x}=-\frac{2\pi\nu}{\delta}\frac{q}{A}, \tag{1}$$

where $A(x,t)$ is the cross-sectional area, $q(x,t)$ is the volumetric flow, $p(x,t)$ is blood pressure, ρ is blood density, η is kinematic viscosity, and $\delta=\sqrt{\nu T/2\pi}$ is the boundary layer thickness with T denoting the length of a cardiac cycle. In the large vessels, WSS is $\tau=-\mu\frac{\partial u}{\partial r}$.

Small Vessels Arterioles and venules are represented by asymmetrical bifurcating structured trees (Figure 1a) generated using physiology-based scaling laws. The structured trees are connected to the large vessels via an admittance matrix [2]. At each junction, the daughter vessel radii and lengths are scaled by factors α and β to the parent vessel based on computations found in [3]. Scaling parameters, along with a prescribed minimum radius determine the number of generations and vascular bed density encompassing the small arteries, arterioles, veins, and venules.

Since viscous effects are dominant in small vessels, we can ignore nonlinear inertial terms in equation (1) yielding the following momentum and continuity equations

$$\frac{\partial u_x}{\partial t}+\frac{1}{\rho}\frac{\partial p}{\partial x}=\frac{\nu}{r}\frac{\partial}{\partial r}\left(r\frac{\partial u_x}{\partial r}\right), \qquad C\frac{\partial p}{\partial t}+\frac{\partial q}{\partial x}=0 \tag{2}$$

where $u_x(x,t)$ is the axial velocity, r is the radial coordinate, and $C=\partial A/\partial p$ is the compliance.

As the fluid moves back and forth due to an oscillatory pressure gradient, the WSS exerted by the fluid on the tube wall is given by

$$\tau_\phi(t)=\frac{\Lambda}{\pi R^3}\frac{J_1(\Lambda)}{J_0(\Lambda)-\frac{2}{\Lambda}J_1(\Lambda)}q, \tag{3}$$

where $\Lambda=\left(\frac{i-1}{\sqrt{2}}\right)\Omega, \Omega=R\sqrt{\frac{\rho\omega}{\mu}}$, R is the tube radius, J_0 and J_1 are Bessel equations. To find the percentage of CS in vessel we divide the area deformation by the maximum area and multiply by 100.

Capillaries. The dense network of pulmonary capillaries can be modeled as a sheet of fluid flowing between two membranes held apart by

equally spaced posts. Based on work by Fung [4], the flow within a capillary sheet can be expressed as

$$\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right)h^4 = 0, \quad (4)$$

where $h = h_0 + a(p - p_{alv})$ is the average sheet height where p is the blood pressure, p_{alv} is the pressure of the air in the alveoli, a is the compliance constant, and h_0 is a constant such that $h = h_0$ when $p = p_{alv}$. Extending the WSS calculation for arterioles and venules will allow us to predict this quantity in the capillaries.

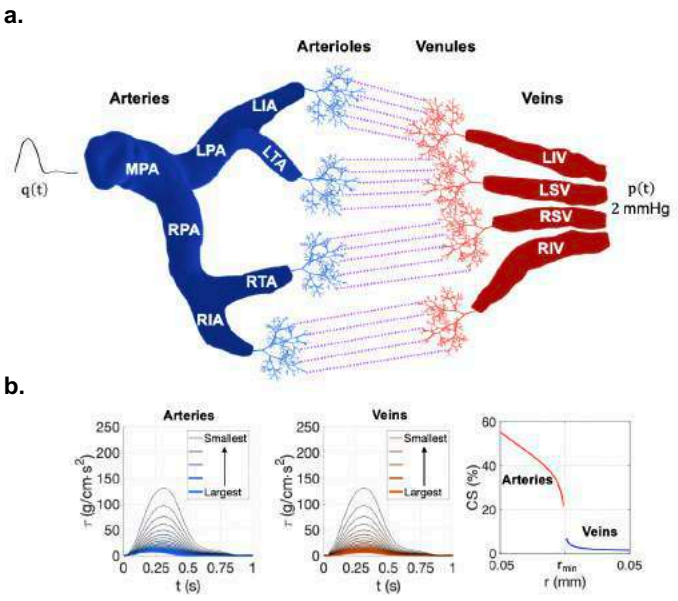

Figure 1: Schematic of the pulmonary circulation arranged in order of large arteries, arterioles, capillaries, venules, and large veins (a). Imposed inflow profile and imposed left atrial pressure are found using a structured tree model for experimental conditions of left atrial pressure of 2 mmHg and typical cardiac output. Predicted WSS and CS for small arteries and veins in the structured tree (b).

RESULTS

Large Vessels. Pressure in the large vessels ranges between 8 and 30 mmHg with pressure in arteries being more dynamic than that of the veins. The mean flow decreases as it is distributed to the downstream vasculature with large arteries having a higher volumetric flow rate of blood than veins. The area in arteries is more dynamic over a cardiac cycle than veins. The area for large veins does not fluctuate as much as the large arteries throughout a cardiac cycle and is less than that of the arteries. This is due to the fact that veins are twice as stiff as arteries in our model. For large vessels, we use a Stokes boundary layer formation along the large arteries and large veins. The mean pulmonary artery (MPA) has the largest shear stress of the large arteries. In general veins have higher shear stress than arteries. Shear stress for veins ranges from 0-7 g/cm^2s whereas shear stress for arteries ranges from 0-5 g/cm^2s.

Small Vessels. In the small arteries and veins, arterioles and venules the pressure decreases with decreasing vessel radius with a maximum pressure of about 30 mmHg and minimum pressure of about 2 mmHg. By contrast, for venules, smaller vessels have larger pressure. For both arterioles and venules, the flow decreases with decreasing vessel radius. For the small vessels, shear stress is predicted along the structured tree. We see that in both small arteries and veins, smaller vessel radius results in higher shear stress (Figure 1b). We find that the arterioles have a higher percentage of CS than venules due to differences in stiffness. Generally, CS decreases with decreasing vessel radius (Figure 1b).

DISCUSSION

The objective of this study is to model pressure and flow propagation and calculate WSS and CS in the pulmonary circulation by setting up a network that includes large and small arteries and veins. This is an extension of several studies that utilized structured tree models to simulate the pulmonary circulation, but it is the first to develop a multiscale model predicting WSS in both large and small arteries and veins. Through our model simulations, we find that large arteries have higher pressure and flow than large veins, as well as more pronounced changes in area throughout the cardiac cycle. In small vessels, we see that as vessel radius decreases, pressure decreases for arterioles but increases for venules. As vessel radius decreases, we also find that volumetric flow decreases.

Our results for pressure, flow, and area in the large arteries and veins generally agree with results found in literature [2]. Several previous studies [5,6] used computational fluid dynamics models to predict WSS in large arteries. While our WSS results for large arteries agree with literature, we are the first to predict WSS in both large and small arteries and veins. This is a significant development because PH begins in the left ventricle and propagates to the left ventricle through the pulmonary veins, venules capillaries, arterioles, and large pulmonary arteries. Thus, by studying both the pulmonary macrovasculature and microvasculature, we are able to advance our understanding of PH pathogenesis.

Results presented here report WSS and CS in the large arteries and veins for a healthy subject and we are currently working on extending these results to a) study how shear stress changes in patients with PH-LHF and b) expanding the model to also include predictions in the capillaries. To simulate LHF-PH, we are working on generating sub-models to progressively increase disease severity by increasing left-atrial pressure, increasing stiffness, and decreasing flow. To capture dynamics in the capillaries, we will couple the structured tree models to the sheet model in [4]. Analyzing results that correspond to disease progression will allow us to further understand the mechanistic quantities that are involved in PH pathogenesis. In addition, we do not yet account for the gravitational gradient that impacts hemodynamics in the veins. Despite these noted limitations, the in-silico computational fluid dynamics model presented in this study is an important tool that provides a new way to analyze and investigate hypotheses related to understanding the physiological mechanisms underlying the progression of pulmonary diseases.

INTRODUCTION

As of the 2018-2019 academic year there were approximately 300 higher education programs in prisons across the United States.[1] These programs offer varying modes of instruction (e.g. face-to-face, online, correspondence), degree offerings, and curricular and extracurricular activities[1]. Data has demonstrated a role for prison education programs to reduce recidivism and increase the rates of employment for people who have been formerly incarcerated, but the programs may also serve a role in addressing structural racism in both the education and justice systems[2]. The number of higher education programs in prisons have been increasing over the past decade[1] as has the availability of STEM programs for incarcerated students[3,4]. Technology companies including Slack have begun to offer internships/training programs in coding to formerly incarcerated individuals[3] while other programs such as The Last Mile work with currently incarcerated scholars to learn business and technology skills[4]. Other STEM programs outside of formal classroom settings have been shown to promote development of scientific identities, ideas of being "science-capable" and an interest in participating in further scientific education[5]. These effects are similar to the known benefits of participating in undergraduate research as demonstrated for non-carceral students[6]. In contrast, there is less known about the impact of engaging incarcerated students in academic STEM research as knowledge creators.

Washington University's Prison Education Project (PEP) PEP began teaching college-level, for-credit courses to incarcerated students and correctional staff at Missouri Eastern Correctional Center (Pacific, Missouri) in 2014[7]. Since then, PEP has awarded both Associate in Arts and Bachelor of Science in Integrated Studies degrees and offers programs for intellectual engagement outside of the classroom including tutoring services, lecture series, and reading groups which are available to both PEP students and other individuals at MECC[7]. Here we present a model (Fig. 1) for an engineering research independent study course designed to promote the documented benefits of traditional undergraduate research experiences for currently incarcerated students. Through this new course, PEP students were invited to participate in engineering research, an offering previously unavailable to PEP students through Washington University in St. Louis.

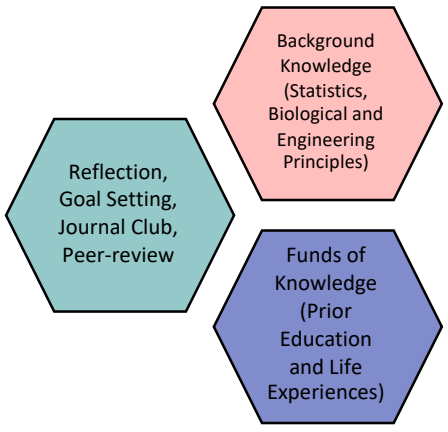

Figure 1: The core components of this course (leveraging funds of knowledge, creating opportunities for reflection, and introducing scientific theory) were integrated and applied in context of engineering research.

METHODS

PEP academic advisors and administrators provided information about the course offering to PEP students at MECC pursuing a Bachelor of Science in Integrated Studies with a STEM focus. Five students with

varying levels of experience in technical fields enrolled in the 2-credit pass/fail course which began in September 2020. Due to the COVID-19 pandemic, this course was offered entirely virtually. Additionally, the course was specifically designed to allow students to conduct research activities using the technology already available to the students and without necessitating access to laboratory equipment. Each PEP student has access to a tablet with word processing and spreadsheet software. The tablets also allow students to utilize a proprietary learning management system (LMS) but do not allow students to directly access the internet. Therefore, all course materials were made available to students directly through the LMS and students submitted assignments through the same mechanism. Lastly, all communication between instructors and students was conducted through the messaging feature within the LMS.

During the first section of the course, students reflected on their personal learning goals and engaged in modules which provided overviews to topics such as research statistics, data visualization, scientific communications, data literacy, and experimental planning. These modules provided a framework for subsequent course activities and established necessary background information so that the course could engage all students without requiring prerequisites of either coursework or technical experience. Each module consisted of a PowerPoint presentation and/or a pre-recorded lecture video, a worksheet, and supplementary materials as needed (e.g. manuscripts or textbook chapters).

In the next section of the course students explored the scientific literature through mediated journal club discussions, analyzed research data, and interpreted the findings. Background information on the research topic was provided to the students through a video recording and/or PowerPoint slideshow. Additionally, students were given access to the manuscript, a glossary of terms/concepts, and two worksheets. The first worksheet guided students through reading the manuscript and asked students to answer questions related to the scientific theory, data as it was presented and interpreted by the authors, and the organization of the manuscript. Because the course was offered asynchronously, and the learning management system did not offer discussion boards, the second worksheet was used to facilitate journal club discussions. Using this second document, students reflected on the experience of reading the paper, aspects of the manuscript they enjoyed, elements they found confusing, and a future direction for the research they think could be interesting to explore. Once students submitted their own journal club sheet, they were sent a document from one of their peers and asked to read it, compare and contrast their experience of reading the manuscript to those of their peer, and to identify something they learned from their peer's response.

This virtual journal club was conducted in order to foster scientific community and to promote some of the most beneficial aspects of in-person journal clubs where scientists are able to learn from one another, share and hear differing experiences or perspectives, and discuss ways to apply the results to future experimentation. Additionally, this activity helped to acclimate the students to reading scientific literature as well as serving the important function of modeling that conducting research requires collaboration and benefits from diversity of perspectives and backgrounds. The instructors also demonstrated this by providing detailed feedback to the students on all the submitted assignments or questions sent via email. These communications were used to address not only the scientific theory and to provide clarifications or corrections but also allowed the instructors to offer messages of encouragement and to share their own research and educational experiences.

In the final course section, students identified an area of their own scientific interest and applied the skills they developed earlier in the course to generate a testable hypothesis, plan a theoretical experiment, propose hypothetical research data, interpret these results, describe limitations of the study, and cite opportunities for future work. For the final deliverable, students compiled these efforts and wrote a 1-page abstract or designed a scientific poster (both based on templates from biomedical engineering conferences held in 2020). The students were given the option of presenting their work in the more text-based or more visual format (scientific abstract or poster, respectively). As with the prior assignments, both instructors served as mentors to the students as they worked on the independent projects by providing scientific literature to the students (who didn't have internet access), helping to workshop the research plans, and assisting with formatting and editing the final documents.

RESULTS

This course was offered for the first time during the Fall 2020 semester (September – December 2020). The impact of this program will be assessed through anonymized student feedback and future iterations may employee pre- and post-tests to quantitatively track student gains. Informal feedback from students has indicated that they found the course to be interesting and that they benefitted from the opportunity to apply previous knowledge in an engineering research context, learn new scientific skills, and gain experience with scientific writing. Students also noted ways in which this experience contributed to gains in self-confidence, interest in future STEM learning and careers, and development of a scientific identity. Given student interest, a second iteration of the course will be offered during the Spring 2021 semester and all students who participated in the first semester have chosen to enroll in the course again.

DISCUSSION

This course represents the first opportunity for students pursuing a Bachelor of Science in Integrated Studies through PEP at Washington University in St. Louis to engage in academic research as knowledge creators. The design of this course emphasized a holistic approach to research that included data collection and analysis along with literature review, experimental planning, and engaging in a scientific community. Additionally, the course combined elements of both classroom instruction as well as mentored research experiences. This model requires validation using both qualitative and quantitative data, but the available feedback from the students demonstrates the value of this asynchronous, virtual research-based course. The use of a similar model may be applicable to other contexts of academic research or in different higher education settings as a method of providing mentored experiences to students who are either incarcerated or otherwise are underserved by traditional programs, however, optimization of the curriculum should be conducted in partnership with the students in order design a system that best meets their personal, professional, and educational goals.

ACKNOWLEDGEMENTS

The authors wish to thank the students who have participated in this course and the Prison Education Project at Washington University in St. Louis and Missouri Eastern Correctional Center (particularly Dr. Barbara Baumgartner and Natasha Narayanan). Additional thanks to Drs. Lori Setton and Jai Rudra for their support of this course. JES has received financial support from the Spencer T. and Ann W. Olin Fellowship for Women in Graduate Study.

INTRODUCTION

Blood pressure (BP), the pressure of circulating blood within the arteries, is routinely used as a measure of cardiovascular system's function. Parameters derived from BP and artery dimensions, such as distensibility, have been broadly used as indicators of mechanical properties of arteries. However, they rely solely on systolic and diastolic pressure values, and the mechanical information associated with the blood pressure waveform (BPW) is not well understood. For example, there is a marked difference in BPW measured in central and upper limb (brachial) arteries between young and older individuals, and this mainly arises from the phase difference between the blood pressure downstream wave and the upstream reflected wave[1]. Stiffening of central elastic vessels, such as the aorta and the carotid arteries, results in a pressure augmentation from the propagating and reflected waves, which increases the peak of the waveform in the systolic phase of the cardiac cycle[2]. Therefore, the BPW is also associated with arterial stiffness. The purpose of this study is to assess changes in BPW in the settings of diet-induced hypertension and establish the relationship between BPW and arterial stiffness.

METHODS

Animal model: All procedures were approved by the Boston University Institutional Animal Care and Use Committee. Male (n = 20) C57Bl/6J mice were purchased from the Jackson Laboratory (Bar Harbor, ME). After acclimation, 2-mon-old mice were fed a control normal diet (ND: 4.5 % fat, 0% sucrose) or high fat, high sucrose diet (HFHS: 35.5 % fat, 16.4 % sucrose). This is a well-established model of diet-induced obesity which develops hyperinsulinemia, glucose-intolerance, increased arterial stiffness and hypertension within 8 months on diet, closely mimicking the human metabolic syndrome[3].

In vivo blood pressure measurements: BP was measured using radiotelemetry[3] (Data Sciences International, St Paul, MI, USA). Briefly, mice were kept anesthetized (1% isofluorane) as a gel-filled catheter was inserted in the aortic arch via catheterization of the left carotid artery. After recovery from surgery (1-2 weeks), BPW recordings were acquired for 20 secs every hour over a 24 hour period (Fig. 1). *In vivo* BP measurements were made when the mice were 2-14 months old in the following 5 groups: 2mon ND (n = 6), 10-14mon ND (n= 5), 3mon HFHS (n = 6), 4mon HFHS (n = 5), and 10-12mon HFHS (n = 4).

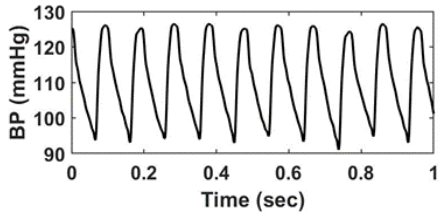

Figure 1: Representative *in vivo* blood pressure waveform over 1 sec time period measured using radiotelemetry.

Harmonic distortion: To quantify the shape of BPW, we introduced a parameter, harmonic distortion (HD), defined as:

$$HD = \frac{\sum_{k=2}^{n} A_k^2}{A_1^2} \quad (1)$$

where A_i are the BPW's Fourier coefficients obtained via discrete Fourier transform. Thus, HD is essentially the ratio of energy above the fundamental frequency and energy at the fundamental frequency of the waveform. For an ideal sinusoidal wave (no distortion), the HD is 0. To obtain HD, individual heartbeat cycles isolated from the 20 sec BP recordings were analyzed using a custom MATLAB code according to

Equation (1). The HD value and the corresponding heartbeat's systolic BP (SBP) was then recorded.

In vitro biomechanical measurements: Carotid arteries were excised from the following mice: 4mon ND (n = 3), 4mon HFHS (n = 2), 10mon ND (n = 3), and 10mon HFHS (n = 2). Biaxial tension-inflation tests were performed using a pressure myograph (Danish Myo Technology, Denmark). From the circumferential Cauchy stress-stretch curve, tangent modulus (TM) was determined at every 10 mmHg between 100 and 140 mmHg transmural pressure. HD vs. TM curves were then plotted at the corresponding transmural pressure.

Statistical analysis: Paired student t-tests were performed on the HD data contained within defined BP bins for the age and diet groups. A two-way analysis of variance (ANOVA) test was performed on the slopes of linear regressions of TM vs. HD. A p-value of 0.05 or lower was considered significant ($^{*}P<0.05$).

RESULTS

Figure 2 shows the HD vs. luminal SBP obtained from BPWs over a 24-hour period for a 10mon ND mouse. HD shows a negative linear relationship with SBP. To further resolve relationship between HD and luminal SBP for the mouse groups, for each mouse, the maximum and minimum SBPs were identified and 12 equally spaced SBP bins were used to average the HD and SBP values within each bin. The average HD vs. SBP were then plotted. A linear regression between HD vs. SBP was performed on the 5 age and diet groups (Fig. 3).

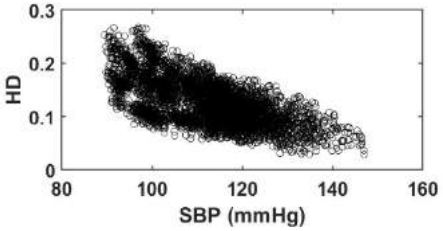

Figure 2: Harmonic distortion vs. luminal systolic blood pressure for a 10mon ND mouse.

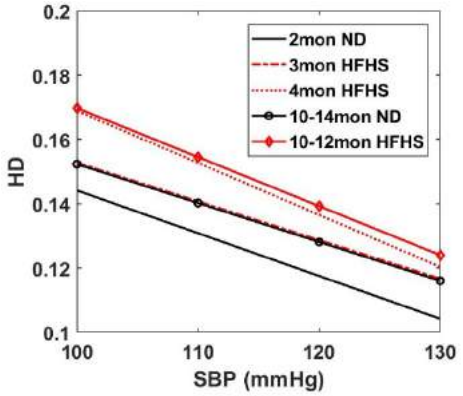

Figure 3: Linear regressions between HD and luminal SBP for the 5 age and diet groups

One-way ANOVA showed that there was a significant difference among the group means for both the slopes (p=0.046) and the intercepts (p=0.007). Pairwise, the slopes were not different, but the intercepts between 4mon HFHS and 3mon HFHS as well as between 4mon HFHS and 10-14mon ND were different. HD values within transmural BP bins ranging from 100-130 mmHg were also found to be statistically significant from one another. This suggests that the linear relationships between HD and transmural BP follows a linear trend for all age and diet groups with a similar slope, however aging and diet results in a significant upward shift of the linear curves.

HD obtained from *in vivo* BPW and tangent modulus from *in vitro* biomechanical measurements at the corresponding transmural BP was found to be linearly related, i.e., as the tangent modulus increases, HD decreases consistently (Fig. 4a). Note that in order to pair HD and TM at the corresponding transmural pressure, *in vivo* perivascular pressure needs to be accounted for[4]. This value was found to be 13.25 mmHg and was subtracted from the *in vivo* luminal SBP. The slopes of the linear relationships were found to be significantly different between ND and HFHS diet groups (p=0.024).

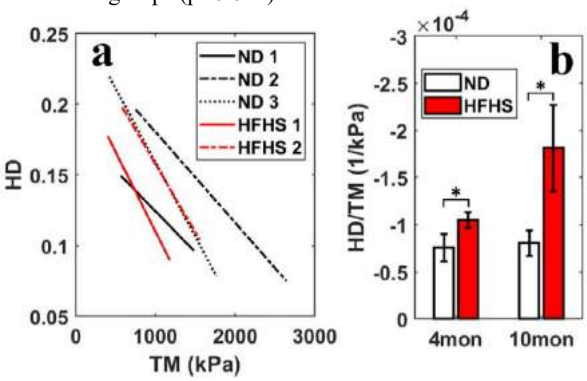

Figure 4: (a) Harmonic distortion vs. tangent modulus for 4mon ND and HFHS mice. (b) Average slopes of the harmonic distortion vs. tangent modulus linear fits for age and diet groups ($^{*}P<0.05$).

DISCUSSION

BPW contains information from the coupled interactions among the forward propagation wave, reflected wave, as well as the arterial wall mechanics. The inverse linear *relationship* between HD and SBP (Fig. 2) suggests that HD is sensitive to changes in arterial stiffness, since with higher BP, the arterial stiffness increases. This is further confirmed by Fig. 4a, in which HD is directly related to the tangent modulus. These findings suggest that HD of BPW shows promises in assessing arterial wall stiffness. Our results further suggest that for the HFHS and the aging groups, HD is more sensitive to changes in arterial wall stiffness (Fig. 4b). The linear relationships between HD and SBP appear to be similar for the 3mon HFHS and the10mon ND groups (Fig. 3), suggesting accelerated changes in BPW with HFHS diet. Interestingly, the 4mon HFHS group is not significantly different from 10mon, suggesting changes in the arterial wall mechanics have already occurred in the 4mon HFHS group. However earlier studies suggested that hypertension was not developed in the 4mon HFHS groups[3], thus HD can potentially be used as a noninvasive predictor of hypertension which warrants further studies.

INTRODUCTION

The mechanical function of the uterus is critical for a successful pregnancy. During gestation, uterine tissue grows and stretches to many times its size to accommodate a growing fetus; it is hypothesized that uterine tissue stretch triggers the onset of contractions. Early contractile activation (defined as ≤ 37 weeks) of uterine tissue can lead to preterm labor and birth (PTB) [1]. In 2015, more than 10% of pregnancies globally ended in PTB. It is also the leading cause of death in children under five years of age [2]. Therefore, characterizing the uterine tissue's mechanical properties and responses during pregnancy is essential for understanding the mechanical failures' mechanisms and causes of PTB.

A previous study found the fibers' orientation and dispersion in biological tissue greatly impact its mechanical responses [3]; this likely holds for uterine tissue, as well [4]. Spherical indentation and uniaxial tension have been combined with inverse finite element analysis (IFEA) to study fibrous biological tissues including the human cervix [5]. In this study, we apply indentation, tension, and video extensometry to capture material responses under compression and tension. We translate previously reported fiber architectures [6] into a constitutive model to describe material responses. We then use IFEA with a genetic algorithm to characterize uterine tissue's anisotropic mechanical properties.

METHODS

Specimen preparation: 27 uterine specimens were collected from consenting a non-pregnant (NP) patient and a pregnant (PG) patient who underwent hysterectomy. Specimens were collected across the full uterine wall thickness (15 to 25 mm) from three anatomical locations: anterior, posterior, and fundus (Fig. 3a). The approximate dimensions of each specimen are 12, 12, and 4 mm in width, length and thickness. Specimens were stored in a –80°C freezer immediately after sectioning. Before testing, the specimens were thawed at 4°C for 12 hours in phosphate buffered saline (PBS) to equilibrate.

Fiber distribution characterization: We developed a hybrid method in R 4.0.2, and fitted a π-periodic von Mises distribution (or a mixture of them) to a fiber orientation previously determined by OCT. A single π-periodic von Mises is defined as:

$$f(x|\mu,\kappa)\frac{1}{\pi}\frac{e^{\kappa\cos(2(x-\mu))}}{I^0(\kappa)} \quad (1)$$

where μ is mean orientation (preferential fiber direction); κ is concentration (the reciprocal of dispersion, where small κ denotes a less concentrated [more dispersed] distribution about the angle μ); and I^0 is the modified Bessel function of order of zero.

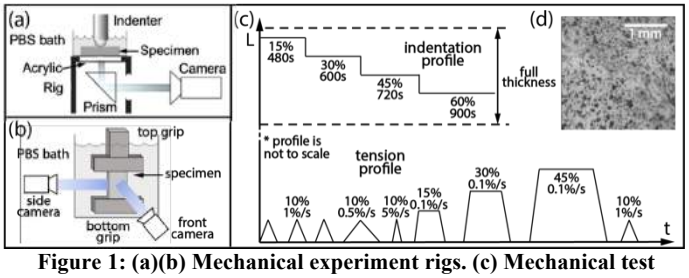

Figure 1: (a)(b) Mechanical experiment rigs. (c) Mechanical test profiles. (d) A representative specimen speckle pattern.

Mechanical testing and digital image correlation (DIC): Specimens were speckled with Verhoeff's stain on one surface for DIC. For indentation, the specimen was positioned in the PBS bath (Fig. 1a) with an acrylic bottom surface. A 90º prism was fixed under to reflect the speckled surface into a camera to capture the full-field displacement. A four-level ramp-hold indentation test was performed (Fig. 1c) on a universal testing machine (Instron, Inc., Norwood, MA) using a 6-mm diameter spherical indenter attached to a 5N load cell. The ramping rate was 1%/s for all specimens. The holding time following each ramp was

480, 600, 720, and 900 seconds, respectively. For tension, the specimen was sectioned three ways: with the preferential fiber orientation at 0º, 45°, and 90º to the uniaxial tension direction. The sectioned specimen was held vertically in PBS (Fig. 1b) with the speckled surface facing forward. Two perpendicular cameras captured the tissue's deformation and displacement from the front and side. The test protocol includes six load-unload cycles with different strain rates (0.5%/s ~ 5%/s) and three incremental load-hold-unload cycles (0.1%/s). The holding time was 30, 45, and 60 minutes for the three levels, respectively (Fig. 1c). Force-time data were collected using material test software (Instron, Inc., Blue Hill). For both testing scenarios, images were taken and processed using Vic-Snap (Correlation Solutions, Irmo, SC). The first (e_1^{DIC}) and second (e_2^{DIC}) Lagrangian principal strains were calculated using a 90% centered Gaussian filter and extracted.

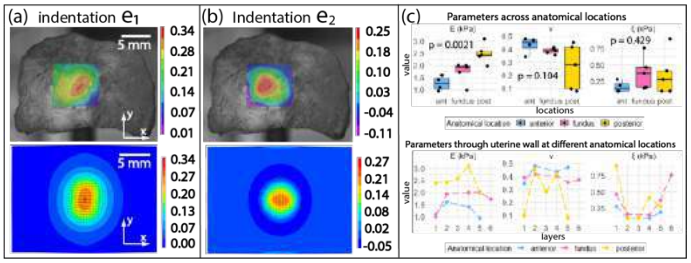

Figure 2: (a)(b) Indentation and tension DIC and FEA first Lagrangian principal strain comparisons show good match. (c) Optimized NP tissue parameters plotted across anatomical locations and uterine layers (1 = outermost, 6 = innermost).

Finite element analysis (FEA) and constitutive model: FEA was performed for comparison with mechanical tests (Fig. 2ab) using FEBio Suite (Salt Lake City, Utah). A rectangular cuboid represented the specimen, a 6-mm diameter sphere represented indenter, and two small rectangular cuboids represented the tension grips (not shown). All geometries were meshed with HEX-8 elements. Uterine tissue was modeled using a previously verified constitutive model [5], described by five material parameters including Young's modulus E, Poisson's ratio ν, fiber stiffness ξ, and OCT-informed preferential fiber direction θ and fiber concentration κ (reciprocal of dispersion).

Inverse finite element analysis (IFEA): An IFEA method using a genetic algorithm optimized the constitutive model's parameters to fit our experimental data. Three material parameters (E, ν, and ξ) were optimized with the objective function:

$$\Xi(E,\nu,\xi) = \sum_{i=1}^{N}\left|\frac{e_1^{FEA^i}-e_1^{EXP^i}}{e_{norm}^{EXP^n}}\right| + \sum_{i=1}^{N}\left|\frac{e_2^{FEA^i}-e_2^{EXP^i}}{e_{norm}^{EXP^n}}\right| + \sum_{i=1}^{N}\left|\frac{F^{FEA^i}-F^{EXP^i}}{F^{EXP^n}}\right| \quad (2)$$

where i is number of mechanical test levels, e is the equilibrium principal strains of the specimen, and F is the equilibrium force recorded by the testing machine. "FEA" and "EXP" denote the data of the finite element model and experiment, respectively.

Statistical analysis: One-way ANOVA ($p \le 0.05$) was performed in R. Optimized parameter set (E, ν, and ξ) were compared in groups according to (1) patient gravidity (NP, PG), (2) anatomical locations (anterior, posterior, and fundus), and (3) relative specimen depth in the uterine wall (outermost, mid, and innermost layers).

RESULTS

Human uterus' compressive are reported in this abstract. Further research is underway to complete its tensile counterpart.

Fiber distributions are significantly different between the NP and PG tissue, both anisotropic (Fig. 3). Each line represents a fiber family, and the concentration κ about the preferential direction θ is indicated by the color bar. Blue denotes a concentration factor equal to zero for a uniform distribution; while red for a more anisotropic distribution.

The best-fit material parameters under indentation are averaged and listed in Table 1. Values reflect data of all 27 indentation tests.

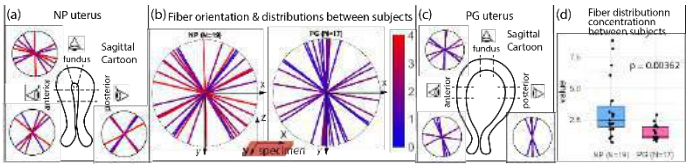

Figure 3: (a)(c) NP & PG tissue fiber distributions by locations. (b) The dominant fiber directionality of NP tissue appears to be at around π/4 & 3π/4 while PG is at π/2. (d) PG tissue show smaller concentration factors, indicating a more uniform distribution.

Heterogeneous mechanical properties are seen in human uterine tissue at different anatomical locations and across different uterine wall layers (Fig. 2c). Specially for NP tissue, Young's modulus E appears to be significantly different between anatomical locations. When comparing the middle layers of NP uterine wall to its most outer and inner layer, the Young's modulus E is larger and fiber stiffness ξ is smaller. For PG tissue, its Poisson's ratio ν is larger at the outer uterine wall for anterior and fundus locations (not shown).

Table 1: IFEA & von Mises fitted material parameters.

Parameter	Mean value	Standard deviation
E [0.1, 100] kPa	1.756 kPa	0.685 kPa
ν [0, 0.499]	0.329	0.124
ξ [0.1, 10] kPa	0.393 kPa	0.347 kPa
κ [0 $\propto$]	2.46	1.99

DISCUSSION

In this study, we aim to characterize the material behavior of human uterus under compression and tension with a single set of mechanical properties. While results reported in this abstract only reflect compression, the tension counterpart is underway; asymmetries in material behavior between compression and tension may change our estimate of fiber stiffness ξ. Both NP and PG tissue have anisotropic material properties, but PG tissue fibers are more dispersed than NP tissue fibers. NP tissue exhibits a basket-weaving or circularly arranged fiber architecture (Fig. 3a), consistent with prior work [3]. PG tissue exhibits a longitudinally or meridionally arranged architecture (Fig. 3c) as the uterus undergoes a sixfold increase in length during pregnancy. Similar to the human cervix [5], the force response of the human uterus under indentation is time-dependent and non-linear, and uterine fiber architecture dictates 2-D principal strain fields. Human uterine tissue also shows heterogeneous mechanical properties at different locations.

The research and conclusions described here have the following limitations: compared to ground substance, fiber stiffness is less sensitive to compressive loads and so will be better informed by the ongoing tensile data analysis; for obvious reasons, specimens collected from hysterectomy are usually pathological, and this may reduce our study's external validity; racial differences in uterine material properties have been demonstrated elsewhere but not explored here.

INTRODUCTION

Glaucoma is an ocular disease characterized by degeneration of retinal ganglion cell axons [1], and increase in intraocular pressure (IOP) is associated with the progressive loss of the axons at the optic nerve head (ONH) [2]. The axons are mechanically supported by a connective tissue called lamina cribrosa (LC) at the ONH. The human LC consists of a network of collagen beams with astrocyte cells spreading along the beams and across the pores to form passages for the axons [3]. In rodent lamina, the astrocytic processes also surround the axonal bundles despite the absence of collagen beams. Thus, the astrocytic lamina (AL) in rodents is functionally comparable to the human LC. Confocal images revealed that 3-day ocular hypertensive (OHT) nerves have larger coverage of actin cytoskeleton, lower area fraction of the astrocytic intermediate filament, GFAP, and thinner astrocyte processes [4]. Previous inflation tests of mouse eye explants showed that pressure-induced strains in 3-day OHT nerves were greater than those in the controls [5]. Therefore, it is hypothesized that the changes in the astrocytic structure may affect the local strain response.

The objective of this study was to develop a computational model for the mouse AL and investigate the effect of the AL network structure on the local stress and strain responses. Understanding the relationship between structure and strain variations will elucidate how glaucoma-induced remodeling affects mechanical insult to the axons and astrocytes in the AL.

METHODS

Specimen preparation: Seven intact eye globes from mice expressing the green fluorescent protein in all astrocytes (FVB/N-Tg(GFAP-GFP)14Mes) were used for inflation tests [5]. The eyes were glued to a plastic holder, cannulated at the cornea and connected to a fluid reservoir for control of IOP. IOP was elevated from a baseline of 10 to 30 mmHg and the ONH was imaged with two-photon laser source at an excitation wavelength of 895 nm (Zeiss, LLC) at both pressures. Displacement fields between baseline and deformed images were calculated using digital volume correlation (DVC) [6,7].

Optic nerve of a 6-month old GFP-GLT1 transgenic mouse was excised and cryosectioned for immunolabeling of GFAP and staining of actin and nuclei [4]. Confocal fluorescent images were obtained at an in-plane resolution of 0.104 μm/pixel (Fig. 1a). The non-actin and non-GFAP regions were segmented as axonal compartments (ACs). The area of ACs and width of actin and GFAP combined processes were recorded for structure-strain comparisons.

Finite Element Model: The AL geometry was created using the segmentations of the GFAP, actin and AC structures. The segmented image was down-sampled to a resolution of 1.13μm/pixel and extruded to a thickness of 11.3μm. The geometry was meshed with trilinear hexahedral elements (HEX8) in the Gibbon Toolbox (Fig. 1b, [8]) and imported into FEBio 3.0 [9]. Nodal displacements were prescribed to the side surface of the AL using boundary displacements from the aforementioned inflation test. In addition, a pressure of 20 mmHg was applied to the anterior surface of the AL to simulate the increase in IOP (Fig. 1c). All three materials were assumed to be incompressible Neo-Hookean materials. Shear modulus (G) of 2.4MPa for GFAP was obtained from existing measurement of intermediate filament vimentin [10], and G for actin was found to be 8.8 times larger than that for vimentin [11]. The AC was assigned a G of 1.9 kPa [12] as measured from white matter of brain tissues. Bulk modulus for each material was set to 100 times larger than its G.

Statistical Analyses: Comparisons among the strain outcomes and among the 3 materials were conducted using 1-way analysis of variance (ANNOVA). Correlations between structural properties and simulated strains in the AC and astrocyte processes were analyzed using a linear regression model in MATLAB.

RESULTS

In the control ONH, preliminary results showed that the average nasal-temporal strain (E_{xx}= 0.033) in the AL was higher than the inferior-superior strain (E_{yy}= 0.026), while the anterior-posterior strain was compressive (E_{zz}= -0.021, p<0.01). The result of higher E_{xx} compared to E_{yy} was consistent with that measured in the inflation tests (0.029 and 0.012 respectively). The maximum principal stress (σ_{max}) was lower in the ACs (0.002 MPa) when compared to that in the GFAP (0.021 MPa) and actin structures (1.83 MPa, p<0.01, Fig. 1e & 2a). However, the ACs have larger maximum principal strain (E_{max}, 0.25 ± 0.25) than that experienced by GFAP (0.07 ± 0.04) and actin (0.03 ± 0.02, p<0.01, Fig 1f and 2b). Similarly, tensile strain E_{xx} and E_{yy}, and compressive strain E_{zz} were highest in the ACs (p<0.01 for all).

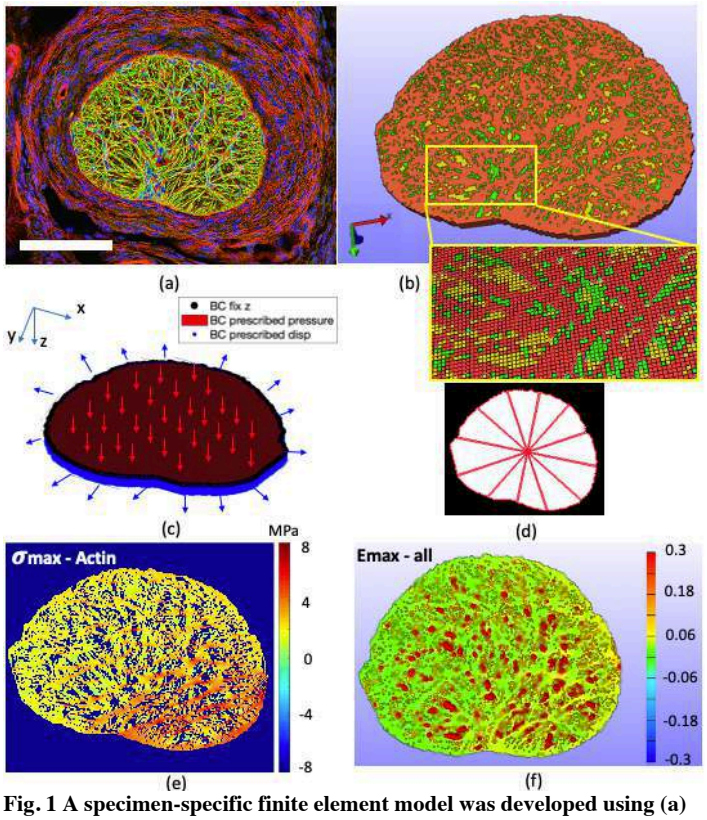

Fig. 1 A specimen-specific finite element model was developed using (a) image acquired from the unmyelinated zone of a mouse optic nerve that was labeled for GFAP (green), actin (red) and nuclei (blue). Non-actin and non-GFAP labelled regions were marked as axonal compartments (ACs). (b) The actin (red), GFAP (green) and ACs (yellow) were then converted to a finite element model with HEX8 elements using Gibbon toolbox and imported into FEBio 3.0. (c) Pressure was applied on the anterior surface to simulate increase in IOP and nodal displacements were applied on the side surface using average of experimental results from previous inflation study. (d) AL was divided into 12 sectors for calculation of pore volume fraction in each region. (e) Color map of maximum principal stress (σ_{max}) in actin and (f) of maximum principal strain (E_{max}) experienced in all 3 materials. Scale bar = 100 µm.

The average area for ACs was 5.4 ± 7.6 µm^2 and the average process width was 5.7 ± 2.1 µm for this specimen. Greater tensile strains E_{max}, E_{xx} and E_{yy}, and greater compressive strains E_{zz} were associated with larger ACs (Fig. 2c, p<0.01). In addition, thicker processes were more inclined to have lower strain magnitudes**.** When divided into 12 sectors (Fig. 1d), AL sectors with higher volume fraction of AC had higher average Emax in the corresponding actin and GFAP processes (Fig. 2d, p<0.01). Other structural measurements such as tortuosity and aspect ratio of the processes will also be analyzed for their effects on local stress and strain responses.

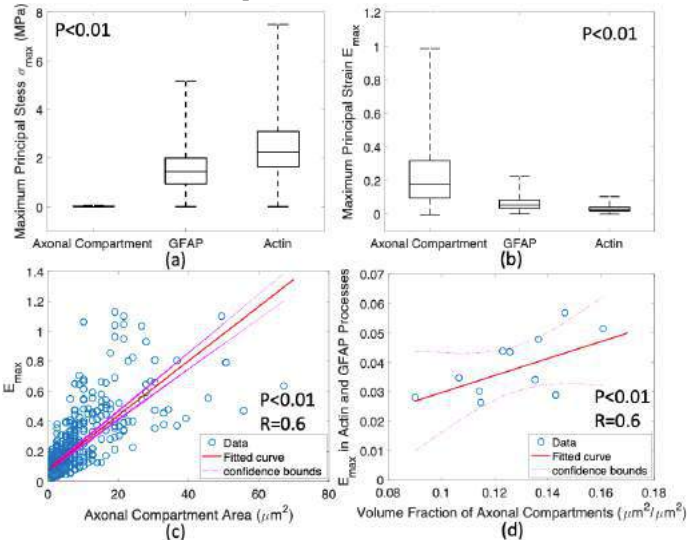

Fig. 2 Results from the specimen-specific finite element model of the mouse astrocytic lamina, showing (a) higher maximum principal stress in actin than in ACs and GFAP, while (b) ACs experienced higher strain Emax than in GFAP and actin. (c) ACs with larger area had larger E_{max}, and (d) sectors with higher volume fraction of ACs is correlated with higher E_{max} in their corresponding actin and GFAP processes.

DISCUSSION

Models of the human lamina cribrosa have been developed for investigation of structural effects in pressure induced strains [13, 14]. However, there have not been models that directly incorporate both experimentally-derived boundary displacements and applied pressure on a specimen-specific model of the AL. The model presented in this abstract included both boundary conditions and simulated strain response in the ACs. The result of E_{xx} larger than E_{yy} agreed with the results from the inflation tests. Further, local strain response was found to be associated with variations in structural properties.

Studies in brain injuries have shown that a strain of 0.05 - 0.3 causes moderate to severe diffuse axonal injury [15]. Our model showed that larger ACs experienced strains much higher than this threshold and may be more susceptible to axonal insult in glaucoma. We are currently developing more specimen-specific models of both control and 3-day OHT samples to further investigate the relationship between structural properties and local strains in the AL. The models will be validated by comparing to experimental measurements of the strain-structure relationships [16]. We will also examine the sensitivity of the predicted structure-strain and stress relationships to model assumptions for the material properties and for the segmentation and reconstruction of the astrocytic lamina.

CONTINUUM-BASED INTERPRETATIONS OF MECHANO-ADAPTATION IN EPITHELIAL MICRO-TISSUES

Bernard L. Cook (1), Patrick W. Alford (1)

(1) Department of Biomedical Engineering
University of Minnesota
Minneapolis, MN, USA

INTRODUCTION

During development, epithelial tissues, such as the endocardium that lines the lumen of the developing heart, undergo morphogenesis, or shape change, which gives mature structure to amorphous tissue. It has been suggested that this shape change is driven by the epithelia mechano-adapting to rapidly changing loading conditions experienced during development [1]. Though progress has been made towards understanding short-term epithelial mechanics, long-term mechano-adaptation in epithelial tissue has yet to be systematically characterized.

Here, we use Cellular Microbiaxial Stretching (CμBS) to show that stresses in micro-tissues consisting of Madin-Darby Canine Kidney (MDCK) cells evolve at the tissue scale following a sustained stretch, a phenomenon captured with a continuum-based architecture dependent growth law that attributes stress evolution to cytoskeletal remodeling.

METHODS

Stretching device. The CμBS device [2] is comprised of a silicone membrane secured between metal clamps fastened to linear actuators (Fig. 1A). Bead-doped polyacrylamide gels are chemically bonded to the membrane, onto which cells are micropatterned into designated geometries (Fig 1B). The device is fixed above an inverted confocal microscope (Fig. 1C) and housed within a chamber maintained at physiological conditions. The linear actuators are used to precisely stretch micropatterned cells, while the confocal microscope is used to quantify cell-generated forces and cellular architecture (Fig 1D).

Substrate preparation. For all stretching experiments, MDCKs were micropatterned into square "micro-tissues" (8000 μm^2) (Fig. 1D, i) and cultured in standard cell growth medium.

Micro-tissue stretching protocol. A stretching protocol used to assess single-cell mechano-adaptation was adapted from a previous study [3]. MDCK micro-tissues were uniaxially strained to 30% (applied stretch ratios λ_x=1.3, λ_y=1) at a rate of 2%/s and held in this configuration for 24 hrs (Fig. 1D-E). For stress experiments, brightfield

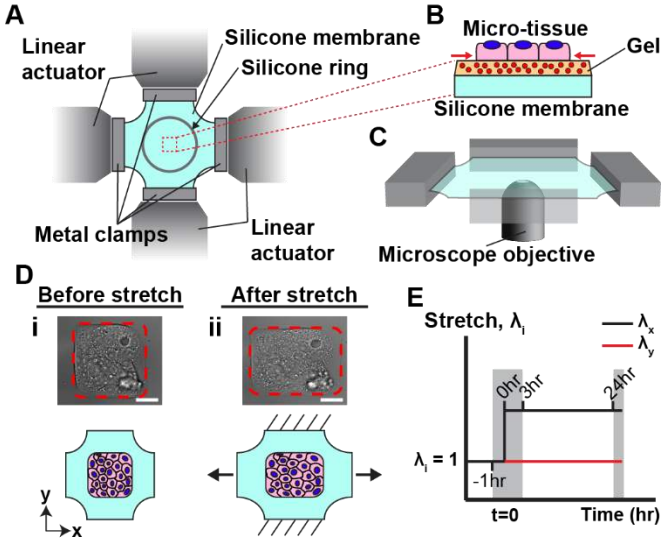

Figure 1. CμBS device is used to assay cell-scale mechano-adaptation. A) Stretching device. Silicone ring contains cells. B) Micropatterned cells. Cell forces deform the gel (arrows); this deformation is captured using C) a confocal microscope. Traction stresses are quantified from these deformations using traction force microscopy. D) MDCKs micropatterned into micro-tissues before (i) and after (ii) uniaxial stretch. E) Mechano-adaptation stretch protocol. Data is captured in regions boxed in grey. Scale: 30 μm.

and bead images were captured before and after stretch (Fig. 1E). After the experiment, cells were lysed with 0.1% SDS and microbead images were captured in both the deformed and undeformed configuration to quantify bead displacements used to determine traction and midplane Cauchy stresses. For architecture experiments, MDCKs were stained with CellMask Deep Red and imaged before and after stretch.

Cell stress and structure. Traction stresses (Fig. 2A) and midplane Cauchy stresses (Fig. 2B) were calculated as previously described [2]. Midplane cross-sectional areas were estimated with monolayer height [4] and micro-tissue geometry. Architecture alignment was quantified from images of stained MDCKs and quantified (Fig. 2C-D) with a ridge-detection algorithm [5].

Modeling mechano-adaptation. Micro-tissues were assumed to be incompressible, and undergo shear-free, axisymmetric deformation. Micro-tissues were taken to be comprised of a population of discrete actin fibers embedded in a surrounding matrix, representing non-fiber components of the cell. Micro-tissue strain energy density was taken to be comprised of a term that represents the cellular matrix and a second term that represents fiber contributions as in Eq.1,

$$W = \frac{\mu}{2}(I_1 - 3) + \frac{1}{n}\sum_{i=1}^{n}\frac{C_f}{2}\left(\left(\frac{\lambda_{fi}}{\lambda_{gfi}}\right)^2 - 1\right)^2 \quad (1)$$

where shear modulus μ and fiber stiffness C_f and are material parameters, $I_1=\lambda_x^2 + \lambda_y^2 + \lambda_z^2$, where λ_i is the elastic stretch in the i^{th} direction, λ_{fi} and λ_{gfi} are the fiber stretch and growth of the i^{th} fiber, respectively, and n is total number of fibers. Fiber stretch is related to elastic stretch through $\lambda_f^2 = \lambda_x^2 cos^2\theta + \lambda_y^2 sin^2\theta$. Midplane stresses were calculated assuming cells were unconstrained (i.e., stress-free) in z. Single-fiber stress was calculated assuming fibers to be 1-dimensional.

Here, we explored two models of mechano-adaptation. In a targeted growth formulation, we assumed cytoskeletal fibers grew following stretch according to Eq. 2,

$$\frac{\dot{\lambda}_{gf}}{\lambda_{gf}} = \frac{1}{T_f}(\sigma_f - \sigma_{f0}) \quad (2)$$

Where $\dot{\lambda}_{gf}$ is the rate of change of λ_{gf}, T_f is a time constant, and σ_f and σ_{f0} are the current and homeostatic fiber stress, respectively. In a hyper-restoration formulation, we assumed that fibers grew according to Eq. 2; however, fiber target stress σ_{f0} was taken to evolve according Eq. 3,

$$\dot{\sigma}_{f0} = -\frac{1}{T_s}(\sigma_f - \sigma_{f0}) \quad (3)$$

where $\dot{\sigma}_{f0}$ is the rate of change of σ_{f0} and T_s is a time constant.

Model optimization. To fit each model to experimental stress data, micro-tissues were assumed to be comprised of an incompressible matrix embedded with 2000 discrete actin whose orientations were randomly sampled from experimentally measured PDFs of fiber alignment (see Fig 2C). Before stretching, it was assumed that $\lambda_x=\lambda_y=\lambda_z=\lambda_f=1$. Micro-tissues were stretched ($\lambda_x=1.3$), stresses solved, and growth and homeostatic stress evolution evaluated with finite differences. Constants C_f, μ, λ_{g0}, and T_f and T_s were optimized using least squares minimization between experimental and model stresses.

RESULTS

Before stretch, micro-tissues had architecture aligned primarily at 0° and ±90°. Following stretch, architecture was passively realigned in the direction of stretch (Fig. 2C-D).

Following stretch, micro-tissue traction stresses spatiotemporally evolved (Fig. 2A), suggesting an active response to stretch. At the tissue scale, stresses increased following stretch; over time, however, stresses decreased. By 25 hrs post-stretch, stresses fell below pre-stretch magnitudes, indicating that MDCKs adapted to the loading (Fig. 2E). Both mechano-adaptation models captured early stress behavior (Fig. 3D-E); however, the hyper-restoration model more aptly captured the stress overshoot observed 24 hrs post-stretch (Fig. 3E).

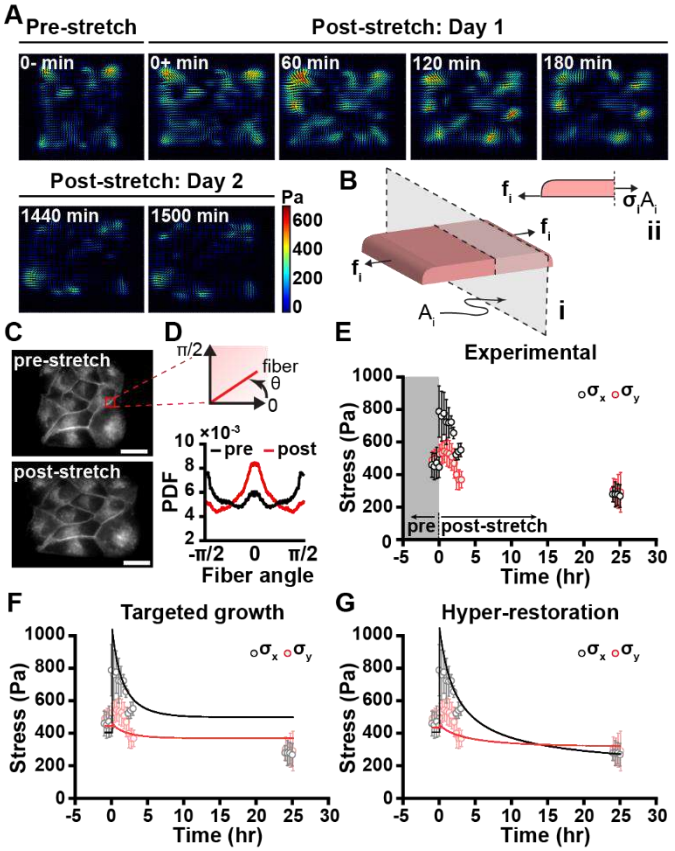

Figure 2. Epithelial micro-tissues mechano-adapt. A) Traction stresses before and after stretch. B) Cauchy stress calculation, where f_i is cell force (calculated from traction stresses), A_i is midplane cross sectional area, σ_i is midplane Cauchy stress, and i = x, y. B) Coordinate system used to determined orientation of cell architecture (top), from which probability density functions for architecture alignment are quantified (bottom). C) Experimental Cauchy stresses. D-E) Models fit to experimental data. Scale: 30 μm.

DISCUSSION

Here, we used our CμBS device to measure and characterize mechano-adaptation in epithelial micro-tissues. We find that tissue-scale stress evolution can be captured with a continuum-based formulation of mechano-adaptation that attributes changes in stress to cytoskeletal remodeling. The present work is a first step towards creating stronger models of morphogenesis that investigate the role of forces in shaping developing tissues, and elucidating which forces lead to maladaptive changes in shape. Ultimately, this work will serve as a framework that will be applied towards understanding mechano-adaptation in specific developing tissues, such as the embryonic heart.

INTRODUCTION

Deep vein thrombosis (DVT) is a pressing clinical issue that requires further investigation into both the disease pathway and clinical intervention. DVT is characterized by slow clot formation over months, with symptoms beginning as mild pain and swelling in the afflicted area and growing to pulmonary embolisms and strokes **[1]**. Complications associated with DVT are estimated to result in between $5-8 billion in annual domestic medical spending [**2]**. Anticoagulants are a common treatment, but often either fail to stifle thrombosis sufficiently or result in severe side effects such as excessive bleeding **[3]**. Due to a lack of accessibility and poor clot visualization, clinical diagnostic practices are ripe for improved imaging resolution and alternate approaches.

The mechanics by which clots form in the venous circulation are still not fully understood. Certainly, the venous valves serve as a nidus for clot formation due to flow stagnation and recirculation within the sinus region. However, how procoagulant conditions arise are not clear **[4]**. Venous thrombosis is markedly different from arterial clots, as thrombus composition is predominately red blood cells and fibrin. Knowing that clot formation can be interpreted through the lens of Virchow's Triad, it is important to target the appropriate pillars, namely hemostasis and increased thrombogenicity.

Combining therapeutic innovation with improved diagnostic methods would therefore serve a pressing clinical purpose. Ultrasound (US) is both a common diagnostic method for DVT and a prospective delivery method for thrombolytic agents. The use of ultrasound has the advantage of localized drug delivery over the current method of systemic anticoagulation **[3]**. B-mode imaging displays a grayscale visualization of physical structures while Doppler imaging assesses flow magnitude and direction **[5]**. Combining the two elements of ultrasound imaging allows for analysis of both clot location and structure, as well as the alteration in flow regimes that arise due to the growing thrombus. A method of increasing imaging resolution at the boundary of deep veins and the internal site of clot formation would be an important step in *in vivo* diagnosis of DVT.

A novel nanoparticle, described as a nanopeptisome, acts as an ultrasound sensitive scattering agent. This nanoparticle serves the dual purpose of increasing the imaging depth of contrast US and competitively inhibiting clot formation. The Arginine-Glycine-Aspartate (RGD) ligand incorporated within the self-assembling peptide shell of the nanopeptisome targets the $\alpha_{IIb}\beta_3$ binding site, limiting platelet-platelet adhesion. This nanoparticle is designed with the intention to localize to activated platelets, limiting further aggregation via competitive inhibition, and aiding in detection by scattering acoustic signals. The development of an *ex vivo* platform will allow for the testing of these properties.

METHODS

Blood was obtained from a bovine jugular vein the same day as experiments, into an CPDA-anticoagulated blood bag. After checking the hematocrit and platelet count, the blood was recalcified to 20mM prior to flow loop circulation in order to restore coagulability. Bovine carotid vessels were obtained from Lampire Biological Lab LLC (Everett, PA) and sectioned into 15 cm strips for insertion into the flow loop. The vessels were untreated and used one day after harvesting while shipped in a refrigerated DMEM suspension. The vessel was trimmed and secondary outlet vessels were ligated to prevent leakage. Both the proximal and distal ends of the sectioned vessel were attached to the flow loop with barbed connectors and sealed using a plastic clamp. A 2000IU/mL solution of bovine lung thromboplastin (BioPharm LLC, UT) was prepared from frozen stock on the day on experimentation. A 26.5g needle was inserted into the vessel so that the angled tip was flush with the vessel wall, serving as an injection port for

the thromboplastin. After operation of the flow loop, the clamps were unfastened, and the vessel was removed from the connectors for dissection and clot observation.

Nanoparticles were fabricated via an emulsification procedure utilizing perfluoropentane and a fluorinated amphiphilic peptide containing an RGD binding motif, as previously described **[6].** The nanopeptisome solution was diluted 1:20 within the blood and circulated throughout the loop.

In vitro clotting studies were performed in both static and dynamic conditions. Nanoparticles were diluted in recalcified bovine blood within 24 well plates on a rocker, or within a Chandler loop operating at 1 Hz and allowed to clot overnight at 37˚C. A flow loop was designed to create a closed-loop system for initiation and localization of thrombosis within the *ex vivo* platform. A centrifugal pump, was used to drive flow at Reynolds number 200. Flow rate was confirmed to be steady by an ultrasonic flow probe downstream of the vessel platform. A tissue analogue model was fabricated of 2% agarose within a plastic container with a channel bore for the vessel. Agarose was suspended in water and cured overnight at 0˚C**.** The loop was operated for 30 minutes or until complete occlusion. After flow cessation, the vessel was removed from its tubing attachments and dissected longitudinally to observe the clot. A Verasonics (Kirkland, WA) research ultrasound system was used to collect B-mode and Doppler signals. The 5MHz ultrasonic transducer was aligned with the longitudinal axis of the vessel.

RESULTS

In vitro clotting experiments yielded data regarding the efficacy of clotting inhibition via nanopeptisomes as a function of both hematocrit and nanoparticle concentration. The nanoparticle demonstrated an ability to localize activated platelet binding sites at a significantly higher rate than nonspecific binding in similar conditions (**Fig 1A and 1B).** The activation of platelets causes a change in conformation that exposes additional binding sites. Clot mass was shown to be significantly reduced with blood samples of 40 and 60% HCT (**Fig 2)**, indicative of venous blood composition.

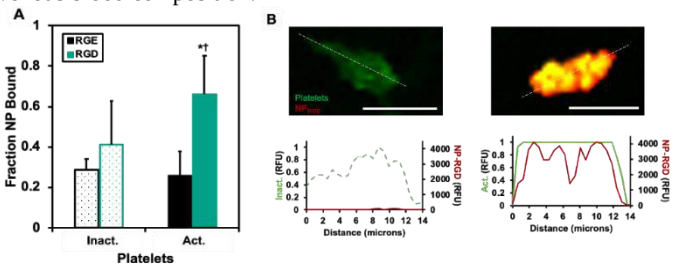

Figure 1: (A) Increase in ligand binding affinity and specificity as a result of platelet activation
(B) Specific localization of nanoparticles to platelet binding sites

Within the *ex vivo* flow loop, case studies (n=6) showed a similar ability of the nanoparticles to inhibit clotting on the vessel test surface under physiological conditions. The ultrasound system was able to detect and measure clot growth within the deep tissue analogue with sufficient resolution for identification and measurement (**Fig 3)**.

(B) Nanoparticle effect on *in vitro* clot mass with respect to HCT

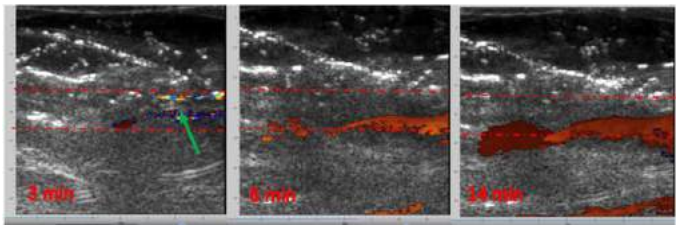

Figure 3: Clot growth within vessel visualized with Doppler US. The red outline denotes the vessel region while the green arrow points out the initial clot location

DISCUSSION

This study consisted of a two-pronged approach in developing an *ex vivo* platform for initiating, visualizing, and inhibiting thrombus formation. Nanopeptisomes were fabricated to be used as both an acoustic marker and a competitive inhibitor for platelet binding. Due to the embedded RGD motif within the peptide shell, nanoparticles were shown to effectively inhibit platelet-platelet binding at $\alpha_{IIb}\beta_3$ sites at both the *in vitro* and *ex vivo* levels. *In vitro* clotting was significantly inhibited at 40% and 60% hematocrit. In both static and dynamic conditions, clot inhibition was most pronounced at higher hematocrits and nanoparticle concentrations, suggesting an effect caused by the ratio of nanoparticles to platelets. This is likely due to increasing availability of nanoparticles, and the decrease in total platelets to be suppressed as this ratio shifts. As hematocrit decreases, total platelet count is increased and available nanoparticles are distributed more sparsely throughout the binding sites, indicating that it might be possible there is a minimum effective threshold for clot inhibition. *Ex vivo* experiments were conducted as a series of case studies, in which each case demonstrated reduced clot growth in the presence of nanoparticles relative to absence. Additional studies are currently being conducted on preformed clots within the *ex vivo* platform to further investigate the acoustic properties and thrombolytic capability of the nanoparticles.

INTRODUCTION

Epithelial tissue sheets undergo dramatic changes in shape and structure to build organs during development. These tissues comprise collections of cells whose behaviors must be coordinated to generate complex structures (1-3). Mechanical forces generated by cells are a major driver of tissue shape changes and movements (4-5) and of tissue mechanical properties (6). The mechanical forces driving tissue morphogenesis have been largely attributed to cellular actomyosin networks (7-13), which are mechanically coupled across the tissue through cell adherens junctions. Contractile forces generated by the myosin II motor protein (myosin) are essential to tissue morphogenesis (10), and the localization pattern of myosin in a specific tissue tends to correlate with how the tissue changes shape (11-15). For example, during *Drosophila* axis elongation, myosin accumulates at cell junctions in a planar polarized pattern (higher accumulation at "vertical" contacts between cell neighbors along the AP axis), driving cell intercalation that narrows the tissue along one axis (converges) and elongates it along the other axis (extends) in a flow that doubles the length of the tissue in 30 min (Fig. 1). In contrast, a more isotropic pattern of myosin is observed during *Drosophila* ventral furrow formation. Recent studies of ventral furrow formation reveal a myosin network spanning the tissue that increases in density over time to form a robust network that is resilient to perturbation (13). Yet, it is not well understood how specific properties of myosin network architecture contribute to tissue mechanical behavior in other contexts, such as in convergent extension, or how myosin networks are regulated to promote fluid-like tissue flow in some regions of the embryo and solid-like behavior in others.

To understand how myosin network architecture contributes to convergent extension tissue flows, we identified and analyzed the myosin network in the germband during *Drosophila* body axis elongation. To visualize myosin, we used existing *Drosophila* lines expressing an mCherry-tagged myosin and imaged the embryos by confocal microscopy. To extract the myosin network, we developed a custom MATLAB-based code designed to trace myosin fluorescence intensity. We find that convergent extension coincides with myosin network reorganization, suggesting that myosin network architecture may play a key role in this fluid-like tissue flow.

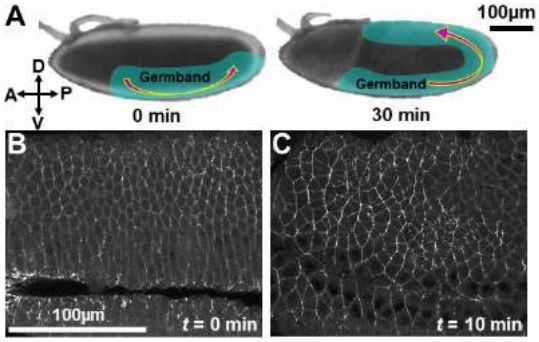

Figure 1. During *Drosophila* body axis elongation, the germband epithelium rapidly extends to twice its length in a convergent extension movement. This tissue flow (A) is thought to be driven by a planar polarized pattern of myosin that produces anisotropic stresses. Planar polarized myosin localization at $t = 0$ (B) and $t = 10$ min (C).

METHODS

Fly Stocks. Fly stocks were from the Bloomington *Drosophila* Stock Center (BDSC). Myosin II was visualized with an mCherry-tagged myosin regulatory light chain (sqh-mCherry).

Time-Lapse Imaging. Collected embryos were dechorionated for 2 min in 50% bleach and washed with distilled water for 2 min. Embryos were mounted between a glass slide and an oxygen-permeable

membrane in halocarbon oil. Confocal imaging was performed with a Zeiss LSM880 laser-scanning confocal microscope on the ventrolateral region of the embryo at 15µm z-steps and 15 s time intervals.

Image Processing and Quantification. Analysis was performed on maximum intensity projections of 3 z-slice images at the apical side of the tissue at the level of adherens junctions. Myosin networks were mapped by combining a watershed algorithm (16) with a mask in MATLAB. Tortuosity and intensity measurements were performed in MATLAB. Tortuosity is the ratio of total segment length to linear node-node distance, with values ≥1. The time point $t = 0$ represents the start of body axis elongation.

RESULTS

The myosin network we identified spans the tissue and dynamically changes during convergent extension. The myosin network predominantly comprises segments connected to the network at both ends (Fig. 2); these segments correspond to myosin at cell junctions as well as in the cell medial-apical domain. The network contains more dendritic strands (not connected to the network at both ends) when the tissue is rapidly flowing at $t = 10$ min (Fig. 2B) compared to at the onset of tissue flow (Fig. 2A).

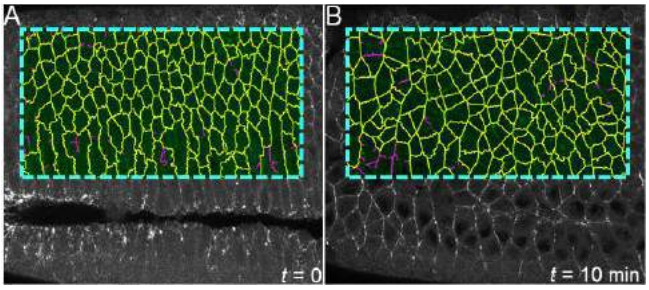

Figure 2. Analyzing the myosin network in the flowing germband epithelium during *Drosophila* convergent extension. The network at the onset of axis elongation $t = 0$ (A) and during rapid tissue flow $t = 10$ min (B). Color map represents connectivity of segments in the network. Yellow segments are connected to two nodes and fully connected to the network. Magenta segments are not connected at both ends to the network and might not robustly transmit forces. Cyan rectangles denote regions used for analyses.

To further characterize the identified myosin network, we quantified the tortuosity (Fig. 3A,B) and orientation (Fig. 3C) of each network segment. We find 2-3 times more segments oriented vertically (along the DV axis) than horizontally (along the AP axis).

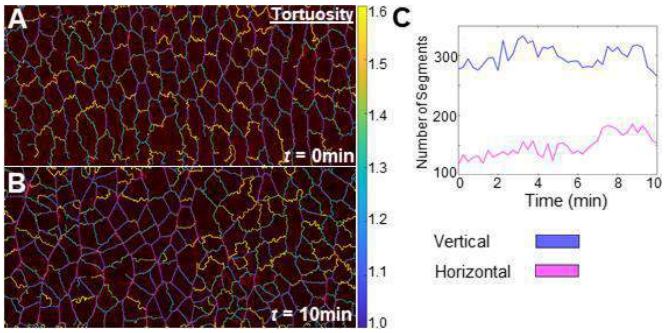

Figure 3. Tortuosity and orientation of myosin network segments during convergent extension. Segments color-coded by tortuosity at $t = 0$ (A) and $t = 10$ min (B). (C) Number of myosin segments oriented vertically (along DV axis) or horizontally (along AP axis) over time.

The average tortuosity of segments decreased over time, but the tortuosity of "horizontal" segments was consistently higher than for "vertical" segments (Fig. 4A). Consistent with the planar polarized pattern of myosin in this tissue (Fig. 1), we observed higher myosin intensities at "vertical" compared to "horizontal" segments (Fig. 4B). The trends for tortuosity and myosin intensity were inversely correlated.

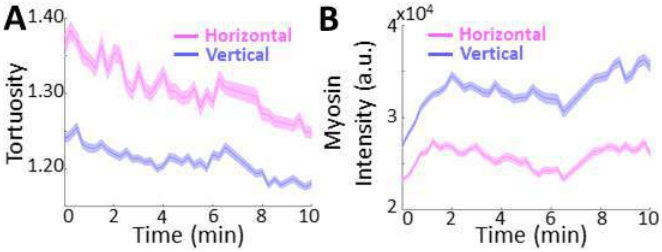

Figure 4. Tortuosity and myosin intensity of network segments show opposite trends during convergent extension. (A) Mean tortuosity of "vertical" and "horizontal" segments over time. (B) Mean myosin intensity of "vertical" and "horizontal" segments over time. Error bars, standard error.

DISCUSSION

In this paper, we identified and analyzed the myosin network spanning the converging and extending germband epithelium during *Drosophila* axis elongation. We quantified how the orientation, tortuosity, and intensity of network segments changed over time. We found fewer segments in the horizontal orientation, possibly reducing resistance to tissue extension along the AP axis during tissue flow. Additionally, we found opposing trends in network segment tortuosity and myosin intensity. Segments displayed increased myosin accumulation and decreased tortuosity over time, with vertical edges having the highest intensity and lowest tortuosity. Overall, these results show that there is a myosin network spanning the germband tissue during convergent extension and that the network architecture changes during this process. These changes in network architecture are likely to alter the mechanical properties and force transmission in the tissue, which may contribute to rapid convergent extension and tissue flow. In future work, we will directly compare these myosin network properties of the flowing germband to the myosin networks present in tissues that show more solid-like behavior, such as during ventral furrow invagination (13), which will help link myosin network architecture and tissue mechanical behaviors, such as tissue fluidity versus solidity.

IMPLEMENTING VARIABLE-STIFFNESS SPRINGS FOR MODELING THE VISCOELASTIC BEHAVIOR OF THE PORCINE URINARY BLADDER

Tyler G. Tuttle (1), Sara Roccabianca (1)

(1) Mechanical Engineering Department
Michigan State University
East Lansing, Michigan, United States

INTRODUCTION

The lower urinary tract is composed of the urinary bladder, internal and external urethral sphincters, and urethra. During urine storage, a healthy bladder maintains a low pressure through relaxation of the bladder wall as the organ fills. The bladder wall consists of smooth muscle cells (SMCs) and extracellular matrix (ECM). The ECM, which is comprised of proteins, proteoglycans, and glycosaminoglycans, acts as a support structure that gives strength and compliance to the bladder. Because of the prevalence of lower urinary tract pathologies that are associated with tissue mechanical dysfunction, such as decrease or increase in distensibility, it is important to understand the mechanical characteristics of the bladder wall.

An effective way to analyze and quantify mechanical behavior is through the use of constitutive models. These can be either phenomenological or microstructurally motivated, and can give insight into mechanical behavior that is not possible to observe from purely experimental data. Soft-tissue mechanical behavior is generally modeled as hyperelastic or viscoelastic. In this study, we utilize a combination of experimental testing and viscoelastic constitutive modeling to describe the stress-relaxation behavior of the porcine bladder wall.

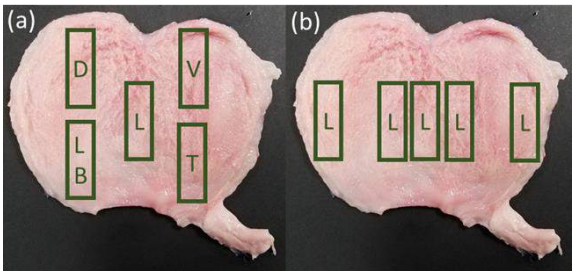

Figure 1: Representative bladder depicting sample locations for (a) location experiments, and (b) osmolarity experiments.

Mechanical characteristics of the bladder have been shown to differ between anatomical locations[1]. However, no study has evaluated location dependent viscoelastic behavior in the bladder. Furthermore, inflammatory response to pathological conditions is seen in many tissues, including the bladder[2], and this can lead to increased tissue swelling. Hence, in this study we also aim to evaluate the effect of swelling on the viscoelastic response of the bladder wall.

METHODS

Porcine bladders (n=6) were obtained at time of slaughter and then were cut along the lateral edge and flattened. A 10mm × 30mm rectangular punch was used to create rectangular samples from the bladder wall in the longitudinal (apex-to-base) direction. The stress-relaxation experiments were split into two separate sets of experiments – i.e., to identify location-specific behaviors (n=3), and the effect of solution osmolarity (n=3). For the location experiments, one sample was taken from each of the five anatomical locations, namely dorsal (D), ventral (V), lateral (L), lower-body (LB), and trigone (T), Figure 1a. For the osmolarity experiments, five samples were taken from the lateral location, Figure 1b.

For the swelling procedure, samples were submerged in 10 mL of modified Krebs-Henseleit buffer solution for 18 hours. For the location experiments, all samples were soaked in solution with an osmolarity of 300 mOsm/L. For the osmolarity experiments, samples were soaked in solutions of either 100, 300, 600, or 900 mOsm/L to induce different levels of swelling.

Uniaxial stress-relaxation experiments were performed with samples fully submerged in modified Krebs-Henseleit buffer solution.

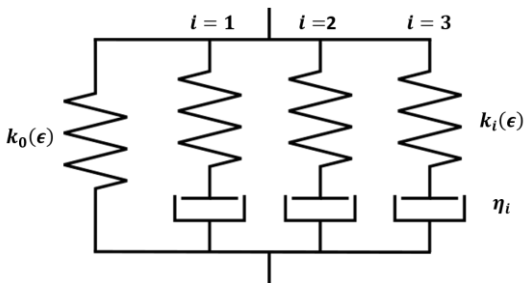

Figure 2: Modified Maxwell-Wiechert model with strain dependent spring stiffness.

For the osmolarity experiments, one sample from each bladder was tested dry to observe the difference in submerged and open-air experiments. Multi-step stress-relaxation was performed at strains of 0.25, 0.5, 1.0, 1.5, and 2.0 with a displacement rate of 50 mm/s, and relaxation times of 30 minutes for the first step, and 45 minutes for all subsequent steps. Sample images were taken at each step to estimate cross-sectional area.

Stress, σ, as a function of time, t, was calculated as follows,

$$\sigma(t) = F(t)/A_\epsilon \quad (1)$$

$$A_\epsilon = b_\epsilon h_\epsilon \quad (2)$$

where $F(t)$ is the force as a function of time; A_ϵ, b_ϵ, and h_ϵ are the cross-sectional area, width, and the thickness for the sample, respectively, measured at each strain level.

For this study we employed a modified Maxwell-Wiechert model[3] with three Maxwell elements (see Figure 2). Nonlinear spring elements were used to capture the nonlinear mechanical behavior of the bladder. Specifically, the standalone spring has a stiffness, $k_0(\epsilon)$, that increases exponentially with stretch,

$$k_0(\epsilon) = c_a e^{c_b \epsilon}\,, \quad (3)$$

where c_a and c_b are spring stiffness parameters with units of stress and nondimensional, respectively. Additionally, the Maxwell element springs have stiffness, $k_i(\epsilon)$, that increases linearly with stretch,

$$k_i(\epsilon) = c_i \epsilon\,, \quad (4)$$

where c_i (units of stress) is a spring stiffness parameter for the given Maxwell element. All dashpots in this model are standard dampers where stress is proportional to rate of strain. The relaxation function for this model, $G(t)$, is as follows,

$$G(t) = \epsilon c_a e^{c_b \epsilon} + \sum_{i=1}^{3} \frac{4\eta_i}{\left(2t\sqrt{c_i} + \frac{2\eta_i}{\epsilon\sqrt{c_i}}\right)^2}\,, \quad (5)$$

where η_i represents the dashpot constants. Time constants, τ_i, for the modified Maxwell elements in this model are as follows,

$$\tau_i = \frac{\eta_i}{8 c_i \epsilon}. \quad (6)$$

Due the strain-dependent stiffness of the springs in the modified Maxwell elements, the time constants are also strain dependent.

The parameter estimation has been performed in two steps, to lower the uncertainty in parameter values by lowering the number of simultaneously estimated parameters. First, we quantified the exponential spring parameters (c_a and c_b) by minimizing the sum of squared error between the relaxed model stress response at each level of strain, and the stress-strain data resulting from using the final stress point in each relaxation step. Second, the remaining parameters are estimated using the time dependent stress-relaxation data. Parameter estimation for this step is done using sum of absolute error, which lessens the impact of short-time stress response deviation from model prediction. Figure 3 shows a representative model fit to experimental data. Statistical analysis for estimated model parameters consisted of 2-way ANOVA's, followed by Tukey-Kramer multiple comparisons tests.

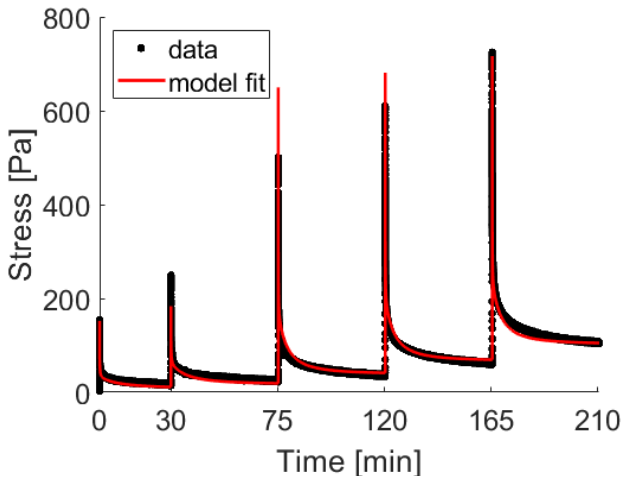

Figure 3: Model fit to experimental data from a representative sample.

RESULTS

For the location-specific experiments, no significant differences were seen between any groups for the viscoelastic parameters (i.e. parameters associated with the modified Maxwell elements). In fact, for many combinations of groups and parameters, p-values are greater than 0.9. When looking at the elastic parameters (i.e., exponential spring), c_a is significantly higher in the lateral location compared to the trigon, and c_b is significantly higher in the trigone compared to all other locations.

For the osmolarity experiments, c_a is significantly higher for 900 compared to all other osmolarities and c_b is significantly lower in 900 compared to dry. For c_3, dry is significantly lower than 100, 600, and 900, and 300 is significantly lower than 900. For η_2, dry is significantly lower than all osmolarities, and η_3 is significantly lower in 300 than 900. τ_2 and τ_3 are significantly higher for dry samples compared to all osmolarities.

DISCUSSION

The differences seen in elastic parameters for the location experiments supports previous work[1] that shows the trigone region having different mechanical properties than other regions of the bladder. However, the lack of differences seen in viscoelastic parameters suggests that all regions may behave similarly in terms of time-dependent behavior.

The differences in viscoelastic parameters based on solution osmolarity suggest that tissue swelling in the bladder wall could change the time-dependent behavior of the bladder. It is possible that this may be a driving factor for remodeling that is seen in diseases and disabilities that are associated with inflammation or changes in urine osmolarity.

Differences in parameters between dry and submerged samples underscores the importance of tissue hydration in mechanical testing. Likewise, it is important to consider differences in protocol when attempting to compare mechanical data from different studies.

INTRODUCTION

Many cardiac diseases ranging from myocardial infarction (MI) to pulmonary arterial hypertension (PAH) lead to substantial adaptations in cardiac tissue structure and mechanical behavior, often including hypertrophy or degradation of the myofibers, remodeling of the collagen fiber network, and dilation of the ventricles. While the tissue-scale (~1-cm) structure and mechanics of normal and diseased myocardial tissue have been studied previously [1], the mechanical contributions of and interactions between myofibers and the surrounding extracellular matrix (ECM) remains incomplete. In particular, although there has been evidence that the arrangement of myofibers and ECM collagen in myocardium gives rise to unique tissue-level coupling behavior observed for myocardium, such coupling has yet to be characterized at the scale of individual myofibers.

To this end, multiscale computational modeling of the heart has become an important tool for understanding cardiac function. However, there is a need to develop models that are faithful to the microstructure of the myocardium in order to gain insight into the cellular-level mechanical environment, especially to identify mechanisms driving adaptations to structural heart disease. Thus, in this study, we developed a microanatomically realistic finite element model for ventricular myocardium. For this first study, we based our model on a high-resolution 3D imaging dataset from the murine right ventricular free wall (RVFW) to study fiber-specific interactions under planar deformations, with the aim to match the results of our previous tissue-level model [1].

METHODS

Finite element mesh construction

A 3D imaging dataset was acquired from a ~200x200x60-μm section of murine RVFW via confocal microscopy, with tissue components labeled using antibodies and fluorescent markers [2]. The resulting geometry, including myofibers, ECM, myofibroblasts, and coronary blood vessels, was used to generate a volumetric finite element (FE) layer model consisting of myofiber and ECM elements (Fig. 1).

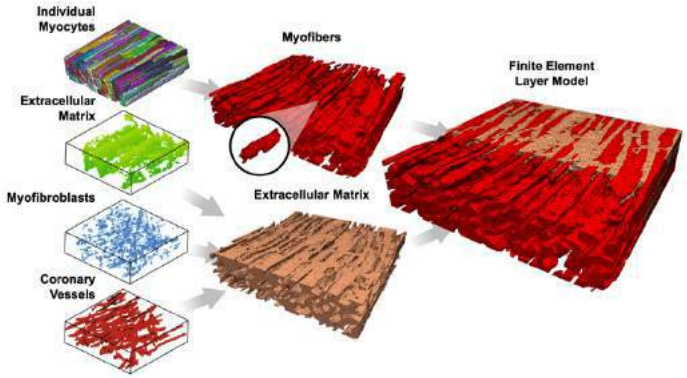

Figure 1: FE layer model developed from 3D geometry [2].

Material modeling

The passive behaviors of the myofiber and ECM phases were modeled with nearly incompressible, nonlinear anisotropic materials derived from our previous studies [1]. The myofibers were represented using a locally orthotropic constitutive form [3], consisting of an isotropic matrix stiffened by mutually orthogonal fiber families in the myofiber (f) and cross-fiber (s) directions within the layer, given by

$$\psi_{\mathrm{myo}} = \frac{\mu_{\mathrm{m}}}{2}(I_1 - 3) + \sum_{i=\mathrm{f,s}} \frac{a_i}{2b_i}\{\exp[b_i(I_{4i} - 1)^2] - 1\}, \qquad (1)$$

where I_1, I_{4f}, and I_{4s} are the first, fourth, and sixth invariants of the right Cauchy-Green tensor, respectively. The ECM was modeled as an isotropic matrix reinforced by a distribution of undulated, linearly stiffening collagen fibers, described by the orientation distribution function Γ_θ and recruitment function Γ_s, given by

$$\psi_{\mathrm{ECM}} = \frac{\mu_c}{2}(I_1 - 3) + \frac{\eta_c}{2}\int_\theta \Gamma_\theta(\theta)\int_1^{\lambda_\theta}\Gamma_s(\lambda_s)\left(\frac{\lambda_\theta}{\lambda_s} - 1\right)^2 \mathrm{d}\lambda_s \mathrm{d}\theta, \quad (2)$$

where θ is the fiber angle, λ_θ is the fiber stretch in the θ direction, and λ_s is the fiber slack stretch at which collagen fibers begin contributing to the ECM stress. Fiber splay and slack stretch were determined based on previous modeling results [1], which also indicated the collagen fiber distribution was aligned with the myofibers (f) in the FE mesh.

FE simulations

The FE layer model was used to simulate planar deformations in order to reproduce previous tissue-level studies [1]. Myofiber and ECM elements were assigned their corresponding material models and assumed to be perfectly bonded. Deformations were applied in E_{11}:E_{22} = 0.30:0.30, 0.15:0.30, and 0.30:0.15 configurations. The material parameters for myofibers and ECM were calibrated to match the stress-strain response predicted by our previously developed tissue-scale structural model [1]. All simulations were performed on the Stampede2 supercomputer at the Texas Advanced Computing Center using FEniCS (fenicsproject.org). Finally, the FE layer simulation was extended to simulate the full-thickness transmural RVFW by stacking 15 individual layer models, each rotationally positioned to capture the reported transmural variation in fiber orientation.

RESULTS

The stress response FE layer microanatomical model successfully reproduced the tissue-scale structural model prediction (Fig. 2). As the FE layer model contained highly aligned myofibers oriented along the f direction, the model showed exponentially stiffening myofiber stress in E_{11} with negligible stress along E_{22}. The ECM exhibited nonlinear stiffening during collagen fiber recruitment ($0.17 < E < 0.20$), after which fibers were fully recruited and the ECM response became linear, as demonstrated previously [1]. Comparing the stress profiles of the myofiber and ECM phases indicated that total response was governed by myofiber behavior in the low-strain regime (below $E < 0.17$). At higher strains, the ECM collagen fibers became the major contributor to the RVFW stress.

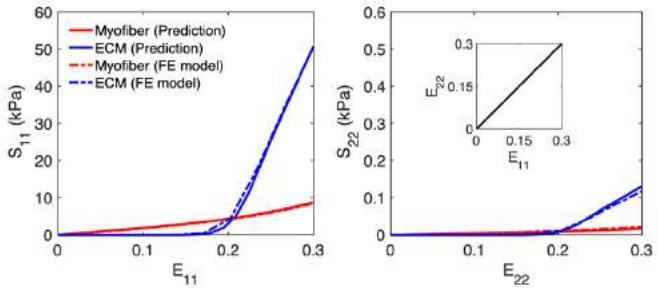

Figure 2: Contributions of myofibers and ECM to the total stress in response to equibiaxial strain. Solid lines: predictions from tissue-scale structural model. Dotted lines: fitted response of microanatomical FE layer simulation.

At maximum deformation, the stress state at the myofiber-ECM interface was visualized via projection of the myofiber stress onto the boundary of selected myocytes, which indicated that the myofiber stress was transferred outward from the myocytes, preferentially along the fiber axis of the layer, but with a persistent cross-fiber component in regions further away from the myocyte ends (Fig. 3).

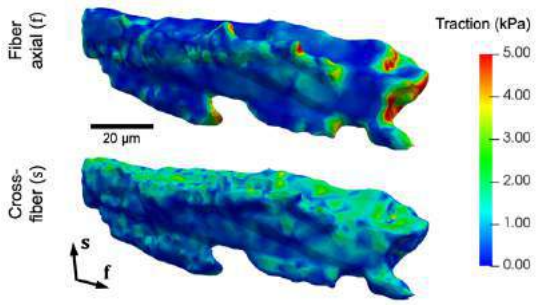

Figure 3: Myofiber-ECM traction magnitudes in fiber axial (f) and cross-fiber (s) directions for a representative myocyte.

The full transmural simulation also demonstrated the effect of transmural variation in fiber orientation through the generation of significant cross-fiber stress in both the myofiber and ECM phases, resulting in stress-strain behavior showing qualitative similarity to tissue-level studies [1] (Fig. 4).

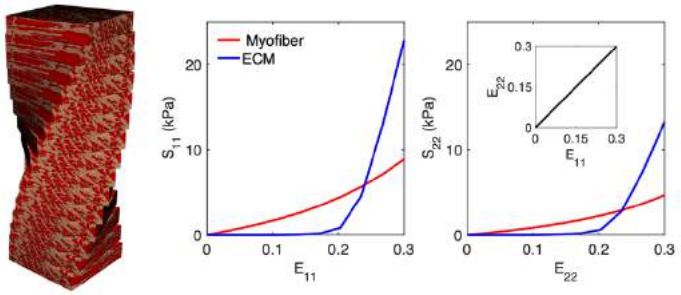

Figure 4: Full-thickness RVFW simulation (left) and equibiaxial stress-strain response (right).

DISCUSSION

To the best knowledge of the authors, this study constitutes a major first step in the development of microanatomically-based computational models of cardiac tissue. The fiber axis-focused profile of stress transfer from myofibers to ECM provides insight into possible mechanisms for the coupling interactions hypothesized in previous work. Through this microanatomical approach, exploration of cellular-scale stress transfer between myocytes and their surroundings can be integrated into larger-scale models and used to further probe the effect of micro-level events on organ-level function. Ultimately, our microanatomical model will allow us to investigate fiber-specific remodeling of the cardiac microstructure in response to structural heart disease.

INTRODUCTION

To facilitate understanding of how bone's hierarchical structure naturally resists fracture, it is necessary to examine the morphology of bone and crack propagation at the micro-scale. One advantageous modality for examining bone at this scale is synchrotron radiation micro-computed tomography (SRμCT). This technique uses high flux x-rays to reconstruct an image stack corresponding to the three-dimensional (3D) structure and material composition of a scanned sample. With SRμCT, the crack path of a fractured bone sample can be revealed, and new research has been focused towards determining the stress state during loading and crack propagation using a technique known as digital volume correlation (DVC). In bone, this technique tracks the speckle-like osteocyte lacunae features between different SRμCT scans to determine strain and stress fields. Combining *in situ* mechanical testing with SRμCT and DVC to obtain datasets of crack propagation with near real-time stress and strain states would elucidate crack growth mechanisms at the micro-scale.

This process poses one key challenge: the over irradiation of bone during SRμCT, which damages its mechanical properties [1]. To address this issue, we propose acquiring low-quality scans at a reduced radiation dose to maintain mechanical properties at the cost of reducing the signal-to-noise ratio. Features in these noisy scans cannot successfully be segmented, however, eliminating the possibility of performing DVC. Our solution is to use deep learning to denoise low-quality images. Deep learning has shown promise in learning to remove noise and enhance the signal of images [2]. In this work, a convolutional neural network called a mixed-scale dense network (MS-D net) will be used to denoise low-quality SRμCT scans acquired during *in situ* mechanical testing to obtain internal strain values via DVC without over-irradiation of bone samples.

METHODS

***In Situ* Mechanical Testing at the Synchrotron Microtomography Beamline.** Mechanical testing was performed at the ALS beamline 8.3.2. at Lawrence Berkeley National Laboratory. Pre-notched bovine bone samples of dimensions 1-mm x 2-mm x 10-mm were prepared prior to testing and stored in Hank's Balanced Salt Solution (HBSS) for at least 12 hours prior to testing. Testing is performed in a custom three-point bending chamber with a span of 6-mm. Samples are submerged in HBSS at room temperature during testing to mimic physiological conditions.

A reference high- and low-quality scan are taken of each sample before testing with 3937 and 657 projections respectively. An incident X-ray energy of 24 keV was selected with an exposure time of 100 ms. Final spatial resolution was 1.6-μm/voxel. The three-point bending test was performed at a constant displacement while simultaneously monitoring the recorded force-displacement output of the load cell in the testing chamber. Low-quality scans of the sample are acquired after each drop in load until complete material failure. Reconstruction of SRμCT data was performed in Python open-source package Tomopy and visualization was performed in Dragonfly (ORS) [3].

Mixed-Scale Dense Network. The MS-D net is a convolutional neural network that combines aspects of mixed-scale networks (efficient at resolving features of images at multiple length scales via convolved dilations) and densely connected networks (a network whose feature maps are connected to feature maps of all other layers) [4]. The network used has 100 layers and used Adam as the optimization algorithm with a learning rate of 0.001.

Training was performed on a workstation with an Nvidia GeForce GTX 1080Ti GPU. SRμCT images for each sample at each load step were cropped to a dimension of 1024 x 1024 pixels and approximately 650 images. A training, validation, test split of about 70-15-15 was used

from viable samples, yielding 3240 training images, 680 validation images, and a holdout test dataset (not included in training or validation sets) of 662 test images. Training was performed for 44 epochs using mean-squared error (MSE) as the loss function.

Digital Volume Correlation. DVC was performed using TomoWarp2, a Python based digital volume correlation code [5]. Denoised output from the MS-D net was segmented into a binary image, separating the features of bone (lacunae, canals, and crack) from the matrix. These features were tracked during DVC. For each sample, a correlation window of 25 voxels in all directions and a node spacing of 10 voxels in all directions were chosen. An appropriate search window was selected for each scan.

RESULTS

Network output of the MS-D net for a single image of an SRμCT scan are shown below (Figure 1) compared to the low-quality and high-quality slice accompanied by the Otsu segmentation and image stack grey value histogram.

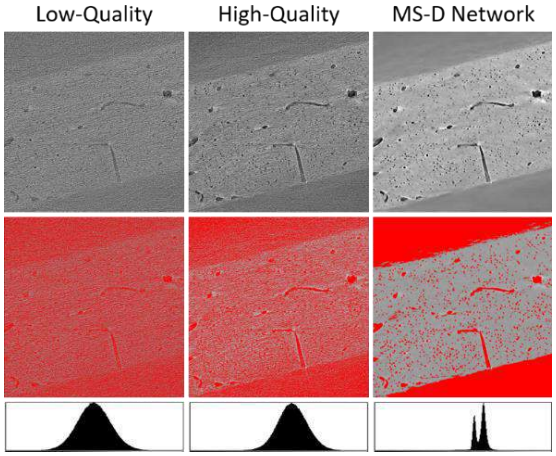

Figure 1: Denoised MS-D network output (right) compared to low-quality scan (left) and high-quality scan (middle)

In both the low- and high-quality images, the image stack histogram is unimodal, meaning the background and bone grey values belong to the same distribution with no clear separation between the two. This is also evident in the corresponding Otsu segmentation for each where bone's background is segmented and colored red. This segmentation does not show a clear distinction from the bone. The output from the MS-D net possesses two clear peaks in the image stack histogram corresponding to bone and background. Segmentation of the image slice shows separation of bone from background, with clear outlines for the bone, notch, canals, and osteocyte lacunae present.

Assessment of network results was performed by examining the MSE and peak signal-to-noise ratio (PSNR) of the network on the validation dataset as well as the DVC results. Metrics compare the MS-D net output and low-quality images to the high-quality images. MSE of the MS-D net output was 9.75, reduced from the low-quality data's MSE of 63.36. This is an expected, positive result because the network minimizes MSE, the loss function. PSNR was increased from the low-quality images compared to the MS-D net with values of 17.43 and 25.52 respectively, indicating a clearer image and reduced noise.

TomoWarp2 was used to correlate the data from loading steps to the reference configuration (0 N load). Shown (Figure 2) is the x-direction strain calculated from the DVC output at the first step of crack growth (20.7 N). Strain in the x-direction is highest for regions of bone around and ahead of the crack path, with strain values varying from 0.05-0.2. The strain field further from the crack path is approximately 0. Two correlations were performed in the preliminary work here, one for a load step with no crack (8.7 N, not shown) and one for a load step with a crack (20.7 N, Figure 2) with mean correlation values of 0.717 and 0.669 respectively. For comparison, DVC was also performed using two high-quality scans with a crack present instead of the MS-D net output, resulting in a mean correlation value of 0.656.

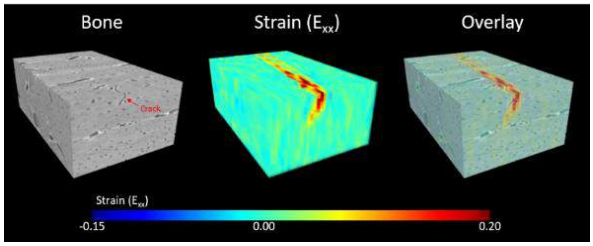

Figure 2: Strain (x-direction) from digital volume correlation on bone sample with a crack.

DISCUSSION

The images denoised by the MS-D net show clear segmentation of bone from background during the *in situ* mechanical test, even more pronounced than the high-quality scan. The implications of this result are twofold; 1) low-quality scans can be taken of a bone sample during SRμCT to limit radiation dose and thus preserve mechanical properties if a denoising method such as the MS-D net used and 2) the resulting network output is clearer in terms of recognizing microstructural features than high-quality scans for the same sample.

While the network output is more easily segmented, the grey values of the bone matrix, directly corresponding to volumetric tissue mineral density (vTMD) and Young's modulus, may be obscured from its true value. Further investigation is required to understand the effects of the MS-D net on vTMD values. Despite this, using SRμCT in conjunction with deep learning has enabled acquisition of *in situ* data at an appropriate time scale for crack propagation to be resolved in near-physiological conditions for use in assessment of features without deterioration of mechanical properties due to over-irradiation.

Performing DVC on time dependent *in situ* data while adhering to guidelines for non-detrimental radiation dose is presently a major limitation of the technique when applied to biological samples such as bone [6]. The presented method yielded promising results, but further validation and analysis of DVC results are required. Preliminary results from DVC have not been validated with data from tests performed without synchrotron radiation and error metrics have yet to be exhaustingly examined. If successful, the proposed method can be used for safely determining the stress/strain state of bone and other biological materials during loading and crack propagation.

INTRODUCTION

Nanomaterials have been designed to efficiently absorb optical or magnetic energy and convert to heat, and have found wide applications[1]. These studies use two modes of nanoparticle (NP) heating[2]. The first involves continuous excitation (seconds to minutes) of nanomaterials and collective tissue heating, the second involves using a short energy pulse to introduce nanoscale confined heating. However, there have been significant debate over past few years on the existence of significant heating by nanoscale and microscale objects, and on how to differentiate between the heating modes[3].

The fate of nanoscale confined and collective heating depends on spatiotemporal evolution of heating by large number of nanoparticles. Keblinski et al. was among the first to demonstrate that the duration of energy excitation drives the transition of heating modes[4]. Baffou et al. illustrated the importance of geometry of nanoparticle distribution on the temperature confinement or delocalization regime under continuous laser excitation[5]. Despite these efforts, it remains unclear on how the spatiotemporal evolution of nanoparticle heating determines the transition from nanoscale heating to collective macroscale heating.

In this report, we investigated the critical transition from nanoscale confined and collective heating by analyzing the heating of NP arrays, and the corresponding biological responses of the heating. We found that heating time and NP area density determine whether a nanoscale confined and collective heating is established. Next, we analyzed the biological responses corresponding to NP array heating, we demonstrate the feasibility for nanoscale selective protein denaturation, whereas it is unlikely to achieve nanoscale selective TRPV1 based on our current understanding of its kinetics[6]. Furthermore, we introduced dimensionless parameter to describe the transition of heating modes. Our work provides a guideline to design innovative approaches that harvest the nanoscale confined and collective heating to modulate molecular or tissue specific activities under realistic physical constraints.

METHODS

For NP array heating, we solve the problem by superposition of the analytical solution of single nanoparticle heating:

$$\Delta T_{multi}(\boldsymbol{r},t) = \sum_{i=1}^{N} \Delta T_{single}^{i}(\boldsymbol{r},t) \quad (\text{~~3~~}1)$$

Here the ~~Wh~~ΔT_{multi} is temperature raise for multi NP heating, and ΔT_{single}^{i} is the temperature raise for ith NP heating. The single spherical particle heat conduction model in spherical system was analytically solved by Laplace transform [7]. The analytical solution was calculated in Matlab 2019b software.

The dimensionless parameter is based on mathematical description for temperature raise in the center point for circular NP array heating (ΔT_{array}). Using the idea of superposition method, the expression for ΔT_{array} of 2D and 3D NP array are as following:

$$\Delta T_{array,2D} = \frac{qd}{2k}\left[R \cdot erfc\left(\frac{R}{2\sqrt{Dt}}\right) + \frac{2\sqrt{Dt}}{\pi}\left(1 - e^{-\left(\frac{R}{2\sqrt{Dt}}\right)^2}\right)\right] \quad (2)$$

$$\Delta T_{array,3D} = \frac{qd}{2k}\left[R^2 \cdot erfc\left(\frac{R}{2\sqrt{Dt}}\right) - \frac{2\sqrt{Dt}}{\sqrt{\pi}} R \cdot e^{-\left(\frac{R}{2\sqrt{Dt}}\right)^2} + 2Dt \cdot erf\left(\frac{R}{2\sqrt{Dt}}\right)\right] \quad (3)$$

Here, q is heating power, d is NP density, P is interparticle distance, for 2D array, $d = P^{-2}$, for 3D array, $d = P^{-3}$. R is the radius of NP array, k and D are thermal properties, t is the heating time.

RESULTS

Firstly, we investigated the effect of the heating time and NP area density on the heating overlap. Here we compared the thermal responses of NP array heating with different heating times and different NP area densities (Fig. 1 A). The nanoscale confined heating can be achieved for

cases with short heating time (Fig. 1 A Case 1) and low NP area density (Case 3), whereas heating overlaps for cases with longer heating time (Fig. 1 A Case 2) and higher NP area density (Case 4). In order to quantify the transition of the two heating modes, wo introduced $\Delta T_{overlap}$ which is defined by the discrepancy between ΔT_{multi} with ΔT_{single} (Eqn. 2). We define the heating condition as no overlap for $\Delta T_{overlap} \leq$ 3 K, and overlap for $\Delta T_{overlap} >$ 3 K. Fig. 1 B demonstrates 3D map for $\Delta T_{overlap}$ = 3 K in terms of heating time, NP area density and heating power, this surface also serves as the boundary between two heating modes.

$$\Delta T_{overlap} = \Delta T_{multi}(\hat{r}, t) - \Delta T_{single}(\hat{r'}, t) \quad (4)$$

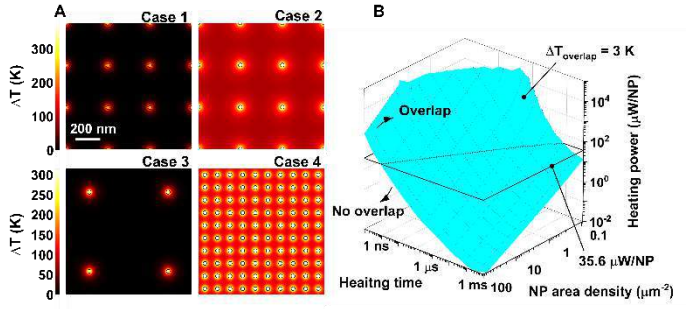

Figure 1. Effect of heating time and NP area density on heating modes. A) Temperature raise (ΔT) profile for 2D NP array heating, Diameter of NP (D_{NP}): 30 nm, heating power (q): 36 μW/NP, case 1: 10 ns heating, 9 NP/μm^2; case 2: 1000 ns heating, 9 NP/μm^2; case 3: 20 ns heating, 2.6 NP/μm^2; case 4: 20 ns heating, 100 NP/μm^2. B) 3D map for $\Delta T_{overlap}$ = 3 K.

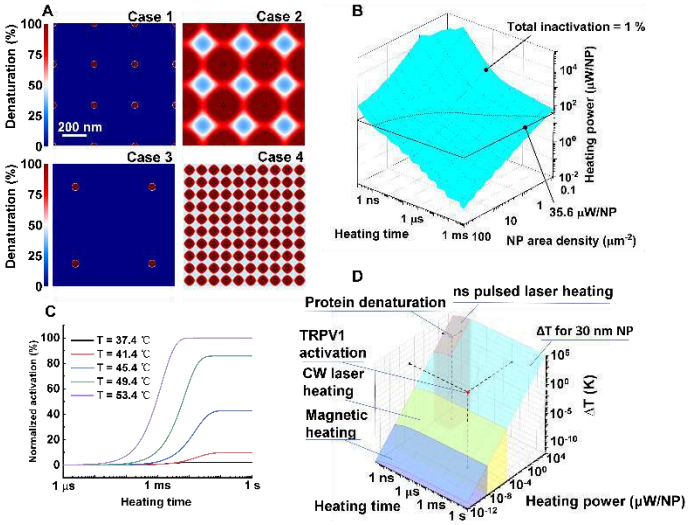

Figure 2. Biological responses for corresponding NP array heating cases. A) Protein denaturation profiles for case 1-4 (α-chymotrypsin). B) 3D map for *total denaturation* = 1 %. C) Kinetic activation for TRPV1 [6]. D) ΔT for 30 nm single NP heating.

Next, we investigated the corresponding biological responses for the NP array heating. Protein denaturation and TRPV1 channel activation are two main biological applications for NP array heating[8]. For protein denaturation, Fig. 2 A shows the protein denaturation profile corresponding to case 1-4. Fig. 2 B illustrates that the 3D map for *total denaturation* = 1% corresponds with 3D map for $\Delta T_{overlap}$ = 3 K. Here we demonstrate the feasibility for nano scale selective protein denaturation, and we found the critical transition from nanoscale confined and collective heating closely matches the shift from minimal and widespread transmembrane protein denaturation. For TRPV1 channel activation, Yao J, et al. demonstrated the TRPV1 channel is activated within 37 – 53 ℃[6]. It takes milliseconds continuous heating for TRPV1 activation (Fig. 2 C). The ns pulsed laser is too short for TRPV1 activation. CW laser and magnetic heating can last for milliseconds, yet they are too weak to heat up single NP to thermally activate TRPV1 (Fig. 2 D). Therefore, it is unlikely to achieve nano scale selective TRPV1 activation with traditional heating methods.

Lastly, we introduced dimensionless parameter to describe the heating modes based on the mathematical description for ΔT_{array} of circular NP array heating (Eqn. 2&3) Fig. 3 A illustrates $\Delta T_{array,2D}$ (temperature raise in center point) in terms of R. For any finite t, when $R \rightarrow \infty$, $\Delta T_{array,2D}$ is finite due a finite heat transfer speed ($\Delta T_{array,2D,R\rightarrow\infty} = \frac{qd}{2k}\frac{2\sqrt{Dt}}{\pi}$). When $\Delta T_{array,2D}$ is close to this $\Delta T_{array,2D,R\rightarrow\infty}$, further increasing R has negligible effect on $\Delta T_{array,2D}$, indicating the heating of NPs located further than R from the center point have negligible effect to $\Delta T_{array,2D}$. Therefore we consider this critical R as a limitation of heat transfer distance in 2D NP array. Based on this idea, we define a Dimensionless parameter (ξ) to describe heating modes by comparing ΔT_{array} with $\Delta T_{array,R\rightarrow\infty}$ and replace R by $P/2$ (half interparticle distance):

$$\zeta_{2D} = \frac{\left(\frac{p}{2}\right)\cdot erfc\left(\frac{p}{4\sqrt{Dt}}\right)+\frac{2\sqrt{Dt}}{\sqrt{\pi}}\left(1-e^{-\left(\frac{p}{4\sqrt{Dt}}\right)^2}\right)}{\frac{2\sqrt{Dt}}{\sqrt{\pi}}} \quad (5)$$

$$\zeta_{3D} = \frac{\left(\frac{p}{2}\right)^2\cdot erfc\left(\frac{p}{4\sqrt{Dt}}\right)-\frac{2\sqrt{Dt}}{\sqrt{\pi}}p\cdot e^{-\left(\frac{p}{4\sqrt{Dt}}\right)^2}+2Dt\cdot erf\left(\frac{p}{4\sqrt{Dt}}\right)}{2Dt} \quad (6)$$

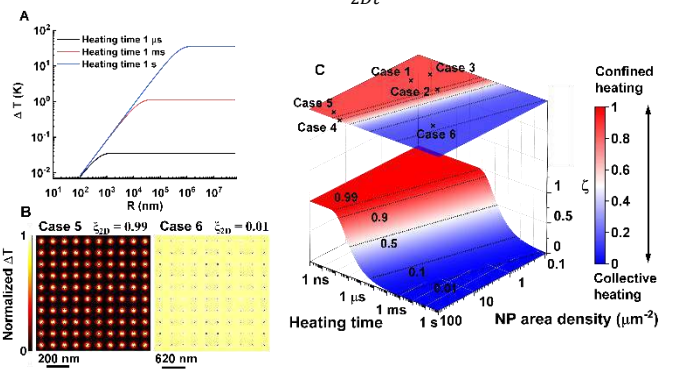

Figure 3. Dimensionless parameter (ξ) for differentiating confined *versus* collective heating. A) ΔT_{array} in terms of NP array radius (R). B) ξ_{2D} for case 5&6; case 5: 2.6 ns heating, 64 NP/μm^2; case 6: 1 ms heating, 12.8 NP/μm^2. C) 3D map for ξ_{2D}.

When $\xi \rightarrow 1$, the heating is confined, while $\xi \rightarrow 0$, a collective heating is established. Fig. 3 B&C shows that ξ_{2D} nicely captures the level of heating overlap between nanoparticles.

THE DIFFERENTIAL IMPACT OF TISSUE HETEROGENEITY ON TRABECULAR PLATES AND RODS IN FINITE ELEMENT MODELS OF HUMAN VERTEBRAL BONE

Jason M. Cox (1), Jacqueline H. Cole (1)

INTRODUCTION

The microarchitecture of cancellous bone is related to its load-bearing ability [1], varies with anatomic site [2], and can be decomposed into trabecular rods and plates [3]. Because they have differing geometry and preferential orientation, plates and rods may have unique mechanical roles in the microarchitecture [4]. Recently, a powerful topology classification algorithm known as individual trabecular segmentation (ITS) enabled trabecular plates and rods to be studied separately in micro-computed tomography (micro-CT) data [5]. Moreover, micro-CT-derived finite element (micro-FE) models of cancellous bone can be used to estimate mechanical properties [6]. Combining ITS and finite element analysis (FEA) allows separate digital manipulation and mechanical analysis of trabecular plates and rods in ways that are impossible with physical specimens [5].

Besides microstructure, the composition of cancellous bone also contributes to its mechanical performance [7]. Varying degrees of mineralization are present throughout trabeculae [8], arising from the continual remodeling of surface bone to repair microdamage [9]. Since bone mineralizes as it matures, mineralization is correlated with both distance from the trabecular surface and tissue age [8], producing a tissue density gradient that increases the amount of microdamage in early loading [10]. Thus, the mineral distribution in trabecular bone contributes to remodeling in a feedback system that ultimately forms the plate-rod microstructure [9], suggesting that the roles of plates and rods may be determined in part by tissue heterogeneity.

Despite the importance of heterogeneity in the processes of tissue damage and remodeling, previous studies implementing ITS and FEA used homogeneous models [5,11]. Therefore, the objective of our study was to examine the effect of tissue heterogeneity on the distinct mechanical roles of trabecular plates and rods through ITS and FEA in human cancellous bone.

METHODS

Cancellous bone cores were extracted from the 12th thoracic and 2nd lumbar vertebral bodies of cadaver spines from 19 Caucasian donors (10 female, 9 male, 58-92 yrs). The cylindrical cores were scanned using quantitative micro-CT and reconstructed at an isotropic voxel size of 17 μm. Tissue mineral density was calibrated using a cortical bone mineral standard. Scans were oriented to align with the vertebral superior-inferior axis and cropped to a diameter of 8.25 mm and length of 17 mm. Specimen-specific thresholds were applied using the Otsu method [12] to segment the bone volume, and the bone voxels were converted to 8-noded linear brick elements in a finite element mesh in MATLAB.

Two sets of finite element models were created. For models with physiological tissue heterogeneity, the elastic modulus (E) for each element was assigned based on the mineral density (ρ) of the associated CT voxel using a power law relationship [7]. For homogeneous models, a single specimen-specific E was assigned to all elements based on the mean tissue ρ for each bone core. For boundary conditions, a compressive strain of 0.25% was applied to the top face of each model, and the bottom face was constrained to prevent bulk translation and rotation. A single-step linear FEA was conducted for all models, and principal strains were obtained for each element using Abaqus. The principal strain with the greatest magnitude was chosen to represent that element, and values surpassing 410 microstrain in tension or -830 microstrain in compression were indicative of failed elements [11].

Individual trabecular segmentation was performed on micro-CT scans of all cores to identify trabecular plates and rods, their relative fraction of total bone tissue, and orientations relative to the core central axis. Orientations (φ) were categorized as longitudinal for $0° < \varphi < 30°$, oblique for $30° < \varphi < 60°$, and transverse for $60° < \varphi < 90°$ [11]. For both FE model sets, plate and rod apparent failed tissue fractions (AFTF) were computed for each core as the total number of failed

elements in plates and rods, respectively, divided by the total number of elements in the model [11]. AFTF was also computed separately for plates and rods within each trabecular orientation group and for elements under tensile and compressive strain in each trabecular core.

Mixed linear models were used to evaluate the effect of material distribution, trabecular orientation, and strain direction on AFTF. Spine donor ID was treated as a random effect to account for repeated measures (2 vertebral levels for each spine), and the Hochberg adjustment was used to correct for multiple comparisons. A significance level $\alpha = 0.05$ was used for all statistical comparisons.

RESULTS

The relative fraction of total bone volume represented by plate-like trabeculae was 70±16%, substantially greater than that represented by rods ($p<0.0001$). Plates were oriented more longitudinally (26±22°, $p<0.0001$), whereas rods were oriented obliquely (55±24°, $p<0.0001$).

Material distribution. Apparent failed tissue fractions did not differ between plates and rods for homogeneous ($p=0.65$) or heterogeneous ($p=0.053$) models, although rod AFTF was higher for both. Total AFTF was 1.63x higher in heterogeneous than homogeneous models (0.160% vs. 0.098%, $p < 0.0001$), for both trabecular plates (0.071% vs. 0.045% $p=0.0012$) and rods (0.089% vs. 0.053%, $p<0.0001$).

Trabecular orientation. For trabecular plates (Fig. 1A), AFTF was higher in longitudinal trabeculae compared to oblique and transverse trabeculae in homogeneous models, and the same trends were observed for plates in heterogeneous models ($p<0.0001$ for all). While AFTF did not differ between heterogeneous and homogeneous models for transverse ($p=0.99$) or oblique ($p=0.97$) plates, AFTF for longitudinal plates was 1.56x higher in heterogeneous than homogeneous models ($p<0.0001$). For trabecular rods (Fig. 1B), AFTF was higher in transverse trabeculae compared to oblique and longitudinal trabeculae in homogeneous models, and the same trends were observed for rods in heterogeneous models ($p<0.0001$ for all). While AFTF did not differ between heterogeneous and homogeneous models for oblique ($p=0.77$) or longitudinal ($p=0.64$) rods, AFTF for transverse rods was 1.69x higher in heterogeneous than homogeneous models ($p<0.0001$).

Strain direction. For longitudinal plates and transverse rods, the apparent fraction of tissue failed in tension was higher than that in compression for both homogeneous and heterogeneous models ($p<0.0001$ for all, Fig. 2A-B). Tissue heterogeneity did not impact the compressive AFTF for these trabeculae ($p>0.99$ for both) but increased the tensile AFTF 1.67x for longitudinal plates ($p<0.0001$, Fig. 2A) and 1.71x for transverse rods ($p<0.0001$, Fig. 2B).

DISCUSSION

Heterogeneous mineral distribution increased bone tissue failure, specifically for longitudinally aligned plates and transversely aligned rods with tensile strains. Plate and rod tissue fractions and orientations in our study agreed with findings from other studies in human vertebrae [5]. Because trabecular plates comprised a greater fraction of vertebral tissue on average, the similar AFTF between plates and rods indicates disproportionately more tissue failure in rods, agreeing with previous findings in human vertebrae [11]. The increase in failed tissue due to tensile strain and lack of change due to compressive strain associated with heterogeneity points to increased trabecular bending. Based on beam theory, a trabecula with material heterogeneity in bending has a strain gradient that runs counter to the mineralization gradient (i.e., highest strains at the surface where mineralization is lowest) [8]. This relationship decreases the bending stiffness but leaves the uniaxial stiffness unchanged relative to a homogeneous trabecula [10].

Because remodeling creates mineralization gradients for all trabeculae, heterogeneity alone cannot explain the disproportionate

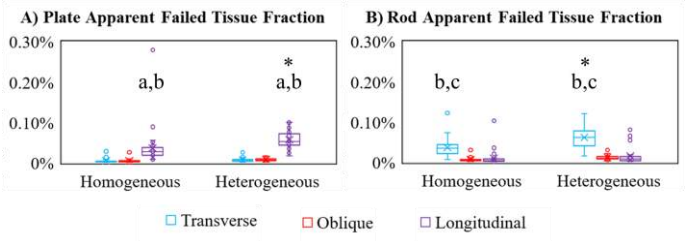

Figure 1: A) Plate and B) rod AFTF by trabecular orientation and material distribution. Symbols denote $p<0.05$ vs. *homogeneous, [a]transverse, [b]oblique, and [c]longitudinal.

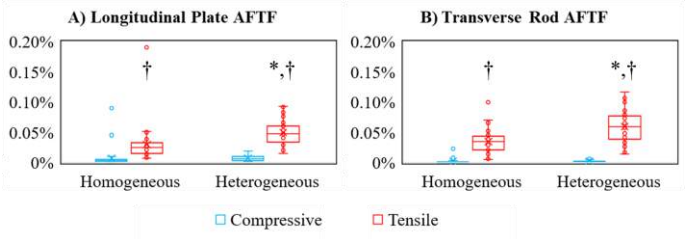

Figure 2: AFTF for A) longitudinal plates and B) transverse rods by element strain direction and material distribution. Symbols denote $p<0.05$ vs. *homogeneous and †compressive.

failure of rods or the different effects on rods and plates by orientation. Other factors promoting trabecular bending also contribute, including a greater trabecular load and transverse alignment to this load. Longitudinal trabeculae bear most of the bulk vertical loading, as shown in previous studies [4,5], and were plate-dominated in the current study, whereas transverse trabeculae were rod-dominated. The compounding effects of orientation and heterogeneity on promoting bending may explain why heterogeneity only increased tissue failure in longitudinal plates and transverse rods. Furthermore, the disproportionate failure of rods in both homogeneous and heterogeneous models indicates that the transverse alignment of rods promotes bending more than the longitudinal alignment of plates. This suggests a possible role for rods as sacrificial elements, protecting the structurally essential plates [5] and converting the energy of loading into reparable tissue damage.

A limitation of the current study was the use of linear FEA that did not directly incorporate element failure. In nonlinear FEA, failed elements weaken the model, increasing the likelihood of additional element failure. Therefore, the values of AFTF we report are likely underestimated. Overall, our results show that heterogeneity is a possible underlying mechanism driving the differential roles of trabecular plates and rods and is important to include in modeling-based approaches for studying cancellous bone tissue failure.

INTRODUCTION

Abdominal aortic coarctation (AAC) is a rare pediatric vascular disease, characterized by a narrowing of the abdominal aorta often with renal and splanchnic arterial involvement. An AAC restricts blood flow causing inadequate perfusion of the kidneys that leads to activation of the renin-angiotensin-aldosterone system (RAAS), which results in vasoconstriction, elevated blood pressure, and significant increases in morbidity and mortality [1].

In severe cases of AAC, renal blood flow may be restored operatively with performance of a thoracoabdominal bypass (TAB) [2]. Although a TAB in these cases may restore renal perfusion, long-term antihypertensive medications are often required post-operatively to maintain normal levels of blood pressure [3,4].

To better understand the cause of these suboptimal surgical outcomes, we previously conducted a computational fluid dynamics (CFD) study of a 9-year-old AAC patient who underwent a TAB repair, and required two antihypertensive drugs to treat her post-operative hypertension [5]. Preoperative CFD analysis revealed high-frequency hemodynamic disturbances in the abdominal aorta and renal arteries (**Fig. 1**). These disturbances were also present in the post-operative 14 mm TAB repair model. Based on these findings, we hypothesize that although a TAB may restore renal perfusion to normal levels, persistent high-frequency hemodynamic disturbances in renal artery hemodynamics may be responsible for increased renin release and persistent RAAS mediated post-operative hypertension.

To test our hypothesis, we propose to investigate the relationship between altered hemodynamics and elevated renin production by combining a computational analysis with a longitudinal experimental study of a canine model of AAC treated with a TAB. The computational results presented in this document will be used to guide the design of suitable experimental AAC and TAB repair models that can reproduce the altered hemodynamics observed in pediatric AAC patients, specifically the disturbed renal waveforms pre- and post-TAB repair of the AAC.

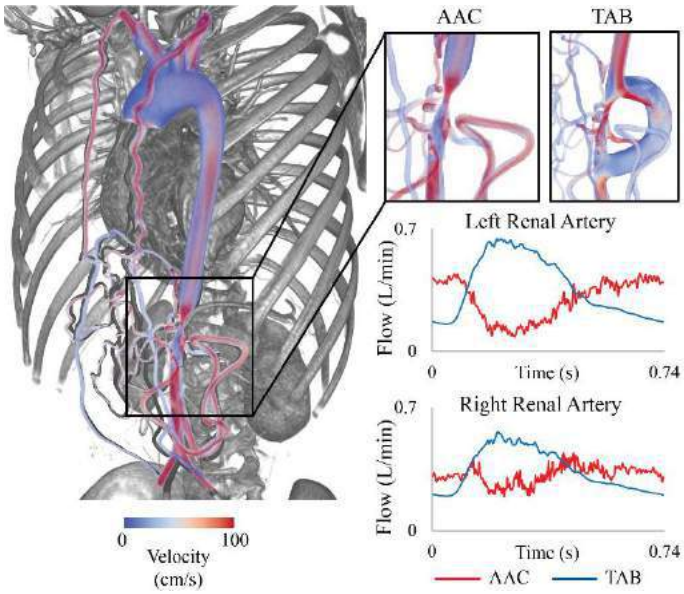

Figure 1. Left: 3D map of AAC peak systolic velocity. Right: High-frequency disturbances are present in the velocity maps and the flow waveforms of both the AAC (red) and TAB repair (blue) models in both renal arteries [5].

METHODS

An arterial fluid-structure-interaction (FSI) model of a 20-30 kg dog was constructed with population-based anatomical data (**Fig. 2**) [6] using the cardiovascular hemodynamics simulation software CRIMSON [7]. This dog weight (20-30 kg) was chosen because the aortic lumen diameter is comparable to that of a 9-year-old child (the subject from our previous study [5]). The ascending aortic flow waveform (**Fig. 2**) [8] was imposed on the inlet face of the model (**Fig. 3**). Spatially-varying mechanical properties – stiffness and thickness – for the aorta were assigned from literature values [9]. Windkessel boundary conditions were prescribed at each outlet face of the model and their parameters tuned to match the available data on experimental pressure [10] and flow splits within 5%. Following calibration, this pre-operative AAC model was modified to introduce varying degrees of coarctation 1 cm above the celiac trunk: 50, 60, 70, and 80% diameter reductions. For each of these geometries, we investigated the degree of disturbance in the renal artery waveforms. Lastly, we simulated surgical repair of the AAC with a 12-mm TAB graft.

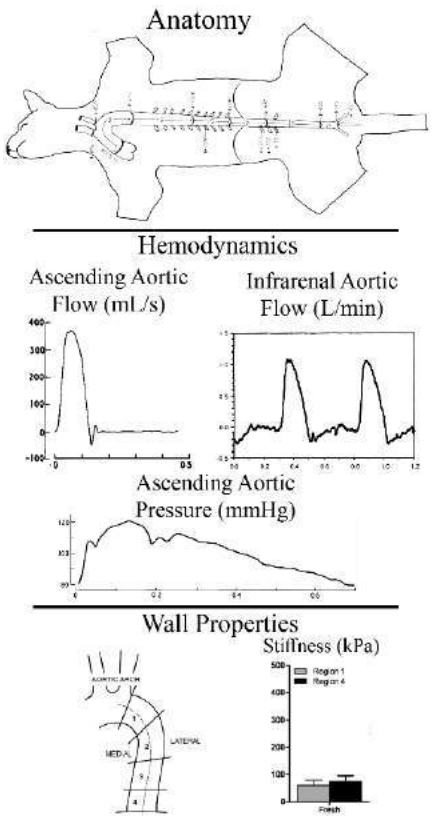

Figure 2. Population-based canine data for anatomy [6], hemodynamics [8,10] and arterial wall properties [9] used in the computational FSI model.

RESULTS

All degrees of AAC diameter reductions led to high-frequency oscillations in the renal artery waveforms. Mesh independence studies were performed to verify that the oscillations were not due to poor mesh resolution. The largest high-frequency content corresponded to the 60% diameter reduction. Highly disturbed velocity patterns were observed in the aorta distal to the AAC and propagating into the renal arteries in both the AAC and TAB models (**Fig. 3**). Computational results also confirmed that while the TAB repair restored mean levels of renal flow and pressure (relative to preoperative conditions), high-frequency disturbances persisted in the renal waveforms, especially in systole.

DISCUSSION

We constructed and calibrated a computational model of a 20-30 kg dog using population-based literature data to investigate the effects of introducing an AAC and TAB repair on hemodynamics within the abdominal aorta and renal arteries. The computational models of AAC and TAB repair confirmed high-frequency disturbances in renal hemodynamics similar to those observed in the human AAC models [5], confirming that the proposed canine model captures the hypothesized biomechanical stimuli triggering elevated renin production.

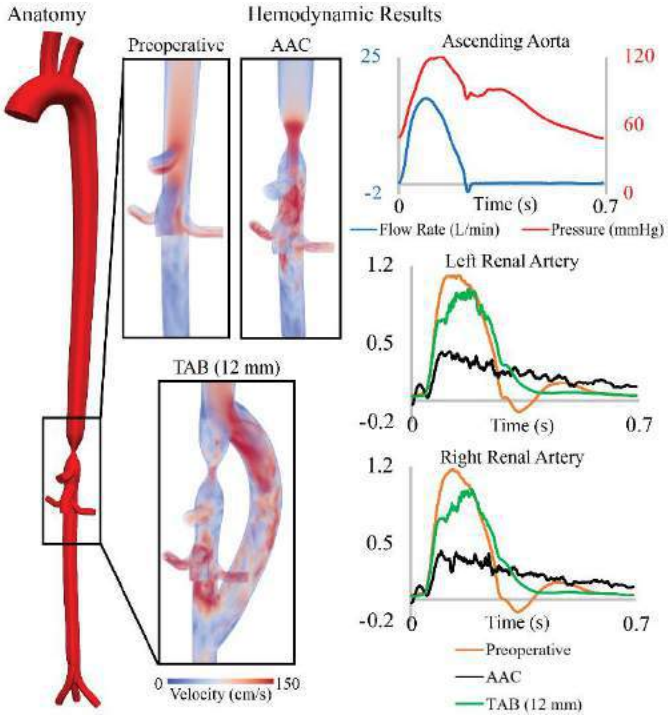

Figure 3. CFD results of preoperative, 60% diameter reduction AAC model, and TAB repair models. Velocity maps and renal waveforms show highly disturbed flow in AAC and TAB models.

Moving forward, a longitudinal prospective study has been designed to combine 20-30 kg canine models, experimental data acquisition, and CFD modeling to investigate the relationship between altered renal hemodynamics and renin production. Given the present study's computational results, a 60% AAC will be created with aortic banding. Data on anatomy, local and global hemodynamics, and renin activity will be acquired at different time points: pre-operatively, following the AAC creation, after the TAB repair, and in long-term follow-up after TAB. This investigation will improve our understanding of the driving mechanisms of RAAS activation. Furthermore, efforts to minimize these hemodynamic disturbances could influence the design of future surgical interventions for AAC repair.

INTRODUCTION

Right ventricular function is an important predictor of morbidity and mortality in patients with pulmonary arterial hypertension (PAH). The RV remodels in response to increased pulmonary pressure, including myocardial hypertrophy and RV geometric remodeling, but PAH commonly results in intractable right heart failure[1]. Furthermore, there are marked sex differences in PAH incidence (2-4x more in females) and outcome (females fare better)[2]. To investigate these disparities, we sought to characterize sex differences in RV remodeling in the well-established sugen-hypoxia (SuHx) rat model of PAH, using invasive RV blood pressure and volume timeseries measurements and ventricular morphologic measurements to assess chamber function. To distinguish the relative contributions of RV geometric remodeling from myocardial material remodeling to changes in RV function, a biomechanics model was fitted to measured RV pressure-volume relations and morphology after 5-6 weeks of sugen injections. While male SuHx rats demonstrated significant myocardial passive stiffening corresponding with increases in diastolic chamber stiffness, there were no changes in the myocardium from female SuHx rats, pointing to acute differences in the remodeling response in PAH.

METHODS

Seven-week old male and female Sprague-Dawley rats (Charles River Labs) were treated with a subcutaneous injection of 20mg/kg sugen (SU5416, Sigma-Aldrich), a vascular endothelial growth factor receptor inhibitor, and then placed in a hypoxia chamber (10% oxygen) for 3 weeks to induce PAH. After 3 weeks, treated rats were returned to normoxic conditions and studied at 5 and 6 weeks post-injection. Control groups of age-matched and sex-matched rats were kept in normoxic conditions for the same time. During terminal surgeries, a 1.9F admittance catheter catheter (Transonic, Ithica, NY) was used to take invasive pressure-volume (PV) measurements during steady state and during occlusion of the inferior vena cava. From the pressure-volume time series, end-systole (ES) and end-diastole (ED) points were identified from maximum RV pressure to volume ratio and highest volume and lowest volume rate change (dV/dt ~0), respectively. RV blood pressure, myocardium wall mechanics, and ventricular morphology were related by a RV biomechanics model developed by Velez-Rendon *et al.* [3] that assumed the RV to be a fraction of a sphere of radius R and thickness h consisting of RV chamber, free-wall (V_w), and septal (V_{sw}) volumes. Assuming a thin-walled sphere, RV blood pressure was related to myocardial circumferential wall stress T by Laplace's Law with mid-wall radius $r = R - h/2$. Total wall stress was modeled as passive stress (T_p) at ED, and passive plus active stress (T_a) at ES.

$$T_p(l) = k_1(e^{k_2(\lambda-1)} - 1) \quad (1)$$

The active stress T_a was modeled as:

$$T_a(l, k_3) = T_{max}\frac{k_3^2}{{k_3}^2 + \frac{C^2}{e^{B(l-l_o)}-1}} \quad (2)$$

where l_o is the constant sarcomere length at which zero active tension is developed, $Tmax$ is the constant maximal isometric tension achieved at normal activation, and the exponent B modulates the shape of peak isometric tension-length relation. The adjustable material parameters were determined by fitting PV data at ED (k_1, and k_2) and ES (k_3) during changes in preload. The model-generated pressure-volume curves were used to partition the contributions of altered RV volume, geometry and material properties to the differences in end-systolic or end-diastolic pressure between control and SuHx rats. Fitted model parameters were used to predict and analyze resting and active sarcomere length-stress relations per animal.

Descriptive statistics were performed in JMP Pro Statistical software (SAS Institute Inc., NC, USA) with non-parametric Wilcoxon-Kruskal-Wallis tests used for non-normally distributed data to identify differences between treatment groups. The Dunn post-hoc test was used when statistical significance was reached, determined by a significance level of $\alpha = 0.05$.

RESULTS

Male and female SuHx-treated rats reached hypertension (mean pulmonary arterial pressures were above 25mmHg). RV free-wall mass increased in both male and female SuHx rats ($p<0.05$) and RV wall thickness increased in male SuHx, ($p<0.05$) but it did not increase in the females. In fact, female RV wall thickness (1.3±.1mm) was almost 70% greater at baseline than male RV wall thickness (0.7±.2mm). While male and female animals had similar end-systolic pressures at baseline (ESP_{CNT-M} = 24±1 mmHg *vs.* ESP_{CNT-F} = 24±1) and pressures significantly increased with SuHx, males ESP was 35% higher than the females (ESP_{SuHx-M} = 66±3 mmHg *vs.* ESP_{SuHx-F} = 49±3 mmHg). Both male and female SuHx groups preserved stroke volume ($p<0.05$). On the other hand, while male and female animals showed similar end-diastolic pressures at baseline (EDP_{CNT-M} = 1.6±.2 mmHg *vs.* EDP_{CNT-F} = 1.2±.2), there was only a significant increase in end-diastolic pressures in the male SuHx rats (EDP_{SuHx-M} = 4.9±.7 mmHg *vs.* EDP_{SuHx-F} = 1.7±.3 mmHg).

The biomechanical model closely fitted the PV measurements at ES and ED for male and female animals and allowed us to discern the relative contributions of geometric changes (black) and myocardium material properties (blue) (Figure 1). Increase ES pressure was largely sustained by hypertrophy in both male (**A**) and female (**B**) SuHx animals. While male SuHx hemodynamic remodeling significantly increased diastolic chamber stiffness (blue line is significantly higher than green and black lines), female chamber stiffness remained largely unchanged (blue line is close to green line).

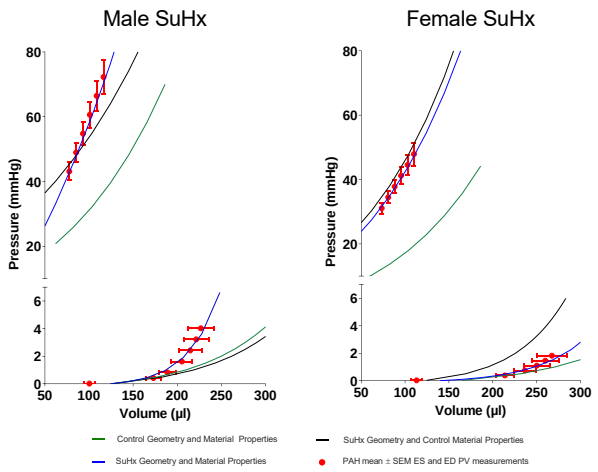

Figure 1. Model predictions of pressure-volume relations using control geometry and mechanical properties (green line), SuHx geometry and control mechanical properties (black line), and SuHx geometry and mechanical properties (blue line) at measured mean ± standard error pressures and volumes at end-diastole and end-systole (red).

From the rat-specific models fitted to pressure-volume data, sarcomere length-stress relations show a significant increase in passive stress in male SuHx rats ventricles, but not in the female SuHx animals (**Figure 2**). While the slope of the active sarcomere length-stress relation increased in the female SuHx animals, no statistical significance was reached ($p = .16$).

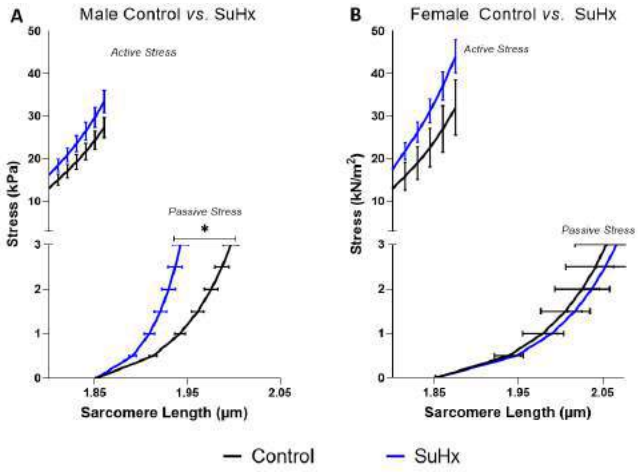

Figure 2. Model predictions of active (top) and passive (bottom) RV free wall stress *vs.* sarcomere length in control (black) and SuHx-treated (blue) male (A) and female (B) rats.

DISCUSSION

In this study, the sugen-hypoxia treatment successfully induced pulmonary arterial hypertension 5 and 6 weeks post-injection. Hemodynamic and morphologic measurements showed associated right ventricular hemodynamic remodeling. Model predictions of sarcomere length-tension relations found significant passive myocardial stiffening in male SuHx rats but not in the female SuHx rats. RV hypertrophic wall thickening maintained end-systolic PV relations in both males and females, whereas myocardial passive stiffening explained end-diastolic PV relations in male rats. Diastolic stiffness may be associated with extracellular matrix stiffness previously identified in male PAH rats [4] and may prevent RV dilation but could also contribute to RV diastolic dysfunction and thus contribute to worse outcome as seen in male patients [5]. In contrast, SuHx-treated female rats showed a maintained ED PV relation with no significant change in passive sarcomere length-stress relations compared to female controls. Instead, greater RV wall thickness at baseline may have helped maintain ED PV relations and prevented material remodeling in the myocardium of female SuHx rats. This study emphasizes the importance of investigating the ventricular adaption to PAH in both male and females and proposes mechanisms that would explain sex-dependent outcomes.

A NONLINEAR FIBROUS VISCOELASTIC MODEL DESCRIBES THE EXPERIMENTAL TENSILE MATERIAL BEHAVIOR OF HUMAN CERVIX

INTRODUCTION

The timely remodeling of the human cervix from a rigid state into a compliant stretchable state is essential for a safe delivery. This dramatic remodeling has been quantified as a 2-order of magnitude decrease in the cervical initial stiffness and the compressive resistance, and a significant increase of the locking stretch using an anisotropic elastic fibrous entropy-chain model [1]. Preterm birth (PTB), defined as birth before 37 weeks of gestation, is believed to be related to premature cervical remodeling and softening. The mechanism of normal and premature cervical remodeling, however, is still understudied. The cervix is a soft tissue mainly composed of a cross-linked collagen fibers embedded in a compressive groundsubstance formed by the negatively charged proteoglycans and glycosaminoglycans [2]. The cervix tissue exhibits complex material properties such as anisotropy and viscoelasticity, due to its complex biological composition.

Cervical viscoelasticity is an important factor in pregnancy because the tissue must be viscoelastic so it does not break in large deformation. The cervical viscoelasticity evolves significantly in cervical remodeling as shown in mouse mechanical studies [3]. To date, limited studies have been conducted on the time-dependent material response of the human cervical tissue, and it is partly due to its strong nonlinearity. The aim of this work is to describe the viscoelastic behavior of the human cervix under uniaxial tensile tests by proposing a nonlinear continuous fibrous viscoelastic constitutive model. Multiple-level-load-hold and load-break uniaxial tensile experiments, coupled with video extensometry, were conducted on human cervical tissue samples. Inverse finite element analysis (IFEA) was utilized to fit the fibrous viscoelastic constitutive model to tensile force responses. Differences in material properties between pregnant and nonpregnant samples are reported.

METHODS

Sample Preparation 4 non-pregnant and 3 pregnant cervical tissue samples were obtained from several consented hysterectomy patients at Columbia University Irving Medical Center. For each cervix, two slices were cut from the upper cervix (UC) and lower cervix (LC), respectively, to conduct an indentation test. For each slice sample, strips were cut along and perpendicular to the preferential fiber direction after the indentation test, where the preferential fiber direction was determined by the displacement response [1]. The samples were stored in a -80^{o}C freezer immediately after the indentation test.

Uniaxial Tensile Experiments Before each test, the tensile sample was swelled in the PBS solution for 24 hours. Then each sample was gripped tightly on both ends and put in the PBS solution. Two cameras were placed perpendicular to each other to capture the front- and side-view deformation during the test (Fig. 1 (a, b, c)). In the load-hold experiment, a displacement-controlled, several-stage ramp-hold uniaxial tensile test was conducted with a ramp rate = 0.1 %/s (Fig. 1 (d)) until the sample broke. In the load-unload test, the sample was loaded and unloaded for several times with a hold between each cycle for sufficient recovery. Two ramp rates (0.1 %/s and 5%/s) were applied sequentially (Fig. 1 (e)). Samples in these two studies were different.

Constitutive Equations The viscoelasticity model in this work is based on the continuous fibrous framework to account for the anisotropy and dispersion of fibers. The continuous fibrous framework is constructed by integrating the contributions of fiber families oriented along all directions emanating from a point in a continuum. The constitutive laws of all fiber families are assumed to be the same and proposed based on the reputation-type tube mechanism and the transient network

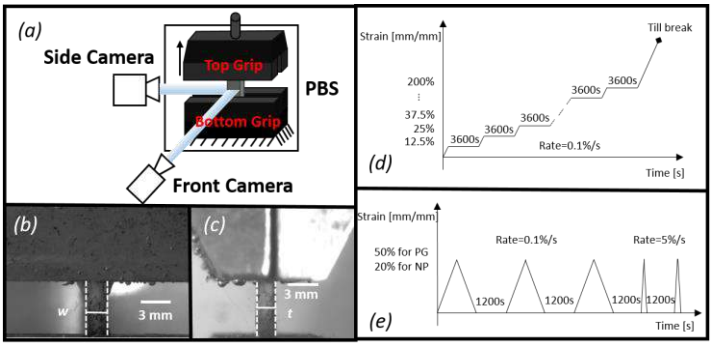

Figure 1: (a) The uniaxial tensile experiment setup. The representative image captured via (b) front and (c) side cameras. Loading profiles of (d) the several-step load-hold tensile test and (e) the load-unload tensile test

mechanism, where a portion of fibers are assumed to be constrained to travel only inside the bounded tube by Brownian motion in a combination of the reptation motion [4]. In this framework, the total stress is the addition of the pure elastic part $\mathbf{T}_{\mathrm{E}}(\mathbf{C},\ \mathbf{n}_0, b)$ (see [1]) and the viscoelastic part $\mathbf{T}_{\mathrm{V}}^r(\mathbf{C}, \mathbf{n}_0, b)$.

$$\mathbf{T}(\mathbf{C}, \mathbf{n}_0, b) = \mathbf{T}_{\mathrm{E}}(\mathbf{C}, \mathbf{n}_0, b) + \int_0^{2\pi}\int_0^{\pi} H(I_n - 1)\frac{1}{\pi}\sqrt{\frac{b}{2\pi}}\frac{e^{2(\mathbf{n}^2-1)}}{\mathrm{erfi}(\sqrt{2b})}\mathbf{T}_{\mathrm{V}}^r(\mathbf{C}, \mathbf{n}_0, b)\sin\phi d\phi d\theta \tag{3}$$

where b is the concentration parameter, $\mathrm{erfi}(\cdot)$ is the imaginary error function, $\mathbf{C}$ is the right Cauchy-Green deformation tensor, $\mathbf{n}_0$ is the original direction of the fiber family, H is the Heaviside function and $I_n = \mathbf{n_0}\cdot\mathbf{C}\cdot\mathbf{n_0}$. For the fiber family r, $\mathbf{T}_{\mathrm{V}}^r(\mathbf{C}, \mathbf{n}, b) = \mathbf{T}_{\mathrm{V}_e}^r\mathbf{T}_{\mathrm{V}_i}^r$, where e and i denotes the elastic and inelastic parts. $\mathbf{T}_{\mathrm{V}_e}^r$ here adopts the form as same as $\mathbf{T}_{\mathrm{E}}(\mathbf{C},\ \mathbf{n}_0, b)$ (see [1]). The total stretch λ could be separated into the elastic and inelastic parts

$$\lambda = \lambda_e\lambda_i \tag{4}$$

The flow rule is as the following form

$$\widetilde{\mathbf{D}}_i = \dot{\gamma}\mathbf{n}\otimes\mathbf{n} \tag{5}$$

where $\widetilde{\mathbf{D}}_i$ is the symmetric part of $\mathbf{L}_i = \dot{\mathbf{F}}_i\mathbf{F}_i^{-1}$ pulled back with $\mathbf{F}_e$, and $\mathbf{n}$ is the current direction of the fiber family. $\mathbf{F}_e$ and $\mathbf{F}_i$ are deformation tensors corresponded to the elastic and inelastic parts. $\dot{\gamma} = \eta(\lambda_i - 1 + \epsilon)^C\left(\frac{\mathbf{T}_{\mathrm{V}}^r}{T_0}\right)^m$. η, T_0, ϵ, C, and m are material parameters with physical meanings related to the microstructure. Specifically, η is the original shear rate, T_0 is the initial flow stress, ϵ is a small constant to guarantee the numerical stability (kept as 0.001 in simulations in this work), m is the hardening coefficient, and C is the reputation stretch coefficient. Other material parameters in $\mathbf{T}_{\mathrm{V}_e}^r$ is also needed, including the viscous initial stiffness ξ_V, the viscous locking stretch N_V, and a dispersion coefficient b.

The "return-mapping" algorithm was applied to numerically achieve the constitutive model, and the Newton method was used to solve for the ordinary differential equations. The constitutive model was coded as a plugin of FEBio (V2.9.1, url: febio.org) and the FEA analysis was done in FEBio to simulate the uniaxial tensile experiments. Then the model was hand-fit to the tensile force responses to get the optimal material parameters.

RESULTS

The load-unload experimental results show the force response is dependent on strain rate, where a higher strain rate produces a larger force response. The load-hold experimental results show the pregnant samples relax more and faster than the nonpregnant samples.

Currently, only the samples from the internal os of one nonpregnant and one pregnant cervix were fitted for each kind of test (load-hold test and load-unload test). The force-relaxation responses of both the load-hold and load-unload tensile experiments are captured well using the proposed nonlinear viscoelastic model (Fig. 2 (a, b)). The best-fit viscous parameters of the load-hold tests are $\eta = 0.0008$, $T_0 = 23\mathrm{kPa}$, $C = -0.2$, $m = 2$, $\xi_V = 3.9\mathrm{kPa}$, $N_V = 1.9$ for the nonpregnant sample and $\eta = 0.0015$, $T_0 = 3.8\mathrm{kPa}$, $C = -0.3$, $m = 1.3$, $\xi_V = 0.23\mathrm{kPa}$, $N_V = 5.5$ for the pregnant sample. The best-fit viscous parameters of the load-hold tests are $\eta = 0.0004$, $T_0 = 52\mathrm{kPa}$, $C = -0.2$, $m = 1.8$, $\xi_V = 3.9\mathrm{kPa}$, $N_V = 2.1$ for the nonpregnant sample and $\eta = 0.0006$, $T_0 = 0.058\mathrm{kPa}$, $C = -0.3$, $m = 1.3$, $\xi_V = 0.53\mathrm{kPa}$, $N_V = 5.5$ for the pregnant sample.

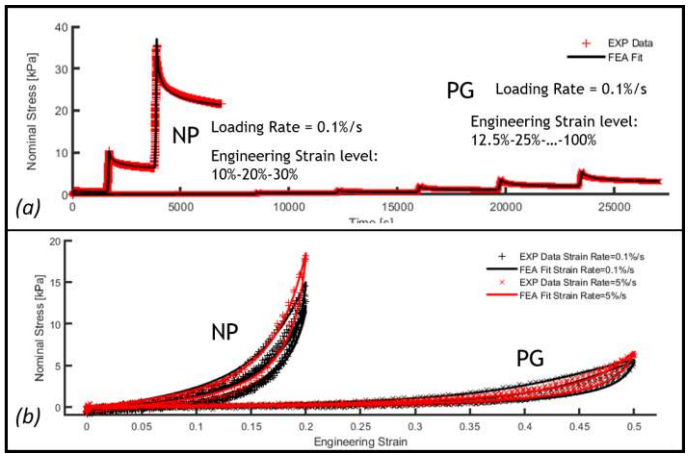

Figure 2: Results: A representative fitted force response of (a) the load-hold tensile test and (b) the load-unload tensile test

DISCUSSION

The main objective of this study was to report tensile viscoelastic material parameters for nonpregnant and pregnant human cervical tissue using a proposed fibrous nonlinear viscoelastic model. Here, we present our experimental data and the load-unload and load-hold uniaxial tensile tests on human cervical samples. Additionally, we prove the constitutive model to fit the experimental data well, though currently only one nonpregnant and one pregnant sample are studied.

Our preliminary results show the cervix remodels to relax more and faster during pregnancy and this change is related to the reduction of the initial flow stress and the viscous initial stiffness, and the increase of the original shear rate and the viscous locking stretch. This demonstrates the ability of our model to capture the intrinsic changes in the microstructure. Next, we will run an automatic IFEA [1] of all of the remaining tensile force data and validate the model by predicting the shape changes obtained from the images captured during the experiments. We will also fit the model to the indentation experimental data. The final goal will be to describe the material behavior of the human cervix under both the tensile and indentation tests.

INTRODUCTION

Displacement Encoding with Stimulated Echoes Magnetic Resonance Imaging (DENSE-MRI) is a technique that allows for the non-invasive, patient-specific quantification of regional arterial wall kinematics. This technique has been applied to the aorta, demonstrating that its *in vivo* deformation is circumferentially heterogeneous at different locations along the aorta.[1] Perivascular support and tethering are likely a relevant factor in vascular mechanics and one of the possible causes of deformational heterogeneity.[2] Nevertheless, most models of aortic function assume a homogeneous adventitial boundary condition, leading to an axisymmetric distribution of strain.[3] In a previous work, we developed an inverse Finite Element Method (iFEM) approach using DENSE-MRI data as target displacement and a heterogeneous Elastic Foundation Boundary Condition (EFBC) at the adventitia to model the effect of different perivascular structures that successfully reproduced the patient-specific *in vivo* deformation of the infrarenal abdominal aorta (IAA). We also showed that the inclusion of periaortic structures affects the image-based estimation of aortic wall properties.[4] However, this method can only account for the passive response of static periaortic tissues. A different approach is needed for active interactions of aorta with the heart and other large arteries (Figure 1b, 1c). In this work, we develop a generalized approach that allows for modeling the effect of active and passive perivascular structures on the *in vivo* function of the aorta, while maintaining a low computational expense. To achieve this, we incorporate a moving EFBC using DENSE-MRI derived displacement data as target for an iFEM.

METHODS

Anatomic model and discretization. Steady state free precession (SSFP) cine and 2D DENSE MRI were taken on 25 healthy volunteers from which we analyzed one of three locations of the aorta distal aortic arch (DAA), descending thoracic aorta (DTA) or IAA (Figure 1a). DENSE-MRI derived displacements were estimated as previously described.[1] Diastolic images were segmented and smoothed to obtain an anatomic model of the cross-section of the aortic wall. The model was discretized into quadratic tetrahedral mesh. A single layer of elements was used in the axial direction to enforce a plane-strain 2D problem.

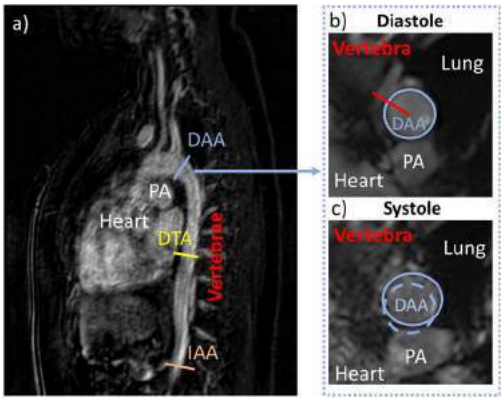

Figure 1. a) Sections of study on sagittal view. b) DAA and surroundings at diastole. Red line: circumferential reference pointing to the vertebra.c) DAA and surroundings at systole. PA: pulmonary artery. Dashed blue line: location of diastolic reference configuration. Solid blue line: current location of aortic wall.

Material model. Fung's orthotropic pseudo-elastic constitutive equation is used as the material model. Assuming orthotropic symmetry and negligible contributions of shear components in the axial direction, the number of material constants is reduced to four. The resulting constitutive equation is given by [2]

$$\Psi = \frac{c}{2}(e^{Q} - 1) + \frac{k}{2}(\ln J)^2, \quad (1)$$

$$Q = a_{rrrr}E_{rr}E_{rr} + a_{\theta\theta\theta\theta}E_{\theta\theta}E_{\theta\theta} + a_{rr\theta\theta}E_{rr}E_{\theta\theta}. \quad (2)$$

To enforce thermodynamic consistency of the material model, material parameters were constrained by following relations:

$$c > 0; \quad a_{ijkl} > 0; \quad a_{iiii} > a_{iijj}. \quad (3)$$

Nearly incompressible behavior was imposed by enforcing $k \gg c$.

Boundary conditions and loads. An EFBC was applied to the outer wall as a distribution of radially-oriented linear springs. Stiffness of each individual spring was calculated as a function of spring density such that the effective stiffness per unit area is set to 10^{-5} times the material constant c. The process is simulated in two quasi-static time-steps. In the first step, the spring ends are fixed and a uniform pressure load of Δp =40 mmHg is prescribed in the lumen. In this step, the aorta expands into an approximately regular-shaped cylinder while compressing all the springs. On the second step, the ends of the springs are displaced on the radial direction to fit the aortic wall to its target shape and position; moving away from the centroid to relax the springs, or moving in and pushing against the adventitial surface to increase the load (Figure 2). The heterogeneous radial displacement (d_n) is set as a piece-wise constant function of a finite number of regions (n) depending on the circumferential position with smooth cubic transitions. Four regions (n = 4) were adequate to obtain good correspondence to DENSE-derived displacement. The angles ϕ_n, representing the boundaries of each region, are measured from a line projected from the luminal centroid to the nearest point of the vertebra, such that the analysis is independent of MRI frame of reference and patient position (Figure 1b).

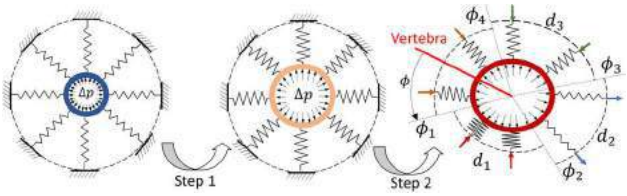

Figure 2. Generalized approach to model active and passive aortic wall interaction with periaortic active and passive structures.

Optimization algorithm. Pixel displacement information from DENSE-MRI was interpolated to the nodes of the FEM mesh as target data. An optimization algorithm, using the *Trust Region Reflective Method* from *Python Scipy* library, was employed to iterate over material model constants $(c, a_{rrrr}, a_{\theta\theta\theta\theta}, a_{rr\theta\theta})$ and EFBC parameters (d_n, ϕ_n) to fit the simulated nodal displacement to the targeted displacement field. The algorithm employs *FEBio 2.9* to solve the FEM forward problem for each iteration until a minimal error is found. To make sure results are not local minima, all cases were run with three sets of starting parameters.

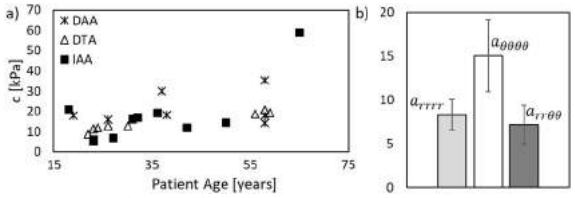

Figure 3. Estimated material parameters: (a) c as a function of patient's age, (b) average anisotropic constants a_{ijkl}.

RESULTS

Displacement fields. Results show a close match between the simulated and targeted deformed geometry converging to averaged nodal displacement errors below pixel size resolution. On average displacement errors were 0.28 ± 0.35, 0.44 ± 0.25 and 0.65 ± 0.33 mm for the IAA, DTA and DAA respectively.

Material properties. Material constant c resulted in the same order of magnitude of those previously reported.[2,4] Standard ANOVA was carried showing significant proportional correlation of c to patient's age (p=0.049), which agrees with the expected increase of artery stiffness with age (Figure 3a).[5] It is important to highlight that other factors not accounted here, such as patient's life-style, also affect arterial stiffness. No significant correlation (p>0.05) was found between mechanical properties and location along the aorta. The circumferential anisotropic term $(a_{\theta\theta\theta\theta})$ was approximately double the radial term (Figure 3b).

Adventitial load distribution. The range and location of the four elastic displacement regions (ϕ_n) showed reasonable correspondence to interactions of the aortic wall to its surroundings. For regions corresponding to rigid structures (vertebra), springs move in towards the aortic wall pushing it to its original position, compensating with a spring compression force equivalent to the resistance of the rigid structure to aortic expansion. Springs move further in to push the aorta beyond its original position to model moving structures pushing the aorta, such as the heart at the DTA or the PA at the DAA. For regions corresponding to soft structures, springs move away from the aortic wall reducing the resistance to expansion. As a consequence, the net transmural force (adventitial minus luminal force) peaks in regions corresponding to stiff or inwardly pushing boundaries. In regions with soft periaortic tissues, net transmural force is lower, and the soft tissues along with the aortic wall absorb a larger share of the pressure pulse energy (Figure 4).

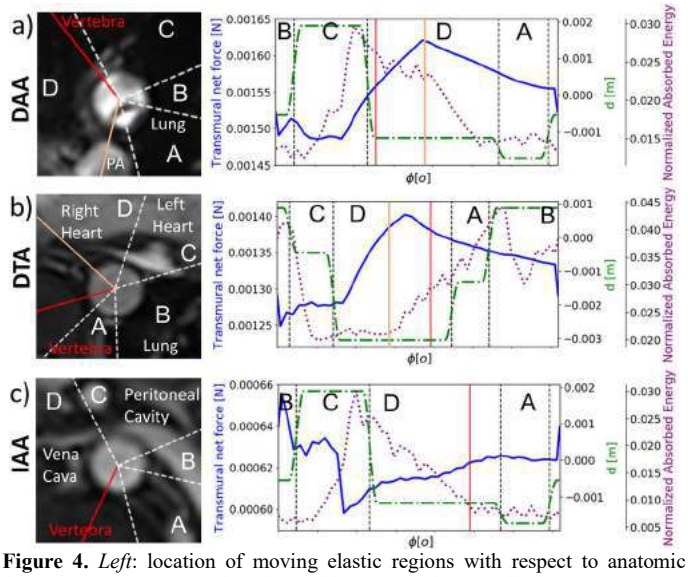

Figure 4. *Left*: location of moving elastic regions with respect to anatomic features. *Right*: transmural net force (blue), optimal EFBC displacement (green), and EFBC stored energy normalized to total aortic wall deformation energy (purple) for (a) DAA from 19 y.o. (b) DTA from 23 y.o. and (c) IAA from 23 y.o. Red line: circumferential reference pointing to the vertebra. Orange line: circumferential reference pointing to moving boundary.

DISCUSSION

Results suggest that modeling the passive and active mechanical effects of periaortic structures can reproduce the *in vivo* heterogeneous deformation and translation of the aortic wall and provide reasonable quantification of *in vivo* patient-specific aortic stiffness at specific locations along the aorta. This method provides an estimation of the distribution of adventitial load and the share of mechanical energy absorbed by the periaortic structures, which could improve our understanding of aortic mechanics and tissue growth and remodeling. The proposed approach has relatively low computational costs as it relies on unidimensional linear springs to model the periaortic structures, while keeping the model parameters to a minimum.

INTRODUCTION

Transcatheter aortic valve (TAV) replacement (TAVR) emerged initially as an alternative procedure to the traditional and highly invasive surgical aortic valve replacement surgery (SAVR). TAVR consists of percutaneously deploying using a catheter, a bioprosthetic valve that can be reduced to a few millimeters in diameter in the aortic annulus, and subsequently, expanding it in the position of interest.

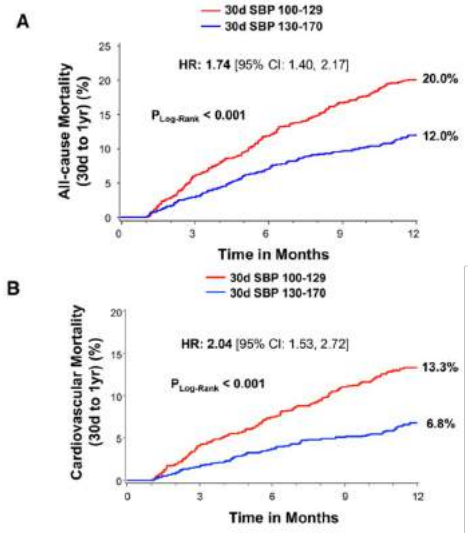

Figure 1: 30 day to 1-year all cause and cardiovascular mortality after TAVR with stable and increased SBP. Image from Ref. 1.

It was reported that more than 50% of aortic stenosis patients (with and without previous history of hypertension) developed hypertensive conditions that proved to be associated with better prognosis[1]. Several studies reported that sustained lower aortic blood pressures post-TAVR were associated with higher incidence of cardiovascular mortality along with alterations in coronary perfusion. In addition, higher arterial elastance (AE), systemic arterial compliance (SAC) and pulse pressure post-TAVR were correlated with increased cardiovascular mortality[2]. These findings, counterintuitive in nature, raised a multitude of questions as they associate typically harmful outcomes with better prognosis. Moreover, coronary perfusion highly depends on the aortic pressures. Studies have shown that the implantation of a TAV alters the sinus flow dynamics leading to potential impairment of coronary perfusion. The goal of this work is to evaluate the impact of various afterload conditions notably blood pressure, resistive and pulsatile load on the performance of TAVs, sinus flow changes, and coronary perfusion.

METHODS

The hemodynamic assessment of a 26mm SAPIEN 3 transcatheter aortic heart valve was performed in a left heart simulator under pulsatile conditions of various aortic pressure, heart rate and flow rate conditions as shown in Table 1. The experimental setup schematic diagram is shown in Fig.2. The fluid used in the experiments was a mixture of water-glycerin with properties similar to those of blood (density of 1060Kg/m^3 and a kinematic viscosity of 3.5cSt). Fifty consecutive cardiac cycles of aortic pressure, ventricular pressure, and flow rate data were recorded at a sampling rate of 100 Hz. The coronary flow was tuned for the experiments at 120/80 mmHg and any variation was recorded as varying from that point. The coronary flow was calculated as varying between 4 – 5% of the total cardiac output. The mean

transvalvular pressure gradient (ΔP) is defined as the average of positive pressure difference between the ventricular and aortic pressure curves during forward flow.

The effective orifice area (EOA) is an important parameter to evaluate valve performance through estimating the available area for flow. EOA was computed using the Gorlin's equation:

Table 2: Experimental and Derived Afterload Conditions

Experimental Conditions				
Transcatheter Aortic Valves	Heart Rate (bpm)	Cardiac Output (L/min)	Conditions of aortic pressure (mmHg)	
26 mm SAPIEN 3 Balloon-Expandable Valve	60, 90 and 120	3.5, 5, and 6.5	Fixed Diastolic Pressure	100/80
				110/80
				120/80
				130/80
				140/80
			Fixed Systolic Pressure	140/40
				140/60
				140/80
				140/100

$$EOA\ (cm^3) = \frac{Q_{rms}\ (cm^3/s)}{51.6\sqrt{\Delta P\ (mmHg)}} \quad (1)$$

The results are presented as mean standard deviations. Statistical analysis was performed using JMP Pro version 13.0.0 (SAS Institute Inc, Cary, NC). For data distributed normally, ANOVA was used followed by the Tukey test for pairwise comparison. For data with non-normal distribution, a Wilcoxon/ Kruskal-Wallis test with a post-hoc Dunn method was performed.

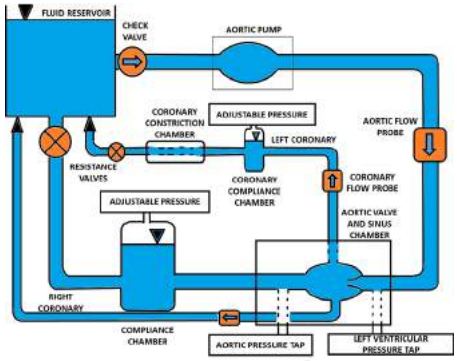

Figure 2: Left heart simulator with coronary flow in-vitro

RESULTS

The EOA variations with increasing systolic blood pressures from 100 to 140 mmHg are shown in Fig.3A and those with increasing diastolic blood pressures from 40 to 100 mmHg are shown in Fig.3B. The variations were shown to be non-monotonic with non-uniform trends depending on the heart rate and the cardiac output. For example, a significant ($p < 0.0001$) decrease in EOA of 1.22 ± 0.06 to 1.08 ± 0.01cm^2 was observed at a CO of 3.5L/min and HR of 60bpm as SBP increases from 100-140mmHg. Whereas, at a CO of 5L/min and HR of 90bpm, a significant ($p < 0.0001$) decrease in EOA of 2.29 ± 0.05 to 1.34 ± 0.01cm^2 going from a SBP of 100-120mmHg, a significant increase of EOA of 1.34 ± 0.01 to 2.14 ± 0.05cm^2 from 120-130mmHg, and a significant ($p < 0.0001$) decrease of EOA of 2.14 ± 0.05 to 1.49 ± 0.18cm^2 from 130-140 mmHg. With varying diastolic blood pressures, a similar observation of non-uniformity in trends was noted. However, for most of the cases, the EOA was found to be decreasing as the diastolic pressures increase.

The coronary flow was found to increase with increasing systolic and diastolic pressures independently from cardiac output and heart rates as shown in Fig.4A and 4B. At the lower pressures (<120mmHg), there was no observed drop in the total coronary flow below the calculated lower acceptable thresholds of 140, 200 and 260 mL/min.

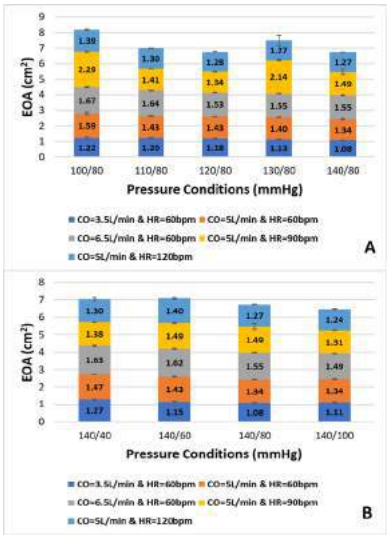

Figure 3: Average EOA variations with varying systolic and diastolic pressures

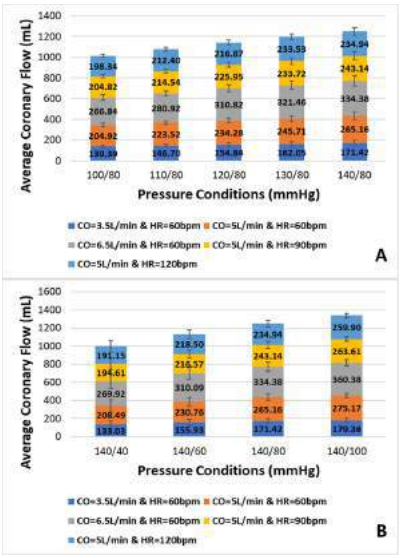

Figure 4: Average coronary flow variations with varying pressures.

DISCUSSION

The TAVR performance parameters vary significantly with various aortic blood pressure conditions. While the variations of the effective orifice area – a crucial parameter to evaluate valve performance – were not monotonic, the data suggest an overall decreasing trend with increasing systolic and diastolic pressures. This suggests the need for additional flow studies such as particle image velocimetry (PIV) to understand the flow dynamics downstream of the aortic valve and in the sinus. In addition, these additional studies would help identify the ideal blood pressure range post-TAVR and further understand the basis of worsening outcomes with lower blood pressure conditions in hypotensive patients. Ongoing work includes computing the variation trends of the valvulo-arterial impedance, a measure of global afterload that theoretically accounts for effects of resistance and compliance, as a function of the total arterial, compliance and resistive loads in addition to PIV experiments.

INTRODUCTION

Two core requirements of a functional tissue engineered vascular graft (TEVG) are the recruitment of host vascular smooth muscle cells (SMCs) into the implant and compliance matching to the native vasculature. Compliance has been shown to have an effect on vascular smooth muscle cell phenotype, inflammatory response, and overall patency of the vessel [1]. Specifically, stiff or hypocompliant grafts change the hemodynamic environment of the vessel leading to stenosis and loss of vessel patency [2]. SMCs are the major muscular component of the vessel responsible for extracellular matrix production and the regulation of vascular tone. The recruitment of host SMCs to the TEVG requires migration, proliferation and its long-term function will require the replacement of the biodegrading TEVG with host extracellular matrix (ECM).

The composition of the TEVG also offers a unique ability to encourage SMC manipulation through the integration of biomolecules into the scaffold. One factor of particular interest is transforming growth factor beta 2 (TGFβ2) which has been shown to modulate SMC phenotype depending on concentration [3]. This growth factor is a pleiotropic cytokine that has been shown to regulate cell cycle, cell differentiation, cell growth, cell death, and ECM deposition and organization. On a larger scale, TGFβ2 has also been shown to have a role in ECM remodeling in vascular, cardiac, and embryogenesis [4]. For SMCs specifically, these cells can be recruited by a low TGFβ2 concentration (0.1 ng/mg) from the scaffold to promote cellular migration, while higher concentrations of TGFβ2 (>5 ng/mg) can arrest cellular proliferation/migration to promote ECM production over the course of a 5-day in vitro experiment [5].

The goal of this study was to modulate the release of TGFβ2 (0 ng/mg, 10 ng/mg, and 100 ng/mg) from a compliance matched (CM) TEVG and evaluate cellular infiltration into the scaffold and ECM deposition. The acellular CM grafts were designed using our tightly coupled computation and experimental approach, electrospun, and compliance matched to rat aorta. Next, these grafts were implanted into Sprague Dawley rats for 5 days, imaged in vivo using ultrasound, and explanted to evaluate cellular infiltration of SMCs, macrophages, and collagen.

METHODS

The composition of compliance matched TEVGs consisted of six alternating layers (A+B) of varying ratios of gelatin to polycaprolactone. The layer thickness and ratio was determined using a computational/experimental optimization scheme to match rat aorta thickness and compliance [6]. TGFβ2 concentrations of 0, 10, and 100 ng/mg were added to electrospinning solution to create the three experimental groups. The constructs were fabricated from these solutions using a commercial electrospinning device and crosslinked in 0.5% w/v genipin at 37ºC. After 24 hours, the constructs were washed,

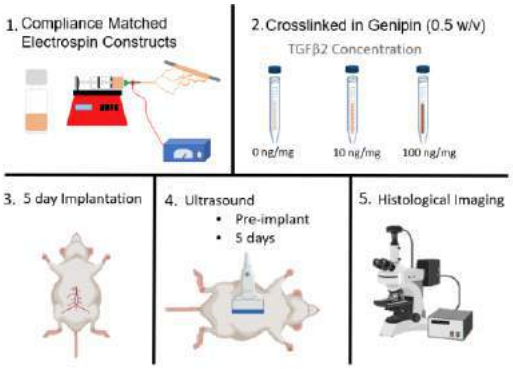

Figure 1: General experimental approach to assess TGFβ2 elution of TEVGs in-vivo.

measured for compliance, and implanted (n=3) into the abdominal aorta of a Sprague Dawley rat for 5 days.

After implantation, the constructs were imaged using in vivo ultrasound at 5 days to determine construct compliance and maximum luminal velocity in relation to the native vessel using a one-way ANOVA. Compliance was calculated using the outer diameter (OD) 120 and 70 as follows:

$$\text{Compliance} = ((OD_{120} - OD_{70})/OD_{70})/50 \text{ mmHg}$$

Each experimental group (0, 10, and 100 ng/mg) was sacrificed at 5 days and evaluated using histology. The 5-day time point was chosen to assess the acute response of the host to various levels of TGFβ2 [5]. For histology, each graft was evaluated cross sectionally in the middle axial region of the graft for SMCs (myosin heavy chain-MHC), macrophages (total-CD68 & M1-CD86), and collagen content. Each group was compared using image processing in MATLAB® and differences were determined using a one-way ANOVA. A general overview of this study is shown in **Figure 1**.

RESULTS

The compliance of CM TEVGs (0, 10, 100ng/mg) matched that of excised rat aorta tissue prior to implantation and were successfully implanted (data not shown). All the rats survived the duration of the study with no known complications.

In vivo compliance measurements showed a general decrease in compliance as TGFβ2 concentration was increased in the TEVG. Specifically, the 100 ng/mg group showed a decrease in compliance compared to native rat aorta, **Figure 2**, while the maximum blood velocity showed no differences.

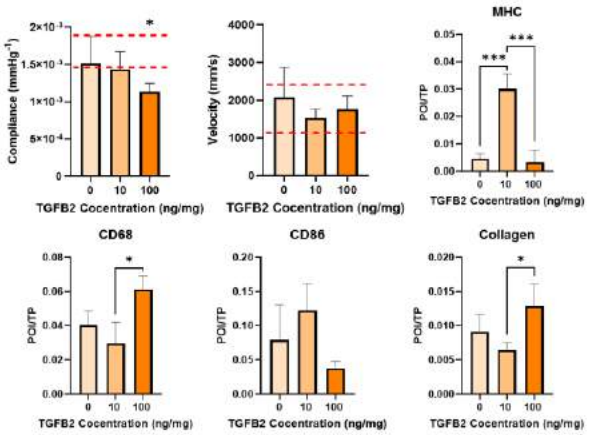

Figure 2: In vivo graft compliance and velocity. Immunohistochemistry of myosin heavy chain, CD68, CD86, and collagen. POI/TP = Pixels of Interest/ Total Pixels *, p<0.05, **, p<0.01, ***, p<0.001

Immunofluorescence of the 5-day explants of 0, 10, 100 ng/mg is shown in **Figure 3** with the implant in green and cell nuclei in blue. For all groups, cells were able to successfully infiltrate the construct and the surrounding tissue regions.

For histology, the majority of the differences were seen from the 10 ng/mg to 100 ng/mg group (**Figure 2**) with increases in the overall immune response in CD68 and collagen in the 100ng/mg constructs, $p<0.05$. No differences were found between all experimental groups for the M1 macrophages marker (CD86). Myosin heavy chain (MHC) expression had the most dramatic differences with an increase in the 10 ng/mg compared to 0 ng/mg and 100 ng/mg groups, $p<0.001$.

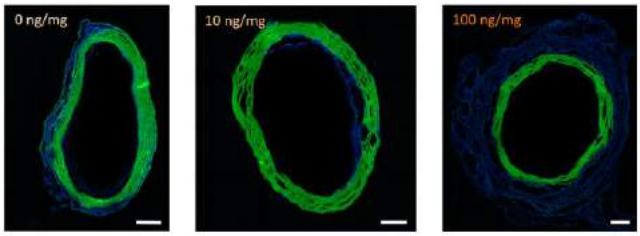

Figure 3: Immunofluorescence images of 5-day explants. Cell nuclei are in blue and the implant is green. Scale bar is 100 µm

DISCUSSION

Our preliminary immunohistochemistry results suggest that the incorporation of TGFβ2 into a compliance matched TEVG promotes increased SMC infiltration and collagen production at an acute 5-day time point. Specifically, the data showed that the low concentration (10 ng/mg) of TGFβ2 will increase smooth muscle cell recruitment (MHC marker). While a higher concentration (100 ng/mg) of TGFβ2 will increase collagen production in the TEVG and create an overall larger immune response. The in vivo ultrasound data also showed that an increase in TGFβ2 concentration will lead to an increase in TEVG stiffness.

Moving towards a functional TEVG, the incorporation of SMCs are vital. In this work, the results suggest the incorporation 10 ng/mg TGFβ2 to the TEVG promotes more positive MHC cells and agrees with past in vitro work. Specifically, Ardila et al. has shown that exogenous low TGFβ2 concentrations (<0.01 ng/ml) increase cellular proliferation while higher concentrations (>5 ng/ml) promote collagen formation [3]. The low concentration of TGFβ2 in this study promoted more MHC positive cells and the higher concentration promoted more collagen development. While the concentrations used in vitro are different, this difference in concentration would most likely be related to in vivo differences seen in the rat.

Given that our implant was only implanted for 5 days, one of the most surprising results from this study was the increase in TEVG stiffness as TGFβ2 concentrations increased. Our groups prior 4 week implantations of non-TGFβ2 eluting TEVGs has been able to maintain host compliance [7]. These two results in combination may be useful in our future work for longer term implantation where delated release of large amounts of TGFβ2 can be used to maintain in-vivo TEVG compliance as our graft fully degrades.

Some important limitations of note in this work include the acute time point of 5-days and the small sample size. As this work is continued, longer time points will be added to this study as well as the incorporation of a hypocompliant (stiffer) TEVG.

FIBROUS MICROENVIRONMENTS REGULATE NUCLEAR SHAPE IN A DIAMETER-DEPENDENT MANNER

Aniket Jana (1), Amrinder S. Nain (1)

(1) Department of Mechanical Engineering
Virginia Tech
Blacksburg, VA, USA

INTRODUCTION

Proper cellular functions during fundamental biological process like cell migration, differentiation and tissue morphogenesis, are often associated with a tight control on nuclear shape and size. Aberrant nuclear morphologies are implicated in various diseased states like muscular dystrophy, progeria and cancer metastasis. Additionally, nuclear shape remodeling has been associated with various downstream effects, including, nucleo-cytoplasmic shuttling of transcription factors[1] like YAP/TAZ, MKL1 and alterations in transcriptional activity. Previous studies on flat continuous substrates have demonstrated nucleus shape control through a special class of apical actin stress fibers; the perinuclear actin cap[2]. However how such shape regulation occurs in fibrous microenvironments like those commonly observed in skeletal muscle tissue and around highly metastatic tumors, remain poorly understood. In this study, we utilize our previously reported[3] non-electrospinning Spinneret Tunable Engineered Parameters (STEP) technique to manufacture aligned and suspended fiber networks with a wide range of diameters (~150 nm-7 µm) and tunable fiber density to investigate their role in modulating nuclear shape and translocation of YAP/TAZ during cell spreading. We observe that contrary to flat substrates, in suspended fibers which mimic the native extracellular matrix (ECM), the cell cytoskeleton is arranged as a symmetric cage without any apico-basal polarity. Our results also indicate that larger fiber diameters result in increased cytoskeletal tension leading to higher levels of nuclear compression and nuclear translocation of the mechanosensitive transcription factor YAP. Such cytoskeletal mediated force transmission can also result in deep (~1.5-3 µm) nuclear invaginations near the cell-fiber interface. Overall, we demonstrate how physical characteristics of the fibrous ECM, can regulate cell contractility, leading to an exquisite control over nuclear shape.

METHODS

Suspended fiber networks were manufactured from solutions of polystyrene (MW: 2,000,000 g/mol; Scientific Polymer Products and MW: 15,000,000 g/mol, Agilent Technologies) was dissolved in xylene (Thermo Fisher Scientific) using the non-electrospinning STEP technique. C2C12 mouse myoblasts (ATCC) were cultured in Dulbecco's modified Eagle's medium (Invitrogen) supplemented with 10% fetal bovine serum (Gibco) in T25 flasks (Corning). Immunofluorescent staining was performed in paraformaldehyde (4%) fixed cells. Images were taken using a confocal microscope (LSM 880, Carl Zeiss Inc.) with 0.3-0.36 µm z-slice thickness. Image processing was performed in Zen Blue software (Carl Zeiss Inc) or Image J (NIH). *,**,***,**** represent $p< 0.05$, 0.01, 0.001 and 0.0001 respectively.

RESULTS

Here, we utilized force-measuring nanonets composed of horizontal arrays of densely spaced (~10-12 µm spacing) small diameter (200 nm, 350 nm and 800 nm) fibers deposited on top of orthogonal large diameter (~2 µm) support fibers (Fig. 1a). Cells usually adopted symmetric parallel-cuboidal morphologies (Fig. 1b) as they spread along fiber doublets. Well-defined focal adhesion clusters (FAC) formed at all 4 cell poles, with FAC sizes increasing with fiber diameters (Fig 1d). Using our previously reported[4,5] Nanonet Force Microscopy (Fig 1c), we quantified the temporal evolution of cell-fiber adhesion forces and observed that spread-state cell contractility was indeed significantly higher for larger fiber diameters (Fig 1e) and in good agreement with higher adhesion sizes observed. To understand how such mechanical forces were transmitted to the cell nucleus we imaged the 3D localization of the cell cytoskeleton surrounding the nucleus. Contrary to the predominantly apical localization of cytoskeletal elements and nuclear envelope proteins (Lamin A/C) on

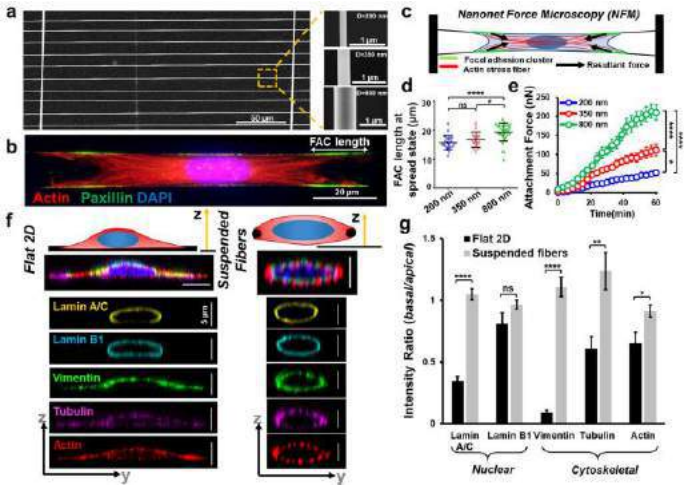

Fig 1: Cells on suspended fibers a) Aligned nanonets with 3 fiber diameter choices, b) Representative immunostained cell on fiber doublet, c) Schematic for nanonet force microscopy d) Comparison of FAC lengths at spread state (60 min. timepoint during spreading) e) Attachment forces during spreading f) Representative confocal side views (yz) of stained cells on Flat 2D and on suspended fibers g) Intensity analysis of apical and basal localization of different proteins in suspended cells and cells cultured on flat 2D glass.

Flat 2D, we observed no such apico-basal polarity on suspended fibers (Fig 1f), with the nucleus surrounded by a symmetric cytoskeletal caging structure (Intensity ratio$_{basal/apical}$~1, Fig 1g).

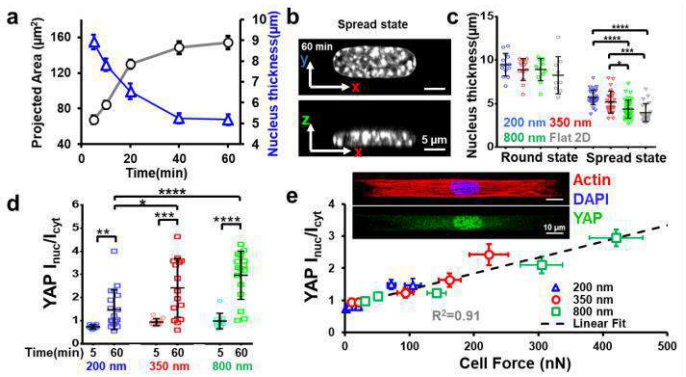

Fig 2: Nucleus shape and YAP localization in cells on fibers a) Evolution of projected area and nucleus thickness during cell spreading b) Representative top and side views of nucleus at spread state (60 min. timepoint) c,d) Comparison of nucleus thickness and YAP localization at round (5 min.)/spread (60 min.) state for different substrates respectively e) Impact of cell force on nuclear entry of YAP

To understand cytoskeletal tension-mediated regulation of nuclear shape, we imaged nuclei fixed at different times (5,10,20,40 and 60 min.) during cell spreading. As cells spread, progressive flattening of the nucleus was observed, characterized by an increase in projected area and reduction in thickness (Fig 2a, b). Interestingly, nucleus thickness in spread cells was found to be significantly lower in larger diameter fiber doublets (Fig 2c). Such higher levels of nuclear compression also resulted in significantly enhanced nuclear translocation of the YAP transcription factor (Fig 2d). In fact, such nuclear entry correlated excellently with the overall cell contractility (Fig 2e), with YAP localization primarily cytoplasmic in the low force regime (Fig 2d, e).

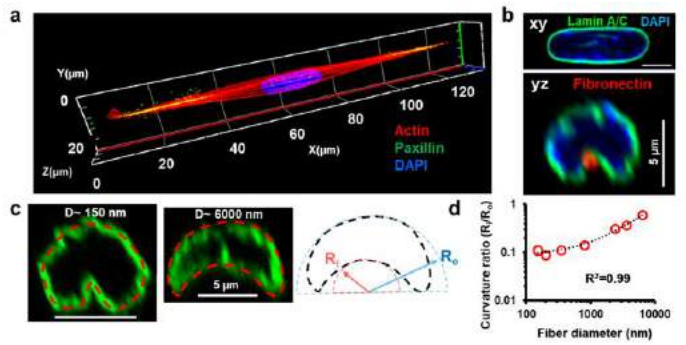

Fig 3: Fiber-mediated nuclear invaginations a) Representative spindle-shaped cell attached to single fibers, b) Stained nuclei showing invagination locally around fiber (red) c) Nuclear invaginations on small and large diameter fibers, R_i and R_o radius of curvature at the invagination side and the apical side respectively, d) Fiber diameter dependence of nucleus invagination curvature ratio (R_i/R_o)

Interestingly, in cells spreading along single fibers (Fig 3a), mechanical forces transmitted by actin stress fibers anchored at FACs at either cell pole can impinge the nucleus against the fiber to cause deep invaginations (Fig 3b). Invaginations were sharp at very low (~150 nm) fiber diameters and smooth on micron-scale (~6-7 μm) fibers (Fig 3c). To quantify such differences in shape, we computed the ratio of the radius of nuclear membrane curvature at the invagination site (R_i) and the radius of curvature at the apical side of the nucleus (R_o). On micron-scale fibers, we observed both radii to be similar, with an almost linear scaling of the curvature ratio (R_i/R_o) with the fiber diameter (Fig 3d).

DISCUSSION

Here, we demonstrate the remarkable mechanosensitivity of cells towards fibrous microenvironments and how ECM fiber geometry and diameter are instrumental in regulating nuclear shape and functions. Our observation of cytoskeletal caging of nucleus is in good agreement with previous studies on 3D microenvironments like microchannels[6] and dense collagen gels, which also show cytoskeletal force transmission from all sides. Higher levels of nuclear compression have been previously associated with nuclear pore complex (NPC) stretching[1] which enhances nuclear entry of various biomolecules. This can potentially explain why cells on larger diameter fibers show enhanced nuclear YAP. ECM–mediated localized nuclear deformations have been previously demonstrated in micropillared substrates[7], but we show for the first time, presence of such deformations in physiologically relevant fibrous matrices. Taken altogether, our findings on nuclear shape control will shed fundamental insights on how the local cellular microenvironment contributes to alterations in the sub-nuclear chromatin organization and overall gene-expression during cell differentiation, myogenesis and cancer metastasis.

INTRODUCTION

Chiari Malformation I (CMI) is a common and often debilitating craniocervical junction neurosurgical disease diagnosed in approximately 1% to 4% of patients who receive MRI scans [1,2]. It is often characterized by the structural defects in the cerebellum, and more specifically, the herniation of the cerebellar tonsils 5 mm below the foramen magnum. It is associated with a vast range of symptoms which can include recurrent headaches, nausea, muscle weakness, sleep disorders, and in the most extreme cases, even paralysis [3,4].

So far, the diagnosis of CMI has been based on an assessment of the patient's neurological history combined with the measurement of cerebellar tonsils downward herniation from MRI examination. However, the lack of a uniform and clear symptomatology among subjects is so pronounced that an estimated 33% of the patients affected do not show symptoms significant enough to lead to a diagnosis [3]. Determining which patient to not operate upon, on the other hand, is equally important, as the surgery can carry patient-related morbidity. More recently, the intrinsic motion of the brain during the cardiac pulsation has also been suggested as a potential diagnostic criterion for CMI [5]. Until now, however, the effect of cardiac pulsation and CSF circulation on the subtle motion of the brain tissue has proven difficult to analyze. Conventional imaging techniques such as phase-contrast MRI [6] or DENSE MRI [7] have attempted to study such motions but had certain limitations with scan time and spatial resolution. Recently, a new image processing technique called 3D amplified MRI (3D aMRI) was introduced [8-10]. 3D aMRI allows to selectively amplify the 3D motion in specified frequency bands, thereby making even imperceptible motions visible and quantifiable [8-10]. Having been previously used on against digital phantoms and 3D cine MRI of healthy subjects, in this work, 3D aMRI algorithm was applied to healthy and CMI patients and local distribution of motion in cerebellum and pons were measured and compared.

METHODS

Human subjects and imaging protocol: With IRB approval and informed consent, scans were performed on 4 healthy adult volunteers (2 females and 2 males between 26 and 32 years of age) as well as 4 CMI patients (4 females between 24 and 34 years of age) using a 3T MR imaging system (Skyra, Siemens Healthcare AG, Germany) with a 32-channel head coil at Icahn School of Medicine at Mount Sinai. For each subject, whole-brain 3D cine MRI were acquired using the following imaging parameters: acquisition matrix = 240×173, flip angle = 26◦, FOV = 216×240 mm^2, TR/TE=36.6/1.6 ms, pixel bandwidth = ±990 kHz, 16-23 cardiac phases, and 128 slices with 1.2 mm thickness.

3D aMRI algorithm: The 3D aMRI method is based on the extension of the 2D aMRI algorithm [11-13] to 3D, allowing the visualization and quantification of very subtle voxel displacements in 3 directions ([8-10]; Fig 1). In the first step, a 3D cine MRI data set is used as an input to the algorithm. Then, a 3D steerable pyramid is used to decompose the volumetric data, resulting in local phases of each time frame at different scales and orientations [8-10]. In short, the steerable pyramid is composed of steerable filters with multi-scale decomposition which recursively performs low band-pass filtering and down-sampling of each phase image. The temporal variations of the decomposed phases are then temporally filtered, amplified, and added back to the original phases. Finally, by collapsing the pyramid, the modified video is reconstructed which allows for visualization of the almost imperceptible motion. The schematics of the 3D aMRI algorithm is shown in Fig. 1.

Displacement tracking in the amplified data: Having amplified the 3D cine data in 3-direction, an image registration algorithm based on the Demons [14] was then applied to the amplified data and the overall

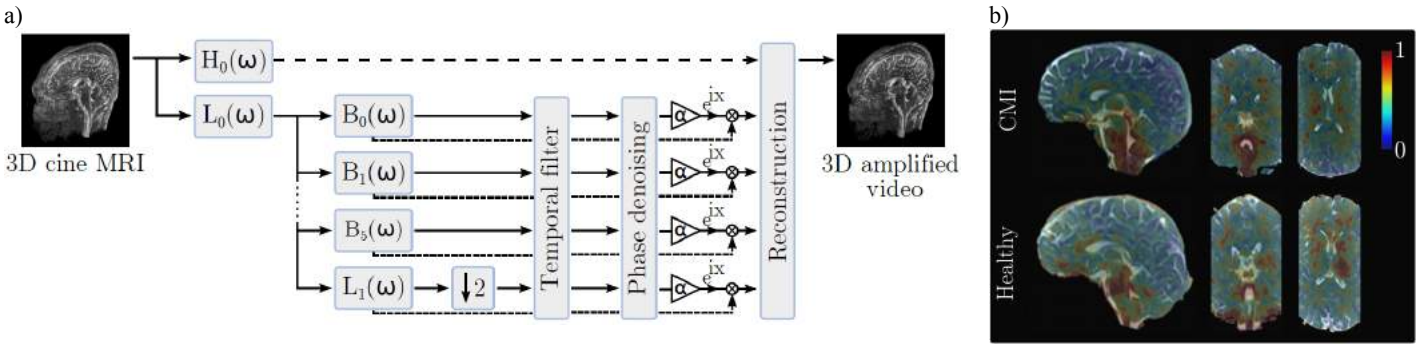

Fig. 1. (a) 3D aMRI algorithm pipeline. (b) Comparison of the CMI and healthy brain displacement between 2 age-matched female cases.

3D brain displacements of the subjects were quantified. We then mapped the acquired displacement fields on a brain atlas and selected a circular region (30 mm^2) at the bottom of the cerebellum and at the bottom of pons near the medulla (Fig. 2). The circular region was further extended to cover 7 adjacent sagittal slices for each subject, and the mean of maximum displacement within this region and across all the slices was then calculated and compared between the healthy and CMI subjects. This region was chosen since previous studies have suggested abnormal motion in the lower parts of the brain in CMI patients [5,9].

RESULTS

Having amplified the 3D cine MRI of the healthy and CMI subjects with an amplification factor of 8, and within the frequency range of 0-4 Hz, the displacement fields of each subject were then measured. In both the healthy and CMI subjects, the maximum displacement was observed to be near the pons and the 4th ventricle (Fig. 1b). When comparing the results between the two groups, we observed that the motion at the bottom of the cerebellum and the pons were significantly higher in the CMI patients as compared to the healthy subjects ($p<0.05$). In the pons, while the mean of the maximum displacement in the region of interest (ROI) was 1.06 ± 0.19 pixels, the ROI_{Pons} of the healthy subjects experienced a displacement of 0.74 ± 0.13 pixels ($p<0.05$, Fig. 2). We also observed a significantly higher displacement of 1.31 ± 0.4 pixels in the selected $ROI_{Cerebellum}$ of CMI patients as compared to the displacement of 1 ± 0.11 pixels in the healthy subjects ($p<0.05$, Fig. 2).

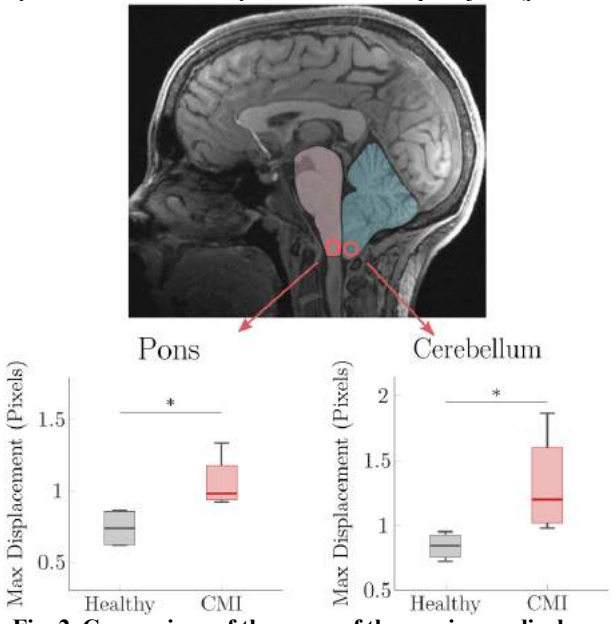

Fig. 2. Comparison of the mean of the maximum displacement between 4 healthy and 4 CMI subjects.

DISCUSSION

In this work, the 3D aMRI method was used to measure the brain's intrinsic motion in CMI patients for the first time. We observed that the highest displacement in both the healthy and CMI subjects is near the pons and the 4th ventricles. Additionally, we demonstrated that the displacement at the bottom of the cerebellum and pons (near the medulla) was significantly higher in the CMI patients as compared to the healthy subjects. Our findings are in line with previous observations that reported abnormal brain intrinsic motion in the lower parts of the brain [5,9,15]. Using the DENSE method, it was recently shown that the displacement in the lower part of the cerebellum and brainstem was much higher in CMI patients [5]. We hypothesize that this difference is mainly due to the geometrical variances between the cerebellum of the healthy and CMI subjects. The morphological changes as a result of CMI could result in partial blockage of the subarachnoid space near the foramen magnum [16]. This could result in the obstruction of the CSF circulation and potentially decrease the CSF volume through there [16]. However, since the driving pressure from the blood flow is higher than the intracranial pressure, the same volume of CSF at a higher velocity would potentially pass through the region, which results in a higher displacement of the lower parts of the cerebellum and pons [16].

Our results show 3D aMRI's capability as a potential diagnostic tool for CMI. 3D aMRI is a post-processing algorithm which is applied on cine MRI data that is already implemented in the standard clinical routine; therefore, it could be used in the current protocols and potentially have an immediate clinical impact.

INTRODUCTION

Despite the multifactorial nature of Osteoarthritis (OA), a disease of the synovial joint, mechanical stresses play a key role in the destructive evolution of the disease [1–4]. Both overloading and reduced loading of cartilage induce molecular and microstructural changes that lead to mechanical softening, fibrillation and erosion. Crucially, there is currently no direct method to correlate spatially resolved intra-tissue stresses with progression of OA in individual patients. This unmet need renders us unable to identify the most significant stimuli in the progression of OA, and thus unable to identify reliable targets for treatment or to design new therapies.

Computational models of cartilage and joints have enabled estimates of responses and properties, e.g. distributions of intra-tissue stresses and evolving mechanical properties, especially in the early stages of OA. In this study, we aimed to establish a methodology to calibrate our constitutive models of cartilage by leveraging experimental data we previously published and determine the evolution of material parameters with respect to the severity of OA quantified via the standard OARSI grade [5], especially in early disease stages.

METHODS

We described articular cartilage as a biphasic continuum $\varphi = \varphi^{\mathrm{S}} + \varphi^{\mathrm{F}}$ consisting of a porous solid phase φ^{S}, and saturated with the fluid phase φ^{F}. We calculated the total Cauchy stress tensor as [6]

$$\boldsymbol{\sigma} = -p\mathbf{I} + 2\rho^{\mathrm{S}}\mathbf{F}_{\mathrm{S}}\frac{\partial\Psi^{\mathrm{S}}}{\partial\mathbf{C}_{\mathrm{S}}}\mathbf{F}_{\mathrm{S}}^{\mathrm{T}} = -p\mathbf{I} + \boldsymbol{\sigma}_{\mathrm{E}}^{\mathrm{S}}\,, \tag{1}$$

where p is the fluid pressure, $\mathbf{I}$ is the identity tensor, ρ^{S} is the partial density of solid, $\mathbf{F}_{\mathrm{S}}$ is the deformation gradient of the solid, $\mathbf{C}_{\mathrm{S}}$ is the right Cauchy–Green tensor, and $\boldsymbol{\sigma}_{\mathrm{E}}^{\mathrm{S}}$ is the effective Cauchy stress tensor. We use an additive decomposition of the superimposed solid Helmholtz free-energy function Ψ^{S} into a Donnan osmotic pressure part $\Psi_{\mathrm{OP}}^{\mathrm{S}}$, an isotropic matrix part $\Psi_{\mathrm{IM}}^{\mathrm{S}}$, and a fiber network part $\Psi_{\mathrm{FN}}^{\mathrm{S}}$ as

$$\Psi^{\mathrm{S}} = \Psi_{\mathrm{OP}}^{\mathrm{S}}(J_{\mathrm{S}}) + (1-\nu)\Psi_{\mathrm{IM}}^{\mathrm{S}}(J_{\mathrm{S}},\, I_1) + \nu\Psi_{\mathrm{FN}}^{\mathrm{S}}(\mathbf{C}_{\mathrm{S}})\,, \tag{2}$$

where $J_{\mathrm{S}} = \det\mathbf{F}_{\mathrm{S}}$ is the Jacobian, ν is the volume fraction of collagen to the total solid, $I_1 = \mathrm{tr}\mathbf{C}_{\mathrm{S}}$ is the first invariant of $\mathbf{C}_{\mathrm{S}}$. We model the contribution from the osmotic pressure to the Cauchy stress as

$$\boldsymbol{\sigma}_{\mathrm{OP}}^{\mathrm{S}} = -R\Theta\left[\sqrt{4(\bar{c}_{\mathrm{m}})^2 + (c_{\mathrm{m}}^{\mathrm{fc}})^2} - 2\bar{c}_{\mathrm{m}}\right]\mathbf{I}\,, \tag{3}$$

where $\mathrm{R} = 8.314\times10^3\ \mathrm{mJ/(K\cdot mol)}$, Θ is the absolute temperature, and $\bar{c}_{\mathrm{m}}$ is the ion concentration of the external solution. The concentration of the fixed charge depends on the deformation as

$$c_{\mathrm{m}}^{\mathrm{fc}} = c_{0\mathrm{S}}^{\mathrm{fc}}\left(1-n_{0\mathrm{S}}^{\mathrm{S}}\right)\left(J_{\mathrm{S}}-n_{0\mathrm{S}}^{\mathrm{S}}\right)^{-1}, \tag{4}$$

where $c_{0\mathrm{S}}^{\mathrm{fc}}$ is the initial concentration of fixed charge (within the tissue) and $n_{0\mathrm{S}}^{\mathrm{S}}$ is the initial solid volume fraction, and $J_{\mathrm{S}} = \rho_{0\mathrm{S}}^{\mathrm{S}}/\rho^{\mathrm{S}}$ where $\rho_{0\mathrm{S}}^{\mathrm{S}}$ is the initial solid partial density. We model the (largely) proteoglycan solid matrix $\Psi_{\mathrm{IM}}^{\mathrm{S}}$ using a neo-Hookean function extended with compaction effects. To model the dispersed network of collagen $\Psi_{\mathrm{IM}}^{\mathrm{S}}$ we use $\rho(\mathbf{m_0})$, the orientation distribution function, within

$$\Psi_{\mathrm{FN}}^{\mathrm{S}} = \frac{1}{\rho_{0\mathrm{S}}^{\mathrm{S}}}\int_\Omega \rho(\mathbf{D})\frac{k_1}{2k_2}\{\exp[k_2(I_4-1)^2]-1\}\mathcal{H}(I_4-1)\,\mathrm{d}\Omega\,, \tag{5}$$

where $\Omega = \{\mathbf{m_0}\in\mathbb{R}^3 : |\mathbf{m_0}| = 1\}$ is the unit sphere, $\mathbf{m_0}$ is the reference fiber orientation, $k_1, k_2 > 0$ are fiber parameters $I_4(\mathbf{m_0}) = \mathbf{m_0}\cdot\mathbf{C}_{\mathrm{S}}\mathbf{m_0}$ is the square of the fiber stretch, and $\mathcal{H}$ is a Heaviside step function. We consider the viscoelasticity of both the proteoglycan and collagen solids using two parameters: β [-], a magnitude factor, and τ [s] the associated relaxation time, cf. [6]. The diffusion tensor $\mathbf{D}$ reflects the distribution of collagen fibers and we obtain this from DT-MRI. We calculate the average $\mathbf{D}$ for a representative volume of interest using the Log-Euclidean mean. We modeled the corresponding permeability $\mathbf{K}_{\mathrm{F}}$ as

$$\mathbf{K}_{\mathrm{F}} = \frac{k_{0\mathrm{S}}}{4\pi}\left(\frac{n^{\mathrm{F}}}{1-n_{0\mathrm{S}}^{\mathrm{S}}}\right)^{m}\int_{\Omega}\frac{\rho(\mathbf{m}_0)}{\mathrm{I}_4}\mathbf{m}\otimes\mathbf{m}\mathrm{d}\Omega\,, \tag{6}$$

where $k_{0\mathrm{S}}$ is the initial Darcy permeability and m is a parameter controlling the deformation dependence of the permeability. In order to recover the initial (non-zero) stress distribution resulting from osmotic swelling, we applied the backward displacement method to find an initial equilibrium state before external loading. [7]

In previously published experiments using large-strain shear, we harvested 106 3×3 mm, full-thickness specimens of healthy and OA damaged cartilage from 17 donors [8, 9]. Using standard histological scoring we determined the OARSI grade of each specimen [5]. Prior to shear testing we applied an axial pre-compression of 1% of the undeformed thickness and allowed the specimens to equilibrate for 4000 s. Next, we applied cyclic simple-shear displacements at a rate of 75 μm/min for six cycles. We applied maximum displacements corresponding to shear strains of 5%, 10%, 15%, 20%, and 25%. Many mechanical tests failed at 20% shear strain and here we used data only up to 15% shear strain.

To simulate the shear tests, we modeled the center slice of the specimens under plane strain (**Fig. 1(a)**) and along the shear direction using 20-node hexahedral elements in FEBio (U. of Utah) (**Fig. 1(b)**). We validated our mesh using an *h*-refinement test [6,7]. We assigned three different sets of material parameters corresponding to the superficial zone (SZ), middle zone (MZ), and deep zone (DZ) based on the thickness, which has thickness of 15%, 55% and 35% respectively [7]. In light of the data available, and to minimize the computational burden, we leveraged previous studies to establish some of the parameters (**Table 1)**, where $z^* \in [0,1]$ is the normalized tissue thickness (zero refers to the articular surface and one refers to the interface with subchondral bone). We set $z^*_{\mathrm{SZ}} = 0.075$, $z^*_{\mathrm{MZ}} = 0.425$ and $z^*_{\mathrm{DZ}} = 0.85$.

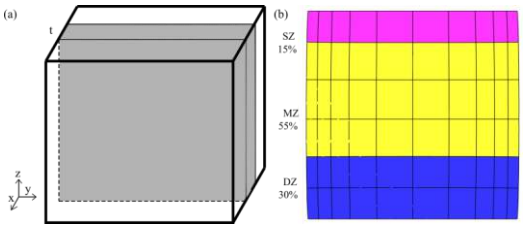

Figure 1: Finite element model of the shear experiment: (a) schematic with center slice in plane strain; (b) mesh with three distinct zones through the thickness.

Table 1: Model parameters from our previous studies [6,7].

Parameter	Value	Unit
$\boldsymbol{\Theta}$	310.15	K
$\boldsymbol{c}^{\mathbf{fc}}_{\mathbf{0S}}$	2.0×10^{-7}	$\mathrm{mol/mm^3}$
$\bar{\boldsymbol{c}}_{\mathbf{m}}$	1.5×10^{-7}	$\mathrm{mol/mm^3}$
$\boldsymbol{\mu}$	0.23	MPa
$\boldsymbol{k_2}$	8	–
$\boldsymbol{n}^{\mathbf{S}}_{\mathbf{0S}}(\boldsymbol{z}^*)$	$0.15+0.15(z^*)$	–
$\boldsymbol{\nu}(\boldsymbol{z}^*)$	$0.43(z^*)^2-0.60(z^*)+0.85$	–
$\boldsymbol{J}^{\mathbf{S}}_{\mathbf{cp}}(\boldsymbol{z}^*)$	$0.36+0.11(z^*)$	–
$\boldsymbol{k}_{\mathbf{0S}}(\boldsymbol{z}^*)$	$(1-0.9)(z^*)\times10^{-3}$	$\mathrm{mm^4/(N\cdot s)}$
$\boldsymbol{m}(\boldsymbol{z}^*)$	$3.0+5.0(z^*)$	–

We fitted the model parameters using the "Levenberg–Marquard" method within FEBio [10]. To fit our constitutive model as a function of OA severity we first extracted target data for fitting each specimen. To eliminate noise and to align the loading state, we used data from the first peak force to the last peak force. In between each pair of peaks, we resampled the data at 24 evenly-spaced intervals. We first assumed cartilage was homogeneous, setting all three zones with the same as the MZ, to fit viscoelasticity of fiber network (β_{FN}, τ_{FN}) and estimate the fiber parameter k_1. We then fixed the viscoelasticity and, using our heterogeneous model, fit fiber parameter k_1 for all three zones.

RESULTS

Figure 2 shows fitted results of two representative specimens: one healthy and one at OARSI grade 3.5. The *x*-axes display the time of the test, including the pre-compression and relaxing periods while the *y*-axes display the reaction force in the direction of shearing. **Table 2** shows the fitted parameters of these two specimens.

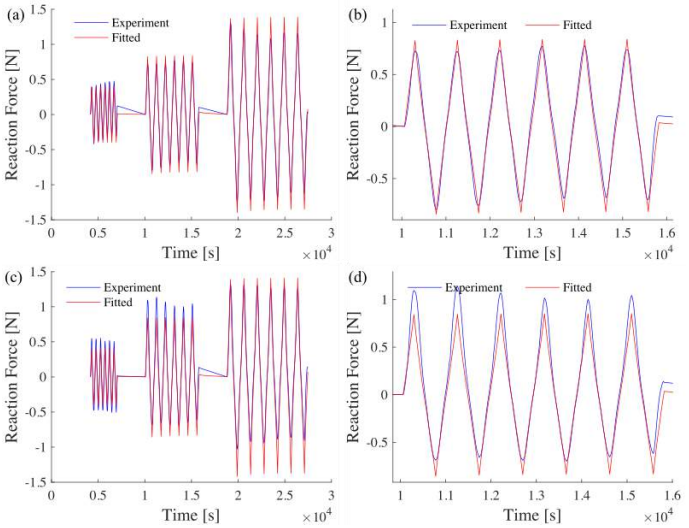

Figure 2: Representative fitting results: (a), (b) are from a healthy specimen while (c), (d) are from an OA specimen (OARSI grade 3.5). (a), (c) are the complete data while (b)(d) focus on 10% shear.

Table 2: Fitted parameters for healthy and OA specimens.

	Parameter	Value	Unit
Healthy Specimen	β_{FN}	1.680	–
	τ_{FN}	1598	s
	$k_1(\mathrm{est})$	2.266	MPa
	$k_1(\mathrm{SZ})$	1.417	MPa
	$k_1(\mathrm{MZ})$	2.890	MPa
	$k_1(\mathrm{DZ})$	3.535	MPa
OARSI Grade 3.5 Specimen	β_{FN}	1.470	–
	τ_{FN}	1697	s
	$k_1(\mathrm{est})$	3.605	MPa
	$k_1(\mathrm{SZ})$	3.363	MPa
	$k_1(\mathrm{MZ})$	4.256	MPa
	$k_1(\mathrm{DZ})$	4.811	MPa

DISCUSSION

Our preliminary results are currently insufficient to yield statistical conclusions, but we do see notable changes in the fitted parameters corresponding to both the through-thickness zones and health conditions of the specimens. The fiber parameter k_1 increases from cartilage surface to the bone interface, indicating stiffer individual fibers in DZ. The decreased β_{FN} in the OA specimen indicates a reduced viscoelastic response that likely reflects degeneration. As we fit more specimens our parameters, and the corresponding statistical analyses, will facilitate new simulation-based analyses and insights.

INTRODUCTION

Magnetic resonance elastography (MRE) is a non-invasive method that can measure mechanical properties of brain tissues in vivo [1]. Different from the clinical application of MRE in liver tissue measurements, shear waves must be effectively transmitted through the skull into brain [2]. Therefore, an effective actuator for brain MRE is desired.

Current clinically used actuator is pneumatically driven [3], but studies have shown that it might produce extra peaks in the frequency spectrum [4]. The mechanical actuator can produce accurate frequency but may produce extra noise [4]. Electromagnetic actuator, like the piezo-electric actuator, is convenient to control, and can produce an accurate actuation frequency [5]. However, electromagnetic compatibility [6] and ergonomic design are crucial for the clinical application of the electromagnetic actuator [7].

In this study, we proposed an electromagnetic actuator for brain MRE. A grappler design was used to transmit shear waves to the whole brain efficiently. The performances of the actuator in terms of frequency accuracy, electromagnetic compatibility, and wave generation were evaluated.

METHODS

With a splint-like structure, a support frame held the actuation coil in place on the top of the MR head coil to keep the coil away from the MRE imaging region (Figure 1a). A transmission bar was designed to connect the actuation coil to the vibration plates, transmitting the vibration from the actuation coil to the plate. A curved design was adopted for all vibration plates for ergonomic consideration. The components that were outside of the head coil had a height of 7.5 cm (Figure 1b). Therefore, the whole actuator could fit into the MR bore easily.

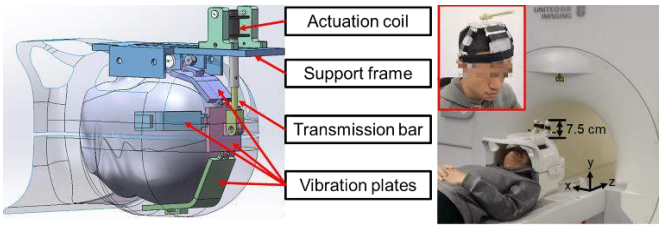

Figure 1: (a) A 3D rendering of the electromagnetic actuator for brain MRE in working position. (b) A volunteer wearing the actuator before moving into the MR bore for MRE. The part of the actuator that extrudes out of the head coil is 7.5 cm in height, leaving enough space for positioning.

We evaluated the performance of frequency actuation of the proposed actuator and compared it with that of a pneumatic actuator. A 3T MRI scanner (uMR 790, United Imaging Healthcare, Shanghai, China) was used for the experiment and all following imaging. Vibrations of the actuator during MRE were recorded using an accelerometer with a gradient echo (GRE) based MRE sequence.

To estimate the magnetic field produced by the actuation coil more precisely, finite element simulations were carried out using COMSOL. In addition, to evaluate the overall influence of the metal components, we tested the electromagnetic compatibility by measuring the signal-to-noise (SNR) ratio of a spherical liquid phantom with T1 weighted (T1W) and T2 weighted (T1W) clinical sequences, respectively.

A cylindrical phantom was manufactured to evaluate the actual shear wave generation performance of the actuator. The phantom was made of glycerol gelatin. The quality of the produced shear wave within

the region of interest (ROI) was assessed by using the octahedral shear strain (OSS) signal-to-noise ratio OSS_{SNR} [8].

$$OSS_{SNR} = \frac{\bar{\epsilon_s}}{\bar{\epsilon_s}^{noise}} \quad (1)$$

where $\bar{\epsilon_s}$ is the average value of OSS over one harmonic cycle and ϵ_s can be calculated as:

$$\epsilon_s = \frac{2}{3}\sqrt{\begin{matrix}(\epsilon_{xx}-\epsilon_{yy})^2+(\epsilon_{xx}-\epsilon_{zz})^2+\\(\epsilon_{yy}-\epsilon_{zz})^2+6(\epsilon_{xy}{}^2+\epsilon_{xz}{}^2+\epsilon_{yz}{}^2)\end{matrix}} \quad (2)$$

where ϵ_{xx}, ϵ_{yy}, ϵ_{zz}, ϵ_{xy}, ϵ_{xz}, and ϵ_{yz} are the components of the Cauchy strain tensor.

RESULTS

The frequency response of the proposed actuator along the x, y, and z axes showed an increased acceleration magnitude with larger vibration frequencies along all three directions (Figure 2a). Compared with the spectrum of the pneumatic actuator, we observed lower frequency offsets for the vibration frequencies, especially at 60 Hz (Figure 2b).

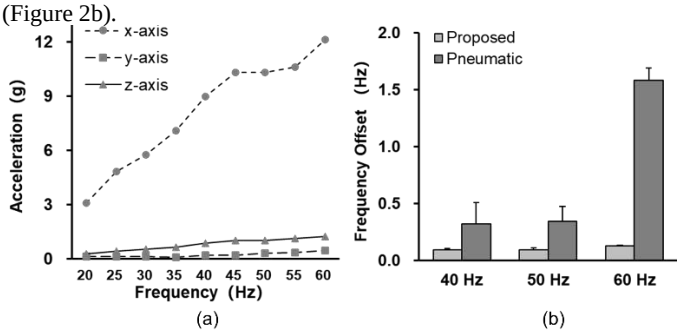

Figure 2: (a) Measured acceleration vs. actuation frequency. The primary motion of vibration was along the x direction. (b) Comparison of frequency offsets between the proposed and the pneumatic actuator at 40 Hz, 50 Hz, and 60 Hz.

The simulated magnetic flux density showed that the ROI of the MRE imaging was outside the 3-G contour (Figure 3), which was less than one part in 10000 compared with the 3-T B_0 field. Therefore, the interference of the fringe field produced by the actuator was at a paltry level.

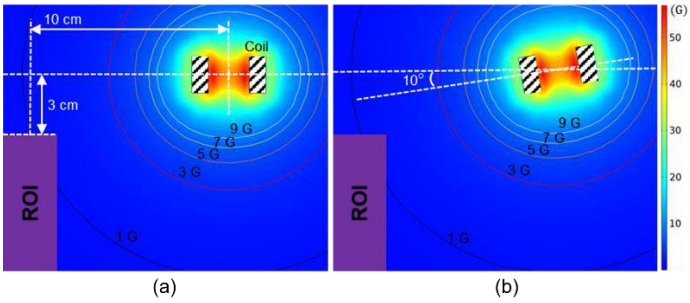

Figure 3: Contour plots of the magnetic flux density for the actuation coil at (a) the horizontal position or (b) the maximum tilt angle. Both cases showed the ROI was outside the 3-G line of the magnetic fringe field.

Analysis of the SNR values from 6 different slices from each set of TIW and T2W images showed no significant differences (Figure 4). This indicated that the proposed actuator did not interfere with the imaging.

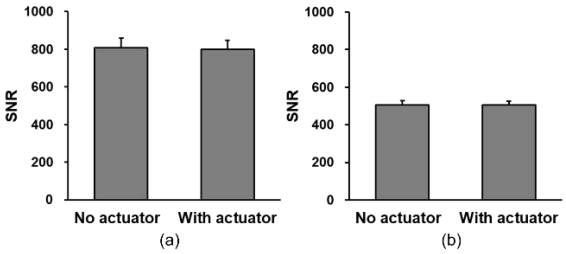

Figure 4: The bar charts showed the mean value and standard deviations of SNR evaluated from 6 different slices for the (a) T1W and (b) T2W images.

For the phantom imaging, we observed an increased stiffness with the frequencies (Figure 5). About 96.9% of the image pixels had $OSS_{SNR} \geqslant 3$ for all actuation frequencies. This indicated that the proposed actuator could generate stable shear waves for stiffness estimation.

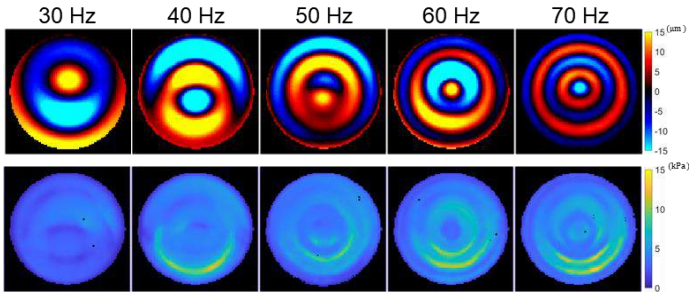

Figure 5: Wave images (top) and the corresponding stiffness maps (bottom) with pixels having OSS_{SNR} > 3 with five different frequencies.

DISCUSSION

In this study, an electromagnetic actuator was proposed for brain MRE. The spectra analysis demonstrated that the proposed actuator could produce waves with accurate frequencies. In addition, the actuator did not interfere with other imaging sequences. Phantom experiments verify the performance of the wave generation.

This study has many limitations. The GRE-based MRE sequence was used for the actuator tests. However, this multi-shot acquisition method may produce a long scanning time and bring potential vibration interference. Therefore, specifically designed and optimized MRE sequence is needed and will be developed in future studies.

INTRODUCTION: Disc degeneration is characterized by elevated levels of pro-inflammatory cytokines [1]. Inflammatory stimulation of intervertebral disc nucleus pulposus (NP) cells can lead to a catabolic breakdown of disc extracellular matrix (ECM), acting as a positive feedback of further loss of tissue integrity and inflammation [2]. We have previously shown that pro-inflammatory stimulation significantly alters NP cellular biomechanical properties and morphology [3]. While actomyosin contractility is well known to regulate cell morphology and cell stiffness, its direct role in mediating response of cells to inflammatory stimulation is unknown. In the current study, we investigate the role actomyosin contractility in mediating multiscale mechanobiology in an inflammatory microenvironment. We investigated the gain and loss of function of actomyosin contractility (i.e., effects of myosin-II inhibitor, Blebbistatin, which decreases contractility; CN03, a RhoA activator that increases contractility). We hypothesize inflammatory-induced changes to NP cell biomechanics are driven by a loss of actomyosin contractility. Therefore, increasing contractility can mitigate the degradative effects of inflammatory stimulation of the NP at the cellular and tissue levels.

METHODS: Cell Isolation: Cells were isolated from bovine NP tissue using standard enzymatic digestion and cultured in 3D culture in 1.2% alginate beads to promote round morphology. NP Explant Culture: NP explant tissue punches were isolated from bovine caudal IVDs and cultured in 24 well-plates in a swelling restricted culture system [4]. Treatment: Cells in alginate and NP explants were separately cultured in one of the following groups: (1) untreated, (2) 10ng/ml TNFα, (3) 10µg/ml Blebbistatin, (4) 1ug/ml CN03, or (5) 1ug/ml CN03 + 10ng/ml TNFα. Fluorescence Imaging: Cells were immunostained for pMLC as an indicator of actomyosin contractility, then released from alginate beads and analyzed using an Amnis ImageStream imaging flow cytometer. Cells in explants were stained for actin with Phalloidin and imaged using confocal microscopy. Cell circularity was determined from actin staining in explants. RNA Sequencing: Sequencing of RNA isolated from NP cells was performed on an Illumina NovaSeq 6000 (reference transcriptome: Bos Taurus, ARS-UCD1.2). DESeq2, was used to test for differentially expressed genes between groups. Osmotic properties: Step hyper-(333 to 466 mOsm/L NaCl) and hypo-(466 to 333mOsm/L NaCl) osmotic loads were applied to cells in a custom microfluidic chamber [3]. Volume response was observed using DIC microscopy and analyzed using multiphasic mixture theory [5] to compute hydraulic permeability (Lp) and cell radius. Atomic Force Microscopy (AFM): Force indentation curves were obtained from NP cells using an Asylum MFP-3D BIO AFM with spherical tip probes. Curves were fitted to a Hertzian model to determine cell elastic modulus. GAG Analysis: Explants were fixed, paraffin embedded, sectioned, and stained with alcian blue. Explants digests were assayed for GAG content using DMMB assay. Statistics: Data was analyzed by ANOVA with Fisher LSD post-hoc (Graphpad), $p<0.05$ significant.

RESULTS: TNFα stimulation significantly decreases pMLC staining and alters the expression of genes regulating actomyosin contractility and the cytoskeleton, as indicated by RNA sequencing analysis (Fig1). Decreasing actomyosin contractility with Blebbistatin significantly increases hydraulic permeability and cell size and decreases cell elastic modulus, similar to TNFα stimulation (Fig2). Conversely, increasing actomyosin contractility with CN03 mitigates the effects of TNFα on these same cell biomechanics (Fig2). We confirmed that TNFα increases gene expression of matrix degrading enzymes and decreases expression of ECM genes, and found that CN03 mitigates this catabolic gene expression (Fig3). We found that TNFα altered NP cell morphology in explants, significantly decreasing cell circularity (Fig4).

Increasing actomyosin contractility with CN03 mitigates catabolic effects of TNFα in explants, preventing TNFα-induced GAG loss. Moreover, decreasing actomyosin contractility with Blebbistatin mimicked the catabolic effects of TNFα on explant GAG loss (Fig5).

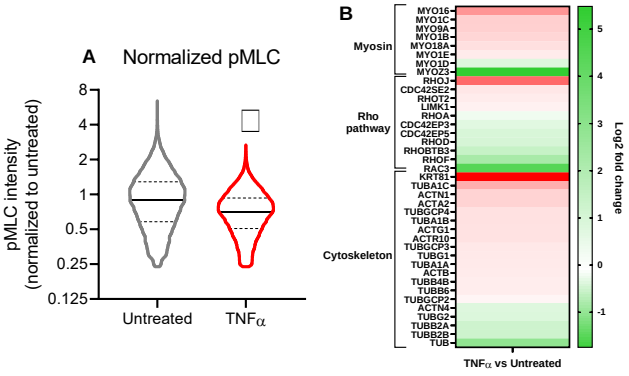

Figure 1: TNFα significantly decreases pMLC staining (A) and alters cytoskeleton gene expression (B). (*p<0.05 vs untreated).

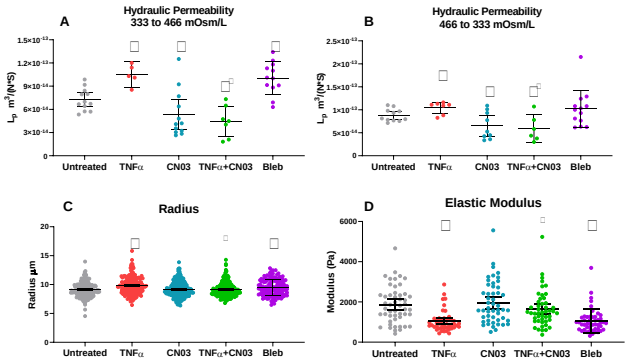

Figure 2: TNFα & Blebbistatin significantly increase cell hydraulic permeability (A,B), size (C), and decrease modulus (D)**.** CN03 mitigates effects of TNFα. (*p<0.05 vs untreated, §p<0.05 vs TNFα).

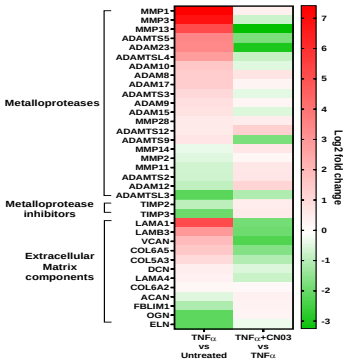

Figure 3: CN03 mitigates effect of TNFα on matrix degrading enzyme and ECM gene expression

DISCUSSION: TNFα stimulation was found to significantly disrupt NP cell mechanobiology, as indicated by altered cytoskeleton gene expression and decreased pMLC staining. Using gain and loss of function approaches, we have shown that actomyosin contractility mediates the effects of TNFα-stimulation on cell biomechanics and tissue level mechanobiology. At the cellular level, decreasing

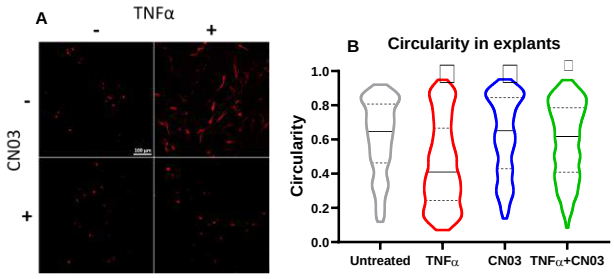

Figure 4: F-actin staining of NP cells in explants (A). Cell circularity quantification (B) . (*p<0.05 vs untreated, §p<0.05 vs TNFα).

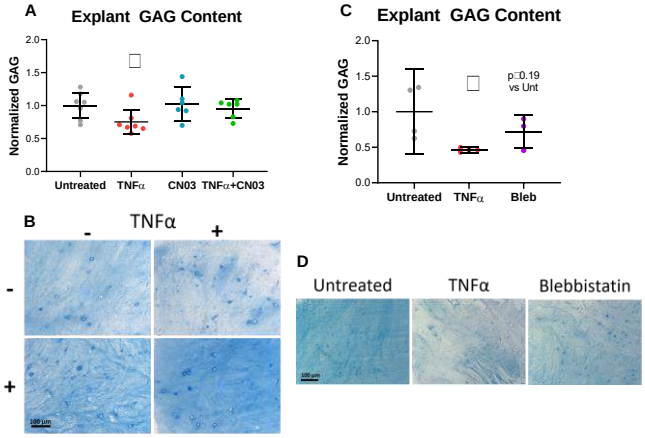

Figure 5: CN03 mitigates TNFα-induced GAG loss as determined by DMMB assay (A) or Alcian blue staining (B). Blebbistatin promotes GAG loss similar to TNFα (C, D). (*p<0.05 vs untreated).

actomyosin contractility mimicked the effects of TNFα on cell stiffness and permeability. At the tissue level, decreasing actomyosin contractility promoted NP GAG loss, similar to the effects of TNFα. We further found that increasing contractility mitigated the effects of TNFα on cell biomechanics and explant ECM, protecting against the deleterious effects of TNFα on NP cell phenotype, mitigating catabolic gene expression, NP cell polarization, and protected against TNFα-induced GAG loss. These findings suggest that cell contractility is critical in the maintenance of tissue integrity. Previously both inflammatory stimulation as well as injurious mechanical loading have independently been shown to lead to similar catabolic responses in disc cells [1,6]. Our findings suggest these responses may share common mechanisms, being mediated through cellular actomyosin contractility. Our results demonstrate that decreased actomyosin contractility mediates the response of NP cells to TNFα-stimulation at both the cellular and tissue levels and highlight actomyosin contractility as a possible point of intervention for the prevention of inflammatory induced degenerative effects in the disc.

INTRODUCTION

Improved biomaterials promise to reduce the morbidity and mortality associated with congenital heart disease. The common lack of homologous tissue for reconstructive surgery necessitates the use of cadaveric, xenograft, or synthetic materials.[1] These biomaterials have limited durability and particularly relevant to the pediatric population, they lack growth potential and are associated with complications.[2,3] Tissue-engineering offers an alternative to currently available biomaterials by stimulating the growth of autologous tissue for surgical use. Our group has pioneered the use of tissue-engineered vascular grafts (TEVG) in the modified extracardiac Fontan procedure for single ventricle palliation whereby the inferior vena cava is connected to the pulmonary arteries via a vascular graft. This scaffold is implanted directly, and over time, the scaffold degrades and the TEVG develops into a neovessel with the ability to grow and remodel.[4,5]

TEVGs provide several advantages over the traditional choice of material for the extracardiac Fontan procedure, poly(tetrafluoroethylene) (ePTFE). ePTFE grafts engender several known risk factors including stenosis, thrombosis, and calcification, with the additional disadvantage of lack of growth potential.[6-9] This lack of growth potential necessitates delayed insertion and oversizing to ensure long-term functionality. Delayed insertion subjects the patient to a period of progressively worsening cyanosis and hypoxia, whereas oversized grafts may affect the hemodynamic performance of the Fontan circuit until the child grows.[10-14]

Clinical application of our TEVG technology in Fontan patients has shown that these grafts can be successfully implanted without significant long-term risk of thrombosis or calcification.[4,5,12,15,16] The primary graft related complication has been stenosis, or narrowing, of the graft.[16] While the majority of patients with graft stenosis were asymptomatic and the stenosis was successfully treated with balloon angioplasty, stenosis represents a major hurdle to widespread clinical adoption of this otherwise promising technology. Understanding the natural history of TEVG remodeling within the Fontan circulation and how these changes impact hemodynamic performance is critical to the continued use of these grafts.

In this study, we provide insight into TEVG behavior *in vivo* through a detailed analysis of the U.S. clinical trial data. Using a closed-loop lumped-parameter network (CL-LPN), we show how patient-specific changes to conduit geometry and properties affect Fontan hemodynamic performance and compare TEVG, stenotic TEVG, and ePTFE performance.

METHODS

From MRI imaging data, patient-specific CFD models were created for four patients at 6 months and 3 years post-Fontan. The models were virtually modified to mimic varying degrees of stenosed geometry (stenosis defined as the percent decrease in cross-sectional area at the mid-TEVG). To compare against the current standard of care, ePTFE grafts with no growth potential, we investigated both the effects of changing the TEVG MRI compliance to match that of a ePTFE graft and virtually implanting a 16mm diameter ePTFE graft (Figure 1). These are labeled as "Rigid" and "ePTFE" respectively.

Using the flow and deformation measurements from PC-MRI data and estimated pressure outlet boundary conditions, the wall material property values were first tuned to match observed PC-MRI deformation. Then, open-loop boundary conditions were replaced with boundary conditions defined by an LPN based on work by Kung et al.[17,18] We adapted the LPN to model pediatric flows and responses to metabolic rate and further tuned the parameters to match patient-specific clinical values at each time point. In stenosis simulations, max

aortic pressure was matched to the TEVG reference geometry by scaling the total excess blood volume, as an approximation to the body's long-term response mechanism to decreased preload. Wall boundary conditions were defined via elastic moduli that were tuned to match the fractional area change observed *in vivo* over a cardiac cycle.

Patient-specific simulations were run at a youth metabolic equivalent (MET) of 1, 3, and 5 to simulate oxygen consumption states of rest, moderate exercise, and maximum exercise respectively. MET is the ratio of metabolic rate (described as VO_2) used during an activity to the basal metabolic rate (6.5 ml/kg/min in children).[19] MET 5 is a standard maximum metabolic rate found in non-TEVG Fontan children. Oxygenation metrics, systemic/venous metrics, and local hemodynamic metrics describing the *in silico* performance of each model were then calculated from the simulation data.

RESULTS

The oxygen extraction ratio (OER), mixed venous oxygen saturation (sVO2), systemic pressures, venous pressures, and cardiac index calculated from our simulations remained within normal Fontan ranges for stenosis up to 75% at MET 1. At MET 3 and MET 5, performance metrics were more sensitive to stenosis levels, but still showed physiological performance up to 75% stenosis. Energy efficiency also remained with normal ranges up to 75% stenosis. ePTFE performance was nearly identical to TEVG performance up to 25% stenosis, suggesting that even with mild narrowing TEVGs match the performance of the current standard of care (Figure 2).

To determine the risk of thrombosis and quantify the presence of blood recirculation inside the graft, we computed maximum residence time (RT), the maximum time a particle remains in the volume of interest on average, and the oscillatory shear index (OSI). Max RT and OSI were three times larger in ePTFE graft models than in TEVG reference geometries (Figure 2).

To validate our LPN simulations, we compared the velocities predicted by our simulations with the velocities measured via echocardiogram at time points between MRI scans. Each echocardiogram was paired with the simulation that closely matched its post-operative time point and estimated stenosis level. The resulting comparison to the original echocardiograms indicated good agreement between clinically-measured velocity and our simulations.

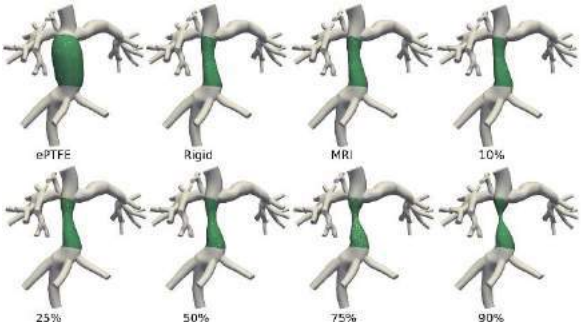

Figure 1. Example of stenosed TEVG and ePTFE models.

DISCUSSION

Our modeling-based evaluation demonstrates that Fontan physiology is robust to large changes in TEVG geometry, including the majority of the narrowing observed clinically in our patient cohort (typically less than 67%). Despite these significant anatomic changes, our models at these timepoints maintained relatively consistent hemodynamic performance metrics, remaining well within the expected physiological range for Fontan patients. The high degree of stenosis required to impact patient hemodynamic performance is in agreement with clinical observation; patients in our study were generally asymptomatic, and rarely reached the levels of stenosis predicted to significantly change performance. One patient in our study did develop stenosis approaching the critical level observed in our modeling. Patient 4 at 5 months post-operation developed stenosis measuring 72% compared to their 6 month MRI geometry or 95% stenosis compared to baseline at implantation. This patient reported symptoms of abdominal pain, in agreement with the computational threshold we identified.

Widening the conduit diameter to 16mm and applying a rigid material property to mimic ePTFE behavior had no effect on the global flow at MET 1 and had minimal impact on simulation results at MET 3 and MET 5. The most striking differences in the ePTFE graft were in OSI and RT. The 3-fold increase in max RT observed in the ePTFE graft models implies the presence of recirculation in the oversized graft that is not present in the integrated TEVG. The higher RT and OSI values also suggest increased thrombotic risk in ePTFE grafts. In particular, average residence times above two cardiac cycles in the coronary/systemic circulation have been linked to higher risks of thrombosis which regions in most of our ePTFE grafts exceed.[20]

In this study, we have confirmed several key advantages of the use of TEVGs as Fontan conduits, including growth potential and potentially reduced thromboembolic risk. We have also quantitatively shown that the primary graft related complication, graft stenosis, is well-tolerated up to most clinically observed levels. Future use of TEVGs in Fontan patients and other forms of congenital heart disease will further our understanding of how TEVGs can be used to replace traditional biomaterials and advance treatment of congenital heart disease as well as other cardiovascular conditions.

INTRODUCTION

Back and neck pain can be associated with excessive strain on the axons embedded in the facet capsular ligament (FCL) [1]. This tension due to this excessive strain is believed to depend on both the magnitude and the rate of strain applied to the tissue [2,3]. The emergence of experimental models involving axons embedded in collagen gels shows a relationship between macroscale tissue strains and nociceptive pain signaling [3–6], but raises the question of how collagen viscoelasticity could affect the rate-dependent response of the system.

We have developed various computational models to analyze load transmission between a collagen gel and an axon [7,8]. In these models, the axon is embedded in a discrete network of nonlinear elastic collagen fibers. In these studies, a purely elastic version examined the effect of heterogeneity and alignment on the axonal deformation but did not address the effect of viscoelasticity and strain rate. Therefore, this study modified a discrete fiber network model to explore how strain rate applied to a fiber network affects the micromechanical environment of an embedded neuron.

METHODS

To model the fibrous environment of an innervated tissue such as the FCL, a 3D discrete fiber network model [7,8] containing a cylindrical representation of an axon embedded in a fiber network was created (Figure 1) and then stretched.

The previous model's connector elements were changed to visco-elastic truss elements to account for rate-dependent behavior of the collagen fibers. Each fiber was modeled as a Prony viscoelastic material with four time constants (2s, 20s, 200s and 2000s), to cover the broad spectrum of collagen fiber relaxation time constants. Parameters were optimized so that stress relaxation results for a $40\times40\times50\mu m^3$ fiber network (without axon) matched the PK1-stress-vs.-time behavior of uniaxial collagen gel measured in a stress relaxation experiment [9].

A 1μm diameter, 30μm long cylindrical idealization of the axon [7] was embedded within the fiber network (Figure 1). The cylinder's bottom surface was placed on the lower *xy*-plane of the network, and its axis was centered within the network. The cylinder was modeled as an elastic matrix (E=43.3MPa) reinforced by longitudinal microtubules (with spring constant of 0.94N/m) and circumferential nonlinear fibers around the perimeter.

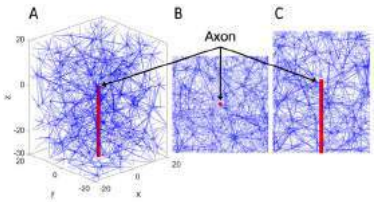

Figure 1: Image of network containing collagen fiber (blue) and axon (red). A) Isometric view. B) Top view. C) Side view.

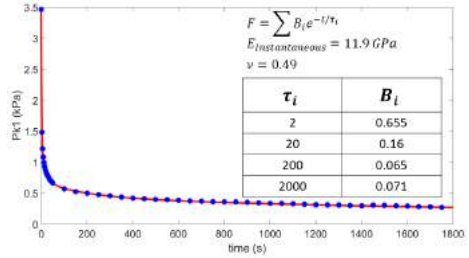
Next, a series of displacement-controlled stretches were simulated. The network was displaced to 10% macroscopic strain at rates of 0.01 to 500%/s. The top surface of the network (normal to cylinder axis) was displaced in the z direction while the opposite side was kept fixed in all 3 directions. The lower surface of the cylinder was fixed in all directions. To allow network contraction during stretch, fibers with one node attached to the side faces of the network were made to be two orders of magnitude less stiff than the rest of the network. These nodes were free to move in the z direction. The cylinder was fixed to the network at intersections of the cylinder and the network fibers. These intersections included an additional 5 focal adhesion fibers that were half as strong as each network fiber.

Simulations were performed in Abaqus CAE standard using the Visco analysis step. The average and the top 1% maximum principal strain on the axon elements were calculated.



τ_i	B_i
2	0.655
20	0.16
200	0.065
2000	0.071

Figure 2: Parameter optimization by fitting the simulation (red line) to the experiment (blue dots).

RESULTS

A regression of a neuron-free viscoelastic fiber network model behavior to collagen gel stress relaxation data [9], shown in Figure 2, was used to specify the model with four relaxation times from 2 to 2000s. These parameter values were used for all subsequent simulations.

A representative deformed network and the embedded neuron shows relatively homogeneous fiber deformation with a slight bend in the axon (Figure 3A).

Axonal strain maps show heterogeneous strain fields on all axons despite differences in the applied strain rate (Figures 3B). The maximum strain is most noticeable in the zoomed-in view indicated by the red boxes in Figures 3B.

The average max principal strain and the average of top 1 % max principal strain of the axon for different strain rates during their specific stretch periods indicate differences in the rate of increase in the average axon strain (Figure 3C) and top 1% of axon strain (Figure 3D). All strain rates at or above 7% appear to increase axon strain at the same rate.
The max principal strains for all networks rise to different values then relax to similar values after long time periods (Figure 3E, 3F). Increasing the strain rate by two orders of magnitude from 0.01% to 20%/s will increase the average strain by 5%. The top 1% of strains were much more affected by this change in strain rate. The top 1% of strains increased by 15%. All strain rates allow the average max principal strain to reach an average max principal strain of approximately 0.097 after 1800sec of loading. Similarly, all strain rates allow the top 1% of max principal strains to reach approximately 0.4 after 1800sec of loading. Strain rates applied to a network will affect the observed axon strain fields.

DISCUSSION

This study used a computational method to show the effect of strain rate on the axon strain field during gel extensions. Slower strain rates are associated with smaller instantaneous max principal strains in the axon, whereas higher rates lead to higher instantaneous axon strain. These instantaneous axon strains may be important for understanding when and how long an axon will express more signaling molecules. Additionally, the instantaneous strains/stresses that an axon experiences may cause microtubule breakage or other axon damage.

There appears to be an upper threshold for the strain rate at which strain rates do not continue increasing the peak axon strain. In the context of the Prony series model, this case represents most or all of the elastic components of the fibers contributing to load transfer. There should also be a low-strain-rate plateau, corresponding to only the parallel elastic component contributing. Even at 0.01%/s the peak is still higher than the equilibrium so the rate dependency is having an effect.

As seen in Figure 3E and F, the average top 1% max principal strain is approximately 4.5 times the average max principal strain (averaged for different strain rates). This confirms the observation in Figure 3B-F that there is a local hot spot with significantly higher strain.

Incorporating viscoelasticity into a discrete fiber network model provides evidence to understand how changes in network viscoelasticity and applied network strain rate could affect the axon strain field and expression of nociceptive pain signaling molecules.

SLOW STRETCH MIRRIORING ACL GROWTH RATES DRIVES ZONAL LIGAMENT-TO-BONE ENTHESIS MATURATION

M. Ethan Brown (1), Jennifer L. Puetzer (1,2)

INTRODUCTION

The anterior cruciate ligament (ACL) is connected to bone via a structurally complex tissue known as the enthesis. Entheses are critical for mechanical function, acting to translate load from elastic ligament to stiff bone via a compliant fibrocartilage region with gradients in collagen organization and biochemical composition. Currently, these gradients are not restored in healing, repair, or engineered replacements, yielding limited repair options and high failure rates [1]. Previously, we developed a novel culture system utilizing compressive boundaries that guide ligament fibroblasts in high-density collagen to develop native-sized collagen fibers by 6 weeks [2]. Further, we demonstrated that the tensile-compressive environment at the clamp interface of this system drives early postnatal enthesis-like development by 2 weeks [3]. This system holds great promise for producing functional engineered bone-ligament-bone replacements but is currently limited by a plateau in properties by 6 weeks and long culture times. Developmental mechanical cues, such as slow elongation from growth, are necessary for enthesis maturation *in vivo*, and if not present the enthesis fails to mature [1,4]. The objective of this study was to leverage these developmental cues to investigate whether continuous slow stretch, mimicking ACL growth rate [5], could significantly improve enthesis maturation in our system. We hypothesize that the addition of slow stretch to our tensile-compressive culture system will significantly improve zonal organization, zonal composition, and mechanical properties compared to statically clamped controls, ultimately producing entheses similar to late postnatal tissue.

METHODS

Engineered constructs were made using rat tail type I collagen, extracted and reconstituted as previously described [2], and bovine ACL fibroblasts, isolated from immature bovine ACLs. Cells and collagen were mixed together prior to gelation, to yield sheet gels at 20 mg/ml collagen and 5x10^6 cells/ml. Rectangles (8 x 30 mm) were cut from the sheet gels and divided between experimental groups. Control samples were cultured statically clamped in our culture device for up to 24 days. Bioreactor samples were cultured for 14 days statically clamped in our culture device to induce early postnatal-like enthesis development [3] and then transferred to a modified CellScale tensile bioreactor and stretched for 10 days at 0.1 mm/day [5]. Constructs were cut into half samples (H.S.) or sectioned into middle (M), transition (T), and clamped (C) regions for analysis of zonal organization, composition, and mechanical properties (Fig 1A). Confocal reflectance was performed to analyze zonal collagen fiber organization. Sectioned regions were characterized for zonal composition of DNA, glycosaminoglycan (GAG), collagen content, and alkaline phosphatase (ALP) activity via PicoGreen, DMMB dye, hydroxyproline (hypro), and paranitrophenol assays, respectively, and normalized to dry weight (DW) or DNA. Mechanical testing of the middle to clamp transition was performed via tensile tests at 0.75% strain rate. All data are expressed as mean±SD. Statistical analysis was performed by 1- or 2-way ANOVA with Tukey's post-hoc ($p<0.05$ significant, $p<0.1$ trending).

RESULTS

Control and bioreactor constructs contracted similarly over 24 days, with bioreactor constructs developing a noticeably smoother transition from middle to clamp (Fig. 1A). Confocal imaging revealed samples begin as an unorganized matrix, and by 14 days in culture, constructs develop early postnatal-like zonal collagen organization with aligned parallel fibers in the mid-section, perpendicular fibers in the transition, and unorganized collagen under the clamp (data not shown). By 24 days, control constructs maintain this organization in the mid and transition section and developed a more porous organization under the clamp. Slow stretch further developed this zonal organization, with more distinct fibers in the mid-aligned section, a shift from perpendicular fibers to isotropic organization in the transition, and a porous clamped section, resembling immature ACL tissue (Fig. 1B).

By 24 days, DNA content significantly increased in the middle zone for control constructs and in the middle and transition zones for bioreactor constructs while it remained constant in clamped zones for both groups (Fig 2A). Collagen content remained steady at ~60% native tissue [2], with no significant differences in any zones for both groups (Fig 2B). GAG normalized to DNA significantly increased under the

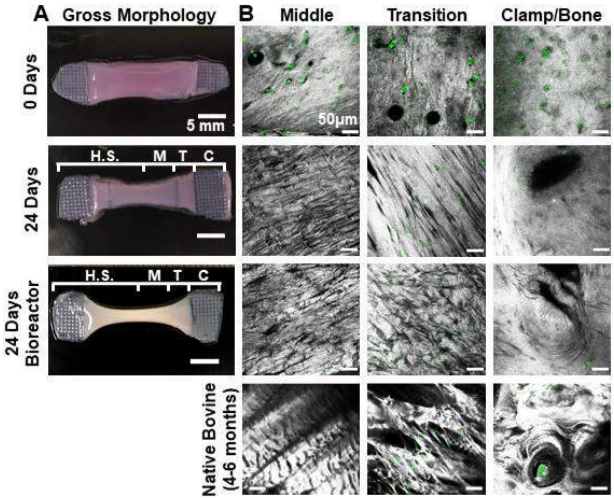

Figure 1: A) Gross morphology of constructs with sections depicted. B) Representative confocal reflectance of collagen organization. Collagen = grey, cells = green.

compressive clamp for both control and bioreactor constructs by 24 days compared to 0 day, middle, and transition zones (Fig. 2C). ALP activity remained relatively constant in control constructs with no differences between zones, whereas slow stretch resulted in zonal ALP activity, with ALP activity significantly increased under the clamp compared to the middle zone at 24 days (Fig 2D).

Continuous slow stretch significantly increased the tensile modulus across the enthesis to ~5 MPa by 24 days, while the control group remained constant at ~1 MPa throughout culture (Fig. 3A). Additionally, slow stretch significantly increased ultimate tensile strength (UTS) and the transition stress 3-fold over control constructs to 1.2 MPa and 120 kPa, respectively (Fig 3B), and led to a trending increase in toe modulus over control samples at 24 days. Slow stretch had no significant effect on the strain properties for both strain at failure and transition strain (Fig 3C).

DISCUSSION

Ten days of continuous slow stretch resulted in enhanced zonal collagen organization, zonal composition, and significantly increased mechanical properties. Both control and slow stretch constructs had significantly elevated GAG accumulation under the clamp, indicating

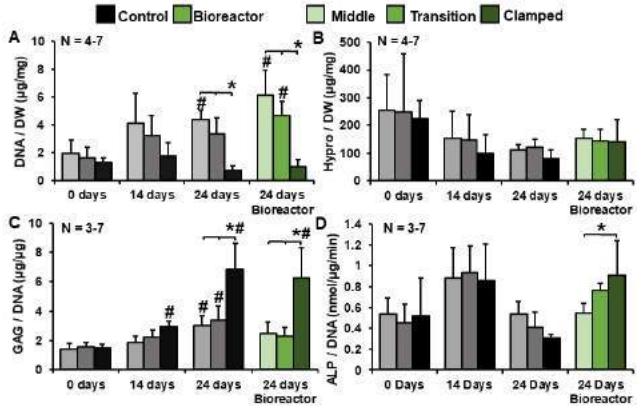

Figure 2: Zonal composition of A) DNA/DW; B) Collagen content (Hypro) /DW; C) GAG/DNA; and D) ALP/DNA for all timepoints. Significance compared to #0 week and *bracket.

that the compressive environment under the clamp drives cells to shift to a more chondrocyte-like phenotype similar to that observed in early postnatal enthesis fibrocartilage [3,6]. This increased GAG content, combined with the increased ALP activity stimulated by slow stretch, signifies further developmental maturation, since ALP is a known marker in formation of mineralized fibrocartilage and bone [7].

Similarly, slow stretch drove significant increases in tensile properties across the enthesis, including increased elastic and toe modulus, UTS, and transition stress. The increased elastic modulus surpassed reported bovine neonatal ACL entheses moduli [1], indicating maturation beyond the neonatal stage. Since the major matrix components, mainly collagen and GAG, did not change with slow stretch, this increase in modulus is most likely attributed to the increased collagen organization in loaded constructs. This maturation in organization closely resembles postnatal development, where collagen fibers in the enthesis shift from being perpendicular to the ligament to more parallel with the ligament, while still maintaining some degree of disorder in mature tissues [8]. This diffuse fiber organization of the enthesis is critical to reducing stress concentrations and allowing for functional transfer of load [9]. Further, with just 10 days of slow stretch, mechanical properties and organization surpassed what was obtained previously with 6 weeks of static culture in our clamping device [3], demonstrating the importance of mechanical stimulation in enthesis formation. On-going work is evaluating collagen I, II, and X distribution and hierarchical organization. This study provides insight into the role that slow stretch elongation from postnatal growth plays in ligament enthesis development and creates an *in vitro* model for further exploration of the mechanical cues that drive enthesis maturation. A better understanding of the mechanical cues that drive enthesis maturation will not only help to develop functional replacements but will shed light on ways to stimulate regeneration after injury.

INTRODUCTION

The menisci and cruciate ligaments of the knee joint are key fibrous tissues whose specialized extracellular matrices (ECMs) allow for resistance to high mechanical forces during load bearing. In particular, the menisci are semi-lunar wedge-shaped structures that lie between the femur and tibia and distribute forces across the joint. The menisci have a regionally distinct ECM composition that functions to withstand both tensile and compressive loads, with the inner region being proteoglycan (PG) rich and the outer region containing circumferentially aligned collagen fibers. How these tissues establish their unique shape and composite matrix structure, however, is not well understood. It is known that menisci, along with most fibrous knee joint tissues, are formed from interzone cells specified during hindlimb embryonic development [1]. Interestingly, forces generated by limb motion influence meniscus assembly in the chick embryo, suggesting that biophysical cues may play instructive roles in fibrous tissue formation [2]. To further the understanding of mechanobiologic aspects of fibrous tissue formation, this study evaluates the spatiotemporal cellular and ECM patterning and growth of the embryonic meniscus and demonstrates that loss of muscle contraction during this developmental window significantly impacts these processes.

METHODS

Mouse models: Wildtype CD1 mouse embryos were harvested at E13.5, E15.5, E17.5, and P0. Muscle dysgenesis (*mdg)* mutants were harvested alongside littermate wild-type (WT) controls at E15.5 and E17.5. Sample preparation: Knee joints (n=3/timepoint) were harvested, fixed, cryo-embedded, and serially sectioned in the sagittal, coronal and/or transverse planes. Staining: Sections were stained using picrosirius red (collagen), alcian blue (PGs), Lamin A/C (ab133256) antibody, AF546 Phalloidin (actin), and/or DAPI (nuclei). Imaging: Confocal fluorescent microscopy was performed. Multiphoton second harmonic generation (SHG) imaging of transverse sections or explanted whole menisci was performed to visualize collagen fiber organization. Gene expression: Coronal sections at P0 (n=4 animals) were acquired and inner and outer regions were harvested using laser capture microdissection. Extracted RNA was analyzed using a Fluidigm 96.96 Gene Expression Assay for expression of 93 genes [3]. Hierarchical clustering was done with the ClustVis online tool [4]. Quantification: Z-stacks for individual nuclei were acquired (2 animals/genotype/timepoint) and nuclear aspect ratios (NARs) were calculated using Fiji (n=50 nuclei/group). Measurements were pooled per timepoint and compared via a 1-way ANOVA with Bonferroni post-hoc for Fig. 1b and a Student's T-Test for Fig. 3e ($p<0.05$ cutoff). Cell numbers (nuclei) were also counted in the meniscus body region from coronal sections (n=2-3 animals/genotype/timepoint reported).

RESULTS

Between interzone (IZ) specification (E13.5) and joint cavitation (E15.5), the actin cytoarchitecture of IZ and adjacent neocartilage (NC) cells diverged—with E15.5 IZ cells (meniscus and cruciate ligament precursors) obtaining a highly aligned, fibrillar actin cytoskeleton and NC cells adopting a rounded, cortical actin structure (**Fig. 1a**). Within this timeframe, IZ cells also developed more elongated nuclei (higher NAR) compared to NC cells (**Fig. 1b**). IZ nuclear shape change coincided with a dramatic nuclear envelope enrichment of Lamin A/C in fibrous tissue precursors compared to the surrounding NC cells (**Fig. 1c**). These observed differences in cytoarchitecture, nuclear shape, and Lamin A/C abundance persisted in E17.5 formed fibrous tissues (**Fig 1** tendon/ligament data not shown).

While IZ cells were fully patterned by E15.5, no fibrillar collagen could be detected in fibrous tissue condensates by SHG (not shown). By E17.5, however, aligned collagen fibrils percolated through the meniscus cell template (**Fig. 2a**), as well as the patellar tendon and cruciates (not shown). In the meniscus, robust fibrillar collagen matrix was observed at P0 (**Fig. 2a**) but was localized to the outer region (**Fig. 2b-left**). Conversely, the inner zone of the tissue was enriched for proteoglycans (**Fig. 2b-right**), suggesting that regional distinctions in the matrix structure and composition were present by birth. Indeed, this differential matrix accumulation was mirrored by phenotypic divergence of inner and outer cell populations, where hierarchical clustering of gene signatures of P0 cells [3] segregated the profiles based

on tissue region (red line in **Fig. 2c**).

We further analyzed meniscus development in embryos with abrogated hindlimb motion as a result of non-contractile skeletal muscle (*mdg*). Strikingly, anterior horn regions of both menisci—which anchor the tissues to the tibial plateau—failed to condense in *mdg* mutants and were completely missing by E17.5 (**Fig. 3a**). The body regions of the meniscal wedges also had significantly fewer cells (**Fig 3b**), while the posterior horns and their tibial attachments were present but greatly diminished (not shown). Interestingly, cells were correctly positioned at the sites of the patellar tendon (PT) and ACL in E15.5 *mdg* joints, with linear assembly of cells with fibrillar actin structure similar to WT (**Fig. 3c, d-top panel**). However, *mdg* PT and ACL contained cells with hyper-elongated nuclei, (**Fig. 3e**), and by E17.5, both were reduced in size in mutant mice (**Fig. 3d-bottom panel**). Unexpectedly, an ectopic fibrous tissue (**Fig. 3c-arrowhead**) also formed anterior to the cruciates within the *mdg* joint—possibly as a result of abnormal condensation.

DISCUSSION

In all, this work outlines biophysical aspects of the embryonic meniscus microenvironment that may mechano-regulate tissue development. During tissue patterning (E13.5-E15.5), IZ cells adopted an elongated nuclear morphology and fibrillar actin cytoarchitecture, which may indicate increased contractility of fibrous tissue precursors as condensation occurs (**Fig1 a, b**). The nuclear deformation (possibly due to cell tensioning) corresponded with enrichment of Lamin A/C in the nuclear envelope (**Fig. 1c**), consistent with reports of mechano-adaptative nuclear stiffening [5]. Indeed, the severe defects observed in in E15.5 meniscus condensation and cell patterning in muscle mutants indicate that these processes are sensitive to extrinsic mechanical stimuli (**Fig. 3a, b**). Importantly, the fact that anterior regions of the tissue completely failed to form, while posterior portions partially formed, indicates that biophysical and/or molecular factors may influence meniscus assembly in a region dependent manner.

Later stages of embryonic meniscus growth (E15.5-P0) were characterized by a replacement of the E15.5 cellular template with aligned collagen matrix (**Fig. 2a**). In fact, regional variation in matrix composition was apparent by P0 (**Fig. 2b**), suggesting differences in the synthetic activity of inner and outer resident cells arise during embryonic growth, consistent with the distinct gene expression signatures in cells of the two regions at P0 (**Fig. 2c**). Whether these differences are due to differential cell origin or a divergent response to evolving microenvironmental cues remains unclear.

Finally, while mechanobiologic aspects of cell patterning and matrix deposition were similar for menisci and cruciate ligaments and PT (not shown), the latter tissues were able to pattern without muscle contraction, unlike the menisci (**Fig. 3c-e**). Interestingly E15.5, resident cells of the *mdg* PT had very elongated nuclei, which may be reflective of a hyper-contractile cell state. Heightened cell-generated forces, in turn, may have caused the nascent tissues to tear themselves apart, resulting in the reduced tissue size (**Fig. 3d**) and loss of organized fibrillar matrix (not shown) observed at E17.5. Taken together, this study indicates the critical role of extrinsic forces and the local cell mechanical microenvironment in the morphogenesis of dense fibrous tissues of the joint, which may inform future repair strategies.

INTRODUCTION

Pancreatic cancer is predicted to be the second leading cause of US cancer deaths by 2030[1]. Current diagnostics and treatment methods are not effective enough to improve the five year mean survival rate >10%[1]. To address this need, our group proposed to apply plasmonic photothermal therapy (PPTT), in which gold nanorods (GNRs) and laser light are used to induce localized thermal ablation in tissue[2]. Delivery of GNRs will be carried out using a fiber optic microneedle device (FMD), which provides enhanced infusion via photothermal heating[3]. The treatment will be delivered endoscopically, and the GNR-infused tumor will be visualized using 3D endoscopic ultrasound. This approach has advantages over other intratumoral therapies as GNRs can be tuned to absorb more light under near infrared (NIR) illumination (high physiological transmissivity), and bioconjugation with tumor tissue can be enhanced by surface functionalization for minimal thermal effect on surrounding healthy tissue[2]. Prior research by this group demonstrated that local photothermal heating by 1064 nm laser energy (higher absorbance by physiological tissue) enhances the volumetric dispersal of macromolecules in rodent cerebral tissue[4]. Similar effects might be evident in pancreas tissue, but this concept is still under investigation. To date, our team has characterized the FMD platform, synthesized GNRs with an absorption peak at 808 nm, developed a Multiphysics computational model to study the optical properties of GNRs, and the subsequent plasmonic heating due to light particle interaction[3, 5]. Tissue specific thermal and optical properties are required to develop the computational model for light-GNR-tissue interaction. Literature review revealed a substantial knowledge gap in the thermal and optical properties of healthy pancreas tissue that prompted many researchers to assume porcine liver properties similar to pancreas tissue[6-8]. We hypothesize that the thermal and optical properties of porcine pancreas tissue differ significantly from porcine liver tissue. Hence, the aim of this research is to investigate *ex vivo* porcine pancreas tissue to evaluate thermal conductivity and optical transmittance, reflectance, and attenuation at both 808 nm and 1064 nm wavelengths in comparison to publish porcine liver data.

METHODS

Fresh pancreas tissue samples were collected from a USDA approved abattoir. Multiple samples were harvested from different size and weight pigs (adult male) and transported to the research facility for immediate use. The method used in this study was modified from Valvano *et al.*[8]. Briefly, a hot plate technique leveraging basic concepts of heat conduction (one-dimensional) and convection was applied. The hot plate temperature was set at 40°C. Two K-type thermocouples were calibrated and maintained against a cold junction prior to the experiment. An approximately (3x3x1) cm^3 porcine pancreas tissue sample was placed on the hot plate while keeping a thermocouple in between the sample and the hot plate (Figure 1A). Another thermocouple was placed on top of the sample. A 3D printed border (high temperature resin, low thermal conductivity at 0.15 $Wm^{-1}K^{-1}$) was used to encompass the periphery of the tissue sample to limit the convection and radiation effects to the outside environment. The following equation was used to measure the thermal conductivity (K) while assuming that at steady state the amount of heat conducted through the thickness of the tissue (1D) is equivalent to the amount of convection at the top surface[9]:

$$K = h * x * \frac{(T_{top} - T_{room})}{(T_{bottom} - T_{top})} \quad (1)$$

Here, h is the convection heat transfer coefficient, x is the tissue thickness (1 cm), and T is the temperature (at top/bottom of the tissue and room). To validate the measurement of h, a control experiment was

conducted using a similar setup with a silicone polymer (Sylgard® 184 elastomer) with known thermal conductivity (0.27 $Wm^{-1}K^{-1}$). Results from this test indicated h was 15 $Wm^{-2}K^{-1}$ at 22°C room temperature. This experiment was replicated with 17 different pancreas tissue samples (n=17).

Tissue optical properties were measured by using two laser sources (808 nm and 1064 nm CW collimated beam) and an integrating sphere for detecting optical power (Figure 1B). Thin sliced tissue samples (thickness 1-8 mm) were placed in between two glass slides. A 3D printed fixture was employed to maintain a consistent gap between the glass slides and to prevent excess force on the tissue sample. The incident laser was aligned vertically with the integrating sphere for the transmittance measurement. Samples were placed on top of the integrating sphere and the output laser power was measured over a range of input powers (0-500 mW). A negative control experiment was first conducted by conducting the experiment with glass slides only (sans tissue sample). The distance between the laser source and the tissue samples (12 mm), as well as the laser intensity (5 mW/mm^2), were maintained consistently for both lasers. The experiment was replicated 18 times for each tissue thickness.

Light reflectance measurement was conducted with similar setup except the integrating sphere was placed in between the laser source and the tissue sample so that the reflected beam from the tissue would be captured by the sphere. First the setup was calibrated against a reflectance standard and the test was repeated 5 times for each sample thickness (thickness 2-4 mm).

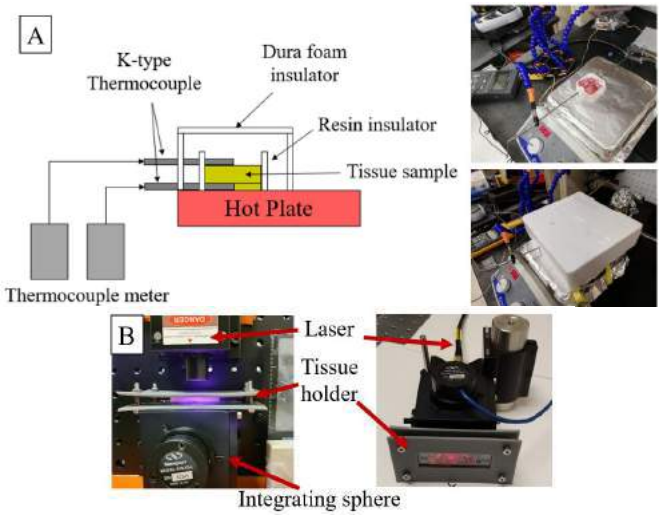

Figure 1: Experimental setup for (A) thermal conductivity measurement, (B) Transmittance and reflectance measurement

RESULTS

Figure 2A exhibits the results of thermal conductivity measurement. Applying Chauvenet's criterion, 3 outliers were eliminated which resulted in an average thermal conductivity of 0.454±0.08 $Wm^{-1}K^{-1}$. Figure 2B shows the exponential decay of light transmittance with respect to the tissue thickness. Applying curve fitting tool, two equations were obtained for both 1064 nm and 808 nm lasers. If the attenuation coefficient is independent of tissue thickness (mean free path of photon propagation inside tissue is constant), then Beer-lambert's can be compared with these equations. Attenuation coefficients (μ) for 1064 nm and 808 nm wavelength were measured as 0.073 mm^{-1} and 0.498 mm^{-1} respectively. Light reflectance measurements were corrected by deducting the reflectance of glass slide and resulted in an average of 0.23±0.05 for 2-4 mm thick tissue samples.

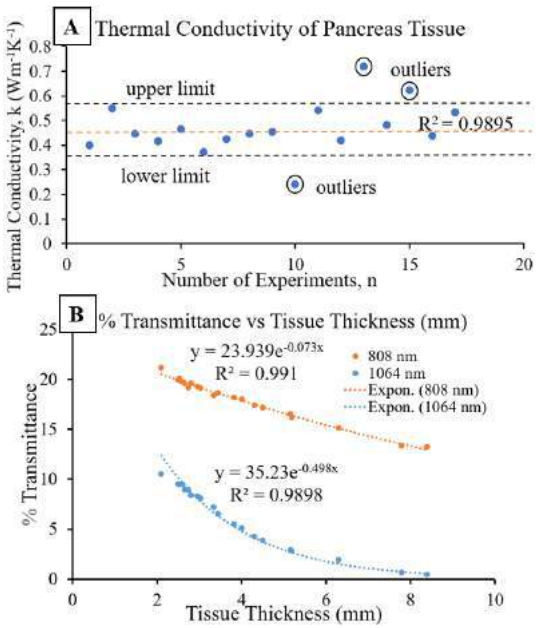

Figure 2: (A) Thermal conductivity, (B) Light transmittance of porcine pancreas tissue

DISCUSSION

The measured thermal conductivity of porcine pancreas tissue was lower than the porcine liver tissue (0.542 $Wm^{-1}K^{-1}$)[7, 8]. The following assumptions were applied that may affect results: only 1D heat conduction was considered, lateral heat convection was omitted due to the use of a boundary insulator, and slight variations in tissue thickness were not considered, among others implicit with the models employed. Light transmission and reflection tests were affected by the variation of physiological properties of the frozen tissue samples. Light transmittance for 808 nm wavelength was found higher than the 1064 nm and thinner tissue samples showed more exponential rise of light transmittance for both wavelengths. This was expected from literature values[2, 10]. Light reflectance measurement could be fine-tuned by using fresh tissue samples with varieties of thickness. In summary, the study hypothesis was verified as both the thermal and optical properties observed in this study were significantly different from the porcine liver tissue as reported in the literature[7, 11]. This is a critical finding with impactful implications for future computational studies and surgical planning around pancreas tissue. Next steps include replicating this study in human tissue, both healthy and malignant.

THE STRUCTURE-FUNCTION RELATIONSHIPS OF THE HUMAN VERTEBRAL ENDPLATE

Yuanqiao Wu (1), Elise F. Morgan (1,2,3)

INTRODUCTION

The vertebral endplate (VEP), a thin, porous layer of bone tissue between the vertebral centrum and intervertebral disc, has gained increasing attention because of its high relevance in the development of vertebral fractures [1] and other age-related problems, such as disc degeneration [2]. The VEP plays a crucial role in maintaining the structural and mechanical integrity of vertebral body [3,4] and undergoes age-related changes in structure [5] that are not well correlated with those in the rest of the vertebra [6]. VEP mechanical behavior also influences the load distribution within the disc. Study of its structure-function relationships is therefore necessary to understand the development, treatment, and prevention of spinal conditions.

Scant data exist on the mechanical behavior of the VEP. Indentation tests at the microscale suggest that the elastic modulus of the VEP tissue is similar to that of trabecular tissue [7]. Larger-scale (~2-3mm) indentation tests have indicated associations between strength and density [8,9]. Although useful, these studies have not addressed the mechanical behavior of the VEP for the larger length scales and loading conditions that are also relevant to vertebral fracture. Moreover, although vertebral fractures more commonly occur in the superior endplate region [10], whether this arises from differences in mechanical properties of the superior vs. inferior VEP is unknown. Thus, the overall goal of this study is to quantify the mechanical behavior of the VEP in flexion and its association with density and mineral content.

METHODS

Rectangular specimens (n=80; ~30mm×12mm×1.5mm) of VEP were machined from the lumbar central endplates (L1-L4) of fresh-frozen spines (24 males, 15 females; mean ± std age: 77.72 ± 6.50 yrs). Care was taken to remove the cartilage endplate. After using micro-computed tomography (μCT) (μCT40, Scanco Medical; 16μm/voxel, 70kV, 114μA; threshold=510 mg HA/ccm) to quantify bone volume fraction (BV/TV), apparent density (ρ_{app}), and tissue mineral density (TMD), each specimen underwent a four-point bend test (outer span=16 mm; Instron 5565; Canton, MA). Linear elastic beam theory was used to calculate the apparent modulus (E) and lower apparent yield stress ($\sigma_{y,l}$). The latter was measured at the initial yield point. The elasto-plastic beam theory was used to calculate the upper apparent yield stress ($\sigma_{y,u}$), which corresponded to the "fully plastic" point [11]):

$$E = \frac{L^2 \times k}{12 \times I} \quad (1)$$

$$\sigma_{y,l} = \frac{M_l \times h}{2 \times I} \quad (2)$$

$$\sigma_{y,u} = \frac{4 \times M_u}{b \times h^2} \quad (3)$$

In equations (1)-(3), L, b, h and I are the length, width, thickness and moment of inertia of the outer span, k is the maximum slope of the moment-displacement curve, M_l and M_u are the moment at initial yield and ultimate point, respectively. The tissue-level yield stresses corresponding to these upper and lower points were calculated in a similar manner but by using the binarized μCT images, rather than the bulk dimensions of the specimen, to calculate the section modulus [12]. Ultimate strain (ε_u, strain at M_u) and fracture strain (ε_f, strain at which there was both an audible cracking noise and a sharp drop in moment) were calculated from a video recording of each test. After mechanical testing, specimens underwent a sequence of washing, defatting, weighing, drying, and ashing (650 ºC for 16 hours) steps to measure tissue density (ρ_{tissue}), ash fraction (p), and ash density (ρ_{ash}).

Following log transformation where appropriate, linear regression (JMP, SAS Institute) was used to examine the dependence of the

mechanical properties on density and mineral content, and also on age. Multiple regression was used to test for dependence of modulus and strength on both BV/TV and ash fraction [13]. Pearson correlation analysis was used to examine associations between mechanical properties. These statistical analyses were performed separately for specimens from superior (S) vs. inferior (I) VEPs (defined relative to the vertebral body), to avoid having the presence of multiple VEPs from each donor violate the assumption of independence in the regression and correlation analyses. Properties were also compared between superior and inferior VEPs using paired *t*-tests.

RESULTS

Many of the elastic and failure properties were dependent on BV/TV and ρ_{app}. The apparent modulus (S: r^2=0.52, p<0.001. I: r^2=0.51, p<0.001) and both lower (S: r^2=0.43, p<0.001. I: r^2=0.49, p<0.001) and upper (S: r^2=0.44, p<0.001. I: r^2=0.49, p<0.001) yield stresses increased with increasing ρ_{app} (Figure 1). Similar results were found for the dependence of these properties on BV/TV (r^2>0.41, p<0.001). In contrast, none of these three mechanical properties, nor the tissue yield stress, depended on TMD, tissue density, or ash density (r^2<0.09, p>0.16). Adding ash fraction to the regression of apparent modulus and strength against BV/TV moderately improved the fit for the upper yield stress of inferior VEPs (r^2 increased to 0.63, p=0.02) but not for modulus or lower yield stress (p>0.09). The ultimate and fracture strains of inferior VEPs decreased with increasing BV/TV (r^2>0.29, p<0.05) and ρ_{app} (r^2>0.31, p<0.05), while no such dependence was observed for superior VEPs (r^2<0.28, p>0.05).

Correlations were observed between the apparent modulus and many of the failure properties. Apparent modulus was positively correlated with both lower (S: r=0.93, p<0.01. I: r=0.97, p<0.01) and upper (S: r=0.93, p<0.01. I: r=0.98, p<0.01) yield stresses (Figure 2A). In contrast, apparent modulus was negatively correlated with fracture strain for the inferior VEPs (r=-0.67, p=0.02) (Figure 2B).

Superior and inferior VEPs differed from each other in structure but not mechanical properties. When compared across a disc, *e.g.*, inferior L3 vs. superior L4, the inferior VEPs had higher ρ_{app} (p=0.02) and BV/TV (p=0.01). However, when compared within a vertebra, *e.g.*, inferior L3 vs. superior L3, no differences were found (p>0.09).

DISCUSSION

In light of the central role of the VEP in spinal conditions such as vertebral fracture, the goal of this study was to quantify the mechanical behavior of the VEP and its association with density and mineral content. BV/TV and ρ_{app} were each found to be good predictors of the apparent-level elastic and failure behavior of the VEP. With increasing BV/TV and ρ_{app}, VEP specimens were stiffer, stronger, and less ductile. Notably, these structure-function relationships did not extend down to the tissue-level: the tissue yield stress did not depend on TMD, tissue density or ash density, and these three density measures also were not predictive of the apparent modulus or strength.

These results suggest new possibilities for non-invasive assessment of vertebral fracture. Non-invasive estimates of bone stiffness and strength from density measurements is well established, but thus far this approach has not been applied in a data-driven manner for the vertebral endplate. Prior work has shown that the density of the endplate region is poorly correlated with the average density of the vertebral body, particularly in women [6]. Our data suggest that measurement of VEP density can be useful for a more accurate estimate of the mechanical behavior of this biomechanically critical structure and, perhaps by extension, the mechanisms of vertebral fracture.

Our findings also raise new questions. First, although clinical data show that vertebral fractures more frequently affect the superior region of the vertebra [10], we found no difference in mechanical behavior between superior and inferior VEPs. It is possible that a larger sample size is needed to discern differences that may exist or that other factors, such as asymmetry in the shape of the vertebral body, disc loading, or properties of the underlying trabecular bone, contribute to the asymmetry in fracture location. Second, comparison of the VEP data to those for trabecular bone from the vertebral centrum (Figure 2A) suggest that these two tissues, although anatomically adjacent, are mechanically distinct. One reason for the differences seen in Figure 2A may be loading mode, as flexural moduli tend to be lower than compressive and tensile moduli. However, our values of tissue density (mean±std=1.51±0.11g/ccm) and ash fraction (0.60±0.09) in the VEP are lower than those reported in vertebral trabecular bone (1.79±0.04 g/ccm and 0.61±0.02, respectively), and unlike prior reports of correlations between ash fraction and bone stiffness and strength [15], we found no such association for the VEP. Hence, the findings of this study suggest the intriguing possibility that the composition and mechanical behavior of the VEP are different from the rest of the vertebra. Further study of this tissue can lead to better understanding of spine health.

INTRODUCTION

Cryoballoon ablation (CBA) is becoming a promising alternative to radiofrequency (RF) ablation to isolate the pulmonary vein (PV) as a treatment of atrial fibrillation (AF). In CBA, the targeted PV is occluded by inflation of a balloon catheter, and a refrigerant is then sprayed into the balloon to locally freeze the cardiac tissue to create a lesion. Compared to RF ablation, CBA can significantly reduce the treatment time. The effectiveness and safety of CBA, however, depend on multiple factors, such as the cooling rate, leakages, minimal temperature and isotherm distribution. Experimental and a few numerical studies [1,2,3], have been undertaken to investigate CBA. Analysis of tissue damage in CBA [1] have shown that a tissue temperature of -20°C maintained for at least 60s is necessary for creating a lesion in the tissue. If the temperature is held below -40°C, however, the required freeze time for a lesion to form is nearly insignificant because of direct cell damage. In addition, the presence of leakages from the PV ostium may necessitate lower balloon temperatures and unduly increase hold times.

Given these issues, there is a need to investigate factors affecting the temperature (and flow) field in the area surrounding the PV ostium, which may help optimize the treatment. As such, the goal here is to develop a computational modeling framework to investigate blood flow and temperature field during cryoablation. Specifically, we seek to investigate how the presence of a cryoballoon affects hemodynamics in the left atrium (LA) and PV ostium, and how in presence of leakage during PV occlusion affects temperature distribution in the PV.

METHODS

Hemodynamics is simulated in a patient specific 3D model of the LA (including the PV) [4] using the finite element method (FEM). The strong form of the problem's governing equations in non-dimensional form are given as follows:

$$\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u} \cdot \nabla \boldsymbol{u} = \nabla \cdot \boldsymbol{\sigma} + \boldsymbol{f} \tag{1}$$

$$\nabla \cdot \boldsymbol{u} = \boldsymbol{0} \tag{2}$$

$$\frac{\partial T}{\partial t} + \boldsymbol{u} \cdot \nabla T = \frac{1}{Pe} \Delta T \tag{3}$$

In the above equations, $\boldsymbol{u}$ is the velocity field and T is the temperature field. Blood that is assumed to behave as a Newtonian fluid with stress $\boldsymbol{\sigma}(\boldsymbol{u}, p) = -p\boldsymbol{I} + \frac{2}{Re}\boldsymbol{D}(\boldsymbol{u})$, where $\boldsymbol{D}(\boldsymbol{u}) = \frac{1}{2}(\nabla \boldsymbol{u} + (\nabla \boldsymbol{u})^T)$ is the strain rate tensor. Based on the physical properties of blood, the following dimensionless control parameters are introduced in the problem, namely, Reynold's number $Re = \frac{V_{sc}\, L_{sc}}{\upsilon} = 1047$ and Prandtl number $Pr = \frac{\upsilon}{\alpha} = 27$. The diameter and velocity at the left-superior PV inlet are taken as the characteristic length and velocity scale, respectively. Laminar flow is assumed in the problem.

A closer look at the control parameters reveals that temperature transport is advection dominated, especially in Eq. (3) when the Peclet number is high (i.e., $Pe = Re \cdot Pr \approx 10^4$). Numerical stability to capture sharp spatial gradients at such high *Re* and *Pe* flows is achieved by applying streamline-upwinding (SUPG) and crosswind stabilization schemes to the weak form of the governing equations. Also, apart from Incremental Pressure Correction (IPCS) for velocity-pressure coupling, the following discretization schemes are employed: forward Euler for inertia, two-step explicit Adams-Bashforth for the convection term and Crank-Nicolson velocity for the viscous term. The resultant time-

discretized weak form of the governing equations (with $\boldsymbol{v}$ and w as test functions) is given below:

$$\int_{\Omega} \frac{\boldsymbol{u}^* - \boldsymbol{u}^n}{\Delta t} \cdot \boldsymbol{v} \cdot dx + \int_{\Omega} \frac{1}{2}(3\boldsymbol{u}^n \cdot \nabla \boldsymbol{u}^n - \boldsymbol{u}^{n-1} \cdot \nabla \boldsymbol{u}^{n-1}) \cdot \boldsymbol{v} \cdot dx + \int_{\Omega} \left[-p^n \boldsymbol{I} + \frac{\frac{1}{2}(\boldsymbol{D}^* + \boldsymbol{D}^n)}{2Re}\right] : \nabla \boldsymbol{v} \cdot dx + \int_{\Omega} \tau^1{}_{SUPG} \cdot P(\boldsymbol{u^n}, \boldsymbol{v}) \cdot R_1(\boldsymbol{u}) \cdot dx + \int_{\Omega} (\tau^1{}_{CW} \cdot Q(\boldsymbol{u^n}, \boldsymbol{u})) : \nabla v = 0 \quad (4)$$

$$\int_{\Omega} \frac{T - T^n}{\Delta t} \cdot w \cdot dx + \int_{\Omega} \frac{1}{2}(3\boldsymbol{u} \cdot \nabla T^n - \boldsymbol{u}^n \cdot \nabla T^{n-1}) \cdot w \cdot dx + \int_{\Omega} \left[\frac{\nabla T + \nabla T^n}{2Pe}\right] \cdot \nabla w \cdot dx + \int_{\Omega} \tau^3{}_{SUPG} \cdot P(\boldsymbol{u}, w) \cdot R_3(T) \cdot dx + \int_{\Omega} (\tau^3{}_{CW} \cdot Q(\boldsymbol{u}, T)) : \nabla w = 0 \quad (5)$$

where $\boldsymbol{u}^*$ $(\boldsymbol{u})$ is the intermediate (final) velocity, $P(\boldsymbol{a}, \boldsymbol{b}) = \boldsymbol{a} \cdot \nabla \boldsymbol{b}$ and $Q(\boldsymbol{a}, \boldsymbol{b}) = \boldsymbol{M}(\boldsymbol{a}) \cdot \nabla \boldsymbol{b}$ are the SUPG and crosswind stabilizing operators, $\boldsymbol{M} = \begin{Bmatrix} \boldsymbol{I} - \frac{\boldsymbol{a} \otimes \boldsymbol{a}}{|\boldsymbol{a}|^2} & if\ \boldsymbol{a} \neq \boldsymbol{0} \\ \boldsymbol{0} & if\ \boldsymbol{a} = \boldsymbol{0} \end{Bmatrix}$, and $R, \tau_{SUPG}, \tau_{CW}$[5,6] are the residuals and constants for SUPG and crosswind stabilization respectively.

Taylor hood element is used for spatial discretization of the velocity and pressure fields, while quadratic element is used for discretizing the temperature field. The problem is solved using the open-source FE library FEniCS. Simulations were performed on a patient specific LA geometry (model dimensions [4] are given in Table 1) with a spherical cryoballoon of diameter 23 mm occluding the right-inferior PV inlet (Fig 1). PV isolation was simulated by applying a temperature of -70°C on the cryoballoon. Patient specific PV flow rate measurements [7] (at a heart rate of 63 bpm) was imposed as boundary conditions in the model. Blood temperature was set at 37°C as the initial condition. The problem is solved for 10 heart cycles on an FE mesh consisting of 124238 nodes with a Courant number < 0.15.

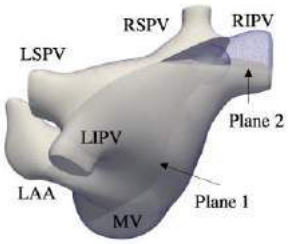

Figure 1: A schematic of the patient specific LA with cryoballoon at the RIPV, mesh and two cross-sections.

Table 1: Areas and diameters of PV's extracted from MRI data

	LSPV	LIPV	RSPV	RIPV
Area (mm^2)	322.5	209.9	188.35	437.6
Av. Dia. (mm)	20.26	16.34	15.48	23.6

RESULTS

Figure 2 shows the velocity and temperature isotherms surrounding the cryoballoon at two different sections of the LA. There is a considerable blood leakage on one side as compared to the other due to the position of the cryoballoon (Fig. 2b). On the side with leakage (with a distance 3.76 mm between the balloon and LA wall), blood accelerates past the cryoballoon, which results in substantial heat convection. As a result, temperature at the wall remains close to 37°C and it is unlikely for lesion to form at the LA wall. We also note that vortices are shed downstream and transported further into the LA on the side with leakage due to the pulsating flow through the PV. However, on the side where the cryoballoon is close to the LA wall (at a distance 0.6 mm), the local wall temperature falls below -20/-40°C, which is below the threshold at which lesion forms.

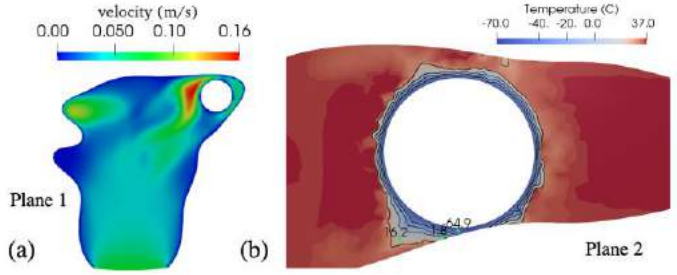

Figure 2: (a) Velocity contours on Plane 1. (b) Temperature isotherms on Plane 2 after 10 heart cycles, four different isotherms correspond to -40, -20, 0, 27 ^{0}C.

DISCUSSION

Here, we have developed a novel computational framework to simulate cryoablation for PV isolation. We show that the LA wall temperature (and effectiveness of PV isolation) is sensitive to the leakage at the PV ostium. Correspondingly, there is a minimum threshold for the distance between the cryoballoon and the LA wall to create a lesion for isolating the PV. Our results suggest that the threshold distance may depend on other factors such as balloon temperature and PV and mitral flow velocity. The developed computer framework may be useful for understanding and optimizing the cryoablation treatment to determine the conditions (e.g., maximum leakage that is permissible) at which lesions will form. Moreover, the framework may be useful for determining the conditions that will avoid phrenic nerve injury (one of the major challenges of CBA) while attaining complete occlusion of the right PV's. There are some limitations associated with this study. First, heat conduction of the LA wall was not taken into account, which may help further reduce the wall temperature. Second, motion of the LA wall is not considered here.

COMPARATIVE COMPUTATIONAL ANALYSIS OF PASCAL AND MITRACLIP IMPLANTATION IN A PATIENT-SPECIFIC LEFT-HEART MODEL

INTRODUCTION

Around 2.5% of the U.S. population is living with a heart valve disease (HVD) [1]. The most common HVD is mitral regurgitation (MR). It is prevalent in 1.7% of the U.S. population and rises to 9.3% prevalence in individuals over the age of 75 [1]. MR is caused by a dysfunctional mitral valve (MV), which is the valve that separates and controls blood flow between the left atrium (LA) and left ventricle (LV). In MR, the MV does not close tightly during LV systole (contraction), which allows retrograde blood flow from the LV into the LA. This may cause death, fatigue, shortness of breath, and other symptoms. There are two types of MR, degenerative MR (DMR), which is caused by intrinsic destruction of the MV tissues, and functional MR (FMR), which is caused by improper LV function and geometry. Most patients living with MR are not candidates for open-heart surgery due to comorbidities. Furthermore, patients with untreated DMR or FMR have a poor prognosis.

Within the last decade, minimally-invasive transcatheter MV repair (TMVRep) devices have been developed. These devices are implanted in the MV and coapt the two MV leaflets, which are the anterior mitral leaflet (AML) and posterior mitral leaflet (PML). The leaflet coaptation mimics the Alfieri Stitch surgical procedure and results in a valve with multiple orifices. The most widely used TMVRep device is the MitraClip (Abbott Vascular) [2]. This device received CE mark in 2008, FDA approval in 2013 for DMR treatment, and FDA approval in 2019 for FMR treatment. The 2019 FMR approval occurred after the COAPT clinical trial showed there was a significant reduction in all-cause mortality and hospitalization for patients treated with MitraClip compared to a control group [3]. However, the results of a separate concurrent trial (MITRA-FR) indicated MitraClip did not improve FMR prognosis [4]. These conflicting results likely stem from patient selection, degree of MR, and surgeon experience [5].

A novel TMVRep device, PASCAL (Edwards Lifesciences), received CE mark in 2019 and has ongoing clinical trails to earn FDA approval for DMR and FMR treatment. Similar to MitraClip, PASCAL mimics the Alfieri Stitch. However, PASCAL has unique design features including a central spacer, broad and curved paddles, a larger size, and a shape-retaining material. These features are designed to plug the regurgitant orifice and decrease the stresses in the MV leaflets. Given the opposing clinical trial results for MitraClip and the short clinical history for PASCAL, a greater understanding of the human host to device interaction and a direct biomechanical comparison between the two devices is needed. To do this, computational simulations will be used to simulate MitraClip and PASCAL implantation in a patient-specific left-heart model. Post-repair cardiac dynamics will be quantified and compared between the two devices.

METHODS

Left-Heart (LH) Model: A patient-specific computational model of a de-identified patient that was diagnosed with FMR was constructed from multi-slice computed tomography (MSCT) images (with IRB approval). The model includes the MV and subvalvular structures, LA, LV, aortic valve, and aortic root. The model was developed and validated using the methods explained in the literature [6].

Material Models: The material properties for the LH structures were obtained by applying hyperelastic models to the mechanical testing data of an age- and gender-matched cadaver heart.

Implant Models: The MitraClip was modeled using methods described in the literature [7]. The PASCAL was modeled by importing and appropriately scaling the images shown in Fig. 1 into Solidworks and using the images as a reference to create a 3-D computer model.

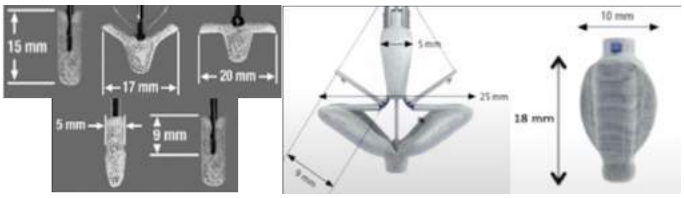

Figure 1: Design of MitraClip (left) and PASCAL (right)

Finite-Element (FE) Simulation: The MV closure dynamics were simulated using methods from the literature [8] and validated by comparing the FE leaflet geometry outputs to systolic CT MV images. In the implantation simulations for both devices, the clips/paddles were opened, positioned in the MV, and closed on the leaflets during systole. After device closure, rough (no separation) contact was applied between the device and leaflets. Systolic and diastolic pressures were applied to the leaflets to simulate post-TMVRep cardiac dynamics. Each device was implanted in a central and lateral MV location, and the max principal stress results from the AML and PML were output during peak systole and compared across devices and implant locations. Elements nearest the mitral annulus (MA) and the highest 1% of peak stress values were ignored to avoid boundary effects and eliminate bias due to local extreme stress-concentration, respectively [9].

RESULTS

The stress results of the FE simulations are shown in Table 1. MitraClip results from the literature were referenced [7].

Table 1: Summary of leaflet stress results

		Pre-TMVR	Central		Lateral	
			MitraClip	PASCAL	MitraClip	PASCAL
AML peak stress	Value (kPa)	564.2	611.0	530.5	924.1	467.7
	Change (%)	0.0	8.3	-6.0	63.8	-17.1
AML average stress	Value (kPa)	112.7	122.5	79.2	167.6	88.5
	Change (%)	0.0	8.7	-29.7	48.7	-21.5
PML peak stress	Value (kPa)	716.9	1163.3	391.4	800.3	736.8
	Change (%)	0.0	62.3	-45.4	11.6	2.8
PML average stress	Value (kPa)	61.2	89.5	39.0	79.1	57.5
	Change (%)	0.0	46.3	-36.3	29.2	-6.0

For the central implant location, the peak and average stress in the AML increased by 8% and 9% post-MitraClip repair, respectively, while that of the PASCAL decreased by 6% and 30%. The peak and average PML stresses had respective increases of 62% and 46% post-MitraClip repair, whereas the corresponding results after PASCAL implantation were a decrease of 45% and 36%, respectively. The lateral results showed similar trends. The peak and average stresses for the AML and PML increased by 64%, 49%, 12%, and 29%, respectively, after MitraClip implantation. In post-PASCAL repair, the peak and average stresses for the AML decreased by 17% and 21%, respectively, and the peak and average stresses for the PML increased by 3% and decreased by 6%, respectively. For both devices, average stresses were higher in both MV leaflets for the lateral location compared to the central location, except for the PML in post-MitraClip repair.

The maximum principal stress distribution in the MV leaflets for post-PASCAL repair is shown in Fig. 2. The implant location site is highlighted in red and the detailed view (top center) shows the stresses surrounding the region of contact between the implant and leaflets. Some elements in the contact region experienced compressive stresses. Additionally, stress concentration is present near the contact region. The stress concentration is reduced compared to the MitraClip, and in general, the PASCAL and MitraClip stress distributions are similar [7].

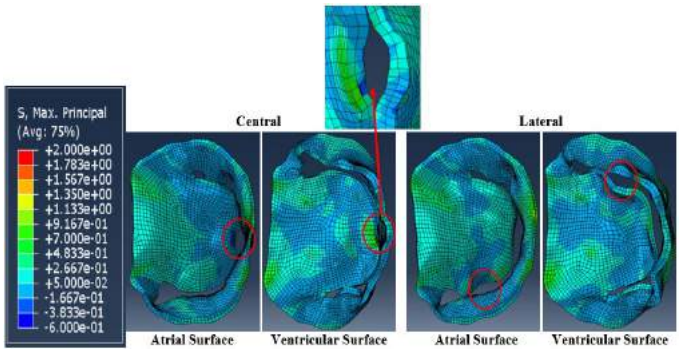

Figure 2: Post-PASCAL repair, distribution of maximum principal stress (MPa) in MV leaflets

DISCUSSION

The results indicate the PASCAL outperforms the MitraClip in terms of limiting/decreasing leaflet stresses. While implantation of the MitraClip results in an increase of peak and average stresses in both MV leaflets, implantation of the PASCAL reduces the leaflet stresses. This is likely due to the central spacer feature of the PASCAL. Since the spacer fills the regurgitant orifice, the PASCAL does not have to pull the MV leaflets as far as the MitraClip in order to coapt the leaflets. Additionally, the PASCAL's contoured paddles and larger size seem to reduce the stress concentration seen at the contact region. With a larger and smoother contact area, the force applied on the leaflets from the paddles is distributed over a larger area which results in a reduction of stress. Furthermore, the MitraClip is a rigid device that locks closed, whereas the PASCAL is made of nitinol, which is a hyperelastic, shape-retaining material. After implantation occurs, the nitinol material allows the paddles to undergo subtle opening and closing motions. As the geometries of the MV leaflets change due to changes in pressure throughout the cardiac cycle, the slight motion of the paddles accommodates the leaflet geometry and limits the stress concentrations.

This study has the limitations of only studying one patient-specific LH model, and the implantation simulations were not validated with clinical data. Future work may include simulating the clip procedure in more patient models, as well as quantifying and comparing other pertinent parameters for characterizing MR reduction such as the regurgitant orifice area and MR hemodynamics. This study shows PASCAL is a viable treatment option for MR. The PASCAL may reduce MR more effectively than the MitraClip, and the information from this study may aid clinical decision-making regarding MR.

INTRODUCTION

Intracranial aneurysms (IA), the pathological enlargement of the cerebral arterial wall, and present in about 3.2% of the adult population [1]. Spontaneous rupture of an IA is fatal for approximately 45% of patients, while 50% of the survivors suffer from disabilities that prevent them from returning to work [2, 3]. Currently, it is difficult for clinicians to confidently select aggressive and somewhat risky treatments that can exceed the risks associated with an IA rupture which occurs at an average rate of 1.1% per year [4, 5]. Thus, there is a pressing need for improved evidence-based methods to stratify the aneurysms at a higher risk of rupture and avoid unnecessary risky treatment in others.

As IA rupture is ultimately mediated by structural failure of the aneurysm wall, understanding of structure-failure property relationships for the wall tissue has the potential to reveal mechanisms leading to the loss of IA biomechanical integrity. Indeed, aneurysmal wall structure anomalies such as remodeled collagen architecture, inflammation, and the presence of lipid pools or calcified regions within the wall tissue have been variously implicated as wall-weakening mechanisms leading to the IA rupture. Our group recently reported that wall calcification is more prevalent in human IA wall tissue than previously believed [6]. We also found that physical environment around the calcification is altered compared to the native tissue. For example, calcification could exist within or separate from lipid pools in the wall [6]. Additionally, we found that for ruptured aneurysms, the calcification was never co-localized with lipid pools, suggesting the structural milieu around the calcification is of importance.

In the present work, we computationally investigated the multifactorial nature of IA rupture to understand how the calcification and its surrounding wall tissue environment influence the rupture risk. We hypothesized that the material composition of the Near-Calcification Region (NCR) of the IA wall tissue influences the mechanical stress distribution within the tissue, and thus impacts the overall failure behavior of the calcified IA tissue.

METHODS

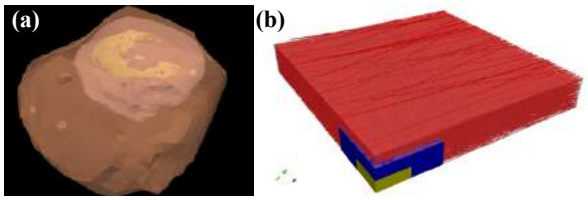

Figure 1. (a) Segmentation of MicroCT data of cerebral aneurysm tissue (orange) with macro-calcification (yellow) embedded in lipid pool (grey) and (b) parametric solid model designed to reproduce cerebral aneurysm tissue with macro-calcification embedded in a lipid pool while limiting the effect of boundary conditions during loading. The computational domain exploits problem symmetry.

We have performed finite element-based stress analysis for a model geometry of the tissue specimen including a central disk-shaped calcified region surrounded by an NCR, see Figure 1. The simplified geometry was chosen to remove the effect of local surface topology of the calcification on the ensuing stress field so that insights gained from the parametric study are general in nature. The diameter of the calcification was motivated from the size of a human aneurysm calcification. The convergence criterion was taken as the change in peak stress, measured from the stress-stretch curve, to be less than 5% between successive mesh refinements. We utilized a recently developed fiber-embedded finite element method, details of which can be found in our previous publications [7, 8]. Briefly, this method models the fibrous soft tissue microstructure as a network of discrete 1D rod elements

embedded within the 3D continuum at the sub-tissue level, while the biaxial testing procedure was simulated at the specimen level by upscaling the information gathered at the lower length scale.

Material parameters, such as matrix and fiber stiffness, for the tissue were regressed from uniaxial experiments on aneurysm tissue with similar dimensions. Other material properties, such as organization and density of the fiber network were motivated by multi-photon imaging of the same tissue using a previously established protocol for aneurysm tissue [9-11] . The calcification properties were taken from literature [12, 13]. Finally, the shear modulus of the NCR was varied parametrically and used to define the shear moduli ratio (SR) of the NCR to tissue matrix ($\frac{\mu_{NCR}}{\mu_{matrix}}$). The range of the SR ratio (0.01-1000) was motivated by published mechanical properties describing soft lipid pools, μ_{NCR}=0.1-1 kPa, to stiff calcification [12, 13].

RESULTS

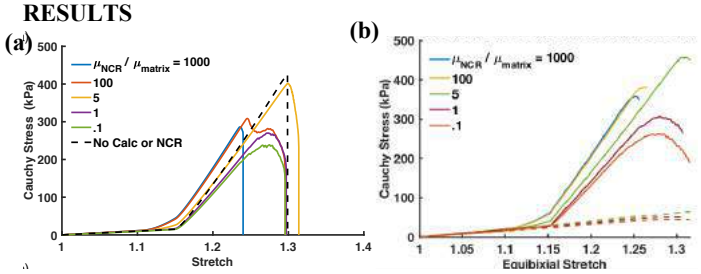

Figure 2. (a) Cauchy stress versus uniaxial stretch curves for an in-situ parametric study of the effect of NCR stiffness relative to the tissue matrix stiffness. For reference a case in which no inclusion was included and displayed as black-dashed line. (b) Cauchy stress versus equibiaxial stretch curves for the same parametric study of NCR stiffness. Solid lines represent circumferential response while dashed lines are corresponding longitudinal responses

Uniaxial stress-stretch curves for the stiffness ratio varying from SR = 0.1 to 1000 are presented in Figure 2 (a). For reference, we also simulated a specimen with without any calcified or NCR. As expected from the rule of mixtures, incorporation of higher modulus NCR resulted in a steady increase in the pre-failure slope of these curves. Peak stress for all cases of NCR stiffness were lower than the "control" tissue, revealing adverse effects of the calcification and NCR on the tissue failure properties. Also, the peak stress varied non-monotonically with the increase in SR. In comparison to the uniaxial case, Figure 2(b), illustrates under equibiaxial stretch the same pattern can be observed in the non-monotonic relationship between SR and peak stress. Also, peak stresses are consistently higher in equibiaxial stress cases. We observed an inversely proportional relationship between the biaxial loading ratio (B) and peak stress. Namely we noticed for all cases of SR, peak stress and stretch at peak stress reduced as B increased from 0.5 to 2.

Stress distribution in the collagen fibers and the non-collagenous matrix of the tissue and NCR before the peak of the stress-stretch curve for SR = 0.1,1,5, and 1000 under equibiaxial stretch is shown in Figure 3. For SR ≤ 5, the fiber stress concentration appears in the vicinity of the NCR orthogonal to the loading axis. For the SR=1000 case shown in Figure 3, the fiber stress concentration can be observed along the loading direction. Subsequently, the tear initiated and propagated from the stress concentration zone observed pre-peak. These stress concentrations and tear patterns were consistent between uniaxial and equibiaxial loading as well as in other loading scenarios B=0.5 and B=2.

DISCUSSION

In the current study, we demonstrated that while the presence of the calcified region elevates the mechanical stress in its vicinity, mechanical properties of the NCR determine how that high stress is propagated and distributed to the rest of the tissue. Our simulations revealed that softer NCR properties, SR≤ 1, allowed for large deformation of the NCR and shielded stress around the NCR along the loading direction but creating high concentrations at the poles of the NCR orthogonal to the loading direction. These highly localized fiber stresses created local micro-tears that propagated at a lower applied stretch, resulting in a low peak of the specimen stress-stretch curve. In contrast, the NCR with shear modulus higher than the tissue matrix (SR>1) distributed the stress to a greater volume of the tissue and failed a higher peak stress.

Our study has the following limitations. In our tissue microstructure model, some of the collagen fibers abruptly ended at the edge of the NCR, while microscopic observations have shown that collagen fibers may also skirt around calcifications. We anticipate that incorporation of such fiber structure will introduce additional stress propagation paths in the vicinity of the calcification. We are currently working on this improvement, but in its current state this study illustrates the role of the calcification and NCR on the IA tissue failure properties contributing to a better understanding of the IA rupture process and assessing rupture risk.

THE EFFECT OF HEMATOCRIT ON THE THICKNESS AND ASYMMETRY OF THE CELL-FREE LAYER IN ARTERIAL BIFURCATIONS

INTRODUCTION

In the microcirculation, the migration of red blood cells (RBCs) towards the center of vessels leads to the formation of an RBC core and a cell-free layer (CFL) near vessel walls. This separation directly influences physiological processes such as tissue oxygenation and vasodilation and contraction. Previous works have extensively studied how the CFL develops in microvascular networks both *in vivo* and *in silico* [1-3], noting how geometric characteristics of the CFL such as thickness and asymmetry are linked to changes in downstream cell distributions at branching vessels. Arterial bifurcations disrupt the CFL profile, and the downstream recovery in terms of CFL size and asymmetry can play a crucial role on CFL behavior in a succeeding bifurcation. Although experimental [4] and numerical [5] works have explored the recovery of CFL symmetry downstream of a bifurcation, the role of varying hematocrit (Hct) on CFL recovery has yet to be fully explored.

In this work, we use a 3D computational approach to study the CFL development downstream of bifurcations at two possible hematocrit levels: 15% and 30%. The use of numerical methods allows for the focus on a specific parameter to determine its effect on the quantities of interest while minimizing the effect of other factors. We sample the size of the CFL and its asymmetry in a single-branching bifurcation along several points in the daughter branch to determine where these two quantities to stabilize. Studying the recovery of CFL thickness and asymmetry and comparing across various levels of hematocrit is the first step to linking their effects to CFL development down further branching vessels.

METHODS

To numerically probe the effect of varying hematocrit while holding other hemodynamic parameters constant, we employ the use of HARVEY, a massively parallel computational fluid dynamics solver [6]. The lattice Boltzmann method is used to model the flow of RBCs suspended in plasma, which is treated as a Newtonian fluid. A finite element model is used for the cells and these are coupled via the immersed boundary method.

Fluid and cell simulations. The lattice Boltzmann method is procedure to numerically solve the Navier-Stokes equations; the fluid is treated as a set of discrete particles moving at nodes on a regularly spaced lattice. The probability of particles residing at lattice point $\boldsymbol{x}$ and time t with a discrete velocity $\boldsymbol{c_i}$ is designated by the particle distribution function $f_i(\boldsymbol{x} + \boldsymbol{c_i})$. For a fluid with an external force field, the lattice Boltzmann equation which governs the evolution of these particles is

$$f_i(x + c_i, t + 1) = \left(1 - \frac{1}{\tau}\right) f_i(x,t) + \frac{1}{\tau} f_i^{eq}(x,t) + F_i(x,t) \quad (1)$$

for an external force distribution F_i, equilibrium distribution f_i^{eq}, and relaxation time τ.

RBCs are modeled as biconcave discs with zero-thickness triangulated mesh. The membrane forces are calculated using a finite element model which also includes elasticity and bending stiffness. The Skalak constitutive law governs the shear and dilational elastic responses of the mesh [7].

CFL thickness and asymmetry calculations. To show the development of the average thickness of the CFL and its asymmetry, we present data averaged over time. For each simulation, cell vertices are saved every 10,000 timesteps. For calculations at a radial slice in the vessel, all of the cell vertices laterally located within 5 μm are returned and flattened on the axial plane. Eight wall points are generated along the surface of the vessel. For each wall point, the nearest cell vertex is

identified and a straight-line distance δ from that cell vertex to the wall is stored. To obtain the CFL thickness, this δ is averaged across all of the wall points, while asymmetry is calculated as $\delta_{max}/\delta_{min}$. An example of low and high asymmetry is shown in Figure 1.

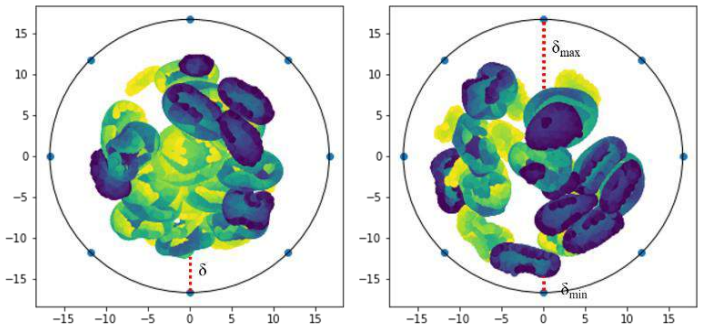

Figure 1: CFL and asymmetry calculations at an instantaneous timepoint in a 2D slice. An example of a low and high asymmetry slice is shown on the left and right, respectively. Recovery of the CFL can be quantitively measured by the CFL thickness and asymmetry reaching a steady state.

RESULTS

Model comparison. Two sets of simulations are performed in straight vessels at diameters of 10 and 20 μm at 15% hematocrit. An external force is generated to match the plasma velocities in a similar computational setup in [8]. Simulations are run with periodic boundary conditions until a relatively steady CFL size is reached. The CFL thickness is calculated to be 2.3 μm and 4.2 μm respectively, in good agreement with the results from [8], where values of 2.4 and 4.3 μm, respectively, were reported.

Single bifurcating channel. A bifurcation geometry is generated using PTC Creo with a daughter arm length of 500 μm. The parent and daughter branch diameters are 40 μm and 33.33 μm, determined from Horton's law to maintain a diameter reduction consistent with that observed in physiology. An input velocity of 8 mm/s is used to generate the flow and initialized with 15% and 30% hematocrit. The average CFL size and its asymmetry are calculated at every 50 μm along the length of the daughter branch; slices are marked in Figure 2a. The time average CFL thickness and asymmetry at each of these slices are presented as a function of distance from the bifurcation in Figure 3.

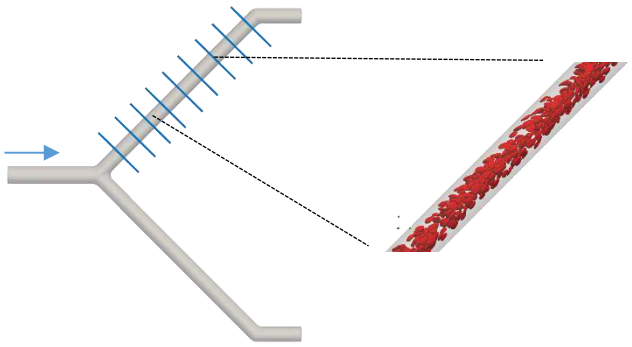

Figure 2: Single bifurcating channel with sample slices taken every 50 μm. CFL thickness and asymmetry are calculated at each slice and averaged over time.

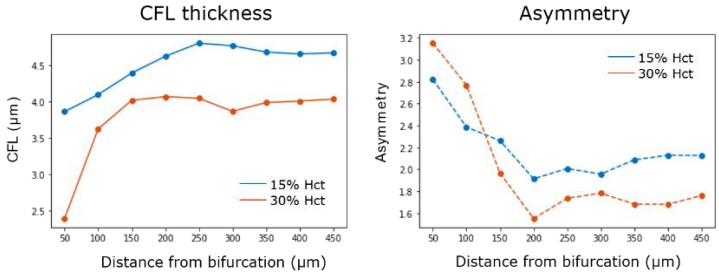

Figure 3: CFL (left) and asymmetry (right) in the daughter branch vs distance from bifurcation. These quantities reach a steady state approximately 250 microns along the vessel.

DISCUSSION

In the single bifurcation simulations, we find that the time average CFL size increases as a function of distance from the bifurcation for both the 15% and 30% hematocrit cases until stabilization. The 15% Hct takes longer to reach a steady CFL thickness at around 250 μm, whereas the 30% maintains its value starting around 150 μm from the bifurcation, shown in Figure 3a. As expected, the lower Hct case has a higher CFL across the board; since there are fewer cells, there will be an increased distance between the RBC core and the vessel wall.

Both Hct cases see a significant drop in asymmetry compared to the beginning of the daughter arm; since the bifurcation changes the motion of flow, we would expect to find a high asymmetry near the beginning of the daughter branch, shown in Figure 3b. Both stabilize roughly 200 to 250 μm into the channel, although the asymmetry of the lower Hct case remains higher; this could be due to the motion of stray RBCs away from the core which results in a lower δ_{min}, which in turn gives a higher asymmetry. There is also a slight rise in asymmetry at both 15% and 30% Hct towards the end of the daughter vessel, which could be influenced by the curve at the end of the channel.

These single bifurcation simulations show that the CFL thickness and skew of RBC distribution stabilizes around halfway through the vessel. The CFL size for the higher Hct equalizes slightly earlier. The lower Hct case stabilizes at a higher CFL thickness and asymmetry than the higher Hct run. Future work can utilize this knowledge to simulate multi-branching vessels and explore the effect of a recovered and non-recovered CFL on further downstream branches.

FGF-10-MEDIATED BUCKLING MORPHOGENESIS OF THE EMBRYONIC AIRWAY EPITHELIUM

Kara E. Peak (1), Victor D. Varner (1)

(1) Department of Bioengineering

Richardson, TX, USA

INTRODUCTION

Ramified networks form the basic architecture for many organs in the body including the lung, kidney, and salivary gland. In the embryonic lung, these structures are formed via a process known as branching morphogenesis. The lung primordium originates as an out-pocketing of foregut endoderm, which undergoes a series of recursive branching events to build the bronchial tree [1]. This process is regulated by a complex network of signaling pathways, but fibroblast growth factor (FGF) signaling has emerged as a crucial regulator of airway branching. New epithelial branches are thought to arise next to focal regions of FGF-10 expression in the pulmonary mesenchyme, but it is unclear how FGF-10 signaling drives the macroscopic changes in tissue form that shape emerging branches. Here, we used FGF-10-loaded beads to create ectopic sources of FGF-10 to stimulate the formation of supernumerary branches in cultured embryonic lungs. *Ex vivo* organ culture experiments were combined with quantitative fluorescence microscopy, pharmacological modulation of luminal fluid pressure, and computational modeling to determine how cellular behaviors downstream of FGF-10 work in concert with exogenous mechanical forces to sculpt the embryonic airway epithelium.

METHODS

Fertilized White Leghorn chicken eggs were incubated at 37 °C to Hamburger and Hamilton (HH) stage 26. Embryonic lungs were dissected in phosphate-buffered saline (PBS). Small agarose beads, soaked in either PBS or 100 μg/ml FGF-10 in PBS for 2-3 hr at room temperature, were then implanted into the pulmonary mesenchyme along regions of the airway epithelium that normally remain unbranched. The explants were then cultured on Nucleopore membranes at the air-liquid interface in DMEM/F12 medium (without HEPES) supplemented with 5% fetal bovine serum (FBS) and antibiotics. In some experiments, the medium was also supplemented with 1 μM aphidicolin to inhibit cell proliferation, or with either 10 μM forskolin or 200 μM bumetanide to activate or inhibit, respectively, rates of epithelial fluid secretion.

Bright-field images of cultured explants were captured at 0 and 24 hr to quantify the number of ectopic branches, as well as changes in epithelial morphology. Timelapse images were also captured at 30 min intervals to observe the dynamics of supernumerary bud formation. In other experiments, we used the Click-iT EdU Imaging Kit to quantify rates of cell proliferation. These explants were co-stained for LCAM (E-cadherin) immunofluorescence and imaged as whole-mounts using a laser scanning confocal microscope. Other explants were frozen in OCT compound, sectioned into 20 μm slices using a cryostat, and stained for F-actin and phosphorylated myosin light chain (pMLC) immunofluorescence to visualize areas of active actomyosin contractility. In addition, we created a computational model of FGF-10-induced budding morphogenesis using COMSOL Multiphysics and compared our results with *ex vivo* culture data.

RESULTS

Agarose beads containing 100 μg/ml FGF-10 were embedded in the pulmonary mesenchyme of embryonic chicken lungs along regions of the airway epithelium that normally remain unbranched. To our surprise, individual FGF-10-loaded beads stimulated the formation of multiple supernumerary buds after 24 hr of culture. These ectopic buds exhibited a common (or characteristic) wavelength and formed simultaneously, in a manner similar to the buckling morphogenesis of isolated airway epithelial explants cultured in 3D gels of reconstituted basement membrane protein [2]. The formation of these supernumerary buds depended crucially on increased epithelial proliferation, as

determined by EdU quantification and a loss of supernumerary buds in explants treated with aphidicolin.

We also stained explants for phalloidin and pMLC immunofluorescence, which label F-actin and regions of active actomyosin contractility, respectively, since previous studies have suggested that localized regions of contractility can promote the apical constriction of airway epithelial cells and the formation of new branches [3]. The FGF-10-induced supernumerary buds contained no discernible increases in the intensity of either F-actin or pMLC staining, suggesting that apical constriction is not involved in the formation of ectopic branches.

Taken together, these results suggested the possibility that ectopic sources of FGF-10 promote increased proliferation within the airway epithelium, causing it to buckle and form multiple supernumerary buds. To test this more directly, we also modulated rates of epithelial fluid secretion (and thus luminal fluid pressure) to determine if increased epithelial tension could suppress the formation of ectopic branches. Treatment with forskolin, an activator of cAMP activity and epithelial fluid secretion, caused the embryonic airways to inflate dramatically, and suppressed the formation of supernumerary branches in response to an FGF-10-loaded bead (Fig. 1). In other experiments, explants were cultured in the presence of bumetanide, an NKCC1 inhibitor and antagonist of fluid secretion, to determine if decreased epithelial tension might promote buckling, and thereby ectopic branch formation. Indeed, treatment with bumetanide resulted in a greater number of supernumerary buds, which exhibited a shorter wavelength and formed at an earlier timepoint during *ex vivo* culture (Fig. 1).

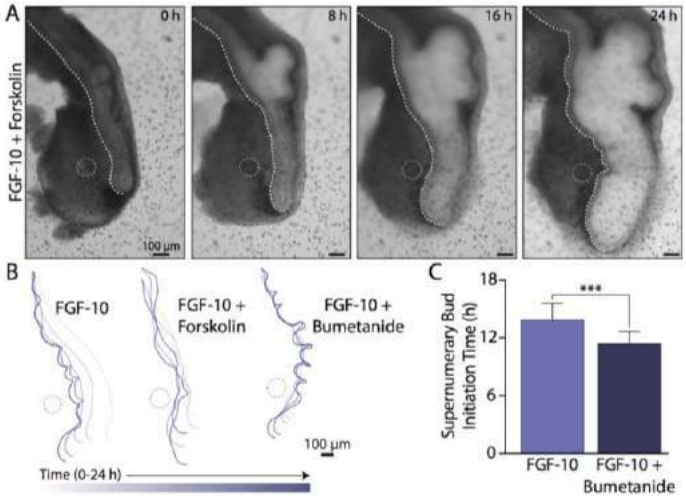

Figure 1: Fluid pressure modulates epithelial buckling and resulting supernumerary bud formation.

Lastly, to more completely understand the mechanics of ectopic bud formation, we also created a nonlinear computational model of the embryonic airway epithelium. Our experimental data suggested that the growth (or expansion) of the epithelium in response to FGF-10 is constrained by the surrounding mesenchyme, which causes the epithelium to buckle and form ectopic branches. To test the plausibility of this mechanism, we modeled the epithelium as a growing bar supported by a spring foundation, to account for the mechanical constraint of the mesenchyme (Fig. 2). The bar was assumed to behave as a hyperelastic material with a Blatz-Ko strain-energy density function, and growth was included by decomposing the overall deformation gradient tensor ($\boldsymbol{F}$) into a component due to growth ($\boldsymbol{G}$) and a component due to elastic deformation ($\boldsymbol{F}^*$) via $\boldsymbol{F} = \boldsymbol{F}^* \cdot \boldsymbol{G}$. Longitudinal growth was included in the epithelium by specifying the components of the growth tensor $\boldsymbol{G}$. As the epithelium elongated, compressive axial forces caused it to buckle, creating numerous epithelial buds, similar to those observed in our FGF-10 bead experiments (Fig. 2). The simulated buds, moreover, formed simultaneously and exhibited a characteristic wavelength, even though the longitudinal growth specified along the epithelium was spatially uniform. Buckling could also be suppressed in the model by stretching the bar longitudinally, in a manner that simulated the dilation of the airway observed upon treatment with forskolin (Fig. 1).

Taken together, these results suggest that ectopic sources of FGF-10 can promote the buckling morphogenesis of the embryonic airway epithelium.

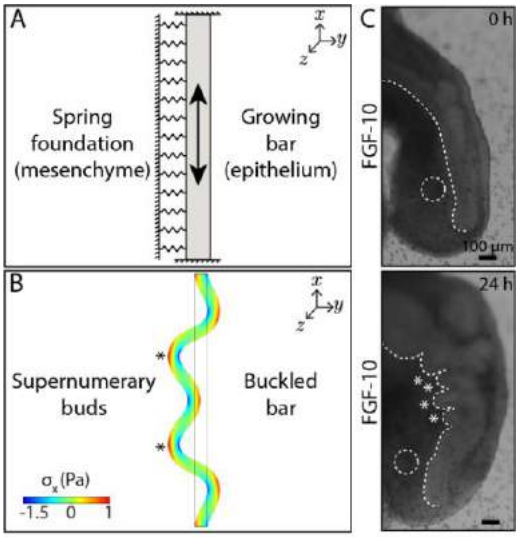

Figure 2: Nonlinear elastic growth-induced buckling model recapitulates experimental supernumerary bud formation

DISCUSSION

The complex network of signaling pathways that regulate branching morphogenesis in the embryonic lung make it difficult to experimentally parse the effects of any individual growth factor. Here, we have used growth factor-loaded beads to isolate the effects of a single growth factor, FGF-10, which is thought to regulate the overall airway branching pattern. Focal sources of FGF-10 are purported to act as chemoattractants that promote the outgrowth of new epithelial branches, with individual buds corresponding to individual domains of FGF-10 expression [4-5]. However, our work has demonstrated that a single focal source of FGF-10 can stimulate the formation of multiple branches via a proliferation-dependent buckling mechanism. Epithelial buckling (and thus branch formation) was modulated by changes in either epithelial proliferation or luminal fluid pressure, suggesting that airway branching is not specified by patterned FGF-10 expression alone. Instead, growth-factor mediated changes in cell behavior act in concert with exogenous mechanical forces to sculpt the bronchial tree.

INTRODUCTION

The kidney is a highly complex organ that filters fluids in the body to regulate their volume and composition. It does so, in part, using a tree-like network of collecting ducts, which forms during embryonic development via a process known as branching morphogenesis. The metanephric kidney initiates when the ureteric bud forms along the Wolffian duct and undergoes a series of repeated branching events to build a tree, the tips of which interact with renal vesicles to direct the formation of developing nephrons [1]. Branching morphogenesis is thus intimately tied to nephron number, and defects in this process can lead to congenital abnormalities that compromise renal function.

Proper renal branching depends crucially on proliferation and elevated levels of proliferation are thought to be localized to the morphogenetically-active tips of the branching ureteric tree [2]. Still, it is unclear how this spatial pattern of proliferation is developmentally patterned. Mechanical forces have been shown to regulate the morphogenesis of other branched organs, such as the lung and mammary gland [3], but the possibility that biophysical cues, such as patterned ECM stiffness, might impact renal branching morphogenesis remains ill-defined.

Here, we used microindentation tests to quantify spatial distributions of stiffness within sagittal sections of developing mouse kidneys. These distributions were then compared with patterns of proliferation along the ureteric tree in 3D reconstructions of embryonic kidneys. We then used a polyacrylamide gel system to determine if changes in substratum stiffness could control the proliferation of cultured collecting duct epithelial cells in vitro. Since disrupted Yap signaling is associated with abnormal renal branching, we also investigated the role of Yap in regulating these stiffness-dependent effects.

METHODS

Microindentation tests: We used the CellScale MicroSquisher to measure tissue stiffness along the cortical-medullary axis in developing mouse kidneys. Briefly, we obtained thick (~500 μm) sagittal sections of postnatal day (P) 4 mouse kidneys (Fig. 1A), and a 70 μm-diameter cylindrical microindenter was used to probe tissue stiffness at different points along the cortical-medullary axis (Fig 1B-C).

Embryonic kidney dissection and culture: Embryonic day (E) 13 mouse embryos were harvested from timed-pregnant CD1 mice (Charles River). Kidneys were dissected in phosphate-buffered saline (PBS) and cultured at 37°C on Nucleopore membranes in DMEM/F12 medium supplemented with 5% fetal bovine serum (FBS) and antibiotics.

Polyacrylamide gel fabrication: Polyacrylamide gels of varying stiffnesses were fabricated on glass coverslips. These gels were then functionalized with 50 μg/ml of either type I collagen, fibronectin, laminin, or type IV collagen [4].

Cell culture: Functionalized PA substrata were plated with immortalized mouse inner medullary collecting duct epithelial cells (m-IMCD3) and cultured for 48 hr at 37°C in DMEM/F-12 medium supplemented with 10% fetal bovine serum and antibiotics. In other experiments, we also used an immortalized line of mutant collecting duct epithelial cells (Lats KO cells) that lack Lats, the kinase that phosphorylates Yap and modulates its subcellular localization.

Quantifying proliferation: Proliferating cells were detected using the Click-iT EdU Imaging Kit.

Confocal microscopy: Samples were fixed using 4% paraformaldehyde and stained for either E-cadherin or Yap immunofluorescence, as well as phalloidin and DAPI. 3D microscopy of fixed samples was

performed on a Zeiss LSM 800, and 3D reconstructions were created using Imaris.

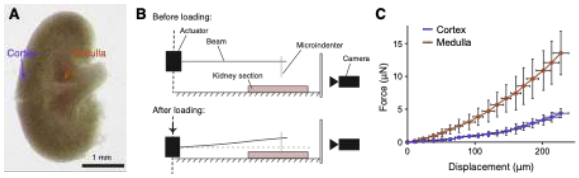

Figure 1: Microindentation tests of P4 mouse kidneys reveal differences in tissue stiffness between cortical and medullary regions of the developing kidney

RESULTS

We performed microindentation tests along the cortical-medullary axis in sagittal sections of P4 mouse kidneys (Fig. 1). We were able to detect reproducible and significant differences in stiffness between cortical and medullary regions of the kidney, with elevated tissue stiffness in more medullary regions. To determine how these regional differences in stiffness compare to distributions of proliferation along the branched network of collecting ducts, we cultured E13 kidney explants ex vivo for up to 96 hr and measured EdU incorporation to quantify spatial distributions of proliferation along the ureteric tree at different stages of branching (Fig. 2). We observed clear differences between cortical and medullary regions of the cultured explants, with substantially increased levels of proliferation in the three most cortical generations of branches.

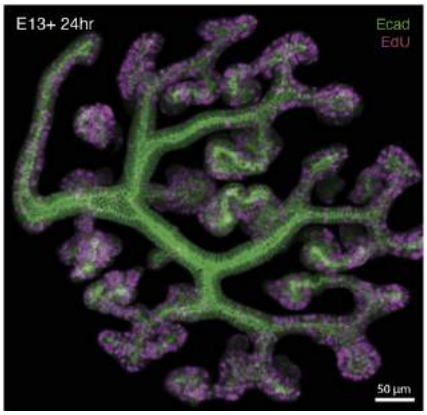

Figure 2: Proliferation is elevated in the a few generations of outermost branches within the kidney.

Taken together, these results suggest the possibility that regional differences in stiffness might regulate the pattern of proliferation within the developing ureteric tree. To test this idea more directly, we cultured collecting duct epithelial cells on PA substrata of different stiffnesses and quantified rates of EdU incorporation to determine if substratum stiffness was sufficient to modulate rates of proliferation. We found that the proliferation of collecting duct epithelial cells depends upon both substratum stiffness and ECM composition, with cells exhibiting higher proliferation on stiffer substrata on either laminin-, fibronectin-, or collagen IV-functionalized gels. On collagen I-coated substrata, however, the cells exhibited no stiffness-dependent differences in behavior. These proliferative phenotypes were accompanied by clear differences in the subcellular localization of Yap. We observed nuclear Yap in cells with elevated levels of proliferation and cytosolic Yap in cells with decreased proliferation.

To determine if Yap activity could be modulating these stiffness-dependent effects, we repeated our PA gel experiments using a mutant cell line (Lats KO), which lacks Lats (the kinase that phosphorylates Yap), resulting in elevated Yap activation. Disrupted Yap signaling altered the observed stiffness-dependent differences in cell proliferation (Fig. 3). Lats KO cells no longer exhibited low levels of proliferation on soft substrata, suggesting that changes in Yap activity underlie the observed stiffness-dependent differences in collecting duct epithelial cell proliferation.

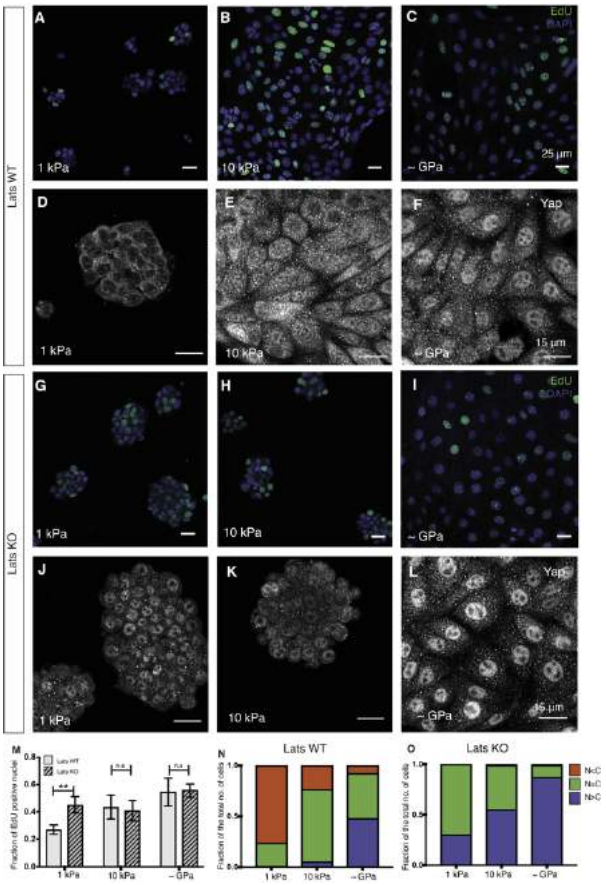

Figure 3: Disrupting Yap signaling disrupts stiffness-dependent cell proliferation for cells cultured on Laminin.

DISCUSSION

Taken together, these data suggest that differences in ECM stiffness may regulate the patterns of proliferation that sculpt the developing network of collecting ducts in the embryonic kidney. Previous work has shown that disrupted Yap activity inhibit branching morphogenesis during renal development [5], but it is unclear how these changes affect either regional differences in tissue stiffness or the patterns of proliferation that are normally present along the ureteric tree. Future work will explore how ectopic stiffening within cultured embryonic kidney explants regulates both the proliferation and branching of the developing collecting ducts.

INTRODUCTION

The biomechanics of the optic nerve head region including the lamina cribrosa (LC) and sclera is fundamental for the development and progression of glaucoma. The LC is a porous collagenous disc located in optic nerve head and it undergoes significant remodeling in the presence of the disease [1-2]. Several finite element approaches have been utilized to investigate the biomechanical response and the material properties of this region [3-4]. Although both subdomain and full geometries have been used to model the LC using finite elements, the difference between conforming mesh (based on the geometry and structure) and non-conforming mesh has not been quantified. The purpose of this study is therefore to investigate the differences between a conforming and non-conforming mesh on a small region of a human lamina cribrosa.

METHODS

A non-glaucomatous human eye was imaged using a multiphoton microscope while simultaneously conducting a pressure inflation experiment. Second harmonic generation images were collected and utilized to generate a 3D segmentation geometry of the LC. A small subdomain region was created from the segmented LC (Figure 1) and meshed using a conforming tetrahedral mesh, non-conforming hexahedral and a non-conforming tetrahedral mesh. Representative images of these meshes are shown in Figure 1B for the conforming mesh and Figure 2A & 2B for the nonconforming mesh. Element sizes were varied (coarse to fine) in each group and finite element simulations were run using identical boundary conditions, load (pressure) and material property parameters. A few locations (x, y, z coordinates) were selected to output displacement results after each simulation. These results were compared across the groups and the percent error was calculated.

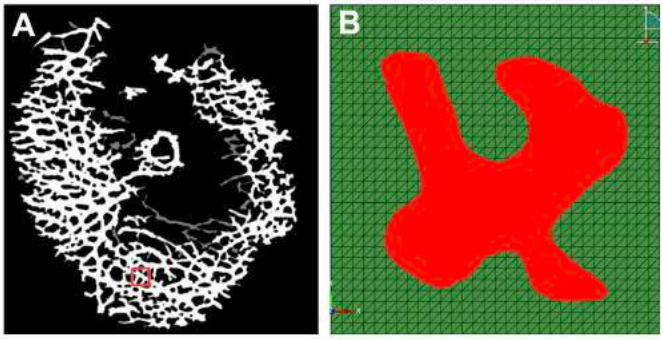

Figure 1 A small subdomain selected from human LC Panel A) a segmented human LC collagen with the subdomain shown in a red box; Panel B) conforming tetrahedral mesh of the subdomain

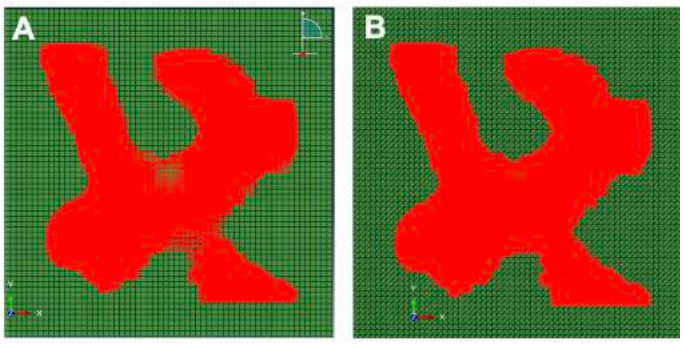

Figure 2 Representative nonconforming mesh of the subdomain Panel A) Hexahedral mesh; Panel B) Tetrahedral mesh of the subdomain

RESULTS

The mesh convergence study within each of the three groups are shown in the following figures. Figure 3 is the conforming tetrahedral mesh, Figure 4 is the nonconforming hexahedral mesh and Figure 5 is the nonconforming tetrahedral mesh. The percent error was calculated using the conforming mesh finest mesh as a reference. The conforming mesh showed the maximum of 6.21 $\pm$ 0.29 % error variation across different element size and the error was smaller than 1% for element sizes greater than 1 million. The hexahedral mesh had a maximum error of 69.76 $\pm$ 8.21% at the coarse mesh size and that of the nonconforming tetrahedral mesh was 57.83 $\pm$ 4.24%.

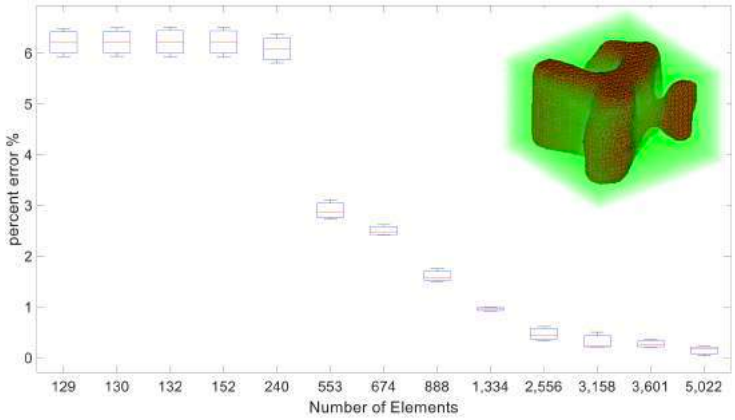

Figure 3) Conforming tetrahedral mesh plots with varying mesh size from coarse to fine. The image in the top right of panel A shows a representative 3D mesh of the LC subdomain region used in the simulations where red indicates the collagen in the LC and green illustrates the non-collagenous extra cellular matrix in the subdomain.

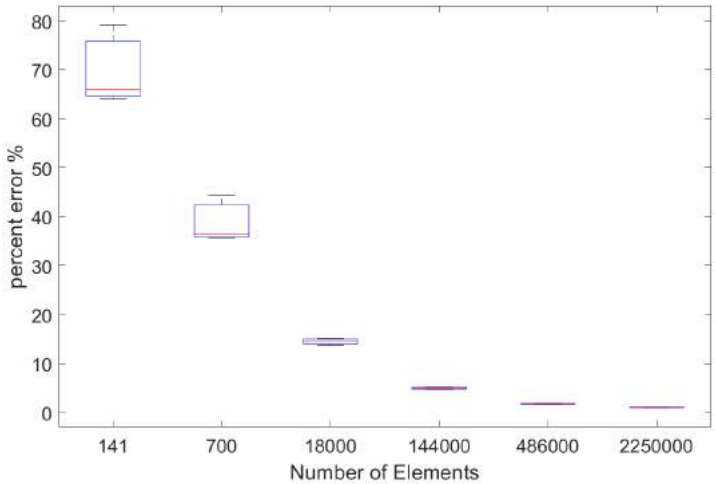

Figure 4) Nonconforming hexahedral mesh plots with varying mesh size from coarse to fine.

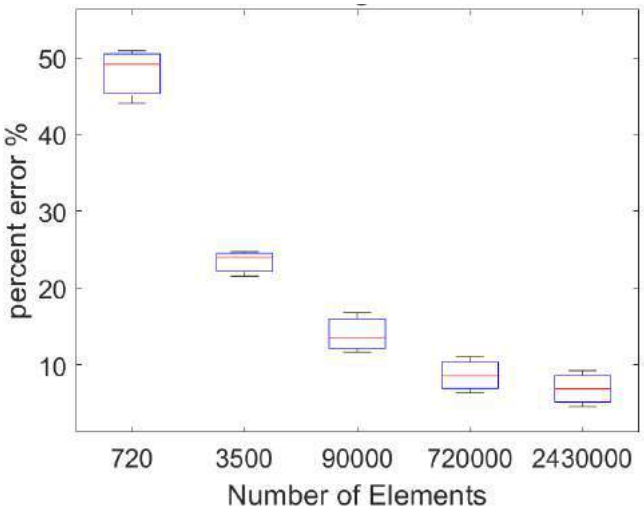

Figure 5) Nonconforming tetrahedral mesh plots with varying mesh size from coarse to fine meshes.

DISCUSSION

The non-conforming mesh simulations results in acceptable percent error values (<5%) at finer mesh sizes. While the geometry in this study was small and the conforming mesh simulations were not computationally demanding, generating conforming mesh finite element simulations for a complex 3D structures such as the LC require large computational resources and time. Therefore, mesh converged nonconforming models that result in small error can be a great alternative. We are currently using these results to estimate the degrees of freedom and total number of elements in our full LC simulations. In addition, these results are utilized to determine the subdomain size to run the full LC finite element analysis.

INTRODUCTION

Due to the extreme deformability of RBCs, they do not get critically damaged even though experiencing a significant level of shear stress. That is why the deformability of RBC has been extensively studied over the last few decades. Studies have been carried out to associate RBC deformation to several pathological alterations due to malaria [1], sickle cell anemia [2], hereditary disorders [3], diabetes [4], myocardial infarction [5], etc. Changes in the RBC membrane due to these diseases are the reason behind altered deformability. The deformability of RBC can also be altered by shear stress [6]. This is mostly due to the altered association between membrane skeletal proteins and integral proteins that serve as an anchor to connect the skeleton to the lipid membrane. Blood experiences various geometry and flow-induced stresses in blood-wetting devices. These devices include mechanical heart valves, axial and centrifugal blood pumps, ventricular assist devices (VAD), etc. High shear in these devices can damage the RBCs that can potentially be fatal. So, it is important to develop a better understanding of shear-induced damage to RBCs.

Investigating shear-induced damage of RBCs in the single-cell scale is essential for developing a numerical model for predicting cell damage. There have been several efforts to study single-cell shear-induced damage to RBCs. Polycarbonate sieves with micropores have been used to study the resistance of RBCs against mechanical hemolysis during filtration [7]. Abkarian et al. studied the RBC deformation and hemolysis in confined channels and tried to estimate hemolysis based on shear stress and exposure time using empirical correlations [8], [9].

A quantitative study of the changes in the biophysical and mechanical properties of RBC due to shear stress has not been carried out yet. In our previous study, multiscale modeling has been employed to predict hemolysis during microfiltration [10]. But microfilters are not suitable to control the shear stress on a single cell. This method will provide a more quantitative comparison between single-cell shear-induced damage simulation and experiment by utilizing the recently developed light absorption based single-cell hemoglobin, volume, membrane tension, and bending modulus measurement [11].

METHODS

Microfluidic channels with different width and length are used to control the shear stress magnitude and duration while the thickness of the channel is used to control the orientation of the RBC flowing through the channel. The devices have been made with standard photolithography and PDMS molding technique [11]. The squeezing channels have a width ranging from 1 µm to 5µm and length ranging from 10 µm to 200 µm with a fixed thickness of 3 µm to keep the RBCs in a horizontal orientation to the squeezing channel. Another set of squeezing channel has been used to mimic the spleen to check RBC viability. These channels have a high aspect ratio and smaller constriction. The width is only 0.8 µm while the thickness of the channel is 12 µm to fix the RBCs perpendicular to the squeezing channel during squeezing.

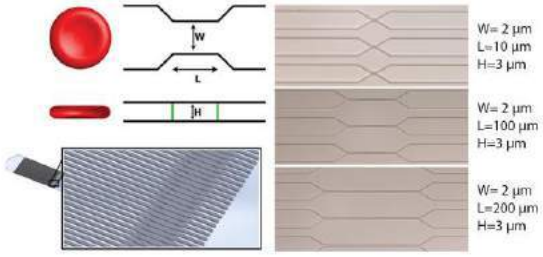

Figure 1: Design of the squeezing channels for the experiment

RBCs are prepared for squeezing by the procedure mentioned in the previous study [11] and inserted in the device with a pressure pump (Precigenome LLC, CA, USA). The RBCs are analyzed in a customized 2 LED (405 nm and 630 nm) illumination with a high-speed CMOS color camera (XIMEA CB120CG-CM). The light absorption due to the RBC has been analyzed to measure the hemoglobin content and volume of the RBC.

The D3Q19 (three dimensions with 19 discrete velocities) version of the Lattice Boltzmann Method (LBM) has been used for the simulation. Spring connected network (SN) is used as the RBC model. The immersed boundary method (IBM) is used for coupling SN and LBM.

RESULTS

The squeezing in a 3 µm wide channel with a velocity of 1.2 mm/s shows that the simulation can accurately predict the deformation and shape of the RBC in high shear flow (**Figure 1**).

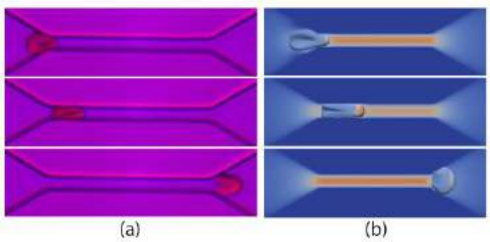

Figure 2: (a) Images captured from the high-speed recording of RBC squeezing through a narrow constriction. (b) Visualization of the numerical model of an RBC squeezing through a narrow channel

The numerical model can be used to determine the areal strain on the membrane that will be used to predict the pore size and hemoglobin release during the squeezing process. For example, **Figure 2** shows the areal strain of the RBC model during theoretical rupture as determined by comparing with the results from Abkarian et al. [8].

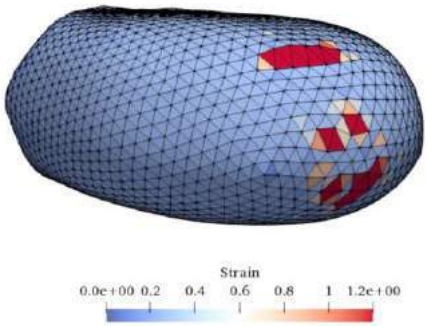

Figure 3: Areal strain predicted by the numerical model

High-speed quantitative light absorption imaging during the squeezing process shows an overall hemoglobin loss by the RBC in the microchannel.

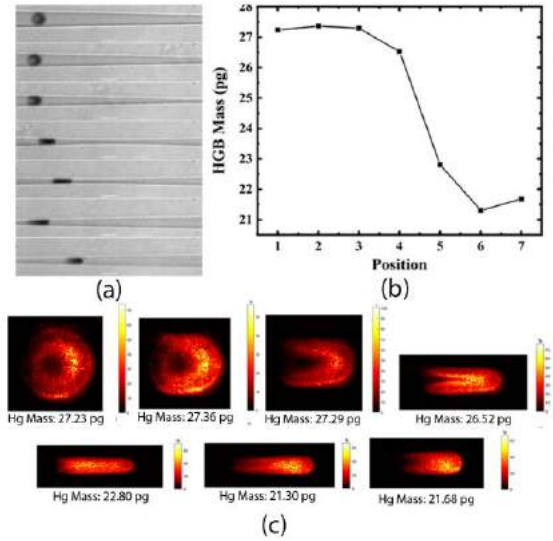

Figure 4:(a) Image sequence of an RBC squeezing through a 3 µm wide and 10 µm long channel. (b) a plot of total hemoglobin mass vs the position of the RBC as measured by quantitative light absorption imaging (c)visualization of the hemoglobin mapping for the RBC at different positions.

Healthy RBCs flowing through the spleen mimicking channel shows that healthy they can pass through them easily.

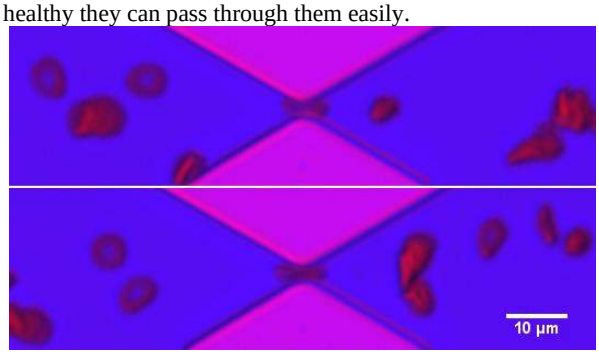

Figure 5: Healthy RBC squeezing through spleen like channel

DISCUSSION

The combined microfluidic and numerical modeling approach can be a powerful tool to predict RBC damage in shear stress. The quantitative light absorption imaging can be further used to calculate the change in RBC volume and membrane tension that will help correlate the mechanical changes to shear stress. If the numerical model can be validated for the hemoglobin loss in high shear rate cases, it can be used to simulate bulk RBC damage in medical devices.

INTRODUCTION

Aberrant wound healing impacts tens of millions of people in the US annually, with treatment costs over $20 billion dollars [1]. Problems in wound healing can occur from imbalances at any stage of healing, including prolonged and elevated exposure to growth factors and cytokines, increased mechanical tension, and altered rates of matrix degradation and remodeling. Adipose tissues and cells also appear to contribute to multiple wound healing events, both directly and indirectly. Fat grafts, for example, which initially were used to shape and contour tissue defects, were also found to reduce scarring and promote healing. The efficacy of fat grafting, however, remains unclear, as there is little clarity on what components of the graft and what underlying mechanisms are responsible for the reported improvements.

Consequently, we are investigating how the components of fat grafts (*e.g.*, adipocyte derived stem cells, pre-adipocytes, and adipocytes, influence fibroblasts, the major arbiters of matrix remodeling during wound healing. Previously, we found that 3D adipocyte spheroids secreted factors that promoted fibroblast to myofibroblast conversion as evidenced by an increase in human dermal fibroblast collagen production, contractile force generation, and cytoskeletal α-smooth muscle actin (α-SMA) [2]. This conversion appears to be through a mechanism that is independent of TGF-β1, the factor most commonly associated with driving the differentiation of fibroblasts to myofibroblasts. Here, we report on our efforts to identify what adipocyte-secreted factor(s) are responsible for myofibroblast conversion and what the implications to wound healing might be.

METHODS

3D Pre-Adipocyte and Adipocyte Spheroid Culture and Conditioned Medium Collection: Pre-adipocyte and adipocyte spheroids (each containing ~20,000 cells) were generated by growing immortalized pre-adipocyte spheroids using the standard hanging drop method. Spheroids were either maintained or differentiated in pre-adipocyte growth or differentiation medium (PGM2, PDM2) from the Lonza Bullet kit, respectively. After 10 days the growth and differentiation medium were removed, the spheroids were rinsed gently with 1X PBS, then 0.75 mL of Dulbecco's Modified Eagle Medium (DMEM) containing 0.5% fetal bovine serum, 1% penicillin/streptomycin and 0.1% amphotericin B was added to each well. After two days, this medium, termed pre-adipocyte or adipocyte conditioned medium (PCM, ACM) was collected and stored at -80^{o} C.

LEGENDplex Human Adipokine Panel: PCM and ACM were first screened with a multiplex adipokine assay in order to measure levels of common cytokines, hormones, and other factors commonly secreted by adipose tissues. Collected medium was processed and run in triplicate via flow cytometry as described by the manufacturer (Biolegend).

Heat Inactivation & Lipid Inactivation: ACM was heat inactivated by maintaining the medium at 85^{o}C for 1 hour with a benchtop hotplate. Separately, ACM was treated with Cleanascite HC to remove lipid as described by Castro *et al*. [3]. 0.5 mL of Cleanascite HC was added to Eppendorf tubes and centrifuged to remove the saline and the pellet was resuspended in ACM. ACM was then incubated at 4^{o}C overnight with gentle agitation, then centrifuged to remove the pellet of lipid-bound beads. The ACM was decanted into a separate Eppendorf tube and filtered through a 0.45 μm pore size filter to remove residual polymer particles.

Molecular Weight Fractionation of ACM: ACM was fractionated into different molecular weights using cutoff filters of 100 kDa, 30 kDa, 10 kDa, and 5 kDa (Vivaspin and Amicon). Filters were pre-rinsed and

medium was centrifuged sequentially through the filters. Each collected fraction was stored at -80 ^{o}C.

Myofibroblast Conversion Assay: Human dermal fibroblasts were plated at 20,000 cells/cm^2 in 96-well well clear-bottom, black walled plates. In triplicate, the cells were treated for 2-days with ACM that was either heat inactivate, lipid depleted, or fractionated as >100kDa, 30 -100kDa, 10-30kDa, 5-10kDa and <5kDa. Other conditions included control (0.5% FBS DMEM), and positive control (control plus 1 ng/mL TGF-β1 & 50 μg/mL ascorbic acid). After treatment, samples were rinsed, fixed, permeabilized, blocked in 5% BSA-tween solution, and incubated with a primary mouse anti-human α-SMA antibody solution followed by secondary antibody staining using a SuperBoost secondary antibody kit (ThermoFisher). Cell nuclei were labeled with DAPI α-SMA and the proportion of converted myofibroblasts was quantified by measuring fluorescence with a VarioSkan Lux multimode microplate reader.

RESULTS AND DISCUSSION

In order to determine what factor(s) in ACM but not PCM might be responsible for myofibroblast conversion, both types of conditioned medium were subjected first to an adipokine panel (Fig. 1). Differences in the secretion profile of PCM and ACM were found. PCM contained greater amounts of MCP-1, IL-6, and IL-8 than ACM, and ACM contained greater amounts of adiponectin, adipsin, RBP4, and IFN-γ (Fig. 1).

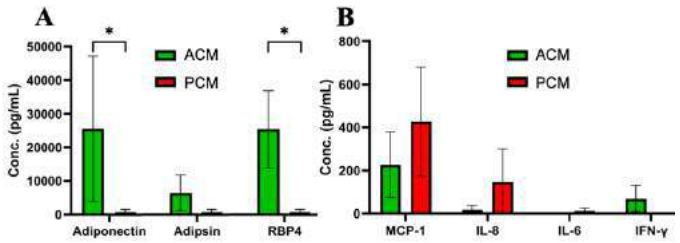

Fig. 1: (A) ACM contained high levels of adiponectin, adipsin, and RBP4, adipokines not present at detectable levels in PCM. (B) Lower levels of MCP-1, IL-8, IL-6, and IFN-γ were present differentially in PCM and ACM. Data is mean ± SD. Two-way ANOVA was conducted * p<0.05.

In parallel, a myofibroblast conversion assay was conducted on heat inactivated, lipid deleted and protein fractionated ACM (Fig. 2). It revealed that the factor(s) responsible for myofibroblast conversion is a protein between 30-100 kDa. The recombination of heat inactivated and lipid depleted fractions also did not lead to myofibroblast conversion, suggesting that lipid soluble co-factors are also not responsible (Fig. 2).

We also fractionated our positive control medium through 100 kDa and 30 kDa molecular weight cutoff filters to confirm that TGF-β1, a 25 kDa homodimer, is not retained in the 30-100 kDa fraction (Fig. 3). We found that α-SMA induction was significantly higher than baseline only in the <30 kDa fraction and not significantly different from the unfractionated positive control. These results provide more evidence that supports the notion that myofibroblast conversion is occurring through a TGF-β1 independent mechanism. Our efforts are now focused on screening several candidate molecules between 30-100 kDa and consistent with our other findings, such as adiponectin. Adiponectin is a 30 kDa protein in abundance in ACM. It also associates into trimers and other multimeric forms that are believed to have differential functions related to cell metabolism. In addition, there is evidence that adiponectin plays a role in wound healing. For example, Ezure *et al.*

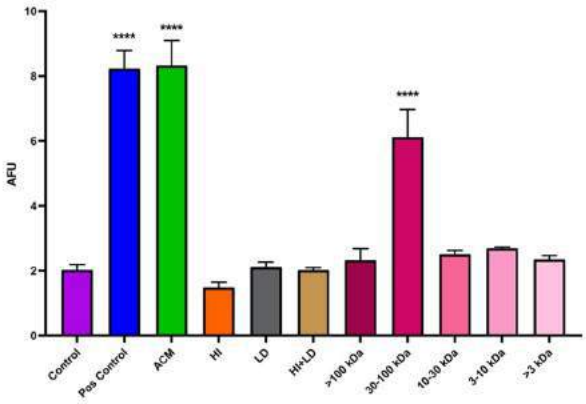

Fig. 2: Myofibroblast Conversion Assay. Fluorescently labeled α-SMA indicates that factor(s) in ACM responsible for myofibroblast conversion are proteins contained in the 30-100 kDa molecular weight fraction. Data presented as mean ± SD, one-way ANOVA conducted with Tukey Multiple comparisons test (** p<0.001).**

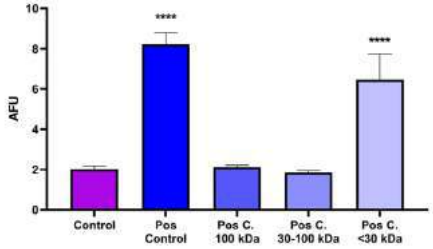

Fig. 3: Positive control fractionated medium shows myofibroblast conversion of fibroblasts from <30kDa protein fraction.

reported that adiponectin upregulates dermal fibroblast matrix production *in vitro* [3]. In contrast, Marangoni *et al.* reported that adiponectin produces anti-fibrotic effects in a mouse model [4]. Regardless, current work is focused on identifying the secreted factor and determining what role it plays in directing fibroblast activity during tissue remodeling. Such information will provide a better understanding of how adipocytes and other components of fat grafts contribute wound healing and how these different components can be optimized to provide maximum therapeutic benefit of fat-related wound healing treatment strategies.

INTRODUCTION

Cardiac tissue engineering (CTE) is a promising solution for myocardial infarction. A main strategy in CTE is the scaffold-based approach that aims to recapitulate the native extracellular matrix (ECM) with biomaterials to induce native ECM formation from cells and ultimately regenerate healthy myocardium.[1]

The native myocardium ECM consists of collagen nanofibrils and possesses a DC conductivity around 0.1 S/m.[2] Electrospinning is the most common way to fabricate nanofibrous scaffolds to mimic the ECM's submicron architecture, but the lack of electrical conductivity in most biomaterials restricts the electrical signal propagation between cardiomyocytes (CMs) and hinders tissue contractility restoration. It urges the incorporation of electrically conductive materials, including conducting polymers like polypyrrole (PPy) that possess comparative electrical conductance to metals and semiconductors.[3] Conductive nanofibers containing PPy have been investigated to deliver both the topographical and electrical cues for tissue regeneration. Though PPy-coated electrospun mats showed elevated electrical conductivity, the mechanical properties were too high for CTE. Alternatively, base biomaterials can be blended with PPy to improve the poor spinnability of PPy and balance the overall stiffness of the mat. Kai. *et al.* embedded PPy to Polycaprolactone (PCL)/gelatin electrospun fibers, whose enhanced conductivity promoted CM cardiac gene expression.[4] However, CM's contractility was not reported.

To our knowledge, this study is the first one to blend PPy with natural polymers for electrospinning. Silk fibroin (SF) is naturally derived, which is also relatively easy to be electrospun. We hypothesized that PPy would improve the electrical conductivity of the fibers while SF would increase the spinnability and soften the mechanical properties of the hybrid scaffold for CTE applications. Furthermore, we examined the biofunctional development of CMs on the PPy-SF electrospun mat *in vitro* to evaluate its potential for CTE.

METHODS

Bombyx mori silkworm cocoons were degummed, dissolved and dialyzed against distilled water. Doped-PPy was added to the 7% SF/Hexafluoro-2-propanol solution at three PPy-to-SF ratios (15:85, 30:70, 40:60) and stirred overnight. The spinneret was connected to the negative potential, and fibers were collected with a feed rate of 0.6 mL/h and a voltage of 10.5 kV. Methanol treatment was performed for β-sheet formation. Specifically, mat with PPy-to-SF ratio of 15:85, 30:70, and 40:60 was named 7%PPy15, 7%PPy30 and 7% PPy40, respectively.

Fiber morphology was view by an SEM (JSM-6701F, JEOL Asia). Mat's electrical conductivity was measured using a four-point probe machine (Signatone). The conductivity (mS/cm) is the reciprocal of resistivity as calculated by $\rho=4.25$ V/I. The Young's modulus was calculated from the linear-elastic portion of the stress-strain curve obtained from the tensile test using a table-top tensile tester (Instron).

Neonatal rat CMs (NRCMs) and human induced pluripotent stem cell-derived CMs (hiPSC-CMs) were seeded to fibronectin/gelatin-coated sterilized mats at 100,000 cells/mat. Cell viability was assessed by Live/Dead assay on D2. Cell morphology was observed using SEM. Cardiac-specific protein (Sarcomeric α actinin, Connexin 43 (CX43)) expression was assessed by immunostaining. Fast Fourier transform (FFT) analysis was conducted, where elliptically distributed pixels indicate unidirectional distribution. Mat contraction was evaluated by performing a 'Z-projection' of each beating cycle, where the mat's displacement was defined by the width of the stacked-edges. Contraction frequency was presented in beats per minute (BPM).

All the data are presented as mean ± standard deviation (SD) of the mean. One-way and two-way analysis of variance (ANOVA) was used with Tukey's post hoc correction. P-value less than 0.05 was considered

significant, where *p < 0.05, **p < 0.01, ***p < 0.001. All experiments were performed in at least triplicates.

RESULTS

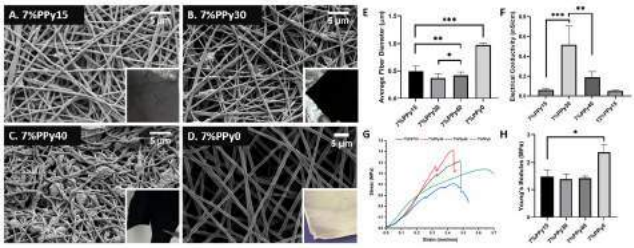

Figure 1: Chacterization of the PPy-encapsulated SF Mats. (A-D) SEM images. (E) Average fiber diameter. (F) Electrical conductivity. (G,H) Mechanical properties.

The electrospun fibers became black with reduced fiber diameters and rougher surface after blending with PPy (Figure 1A-D). A 'U' shape relationship was displayed between PPy amount and fiber diameter, where the smallest fiber diameter was observed in 7%PPy30 (0.375 ± 0.077 μm) (Figure 1E). Surprisingly, Blending PPy reduced the Young's modulus to an average of 1.437 ± 0.044 MPa, which significantly differed from that of 7%PPy0 (Figure 1H). As shown in Figure 1F, the incorporation of PPy remarkably enhanced the mat's electrical conductivity. The highest electrical conductance of 0.520 ± 0.193 mS/cm was detected in 7%PPy30.

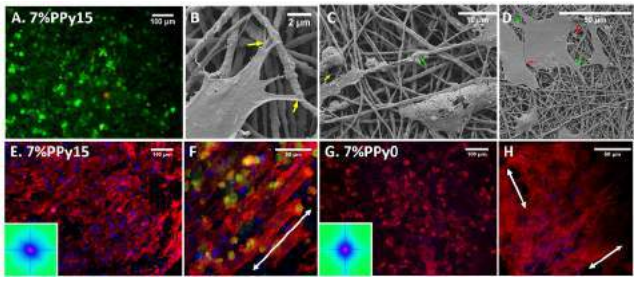

Figure 2: In Vitro Evaluation of the Mats. (A) Live/Dead assay. (B-D) SEM images. (E-H) Immunostaining of cells on mats. Red: Sarcomeric α actinin; Green: CX43; Blue: Nuclei.

PPy-encapsulated SF fibers were biocompatible as high cell viability was observed (Figure 2A). NRCMs anchored cellular process on the PPy-encapsulated SF fibers (Figure 2B yellow arrows). Regarding cell-cell interaction, direct contacts were established between adjacent cells (Figure 2D red arrows), while pseudopodia were developed and bridged remoted NRCMs (Figure 2C green arrows). Though the spindle-like NRCMs on 7%PPy15 had smaller dimensions (Figure 2F) than those on 7%PPy0 (Figure 2H), the sarcomeres were organized anisotropically in 7%PPy15 as a more polarized oval FFT pattern was shown (Figure 2E). In result, the periodic z-lines found on 7%PPy15 were more unidirectional than those on 7%PPy0 (white arrows in Figure 2). CX43 was barely detected from the NRCMs on 7%PPy0 (Figure 2H), but expressed on mats with PPy (Figure 2F).

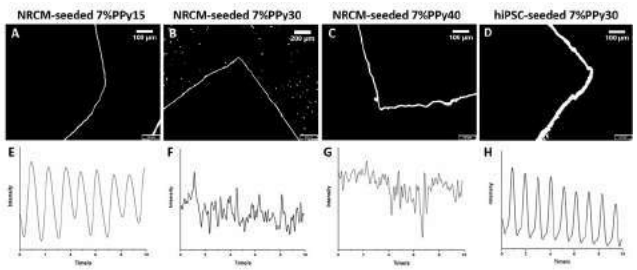

Figure 3: Contraction of the CM-seeded Mats.

All mats did not contract till D5 that 7%PPy15 mat started to show slight consecutive contraction, which became more regular on D7 with a BPM of 45 (Figure 3E). Mats with higher PPy amounts did not show spontaneous contraction but vibrations (Figure 3F,3G). In addition, no contraction was observed from 7%PPy0. Interestingly, for hiPSC-CMs, regular contractions were observed on 7%PPy30 (Figure 3H) with a larger mat displacement than that of NRCM-seeded 7%PPy15.

DISCUSSION

Hybrid electrospun fibers have been gaining interests to advance the scaffold's functionalities. Blending serves as an alternative method to avoid the notable increase of mat's stiffness from coating and the masking of the fiber's nano-topographical cue. To date, PPy has seldom been blended with other biomaterials for electrospinning. Kai *et al.* blended PPy with PCL and gelatin and obtained conductive fibers (0.013~0.37 mS/cm).[4] This study demonstrated that SF as a natural material is another suitable base biomaterial that the hybrid fiber's electrical conductivity was further enhanced to 0.05~0.52 mS/cm (Figure 1F), which falls in the range of that in native myocardium (0.03~6.2 mS/cm).[5] Apart from conductivity, an ideal scaffold should also possess suitable mechanical properties for CMs. Conductive materials are commonly brittle, which could inhibit CM contraction. Our PPy-SF electrospun mats presented an average Young's modulus closer to the desired range for myocardial regeneration than other reported studies (16.8 ± 1.9 ~ 266.7 ± 17.3 MPa). We assumed that the mechanical properties of the composites could be further improved by incorporating softer biomaterials like gelatin.

Though an increased amount of PPy would enhance the electrical property of the scaffold, we found that a moderate amount of PPy (7%PPy15) support CM's functional development better. It is interesting to find that CMs organized anisotropically on 7%PPy15. The alignment of the cardiac tissue regenerated *in vitro* is usually controlled by substrate topography, electrical stimulations, and mechanical loading.[34] Similar to our results, Wang *et al.* reported locally aligned CMs on conductive polyaniline-poly(L-lactic acid) mats.[6] In addition, the most powerful contraction and synchronous electrophysiology were observed from the NRCM-seeded 7%PPy15 mat and hiPSC-seeded 7%PPy30 mat. The different preferences of NRCMs and hiPSCs could be attributed to the species differences. However, both results indicated that the conductive mats would improve CM contraction.

In conclusion, the PPy-encapsulated SF electrospun mats provide nanofibrous features, enhanced electrical conductivity, and suitable mechanical properties for cardiac patches, which supported cell-matrix interaction. CMs from different species showed different preferences on mat that 7%PPy15 best-supported NRCM alignment, enhanced cardiac-specific protein expression, and induced strong contractions, while hiPSC-CMs developed the best contractility in 7%PPy30. Hence, this study demonstrated that PPy-encapsulated SF mat holds great potential as an electroactive scaffold for cardiac tissue regeneration.

INTRODUCTION

Directed cell migration is a crucial step in cancer metastasis, a leading cause of death in cancer patients. During this step, cancer cells are capable of sensing and deciphering either chemical or mechanical signals in determining their migratory behaviors in the microenvironment. [1-3] However, the tumor microenvironment is highly complex. Multiple environmental signals are integrated, including upregulated growth factors, reorganized extracellular matrix (ECM) components, and abnormal interstitial fluid pressure (IFP) variance. [2-3] Although the signals to promote directed cell migration have been widely recognized, the integrated effects of the multiple signals are barely understood.

While a concentration gradient of a growth factor such as TGF-β has been widely recognized in guiding the cell movement—chemotaxis, interstitial flow (IF) also plays an essential role in directed cell migration. [2-3] Recent studies recognized that cancer cell directed migration is regulated by interstitial flow through either cell self-secreting chemokine detection or activation of Focal Adhesive Kinases (FAK) pathways. [3] Moreover, interstitial flow also involves the transport of chemical signals, shaping an abnormal signal environment. [4] Due to distinct features of the tumor microenvironment, IFP could be spatially varied, causing absurd interstitial flow. Nevertheless, it is unclear how interstitial flow influences developing the signal environment in the tumor microenvironment and how cells respond to the integrated signals.

In the present study, we investigated the convection-driven signal environment to address how the signal environment is shaped by integrating interstitial flow with TGF-β concentration gradient. Also, we studied how the cells respond to the integrated signal environment. Our driving hypothesis is that cells determine their migration behaviors from a balance between environmental stimulation and a cell's innate ability to sense and process the signal. We evaluated the hypothesis by engineering the microenvironment *in vitro* to develop a TGF-β concentration gradient presenting interstitial flow.

METHODS

In vitro microfluidic platform comprising center, source, and sink channels was used to engineer microenvironment. The harvested cells were mixed with type I collagen and loaded into the center channel, while the source and sink channels were filled with medium. We used KIC cells, a murine pancreatic cancer cell line isolated from a genetically engineered mouse model of pancreatic adenocarcinoma. We engineered the microenvironment by imposing different concentrations of TGF-β between source and sink channels resulting in a concentration gradient in the center channel. Different hydraulic pressure levels were also applied between the source and sink channel, causing interstitial flow in the center channel. While TGF-β concentration at the source channel was consistently higher than the sink channel, interstitial flow direction was applied either 1) source to sink defined as a *parallel flow* or 2) sink to source as a *counter flow*. (**Figure 1**)

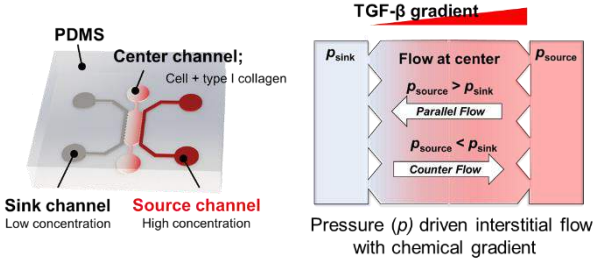

Figure 1: An engineered convection-driven signal environment platform.

We captured migrating KICs using a live-cell time-lapse imaging system inverting a stage top incubator. The directed migration was characterized by directional accuracy represented as directional accuracy index (DAI). We measured DAI = cos θ where θ is an angle between the net displacement of a trajectory and the environmental signal direction. Cells randomly migrate without any signal, showing the spread of DAIs is varied from -1 to 1, where the data points are distributed following cosine shape. The median of the distribution was used as a representative DAI of each control group.

RESULTS

Chemical signals are transported in the tumor microenvironment through both advection and diffusion. [5]

$$\frac{\partial C_i}{\partial t} = \nabla \cdot (D_{eff} \cdot \nabla C_i - v_f \cdot C_i) \quad (1)$$

Here, we considered two different scenarios: i) parallel flow from the source to the sink, and ii) counter flow from the sink to the source, where a chemical signal concentration is higher in the source and lower in the sink. At a steady state, the gradient profiles are non-linear exponential varied by the flow direction and the Péclet number, whereas a linear gradient is developed without the flow. Compared to the linear chemical gradient, two distinct changes were observed in the non-linear chemical gradient. First, the gradient becomes shallower in most regions, except the edge near the boundaries. When the parallel flow was applied, the flow carried the signal molecules and helped to deliver them, increasing the background concentration. Contrarily, the background concentration in the counter flow applied signal environment was relatively low.

The convection-driven signal environment simultaneously exposes both non-linear chemical gradient and interstitial flow to the cells. To interrogate the combined signals' effect, we decoupled those by considering cells' physical detection limit in sensing the chemical gradient. Many types of cells, including cancer cells, are capable of sensing shallow gradients. [6] However, a cell's ability to sense spatial gradient signals is limited due to physical constraints from the cell surface receptor-ligand dynamics and molecule diffusion. Indeed, *Dictyostelium* and cancer cells have recently elucidated to sense as low as ~1% of concentration differences across the cell body. [6-7] Accordingly, we examined the chemical signal environment, whether it satisfies cells' sensing capacity or not. The percent change of the chemical concentration across the cell body was determined as [7]

$$\bar{P}\,[\%] = \frac{ga'}{\bar{c}} \quad (2)$$

Consequently, we decoupled the integrated signal environment by suggesting a region where a chemical gradient effect is negligible with $\bar{P}$ below the cells' physical detection limit (~1%). It implies that the cells cannot sense the chemical gradient to enhance their directional accuracy.

To verify the suggestion above, we investigated cellular response to the integrated signal environment. We analyzed cell trajectories by separating two regions where the percent change is **(i)** above the cell's physical detection limit ($\bar{P}$ > ~1%) and **(ii)** below the limit ($\bar{P}$ < ~1%). (**Figure2A and B**) In the baseline experiments, cells were guided toward either TGF-β gradient (∇T) or upstream direction of interstitial flow (V_f) showing significantly biased DAI distribution toward 1. Remarkably, we observed that KIC cells exposed by the convection-driven TGF-β gradient showed different responses depending on the environmental condition where the physical detection limit for both parallel and counter flow conditions. In both flow directions, cells significantly lost their directional accuracy to the TGF-β gradient at the region (ii) where the TGF-β signal environment does not satisfy the cells' physical detection limit. (**Figure2C and D**) Furthermore, the bias effect induced by the flow signal was eliminated when the background concentration of TGF-β was higher in parallel flow, suggesting that the cell's innate capability in signal processing might compete for chemical and mechanical signals, although further research needs to be performed.

DISCUSSION

The present results elicit an effect of convection on cellular sensing precision for directed cell migration. We evaluated the effect of the complex signal environment by physically decoupling the signals. The flow-applied signal environment alters the TGF-β concentration profiles in non-linear exponentials, where the cells experience the shallow gradient close to the physical detection limit. The cells' movement was highly biased even with the shallow gradient only when they were with the signal above the cells' detection limit. This study provides a novel insight for understanding the complex signal environment inducing directed migration based on quantitative approaches by using an *in vitro* engineered microenvironment.

SUBSTRATUM STIFFNESS MODULATES THE MORPHOLOGY AND PROLIFERATION OF PRIMARY CORNEAL KERATOCYTES IN RESPONSE TO PDGF-BB

INTRODUCTION

The cornea is the soft transparent tissue located at the anterior aspect of the eye, which helps bend light towards the retina [1]. It contains three distinct cellular layers, but the stromal compartment accounts for the majority of the thickness. The stroma has a highly organized extracellular matrix (ECM) that consists of lamellae of aligned type I collagen fibrils [2] and promotes the transparent optical properties of the tissue [3].

A population of cells called corneal keratocytes maintain this highly ordered ECM [3], but following injury or refractive surgery, damage to the cornea can cause growth factors, such as transforming growth factor beta-1 (TGF-β1) and platelet derived growth factor-BB (PDGF-BB) to be released into the stromal space [4]. PDGF-BB has been shown to promote the motility and proliferation of corneal keratocytes [5]. However, the cornea also stiffens substantially following an injury [6], and previous work in our group has shown that the TGF-β1-mediated myofibroblastic activation of corneal keratocytes depends on substratum stiffness [7]. But it is unclear if keratocyte behavior in response to other growth factors, such as PDGF-BB, is similarly modulated by changes in stiffness. Here, we used a polyacrylamide (PA) gel system to determine whether changes in substratum stiffness modulate the proliferation and motility of primary corneal keratocytes treated with PDGF-BB.

METHODS

PA substrata with an elastic modulus of either 1 kPa (soft) or 10 kPa (stiff) were fabricated to mimic the mechanical properties of either normal or fibrotic corneal tissue. The gels were then functionalized with unpolymerized type I collagen.

Primary rabbit corneal keratocytes (NRKs) were harvested from rabbit eyes, as described previously [8], plated on either the PA substrata or collagen-coated glass coverslips, and cultured in defined serum-free media in either the presence or absence of PDGF-BB.

We used a freeze injury model to assay changes in keratocyte motility [9]. Briefly, a circular wound, approximately 1.5 mm in diameter, was created by holding a liquid nitrogen-cooled aluminum rod against the underside of the culture dish. In some samples, the media was supplemented with PDGF-BB and samples were then placed in a stage-top incubator, where images were captured at 1-hour intervals for 4 days. In other experiments, keratocytes were treated with PDGF-BB for 72 hours before fixation. Fixed cells were then stained with phalloidin and DAPI, to stain F-actin and nuclei, respectively. We also used the Click-iT EdU Imaging Kit to quantify rates of keratocyte proliferation in both the presence and absence of PDGF-BB. Confocal images of fixed samples were captured on a Zeiss LSM 800, and quantitative image analysis was performed in ImageJ.

RESULTS

To determine if changes in stiffness affect the motility of cultured keratocytes in response to PDGF-BB, we created freeze injuries on both soft (1 kPa) and stiff (10 kPa) PA substrata, as well as collagen-coated glass coverslips (~GPa). In both the presence and absence of PDGF-BB, cells surrounding the decellularized area migrated into the wound over a 96 hr period. PDGF-BB-treated cells migrated further into the wound and exhibited faster migration speeds than their counterparts in serum-free conditions, as assayed by both the tracked displacements of individual cells, as well as the motion of the leading edge of the wound. We did not, however, observe a stiffness-dependent effect in the motility of the PDGF-BB-treated cells.

We also quantified EdU incorporation in NRKs cultured on substrata of varying stiffnesses in both the presence and absence of PDGF-BB (Fig. 1). Cultured keratocytes were pulsed with EdU 72

hours prior to fixation and stained for EdU and DAPI fluorescence. As expected, cells in serum-free conditions exhibited negligible amounts of proliferation on substrata of all stiffnesses (Fig. 1A, 1C). When treated with PDGF-BB, however, the NRKs proliferate at significantly higher rates in a stiffness-dependent manner, with cells on the stiffest substrata proliferating at the highest rate (Fig. 1B, 1C).

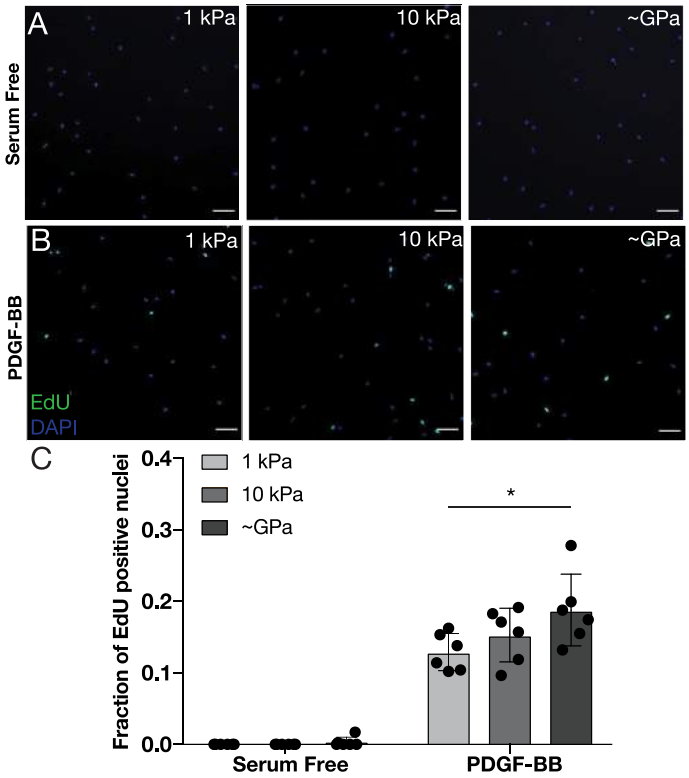

Figure 1: Quantifying keratocyte proliferation on substrata of varying stiffness. Wide-field fluorescence images of NRKs (A) without and (B) with PDGF-BB (C) Quantification of rates of EdU incorporation, scale bar = 100 µm.

Lastly, we analyzed the morphology of PDGF-treated keratocytes cultured on substrata of varying stiffnesses (Fig 2). In serum-free conditions, the NRKs retained a branched, dendritic morphology, indicative of a quiescent keratocyte phenotype (Fig. 2A). Treatment with PDGF-BB, however, promoted striking changes in morphology, as the cells spread out and became more elongated in the presence of this growth factor (Fig. 2B). The PDGF-treated keratocytes also displayed stiffness-dependent differences in morphology, with cells on the stiffest substrata exhibiting the largest cell areas and adopting more highly elongated geometries (Fig. 2C, 2D).

DISCUSSION

Taken together, these data suggest that PDGF-BB-driven changes in keratocyte morphology and proliferation depend on substratum stiffness, in a manner similar to the stiffness-dependent myofibroblastic activation of keratocytes in response to TGF-β1 [7]. PDGF-BB promoted an increase in the motility of cultured keratocytes, consistent with previous studies [5], but we did not detect any stiffness-dependent differences in their ability to repopulate a decellularized wound in vitro. Previous work has suggested that keratocytes treated with PDGF-BB exhibit similar phenotypes in both compressed and uncompressed 3D collagen gels, despite the differences in the mechanical properties of these matrices [5]. Here, however, our use of a polyacrylamide gel

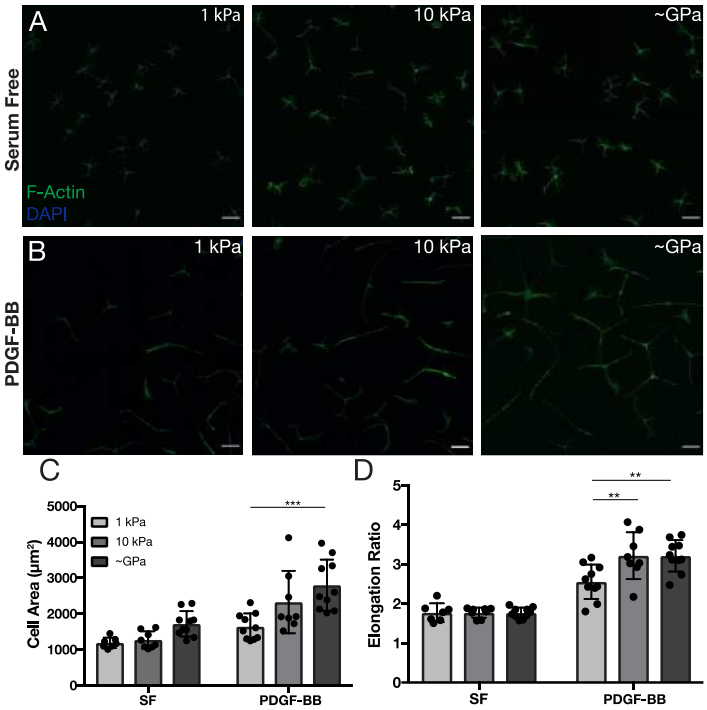

Figure 2: Wide field fluorescence images of phalloidin and DAPI staining in keratocytes cultured on substrata of different stiffness and fixed after 5 days. Cells were cultured either in the (A) absence or (B) presence of PDGF-BB. Scale bar – 100 µm. Quantification of (C) cell area, (D) cell elongation. A two-way ANOVA with a Tukey post-hoc test was used to evaluate significance among groups. (*, p < 0.05; **, p < 0.01; ***, p < 0.001; ****, p < 0.0001; n.s – not significant).

system allowed us to decouple ECM composition from substratum stiffness – two variables that remain coupled in 3D collagen matrices – and we observed striking stiffness-dependent differences in the proliferation and morphology of NRKs treated with PDGF-BB. It is not clear how corneal keratocytes might be detecting these changes in stiffness, and it would be interesting to determine how the traction forces exerted by these cells might (or might not) be regulated by changes in the stiffness of their microenvironment.

CURVATURE SENSING IRSP53 IS CRITICAL FOR MIGRATIONAL PERSISTENCE IN CELLS CRAWLING ON SUSPENDED NANOFIBERS

INTRODUCTION

The Insulin Receptor tyrosine kinase Substrate protein of 53 kDa (IRSp53) is a well-known regulator of cell membrane curvature and is posited to act as an adapter protein, linking the membrane deformations at the cell boundary to changes in the cytoskeletal contractility [1]. Consequently, previous studies have highlighted that the abrogation of IRSp53 leads to impaired protrusive activity at the cell membrane and impeded migration dynamics [2]. However, the role played by IRSp53 in linking the changes in cytoskeletal contractility to the migration cycle remains poorly understood. Additionally, these prior studies have been primarily conducted on flat, 2D surfaces which do not recapitulate the fibrous nature of the extracellular matrix (ECM) *in vivo*.

Here, we used suspended nanofiber matrices to investigate the role of IRSp53 in the migration cycle in IRSp53 knockout (KO) and wild type (WT) U251 glioma cells, which is initiated by the extension of protrusions and subsequent establishment of contractility. We selected two fiber diameters: 135 nm (high curvature) and 500 nm (low curvature) which match reported *in vivo* ECM fiber dimensions [3]. While our results confirmed the role of IRSp53 in limiting both cell protrusive and spreading behavior, we find a surprising association between IRSp53 and cell contractility in mediating the nucleus shape. IRSp53 depletion reduced cell contractility and led to low correlation between nucleus and cell body during migration causing both reduced migration rates and migratory persistence.

METHODS

The non-electrospinning Spinneret based Tunable Engineered Parameters (STEP) method was used to manufacture the fiber networks [4]. Briefly, polystyrene (PS, Scientific Polymer Products, Ontario, NY) of ~2×10^6 g/mol molecular weight was dissolved in xylene (Thermo Fischer Scientific, Pittsburgh, PA) at 6% (w/w) concentration and 10% (w/w) concentration to prepare the solutions for spinning the ~135 nm and ~500 nm diameter fibers respectively.

U-251 cells were obtained from the Japanese Collection of Research Bioresources Cell Bank. The IRSp53 knockout (KO) were generated by the CRISPR/Cas9 system, as described previously [5]. Cells were cultured in high glucose DMEM (Thermo Fisher Scientific) supplemented with 10% bovine calf serum (Thermo Fischer Scientific). Prior to seeding the cells, the fibers were coated with 4 µg/ml Fibronectin (Invitrogen, Carsbad, CA) for 3 hours. Cells were imaged using an AxioObserver Z.1 (with mRm camera) microscope (Carl Zeiss, Germany). Statistical analysis of the data was performed using RStudio (RStudio, Boston, MA) and One-way analysis of variance (ANOVA) with the Tukey test was used to test for statistical significance.

RESULTS

We first investigated the role of IRSp53 in modulating protrusive dynamics on suspended fibers. To this end, we deposited large diameter "base fibers" orthogonal to smaller diameter "protrusive fibers (**Figure 1A**). This configuration of contrasting fiber diameters constrains bulk cell body migration along the base fiber allowing us to investigate individual protrusions along the protrusive fiber. We found that IRSp53 KO cells exhibited protrusions of similar length to the WT cells (**Figure 1B**) but took significantly longer to reach the same maximum protrusion length as the WT cells (**Figure 1C**). Cells sense the suspended fibers by *coiling* (wrapping around the fiber axis) at the protrusion tip [6]. *Coiling* occurs in a cycle with the *coil* width increasing, reaching a maximum value and finally decreasing (**Figure 1D**). We quantified the maximum *coil* width and found that KO cells exhibit diminished *coil* width compared to the WT cells (**Figure 1E**).

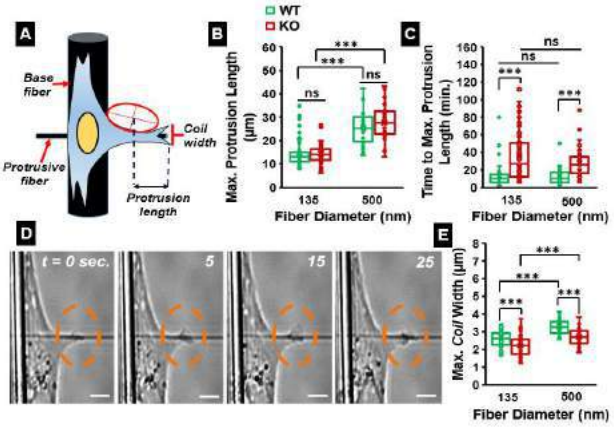

Figure 1: IRSp53 knockout impairs protrusive activity and 3D *coiling* at protrusion tip. (A) Schematic of the fiber network used to quantify protrusive activity. n = 38, 50 for WT and KO cells respectively on each fiber diameter. Quantification of (**B**) maximum protrusion length and (**C**) time taken to reach maximum length**. (D)** Representative phase images showing a typical *coiling* cycle (scale bars are 5 μm). Dashed orange circles show *coiling*. (**E**) Quantification of the maximum *coil* width. n = 30 for both cell types.

We naturally inquired if the altered protrusive activity was connected with cell shape and cytoskeletal contractility. We found that on the flat surface, KO and WT cells both spread at a similar rate and attained equivalent final circularity values (**Figure 2A**). In contrast, on the suspended fibers, the WT cells appeared to spread significantly faster than the KO counterparts and reached a lower steady state circularity signifying elongated cells (**Figure 2B**). Using our nanonet force microscopy (NFM) platform [7, 8] which enables quantification

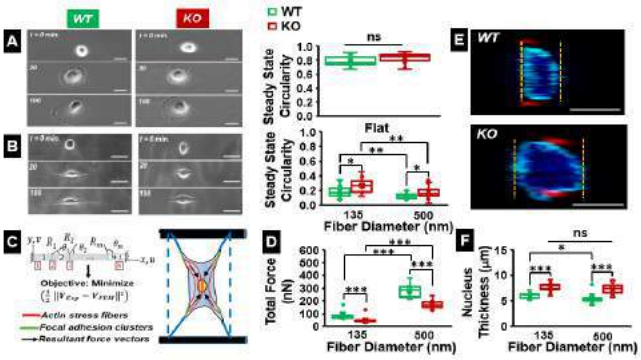

Figure 2: IRSp53 knockout results in impaired contractility. of single-cell forces (**Figure 2C**), we found that the KO cells exerted lower forces than WT (**Figure 2D**) ultimately translating to thicker nucleus (**Figure 2E, F**).

Finally, we investigated if the changes in protrusive activity and contractility resulted in differences in migration dynamics. We found that on both the flat surface and suspended fibers, the KO cells exhibited lower migration speed and persistence of motion (**Figure 3A.i,ii**). Intriguingly, in case of the KO cells, the nucleus displacement lagged behind the centroid whereas in contrast, the WT cells exhibited synchronous nucleus-centroid displacement (**Figure 3B-D**).

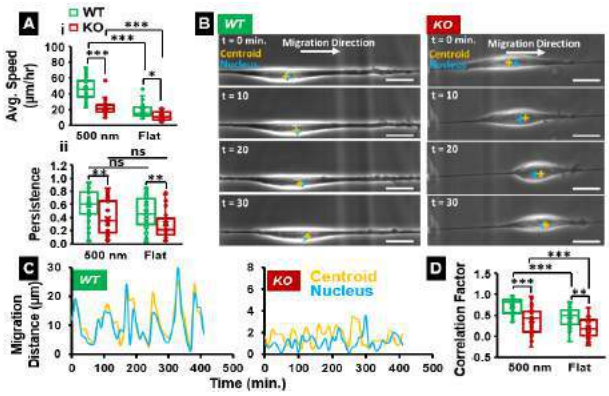

Figure 3: IRSp53 knockout hinders migration dynamics. (A) Quantification of (i) migration speed and (ii) persistence of WT and KO cells on suspended fibers and flat surface. **(B)** Representative phase images showing nucleus (in blue) and centroid (in yellow) tracking for both WT and KO. Scale bars are 25 μm. **(C)** Representative centroid and nucleus profiles during migration for WT and KO cells. **(D)** Quantification of the average correlation factor between nucleus and centroid. n = 35 for each category.

DISCUSSION

In this study, we investigated the role of IRSp53 in linking protrusive activity at the cell membrane to cytoskeletal contractility and resulting migration dynamics on ECM-mimicking suspended fibers.

While previous studies on flat, 2D surfaces have shown that IRSp53 abolishment leads to reduced protrusion length, we find that on ECM-mimicking suspended fibers, the protrusion speed rather than the length is impaired. Furthermore, given that IRSp53 KO has been linked with reduced invasive potential, the lower *coil* width at the protrusion tip concurs with our previous work, in which we have demonstrated a correlation between invasive capacity and *coil* width [6]. Previous studies have also yielded contrasting results regarding the influence of IRSp53 on cell spreading dynamics. Here, we find that IRSp53 KO leads to slower spreading dynamics on suspended fibers and a more rounded steady state morphology compared to WT, differences which are not captured on a 2D substrate. Furthermore, we report, for the first time, that IRSp53 KO results in a change in the nucleus shape which prompts the intriguing possibility of an indirect link between IRSp53 and the gene transcription landscape. In addition to the altered nucleus shape, we find that IRSp53 KO results in an impairment of the nucleus-cytoplasm coupling that alters migration dynamics.

INTRODUCTION

Sophorolipids are biosurfactants derived from non-pathogenic yeasts currently being investigated for anti-cancer applications [1]. Synthesis of these drugs is relatively simple, high-yield, and extremely cost-effective, which would make them a promising alternative to traditional chemotherapeutics, pending their success in preliminary drug screening. Traditionally, these screenings are performed in 2D culture systems due to their simplicity and throughput. However, for more advanced screening, sophisticated models are required to capture the complexity of the 3D microenvironment. Indeed, screening with 2D tumor models, lacking a 3D context, has been implicated in the high percentage of investigated drugs that later fail in clinical trials [2]. Multicellular tumor spheroids (MCTSs) are a promising 3D platform that better mimic *in vivo* structure and pathophysiologic gradients. Previously, our lab has used Optical Coherence Tomography (OCT), a non-destructive structural imaging modality, to assess 3D morphologies of MCTSs formed (via liquid overlay) either with or without the addition of Matrigel (solubilized basement membrane derived from mouse sarcoma). We showed that Matrigel addition shifted aggregate morphology from 2.5D disk-like aggregates to more spherical 3D aggregates **(Fig. 1A & B)** [3].

The aim of this study is to assess the anti-cancer activity of two novel sophorolipid candidates in *in vitro* tumor models of increasing dimensionality - 2D monolayers, 2.5D disk-shaped aggregates, and 3D spheroids - to explore the impact of model morphology on drug efficacy. Additionally, the efficacy of these candidate sophorolipids will be benchmarked against a gold standard chemotherapeutic – Paclitaxel. By calculating the half maximal inhibitory concentration (IC_{50}) for each of the tumor models, we hope to decipher how the dosing changes with *in vitro* tumor model dimensionality, as we work toward more predictive *in vitro* tumor models and explore more cost-effective alternatives to traditional chemotherapeutics.

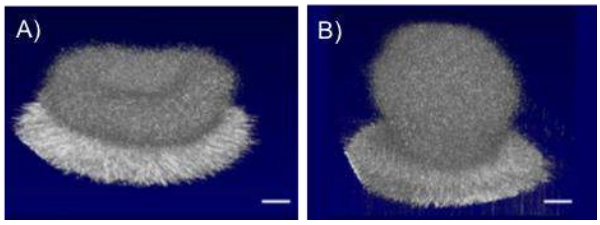

Figure 1: Representative OCT images of (A) Matrigel (-) 2.5D aggregates and (B) Matrigel (+) 3D spheroids, both prepared with M231 cells. Scale bars = 100µm.

METHODS

Sophorolipid ethyl ester diacetate (ESL) and Lactonic/Acidic sophorolipid (LSL/ASL) (ratio 97:3) were synthesized following previously established procedures [4]. Briefly, both sophorolipid mixtures was synthesized by use of *C. bombicola* yeast fermentation under conditions of glucose/oleic acid. ESL was generated from this original mixture via a one-pot reaction with Novozyme 435. To assess cancer specificity, 2D monolayers were prepared using healthy breast epithelial fibroblast controls (CCD-1065Sk) or triple-negative breast cancer cells (MDA-MB-231) by seeding $1x10^4$ cells/well in flat-bottom 96-well plates, and culturing for 24 hours prior to drug-addition. The effect of model dimensionality on drug resistance was assessed by preparing 2.5D aggregates and 3D spheroids using liquid overlay, in which breast cancer cells were seeded ($2.5 x10^4$ cells/well) in non-adherent U-shaped 96-well plates and cultured for 4 days either with or without the addition of 5% Matrigel, respectively [5]. Following 12 hours of drug exposure, samples were treated with

CCK8 metabolic assay and absorbances were measured via spectrophotometer. IC_{50} values were calculated by dividing the absorbance of drugged wells by the absorbance of untreated controls. Next, therapeutic index (TI) was calculated using **Equation 1** to provide a quantitative measure of the efficacy and relative safety of the tested drugs, where a higher TI indicates greater toxicity to cancer cells than neighboring healthy cells.

$$TI = LD_{50}/ED_{50} \qquad \textit{(Equation 1)}$$

The IC_{50} value for the drug on the healthy fibroblasts in 2D monolayer culture was used as the mean lethal dose (LD_{50}), while the IC_{50} value for the drug on a given model was used as the mean effective dose (ED_{50}).

RESULTS

Cell aggregates exhibited higher IC_{50} values in 3D models when compared with both 2.5D and 2D models for all drugs tested, indicating substantially higher drug resistance with greater model dimensionality **(Table 1).** IC_{50} values in 3D were ~4x, 7x, 15x those in 2D monolayers for Paclitaxel, ESL, and LSL/ASL, respectively. ESL was found to be approximately twice as cytotoxic as LSL/ASL in both the 2.5D and 3D MDA-MB-231 models. Both SLs required a ~2-3x higher dose than clinically-used Paclitaxel for nearly all conditions investigated. ESL was the only tested drug that showed cancer-specificity, with a higher IC_{50} value for the healthy fibroblasts than the cancer cells in 2D.

Lastly, we calculated and compared a relative TI for each drug at each model morphology (**Figure 2**). ESL showed the greatest therapeutic index in both 2D and 2.5D models, outperforming LSL/ASL and, notably, Paclitaxel. ESL also showed a comparable TI to Paclitaxel in 3D models, while LSL/ASL showed a poor TI in 3D models.

Table 1: Summarized IC_{50} values for all tested conditions, which revealed increased drug resistance in 3D models, and increased cytotoxicity in ESL over LSL/ASL.

Condition	*Paclitaxel* IC_{50}	*ESL* IC_{50}	*LSL/ASL* IC_{50}
2D monolayer fibroblast control	*15μg/mL*	*36μg/mL*	*14μg/mL*
2D monolayer	*15μg/mL*	*26 μg/mL*	*25 μg/mL*
2.5D aggregate	*54μg/mL*	*48 μg/mL*	*90 μg/mL*
3D spheroid	*65μg/mL*	*180 μg/mL*	*380 μg/mL*

DISCUSSION

Our goal was to provide preliminary data to suggest eventual use of these sophorolipid candidate drugs as a more affordable alternative for clinical interventions. Our data show that synthetically-modified ESL is generally more cytotoxic than LSL/ASL, but its efficacy falls short of clinically-used Paclitaxel, while also demonstrating significant cancer-specificity in 2D models. Taken together, these findings are extremely promising for potential future clinical use of these sophorolipids in cancer treatment.

One of the most striking findings of our study was the influence of model morphology on drug resistance. For all drugs tested, we observed significantly higher IC50 values for 3D models compared to both 2.5D and 2D models, indicating substantially higher drug resistance with increasing model dimensionality. The large IC_{50} differences for the same drug between 2D-2.5D-3D models highlights

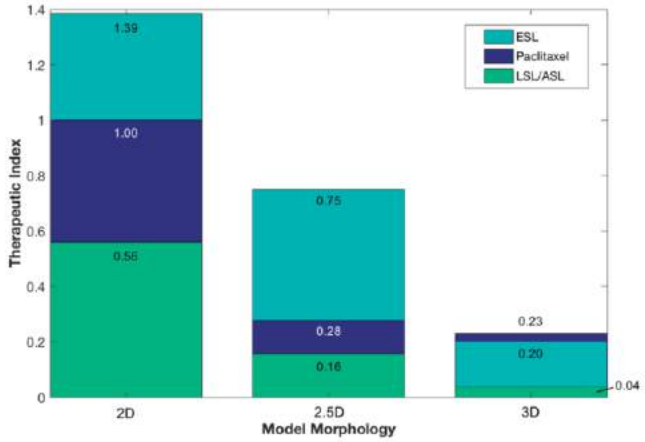

Figure 2: Therapeutic index as a function of model morphology. ESL showed the highest therapeutic index in 2D and 2.5D and was comparable to that of Paclitaxel in 3D models.

the importance of selecting an appropriate model for drug-screening.

Additionally, they indicate that drug toxicity cannot be reliably inferred from 2D models, as the results could differ greatly from *in vivo*-like response, which much more closely mimic the 3D spheroids tested herein (i.e., structure, pathophysiologic gradients). These findings also support the idea that screened drugs' poor success in clinical trials may be attributed, at least in part, to the use of inaccurate drug-screening models [2], such as 2D monolayers, which, despite offering high-throughput capabilities, may greatly overestimate toxicity of a given drug.

Additionally, our 2D testing with a noncancerous cell line showed that the SLs are no more toxic to surrounding cells than our positive control, Paclitaxel. Moreover, Paclitaxel exhibited an identical IC_{50} value for both cell types tested, supporting prior studies which found that Paclitaxel lacks selective cytotoxicity between cancer and normal cells [7, 8]. Interestingly, while the taxol was more toxic to cancer cells than the LSL/ASL, these drugs had comparable IC_{50} values when tested on the fibroblasts, indicating that the LSL/ASL is more toxic to healthy cells than cancer cells. On the other hand, the ESL displayed a higher IC_{50} value for fibroblasts than cancer cells, providing early evidence that this drug formulation may have some cancer-cell specificity. Notably, the TI values are generally lower than similar drug-screening literature, likely due to the heartiness of our selected breast epithelial fibroblast controls compared to weaker healthy cell controls (i.e., immune cells) utilized in those studies. Our future studies will seek to confirm these TI results using additional non-cancerous cells found in the tumor microenvironment (i.e., immune, stromal, and/or endothelial cells), and explore ESL modificaitons to enahance its anti-cancer specificity.

INTRODUCTION

Soft tissues like tendons, skin and cartilage support loads and facilitate tissue compliance for functioning of human body. The assessment of structural organization of soft tissue constituents is essential for understanding of their mechanical functionality and for design of surrogates. Polarized Raman spectroscopy (PRS) has been exploited to characterize alignment of collagen in tendon[1] and bone[2] previously. However, Raman data of soft tissue are often noisy due to their intrinsic complex proteins, which hinders the uniform application of PRS to soft tissue with non-collagen extracellular matrix proteins. Here, we apply PRS coupled with principal component analysis (PCA) to provide intuitive quantifiable alignment of proteins in collagen-rich samples (rat tail tendon and fabricated collagen hydrogels) and complex layers of mouse skin. The alignment can be distinguished via PRS without labels and independent of precise tissue proteins, which confirms adaptability of this method to soft tissue containing complex and varying proteins.

METHOD

Biological samples. Bundles of collagen fibers approximately 50 mm long and 200 μm diameter were dissected from the proximal end of rat tails. To make gels, high-concentration rat tail collagen type I (Corning) was used to fabricate 5mg/mL collagen hydrogels polymerized for 30 mins at 37°C, as previously reported[3]. Samples are submerged in phosphate buffered saline (PBS) before measurement. Mouse skin samples were obtained according to protocols approved by Institutional Animal Care and Use Committee at the University of Florida.

Polarized Raman Measurements. Raman spectroscopy was performed in a Renishaw InVia spectrometer with a 532nm argon-ion laser at 50 mW power. The Raman spectra on each sample were recorded with a spatial resolution of approximately 1 μm (20× objective, 200× total magnification). The spectra were collected using WIRE 4.4 workstation software with a resolution less than 0.1cm^{-1}. Measurements were performed at room temperature with samples submerged in PBS, and 10 μm ROI was scanned at a step size of 1 μm, i.e. 11 acquired spectra, with 2 ROIs for each sample. 12 accumulations were used for each location. PRS measurements were conducted while maintaining the Raman polarizer at a fixed angle with both incident and detected laser polarized in the same direction. By rotating the sample, we varied the polarization angle between laser polarization and the sample alignment axis (Figure 1). The polarized angle was varied from 0˚ to 180˚ in 30˚ increments.

Data processing and PCA modeling. The raw spectra were subtracted from background fluorescence in WIRE 4.4 using an eleven-order polynomial fit. The obtained spectra were then truncated from 1400-1800 cm^{-1} and subtracted from background spectra obtained from blank glass slide submerged in PBS. Resulting spectra were further smoothed by Savitzky-Golay filters with polynomial order of 3 and window size of 11 in Matlab. Descriptive and multivariate statistical PCA analysis (Origin2020, OriginLab) of the muscle layer spectra provided a principal component (PC1) that captured differences in the spectra of different polarized angles. The loading curve of this PC1 was treated as a master loading function that was fed into PCA analysis to be applied to spectra of all other tissue samples. The output of PC1 score as a function of polarized angle for each location was fitted with sine function:

$$y = A \cdot \sin[(\pi(x - xc)/90°) \quad (1)$$

The amplitude of sine fit, *A*, was used as a metric for quantifying the alignment level in soft tissue samples via PRS. Tukey's post-hoc test was used to determine the statistically significant differences between the groups in (JMP15 software, JMP Corporation).

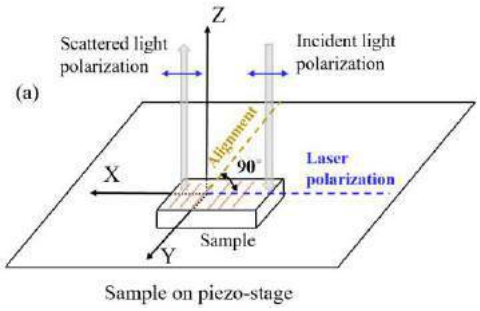

Figure 1: Schematic of the experimental PRS set-up, where the polarized angle is adjusted by rotating the sample counter-clockwise in XY plane with respect the laser polarization axis.

RESULTS AND DISCUSSION

The goal of this work was to leverage PRS to quantify the alignment in soft tissues independent of exact protein composition. To train a loading function that could distinguish the alignment of soft tissue structures, polarized Raman spectra were collected from mouse skin in a region with a known alignment, the paniculous carnosus muscle layer[4] (Figure 2 inset; direction of macroscopic alignment is perpendicular to the visible striations). Generally, intensities of Raman bands acquired in muscle layer were maximal at 0 degree (or 180 degree) and minimal at 90 degree, similar to other reports[6]. PCA was able to distinguish the spectral difference at different polarized angles, with most of the variability (86%) in the data explained by the first principal component (PC1, Figure 3). The PC1 loading curve depicts the Raman bands that exhibit the greatest contribution to the weighted PC1 score, including 1450 cm-1 (ν(CH2)) and 1649 cm−1 (amide I ν(C=O)). This suggests that both CH2 and C=O bonds have orientation-dependent Raman intensities, and indeed, PC1 scores were significantly different among the different polarized angles (Figure 4). Since these bonds are widely present in soft tissue, we hypothesized PC1 could be used to broadly assess alignment of protein structures in tissue.

To establish an analytical method that can quantify alignment in samples within unknown a priori orientation, we analyzed the amplitude of sine fit to the PC1 scores at different polarized angles (Figure 5a). The resulting sine fits reasonably captured the variation in Raman intensity of aligned proteins in tissue (R-square = 0.51±0.17, Figure 5a). Then, we applied the trained PC1 loading function to rat tail fibers (aligned) and collagen gels (unaligned) and obtained the amplitudes of their sine fits. For different structures of similar composition, we found a significantly higher mean amplitude in aligned rat tail tendon compared to the isotropic collagen gel (Figure 5b).

In each case, alignment can be distinguished via PRS without labels and independent of precise protein composition, which confirms adaptability of this method to soft tissue containing different proteins. Future work will focus on confirming utility of trained PCA model on soft tissue samples of different thickness and composition and engineered soft biomaterials, with the ultimate goal of monitoring the evolution of mechanical properties in engineered tissue.

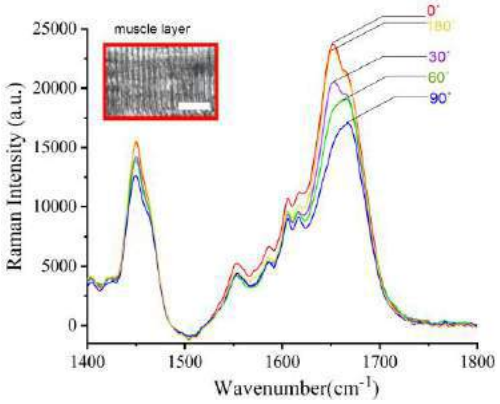

Figure 2: The mean Raman spectra (n = 22 technical replicates) of different laser polarization angles with respect to the muscle layer axis of mouse skin in 1400-1800 cm^{-1} range. Inset: Phase contrast image of muscle layer (scale bar: 10 μm)

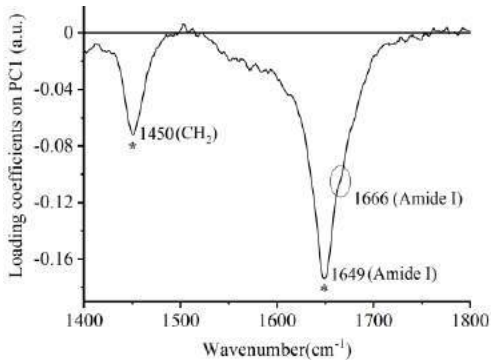

Figure 3: Principal component analysis (PCA) of 22 replicates at 5 angles (110 spectra total) yields a principal loading curve (PC1) that accounts for 86% of the variance among angles. Peaks in the loading curve (e.g., 1450 and 1649 cm^{-1} correspond to CH2 and Amide I bonds).

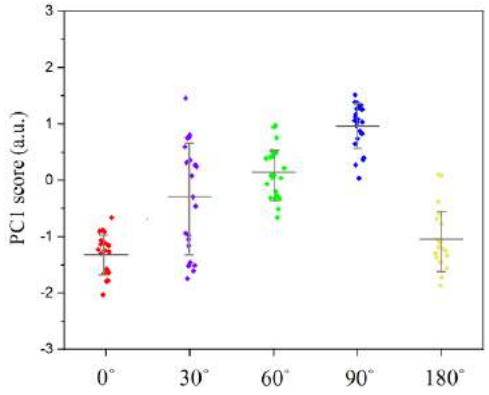

Figure 4: PC1 scores for Raman spectra yield significant differences among polarization angles (p-value ≤ 0.001 for all pairs except 0 ˚and 180˚ [p = 0.64] by Tukey's post-hoc test).

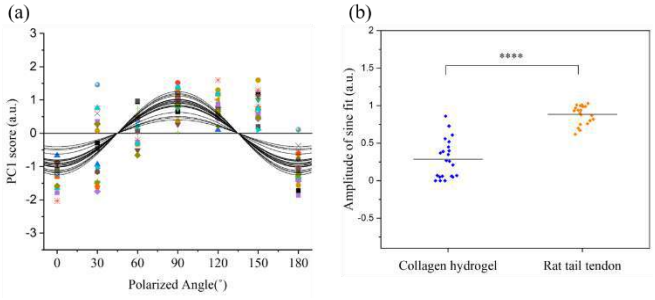

Figure 5 (a) PC1 score as a function of the angle of laser polarization with respect to muscle layer axis was fit by sine Equation 1. The curves show a maximum when the polarization of the laser is perpendicular to the muscle layer axis. (b) This process is translatable to tissues and surrogates with different protein composition than the original training tissue. Here, higher amplitude results for anisotropic tendon compared to the isotropic collagen gels (n=22 technical replicates, p<0.0001).

3D PRINTED MICROSTRUCTURES FOR REGENERATIVE OSTEOCHONDRAL IMPLANTS

INTRODUCTION

Articular cartilage regenerative scaffolds are typically made from soft hydrogels whose lack of load-supporting ability causes degradation of surrounding tissue [1] and subjects embedded cells to high physiological loads. To overcome the mechanical limitations inherent to these soft gels, we expand upon these scaffolds by integrating a 3D printed microstructure within the gel to support loads and shield cells from high stress (**Fig 1**). Our group recently developed a digital light processing (DLP) projection printing platform that is capable of printing overhanging features and complex geometries, with 1-10 µm printing resolution [2] (**Fig 2.a**). With thermal post-processing, the printed material achieves an elastic modulus of ~39 MPa [2], thus enabling the design of composite structures that feature a stiff framework infilled with a soft (50 kPa), degradable hydrogel for mesenchymal stem cell differentiation [3].

Our goal is to design 3D printed structures that 1) mimic the stiffness of native cartilage (~1 MPa), and 2) deliver precise mechanical cues (strain) to different regions of an osteochondral implant. Our group has demonstrated chondrogenesis in a soft (E = 50 kPa) gel scaffold when subjected to dynamic loading of 10% strain [3] and osteogenesis for strains <1.5% [4]. Using Finite Element Analysis (FEA), we designed a structure (**Fig 2.c**) to mimic these strains under physiological load (100 kPa). We then fabricated (**Fig 2.d**) the design and tested its ability to vary in strain between a top 'cartilage layer' and bottom 'bone layer'. In addition to evaluating strains, we also report the effective Young's modulus, E_{struct}, of each layer to describe load-carrying ability. Finally, we qualitatively evaluate the structure's stability under high deformations to identify presence of unwanted local buckling (**Fig 2.b**) in the framework.

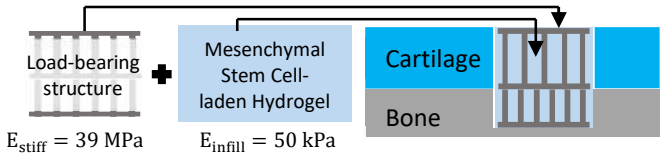

Fig 1. Our approach to creating a mechanically robust osteochondral implant that combines a stiff structure infilled with a soft hydrogel to later serve as a cellular niche.

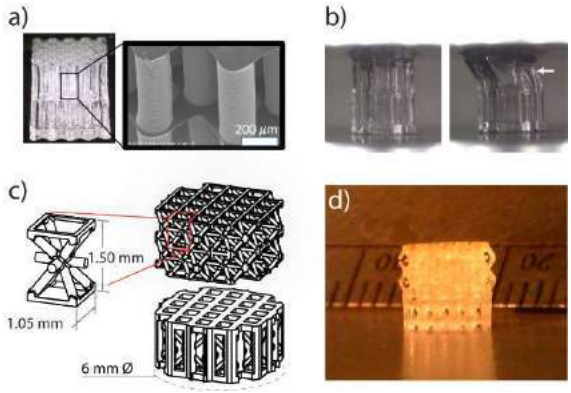

Fig 2. Design evolution of 3D printed structure; a) original design used vertical pillars to support axial load in compression; b) vertical pillars buckled under high (>5%) strains (arrow); c) bilayer design featuring an octet-truss unit cell. Top and bottom geometries differ in stiffness to mimic the osteochondral unit. d) Resulting 3D printed structure, with millimeter ruler in background for reference

METHODS

Design and FEA: We desired a structure that could deliver consistent strains to an infilled gel while bearing physiological load. This approach required a structure capable of resisting buckling under large deformation (>5% strain) while maintaining a stiff, 'structurally efficient' geometry that minimized the volume occupied by the structure. We chose an octet-truss microstructure for the cartilage layer and a simpler arrangement of pillars for the bone layer. Deformation behavior was modeling with FEA in Abaqus, considering non-linear geometric effects. Models used linear elastic material properties ($E = 39$ MPa [4], $\nu = 0.4$), 247k quadratic tetrahedral elements, and displacement-controlled unconfined compression. Thickness of the struts was iteratively changed to achieve the desired stiffness in each layer.

3D printing: The structure was fabricated with authors' custom DLP printer, described in detail in [4]. Materials included an acrylate-based resin, poly(ethylene glycol) diacrylate with pentaerythritol tetrakis(3-mercaptopropionate) (PEGDA:PETMP), and the photoinitiator diphenyl(2,4,6-trimethylbenzoyl) phosphine oxide (TPO). A thermal initiator, 2,2′-Azobis(2-methylpropionitrile) (AIBN) was introduced for post-processing cure.

Mechanical testing: Force-displacement curves were acquired from hydrated structures via displacement-controlled unconfined compression (MTS Insight II), while videos were simultaneously collected with a digital microscope (Dino-Lite) to measure strains in each layer. Tangent modulus was calculated at 10% total nominal strain.

X-ray microscopy (XRM) imaging: Images were collected using X-ray microscopy (Zeiss Xradia 520 Versa; 4×, 40kV, 3W, 4.5s; 801 images, 1.56 μm pixels). Samples were dehydrated in 100% ethanol and air. Unconfined compression was performed in situ with a custom-fabricated device using a micrometer with a non-rotating spindle.

RESULTS

FEA models of the bilayer design predicted the strains for each layer and supported a compressive load of 92 kPa at 5% total strain; E_{struct} was also determined for each layer (**Fig 3.a**). Imaging during compression of fabricated structures resulted in strain measures for each layer (**Fig 3.b**). The peak force was 1.94 N, which was used with the measured diameter (6 mm) and strain to determine each layers' stiffness E_{struct}. Repeated compression cycles resulted in similar force-displacement curves but with softer behavior than predicted by FEA (**Fig 2.c**).

XRM imaging of the dehydrated structure under compression showed no buckling at a strain of 7.7% in the cartilage layer. The bone layer strained to 0.6% (**Fig 4.a**). No buckling was observed during compression (**Fig 4.b**).

DISCUSSION

Our structures were designed to: 1) mimic cartilage stiffness in the top layer and 2) control the distribution of strains in a bilayer scaffold. We were successful in fabricating our bilayer design, and FEA predicts this design will nearly mimic cartilage stiffness in the top layer (0.95 MPa) while delivering a desired strain distribution (10% in cartilage layer [2], <1.5% in bone layer [4] under 92 kPa load. While layer-by-layer strains are reported here, extension of these models is needed to predict the mechanical environment within an embedded soft gel; these models are previously described [5] but require experimental validation.

Mechanical testing of the fabricated structure demonstrated softer behavior than predicted by FEA. Comparisons between XRM scans and the prescribed geometry show discrepancies in the reproduction of horizontal beams. Our next steps will be to optimize printing parameters to better match the exact geometry as designed. The structure was successful in repeatedly deforming without failure and provided two distinct regions of strain; future bioreactor studies may investigate differences in cell behavior between the cartilage and bone regions.

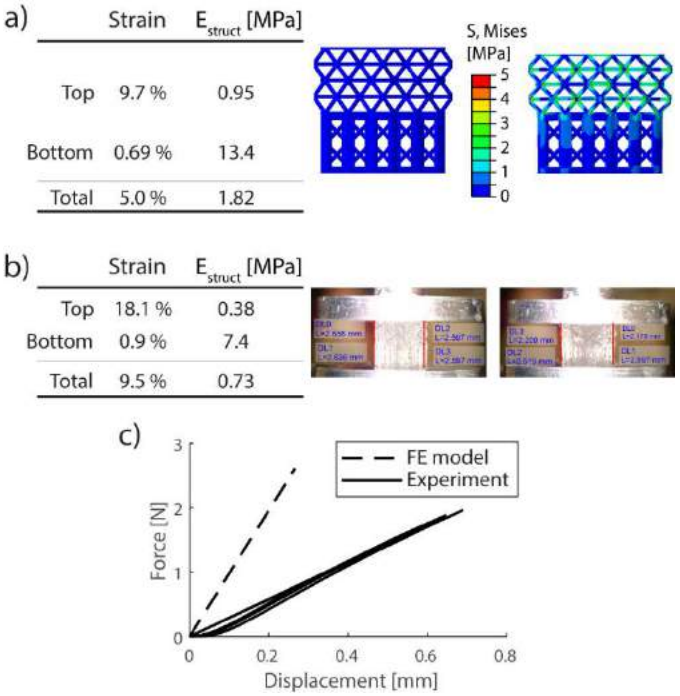

Figure 3: a) FE model results for strain and structural modulus, E_{struct}, in each layer; b) Unconfined compression with imaging results for strain and E_{struct} in each layer; c) force-displacement curves from FE model and experiment.

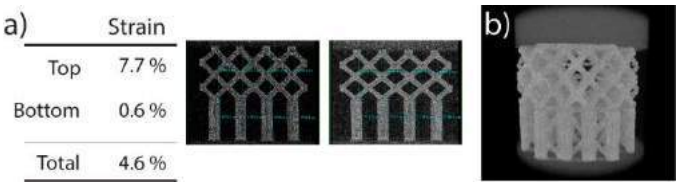

Figure 4: a) Strain in each layer as measured by X-ray Microscopy (XRM); b) 3D image of structure under compression.

XRM of the dehydrated structures under compression revealed a similar strain distribution and showed no evidence of buckling in the cartilage layer at high strain (7.7%). The XRM is a powerful imaging tool for this application as it enables future analysis of 3D printing accuracy as well as microstructure deformation.

The bilayer structure presented here is mechanically robust and offers a new method for controlling the mechanical cues delivered to cells in a scaffold. If successful, these implants could regenerate an osteochondral unit with a strong bone-cartilage interface.

INTRODUCTION

Brain vessel regions of high shear stress are susceptible to the formation of aneurysms due to progressive thinning of the arterial wall. This risk of aneurysm rupture is mainly attributed to factors such as sex, smoking habits and aneurysm size, as diameters of ≥7 mm are more susceptible to rupture [1]. Currently, treatment techniques include surgical ligation or endovascular embolization, where the latter has exhibited lower in-hospital deaths and morbidity. Among these techniques, endovascular coil embolization aims at occluding the aneurysm space using platinum coils, which are transported and delivered using a detachable micro-catheter. While coiling has been extensively applied since its introduction in 1990's, there are currently several limitations, including incomplete occlusion, mass effect, and aneurysm recurrence [2, 3]. To address some of these challenges, shape memory polymers (SMPs) have arisen as a promising alternative owing to their customizability, tunable properties, and biocompatibility.

We have previously designed pristine polyurethane SMPs, studied their thermomechanical properties, and demonstrated their shape recovery capacity [4]. In this work, we aim to advance the design of SMP-based endovascular devices based on a Joule heating activation mechanism. Specifically, we study the use of carbon nanotubes (CNTs) to enhance the required thermal conductivity in the SMP foams and investigate effects of the CNT addition on the thermal-mechanical properties of the SMP foam material.

METHODS

CNT-infiltrated SMP foams were synthesized using a sugar leaching method. Briefly, CNTs and sugar, as porogen (POR), were mixed in ethanol at different weight ratios (0.50, 0.75, 1.00 and 1.25%). CNT/POR solution was then dried in an oven and molded into blocks. SMP was next synthesized using three monomers: hexamethylene diisocyanate (HDI, ≥98.0%, Sigma-Aldrich), hydroxypropyl ethylenediamine (HPED, ≥98.0%, Alfa Aesar), and triethanolamine (TEA, ≥99.0%, Sigma-Aldrich) with a molar ratio of 1:0.05:0.6 (SMP11), resulting in a glass transition temperature (Tg) of ~38 °C. ~15g of uncured SMP solution was poured onto 30x30x10mm CNT/POR blocks, left in a freezer at -4 °C to allow penetration into the template, and cured at 60 °C and 130 °C (1 hour at each temperature) in a vacuum oven under nitrogen protection environment. Porogen was washed out in deionized water in an ultrasonic bath. CNT-infiltrated SMP foams were then dried in a vacuum oven at 50 °C for 24 hours, cut into different dimensions for each experiment, and stored in vacuum.

A comprehensive assessment of the CNT-infiltrated SMP foam was performed. First, we examined the effects of sugar leaching on the measurement of the T_g of the material, which delimits two mechanical states: (i) a glassy state, below the T_g, with strong polymeric chain interactions, and (ii) a rubbery state, above the T_g, where the material can be deformed. We performed differential scanning calorimetry (DSC) in pristine (solid and porous) SMP specimens at different SMP ratios (**Table 1**) and CNT/POR concentrations to measure their T_g.

Table 1: Other SMP monomer ratios used in the DSC test.

SMP type	HDI	HPED	TEA
SMP8	1.000	0.200	0.400
SMP9	1.000	0.150	0.467
SMP10	1.000	0.100	0.533
SMP11	1.000	0.050	0.600

To investigate the effects of sugar leaching and CNT-infiltration on shape recovery properties, we measured the shape recovery times of the CNT-infiltrated foams. In brief, 10x10x10 mm foam specimens were compressed uniaxially, and shape recovery was triggered with a hotplate above T_g (50 °C). Time from contact to ~90% recovery was recorded as the shape recovery time.

Finally, we assessed the Joule-heating capacity of the material. Direct current (0.50, 0.75, 1.00 and 1.25A) was applied to 5x5x5 mm foams with two copper parallel plates touching the two opposite faces of the SMP foam. Surface temperature of one face of the uncompressed foam was monitored using a thermal camera (ETS320, FLIR Systems).

RESULTS

We successfully synthesized CNT-infiltrated SMP foams (**Fig. 1**) with no significant alteration to the porosity and macrostructural features compared to the pristine foams. We observed a significant reduction in the T_g of the porous SMPs versus the solid SMP specimens (p<0.05), although no monotonic, decreasing trend was observed among various monomer ratios (**Fig. 2a**). We also observed that an increasing concentration of CNTs results in a decreased T_g (**Fig. 2b**). This is due to the reduction of hard segments of the polymeric matrix caused by CNT-infiltration, which ultimately reduces the motility of the polymeric chains and affects its thermal properties [5]. Shape recovery was also affected by CNT-infiltration: a decrease was observed in shape recovery time with an increasing CNT/POR concentration (p<0.05) (**Fig. 3**). These results confirm that CNT infiltration significantly affects the thermal properties of the SMP foams.

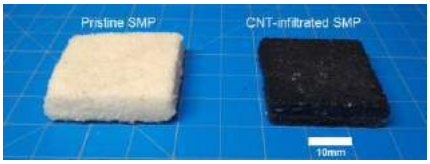

Figure 1: Pristine and CNT-infiltrated polyurethane SMP foams.

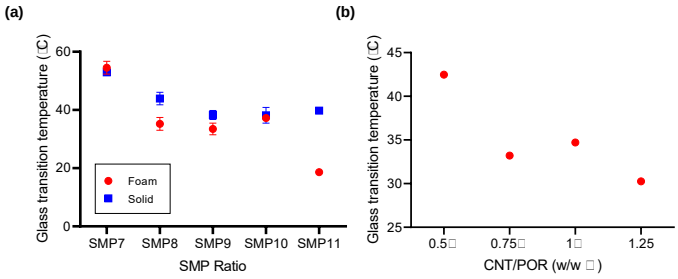

Figure 2: T_g of (a) solid and porous pristine SMP at various monomer ratios, and (b) CNT-infiltrated SMPs with different CNT/POR concentrations.

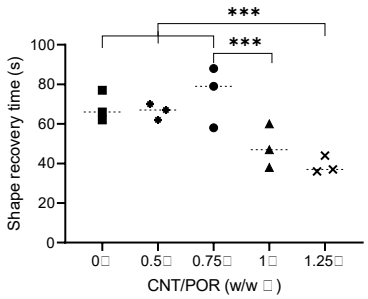

Figure 3: Shape recovery time of CNT-infiltrated SMP foams with different CNT/POR concentrations.

There are several observations from our Joule-heating assessment: (i) CNT-infiltrated foams exhibited Joule-heating when current was applied (**Fig. 4**); (ii) temperature increases faster at the interface between foam and copper plates, due to a high contact resistance; (iii) areas where temperature increased faster were observed, indicate ununiform CNT distribution (**Fig. 4**, dashed circles), and (iv) heating rate is directly related to applied current (**Fig. 4**) and CNT concentration (not shown). This experiment demonstrated the Joule-heating capacity of the proposed CNT-infiltrated SMP foam.

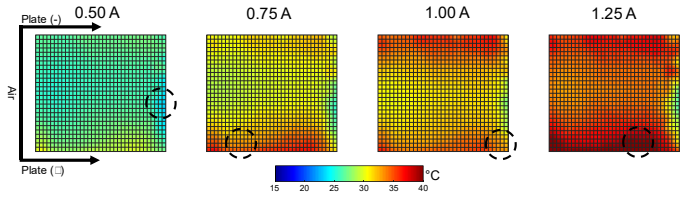

Figure 4: Thermal measurements of CNT-infiltrated foams (0.5% CNT/POR concentration) under Joule-heating activation. Heatmaps at 60s of activation with various applied currents.

DISCUSSION

A Joule-heating triggering mechanism for shape recovery of an SMP foam was designed by means of a CNT infiltration process. This triggering mechanism is key to our design of an endovascular device for brain aneurysm therapeutics, as it will allow timely and accurate triggering of a patient-specific endovascular foam.

In this study, our goal was to quantify the effects of CNT infiltration in the thermal properties of the material. The CNT-infiltrated foams had shape recovery behaviors induced by Joule-heating using parallel copper plates, indicating the promising potential of this triggering method. However, we observed that CNT-infiltration poses new challenges in the design of our endovascular device. First, sugar-leaching significantly reduces T_g, which was also observed as CNT/POR concentration was increased. T_g is a key parameter for shape recovery and foam delivery, as it sets the boundary between thermomechanical states. Special attention should be placed on this parameter due to its importance from a surgical perspective.

In addition, the interface between the foam and the copper plate in the Joule-heating assessment played a key role. We observed a significantly faster heating rate at the interface between the two materials. This is caused by a high contact resistance, that arises from the high dissimilarity between the conductive and thermal properties of the foam and copper tape, as well as a low effective contact surface between the foam and the relatively flat surface of the plate. This observation will play a key role in the design of a catheter that is able to deliver and stimulate the foam into the aneurysm space. Finally, non-uniform heating of the foam was also observed at small areas (**Fig. 4**, dashed circles), indicating the differences in CNT density and the need for improving the process for dispersing CNTs in our future studies.

In conclusion, we determined that CNT infiltration is a promising technique for the design of an SMP endovascular device, as it allows shape recovery in short periods of time with a simple setup. Future studies will address the novel challenges that were presented in this study, which will include the improvement of CNT dispersion methods, design of conductive interfaces to trigger shape recovery and the fine tuning of a surgically relevant T_g that allows *in vivo* implantation.

INTRODUCTION

The onslaught of COVID-19 and its victims' need for mechanical ventilation has underscored the need for a better understanding of how the lung's structure is impacted during ventilation. The pressure-volume (PV) curve of a respiratory cycle (measuring transpulmonary pressure and tidal volume) is commonly used to assess how the lung will respond under mechanical ventilation and to evaluate deviations in that response in diseased states [1]. Landmark studies have explored the effects of varied lung inflation pressures and volumes on the PV curve, but have used pressure controlled, non-continuous devices, yielding results that are not as readily comparable to physiological breathing [2]. The effect of varied breathing rates is particularly of recent interest because multifrequency ventilator oscillation shows promise in improving oxygenation [3]; however, such studies have not focused on the mechanical pressure-volume response, rather the downstream biochemical response of the lung due to injury.

To address this need, we investigate the role of breathing rate and inflation volume on lung compliance and the peak pressure response. Compliance is a metric of interest because it is a surrogate measure of pulmonary stress and strain [4]. We hypothesize that, given faster rates and larger volumes, we will see an increase in compliance as well as an increase in peak pressure, indicative of strain-stiffening, a classical biomechanical response of soft tissues [5]. By exploring the dependency of lung mechanics on various breathing rates and inflation volumes, we aim to lend greater understanding of the effects of mechanical ventilation, and ultimately aim to inform physicians of optimal protective ventilation settings and strategies.

METHODS

C57BL/6J mice were obtained from University of California Riverside's School of Medicine BREATHE Center (IACUC approved). Mice were anesthetized, sacrificed, and lungs were excised. A cannula was inserted into the trachea and was inflated to 0.5ml using a syringe to avoid airway collapse. Testing of each lung was completed within 12hrs after sacrifice and kept in 1XPBS before and during testing to minimize deterioration. To achieve statistical significance, three lungs were tested (COVID-19 interfered with tissue supply).

Tests were performed on our custom-designed, continuous volume-controlled, pressure-measuring electro-mechanical device. A predetermined applied volume of air is applied to the lung, and the effect of air compressibility is accounted for in real time [2]. Mice lungs were inflated by pushing air into the lung at increasing inflation volumes of 0.3, 0.5, 0.7, and 0.9ml. At each volume, varying inflation frequencies of 5, 10, and 20 breaths per minute (BPM) were tested. Lungs were inflated with faster frequencies, followed by slower frequencies to avoid air trapping [6]. To ensure a consistent datum state between each test, the lungs were inflated to a preload pressure of 5 cmH_2O. Each specimen was preconditioned three times, and data was collected from a subsequent test cycle.

Lung compliance was calculated as the ratio of volume change over pressure change, the slope of the PV curve [4]. The average compliance and peak pressures for three mice across varied volumes and rates were reported and statistical comparisons were made by one-way analysis of variance (ANOVA) with significance at $p<0.05$ with Bonferroni post-hoc analysis.

RESULTS

The pressure-volume curve (Figure 1) shows the varied rate response for a representative applied inflation volume of 0.7ml. The pressure-volume inflation response was near identical and varying the inflation rates was not found to significantly impact the compliance.

Figure 2A represents the compliance at varying frequencies and at

three applied volumes. The compliance was found to decrease for increasing breathing rates, however, the decrease was not statistically significant. The compliance increased with increasing inflation volumes, notably different between 0.3 and 0.9ml ($p<0.001$) and 0.5 and 0.9ml ($p<0.001$). In Figure 2B, peak lung pressures are compared over a range of inflation/deflation rates at the given applied volumes. The peak pressure unidirectionally increased at faster rates, but this increase was not found to be statistically significant. Across increasing volumes however, the peak pressures were observed to unidirectionally and significantly increase ($p<0.002$).

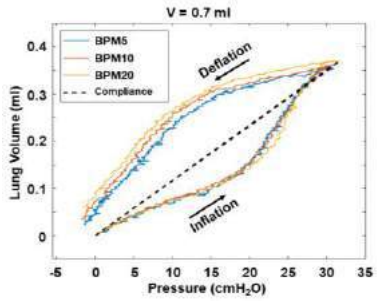

Figure 1: Representative pressure-volume response for an applied inflation volume of 0.7ml, resulting in a compressed lung volume of <0.4ml at breathing rates of 5, 10, 20 BPM.

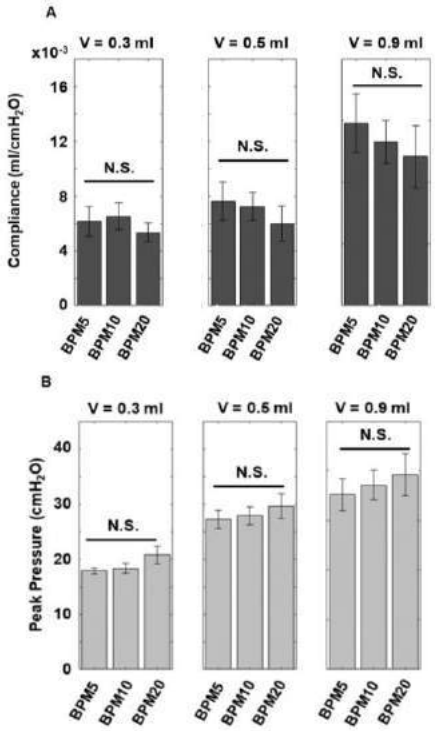

Figure 2: Comparison of mean ± standard deviation of lung compliance (A) and peak pressure (B) at applied volumes of 0.3, 0.5, and 0.9ml, each at three different inflation rates of 5, 10, and 20 BPM. Peak pressure was significantly greater for each applied volume and the compliance was significantly greater for 0.9ml. Neither compliance nor peak pressure was significantly different between any of the breathing rates.

DISCUSSION

In this study the effect of varied inflation volumes and frequencies on the continuous pressure-volume response, compliance, and peak pressure of mice lungs are studied for the first time. Our results show that an increase in breathing frequency does not affect the inflation pressure-volume response, but results in increased peak pressure, decreased compliance, and affects the deflation path.

Various breathing frequencies illustrate near-identical inflation paths and similar inflection points, indicating the shared degree of alveolar opening and airway resistance regardless of breathing rate (Figure 1). However, faster breathing rates resulted in higher peak pressures but lower deflation inflection points. Others have attributed this observed greater pressure drop during deflation to the hyperinflation of the lung; our results show more of these hyperinflated areas in faster frequencies [7].

Furthermore, increased breathing frequency results in increased peak pressures and decreased compliance, which represent increases in lung stresses and mechanical stiffnesses. Similarly, increasing the inflation volume results in greater peak pressure. These findings agree with other studies reporting smaller volumes and slower frequencies reduced ventilator induced lung injury [8]. In line with past work, we also find that compliance significantly increases with greater volumes [9]. This, coupled with our insights on how compliance decreases at faster rates (although not significantly), poses an interesting balancing effect may inform explorations on how to devise protective mechanical ventilation techniques, and lays the foundation for future research.

A limitation to this study is the non-physiological breathing rate, which is challenging given the fast breathing rate of mice. Our rates are in line with that of previous studies [1]. While these rates fall short of representing mice BPM (which can be as high as ten times our fastest rate), choosing physiological rates would no longer allow us to make the quasi-static assumption, because effects of flow would need to be considered [2].

We found that peak pressure significantly increases with larger applied volumes, which is consistent with previous findings [11]. The non-linear pressure-volume relationship is demonstrative of a "strain-limit" in the lungs, beyond which the tissue surpasses physiological thresholds [12]. This is consistent with previous findings suggesting that lowering tidal volumes may be a beneficial protective ventilation method [13]. Additionally, (though not statistically significant), peak pressure unidirectionally increases at faster rates. These trends agree with studies that describe how the lung exhibits strain stiffening at increasing stresses [5], and suggests that faster rates may exacerbate this stiffening.

INTRODUCTION

Ruptured abdominal aortic aneurysms (AAA) carry an overall mortality rate of 90%, while in clinical practice the maximum transverse diameter is the standard marker utilized for assessing AAA rupture risk. However, wall stress measures have been postulated to be better predictors of rupture risk compared to size alone. Along with wall stress, wall strength has also been proposed to accurately assess AAA rupture risk. The rupture potential index (RPI) is one such measure that accounts for both wall stress and wall strength [1]. Estimation of patient specific wall stress requires knowledge of the patient specific blood pressure. Wall strength requires knowing the patient specific familial history of AAA and the patient's sex. The objective of this study was to assess whether these patient specific metrics (blood pressure, familial history, and sex) have a significant effect on the maximum RPI in a cohort of 64 patients. We hypothesized that peak systolic pressure significantly affected the maximum RPI evaluation relative to the other two metrics (familial history and sex).

METHODS

Retrospectively acquired abdominal computed tomography angiography (CTA) scans were obtained from 64 asymptomatic AAA patients treated at Allegheny General Hospital (Pittsburgh, PA) and Northwestern Memorial Hospital (Chicago, IL) following Institutional Review Board approval at both clinical centers. The CTA images were segmented using our custom segmentation code *AAAVasc* (v1.0.3, The University of Texas at San Antonio, San Antonio, TX) [2]. Using another in house MATLAB®-based meshing code, *AAAMesh* [3], volume meshes were created for each AAA post-segmentation (30,000-90,000 quadratic hexahedral elements). These were used to create triangular surface meshes of the outer AAA wall, which were processed following a nonlinear elastic membrane analysis (NEMA) method to compute wall stress [4]. The proximal and distal ends of the models were fixed and an intraluminal patient specific peak systolic pressure (SP) was applied. The first principal stress component of the stress tensor was calculated using the NEMA technique, while wall strength was calculated [5] following Eq. (1),

$$Wall\ strength = 72.9 - 33.5 * \left(\sqrt{ILT} - 0.79\right) - 12.3 * (NORD - 2.31) - 24 * HIST + 15 * SEX \quad (1)$$

where ILT is the intraluminal thrombus thickness (in cm) at each node on the surface mesh, $NORD$ is the local normalized diameter (a dimensionless parameter) at each node on the surface mesh, $HIST$ is the familial history of AAA (+0.5 for positive family history; -0.5 otherwise), and SEX is the sex of the patient (+0.5 for male; -0.5 for female). The ensuing wall strength is calculated in units of N/cm^2.

The maximum RPI for each AAA models was evaluated as the maximum value of the RPI amongst all the surface elements of the AAA wall. To test the effect of each patient specific metric, 5 groups of data were created. Group 1 consisted of RPI evaluated with the actual patient specific SEX, $HIST$, and SP. Group 2 was created with the patient specific $HIST$ and SP, but using the incorrect SEX. Group 3 was created with the patient specific SEX and SP, but the incorrect $HIST$. Group 4 was created with the patient specific $HIST$ and SEX, but using a SP of 120 mmHg. Group 5 was created with the patient specific $HIST$ and SEX, but using a SP of 180 mmHg.

The maximum RPI calculated for Groups 2-5 was compared to the maximum RPI calculated for Group 1, which is the truly patient specific RPI. A linear regression analysis was used to assess the significance of this comparison based on the magnitude of the coefficient of determination (R^2) characterizing the regression. A series of test of

hypotheses were performed with a Bonferroni-corrected significance level of $\alpha_c = 0.05/4 = 0.0125$ to assess the differences in maximum RPI between Groups 2-5 and Group 1.

RESULTS

The mean maximum RPI for the 64 AAA models was 0.46 (for Group 1). Most patients in the study were males (n = 49) and had a positive family history of AAA (n = 62). The mean systolic pressure for the 64 patients was 144 ± 28 mmHg.

Figures 1-4 illustrate the linear regression analyses of the maximum RPI for Groups 2-5 vs. the maximum RPI for Group 1, respectively. These yielded R^2 values of 0.97, 0.62, 0.93, and 0.93, respectively. The regression analyses for Groups 2, 4, and 5 resemble closely the ideal linear relationship (a slope of nearly 1 and a vertical intercept near 0), shown in each figure by the diagonal line across the graph.

The outcome of the hypothesis tests reveal that the differences between Groups 2 and 1 are not statistically significant ($p = 0.35$), the differences between Groups 3 and 1 are statistically significant ($p = 0.001$), while the differences between Groups 4, 5 and 1 are not statistically significant ($p = 0.22$ and $p = 0.10$, respectively).

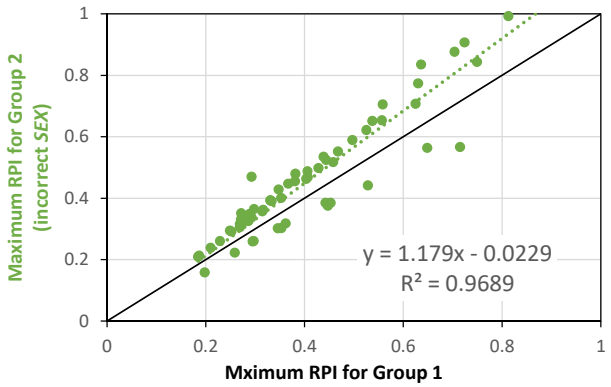

Figure 1: Maximum RPI for Group 2 (incorrect *SEX*) vs. Maximum RPI for Group 1.

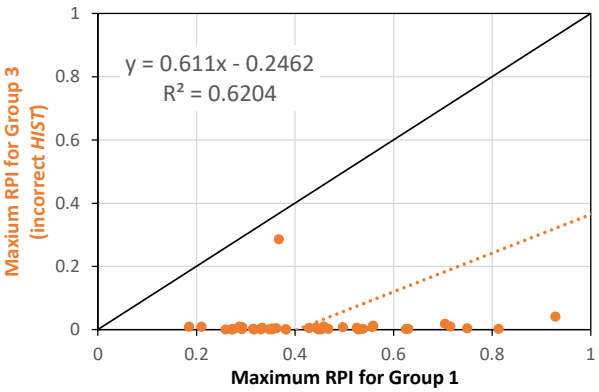

Figure 2: Maximum RPI for Group 3 (incorrect *HIST*) vs. Maximum RPI for Group 1.

DISCUSSION

Maximum RPI evaluated with the incorrect *SEX* or *SP* is statistically similar to the maximum RPI evaluated with the patient specific *SEX* and *SP*. We infer from this outcome that if the sex of an AAA patient is unknown or incorrectly transcribed from the medical records, the uncertainty will not lead to a significantly different prediction of RPI. Similarly, if the peak systolic pressure is assumed to be in the range of 120 to 180 mmHg due to the patient specific *SP* not measured at the time of patient follow up during the CTA exam or otherwise unknown, the predicted RPI is inferred to be similar to the actual RPI. Conversely, using an incorrect familial history of AAA yields a statistically different RPI compared to the actual RPI. We conclude from this analysis that in the estimation of RPI, the family history of the disease plays a far more significant role than sex and peak systolic pressure. Therefore, if *HIST* is unknown or unavailable, it may lead to a significant error in the prediction of maximum RPI.

INTRODUCTION

Bone loss and osteoporosis are common with advancing age leading to frailty due to the alteration in bone morphology and mechanical properties [1]. Osteocytes are the bone cells that sense mechanical loading due to physical activity and initiate biochemical signaling (called mechanotransduction), leading to bone formation. It was predicted that osteocytes detect mechanical loads through fluid flow shear stress (FFSS) around the dendritic processes and local strains around the osteocyte cell body [2]. The deterioration in osteocyte dendrite connectivity that occurs with aging may contribute to age-related bone loss, potentially due to impaired mechanoresponsiveness and disruption of osteocyte regulation of osteoblast and osteoclast function [4]. Depending on the cell and lacuno-canalicular network (LCN) morphology, different bone cells receive different FFSS [5]. Inaccessibility of the osteocyte network in the bone matrix limits *in vivo* experiments and the role of LCN morphology in initiating bone signaling and mechanotransduction is not fully understood. Computational fluid dynamics (CFD) models of bones provide an innovative approach to investigate the load-induced fluid flow inside LCN. Realistic image-derived models can imitate the intricate osteocyte microstructure, including LCN shape and canalicular tortuosity, to assess fluid behavior better than idealized geometries [6]. With advancing imaging techniques, cell processes can be captured in image-derived simulations [7]. A single osteocyte dendrite may develop numerous branches, enabling intercommunication between osteocytes. Despite the load-induced flow pattern's reliance on the LCN topology in the pericellular space (PCS), the existence of canalicular branches is mostly neglected in bone modeling [8]. This study aims to predict FFSS behavior in the osteocyte microstructural network, including the contribution of the canalicular branches, which is not conducive to direct measurement.

METHODS

To generate a confocal image-derived LCN model, confocal images of a 4 month-old mouse femur were stained with FITC dye [9]. The staining protocol enables visualization of most of the canaliculi [4]. The collected z-stacks were imported into the MIMICS to make a surface model after defining a light intensity threshold, as shown in Fig1A. The LCN volume was reduced via the smoothing technique to make the cell membrane and dendrites, where the cell body's annular space is greater than the dendrites [10, 11]. The cell membrane was subtracted from the LCN to create PCS for the fluid analysis.

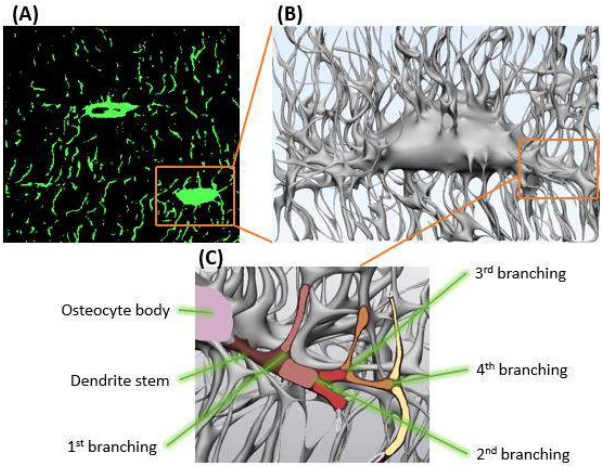

Figure 1: A) 100X confocal scan with a cuboid cropped region of interest (ROI) around the lacuna, B) realistic model of single osteocyte, C) canalicular branching model depicting connected stem process to the cell which forms branches and sub-branches

Fig1B shows the volumetric model of the ROI that was replicated in 3-MATICS software. The dendrites and canaliculi have an average diameter of 0.2 and 0.4 µm, and the annular thickness around the dendrites and the cell are 0.08 and 0.75 µm, respectively. A canaliculus connected to the cell on its left with various branches detached to represent the branching model is shown in Fig1C. These geometries were then imported into the ANSYS CFX for the fluid analysis inside the PCS. They were meshed with CFD preference linear tetrahedral elements, element size of 6e-8 m, and total element number of 10,116,847. To mimic the physiological activity, a fluid pressure gradient of 300 Pa was defined in the inlets while outlets have 0 Pa pressure. The remaining surfaces were considered walls with no-slip condition, and the interstitial laminar fluid was treated as water [10].

RESULTS

Fig2 depicts the wall shear stress distribution of the single-osteocyte model. Dendrites experience higher shear stresses on the walls than the cell membrane on account of an approximately ten times smaller annular space surrounding the dendrites than the osteocyte. The cell body has a maximum FFSS of 0.05 Pa, two orders of magnitude smaller than the maximum FFSS on dendrites, 6.6 Pa, in agreement with previous findings [12].

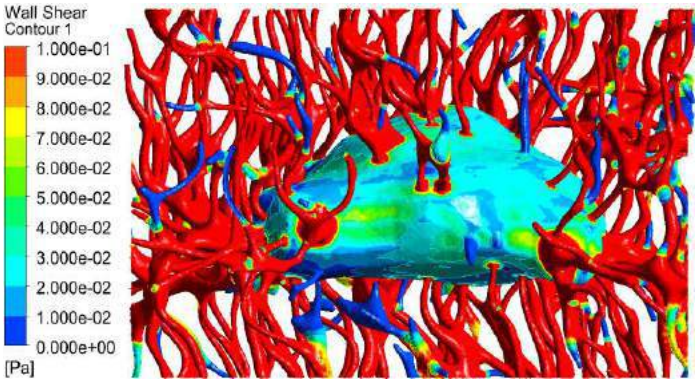

Figure 2: FFSS in PCS surrounding cell membrane

Fig3 shows the range and average FFSS experienced by each branch in the canalicular branching model. The stem has an average FFSS of 0.9 Pa, while the next branches have an average FFSS of 0.5Pa, 0.4 Pa, 0.2 Pa, and 0.07Pa. FFSS distribution and velocity streamlines of fluid flow within PCS is shown in Figs 4A & 4B. It is noticeable that the flow pattern differs in each set of canalicular branches.

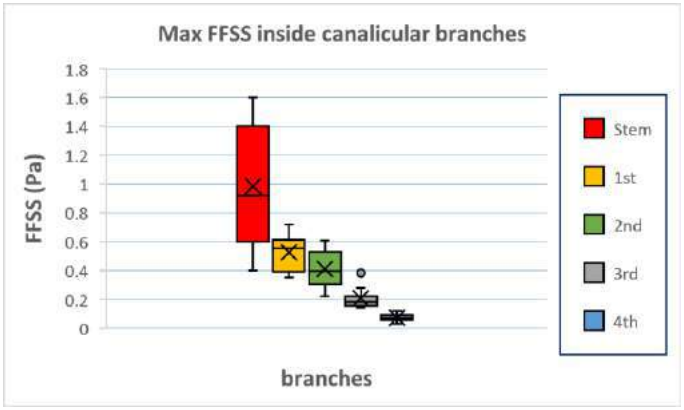

Figure 3: Comparison of FFSS distribution in various canalicular branches

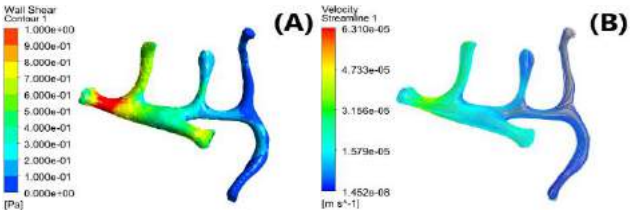

Figure 4: Contour plots of (A) FFSS and (B) velocity streamline in the canalicular branching model

DISCUSSION

Interstitial fluid flow exerts shear stress to the cell membrane besides its other capabilities such as delivering nutrition, eliminating waste, and cell-cell communication through LCN. In the single-cell model, canaliculi have higher shear values (shown in red) than the lacuna. The osteocyte membrane deformation that corresponds to the osteogenic response requires a minimum FFSS of 0.8Pa [13]. The PCS inside the lacuna is much greater than the canaliculi, enabling the lacuna to be a mixing chamber [2]. On the other hand, this large space decreases the fluid velocity and FFSS in the lacuna compared to the canaliculi. Only 18% of the entire domain, specifically canaliculi, reaches 0.8 Pa to bring about intracellular signaling. The canalicular branching model explains that even though all canaliculi experience higher shear values than the lacuna, FFSS differs depending on the branching order. Based on the vicinity of the canaliculus to the cell, FFSS inside the canalicuus is higher. Fluid streams from various branches are merged into the stem canaliculus which is the main route for the fluid enterance to the lacuna. Contributing more canaliculi as fluid inlets drives a higher flow rate and consequently, higher FFSS inside the stem canaliculus attached to the osteocyte. Therefore, the existence of canalicular branches in LCN could be a mechanism to amplify fluid flow and FFSS before entering the osteocyte. It is also apparent that the canalicular diameter decreases by branching, but no data is available for the differences in annular space thickness, so this was kept the same for all branches in this model. All in all, finding a link between the load-induced fluid flow on the osteocytes and its mechano-sensitivity regarding the LCN morphology will bridge the knowledge gap between mechanical load and bone formation.

ELECPHORETIC TRANSPORT OF MOLECULES FOR ENHANCED TISSUE CLEARING.

P. Atsu (1), Z. Nicolella (1), G. Thompson (1)

(1) Department of Chemical Engineering
Rowan University
Glassboro, NJ, USA

INTRODUCTION

The removal of cellular remnants and immunogenic materials from tissue scaffolds is critical to the success of any tissue decellularization process[1]. Removal of immunogenic materials reduces the risk of rejection of the implanted tissue scaffold by the host body. Continuous perfusion has been employed as a tissue clearing method during decellularization over the past decades[2,3]. Though there has been success with clearing tissue with perfusion, the process takes a long time which may lead to tissue degradation. Also, high perfusion fluid pressure can cause disruption of the tissue structure. Electrokinetic transport can be used as an alternate or complementary method for enhanced removal of cell remnants and immunogenic materials from the tissue scaffold[4]. Electrokinetic extraction has the potential of increasing the efficiency of tissue clearing and also shortening the time for the procedure[5].

In this study, the electrophoretic mobility of charged molecules in tissue samples was measured and analyzed using the relative difference of velocities of cationic dyes passing through tissue embedded in agarose gel under an applied electric field. The magnitude of the electrophoretic mobility of the cationic dyes was measured for DC and AC square pulses across the tissue and through the gel. The results demonstrate that pulsed electrophoresis can be used as a method of removing charged cellular remnants during tissue decellularization, with removal rate of the molecules discriminated by their relative sizes.

METHODS

Gels were prepared using 1 mL of 50X Tris-acetate-EDTA (TAE) buffer mixed with 49 mL of deionized water. Once mixed, a 0.5 g agarose tablet was added to the solution to make a 1 % agarose solution. The buffer was prepared using 4 mL of 10X Tris/Borate/EDTA (TBE) and 36 mL of deionized water to create a 1 % TBE solution.

Two dye solutions were prepared, pyronin Y (302.12 Da) and safranin O (350.13 Da). These two dyes bind to nucleic acids and proteoglycans, respectively, and thus were used as their analogues to predict their electrokinetic extraction. Both dyes were prepared by adding 5 mg of the respective dye and 3 mg of sucrose to 7 mL of the previously prepared 1X TBE buffer. Both dyes have a positive N that is ionically bonded to a Cl; so, in an aqueous solution the dyes have a positive charge of 1.

Frozen annulus fibrosus tissues were dissected from whole bovine tails acquired from a local abattoir (Bringhurst Meats, Berlin, NJ, USA). Small pieces of tissue were inserted in wells within the agarose. TBE solution was added on top of the solidified gel, and 7 μL of respective dye solution was added into wells. For data recording purposes, half the wells contained safranin, while the other half had pyronin.

For the DC power supply, the chamber was connected to an Extech (Nashua, NH, USA) DCP60 power supply, and 60 V was applied across the gel for 60 min. The chamber was connected to an A-M Systems (Sequim, WA, USA) 4100 Isolated High Power Stimulator. The chamber was subjected either to DC or to AC waveforms: a pulsed square wave of 60 V on for 10 ms and 0 V for 10 ms. All experiments were run for 60 min.

.

RESULTS

The electrophoretic migration of pyronin Y and safranin O through the annulus fibrosus tissue was driven with DC or AC. All the tested conditions caused migration of each dye within the 60 min duration,

with DC causing the farthest migration of both dyes, as shown in Figures 1 and 2. It is also observed that the distance of migration decreases with increased molecular weight.

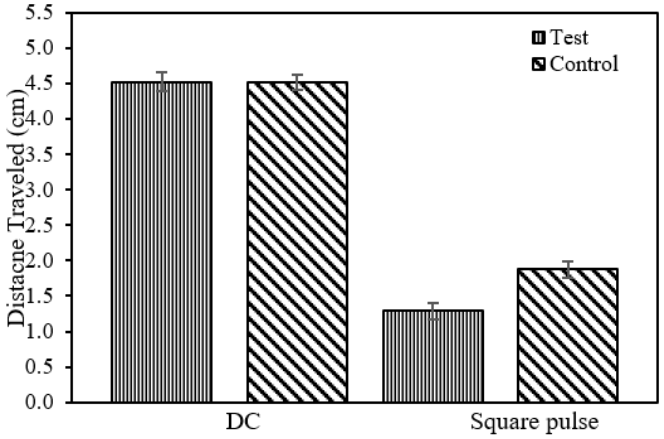

Figure 1. Distance travelled by pyronin Y (302 Da) in AF tissue samples with DC, square pulse and sawtooth pulses as voltage source for electrophoresis.

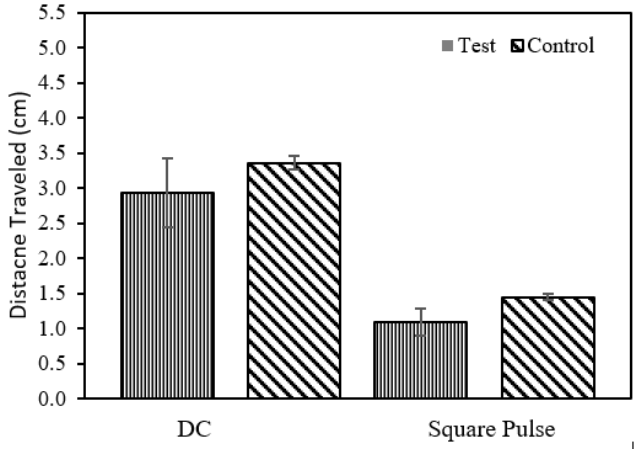

Figure 2. Distance travelled by safranin Y (350.8 Da) in AF tissue samples with DC, square pulse and sawtooth pulses as voltage source for electrophoresis.

DISCUSSION

The applied field being AC or DC affects the mobility of the charged molecules. This is because of the direction and intensity of the electrophoretic flow associated with applied electric fields[4,6,7].When electric field is applied across this medium, the charged molecules experience forces resulting from Columbic interactions, viscous drag, inertia and random thermal motion[7]. The charge relaxation process and associated time scales of the transient motion of the charged particles and ionic cloud can be different for an AC or DC applied field[7,8]. For pulsed electric fields, electrophoretic flow of the charged molecules is instantaneous with the pulse start up, sustained for the duration of the pulse and vanishes almost instantly when the pulse is switched[8]. For DC, the electrophoretic flow is initiated instantaneously when the current is switched and is maintained for the duration of the experiment. This explains the higher distance of dye migration in the DC setup compared to the AC setup as shown in Figures 1 and 2. Other mechanisms such as temperature gradient, fluid convection, and diffusion as a result of concentration gradient also contribute to the transport of molecules in the tissue[5]. The contribution of the individual mechanisms in molecular transport in tissues shall be investigated in our next study.

The electrophoretic mobility of the different dyes were noticeably different. This difference in mobility can be attributed to the molecular weights of the dyes and to specific binding interactions. The measured mobility was inversely proportional to molecular size, as reported in previous gel electrophoresis studies[4]. Pyronin Y ionically binds to the nucleic acids in the tissue whereas safranin O binds to proteoglycans. This makes the transport of safranin through the tissue slower compared to pyronin. The electrophoretic transport of molecules across tissue is therefore limited by the charge and size of the molecule at physiological conditions.

In summary, this was a preliminary study to explore the potential of pulsed electrophoresis as an alternative or complementary method for tissue clearing during decellularization. The study successfully demonstrates the transport of molecules across the tissue sample using pulsed electrophoresis. Our future studies will characterize the electroosmotic flow component from the applied electric fields. Also, a combination of perfusion and electrokinetic transport will be studied for enhanced tissue clearing.

ACKNOWLEDGEMENTS

INTRODUCTION

Mechanical ventilation has existed for over two centuries and the design of ventilators has changed countless times. Modern day ventilators utilize positive pressure ventilation (PPV), yet studies have shown that PPV induces lung damage [1]. Understanding and amending the causes of ventilated induced lung injury has been a major focus of lung mechanics research in recent years.

PPV does not replicate natural breathing, rather negative pressure ventilation (NPV) is the physiological way many animals, including humans, breathe. The contracting diaphragm produces a pressure gradient resulting in lung expansion. Mechanical ventilators based on NPV, such as the "iron lung," have become historically obsolete due to the inability to access the patient's vital organs during hospitalization. NPV could be employed by a patient for decades whereas PPV risks lung injury in only a few days.

Pressure-volume (PV) curves are a primary focus in lung mechanics research and a wide range of mammalian species have been studied and compared [2]. However, the role of various inflation volumes and breathing rates, and particularly their effect on PPV versus NPV mechanics is unknown. Examining the mechanics of physiological versus artificial ventilation mechanics will establish much needed fundamental scientific insights to better understand how to mitigate respiratory harm. To address these knowledge gaps, we investigate the material response of murine lungs under matched positive- and negative-pressure loading conditions.

METHODS

Three mice lungs, C57BL/6J, were obtained from the University of California Riverside's School of Medicine BREATHE Center (a small number of animal specimens are presented due to COVID-19 supply chain disruptions). After mice were anesthetized and sacrificed, a 20-gauge cannula was inserted into the trachea and secured with thread. A syringe was used to inflate the lung with 0.5ml of air to prevent the collapse of airways. The lung was stored in 1XPBS until testing, which occurred no longer than 4 hours after sacrifice.

The lung was transferred to the tank of our custom-designed apparatus to record pressure changes while continuously controlling volume [3]. Four volumes (0.3ml, 0.5ml, 0.7ml, 0.9ml) at three breathing rates (5, 10, 20 breaths per minute, BPM) were considered, totaling twelve PPV tests. To avoid trapping air, inflation tests were done in order of increasing volumes. A preload pressure of 5 cmH_2O was applied to imitate positive end expiratory pressure (PEEP), followed by three preconditioning cycles of inflation/deflation, and subsequent test cycle which was analyzed for peak pressure and elastance.

After each PPV test, NPV was conducted, matching the actual lung volume (compressed air) from PPV tests, as recorded from the pressure-volume response. PV curves for PPV and NPV for various volumes and BPMs were graphed for comparison.

Hysteresis was defined as the area between the inflation and deflation portions of PV curves. Elastance was defined as the reciprocal of compliance and was calculated as the ratio of peak transpulmonary pressure to volume. For the maximum inflation volume of 0.9ml, each breathing rate's peak pressure and elastance for PPV versus NPV was compared (mean +/- standard deviation). Statistical comparisons were conducted using a paired t-test, with significance defined as $p<0.05$.

RESULTS

The shape of the PV curves for NPV and PPV (Figure 1) resemble that of the PV curve for mice found in literature [4]. For both forms of ventilation, the lowest measured volume had minimal hysteresis and did not exhibit the transitory change in slope during inflation. Conversely,

at higher volumes, the inflation slope of both PPV and NPV greatly increased, with a transition point between 20-30cmH_2O.

The mean +/- standard deviation for peak pressure and elastance is shown in Figure 2 for three breathing rates at an inflation volume of 0.9ml. As the breathing rate increased, peak pressure and elastance increased for PPV as well as NPV. Values of peak pressure and elastance were observably higher for NPV, although the difference was not found to be statistically significant.

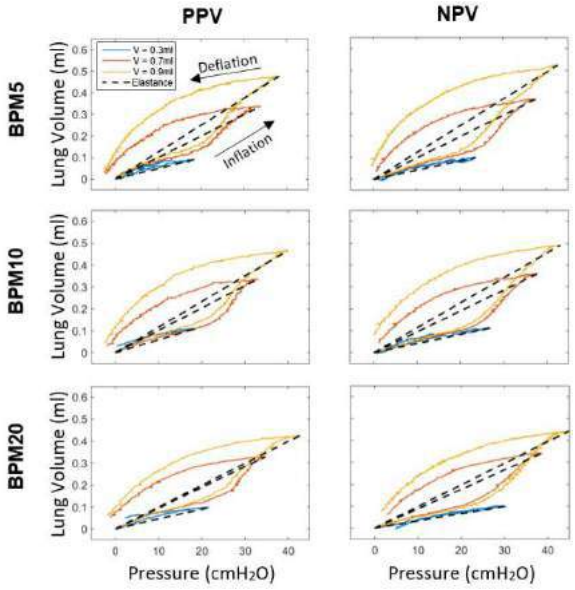

Figure 1: Representative PPV (left) and NPV curves (right) for different inflation volumes. Elastance was calculated as the ratio of peak pressure and peak volume.

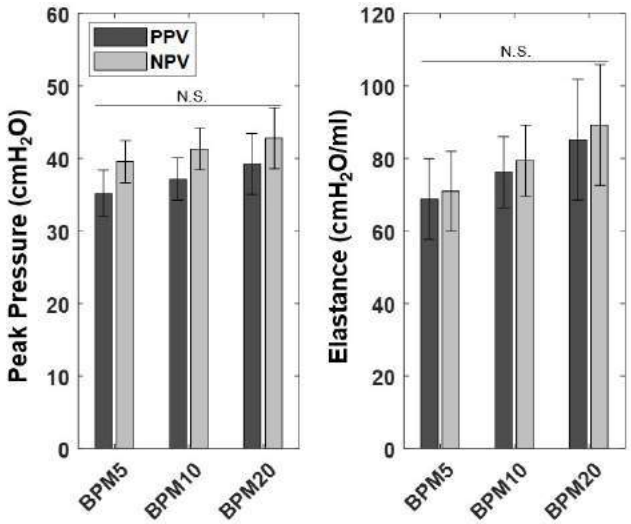

Figure 2: Mean values of peak pressure, left, and elastance, right, at varying BPMs for PPV and NPV at an applied volume of 0.9ml. Error bars are calculated from standard deviation.

DISCUSSION

We hypothesized significant differences between PPV and NPV, in agreement with recent work in our lab on porcine specimens. However, the resultant PV curves show few differences between the two forms of ventilation. This is an unexpected result and does not explain potential reasons for why artificial ventilation causes damage. It is plausible that similarities between PPV and NPV may be isolated to the mouse due to its size and the non-linear scaling of alveoli compared to larger species such as that of the pig or human [5].

One notable difference between PPV and NPV was the sudden pressure drop and resumption during inflation. This sudden alteration in the pressure-volume behavior was observed only during the inflation cycle (not deflation) and only in PPV (not NPV) and may be due to "popping" open the alveoli [6]. Popping may occur because positive-pressure alveolar recruitment is non-physiological. In contrast, NPV appears to inflate the lung through expansion of the distal alveolar regions, resulting in an uninterrupted and continuous PV curve.

In this study lung volume (compressed air) was matched for PPV and NPV. We found that for NPV, a higher transpulmonary pressure was recorded to reach the same volumes as in PPV test counterparts (Figure 1). This divergent behavior between PPV and NPV is most notable at the inflation volume of 0.3ml, where hysteresis is absent, and an elastic response is recorded. Here the PPV pressures were nearly 20cmH_2O, while NPV demonstrated greater pressure values for all breathing rates; NPV pressures collected for 0.3ml inflation in our study reached as high as 30cmH_2O elastically and without hysteresis; however, previous PPV studies, in agreement with our findings, reported hysteresis for pressures reaching 30cmH_2O [7]. The absence of hysteresis for these pressures seen in NPV tests warrants further study.

The observed increase in elastance with increased breathing rate is consistent with a study on excised cat lungs [8]. The stiffening of the whole organ is, in part, due to the local tissue elastance. Studies have shown a logarithmic increase in the dynamic elastance of parenchymal strips as frequency increases [9]. Because this phenomenon occurs in both PPV and NPV, the viscoelastic properties of the lung are a likely attributable cause.

One limitation of this study and of similar studies assessing murine mechanics is the physiological BPM of mice, which is as fast as 250-350, much higher than those tested. Lower BPMs were necessary for the quasi-static assumption, to isolate the lung structure as the main effect of elastance in PV curves [10, 11]. It is possible that the trends observed in this study may not occur at natural breathing rates.

INTRODUCTION

Pulmonary conditions are the predominant cause of morbidity and mortality worldwide with rising concerns due to the novel coronavirus. COVID-19 has necessitated lung biomechanics research due to the increasing number of patients undergoing ventilation and experiencing pulmonary injuries. Modern ventilators use a positive pressure to push air into the lung to deliver oxygenation resulting in overstretching and overstressing of lung tissue [1,2]. Recent investigations seek to compare positive pressure ventilation (PPV) to naturally occurring negative pressure ventilation (NPV) to analyze and mitigate ventilator induced lung injuries (VILI) [3,4]. These previous studies have been limited to evaluating the downstream biochemical response of ventilation instead of characterizing the mechanical strains and pressure-volume behaviors.

Here we introduce novel strain characterization of PPV as compared to NPV through non-contact digital image correlation (DIC) of the whole ex-vivo lung for the first time. Using our custom-designed dual-piston breathing apparatus [5], we subject porcine lungs to various inflation volumes and breathing rates, capturing the altered local strain response at peak inflation to evaluate the mechanics of PPV versus NPV on the same specimens. This investigation yields critical pulmonary mechanics insights for new ventilation schemes, such as high-frequency and multi-frequency oscillatory ventilation [6], aimed at improving patient outcomes, and correlates the bulk global ventilation pressure-volume inputs to the resulting local strain response.

METHODS

DIC was collected using our sealed transparent tank apparatus, applying controlled volumes and measuring the resulting pressure and strain response in both PPV and NPV [7]. PPV was applied by inflating the lung directly, while NPV was induced by removing air from the tank, imitating diaphragm distension. Specimens were inflated in PPV to volumes of 675 ml, 900 ml, and 1350 ml at 10, 15, and 20 breaths per minute (BPM) as clinically relevant [8]; the resulting peak pressure magnitude and change in actual lung specimen volume was measured in real time, enabling NPV loading to directly match the bulk global loading and deformation response in each variable volume and breathing rate test.

Pig lungs were collected from an abattoir and tested on the same day to minimize degradation altering behaviors. The lung was inflated once to open up airways that may have collapsed during transport in 1XPBS, speckled for DIC, and analyzed using Trilion ARAMIS Adjustable 12M system as previously stated [7]. Each lung was preloaded to an inflation pressure of 0.07psi ($5cmH_2O$) to ensure uniform starting states across each specimen and to replicate positive end expiratory pressure (PEEP). Samples were then subjected to three preconditioning cycles at each specified volumes and breathing rate before collecting data from a subsequent test cycle. PPV and NPV lung surface strain contours were analyzed at the peak inflation states. Histograms depicting the relative strain distribution for each sample and resulting mean, range, and median strain values were averaged and compared between PPV and NPV. Three pig specimens were analyzed for statistical significance (despite COVID-19 disrupted tissue supply chains). A paired t-test was used to compare PPV to NPV, and ANOVA with post-hoc Bonferroni was used to compare the breathing rates with defined significance of $p<0.05$.

RESULTS

The qualitative strain contour map of a representative porcine lung at various inflation volumes for PPV and NPV is shown in Figure 1. Local strains increased in response to increased applied inflation volumes. While the lower and upper lobes were noted as the site of minimal and maximal strains respectively in both PPV and NPV, greater

regions of high strain were noted in PPV compared to NPV. Significant changes in strain values and regional distribution were not observed when the breathing rate was varied.

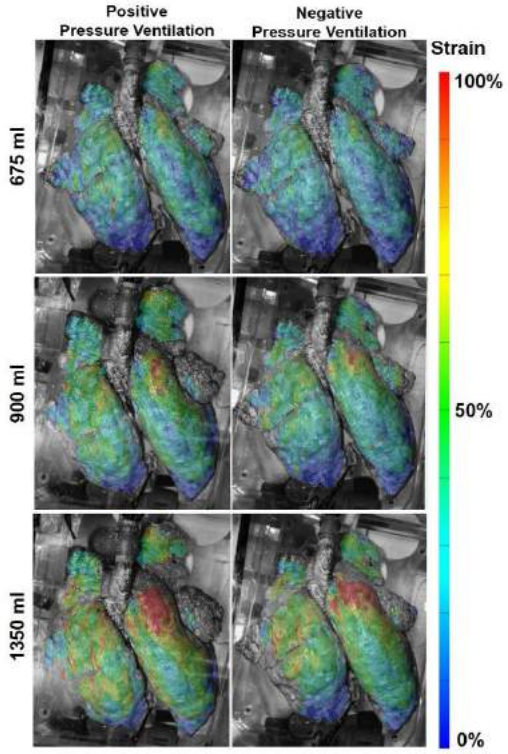

Figure 1: Strain contours of a representative porcine sample inflated at a breathing rate of 10 BPM and at volumes of 675 ml, 900ml, 1350 ml. At each volume, the same lung was inflated using either PPV or NPV.

The resulting strain distribution in PPV and NPV is quantified in Figure 2. The median strains were mainly clustered at <10%. PPV was noted to have statistically significant increased strain ranges relative to NPV across all volumes and breathing rates; NPV peak strains were always much less than peak strains in PPV. While the mean strains in NPV were generally lower than PPV, the decrease was not found to be statistically significant.

DISCUSSION

We expected NPV local strain contours and distribution to significantly differ from PPV but found that the regional behavior did not necessarily differ. In terms of strain distribution, NPV populates lower strain values and has decreased maximum strains compared to PPV; this suggests there are localized strain peaks in artificial ventilation utilizing positive-pressure compared to physiological negative-pressure breathing, underscoring a potential cause of VILI. This finding supports the notion that negative pressure ventilation results in less lung injury [9,10].

The range of strain distribution was not significantly altered for normal (15BPM), slower (10BPM), and faster (20BPM) breathing frequencies in either PPV or NPV. Evaluating if breathing rate could induce varied mean and median strain response for PPV or NPV was inconclusive. While our analysis is restricted to the 3D surface strain profile and ex-vivo specimens, it limits the likelihood of mechanical benefits of varied inflation rates. It may be that multi-frequency oscillatory ventilation improves oxygenation by reducing biotrauma (inflammation) and atelectrauma (opening and closing of alveoli and airways) but not barotrauma and volutrauma [6].

Our recent studies have found that the initial inflation curve of the PPV pressure-volume response (clinically understood as alveoli recruitment) has a significantly smaller slope and is therefore much stiffer compared to NPV [11]; the deflation response was not found to differ. However, the strain analysis performed here was conducted for the matched end-point inflation stage, discounting the temporal evolution and pressure-volume path differences between PPV and NPV. While the end-stage strains for matched peak pressures and applied volumes may minimize differences between PPV and NPV, key physiological and breathing rate distinctions may stem from phases within the inflation cycle. Future studies will consider the strain behavior of PPV and NPV beyond the end-stage inflation state.

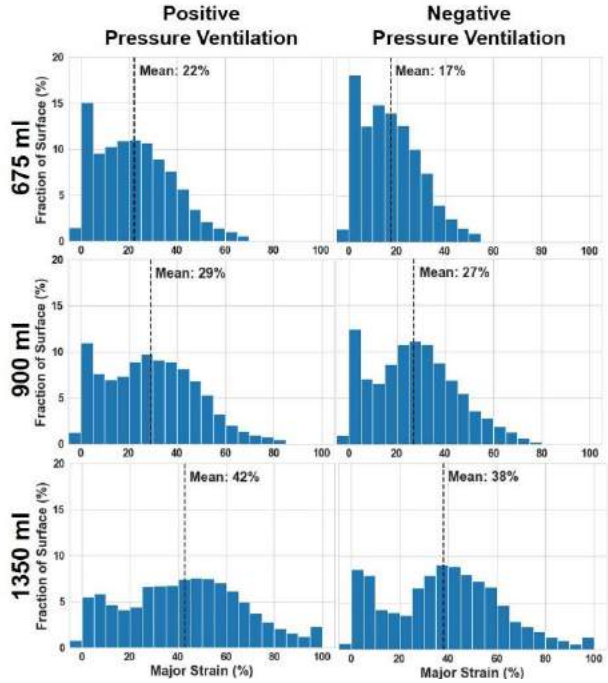

Figure 2: PPV and NPV strain distributions of representative sample inflated at a rate of 10 breaths per minute and at volumes of 675 ml, 900ml, 1350 ml.

INTRODUCTION

The urinary bladder is a highly compliant organ with its mechanical behavior largely mediated by smooth muscle and the extracellular matrix (**ECM**) in the bladder wall [1]. The ECM is susceptible to pathological remodeling wherein the structure of its constituents—collagen and elastin—is altered which impacts stiffness and bladder health/function. Loss of healthy bladder function can reduce the affected individual's quality of life: increasing the risk for depression and suicide, or unhealthy coping methods such as reducing fluids and isolation [2]. Annual healthcare cost for treating poor bladder function in the United States is estimated between $9-100 billion [2, 3].

Common urinary dysfunctions have been associated with an inflammatory response including: neurogenic bladder, chronic urinary tract infection, and interstitial cystitis (or, bladder pain syndrome) [4]. Furthermore, inflammation is believed to be involved in the initiation and progression of these dysfunctions. Chronic inflammation within the bladder wall is associated with ECM remodeling which can damage the organ tissue in the long term [5].

Inhibiting pro-inflammatory mechanisms may be a viable approach to prevent bladder wall remodeling and function deterioration. Specifically, inflammasome-mediated pathways has emerged as driving fibrosis in various organs including the bladder [6]. For example, the NOD-like receptor (NLR) inflammasomes NLRP3 and NLRC4 (Pyrin domain-containing protein 3, and Caspase recruitment domain-containing protein 4, respectively) initiate inflammation in response to environmental factors, including gram-negative bacteria such as E. coli [7]. NLRC4 is found throughout the human body, and in the urothelium—the protective layer between urine and bladder tissue—of the bladder wall [8].

Knockout (KO) of the NLRC4 gene may reduce bladder inflammation as it is functional in activating immune response in the bladder wall [8]. In the first stage of this study, we show that NLRC4 KO alone affects mechanical behavior of bladder ECM in rat models.

METHODS

An NLRC4 KO rat model was developed at the MSU Transgenic and Genome Editing Facility by deleting 252 base pairs corresponding to the NLRC4 gene in Sprague-Dawley (SD) rats. Then heterozygous (NLRC4 +/-) and homozygous (NLRC4 -/-) groups were bred. Controls were SD wild-type. Animals were sacrificed at 12-13 weeks, and whole bladders were extracted, imaged, weighed, sectioned into rings, and frozen until testing. Dissection and testing was randomized and blinded.

Fresh tissue geometry was assessed from top-down photos of the flattened whole organ, as shown in **Figure 1a**. Bladder area was measured by thresholding these profile shots with ImageJ, as shown in **Figure 1b**. As the size and weight of the extracted organ is somewhat dependent upon the location of incision at the bladder neck, these measures were normalized by ratio of bladder weight to area.

After thawing, bladder ring samples were decellularized to isolate the ECM, and mounted to a uniaxial testing machine while submerged in Krebs solution. Tests measured force via load cell and length/cross-sectional area via front/side cameras.

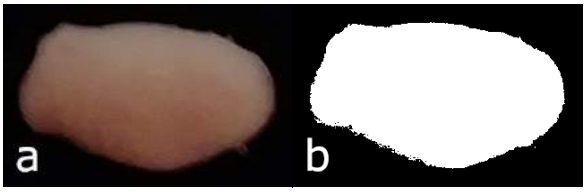

Figure 1: a) Whole fresh bladder after extraction flattened to show profile, b) Threshold applied to measure bladder profile area.

Samples were stretched to four strain levels (5, 10, 15, and 20%). For each of the four tests, the tissue was held at a 2g preload until relaxation diminished, and then cyclically loaded and unloaded at 1% strain/sec. The first test had 10 minute preload and 10 cycles, while the next three tests had 1 minute preload and 5 cycles. This loading protocol ensures each ring is consistently taut and preconditioned so that mechanical behavior becomes repeatable.

Data from the final load cycle at the highest strain level was analyzed and is presented in **Figure 2**. True (Cauchy) stress-strain curves were found using the median cross-sectional area at the preload stage, approximated as a rectangle, and then force and length, recorded continuously, give stress and strain assuming incompressibility. The initial length (reference) used to evaluate stress and strain was each sample's length at the start of the last loading cycle.

RESULTS

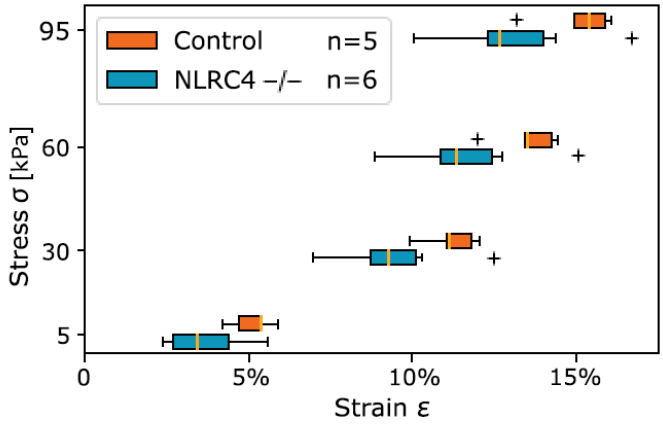

Figure 2: Cauchy stress-strain curve at representative stress levels from bladder ECM tests. Student's t-test of Control v NLRC4 -/- gives P=.049, P=.09, P=.11, and P=.11 at 5, 30, 60, and 95 kPa respectively (no correction).

Figure 2 shows the circumferential mechanical behavior, tested uniaxially, for preconditioned tissue stretched to 20% strain. It should be noted this data is truncated to ~15% strain to better show its non-linear characteristic. The bladder ECM for the KO group (NLRC4 -/-) shows less deformable mechanical characteristics when compared to controls. This difference between control and KO groups was significant at lower values of stress (i.e., 5 and 30 kPa). At higher values of stress (i.e., 60 and 95 kPa), the trend is conserved yet the difference is not significant (P=.11 for both stress values). Heterozygous (NLRC4 +/-) had values of strain in-between control and KO groups for all stress values considered (differences were not significant when compared to either the control or KO animals).

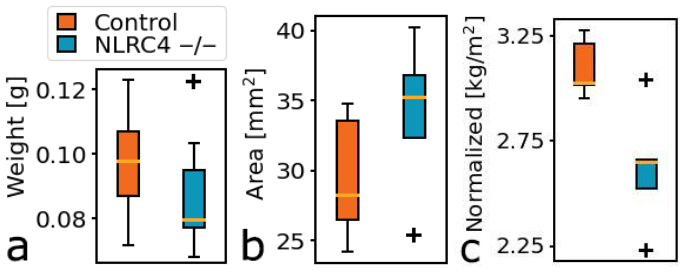

Figure 3: Physical characteristics of fresh whole bladders; a) Weight, b) Flattened area, c) Normalization by weight/area.

Figure 3a shows that whole bladder weight was lower in the KO group compared to controls. Bladder profile area appeared larger in the KO group compared to controls (**Figure 3b)**. Normalization of fresh bladder weight and flattened area (**Figure 3c**) showed marked difference between KO and control groups.

DISCUSSION

These results indicate that NLRC4 KO affects the homeostatic mechanical characteristics of the urinary bladder's ECM. Interestingly, while high distensibility is often problematic and a clinical marker for bladder dysfunction, bladders having comparatively lower distensibility are considered to be stable and healthy [9, 10]. Our data show that NLRC4 KO results in a less distensible ECM and in a lower bladder weight, when compared to controls. This has also been observed in children, where low bladder weight, assessed by ultrasound, was used to predict lower distensibility, as compared to dysfunctional highly distensible bladders [9].

Bladder weight is also considered a marker for bladder inflammation, indeed both NLRC4-driven and bacterial-induced inflammation have shown to double bladder's weight compared to controls [11, 12]. Moreover, bacterial-induced inflammation can trigger detrusor hyperactivity [12], which is compensated for by increased bladder distensibility [13]. Taken together, previously published literature and the results presented here, suggests that the NLRC4 -/- animals had lower levels of inflammation than the control.

Increased bladder area was observed in the KO group vs controls, although reference length (a measure of ECM ring circumference) was similar across groups being 16.8mm +/- 0.5mm. This apparent size discrepancy may be clarified by noting area was measured in relaxed bladders having muscle cells, while reference length was measured in decellularized preconditioned tissue. The difference revealed by normalization may be due to microstructural changes in the detrusor muscle and/or ECM, though that is yet to be determined by histology.

Next steps in this study include histological and immunohistological studies to examine potential microstructural changes between groups as well as the presence and level of inflammatory markers, such interlukin-1β (IL-1β), IL-18 and IL-6. Later steps will include the addition of inflammatory stressors such as a high-fat diet or diabetic predisposition.

ACKNOWLEDGEMENTS

We thank Drs. Elena Demireva and Huirong Xie from the MSU Transgenic and Genome Editing Facility and the Institute of Quantitative Health Science and Engineering for developing the NLRC4 KO rat model. We thank fellow lab members Marissa R. Grobbel and Tyler Tuttle for assistance with mechanical testing protocol. This study was supported by NSF grant CBET 1802992.

INTRODUCTION

Tetralogy of Fallot (ToF), the most common type of cyanotic congenital heart defect, affects 1 in every 2500 newborns annually. Typical surgical repair for ToF requires an initial surgery at a few months of age to close the ventricular septal defect and reconstruct the right ventricular outflow tract (RVOT). The defect and repair often leave the patient without a fully functional pulmonary valve and reintervention may be necessary to place an artificial valve in the patient's early teen years. Bioprosthetic xenograft valves, which are commonly used for this procedure, are subject to degradation and dysfunction over time, typically within 15 years of implantation and often leading to additional surgical interventions [1]. However, these valves fail early and unpredictably in as many as 30% of ToF patients and there is currently little understanding of what hemodynamic factors may lead to early valve dysfunction. More comprehensive knowledge of the flow structure local to the valve and leaflet dynamics may aid clinicians in selecting the best placement and size for optimal long-term valve function.

Our prior work analyzed variations in 3D flow fields over the cardiac cycle in both healthy and diseased RVOT geometries *in vitro* [2]. The flows differed significantly, particularly in vortex formation and reverse flow volume, which could have an impact on the valve leaflet function over time. In addition, we found that changing the rotational orientation of the valve further impacted the flow fields. The orientation affected the flow differently depending on the geometry, revealing the compound effect between geometry and orientation.

The current work examines the effect of cardiac output on valve behavior, coupled with continued studies on valve orientation, in a diseased RVOT model. The impact of varying cardiac output can provide insights on valve sizing, which is of particular interest for pediatric patients. We paired measurements of the full flow fields in the model over the cardiac cycle with high speed camera images of the valve leaflet motion to generate a comprehensive picture of the valve environment at different cardiac outputs.

METHODS

The experimental setup consists of a 3D printed model of the RVOT inserted in a flow loop designed to replicate physiological flow and pressure waveforms. The RVOT model was designed based on the centerline measurements of the pulmonary arteries of healthy patients, but with a 150% dilation immediately downstream of the valve to represent a common disease condition seen in ToF (Figure 1). A 25mm St. Jude Medical Epic porcine valve was implanted in the model. The pulsatile flow through the model is pneumatically driven and was adjusted for three different cardiac output cases: 2 L/min, 3.5 L/min, and 5 L/min. The working fluid was a blood analog water-glycerin solution with 40% glycerin resulting in a viscosity of 3.9 centipoise at room temperature.

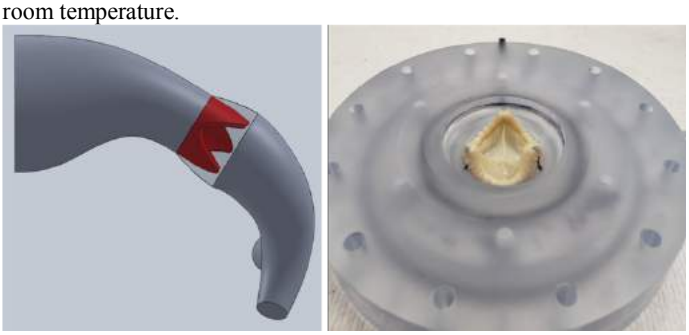

Figure 1: Diseased RVOT model design (left) with 150% vessel dilation in the main pulmonary artery. Bioprosthetic valve inserted in the 3D printed model (right).

For each of the three cardiac outputs, full 3D, three-component, phase-averaged velocity fields were obtained over the cardiac cycle using magnetic resonance velocimetry (MRV) [3]. The experiments were conducted in a whole body, 3 Tesla, General Electric MRI scanner at the Richard M. Lucas Center for Imaging at Stanford University. The MRV sequence was phase-locked, allowing for measurements at different points throughout the cardiac cycle. The spatial resolution of the scans was 0.9mm in the sagittal, axial, and coronal directions. The temporal resolution was 77ms resulting in the direct measurement of approximately 10 phases. For the final results, the resulting data were interpolated to 20 phases throughout the cardiac cycle. The velocity encoding (*venc*) was adjusted for each cardiac output case to account for the differences in maximum velocity.

For all three cardiac outputs, the valve was placed in the native orientation, with a valve leaflet opening along the interior curve. For the 2 L/min and 3.5 L/min cases, the valve was also rotated 180 degrees for additional MRV studies. For the 5 L/min case, the rotated orientation data was only collected with the high-speed camera experiment.

To capture leaflet motion, we took images with a Phantom V2012 Ultrahigh-speed camera with a 105mm Nikkor Lens. The model was submersed in the working fluid to limit distortion due to refraction. The camera was placed downstream of the valve to capture the full leaflet motion over the cardiac cycles. Images were taken at a framerate of 1500Hz, leading to approximately 500 images from valve opening to closing. The MRV and high-speed camera experiments were run with the same experimental parameters and the trigger signal at the start of systole was recorded, allowing us to align the two data sets and examine the relationship between flow fields and leaflet motion.

RESULTS

For 2 L/min, 3.5 L/min, and 5 L/min, the full velocity fields from the MRV scans revealed key differences in flow features due to changes in cardiac output. At peak systole, the shape of the jet through the valve and the formation of vortices are noticeably different for each case. At 2 L/min, the forward flow through the jet is more asymmetric compared to the higher cardiac outputs, and a strong vortex forms, indicating a region of recirculation (Figure 2). The slower overall flow at 2 L/min also produces larger regions of stagnant and reverse flow. At 3.5 L/min, some reverse flow persists as the valves are closing, but at 5 L/min, the faster flow through the valve prevents these reverse flow regions from forming. The valve orientation also has an impact on the flow fields. The rotated orientation results in a large region of reverse flow along the outer curve of the vessel that is not present in any of the native orientation cases. In addition to these differences in the streamwise flow, the radial flow local to the valve was also affected by the cardiac output, with radial flow persisting local to the valve leaflets during diastole only for the low cardiac output cases.

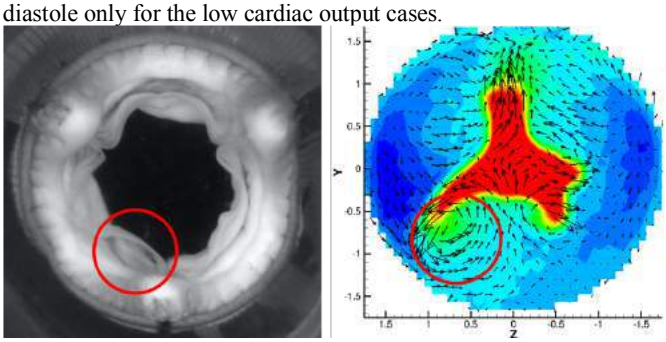

Figure 2: High speed camera image (left) and streamwise velocity contours with in-plane vectors (right) for the 2 L/min case at peak systole. Red circle highlights location where a partially closed section of leaflet influences the velocity fields.

The flow features provide insights into the hemodynamic environment of the valves, while the high-speed camera images capture the instantaneous leaflet motion. The effective orifice area, a key clinical metric in assessing valve performance, changes notably with cardiac output, though the valve orientation has little effect (Figure 3). The largest orifice area occurred at 5 L/min, with an 8.5% decrease for the 2 L/min case, indicating that valve is not operating as effectively at the lower cardiac output. In addition, at 2 L/min, a particular portion of one of the leaflets remains partially closed throughout systole, blocking flow through the valve orifice. This produces the asymmetry seen in the corresponding flow fields from the MRV scans (Figure 2). This connection demonstrates how flow features can reveal valve leaflet behavior.

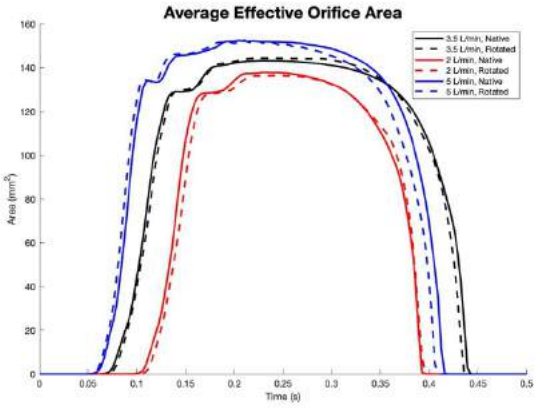

Figure 3: Effective orifice area over the cardiac cycle for 2 L/min (red), 3.5 L/min (black), and 5 L/min (blue)

DISCUSSION

Analyzing both the full flow fields and instantaneous valve motion at different cardiac outputs and valve orientations shows significant differences in stagnant and reverse flow, flow asymmetry, and leaflet behavior. With a 25mm valve, 3.5 L/min represents a normal cardiac output, while 2 L/min represents an oversized valve situation and 5 L/min represents an undersized valve. While some surgeons prefer to oversize the valve in young patients to account for continued growth, the differences in flow features and leaflet function may indicate an adverse environment for long-term valve performance. At 2 L/min, the partial valve leaflet opening produces a recirculation region which may increase risk of calcification. The overall orifice area is also notably lower for the 2 L/min case, which may impair the valve effectiveness. While clinical studies are necessary to fully determine how flow features and valve behavior are correlated with patient outcomes, insights from this study demonstrate that cardiac output significantly affects the valve hemodynamic environment and illustrate connections between the global flow and the instantaneous valve motion. Future work could also use these detailed data for experimental validation of valve fluid structure interaction simulations.

INTRODUCTION

Tissue and organ transplantation remains the most effective treatment for those patients who suffered from acute or chronic organ failures [1,2]. Unfortunately, there is a long waiting list for transplantation due to the lack of an effective organ preservation method. The current hypothermic storage could maintain the viability of hearts and lungs for up to 4 hours, intestine, pancreas, and liver for 8 to 12 hours, and kidney for up to 36 hours [3]. In such a short period, most of the tissues and organs (> 80%) are wasted due to insufficient time to match a recipient or exceeded the maximum storage time during transportation and handling. Cryopreservation, a technology to preserve the biomaterials at low temperatures to pause the biological and chemical reactions, is a potential solution to long-term tissue and organ preservation. To date, successful cryopreservation is limited to small volume biomaterials due to, in part, the challenges remaining in the rewarming process [4]. First, a rapid rewarming rate is needed to avoid fatal ice-recrystallization. Second, this rapid rate needs to be homogeneously distributed within the entire sample (to achieve uniform temperature distribution) to prevent thermal-stress-induced fracture. Therefore, a rapid and uniform rewarming technology is needed.

In this study, we developed a novel single-mode electromagnetic (EM) resonance (SMER) system, successfully converting EM energy into rapid-uniform volumetric heating. A dynamic feedback control loop was embedded to achieve real-time monitoring and adjusting the feeding frequency to maintain the biomaterials' higher absorptivity to the EM power. Thus, the EM cavity associated 'thermal runaway' problem, which is the increasing temperature difference within the sample because of the temperature-dependent EM power absorption, was limited and improved during the warming. Moreover, superparamagnetic nanoparticles (SNPs) were adopted to absorb magnetic field energy to further enhance the energy conversion efficiency.

The SNPs enhanced SMER system achieved ultra-rapid and uniform rewarming for large tissues (> 25 mL) to avoid ice-recrystallization and tissue fracture. The functionality and viability of the cryopreserved rabbit jugular veins using the SMER were comparable to the fresh-tissue control and over 5 times better than using the conventional 37 ℃ water bath (a current gold standard warming method in the clinical settings).

METHODS

Tissue Harvesting and Handling. Rabbit jugular veins were procured from adult male New Zealand rabbits (2-3 kg, N = 26) and immersed in Krebs-Henseleit buffer immediately, then transferred to the research lab within 1 hour. Tissues were sectioned into vein segments with the following dimensions: inner diameter, 2 to 4 mm, wall thickness, 1 to 2 mm, and length, 20 to 40 mm.

Cooling and Rewarming. After loaded with cryoprotective agents (CPAs), tissues with CPA solutions in a sample holder were cooled with liquid nitrogen vapor to -150 ℃ and stored overnight. Three rewarming methods were applied with different warming rates: (1) natural air convection: the cryopreserved tissues were put on the lab bench at room temperature (21 - 23 ℃); (2) water bath heating: the tissues were quickly transferred to 37 ℃ water bath with shaking at 60 RPM in an orbital motion; (3) SMER system: tissues were quickly transferred to the EM resonant cavity with a maximum power of 400 W. Temperature sensors were placed at the center and edge of the tissue holder, the heating was terminated when sample temperature reached 0 ℃.

Viability of tissues. Fresh tissue segments were incubated with growth media plus 10% alamarBlue solution at 37 ℃ and 5% carbon dioxide for 2 hours. The absorbance readings were determined by a

microplate reader at 570 and 600 nm to establish the baseline. The same procedure was repeated to obtain the readings of the warmed tissues.

Biomechanical Assessment of Tissues. Warmed tissues were cut into vein rings in the length of 3-5 mm. Each vein ring was mounted to a high-resolution force transducer in a Falcon tube. After loading the agonist (Histamine) and antagonist (Sodium Nitroprusside), contraction and relaxation response were measured by the transducer.

Tissue cryo-survival data was normalized to fresh tissue controls. Statistical significance is indicated with asterisks:****P <0.0001. The data are presented as the means with SD.

RESULTS

Recorded temperature profiles and thermal gradient between tissue center and edge of three warming methods are shown in Fig 1. The water bath heating achieved an average warming rate at 46.52 ± 4.85 ℃ min^{-1}, with a large temperature difference especially at the beginning of the warming. Natural air heating succeeded in a relatively uniform temperature distribution that confined the temperature difference within 10 ℃, but a slow rate at 4.53 ± 0.14 ℃ min^{-1}. SNPs-enhanced SMER system accomplished the uniform warming while surged the heating rate to 326.91 ± 7.55 ℃ min^{-1}.

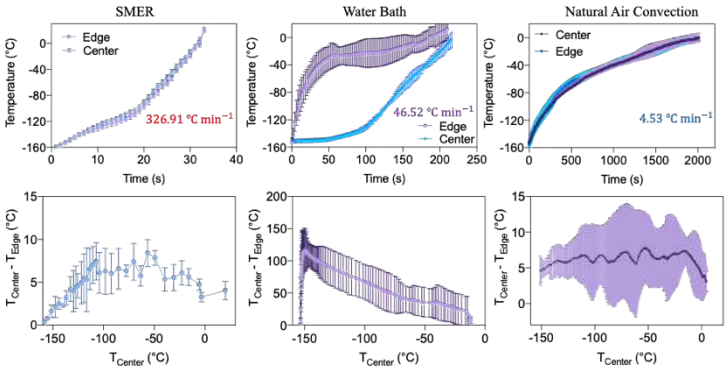

Figure 1. Temperature profiles and thermal gradients of SMER (left), water bath (middle), and natural air convection (right). n = 9.

As shown in Fig 2 left, viability of the vein warmed by SMER showed no statistical difference (P=0.3675) from the fresh samples at $86.54\pm5.63\%$, significantly higher than the convective water bath ($26.73\pm7.75\%$), and air warmed ($32.13\pm11.04\%$). The large decline of tissue viability in water bath and air warmed indicate the cryo-injuries caused by slow and non-uniform warming. The results were supported by Hematoxylin and eosin (H&E) stained histological images. The SMER image (B) demonstrates well-defined intact nuclear morphology

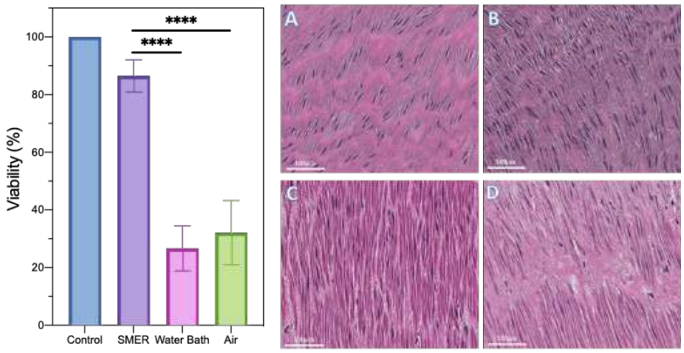

Figure 2. Left, viability of post-thawed vein measured by alamarBlue. **Right,** histological images of H&E stained samples. A, fresh tissue; B, SMER; C, water bath; D, natural air convection.

and structure of the venous smooth muscle cells, and it is comparable to the fresh control group (A). In contrast, the tissue warmed by water bath (C) and air convection (D) showed disruptive structure and dispersed nuclei with apparent hollow space between cells, possibly due to the ice-recrystallization and osmotic injury. The formation of ice could lead to the rupture of the cells and disruptive layered tissues, which could be observed as more hollow space (white area) in the histological images.

Similar to other smooth muscle tissues, contraction and relaxation are the two major biological functions of the jugular veins to maintain blood pressure and transport deoxygenated blood. As shown in Fig 3, fresh tissue and cryopreserved tissue using SMER system indicate the sensitivity of initial contractile and relaxation responses (forces in unit of N) to the agonist and antagonist at a lower concentration. The responses spiked as the concentration increased. Tissues warmed by water bath and air convection show minimal reaction (5 times lower than SMER) to both chemical stimulates and represent the loss of the biological functionalities after the cryopreservation.

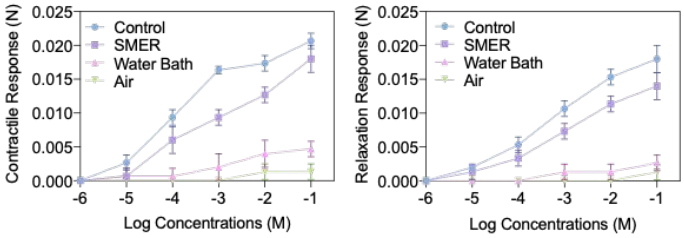

Figure 3. Maximum responses (forces) of post-thawed vein rings to the different concentrations of agonist and antagonist. Left, contractile response. **Right,** relaxation response.

DISCUSSION

In this study, a novel SMER was developed for rapid and uniform rewarming of large biomaterials in cryopreservation. SMER technology were compared with two conventional heating approaches, i.e, water bath heating and room-temperature air heating, respectively, during the cryopreservation of the rabbit jugular veins. Through the systematic examinations of the heating effects on cryopreserved biomaterials, we found that tissue samples rewarmed with slow and non-uniformed methods showed large decline of the viability and damage to the functionality, presumably due to the cell ruptures and tissue facture caused by the lethal ice-crystallization and large temperature gradient. On the other hand, rapid and uniform heating achieved by SMER technology provides a promising approach to the rewarming of large volume biomaterials. All the viability test, histological analysis, and biomechanical assessment results confirmed the successful rewarming of tissues by SNPs enhanced SMER system which maintained the tissue viability and functionality nearly identical to the fresh control. Ongoing and future studies include the further applications of the SMER system for cryopreservation of larger organs like human kidney and heart to meet the increased and urgent needs in organ transplantation.

INTRODUCTION

Transcatheter aortic valve (TAV) replacement (TAVR) emerged initially as an alternative procedure to the traditional and highly invasive surgical aortic valve replacement surgery (SAVR). TAVR consists of percutaneously deploying using a catheter, a bioprosthetic valve that can be reduced to a few millimeters in diameter in the aortic annulus, and subsequently, expanding it in the position of interest.

Leaflet thrombosis emerged as one of TAVR's adverse effects. The likelihood of leaflet thrombosis ranges between 15 – 40% [1]. Because thrombosis is a flow related phenomenon, more particularly a flow stasis related one, it is important to assess the surrounding flow in the neo-sinus and the sinus [2]. The goal of this work is to evaluate the flow dynamics in the sinus and the neo-sinus after implantation of 3 self-expanding TAVs (Medtronic Evolut, Boston Scientific Accurate Neo, and New Valve Technology Allegra) and a balloon expandable TAV (Edwards SAPIEN 3) in a 23 mm polymeric surgical aortic valve.

METHODS

The hemodynamic assessment of a 26mm Evolut, a 23mm SAPIEN 3, a small Accurate Neo and a 23mm Allegra transcatheter aortic heart valves in a 23mm polymeric surgical valve was performed in a left heart simulator under pulsatile conditions of physiological pressure of 120/80 mmHg, 5L/min and 60 beats per minutes. The fluid used in the experiments was a mixture of water-glycerin with properties similar to those of blood (density of 1060Kg/m^3 and a kinematic viscosity of 3.5cSt). Fifty consecutive cardiac cycles of aortic pressure, ventricular pressure, and flow rate data were recorded at a sampling rate of 100 Hz. Particle image velocimetry (PIV) experiments were performed to assess the flow in the sinus and the neo-sinus of each arrangement. The flow was seeded with fluorescent poly(methyl methacrylate)-rhodamine B particles with average diameter of 10µm. a laser sheet created by pulsed neodymium-doped yttrium lithium fluoride single-cavity diode pumped solid-state laser coupled with external spherical and cylindrical lenses shone on the region of interest while acquiring high-speed images of the fluorescent particles within the sinus region. Lagrangian particle tracking was utilized to estimate sinus and neo-sinus washout. Briefly, the PIV data was exported, and particles were seeded numerically on the neo-sinus and the sinus regions in a uniform grid at the beginning of the cardiac cycle. The updated position of the particles is integrated from the velocity information. At the end of every cardiac cycle, the new locations of the particles are extracted and only those that remain after the cardiac cycle time is over are seeded again. This process is repeated until all the particles have washed out. In addition, shear stress was also computed as per equation 1 and probability density functions were calculated and plotted.

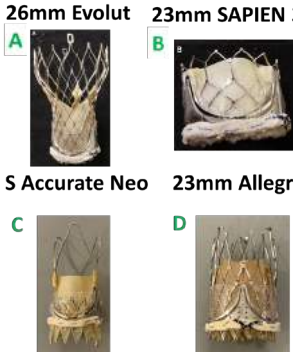

Figure 1: Valves tested. (A) Evolut, (B) SAPIEN 3, (C) Accurate Neo and (D) Allegra

RESULTS

The washout curves in the neo-sinus and the sinus for the 4 self-expanding and the balloon expandable TAVs are shown in Figure 2A and 2B respectively. In the neo-sinus, the Evolut, Accurate and Allegra's washout is nearly 1 cardiac cycle, whereas the SAPIEN 3 washout takes about 3 cardiac cycles.

In the sinus, the Evolut, Accurate Neo and Allegra's washouts are nearly 1 cardiac cycle whereas SAPIEN 3 washout is about 2 cardiac cycles. The results of the shear stress probability density function are

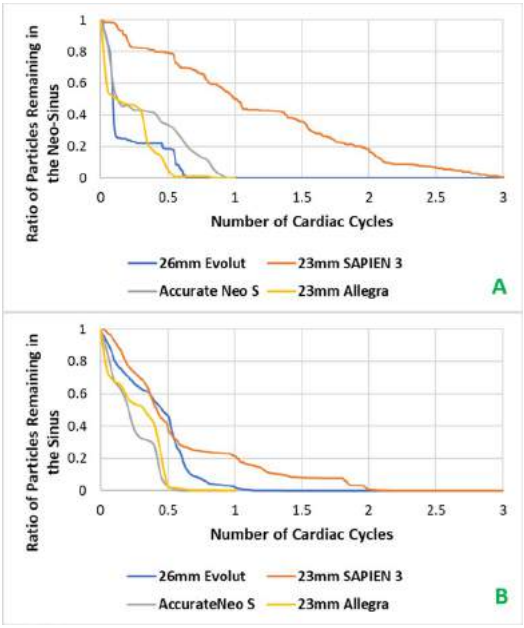

Figure 2: Washout in the neo-sinus and washout in the sinus of the 3 self-expanding TAVs and the balloon expandable TAV.

shown in Figure 3. The range of the shear stress in the neo-sinus and the sinus are shown to be similar (between 1.5 Pa and 3.5 Pa). The Allegra is characterized by the largest shear stress distribution, followed by the SAPIEN 3. In the neo-sinus, the Evolut is characterized by a larger shear stress distribution compared to the Accurate Neo however, in the sinus the Accurate Neo shows a larger distribution with higher likelihoods to develop shear stresses that exceed 1.1 Pa.

The velocity vectors are shown in Figure 4 for the 4 different valve cases. The velocities in the sinus and the neo-sinus were 0.05, 0.078, 0.080 and 0.075 m/s in the Evolut, SAPIEN 3, Accurate Neo and Allegra.

DISCUSSION

The self-expanding TAVs are characterized by a faster washout compared to the balloon expandable TAV, even when the design of the self-expanding valve leaflets was intra-annular and not supra-annular as is the case with the Accurate Neo. The design of the Accurate Neo valve is unique when the frame is considered. Large gaps in the stent show probably allowing more freedom of displacement of the leaflet compared to the SAPIEN 3. The other self-expanding valves are characterized by a supra-annular leaflet design offering a larger and a less confined and restricted neo-sinus area allowing for flow to enter and exit faster. With respect to shear stress in the neo-sinus and the sinus, while larger magnitudes are expected for the self-expanding valves, the balloon expandable SAPIEN 3 shows a larger distribution with larger probabilities compared with the Accurate Neo (with intra-annular leaflet design) and the Evolut (with supra-annular leaflet design). This may be due to the short profile of the SAPIEN 3 that eliminates the potential obstructions for flow to enter the sinus region compared with the other long-frame self-expanding valves.

With the Evolut, given the supra-annular design, it is expected for larger shear stress to occur in the neo-sinus compared with the Accurate Neo (with a smaller neo-sinus, given the intra-annular design). In the sinus

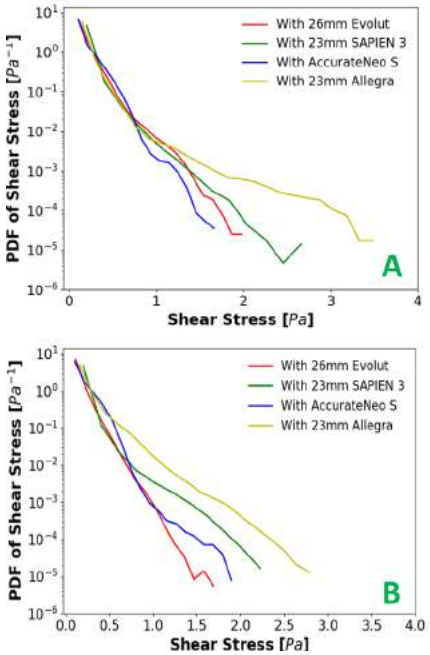

Figure 3: Probability density function of the viscous shear stress in the neo-sinus and the sinus regions of the 3 self-expanding TAVs and the balloon expandable TAV in the (A) neo-sinus and (B) in the sinus over the whole cardiac cycle.

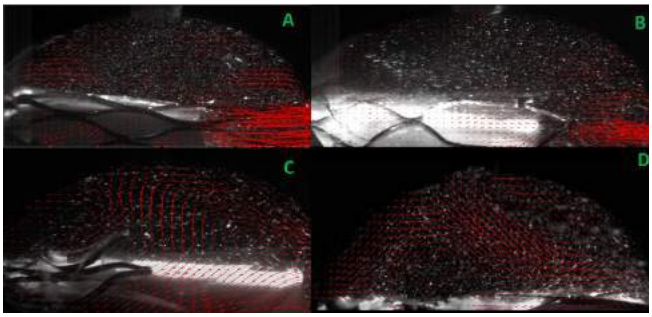

Figure 4: Velocity vectors at peak systole with (A) Evolut, (B) SAPIEN 3, (C) Accurate Neo and (D) Allegra.

however, the Accurate Neo is characterized by a more open frame design allowing for more flow to enter and exit leading to a larger distribution of shear stress there.

In conclusion, Sinus and neo-sinus flow dynamics highly differ between TAVs. Self-expanding supra-annular valves seem to be more advantages compared to an equivalent-size balloon-expandable TAV. We speculate that the data obtained in this study supports the clinical observations where more incidence of leaflet thrombosis is observed with the balloon expandable valves [3].

INTRODUCTION

Bone remodeling is a unique process to bone that continues even after growth. In aging, the balance between bone formation and resorption is not maintained, thus some bones become osteopenic and eventually osteoporotic [1]. Bone quality may be characterized by bone mechanical properties which are estimated by Euler-Bernoulli (EB) and Timoshenko (TI) beam theories. Mechanical testing and image-based finite element analysis (FEA) are commonly used for bone mechanical property assessment; their accuracy is therefore crucial. This study quantified some of the errors in long-bone mechanical property assessments.

In most long bone research studies, Euler-Bernoulli beam theory is typically used, but it is well-established that this beam theory under-estimates the bending deflection of short thick beams [7]. This beam bending theory assumes long slender beams and therefore does not account for shear deformation [2]. Studies on shear deformation in short, thick and non-prismatic beams subjected to bending can be traced back to mid-1800s [2], but few studies in biomechanics have used Timoshenko beam theory (TI) to calculate the elastic modulus from bending tests. Although in bending tests, the main component of bone deformation is bending, shear deflection and roller-indentation also have notable contributions [2]. Previous studies [2, 3, 4] revealed that using the EB to predict the bone mechanical properties like elastic modulus, leads to a considerable underestimation. Consequently, we hypothesized that TI beam theory would be a more accurate analytical method for estimation of bone flexural rigidity (EI). The purpose of this study was to quantify the difference in EI of a short-thick beam in three-point bending using EB and TI beam theories.

METHODS

Three-point bend tests on a bone surrogate [1] were performed with three replicates and six repeats on each using a custom-designed three-point bending apparatus and MTS Bionix 370 Servohydraulic Test System universal materials testing machine. Force was measured by load cell (model# 662-20H-04) while deformation was measured at the crosshead (CH) and midpoint (mid) with extensometer (Epsilon model 3540-001M-ST). Figure 1. Shows the experimental setup. The experimental bending stiffness (K_{CH} and K_{Mid}) were calculated as the slope of the linear portion of their corresponding force-(F) deflection (δ) data (Fig.1).

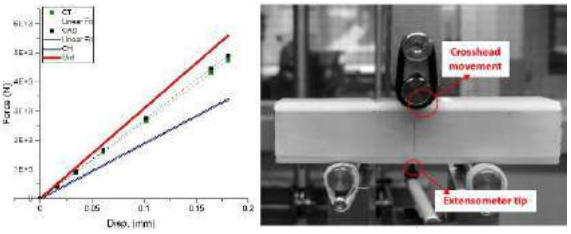

Figure 1: Typical load-displacement curves obtained from a three-point bending test of a bone surrogate. The experimental bending stiffness was calculated as the slope of the linear part of the curve with regression (left). Three-point bend test setup (right)

The same bending test was simulated with FEA (Abaqus CAE/2017) on CAD- and CT-based models. The computational bending stiffness (K_{FEA}) was calculated by dividing the total reaction force at bottom supports over the vertical deflection due to bending at the midpoint. EB and TI beam theories were used to calculate the bone surrogate flexural rigidity (Eq. 1, 2).

$$EI_{EB} = \frac{K_{Exp}(L^3)}{48} \quad (1)$$

$$EI_{TI} = \frac{K_{Exp}l^3}{48(1-\frac{K_{Exp}l}{4kGA})}. \quad (2)$$

Where K_{exp} is stiffness as measured from the bending test; L is the distance between two lower supports (50.8 mm); A is the cross-sectional area from the CAD model of the shell (915.7 mm^2); k shear correction factor for a rectangular cross section (0.83), and G is the shear modulus of the shell (1045.5 MPa) [1]. Theoretical EI value was calculated from the material properties and CAD geometry ($EI_{Theoretical}$= 1.26E+08 Nmm^2) of the bone surrogate shell [1]. Three paired t-tests were conducted to test for statistically significant differences between bone surrogate stiffness determined by different methods (K_{CH}, K_{Mid} and K_{FEA}) (α=0.025, t-critical value=2.45). EI from the bending test with different methods were compared using one-way ANOVA with a Tukey post-hoc test (α=0.05). All statistical analyses were done using OriginPro 2020 and Excel 2013.

RESULTS

Percent error of the bending stiffness was defined in comparison to the three-point bend test results including midpoint deflection data (Figure 2).

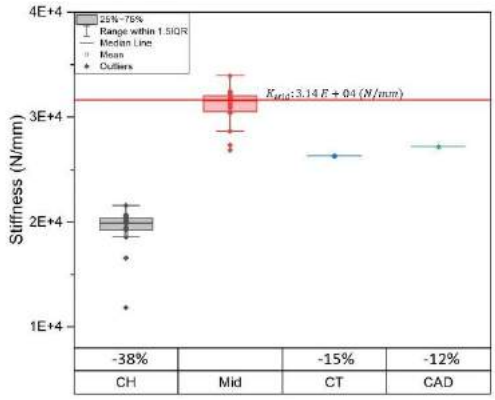

Figure 2: Bone surrogate K and percent error for each method in comparison with midpoint measurements (K_{Mid}), (CH: crosshead displacement, CT: FEA on CT-based model, CAD: FEA on CAD-based model)

Mean K_{CH} was low (-38% error) compared with mean K_{Mid}; and each K_{FEA} was close (-12% and -15% errors) to the mean K_{Mid}. Results were significantly different from the mean K_{Mid} value (p-value< 0.001, α=0.025), (Table 1).

Table 1: Bone Surrogate Bending Stiffness and Percent Errors for each Method. The error was defined with respect to the stiffness obtained from Mid (3.14E+04 N/mm). (CH: crosshead displacement, Mid: midpoint deflection, CT: FEA on CT-based model, CAD: FEA on CAD-based model, TI: Timoshenko beam theory, EB: Euler-Bernoulli beam theory)

	CH	Mid	CT	CAD
Mean (N/mm)	1.87E+04	3.14E+04	2.63E+04	2.72E+04
Std Dev (N/mm)	1.55E+03	8.24E+02	…	…
p-Value	<0.001	…	<0.001	<0.001

In comparison to the theoretical EI (1.26E+08 Nmm^2), Flexural rigidity was under-estimated by EB beam theories (-58% to -32% errors for EI_{CH} and EI_{Mid}), while TI under- and over-estimated the bone surrogate EI (-41% for EI_{CH} and +32% for EI_{Mid}) (Fig. 3). The EI from CT- and CAD-based FEAs as calculated based on TI beam theory had a negligible error (-3% and +2%). In contrast, the EI of the CT- and CAD-based models which were calculated by EB beam theory, had a considerable error (-43% and -41%, respectively) in comparison with the theoretical value ($EI_{theoretical}$= 1.26E+08 Nmm^2).

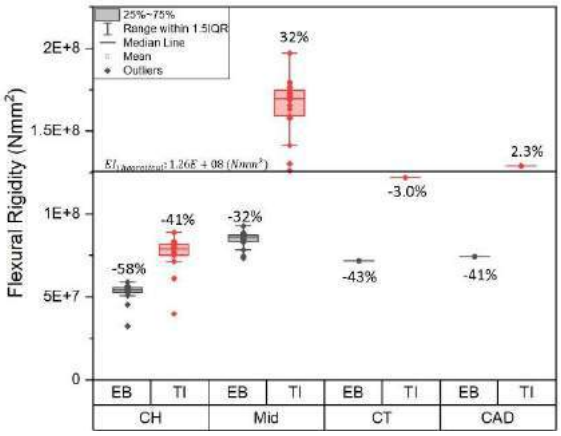

Figure 3: Bone surrogate EI and percent error for each method (CH: crosshead displacement, Mid: midpoint deflection, CT: FEA on CT-based model, CAD: FEA on CAD-based model, TI: Timoshenko beam theory, EB: Euler-Bernoulli beam theory)

DISCUSSION

In this study, K_{Exp} and K_{FEA} of a bone surrogate were measured with a three-point bend test. The corresponding EI for each K was calculated based on EB or TI beam theories. This study confirmed that EB underestimated the bone surrogate EI in all methods and there was statistically significant difference between experimental EI calculated by EB and TI beam theories. EB underestimated EI in comparison to TI beam theory. We found TI beam theory predicted the bone EI more accurately than the EB beam theory for FEA on CT- and CAD-based models. For bone surrogate EI measurements with midpoint deflections, it can be concluded that EB and TI beam theories result in under- and over-predictions, respectively. Future work will include digital image correlation (DIC) to measure the bone surrogate deformation to find the bending stiffness and calculate the corresponding EI. These DIC data would create a gold standard for the comparisons for FEA validation. Limitations of this study were: small sample sizes; not all sources of compliance were not taken into account; and testing was performed on a bone surrogate with simplified geometry and materials. Accurate estimation of bone stiffness and flexural rigidity is crucial for investigations on bone disease, diagnosis, and treatments. The results of this study increase the accuracy of such investigations furthering efforts towards improving bone health.

INTRODUCTION

The theory of porous media (TPM) plays an important role in many diverse areas of engineering, including particularly the biomechanics of soft tissues (e.g. liver, brain, and cartilage) [1,2]. The remarkable macro-mechanics of soft tissues derives from the complex micro-mechanics of their constituents, e.g. proteoglycans, collagens, and electrolytic fluid, and their interactions. To facilitate mechanistic understanding and improved analyses (e.g. of experimental results) of the multi-scale mechanics of soft tissues we aimed to establish a computational framework specific to fluid-saturated, fibrous soft tissues and engineered materials. We can apply experiments to quantify mechanical properties and biology of tissues, and imaging to estimate tissue structure and even strains; however, only computational models can estimate intra-tissue stresses in human joints and tissues during daily activities because the required *in vivo* experiments are impossible or unsafe. Here we established a multi-scale framework combining the TPM and the FE^2-method (performing finite element discretizations of boundary value problems (BVPs) on both macro and micro scales) for fluid-saturated porous media within FEBio (University of Utah).

METHODS

FE^2 Modeling Framework For Porous Materials. To solve the partial differential equations governing the macroscopic BVP we used the finite element method twice: we evaluated the macroscopic material tangent $\overline{\mathbf{A}}$ and measures $\overline{\mathbf{P}}$, $\overline{(\mathbf{E}_\mathrm{S})'_\mathrm{S} : \mathbf{C}_\mathrm{S}]_\mathrm{S}}$, $\overline{n^\mathrm{F}\mathbf{w}_\mathrm{FS}}$ (first P-K stress, Green Lagrange strain rate, right Cauchy-Green tensor, Jacobian, fluid volume fraction, and filtration velocity respectively) at each Gauss integration point by a volume averaged solution of the underlying microscopic Representative Volume Element (RVE), as shown in **Fig. 1**.

Constitutive Model. We described a biphasic material model with two material-incompressible constituents $\varphi^\alpha (\alpha \in \{\mathrm{S},\mathrm{F}\})$ constrained

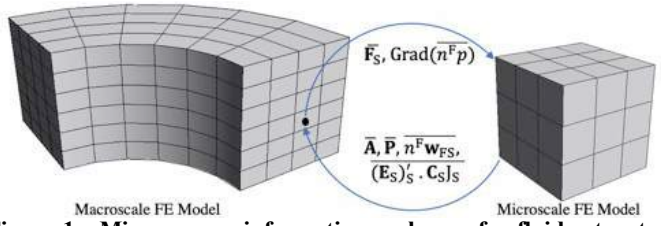

Figure 1: Micro-macro information exchange for fluid-saturated porous media.

by the saturation condition as

$$n^\mathrm{S} + n^\mathrm{F} = 1\,, \tag{1}$$

where n^S and n^F are current solid and fluid volume fractions, respectively. Considering the saturation condition we constrain the material time derivative of the saturation following the solid motion as

$$(n^\mathrm{S})'_\mathrm{S} + (n^\mathrm{F})'_\mathrm{S} = 0\,. \tag{2}$$

We use the balance of mass and the definition of the seepage velocity w_FS to evaluate the entropy inequality of the mixture as [3]

$$\mathbf{d}_\mathrm{S}\left[\boldsymbol{\sigma}^\mathrm{S} + n^\mathrm{S}p\mathbf{I} - 2\rho^\mathrm{S}\mathbf{F}_\mathrm{S}\frac{\partial \Psi^\mathrm{S}}{\partial \mathbf{C}_\mathrm{S}}\mathbf{F}_\mathrm{S}^\mathrm{T}\right] + \mathbf{d}_\mathrm{F}[\boldsymbol{\sigma}^\mathrm{F} + n^\mathrm{F}p\mathbf{I}] + \mathrm{w}_\mathrm{FS}[p\nabla n^\mathrm{F} - \hat{\mathbf{p}}^\mathrm{F}] \geq 0 \tag{3}$$

where p is the fluid pressure, $\mathbf{I}$ is the identity, $\mathbf{F}_\mathrm{S}$ is the solid deformation gradient, $\mathbf{C}_\mathrm{S}$ is the right Cauchy-Green tensor, and $\hat{\mathbf{p}}^\mathrm{F}$ is the interaction force of the fluid. We write partial Cauchy stresses as [4]

$$\boldsymbol{\sigma}^\mathrm{S} = -n^\mathrm{S}p\mathbf{I} + 2\rho^\mathrm{S}\mathbf{F}_\mathrm{S}\frac{\partial \Psi^\mathrm{S}}{\partial \mathbf{C}_\mathrm{S}}\mathbf{F}_\mathrm{S}^\mathrm{T} = -n^\mathrm{S}p\mathbf{I} + \boldsymbol{\sigma}_\mathrm{E}^\mathrm{S}\,, \tag{4}$$

$$\boldsymbol{\sigma}^\mathrm{F} = -n^\mathrm{F}p\mathbf{I}\,, \tag{5}$$

for the solid and fluid, and where $\boldsymbol{\sigma}_\mathrm{E}^\mathrm{S}$ is the effective Cauchy stress.

Validation and Representative Examples. We provide numerical examples demonstrating the performance of our multi-scale approach for fluid-saturated porous material. To validate our implementation we first reproduced 2-D examples from Bartel et al. [6,7] using a neo-Hookean constitutive model for solid the phase [5] and 3-D elements under plane-strain conditions. We first considered a square block of height $H = 10$ mm and width $L = 10$ mm subjected to constant load as shown in **Fig. 2(a)**. We fixed left-bottom corner and used a roller support the right-bottom corner. We used the material properties $\mu = 168$ GPa, $\lambda = 1870$ GPa, $K_d = 0.5$ mm^4/(Ns). We applied a point load $q = 4.55$ N on all nodes at the top surface. We prescribed the fluid pressure $p = 10$ N/mm^2 at top surface and set the pressure to zero on three nodes in the center of the bottom surface. We increased the load and pressure linearly during time ($t = 5$ sec). **Figures 2(b)** and **2(c)** show the corresponding meshes for macroscopic structure (10×10 elements) and the microstructure (5×5 elements), both using eight-node hexahedral elements in plane strain.

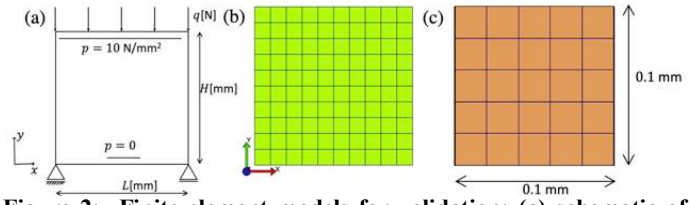

Figure 2: Finite element models for validation: (a) schematic of square block [6]; (b) mesh for macroscopic structure; (c) corresponding mesh for microstructural RVE.

We next considered a cantilever beam of porous material with height $H = 2$ mm and width $L = 10$ mm, as shown in **Fig. 3(a)**. We fixed the left side of beam in all degrees of freedom and prescribed fluid pressure ($p = 10$ N/mm^2) which we increased linearly with time ($t_{\max} = 5$ sec). On the right hand side, we set the pressure to zero. **Figures 3(b)** and **3(c)** show the corresponding meshes for macroscopic structure (40×8 elements) and the microstructure (10×10 elements), using the same elements as above. **Table 1** provides the Lame constants and Darcy permeability of biphasic neo-Hookean used for the RVE.

Table 1: Material parameters of the microstructural RVE.

Material Const	μ [MPa]	λ [MPa]	K_d [mm^4/(Ns)]
Material 1	26	287	0.1
Material 2	16	187	1.0

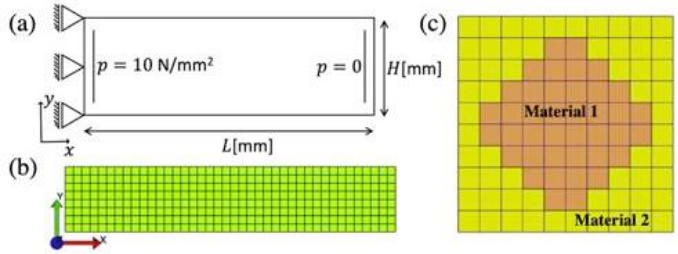

Figure 3: Finite element models for validation: (a) schematic of cantilever beam [7]; (b) mesh for macroscopic structure; (c) corresponding mesh for microstructural RVE.

RESULTS

In **Fig. 4**, we show the results for the macroscopic structure of the first validation case, the square block (**Fig. 2**). **Figures 4(a)-4(d)** show the displacement in the y-direction (u_y), the normal Cauchy stress in the x-direction (σ_{xx}), the fluid pressure (p), and the fluid flux in the y-direction (w_y) for the macroscale model informed by the isotropic microstructural RVE. In **Fig. 5**, we show the results for the macroscopic structure of the second validation case, the cantilevered beam (**Fig. 3**). **Figures 5(a)-5(c)** show the displacement in the y-direction (u_y), the fluid pressure (p), and the fluid flux in the x-direction (w_x) for the macroscale model informed by the heterogeneous microstructural RVE including a hard inclusion. Our macroscopic results from both the square block (**Fig. 4**) and the cantilever beam (**Fig. 5**) match the 2-D results of [6,7], thus validating our multiscale implementation in 3-D.

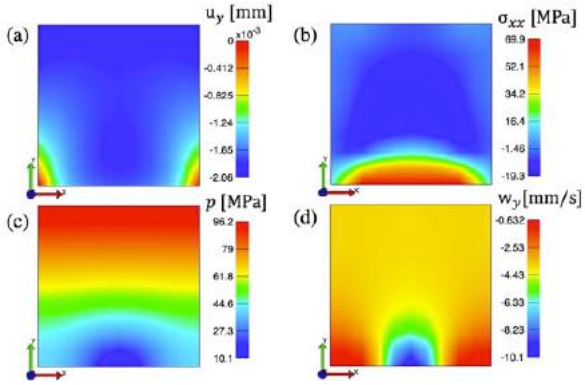

Figure 4: Macroscale results: (a) u_y; (b) σ_{xx}; (c) p; and (d) w_y.

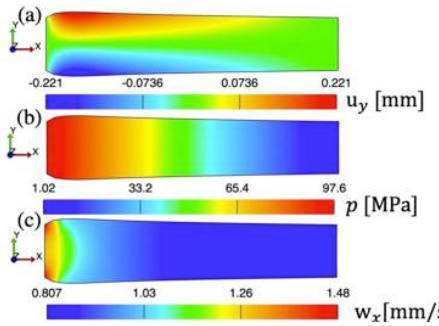

Figure 5: Macroscale results: (a) u_y; (b) p; and (c) w_x.

DISCUSSION

We combined the TPM and the FE^2-method (i.e. the TPM^2 method) to solve two-scale, non-linear, coupled, and time dependent BVPs for materials with a porous microstructures. We considered both isotropic, homogeneous RVEs (**Fig. 2(c)**) and those with inclusions (**Fig. 3(c)**), the latter with relatively stiff and impermeable inclusions. To solve the multiscale BVPs we first provide the microscopic RVEs with macroscopic quantities as boundary conditions (BCs). These BCs must comply with Hill-Mandel homogeneity conditions [7]. The microscopic RVEs must then provide the first Piola-Kirchhoff stress tensors $\bar{\mathbf{P}}$ back to the macroscale model at each integration point. Emerging multi-scale FE^2 methods (FE analyses augmented to derive the material behaviors from a distribution of finer scale FE analyses) are ideally suited to bridge the joint, tissue, and intra-tissue scales, but have not yet been applied to multi-phase, fibrous materials. We will leverage our TPM^2 framework, e.g. to establish how physical activity propagates micro-damage in the collagen network of cartilage.

INTRODUCTION

Previous studies suggested that biomechanical forces play an important role in modulating cardiac morphogenesis, and abnormal biomechanical stimuli may cause congenital heart malformations.

The global effects of prolonged disruption of the hemodynamic environment on morphology and cardiac function have not been fully evaluated. Such analysis can help to improve our understanding of the role of biomechanical environments in cardiac development. Moreover, our understanding of the mechanobiological mechanisms of development is incomplete, and there could be important expression and mechanisms that are yet to be discovered. It would thus be useful to conduct whole transcriptomic analysis of the embryonic heart under heartbeat inhibition to identify candidate expression.

In the current study, we investigated the consequences of administering BDM to 2 dpf zebrafish embryos for a prolonged three-day duration. We characterized changes in cardiac morphology and function caused by the treatment, including using computational fluid dynamics (CFD) simulations to evaluate details of the biomechanical environments during and after the treatment. We also performed whole transcriptomic RNA sequencing of embryonic cardiomyocytes to identify potential pathways for disruption of normal biomechanical environments on the heart development.

METHODS

10 mM of BDM (Sigma, B0753) was used to depress myocardial contractility from 2 to 5 dpf. of a transgenic line, *Tg(phiC31.attP.2A, -0.8myl7: EGFP*), which labels myocardium. BDM was washed out at 5 dpf for two hours, and both control and treated embryos were observed directly thereafter.

The body length, yolk size, cardiac looping angle and ventricular size of control and treated embryos were measured using ImageJ software. Ventricular contractility was also quantified.

CFD simulation of ventricles were performed based on the images taken using line-scan focal modulation microscopy (LSFMM) according to methods established in our previous publication [1]. CFD simulations of three control hearts (Heart I, II & III) and four treated hearts (pre-washout: Treated heart I & II; post-washout: Treated heart III & IV) were completed. Wall shear stresses at the inlet, mid-ventricle and outlet were examined.

GFP-positive cardiomyocytes of control and treated hearts were harvested through fluorescence-activated cell sorting, followed by RNA extraction. The integrity of RNA samples was confirmed (RIN > 7) before RNA sequencing. KEGG pathway analysis was presented.

RESULTS

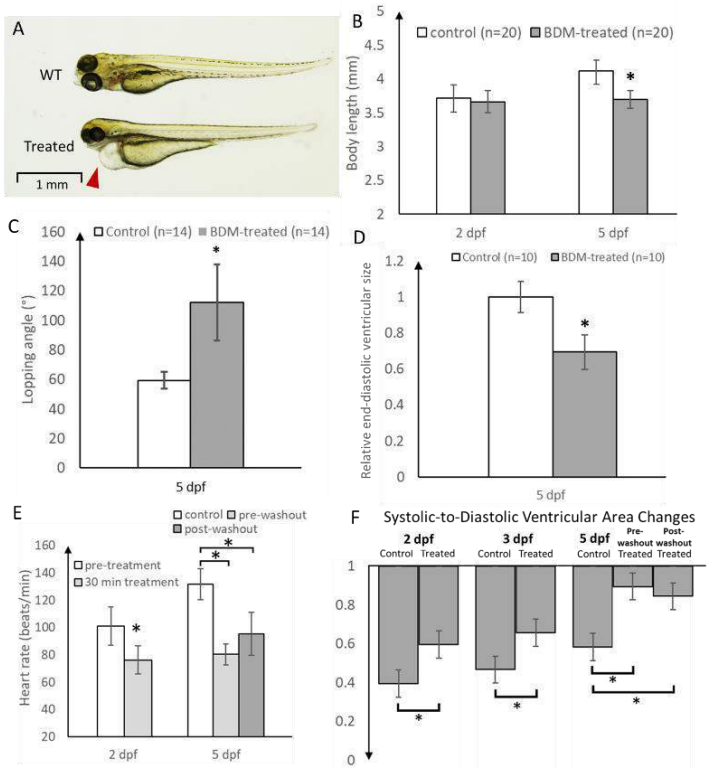

Figure 1. A 5 dpf embryo after 3 days of BDM treatment exhibits

(A) pericardial effusion, (A,B) shorter body length, (C) impaired cardiac looping angle, (D) a smaller ventricular size (relative to normal embryo), (E) decreased heart rate that persisted after BDM washout, and (F) reduced cardiac contractility which also persisted after BDM washout.

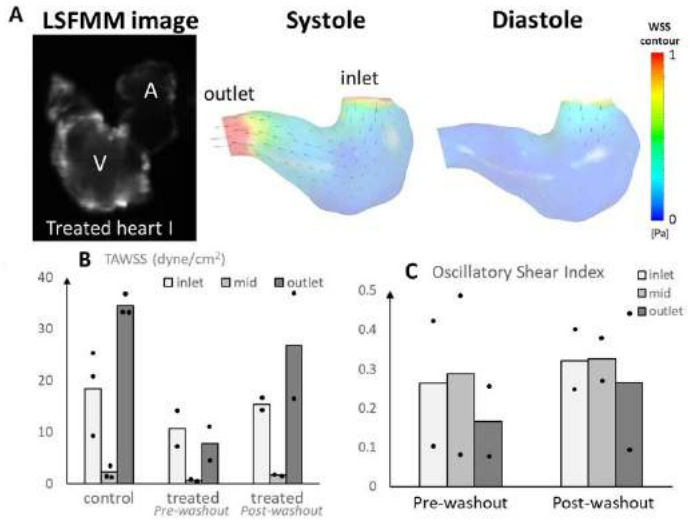

Figure 2. (A) LSFMM image of embryonic heart, and spatial WSS contour results from CFD of a treated heart. A-atria, V-ventricle (B,C)Treated heart retain little function and has low and oscillatory WSS even after BDM washout.

During BDM treatment, most embryos had cardiac contractions completely inhibited, while some had weak and slow contractions. BDM treatment of embryos from 2 to 5 dpf resulted in pericardial effusion, shorter body length and poor cardiac development. Treated hearts exhibit larger looping angle, 30% smaller ventricular chambers (Figure 1), absent ventricular trabeculae and retrograde blood flow.

BDM treatment further resulted in a declined cardiac function, which was determined from embryos after BDM washout. Both heart rate and contractility were significantly reduced (Figure 1E-F). Due to the reduced contractility and regurgitation, cardiac output was significantly reduced, and flow became abnormally oscillatory. This led to reduced and abnormally oscillatory WSS (Figure 2B-C).

RNA sequencing revealed 922 significantly upregulated genes and 1698 significantly downregulated genes, representing alterations to several KEGG pathways in Table 1. First, inflammatory pathways such as the TLR, consisting of several inflammatory genes including *tlr5a*, *tnf-α*, and various interleukins were upregulated. Second, ECM-receptor pathways, ECM remodeling genes including many types of collagen, tenascin and laminin, and cell-adhesion molecule were significantly downregulated. Further, the apoptosis and p53 pathways and a number of apoptosis genes including *fas* and caspases were significantly upregulated. The downregulation of *erbb4a* and *nrg1* suggests perturbations to trabeculation.

Histological investigation confirmed evidence of apoptosis and inflammation in the embryonic hearts.

DISCUSSION

From our results, we propose that BDM treatment has led to disturbed contractile and flow patterns in the heart, leading to inflammation of the endothelium and myocardium, which enhanced apoptosis and reduced growth. Separately, the lack of deformational stimuli decreased ECM-receptor interaction gene responses and ECM remodeling, further impeding growth. The lack of flow stimuli is likely to have prevented trabeculation formations via the notch-neuregulin pathway [2], but interestingly, was found to be accompanied by Erbb4a instead of Erbb2 reduction. A schematic of these pathways is given in Figure 3.

CONCLUSION

Prolonged pharmacologically disruption of the biomechanical environment of zebrafish embryonic hearts resulted in mal-development of cardiac morphology, and significant reduction in cardiac function. These morphological and functional outcomes likely occurred through inflammation and cell-ECM interaction pathways, which enhanced apoptosis and reduced ECM remodeling.

Table 1: Selected list of significant KEGG pathways

Up-regulated	
KEGG Pathways	Corrected P-Value
Toll-like receptor signaling pathway	0.0004
Cytokine-cytokine receptor interaction	0.0008
NOD-like receptor signaling pathway	0.0012
Apoptosis	0.0013

INTRODUCTION

Congenital aortic stenosis has a prevalence of 0.2-0.5 per 1000 live births [1]. It can develop during mid-gestation leading to severe cardiac dysfunction and drastic biomechanical changes. The stenosis results in high LV pressures, the consequent mitral regurgitation, drastically reduced myocardial contraction and stroke volume. Consequently, a substantial proportion of affected fetuses undergo mal-development, and evolve and develop into hypoplastic left heart syndrome (HLHS) by birth [2]. In such cases, fetal aortic valvuloplasty can be used to relief the obstruction, enable better development, and to avoid becoming HLHS at birth [3]. However, neither the biomechanical environments of fetal aortic stenosis nor that introduced by FAV is not well understood, and although FAV produces promising results and statistics, we do not understand why it does not work in many cases. Thus, in this study, we perform image-based finite element (FE) modeling of the biomechanics of the human fetal heart, modelled the various features of critical aortic stenosis, to understand their biomechanical effects.

METHODS

The 3D geometries of three normal human fetal LVs were reconstructed from the 4D (STIC) ultrasound images, and ultrasound measurements in a cohort of 32 fetuses with critical aortic stenosis were acquired, both with IRB approval and patient consent. A validated cardiac motion estimation algorithm [4] was used to track LV motion from an initial segmentation. The FE modelling of the fetal LV was adapted from previous work [5], and featured the Guccione active tension [6], a transversely isotropic Fung strain energy function, epi-to-endo linearly spatially varying fiber orientation, a simplified Windkessel model (Figure 1) [7], and was solved via FEniCS. The fiber angle was adjusted to obtain satisfactory match in LV geometry between FE results and image motion tracking results. Valve flow rate data from the model was translated into valve velocity data via an empirical discharge coefficient formulation, via an iterative solver.

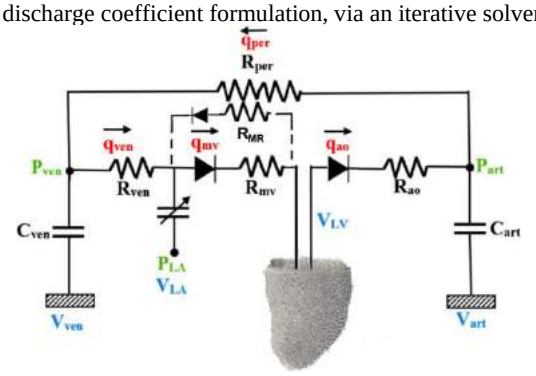

Figure 1. Schematic of the FE model and the simplified Windkessel model.

Subsequently, disease features were modelled as follows.

1. **Aortic Stenosis:** via increasing aortic resistance
2. **Aortic Stenosis and Mitral Regurgitation:** via addition of regurgitation Windkessel element.
3. **Myocardial hypertrophy:** via increasing the wall thickness
4. **Endocardial Fibroelastosis:** via increasing myocardial stiffness.
5. **Cardiomyopathy:** via decreasing active tension magnitude.

RESULTS

The FE modeling was able to produce LV geometries that exhibited a good match with LV geometries from the images, with an average surface distance error of about 1% of the smallest heart's diameter. With aortic stenosis alone (Figure 1), LV pressures were found to elevate by 10-20 mmHg, and stroke volume could be drastically reduced, depending on stenosis severity (leaving the RV to

serve cardiac function alone). With mitral regurgitation in addition to aortic stenosis, LV pressure reduces slightly, and stroke volume increased slightly (Figure 1). Fetal aortic stenosis was further found to extend systolic duration to about 70% of the cardiac cycle, due to an inability to relief pressure, which corroborated with clinical Doppler measurements.

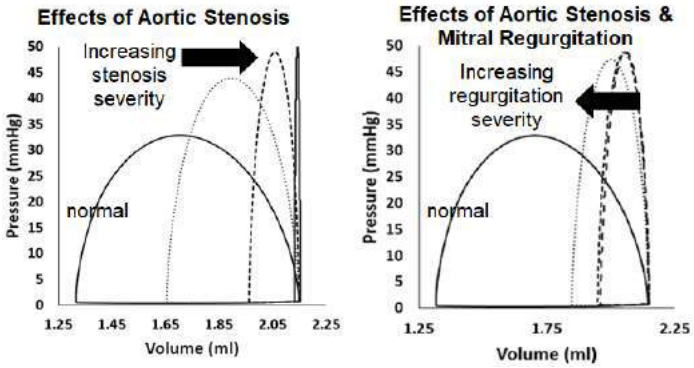

Figure 2. Pressure volume loops of a 28 week old fetal heart with (left) aortic stenosis alone, and (right) aortic stenosis with mitral regurgitation, with various stenosis and regurgitation severity.

With aortic stenosis and mitral regurgitation, aortic valve flow velocity increased to 1.9-2.8 m/s, well above velocities observed in normal fetal hearts (0.6-1.0 m/s). However, we found that aortic valve velocities could not reach high values observed clinically in our diseased cohort (3.4 ± 0.9 m/s). This suggest that myocardial hypertrophy must have occurred to provide greater cardiac power, as our modelling of LV wall thickening demonstrates that significant additional cardiac power can be achieved (Figure 3). A 50% increase in thickness increased systolic pressure by 72% and stroke volume by 54%, and increase aortic valve velocity to 3.9 m/s. Indeed, clinical measurements in 10 our cohort of 32 disease fetuses showed that a 105% increase in wall thickness compared to age-matched normal fetuses, on the average.

However, this typical extent of hypertrophy (100% increase in thickness) was found in our model to generate excessively high LV systolic blood pressures, of about 100 mmHg, which was much higher than invasive clinical measurements of 63 mmHg [8]. This suggested that on top of hypertrophy, typical aortic stenosis fetuses also suffer from reduced contractility. Our model shows that decreased active tension causes a roughly proportional decrease in stroke volume and systolic pressure.

Many fetal aortic stenosis haerts experiences endocardial fibroelastosis, which is a fibrosis of the endocardial layer that is visible in the ultrasound, and which can likely be modelled via increased myocardial passive stiffness. In our modelling, however, stiffness increase of up to 100% demonstrated only modest changes in stroke volume, systolic blood pressure, and myocardial stresses (Figure 3). Thus, contrary to current believes, fibroelastosis is unlikely to impede cardiac function and cause dysfunction, contrary to current clinical beliefs. We hypothesize that fibroelastosis is likely a by-product of the altered biomechanical physiology, rather than a factor impeding function.

DISCUSSION AND CONCLUSION

In this study, we developed and calibrated a FE models of healthy fetal hearts from 4D ultrasound images and then used them to investigate biomechanical changes during disease conditions associated with fetal AS. Our study shed light on how the individual effects of each of the disease features affect the biomechanical environment of fetal heart. We showed that various extent of aortic stenosis, mitral regurgitation, ventricular hypertrophy and cardiomyopathy can cause significant changes to the fetal heart biomechanical environment. These drastic changes are likely to alter the fetal heart growth and remodeling responses, potentially leading to HLHS at birth. We further discovered that changes to the myocardial passive stiffness (fibroelastosis) only had very modest effects cardiac function. Our study thus demonstrated that FE modeling can be a very useful tool in understanding fetal heart diseases. Moving forward, we hope to use the same approach to model the biomechanical effects of the fetal heart intervention in this disease cohort, and develop methods to predict outcomes, such that we can help physicians make clinical decisions. For example, better prognosis can be used to more accurate select patients for intervention, minimizing unnecessary procedural risks and maximizing benefits to the most patients.

INTRODUCTION

Aortic arch repair is continually evolving, and clinicians are now equipped with a wide range of methods to tackle diseases arising in the ascending aorta and aortic arch. Unlike conventional surgical procedures, modern methods such as thoracic endovascular aortic repair (TEVAR) provide a minimally invasive alternative which reduces risks and improves the outcome and speed of recovery. Endografts used in TEVAR vary in design depending on the procedure and application. Branched endografts are commonly used to maintain perfusion of blood to the supra-aortic vessels and the haemodynamic performance of these devices is of significant interest [1,2]. These tend to have internal tunnel branches which run through the lining of the graft wall and emerge from the arch to guide the flow into their respective arch branches, thereby maintaining the constant perfusion of blood to essential organs. This reduces the need for both vascular bypass and fenestrations in the graft body [1]. Implantation of a branched endograft alters the geometry of the treated aorta, which could have a profound influence on the local flow patterns and haemodynamic parameters, such as velocity, pressure, and wall shear stress [3]. Changes in these parameters can be determined by computational modelling. Here we present a detailed computational fluid dynamics (CFD) analysis of the effects of branched endografts on blood flow in the arch.

METHODS

The aortic arch has complex anatomical features unique to every individual: namely its curvature, non-planarity, and major branches originating in the region. Since the focus of this study is to investigate the effect of branched endografts on flow in the arch, we used retrospective CT images from patients who underwent TEVAR using similar branched endografts. These multislice images were analysed using a 3D image processing software, Mimics (v20, Materialise,

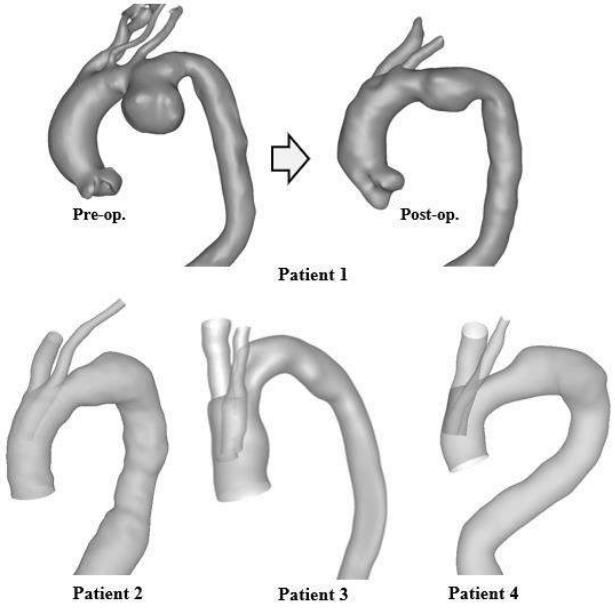

Figure 1: 3D aortic arch reconstructions for patients that have undergone TEVAR using branched endografts: (Top row) showing the aortic arch aneurysm in Patient 1 before and after TEVAR; (Bottom row) other patients that have undergone TEVAR to treat aortic arch aneurysms and Type A aortic dissections.

Leuven, Belgium) to generate anatomically accurate 3D reconstructions of the patient's vasculature, as can be seen in Figure 1. These geometries included the ascending and descending aorta, aortic arch consisting of the supra-aortic vessels, and then internal tunnel branches of the endograft.

Unstructured meshes of approximately 8 million elements, with prismatic boundary layers applied at the walls, were generated using ANSYS ICEM (v15.0, ANSYS Inc., Canonsburg, PA). Physiologically accurate boundary conditions were imposed at the inlet and outlets; these included a 3-element Windkessel model (3-EWM) prescribed at the three outlets and a pulsatile inflow waveform used at the inlet [4]. The wall was assumed to be rigid with a no-slip boundary condition. Numerical solutions were obtained using ANSYS CFX (v15.0, ANSYS Inc., Canonsburg, PA) and the results were analysed using ANSYS EnSight (v10.2) and ANSYS CFD-Post (v15.0) with emphasis being given to haemodynamic parameters such as fluid velocity and pressure, wall shear stress (WSS), displacement forces, and helicity.

RESULTS

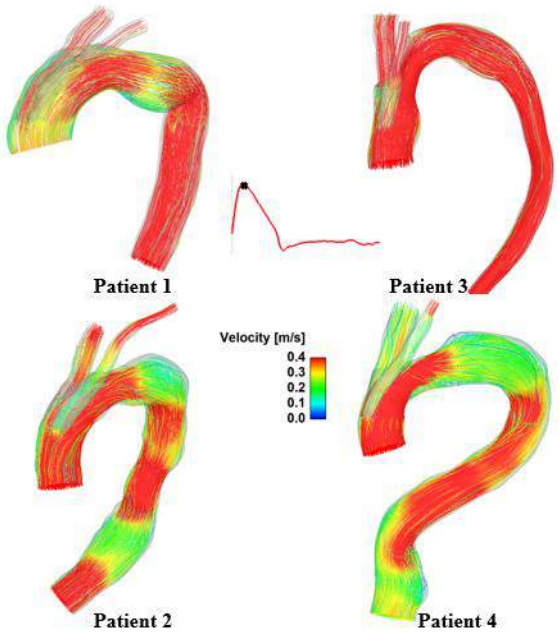

Figure 2: Instantaneous velocity streamlines recorded at peak systole for different patients that have undergone TEVAR.

The effect of branched endografts on flow in the aortic arch is illustrated in Figure 2. Implantation of the endograft results in accelerated flow in the arch, which can be seen more clearly in patients 2 and 4. High velocity flow occurs in the tunnel branches leading into the supra-aortic vessels. The presence of inner tunnels helps guide the flow into the arch vessels, but it also causes significant changes in the local flow patterns in the innominate and left common carotid arteries and in the arch region, that is demonstrated in Figure 2. Structural variations between each patient post-TEVAR also gives rise to varied flow patterns, unique to each patient. To further investigate the effect of tunnel branch diameter, additional models were created with smaller tunnel branch diameters of 10 mm and 8 mm (with the original branches being 12 mm in diameter). Further comparisons were made for WSS-related indices and helical flow index (HFI).

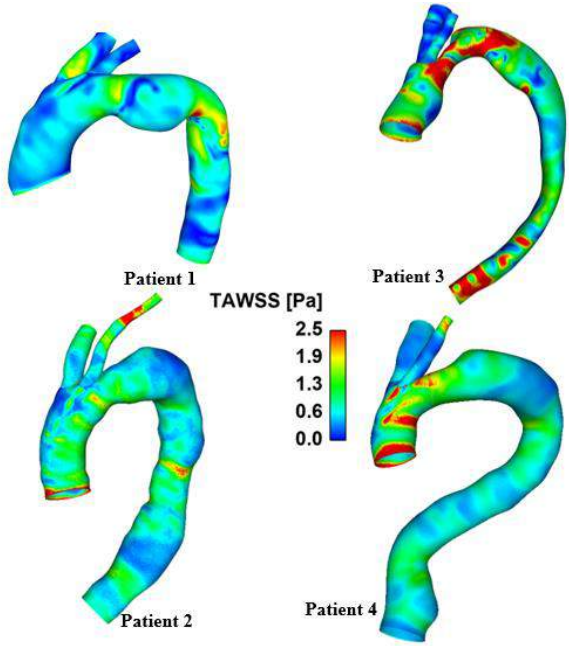

Figure 3: Time-averaged WSS maps showing differing patterns for patients that have undergone TEVAR.

DISCUSSION

Branched endografts have a significant influence on local flow patterns in the arch and the stented supra-aortic branches. Altered flow patterns lead to more spatial variation of WSS (Figure 3), with elevated WSS in the arch where flow is accelerated and low values in regions of flow recirculation. Variations in the endograft position and branch size result in further alterations of the flow in the arch and supra-aortic vessels. Figure 3 further illustrates the geometric variations experienced in different cases, all having undergone TEVAR using the same branched endograft device.

Although double branched endograft implantation offers a minimally invasive approach to the treatment of complex aortic diseases involving the arch, its long-term outcome is yet to be fully assessed. Patient-specific CFD simulations allow for quantitative analysis of haemodynamic parameters which may help predict potential adverse events, such as device migration, endoleaks, or clot formation in the supra-aortic branches.

INTRODUCTION

Solid tumors, such as sarcomas, stiffen as they grow in a host healthy tissue. Stiffening is caused by an increase in the structural components of the tumor, particularly in the density of the extracellular matrix fibers, mainly collagen, and in cancer and stromal cells content. Tumor stiffening can cause blood vessel inefficiency and as a result, it poses major physiological barriers to the effective delivery of drugs. Consequently, there is an urgent need for the development of novel biomarkers, that characterize the mechanical state of a particular tumor so as to support the development of personalized treatments or monitor novel therapeutic strategies, that target the tumor mechanical microenvironment to improve therapy [1].

In this project, Atomic Force Microscopy (AFM) was employed in order to assess unique NanoMechanical FingerPrints of sarcoma during cancer progression [2]. Also, an approved anti-fibrotic drug, tranilast, was re-purposed so as to target the tumor matrix and alleviate stiffness [3]. The AFM data were correlated with *in vivo* ultrasound studies and collagen content measurements with polarized microscopy. The identification of unique AFM-based NanoMechanical FingerPrints can lead to the development of novel biomarkers for treatment perdition and monitoring.

METHODS

Cell culture: Human fibrosarcoma cell line HT1080 was obtained from American Type Culture Collection (ATCC) and were supplemented with 10% Fetal Bovine Serum and 1% antibiotics.

Animal Tumor Models: Orthotopic fibrosarcoma tumors were established by subcutaneous implantation of 5×10^6 human HT1080 cells into the left flank of 6- to 8-week-old NOD/SCID mice (Cyprus Veterinary Services license: CY/EXP/PR.L14/2019).

Animal Treatment: When tumors reach a size of 5 mm, a biopsy (with a semi-automatic biopsy instrument) was obtained. At that point 4 cycles of treatment with a 3-day interval was performed [treatment groups: i) Saline (control), ii) Doxorubicin, iii) Tranilast and iv) Doxorubicin+ Tranilast]. After the first two treatments a 2nd biopsy was obtained. When tumors reached a size of 1200 mm^2, a 3rd biopsy was obtained and the mice were sacrificed via CO_2 inhalation.

Atomic Force Microscopy: The biopsies were transferred into ice-cold PBS supplemented with a protease inhibitor cocktail (Roce Dianostics GmbH). Then each specimen was immobilized on petri dishes and stored at 4°C for 1-72 h. AFM measurements (Molecular Imaging, PicoPlus) were conducted with silicon nitride cantilevers (MLCT-Bio, Bruker). The maximum applied loading force was set to 1.8 nN and 15 different force maps (16×16 point grids over 20x20 μm^2) were recorded per specimen [4]. The force maps were analyzed by AtomicJ using the Hertz model.

Ultrasound elastography and perfusion: Elasticity measurements were performed using the shear wave imaging method (Philips EpiQ Elite Ultrasound, eL18-4 transducer). The average elasticity was acquired from the median elasticity values of 8 regions of interest within the tumor. Also, the vascular status of tumors (microvascular imaging) was assessed using the Color Power Angio imaging mode. Images were analyzed using an in-house MATLAB code.

Polarized Microscopy: Collagen abundance was evaluated via Picro Sirius red staining (Abcam). Briefly, transverse 7μm-thick paraffin sections were produced (SAKURA), deparaffinized and incubated in Picro Sirius red stain for 1h. Then the sections were rinsed with acetic acid and absolute ethanol. Images were acquired at 20x magnification using an Olympus BX53 microscope with linear polarizers. The images were analyzed using custom and built-in algorithms in MATLAB.

RESULTS

First, we studied if AFM can identify unique NanoMechanical FingerPrints in the case of sarcoma tumors. Our results demonstrated that during progression sarcoma tissue presents two distinct characteristics as far as the distribution of elastic modulus is concerned: a lower elasticity peak, due to cancer cell softening, and a higher elasticity distribution, due the collagen overproduction and the desmoplastic reaction (Fig.1A) [2]. During cancer progression, the higher elasticity distribution was significantly increased. In order to correlate the mechanical alterations with collagen content, we performed polarized microscopy on picro sirius red stained samples. With polarized microscopy collagen type I and III fibers are specified in red and green, respectively. The results demonstrated that both collagen type I/ III were increased during cancer progression (Fig.1B).

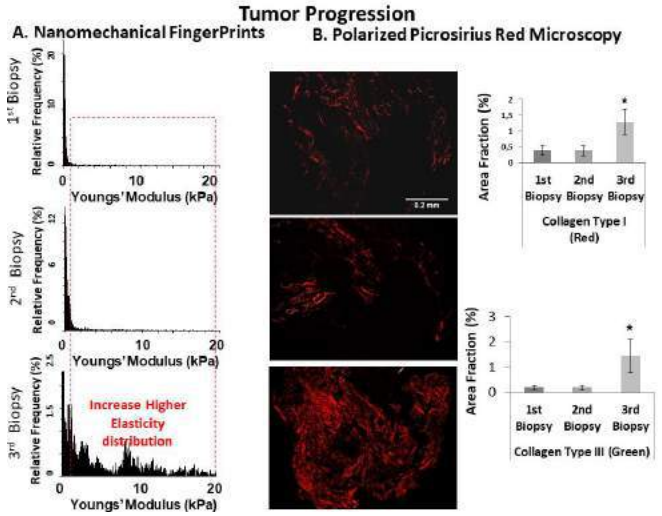

Figure 1: A) AFM Nanomechanical FingerPrints and B) polarized picrosirius red images and analysis during tumor progression.

Next, we studied if tranilast can improve the efficacy of common chemotherapy drugs (i.e., doxorubicin) in the case of sarcoma, as it has been previously found in other tumors [3]. Our results demonstrated that while tranilast itself did not affect tumor growth or mice survival, the combination with chemotherapy improved treatment outcomes (Fig.2A&B). Furthermore, *in vivo* ultrasound studies demonstrated that, both tranilast and the combined treatment, reduced tumor elastic modulus, while tumor perfusion was increased (Fig.2C&D), due to tumor microenvironment remodeling.

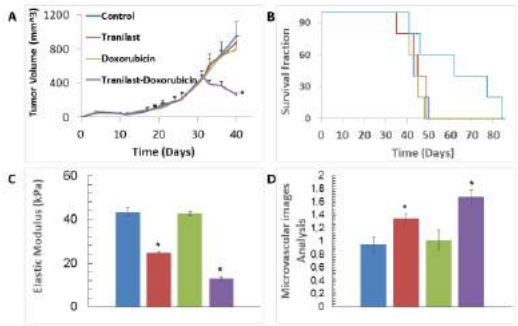

Figure 2: A) Tumor growth curves of tumors. B) Kaplan-Meier survival curves. C) Ultrasound elastography measurments, D) Microvascular image analysis.

Subsequently, we investigated our hypothesis that AFM can access and monitor nanomechanical alterations during microenvironment remodeling as a consequence of external interventions, here drug treatment. Our findings, highlighted that AFM can assess tranilast anti-fibrotic effects tranilast, as the higher elasticity distribution was significantly reduced after treatments (Fig.3A). This decrease was correlated with collagen type I (Fig.3B) and type III (data not shown) reduction. Also, AFM demonstrated that is sensitive enough to distinguish slight nanomechanical alterations between the tranilast and tranilast+chemotherapy groups (Fig.4)

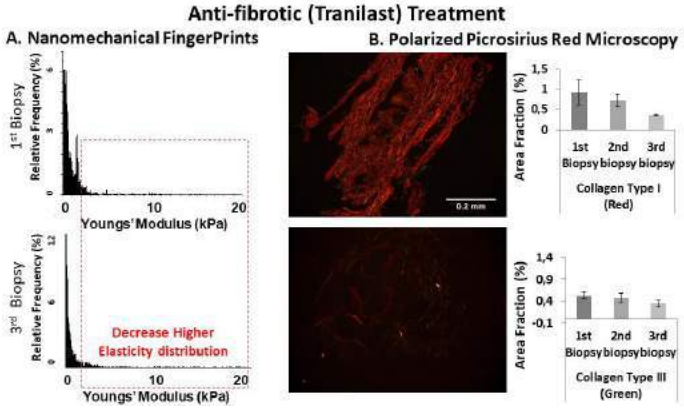

Figure 3: A) AFM Nanomechanical FingerPrints and B) polarized picrosirius red images and analysis during anti-fibrotic treatment.

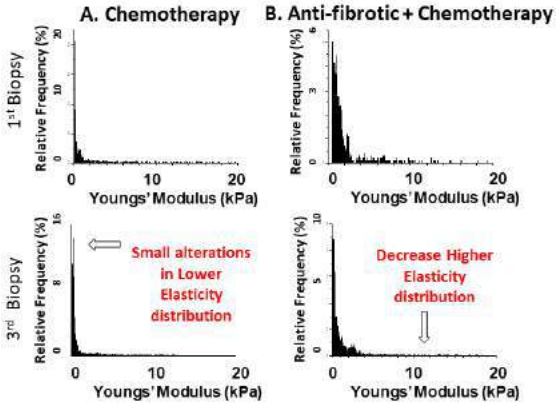

Figure 4: A) AFM Nanomechanical FingerPrints and B) polarized picrosirius red analysis during and after chemotherapy and tranilast+chemotherapy treatment.

DISCUSSION

Our results demonstrated for the first time in the literature that sarcoma tumors present unique NanoMechanical FingerPrints and anti-fibrotic treatment can be used to enhance treatment outcomes. AFM techniques are sensitive to access small nanomechanical modifications after sarcoma treatment with drugs, including chemotherapy and anti-fibrotic agents. Further research in this area will reveal the mechanism of different NanoMechanical FingerPrints for sarcoma and will enable the development of predictive mechanical biomarkers.

PROBING THE MECHANICAL PROPERTIES OF CHICK EMBRYOS USING ATOMIC FORCE MICROSCOPY

Joel A. Lefever (1), Jack L. Edson (1), Ashok Ramasubramanian (1)

(1) Department of Mechanical Engineering
Union College
Schenectady, NY 12308, USA

INTRODUCTION

We study early embryonic development in the chick embryo. Two morphogenetic changes occur between Hamburger & Hamilton (HH) Stages 11-15 [1]: the early embryo rotates, and a series of flexures form in the dorsal wall. The underlying forces causing these phenomena are not fully understood [2].

One hypothesis is that an asymmetry develops in the geometry or material properties of the neural tube, which drives flexure and torsion. Prior research has evaluated the mechanical properties of chicken embryos using flat indenters on sectioned embryonic neural tubes [3]. In order to probe the mechanical properties more thoroughly, it is necessary to perform indentation experiments using a technique which can precisely target various locations on the embryo with micron-level precision. In this paper, we discuss how atomic force microscopy (AFM) can be used to probe the material properties of the early neural tube (Figure 1A).

METHODS

Chicken embryos are harvested at Hamburger and Hamilton Stages 10-15 [1], separated from the yolk, and examined in a Petri dish containing phosphate-buffered saline. The sample is fully submerged to protect the tissue and to mitigate surface tension effects. A coverslip serves as a rigid substrate, and filter paper holds the embryo in place. An AFM probe with a 10 μm diameter colloidal tip (sQube) is used to indent the neural tube of the chicken embryo (Figure 1A) in the stages immediately prior to and following rotation. Building on prior research which performed indentation on sectioned embryos [3], the embryos here are tested intact to minimize invasive procedures; however, the vitelline membrane, which covers the dorsal side of the embryo, is removed in order to improve access to the neural tube. The embryos remain submerged during the indentation process. To avoid interference with the indentation measurements, the heart is removed as necessary. The AFM-based indentation technique provides the unprecedented ability to evaluate mechanical properties at a scale of roughly 5 μm, permitting these properties to be mapped over various locations on the embryo. Force-distance curves (Figure 1B) are extracted and various measurements of mechanical properties can be computed, including the stiffness of the neural tube tissue. The stiffness is evaluated as the slope of the retraction portion of the force-distance curve to eliminate plastic effects (arrow in Figure 1B).

RESULTS

Indentation depths are typically observed to be on the order of 2-5 μm, which is limited by the vertical range of travel of the AFM. This indentation depth corresponds with maximum loads on the order of 4-20 nN. The force curves shown in Figure 1B were taken on the neural tube and are typical of several experiments. For this particular embryo, they indicate a stiffness of 7.3 ± 0.2 nN/μm, which is comparable with prior research [3].

As shown in Figure 2, the measured stiffness varies moderately across a single embryo. Figure 2 presents the stiffness data for the 8 embryos investigated to date. On an embryo in which the vitelline membrane was not removed, the stiffness was found to be approximately one order of magnitude greater (data not shown). Using a glass coverslip as a substrate prevents rigid body translation and allows the stiffness of the sample to be evaluated directly after subtracting the compliance of the probe.

DISCUSSION

The greater stiffness observed in the present results (compared to previously-published results in [3]) likely occurs because, unlike the prior study, our procedure maintains an intact neural tube and its

associated pressure (estimated as 30 Pa [4]). This stiffening effect is only partially mitigated by the smaller indenter, which samples a smaller region of tissue and therefore encounters less resistance.

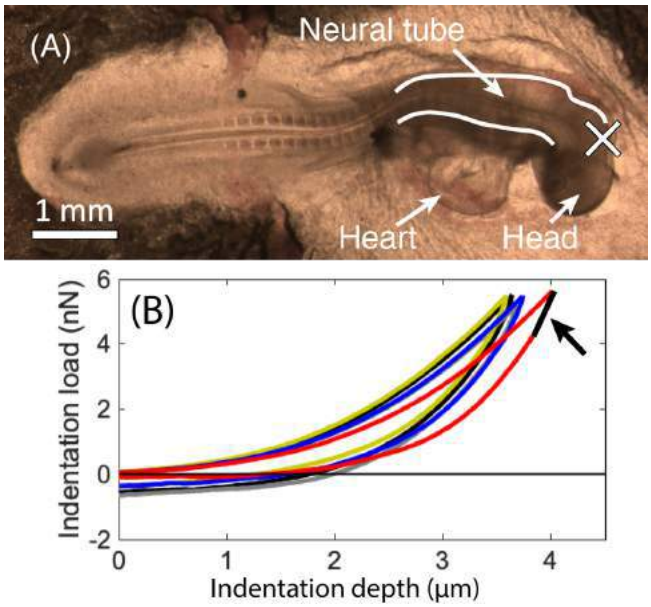

Figure 1: (A) A chicken embryo at HH Stage 14-15 as observed using optical microscopy prior to AFM-based indentation experiments. Major organs are indicated. (B) Five force-displacement curves resulting from a series of indentation experiments in the midbrain region using a colloidal AFM probe, for the embryo shown in (A). The indentations experiments shown in (B) were conducted at the location identified by the X in (A).

The variation in stiffness shown in Figure 2 is likely caused in part by differences in location, the exact stage of development that each embryo was in, and also physical differences between the embryos. Each box and whisker plot represents data from between 2 and 21 locations, as stated on the figure; at each of those locations between 3 and 19 successful indentations were performed. Each of the data points used in the box and whisker plot is an average from these indentations and the standard deviation within each such indentation set is generally small, as evidenced by the minimal scatter in each region in Figure 1(A).

A strong second-order mechanical response was observed in some indents, likely due to fluid flow in the Petri dish and inside the neural tube. This mechanical response affects the linear fit through which the stiffness is calculated; the outliers in Figure 2(B) correspond to the indents where a strong second-order mechanical response was observed.

The methodology described here allows for unprecedented control over the location of the indentation; however, it is not without limitations. The indentation experiment is susceptible to error due to the heartbeat, which cannot be stopped without an invasive operation to remove the heart (which was done for some of the data points) or by stopping the heart using chemicals which may also affect the material response (a chemical inhibitor of heartbeat was not used in this study). In the previous study with which we compare our data, the neural tube was sectioned and removed from the embryo, eliminating the heartbeat as a concern [3]. Experiments must be conducted in the period between heartbeats and it is not possible to confirm whether a heartbeat has occurred except by comparing several indents for uniformity.

Because the material is compliant and highly viscoelastic, it is challenging or impossible in some cases to exactly locate the position at which the indenter makes contact. Therefore, it is challenging to precisely evaluate the indentation depth to compare directly with [3]. We also note that our indenter is spherical, rather than the flat punch used previously [3], which alters the predicted mechanical response from linear to a power-law relationship.

In order to keep the embryos fresh, we attempt to do the indentation experiments as quickly as possible. However, some degradation is visible when the embryos are imaged after the experiments are completed. We notice no strong difference in the measured stiffness or indentation depth from the beginning to the end of the experiments, and therefore believe that this degradation has minimal effect on the measured properties.

The experimental methods described here can be extended to evaluate the mechanical properties across various locations on the embryo, and to determine whether locally stiffer or softer regions are observed. The results of this study will help to elucidate the fundamental mechanisms driving embryonic flexion and rotation.

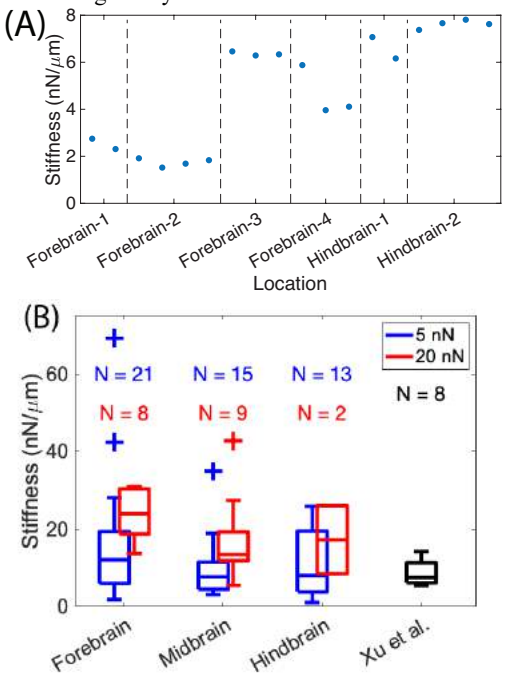

Figure 2: (A) A summary of the stiffnesses measured in six different locations on one embryo and (B) across a total of 68 locations on eight embryos, using AFM. The central mark represents the median, while the top and bottom of the boxes represent the 75th and 25th percentiles; the whiskers represent the range of the data, and crosses represent outliers. Each value of N gives the total number of locations on each section of the brain at which indentations were performed across all embryos. The total number of indentations is much higher. The indentation data in Xu et al. were collected using a custom microindentation device.

INTRODUCTION

Magnetic resonance (MR) imaging has played an essential role in the research of pelvic floor disorder mechanism[1], diagnosis of pelvic organ prolapse[2], and measurement of pelvic floor tissue property[3].

Therefore, obtaining high-resolution 3D MR images is crucial in the above tasks. However, the inter-slice resolution is always worse than the intra-slice resolution due to it has high cost in terms of scanning time and expense. It can save the scanning time to ensure a larger field of view for imaging in some cases, such as Valsalva, at the cost of inter-slice resolution deterioration. This introduces difficulties for MR analysis tasks, such as 3D segmentation and geometric model reconstruction. To improve the inter-slice resolution for 3D high-resolution analysis, several digital techniques can be applied. The interpolation method is the most common approach, but it only considers the continuity of pixel values and ignores the structural and semantic continuity. Model-based methods use models to learn the mapping between the low- and high-resolution image pairs, which produces better results.

Several previous studies have demonstrated the use of convolution neural network (CNN) as models for 2D image super-resolution[4]. However, 3D high-resolution images are not available for model training. Therefore, we aimed to develop a 2D CNN-based algorithm for 3D pelvic MR images super-resolution using low inter-slice resolution data in three scanning directions.

METHODS

The pipeline of our algorithm is shown in Fig. 1. We first define the 3D super-resolution task as recovering $I_{(x,y,z)}$ from $\hat{I}_{(x,y,z)}$, where $I_{(x,y,z)}$ denotes high-resolution 3D MR data, $\hat{I}_{(x,y,z)}$ denotes MR data with low-resolution in one or more dimensions, and *x*,*y*,*z* are scanning directions for coronal, sagittal, and axial MR data, respectively. However, as mentioned previously, clinically acquired MR data always have a low resolution in the scanner movement direction. For example, MR data scanned in the coronal plane have a low resolution in the *x*-axis, denoted as $I_{(\hat{x},y,z)}$. Therefore, we need to reconstruct $I_{(x,y,z)}$ based on $I_{(\hat{x},y,z)}$. As shown in Fig. 1, we first performed isotropic analytic interpolation of $I_{(\hat{x},y,z)}$ by spline interpolation algorithm. Then we sliced 2D slices from the *z*-axis and applied the 2D super-resolution model on these slices. After that, the super resolution of the *x*-axis was obtained. As the result was recovered from the *z*-axis, it is denoted as $I_{(x,y,z)}^{SR-z}$. Similarly, we applied the same procedures starting from $I_{(x,y,z)}^{SR-z}$ but from the *y*-axis. Thus, we could obtain the final 3D super-resolution result. As we achieved super-resolution from the axial view (or *z*-axis) and then the sagittal view (or *y*-axis), we denoted it as $I_{(x,y,z)}^{SR-z-y}$. In this framework, no 3D high-resolution MR data was used; instead, it used 2D high-resolution MR data in three views with a 2D super-resolution model.

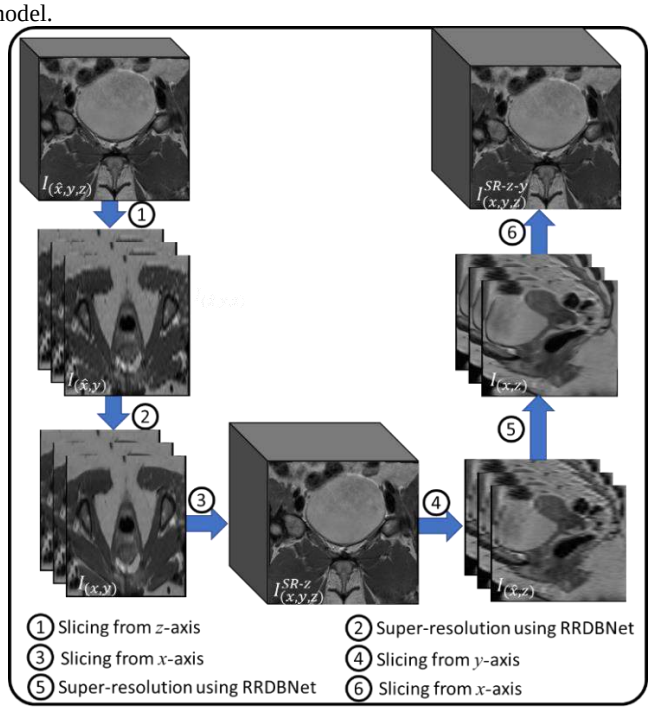

Figure 1: The 3D super-resolution data flow.

The super-resolution was composed of 16 residual in residual dense block (RRDB) modules, so we called it RRDBNet. For the RRDB module, it consists of four residual dense blocks, and in each block there are five convolutional layers connected in a dense way, which ensures efficient feature reuse and better model convergence. Besides, training

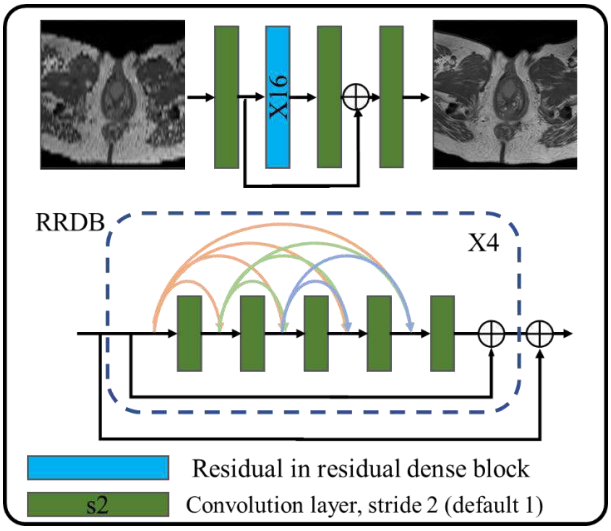

Figure 2: The RRDBNet model structure.

data are important for model training. We simulated the low-resolution training data pairs by downsampling the 2D high-resolution MR images in three views. We used the L1 loss during model training as the cost function and peak signal-to-noise ratio (PSNR) and structural similarity (SSIM) as the evaluation metrics, which are defined as follows.

$$L1 = \frac{1}{MN}\sum_{m,n}^{M,N}|g_{mn} - p_{mn}|\,, \quad (1)$$

where M and N are the lengths for the two image dimensions.

$$PSNR = 20\log\left(\frac{255}{MSE}\right), \quad (2)$$

$$MSE = \frac{1}{MN}\sum_{m,n}^{M,N}(g_{mn} - p_{mn})^2, \quad (3)$$

where MSE is the mean square error between the ground truth and prediction. g_{mn} and p_{mn} are the pixel value for ground truth and prediction, respectively.

$$SSIM = \frac{(2\mu_g\mu_p + 2.55^2)(2\sigma_{g,p} + 7.65^2)}{(\mu_g^2 + \mu_p^2 + 2.55^2)(\sigma_g^2 + \sigma_p^2 + 7.65^2)}, \quad (4)$$

where μ_g and μ_p are the mean values of ground truth and prediction, respectively, σ_g and σ_p are the standard deviations of ground truth and prediction, respectively, and $\sigma_{g,p}$ is the covariance between the ground truth and predicted results.

RESULTS

We used 3D MR data from 48 subjects from the Michigan Pelvic Floor collection with the approval of the institutional ethics review board. For each subject, T2 3D MR data were scanned from coronal, sagittal, and axial views. Each 3D MR sequence had an intra-slice resolution of 0.78 x 0.78 mm and an inter-slice resolution of 5.0 mm. We split this dataset into a training set of 38 subjects' data and a testing set of 10 subjects' data. There were 3037 images in the training set and 796 images in the testing set. We compared our method with the traditional interpolation method. Besides, we also used single-view data for training to explore the difference between single-view data training and three-view data training.

There were 990 coronal, 1020 sagittal, 1027 axial MR images in the training set. When training RRDBNet using single-view data, the final models were named RRDBNet-c, RRDBNet-s, and RRDBNet-a, respectively. We also used all the 3037 images, and the model was named RRDBNet-all. Besides, we performed model evaluation while training with 998 images from 13 subjects and named the model as RRDBNet-partial. All the experiments were performed based on Python (V3.5.2) and Pytorch (V.1.2.0) libraries, using an NVIDIA TITAN RTX graphics card with 24 GB computational memory. The RRDBNet was trained with a batch size of 4 and a learning rate of 2e-4. The testing result was summarized in Fig. 3.

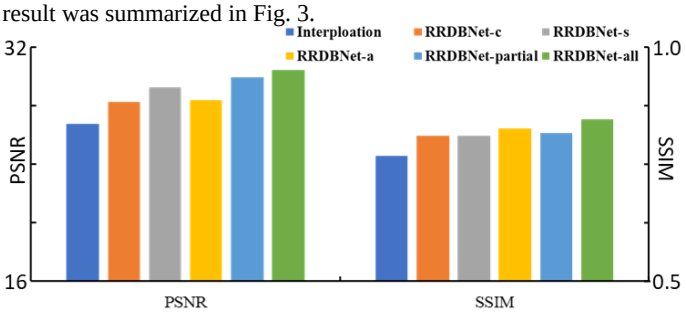

Figure 3: Super resolution performance on the testing set.

Fig.3 indicated that our method has a significant advantage over the interpolation method in terms of both PSNR and SSIM. Besides, RRDBNet-partial obtained higher PSNR and SSIM than RRDBNet-c, RRDBNet-s, and RRDBNet-a. When using all images, RRDBNet-all obtained the best results. We showed the 2D super-resolution and 3D geometric model reconstruction results of the bladder in Fig. 4. From the 2D super-resolution result, we could find that RRDBNet produced results with fewer artifacts and better image fidelity. Small details were also better recovered. In addition, from the bladder reconstruction results, we found that our algorithm produced images with more continuity.

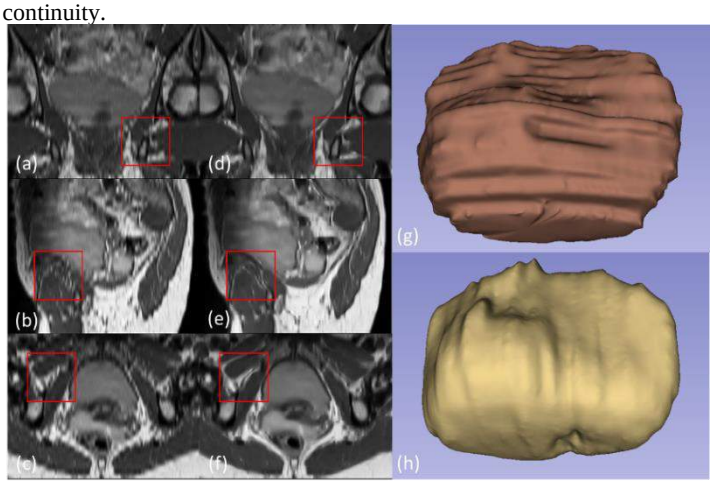

Figure 4: Comparison of super-resolution results. (a)-(c) are results obtained with the interpolation method. (d)-(f) are results obtained with RRDBNet-all. (g) is the geometric model of the bladder with 3D MR images from the interpolation method. (h) is the geometric model of the bladder with super-resolution 3D MR images with RRDBNet-all. (g) and (h) were smoothed in the same configuration.

DISCUSSION

A CNN-based super-resolution algorithm for 3D pelvic MR images was developed, using only low-resolution 3D data. The 3D super-resolution problem was solved as a 2D super-resolution problem using RRDBNet and MR images from three views. We validated that our algorithm outperformed the interpolation method on 2D super-resolution and geometric model reconstruction tasks. In the future, we will validate our algorithm with real high-resolution 3D MR data.

EFFECTS OF CARDIAC GEOMETRIC REMODELING DURING HEART FAILURE ON CARDIAC FUNCTION

INTRODUCTION

Heart failure with preserved ejection fraction (HFpEF, EF ≥ 50%) and heart failure with reduced ejection fraction (HFrEF, EF ≤ 40%) are two main types of heart failure (HF) with similar prevalence. 88% of HFpEF [1] and 80% of HFrEF [2] undergo heart remodeling, typically concentric hypertrophy (CH) for HFpEF and eccentric hypertrophy (EH) for HFrEF. However, there is substantial heterogeneity, and the concentric remodeling (CR) phenotype as well as an absence of geometric remodeling (normal) has also been observed in HF. It is currently unclear whether these various geometric phenotypes favor or impede function.

Currently, the diagnosis of HFpEF remains clinically challenging due to the preservation of EF and clinical heterogeneity. The inability of EF to indicate disease in HFpEF, and reports that EF can be skewed by cardiac geometric changes [3, 4] demonstrate its ineffectiveness as a indicator of function. However, it remains unclear why this is so.

In the current study, we develop a myocardial numerical model that relates strains to cardiac flow function, as informed by porcine animal data and clinical literature data, to explain why EF is ineffective, and to propose a new corrected EF measure to avoid this problem. We also show that cardiac dilation provides geometric advantages to the heart, allowing better conversion of strains to flow function, while wall thickening does not.

METHODS

CMRI of 5 HFpEF porcine animal model (via gradual constriction of aorta), and 10 HFrEF porcine animal model (via circumflex ligation), and sham/healthy are obtained before intervention (baseline) and at the 28th or 42nd day time point (ending). Cardiac anatomic parameters are measured, as are longitudinal strain (LS) and circumferential strain (CS) at both the endocardial and epicardial boundaries, defined as deformation between end-diastole (ED) and end-systole (ES).

A numerical model of the LV, based on a typical porcine heart anatomic dimensions, is reconstructed as an idealized prolate shape with 3 layers, the epicardial, endocardial and mid-wall layers. The model is discretized, and can undergo specific magnitudes of spatially uniform ED-to-ES strain deformations, in an incompressible way. Geometric changes common during HF remodeling can be modelled, such as wall thickening and dilation, and flow function can be evaluated via EF and stroke volume (SV).

The model is also used to test effects of varying HF geometric phenotypes and strain magnitudes on its flow function, using a population data of 4768 participants [5].

RESULTS

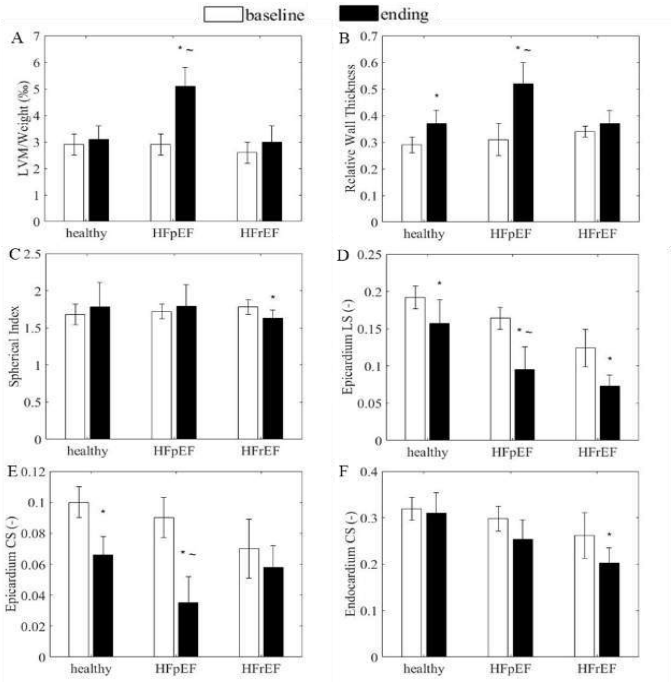

Figure 1. Anatomic characteristics and strain function of the healthy, HFpEF and HFrEF porcine animals. (A) LV mass normalized by weight, (B) relative wall thickness, (C) spherical index. (D-F) Endo- or epicardial longitudinal or circumferential strains. * p<0.05 with baseline. ~ p<0.05 with healthy.

In the porcine animal models, HFpEF and sham EF are above 50%, while HFrEF EF is less than 40%. HFpEF experiences hypertrophy with higher LVM and wall thickness (Fig. 1A-B), suggesting a concentric hypertrophy phenotype. HFrEF has a decreased sphericity index and unchanged RWT, indicating an eccentric hypertrophy phenotype with dilation. Both HF models has decreased strains, but HFpEF endocardial strain is not significantly changed.

With the numerical LV model, increasing wall thickness with no change to strain magnitude (Fig 2A) was found to increase EF but not SV, suggesting that wall thickness changes artificially increased EF when there is no change to flow function. Increasing dilation with no change to strain magnitude (Fig 2B) was found to increase SV, but decrease EF, suggesting that dilation enhances flow function, but EF is not a successful indicator of this.

Our model shows substantial epi-to-endo spatial variability of strain, and this is because during systolic contractions, on top of longitudinal and circumferential strains, there is the radial strain. The radial strain pushes endo-surface inwards, causing further shortening at the endo-surface, but it pushes the epi-surface outwards, causing lengthening at the epi-surface that negate some of the contraction. Epi-strains are thus always lower than endo-strains (Fig 2C, D). Interestingly, wall thickening is found to increase this epi-/endo-difference, as it increases radial displacement during systolic contractions, while dilation reduces the difference, as it reduces the curvature of the LV wall.

The epi- and endo- surfaces are thus not good locations for quantifying strain or volumetric flow function of the heart, and the mid-wall location (in between epi- and endo-) is a better location. Since EF uses the endocardial surface for volume quantification, it becomes skewed by geometric changes of dilation and wall thickening. This explains why it is not a good indicator of function.

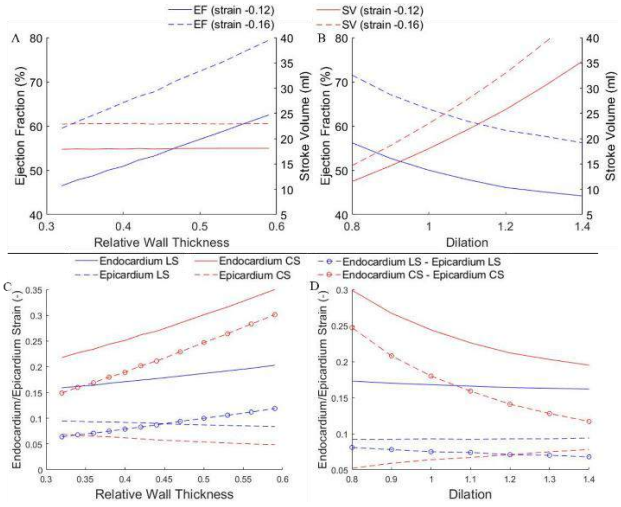

Figure 2. Results of LV myocardial numerical model, showing the dependence of EF and SV on (A) relative wall thickness and (B) dilation at constant strains of -0.12 or -0.16 (at the mid-wall layer), and the dependence of endo- and epicardial strains on (C) relative wall thickness (D) dilation at the same strains.

We thus propose a novel marker, the corrected ejection fraction (CEF), that will not be skewed by cardiac geometric changes:

$$CEF = \alpha \times EF = SV/Vol_{ED,mid} \quad (1)$$

$$\alpha = Vol_{ED,endo}/(Vol_{ED,endo} + LVM/2\rho_{LV}) \quad (2)$$

Where $Vol_{ED,location}$ is the end-diastolic volume calculated at a location, either at the mid-wall or the endocardium, and ρ_{LV} is the myocardium density. The CEF is essentially EF but calculated at the mid-wall layer rather than endocardium layer. When applied to the porcine data, CEF can successfully differentiate between healthy and HFpEF hearts, while EF cannot (Fig. 3). Further, by testing CEF with literature disease data, we can show that CEF is effectively independent of the geometric phenotype, adopting the same value a specific strain magnitude, regardless of the geometric phenotype.

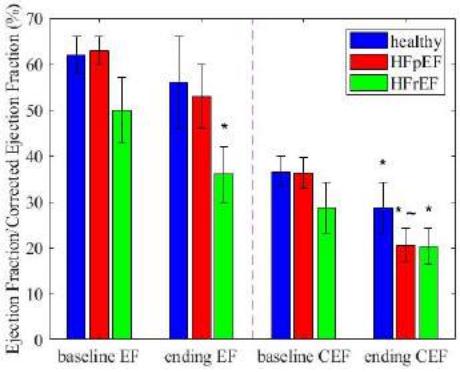

Figure 3. EF and CEF of healthy, HFpEF and HFrEF porcines hearts at baseline and ending time points. * p<0.05 with baseline. ~ p<0.05 with healthy ending. EF cannot differential HFpEF from healthy, but CEF can

With the LV model, we also compared the 4 HF remodeling phenotypes (Norm, CH, CR, EH), in terms of how much increase in strain is needed to achieve a stroke volume of 20% above the normal heart (such as during exercise). Results in Fig 4 shows that the dilated EH phenotype is most geometrically advantageous phenotype in this regard, followed by CH and CR. This suggests that dilation during HFrEF is advantageous to its function, but not the hypertrophic wall thickening during HFpEF.

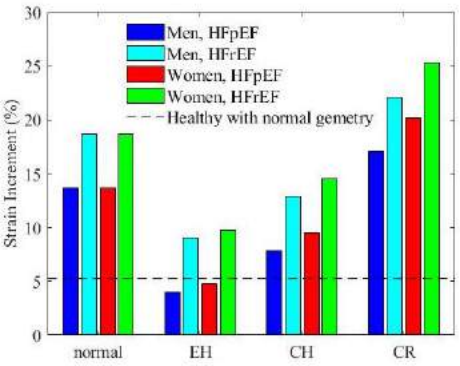

Figure 3. percentage increase in myocardial strain that is required to achieve a stroke volume of 20% higher than a healthy heart, for various HF geometric phenotypes.

CONCLUSION

From our modeling, we find that dilation to be advantageous to cardiac flow function, but not wall thickening. We further find that EF is an imperfect indication of function because it can be modulated by the cardiac geometry changes, such as during HF remodeling, and cannot distinguish some HF phenotypes from normal, and that this is because of its reliance on measurements on the endocardial boundary rather than the mid-wall layer. We proposed a corrected EF measure, the CEF, which we show can remove this geometric dependency and enable a better representation of cardiac contractile function.

INTRODUCTION

The vitrectomy surgical procedure is performed to treat pathological states of the retina and it consists in the removal of the vitreous body from the vitreous chamber. In cases in which the retina is teared, in order to avoid the progression of a retinal detachment, tamponade fluids are inserted in the eye, with the aim to improve the contact between the detached retina and the retinal pigment epithelium, thus facilitating retinal reattachment. At present, the most widely used tamponade fluids are high viscosity silicone oils (SOs). However, SOs cannot be left for very long times in place as they tend to emulsify with the aqueous humor produced by the eye. Emulsion is a highly undesirable event, especially when oil droplets get small enough to move to the anterior segment of the eye where they can block the drainage of the aqueous humor, by accumulating into the trabecular meshwork. This may lead to an increase of the intraocular pressure, which is a significant risk factor for the development of glaucoma.

The release of endogenous molecules from ocular tissues (typically as an inflammatory response to surgery) has a significant role in the generation of an emulsion. The mechanisms behind of the effects of these molecules on the emulsification process depend on their capability to adsorb at the water-oil interface, modifying its mechanical interfacial properties [1, 2]. Furthermore, in order for an emulsion to be generated, mechanical energy must be provided to the system. In this context, some studies have evaluated the role of eye movements in this process in the absence of organic material [3,4]. Recently Wang et al. [5] tried to produce emulsions in a spherical model of the vitreous chamber subjected to a sequence of rotations. Interestingly, the authors never observed the formation of a bulk emulsion, even in the presence of surface-active molecules.

Aim of the present work is to study the effects of mechanical energy provided by periodic eye movements on the emulsion formation in a physical model of the vitreous chamber of the eye in the presence of surfactant biomolecules.

METHODS

A model of a vitreous chamber in Plexiglass with realistic geometry has been employed. The experimental setup composed by an optical diagnostic for monitoring the emulsion, a brushless system controlled by a computer to simulate eye movements and a thermal insulation system to maintain the model at 35°C. In particular, the presence of the lens in the front of the vitreous chamber has been considered, which has a significant influence on the motion of the fluid within the domain [6]. The solutions containing endogenous molecules were prepared using a Dulbecco buffer solution (DPBS) and different concentrations of albumin (0, 1 and 5% of the corresponding concentration in blood). The study involved the characterization of a SO used in ophthalmic surgery (RS-OIL 1000 cSt, Alchimia srl).

Once filled with SO (80%) and aqueous solution (20%), the model is mounted on a support connected to a computer-controlled motor. In this study, harmonic rotations were considered: this choice is suggested by the fact that a harmonic law is the simplest way to represent a sequence of saccadic eye movements in both directions with prescribed amplitude and duration [7]. The model is tested for different values of amplitude (20° – 50°) and with an imposed frequency equal to 5 Hz, for the duration of 1 hour. The temporal evolution of the emulsion has been studied through acquisition of images with a digital camera. An optical microscope (Leica Microsystems, Switzerland) has been used to determine droplets distribution and size. To this aim, acquired images of the emulsions were automatically analyzed by a software developed in MATLAB, able to detect the centers and radii of the drops, based on the concentric circular arrangement (CCA) method [8].

.

RESULTS

Experiments with the sample containing the DPBS alone, did not produce emulsions in the eye model. This result demonstrates that the only presence of a small amount of slightly surface-active impurities in the oil (low molecular weight components) cannot favour the emulsification process. On the contrary, we found formation and persistence of emulsions even when a low concentration of albumin was dissolved in the aqueous solution (1% of the physiological concentration in blood), as shown in Figure 1.

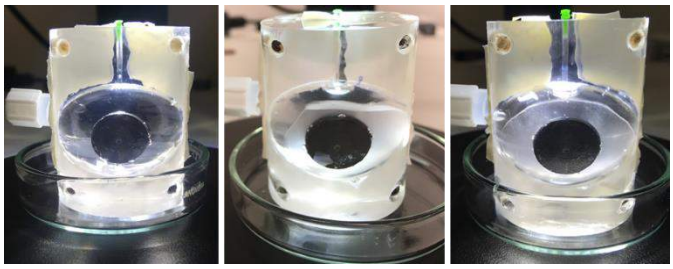

Figure 1: 80:20 volume ratio emulsions between SO and aqueous phases, 1 hour after formation. From left to right: DBPS; albumin 1% in DBPS, amplitude 50°; albumin 1% in DBPS, amplitude 40°.

Moreover, keeping these emulsions on a shelf at room temperature, the situation did not change significantly after 1 week, showing that the emulsions are stable in time.

In order to define a size distribution of the drops for all investigated systems, analysis of the images acquired by the microscope has been carried out considering different ranges of diameters and counting the total number of droplets falling in each range. In general, as shown in the normalized droplets distributions in Figure 2, the majority of the drops has a very small diameter: in the range of 0 – 5 µm. It is interesting to notice that, with 5% albumin solutions, we obtained maximum droplets size of about 55 µm, for all the investigated amplitudes (Fig. 2a). On the contrary, evaluating different amplitudes in the case of 1% albumin solutions, droplets with diameter even above 100 µm have been found (Fig. 2b). For values of amplitude equal to 20° and 30° and 5% and 1% albumin solutions, respectively, the emulsion did not form. A coalescence test has been performed, in order to evaluate the type of the formed emulsion. This allowed us to assess that the continuous phase of the emulsion is the buffer solution and, therefore, we obtained oil-in-water emulsions.

Another important result of this work is represented by the efficiency of the software adopted for image analysis, with an accuracy of 70% of the total droplets within the image.

DISCUSSION

In this work we investigated the effects of surfactant biomolecules and mechanical energy induced by eye rotations on the emulsion formation in a physical model of the vitreous chamber. The considered domain has been developed in order to simulate the real physiological conditions in terms of temperature and geometry. The motion imposed to the eye model by the motor, follows a sinusoidal time law and the imposed values of frequency (5Hz) and amplitudes (20° – 50°) are comparable with those reported in the literature. The experiments have been performed considering a SO in contact with solutions both in absence of proteins and with different concentrations of albumin.

The main result obtained from these experiments consists in the formation of emulsions even when a low concentration of albumin has been dissolved in the aqueous solution (1% of the physiological concentration in blood). The presence of an emulsion did not occur, in absence of proteins, for the same experimental conditions. Moreover, our results confirmed the capability of albumin to form stable SO in water emulsions once formed [1].

Through images analysis acquired by the microscope, we have been able to obtain information about the number of the droplets formed by the emulsification process and their size distribution, for each investigated system. As a result, we found oil-in-water emulsion, in agreement with the Bancroft rule [9], mostly characterized by oil drops with diameter less than 10 µm. This finding has clinical relevance, since droplets of small size can cause occlusion of the trabecular meshwork if they migrate in the anterior segment of the eye and can be swallowed by macrophages that, releasing chemioactive substances, induce inflammatory stimuli.

These experimental results demonstrate that eye movements and the presence of surfactant biomolecules can be considered co-factors of SO emulsification after vitrectomy.

INTRODUCTION

Fetal echocardiography is increasingly used for assessing fetal cardiac and circulatory function. Echocardiographic myocardial strain measurement is a good way to evaluate fetal cardiac function and to evaluate the severity of cardiac dysfunction, such as during twin-to-twin transfusion syndrome (TTTS) [1] or in congenital heart disease (CHD) [2]. Such evaluation can be important to clinical decisions about treatment, such as endoscopic laser ablation for TTTS or fetal cardiac intervention for CHD.

Echocardiographic strain measurements are typically performed with speckle tracking and can be performed in 2D or 3D. Previous work comparing 2D and 3D speckle tracking strains reported specific biased differences between the two [3]. Mararu et al. found the difference to be statistically significant and suggested that it is due to complex motions of the heart that 2D scans cannot capture [4]. However, the exact mechanism for this has not been elucidated. Further, widely varying fetal heart strain values were reported by different studies, leading to contradictions and confusion during interpretation of measured results [5], but reasons for these discrepancies have not been studied in detail.

Here, we attempt to bridge these literature gaps, using a validated cardiac motion estimation algorithm to track cardiac motion in both 2D and 3D echocardiography images of fetal hearts.

METHODS

Healthy Fetal Echocardiography: The 3D cine ultrasound images were obtained from 10 heathy fetuses at 22 and 32 weeks of gestational age, from the National University Hospital, Singapore, with IRB approval (protocol 2014/00056) and patient consent. Acquisition was performed with the STIC mode (4D scans) aligned with the four-chamber view, using the GE Voluson 730 ultrasound, and with a frame rate of 90 ± 38 frames per second. The 2D cine images were extracted from the 3D images, in order to perform a well-controlled comparison of 2D and 3D strain measurements.

Quantification of Myocardial Strain: A validated cardiac motion estimation algorithm [6] was used to track the motion of the fetal left ventricle (LV) in 3D and 2D. To quantify strains, a line at the middle of the LV wall was traced, both in the longitudinal direction on the long-axis view and in the circumferential direction on the short-axis view, and these lines were motion tracked from end-diastole to end-systole for calculation of shortening and thus strain.

The engineering strain was quantified in line with current clinical practices, and the Green was also quantified to stay relevant to the biomechanics community. The intra- and inter- observer variability was checked to be satisfactory via the intraclass correlation coefficient (ICC), based on measurements by two observers for both 2D and 3D sub-endocardial strains from the same set of 10 fetal hearts for 3 repeat measurements.

Quantification of LV twist and fiber orientation: LV twist was also computed from the 3D motion tracking, by quantifying the differential angular rotation at the apex versus the base and by calculating the maximum minus the minimum of this differential rotation parameters. Myocardial fiber orientation was quantified by seeking the direction in which contraction occurred the most, via the calculation of the eigenvector of the strain tensor.

RESULTS

3D longitudinal strain (LS) was found to be significantly lower than 2D LS by 2.7% (Figure 1). This is due to LV twist causing the longitudinal line in 3D quantification to become diagonal after contraction, thus preserving its length after contraction, and 2D quantification cannot capture this effect (Figure 2a). To understand how much of the 2D vs. 3D difference is caused by this effect, we performed

a 3rd quantification of the projected strain, during which we tracked motion in 3D but projected the final location to the original 2D plane before strain calculations, as a way of negating LV twist motion effects. We found that 1.2% of the difference can be explained by LV twist motion.

In the circumferential direction, 3D strain was found to be significantly higher than 2D circumferential strain (CS) by 2.0% (Figure 1). This can be fully explained by the systolic apical motion of heart, which introduces wider transverse cross-sections of the heart into the imaging plane to negate contractile measurements (Figure 1b).

These results agree with and can explain with findings in adult echocardiography studies. Obokata et al. found in 106 subjects that 3D global LS (GLS) is lower than 2D GLS by 2.0%, while the median 3D global CS (GCS) is higher than 2D GCS by 2.0% [7]. In addition, Reant et al. found in 128 subjects that 3D GLS is lower than 2D by 1.1% [4].

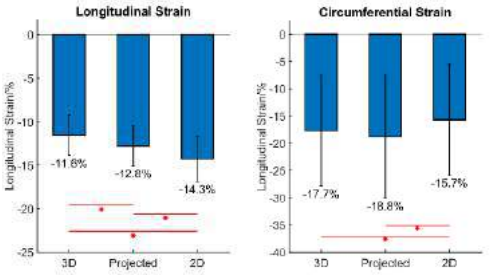

Figure 1. 2D vs 3D strain quantifications from the same ultrasound image.

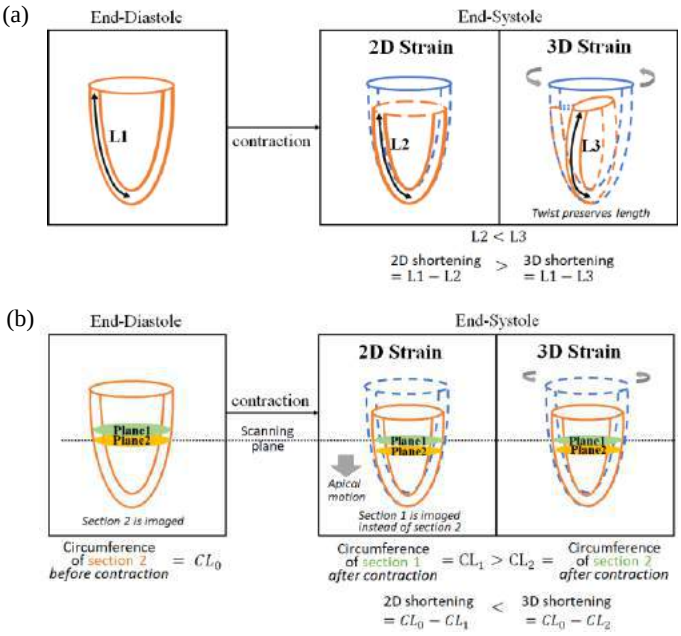

Figure 1: Schematic explanation of differences between 2D and 3D strain in longitudinal (a) and circumferential (b) strain

Further, we observed a timing mismatch between when the longitudinal and circumferential lengths are at their peaks, caused by LV shape changes during the isovolumic contraction period, when the LV momentarily lengthens and narrows [8]. During 2D quantification, strain in each direction is assigned its own zero-strain reference time, but in 3D, a single reference time is necessary for both directions. Thus, in 3D, favoring any one direction when specifying this reference will reduce strain magnitude of the other direction (Figure 3). This accounted for a further 0.7-0.8% difference between 2D and 3D strains.

A spatial variability of strains was also found. Strains at epicardial vs. endocardial locations differed substantially, by 3.6% in the longitudinal direction and 9.3% in the circumferential direction. Since strain quantifications often require manual controls clinically, this can account for wide discrepancies between the different studies mentioned above [5], in which reputable groups reported strain values that differed by 6.3-7.1%. We further found that introducing smoothing during motion tracking can lead to a substantial change in strain values, which can be another reason for wide discrepancies between studies.

Interestingly, 3D motion tracking enabled the quantification of LV twist (7.8 ± 3.3^o from the circumferential axis) and quantification of the myofiber orientations (4.6 ± 4.7^o).

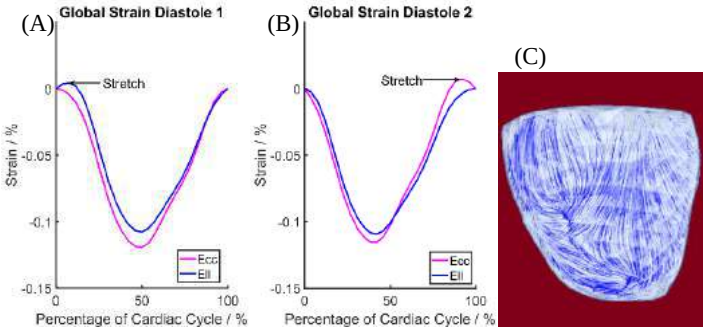

Figure 3. Plots of circumferential and longitudinal strains over time using (A) longitudinal peak as zero-strain reference time, or (B) circumferential peak as reference. (C) Fiber orientation of the heart quantified via eigenvalue of strain tensor

DISCUSSION AND CONCLUSION

In our study, we demonstrate that there are systemic factors that cause specific biased differences between 2D and 3D strain measurements, due to the twisting and apical motion of the LV during systolic contraction and by the timing mismatch between when dimensions in the circumferential and longitudinal directions peaked.

We further found substantial epicardial-to-endocardial spatial variability of strains and significant effects of motion tracking smoothing on strain quantifications, which can explain wide discrepancies in strain values in the literature.

We believe that this calls for caution in interpreting measurements in the literature, until careful standardization of strain measurements can be achieved. Further, although our study was conducted on fetal echocardiography, the results are likely applicable to adult echocardiography as well.

INTRAARTICULAR MMP-1 IN THE FACET JOINT MODIFIES THE CAPSULAR LIGAMENT'S RESPONSE TO LOAD & THAT RESPONSE CORRELATES WITH THE EXTENT OF DEGRADED COLLAGEN

INTRODUCTION

Musculoskeletal pain is the most common type of chronic pain and cause of disability [1]. The spinal facet joints act as pain sensors due to their innervation [2], and their capsule can transmit nociceptive signals under pathologic conditions [3,4]. The interstitial collagenase matrix metalloproteinase-1 (MMP-1) may mediate pathological cascades in painful joints since it increases after trauma and with degeneration [5,6]. It regulates structure and cell-signaling, and degrades Type I collagen that comprises the capsular ligament [7], altering joint biomechanics [6] and possibly mediating signaling in afferents [3]. MMP-1 acts on neuronal receptors and has substrates to neuropeptides and cytokines involved in nociception [7,8]. Despite evidence suggesting MMP-1's involvement in painful diseases, its role in joint pain is undefined.

Injecting intraarticular MMP-1 in the rat C6/C7 facet joint induces immediate and sustained pain and upregulation of the nociceptive peptide substance P [9]. Although MMP-1 may directly mediate facet pain, it is unclear if nociceptive cascades are triggered in afferents by collagen degradation or by MMP-1-mediated signaling pathways [7,8]. Since intraarticular bacterial collagenase also induces pain by inducing microscale degradation of capsular collagen fibers [10], intraarticular MMP-1 may also cause microscale collagen degradation that alters the microstructural kinematics of the fiber network under load. This study investigated isolated C6/C7 facet capsule ligaments from rats at 28 days after bilateral intraarticular administration of MMP-1, when pain persists [9]. One facet from each rat underwent biomechanical testing to define capsular multiscale kinetics and kinematics [11-13]; the other facet underwent a biochemical assay with collagen hybridizing peptide (CHP) to assess the amount of degraded collagen in ligament tissue [14].

METHODS

To assess the effects of intraarticular MMP-1 on ligament macroscale biomechanics, microstructural kinematics, and degraded collagen, spinal columns were harvested from rats (438-532g) after either a bilateral C6/C7 intraarticular injection of either 10μL of human recombinant MMP-1 (n=6) in sterile water (30μg/mL; SRP3117; Sigma) or only sterile water (vehicle; n=5) [9,10], by IACUC-approved procedures. On day 28, spinal columns (occiput-T2) were harvested; the superficial musculature was removed from the facets by fine dissection and the *in situ* length across the C6/C7 facet was recorded [15,16]. A naïve rat was also included for comparison as an un-operated joint.

For biomechanical testing, unilateral C6/C7 facet joints were mounted in an Instron 5865; the *in situ* length was re-established as the unloaded reference position (Fig. 1A) [15,16]. Isolated ligaments underwent tensile loading to failure at 0.08mm/s. Force-displacement data and high-speed images (Phantom v9.1; Vision Research) were acquired at 500Hz. An integrated polarized light imaging system acquired collagen fiber alignment maps before and during loading [11-13]. Force, displacement, and optical data were used to define relevant events during the stretch (Fig. 1B): the first failure, ultimate rupture, and yield (Fig. 1B) [12,15]. Ligament stiffness was also calculated [17].

Collagen fiber alignment maps were generated and used to compute the first occurrence of anomalous fiber realignment [11,12]. Vector correlations generated for every alignment map were used to identify changes between the maps and anomalous collagen fiber realignment (AR) was defined by a decrease of ≥0.35 in the vector correlation [12]. Force, displacement, and collagen fiber alignment maps were extracted at each event. The number of anomalous events [12,16] and the circular variance (CV) were calculated at each event (Fig. 1A), and also at the unloaded reference state [17]. CV quantified the spread of collagen fiber angles (Fig. 1A), with a lower CV indicating a tighter clustering and a higher degree of fiber alignment [17].

To quantify the amount of degraded collagen, the capsular ligament from the other side of the matching facet was isolated and

lyophilized overnight. Ligaments were incubated in 15μM of 5-FAM conjugate of CHP (3Helix) overnight, triple-washed in PBS for 30mins each, and incubated in 1mg/mL Proteinase K for 3hrs at 60ºC [14]. The fluorescence of 200μL duplicates of the homogenate solution was measured [14]; fluorescence values were divided by the wet weight.

Separate repeated-measures ANOVAs with Tukey tests tested differences in CV and AR across events within groups; comparisons in events between groups were tested by Wilcoxon tests. T-tests compared stiffness and CHP fluorescence. Correlations between CHP and CV at events were separately analyzed by linear regressions and ANOVAs.

RESULTS

The force-displacement response of capsules with vehicle injection is similar to that of the naïve rat (Fig. 1B). Yet, the curves for joints with MMP-1 injection are shifted to the right relative to vehicle responses (Fig. 1B), with the yield displacement greater ($p=0.04$) for MMP-1 than vehicle (Fig. 1B). Despite different displacements at yield and nearly a 1.5-fold decrease in stiffness between MMP-1 (1.56±0.87N/mm) and vehicle (2.30±1.28N/mm), stiffness is not different ($p=0.31$).

The microstructural kinematics are different between groups. For vehicle, CV at ligament yield is different ($p<0.03$) from reference (Fig. 2A). However, for MMP-1, collagen fibers do not reorganize until first failure ($p<0.01$) (Fig. 2A). Despite this, the number of AR events increases ($p=0.03$) from the first occurrence to yield after MMP-1 (Fig. 2A). In contrast, the CV of fibers of vehicle capsules is not different between the first occurrence of AR and yield, but differs ($p<0.01$) between yield and first failure (Fig. 2A). MMP-1-injected capsules also experience more events at failure than at yield ($p<0.01$) (Fig. 2A).

Before loading (reference) neither CHP fluorescence ($p=0.84$) nor CV ($p=1.00$) are different between groups. Yet, relationships between CHP and CV differ between groups. The correlation between CHP and CV at reference is significant ($p<0.05$) for all ligaments regardless of group; yet, this relationship is driven by a significant association between CHP and reference CV only with intraarticular MMP-1 ($p=0.02$) and not with vehicle ($p=0.63$) (Fig. 2B). The positive association between CHP and CV with MMP-1 is maintained at both the first occurrence of AR ($p=0.04$) and yield ($p=0.03$) (Fig. 2B).

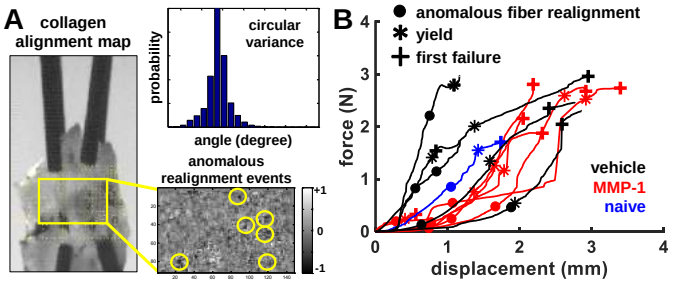

Figure 1: (A) Exemplar image and collagen fiber alignment map at first failure for a vehicle-injected ligament. CV and regions of AR events are computed from the map. (B) Force-displacement responses showing the first occurrence of AR (●), yield (*), and first failure (+). The curves end at ultimate rupture.

DISCUSSION

These findings show that MMP-1, likely via its collagenolytic function [10], alters the biomechanical response and reorganization of the capsular collagen network during its loading (Figs. 1&2). MMP-1 may degrade collagen in several regions of the ligament predisposing it to altered kinematics on the macro- and microscale (Figs. 1&2). That notion is supported by the correlation between degraded and/or partially unwound collagen (CHP) [14] and the spread of collagen fibers (CV) observed for joints in the unloaded state after intraarticular MMP-1 (Fig. 2B). That positive correlation suggests that more damaged collagen fibers correlate to more disorganized fibers. Further, the same correlation at both the first detection of AR and yield (Fig. 2B) supports that the microstructure of the facet capsule is altered by MMP-1 and remains during its loading. A greater displacement at yield for MMP-1 ligaments may indicate laxity in those ligaments [13], which could explain the pain in rats treated with MMP-1 [9]. Ligaments with greater laxity may be more prone to injury during physiologic motions [15,18].

Load mediates the rate of enzymatic breakdown of collagen by protecting strained fibers from degradation [19,20]. Since the capsule's collagen fiber network has varied orientations and undergoes heterogeneous strains with load [21], regions with fibers that are less strained may be preferentially degraded by MMP-1 and could explain the absence of overt structural damage [9]. The occurrence of isolated, yet frequent, AR events that is observed with MMP-1 treatment (Fig. 2A) highlights the possibility that afferents may be more susceptible to activation if they are in regions where the matrix undergoes abnormal kinematics. This study implicates MMP-1 in mediating the structure-function relationships of the capsular ligament and provides a possible mechanism for MMP-1 to induce pain and neuronal dysregulation [9].

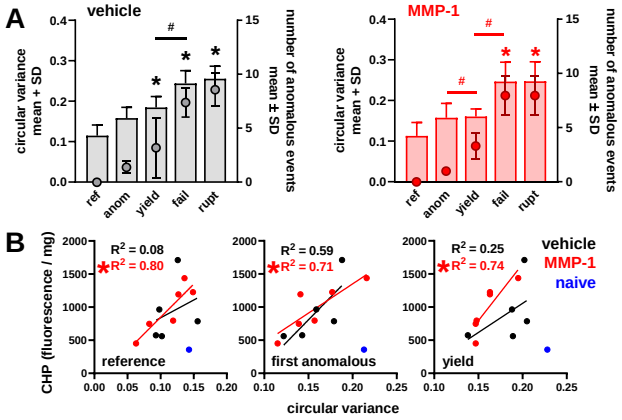

Figure 2: (A) CV (bars; left axis) and number of AR events (points; right axis) at reference (ref), first occurrence of AR (anom), yield, first failure (fail), and ultimate rupture (rupt). CV varies from reference at yield, fail, and rupt with vehicle (*p≤0.03) and at fail and rupt with MMP-1 (*p≤0.01). The pattern of AR events differs between groups (#p≤0.03). (B) CHP and CV are correlated for MMP-1 (*p≤0.04), but not vehicle (p≥0.12). R^2 is goodness-of-fit.

INTRODUCTION

The formation and recovery of gaps in the vascular endothelium governs a wide range of physiological and pathological phenomena, from angiogenesis to atherosclerosis and tumor cell extravasation. However, the interplay between the mechanical and signaling processes that drive dynamic behavior in vascular endothelial cells is not well understood. Here, we explore the formation, stability, and failure of endothelial contacts. We propose a model to describe the three-way chemo-mechanical feedback between (i) VE-cadherin bond turnover, (ii) RhoA-mediated actomyosin contractility, and (iii) Rac1-drived actin polymerization, to uncover how endothelial gaps dynamically form and recover. Simulating a 2D monolayer, we resolve the contradictory influence of RhoA and Rac1 signaling on junction stability and demonstrate how a balance and crosstalk between these critical processes is essential in the regulation of homeostatic function.

MODEL DEVELOPMENT

The maintenance of vascular endothelial cell-cell junctions is predominantly governed by VE-cadherin bonding (**Fig 1A**), which exhibit catch-bond behavior at low forces and slip-bond behavior at large forces (1). The dissociation rate of a bond can be described (2) by

$$k_d = \exp\left(\frac{F_b}{F_s} - \phi_s\right) + \exp\left(\phi_c - \frac{F_b}{F_c}\right), \qquad (1)$$

where F_c is the 'catch' force, F_s is the 'slip' force, and ϕ_c and ϕ_s are associated dimensionless catch-slip parameters. The bound cadherin density c_b is then given by $dc_b/dt = (c_{tot} - c_b)k_a - c_b k_d$, where c_{tot} is the total density and the association rate k_a is assumed to be constant. Further, we note a threshold force F_{crit} for unbinding beyond which bonds will rupture. Adherens junctions connect directly to force generating actomyosin networks in the cell cytoplasm which can apply tension to the cadherin bonds and increase their stability. In turn, the forces generated at intercellular junctions trigger a range of biochemical processes (SFK, RhoA) that promote higher cell tension via actomyosin contractility. Our chemo-mechanical feedback model for myosin-dependent force generation ρ (3) is extended here to consider explicit interactions with cell-cell junctions such that

$$\frac{d\rho}{dt} = -k_\rho\left(\varepsilon_{ec} + \beta(\rho - \rho_0) - \sigma_{ec}\alpha_c\left(\frac{c_b}{\gamma_c + c_b}\right)\right), \qquad (2)$$

where ε_{ec} is the cell strain, ρ_0 is a relative myosin motor density in the quiescent state, k_ρ is a kinetic constant, and α_c and β denote chemomechanical coupling parameters relating stress to signaling where γ_c denotes the cadherin concentration for half-strength signaling. The cell stress depends on both active and passive constituents, such that $\sigma_{ec} = \rho + K_{ec}\varepsilon_{ec}$ where K_{ec} is the passive cytoskeletal stiffness. In the event of junction failure, neighboring cells can reconnect as mediated by actin polymerization at the cell periphery (**Fig 1A**). Rac1 activates the WAVE regulatory complex to drive Arp2/3-associated polymerization of branched actin networks (**Fig 1B**). Compressive stress σ_P generated by such polymerization can drive protrusion of the cell membrane. We therefore propose a model to describe the level of branched actin network polymerization P such that

$$\frac{dP}{dt} = -k_P\left(1 - \frac{\sigma_P}{\sigma_{P_0}} - \frac{\rho}{\gamma_\rho + \rho}\right), \qquad (3)$$

where σ_{P_0} is a reference stress induced by actin polymerization. The polymerization-induced stress $\sigma_P = \sigma_{P_0}P$, and k_P is a kinetic constant. The second term describes the antagonistic interactions between RhoA and Rac1 as determined by suppression constant γ_ρ (signaling through ROCK activates Rac1 GAPs, and myosin activation locally prevents recruitment of Rac1 GEFs (4)).

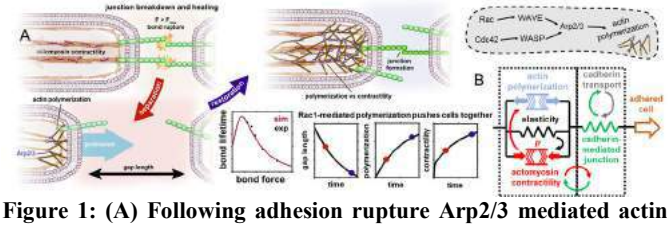

Figure 1: (A) Following adhesion rupture Arp2/3 mediated actin polymerization generates protrusive stress which can ultimately lead to junction restoration; (B) The mechanical model considers stresses induced by polymerization which are opposed by active and passive cell forces. These components couple with cadherin bonds which remodel in response to tension.

This model is implemented in a non-linear 2D spring lattice framework where we discretely consider (i) independent protrusions comprised of active cytoskeletal (polymerizing/contractile) elements, (ii) adherens junction elements that can rupture, remodel, and reform, and (iii) passive membrane/cortical actin elements that connect the protrusions. The system is solved using a Newton-Raphson iterative scheme such that mechanical equilibrium is achieved at every node at every time point in a quasi-static analysis.

RESULTS

Our model predicts that dynamic behavior emerges within a critical feedback strength and polymerization stress range (**Fig 2A**); protrusion facilitates cell-cell contact, enabling spontaneous cadherin bond formation. As the density of bonds increases, the stress-mediated signaling feedback strength also increases which upregulates signaling from SFKs and causes downstream myosin motor phosphorylation and cross-bridge cycling. With higher contractility within a catch regime, bond dissociation is reduced which overall promotes a higher bond density. In conjunction, the polymerization stress is reduced via RhoA-associated Rac1 suppression. However, development of further contractility then drives rapid bond dissociation and rupture, causing cell-cell separation (**Fig 2A**). A loss of adhesion-mediated signaling lowers contractility, in turn facilitating a restoration of the polymerization-induced stress and allowing the cells to reconnect.

Exploring the phase space of α_c and σ_{P_0} facilitates a mapping of the junction state (**Fig 2B**). A high level of Rac1 signaling is predicted to mediate junction weakening, in the form of a closed cell-cell gap but an absence of bond tension and stability. With increasing feedback α_c, the junction strength increases due to higher levels of actomyosin force generation stabilizing cadherin bonds. Impairment of Arp2/3-mediated polymerization is predicted to prevent gap closure, as insufficient stresses are generated to drive development of protrusions. We performed platinum-replica electron microscopy (PREM) on monolayers of cultured HUVECs. This technique permits high resolution imaging of cytoskeletal network organization (5). We observed that the organization of the cytoskeleton was indicative of the junction state at different stages of the rupture/heal cycle. In agreement with model predictions, continuous cohesion of two neighboring cells is characterized by the presence of branched actin networks at the cell-cell junction and actin filament bundles in the junction vicinity (**Fig 2C**). Apparent post-rupture junctions are mainly associated with actin bundles that often form intercellular bridges.

We further cultured a confluent monolayer of HUVECs on collagen gels and studied the evolution of cell-cell junctions (**Fig 2D**). We observed that gaps form at endothelial junctions, grow in size, and heal over time. In agreement, our simulations of monolayer behavior suggest that when a gap forms, separation propagates along the boundary which further increases the gap size (**Fig 2E**). Then, due to the loss in contractility (associated with adhesion rupture and signaling downregulation) and increasing polymerization, the cell membrane protrudes to reestablish contact and bonding. Experimentally, we found that junctions are more frequently disrupted at vertices (multi-cellular junctions) than at borders (bicellular junctions), with quantitative measurements demonstrating that the probability of observing a gap at a vertex is approximately nine-times higher than that at borders (**Fig 2F**). Our model indicates that the forces exerted on cadherin bonds are significantly higher at vertices than at two-cell borders (**Fig 2G**), which can drive bond rupture and junction failure. Gaps were observed to form at the HUVEC vertices approximately once per hour, with ruptures persisting over 30 minutes (**Fig 2H**). Our simulated timescales provide excellent agreement with these data, further supporting the validity of our framework.

DISCUSSION

Our chemo-mechanical model provides new insight into how endothelial junctions are regulated by an interplay between mechanical forces and signaling processes, and indicates the mechanisms governing a range of pathophysiological activity. Vascular barrier function can be compromised during inflammation, with thrombin driving endothelial hyper-permeability through RhoA activation (6). Our analysis suggests that this occurs through increased actomyosin contractility driving cadherin bonds into a slip regime and subsequent rupture. Junction dynamics are also critical to cancer progression; tumor cells have been observed to exploit disrupted connectivity at multi-cellular junctions to transmigrate through the endothelium (7). Simulations indicate that gap formation is critically dependent on stress-sensitive adhesion-mediated signaling that upregulates actomyosin contractility, with junction restoration driven by a subsequent recovery in actin polymerization. Overall, our analysis suggests that a critical balance between RhoA and Rac1 expression is required to maintain junction stability and limit endothelial dysfunction. Our proposed model can help guide the development of therapeutics that target the Rho family of GTPases and downstream active mechanical processes.

INTRODUCTION

Atherosclerotic plaque rupture-induced cardiovascular events are the leading cause of mortality and morbidity worldwide [1]. Biomechanically, plaque rupture occurs when the local stresses in the plaque tissue exceeds the local tissue strength. Although plaque tissue is structurally and hence, mechanically highly heterogenous, our current knowledge on the tissue's mechanical (stiffness and failure) properties is limited to average properties, obtained by homogeneity assumption and global deformation measurements in ex-vivo mechanical tests [2]. Yet, local plaque tissue mechanical properties are of paramount importance for accurate rupture risk assessment. In this work, we aimed to capture local mechanical (elastic and failure) properties of carotid plaque tissue. We have performed uniaxial tensile testing on human carotid endarterectomy samples until complete tissue rupture. Then, the local tissue deformation was obtained by using digital image correlation (DIC), and local heterogeneous mechanical characteristics of the tissue by using nano-indentation technique.

METHODS

Local Strength Measurements with Uniaxial Tensile Testing and DIC

Thirty atherosclerotic human carotid artery endarterectomy samples were collected at the Erasmus Medical Center, in Rotterdam. As a preliminary work, three rectangular shape tissue strips, from the common (n=2) and internal (n=1) carotid artery regions, were prepared for the uniaxial tensile testing and DIC. During the tissue preparation, a speckle pattern was applied to the lumen side of the tissues by using a spray paint for the DIC analysis. After a clear speckle pattern was obtained, the tissue strips were tested by using an in-house-built uniaxial tensile testing setup (Fig.1 (A)). The average thickness of the strips was approximately 2 mm. Their width and length (along the circumferential direction of the artery/plaque) sizes were approximately 5 mm and 25 to 30 mm, respectively. Before the tests, the samples were pre-stretched up to 0.05 N. The gauge length was kept approximately 12 mm, and the samples had a length to width ratio of approximately 2.4 after pre-stretching, which falls within the suitable range for the uniaxial testing of soft tissues [3]. Then, preconditioning was performed up to 10% stretch with a speed of 0.05 mm/s for 10 cycles. The tests were performed with the same speed until complete tissue rupture. The initial rupture in this work was defined as the first micro-failure detected on the gauge length-based stress-strain curve (Fig.1 (B)), further confirmed independently by the tensile-testing camera recordings. The engineering stress was calculated from the force measurements and the original cross-sectional area, while the global Green-Lagrange strain was calculated from gauge length measurements. Following the tensile testing, the DIC analysis was performed with an open-source MATLAB based software (Ncorr, version 1.2) for local Green-Lagrange strain measurements.

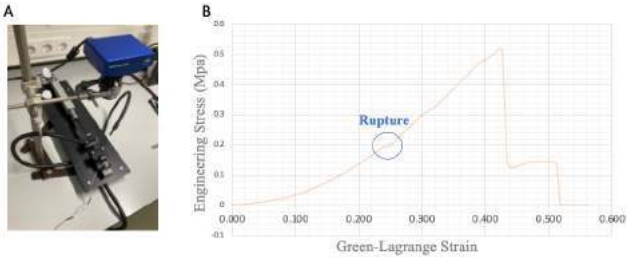

Figure 1: (A) The uniaxial testing setup. (B) Gauge length-based failure detection from the stress-strain curve.

Local Stiffness Measurements with Nano-Indentation

In order to investigate a possible correlation with the local tissue stiffness and the tissue strength, the local mechanical characterization

was performed with a nano-indentation testing. For this purpose, Piuma Nanoindenter (Optics11 Life, the Netherlands) with a 263 micron tip and 0.64 N/m stiff cantilever was used. The ruptured strips were glued to a glass petri-dish from the media side and the petri-dish was filled with a Phosphate-Buffered Saline (PBS) solution (Fig. 2). A total of 10 to 15 measurements were taken from each strip. The testing sites were chosen to be approximately 2 mm apart from each other and the strip edges. The force-indentation displacement curve was fit using a Hertz model to calculate the effective Young's Modulus for each measured location (Fig.2).

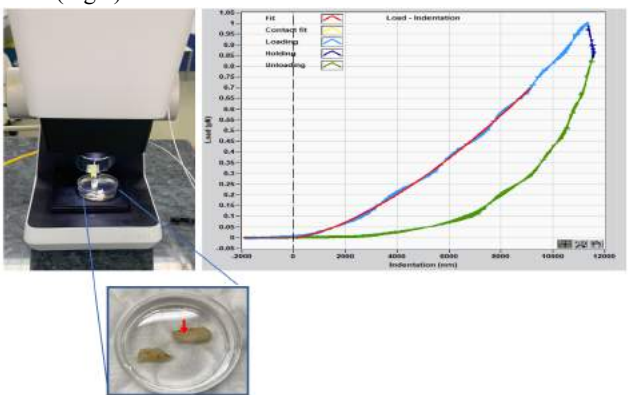

Figure 2: A representative nano-indentation testing, performed near a rupture location indicated by the red arrow. The effective Young's modulus was calculated as 1.21 kPa at this location.

RESULTS

The uniaxial tensile tests of all tissue strips were performed successfully. Speckle patterns were clear and well-captured by the DIC analysis, and local deformation information was obtained. Nano-indentation was successfully performed in total of approximately 40 locations on the three tissue strips, and the Hertz model had a good fit to the load-indentation displacement curves. In total, there were four ruptures in the three plaque strips tested.

By using the gauge length-based analysis, the engineering stress and Green-Lagrange strain at the initial rupture timepoint for the samples were calculated as; 1st strip (at the common carotid): 0.24 MPa and 26%, 2nd strip (at the common carotid): 0.20 MPa and 24%, 3rd strip (at the internal carotid): 0.07MPa and 16%. Then, the DIC based analysis was performed to obtain local deformation measures. The local deformation patterns of Green-Lagrange strain measurements (tensile (E_{yy}) and absolute shear (E_{xy})) are shown in Fig.3. The maximum and mean values obtained for the DIC measurements in the tensile direction are; 1st strip: 84% and 21%, 2nd strip: 59% and 20%, 3rd strip: 53% and 13%.

It was observed that the overall mean values obtained by the DIC analysis were in accordance with the gauge length-based measurements. However, the maximum local measurements obtained by the DIC were much higher than the averaged gauge-length based measurements (65.3% vs 22%). Two of the four rupture sites (1st sample and the 3rd sample, upper left region rupture) were observed at high local tensile strain zones of approximately 84% and 35%. Interestingly, the other two ruptures (2nd sample and 3rd sample, lower right region) were observed at high shear strain regions of approximately 25% and 55%, respectively. The local indentation measures showed a large inter- and intra-sample variation. The stiffness measures obtained for the strips were; 1st strip: 274.8 Pa to 41.8kPa, 2nd strip: 550.9Pa to 53.1kPa, 3rd strip: 968.4Pa to 22.3kPa. The highest stiffness locations of 41.8 kPa, 53.1kPa and 22.3 kPa for the 1st, 2nd and 3rd strips were all observed close to the rupture sites after complete separation.

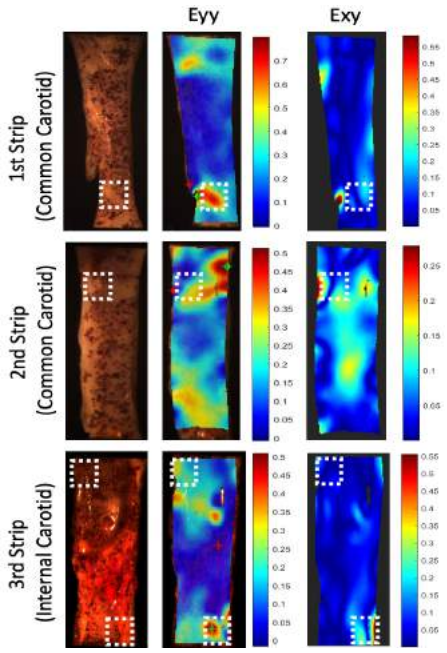

Figure 3: DIC-derived local circumferential Green-Lagrange (E_{yy}) and absolute shear strains (E_{xy}) of the three tissue strips. The rectangular boxes indicate rupture initiation sites.

DISCUSSION

In this work, we have conducted a preliminary research for our new pipeline, which can provide local failure characteristics of highly heterogenous plaque tissue, which is more relevant for real-life plaque rupture than the conventional average ultimate tensile properties obtained by tissue homogeneity assumption. In the developed pipeline, we used uniaxial tensile testing and DIC to obtain local deformation measures at the rupture point, and further, we have used nano-indentation technique to obtain local mechanical properties. First of all, although the test were uniaxial tensile tests, because of the test sample geometries and tissue heterogeneity, DIC measurements showed some high shear strain regions locally, which could not be obtained by traditional, gauge length-derived strain analysis. Furthermore, it was observed that gauge length-derived measurements greatly underestimate tissue rupture strain, due to the inherent homogeneity assumption in the analysis. In addition, DIC measurements demonstrated that the rupture locations were correlated with high tensile and/or shear strain, which implies different failure mechanism due to the tissue's microstructural organization. We plan to address this in the near-future work, by assessing the microstructural (collagen) information with histological examination and correlate that with local mechanical properties. We believe that a possible correlation between the local mechanical and structural tissue properties will provide great insights for the failure mechanisms involved in real-life plaque rupture events.

A PHYSICS-INFORMED MACHINE LEARNING MODEL FOR THE IDENTIFICATION OF ACTIVE CONTRACTION PROPERTIES IN THE VENTRICULAR MYOCARDIUM

Igor A. P. Nobrega, Wenbin Mao

Department of Mechanical Engineering
University of South Florida
Tampa, FL, USA

INTRODUCTION

Heart diseases are the preeminent cause of death, accounting for over 40% of all human mortality [1]. Advancements in the fields of biomedical engineering, computer science and data mining unraveled bright opportunities to fathom important mechanical properties of soft tissues and their influence over its physiological functions. Early signs of disease or physiological complication can be indicated through the analysis of elastic properties of soft biological tissue [2] as these are intertwined with its internal microstructure [3], which are responsible to govern its macroscopic behavior and mechanical functions.

To better understand the mechanical functions of the heart and support the development of effective treatment and prevention of such heart diseases, it is crucial to define realistic descriptions of myocardium structure with constitutive models. Although several models were developed to represent both passive and active contraction of myocardium tissues, most of them are not desirable; these often require extensive computational resources and time, lessening their usage on clinical applications. Considering the hardship that confines the derivation and application of pure constitutive models, the usage of artificial intelligence and machine learning imposes leading advantages over traditional methods.

Taking this into account, the main objective of this study was to develop a constitutive-based machine learning (ML) method to evaluate and predict the behavior of an active contraction model of the left ventricular myocardium in a cardiac cycle by autonomously selecting the best-fitting material parameters under different clinical conditions.

METHODS

The active and passive reactions of myocardium may be assumed to be coupled as an additive decomposition of the Cauchy stress tensor $\sigma = \sigma_p + \sigma_a$. In this equation, σ_p defines the passive stress component, which characterizes the response of the myocardium when the muscle is inactive. Moreover, σ_a determines the active stress component, which is impelled by the electrical activation of the myocardium tissue [4].

A widely accepted representation of the strain-energy function of the passive myocardium tissue proposed by Holzapfel-Ogden [5] was used as the base model. The key advantage of the selected model is the representation of the fiber distribution along layers on the myocardium wall, considering that the ventricular wall presents a multilayered structure with transmural variation of the direction of its myocytes [5]. The passive strain-energy function is composed of eight material parameters a, b, a_f, a_s, b_f, b_s, a_{fs} and b_{fs}, and is given as follows:

$$\sigma_p = \frac{a}{2b} e^{b(I_1 - 3)} + \sum_{i=f,s} \frac{a_i}{2b_i} \left\{ e^{b_i (I_{4i} - 1)^2} - 1 \right\} + \frac{a_{fs}}{2b_{fs}} \left[e^{b_{fs} I^2_{8fs}} - 1 \right] \quad (1)$$

The active model adopted was proposed by Pezzuto et al. [4]. This model presents benefits over its simplicity, yet effective formulation. By introducing just one additional parameter, γ, the active model takes into account the multiplicative decomposition of the deformation gradient, which preserves the ellipticity of the stress tensor and yields an "active strain" approach [4]. The model is defined by:

$$\sigma_a = (1 - \gamma) \boldsymbol{f}_0 \otimes \boldsymbol{f}_0 + \frac{1}{1-\gamma} (\mathbf{I} - \boldsymbol{f}_0 \otimes \boldsymbol{f}_0) \quad (2)$$

, where $\boldsymbol{f}_0$ denotes the unit vector of fiber axis. The constitutive model was implemented in the open-source Finite Element (FE) solver FEBio [6], and was validated by comparing with the analytical solutions of a solid cube under simple shear and biaxial deformations [4], [5]. In

addition, the mesh independence study was conducted on a truncated ellipsoid geometry (representing an idealized left ventricle) under systolic pressure load (Fig. 1a). We found that 12 layers of elements through the thickness are required for linear elements and 6 layers are required for quadratic elements to reach mesh independence. The idealized and patient-specific geometries are shown in Fig. 1a, representing one of its deformed state, and 1c, respectively; along with a sample fiber orientation illustrated in 1b and 1d. As can be seen, the muscle fiber orientations change with position through the wall: from a positive angle ($\boldsymbol{\alpha_{epi}}$) in the sub-epicardial region to nearly 0◦ in the mid-wall to a negative angle ($\boldsymbol{\alpha_{endo}}$) in the sub-endocardial region. To generate the smooth fiber orientation map, we adopted an rule-based reconstruction algorithm using Poisson interpolation proposed by Wong & Kuhl [7].

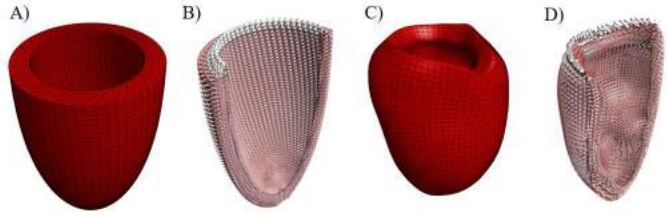

Figure 1: Left ventricular myocardium meshes and fiber orientations: (a) and (b) idealized, and (c) and (d) patient specific.

By conducting a series of FE simulations, we generated an extensive dataset by varying the model's active parameter, **γ**, and fiber's $\boldsymbol{\alpha_{epi}}$ and $\boldsymbol{\alpha_{endo}}$ orientations, while applying pressure load on the endocardium varying from 0 kPa to 16 kPa. Values for endocardium volume, ventricular torsion, wall thickening, longitudinal shortening and radial shortening were computed for each simulation and recorded along with its corresponding **γ**, pressure and fiber orientation. The final dataset consisted of over 4,182,525 sets of datapoints.

Our machine learning model consisted of two main parts: a regressor to find the best combination of $\boldsymbol{\alpha_{epi}}$ and $\boldsymbol{\alpha_{endo}}$ fiber orientations and another regressor to estimate the values for **γ**. Clinically relevant metrics of wall thickening, longitudinal shortening and radial shortening were used as labels for the first regressor, while the values of volume and pressure were used to estimate its corresponding active parameter. To select the best fitting ML model, different methods (Random Forest (RF), Support Vector Machine (SV), Decision Tree (DT), Lasso, Ridge, ElasticNet, SGD, ARD and Bayesian-Ridge regressor models) were used to learn and regress the given dataset and the root-mean-square error (RSME) was used to evaluate their predictions. The best-fitting regressors for each set of input-output were selected and combined into a base model.

RESULTS

For the first part of our ML model, different regressors were tested under different input parameters, the model of "Random Forests Regressor" had the least RSME value, proving to be the most efficient. By the same token, the second part of the ML model was used to predict gamma values for the active contraction under a given PV curve. The "Random Forests Regressor" was again taken as the best-fitting regressor with its RMSE under 10-fold cross validation being 0.0001592.

Furthermore, to test the model's efficiency, we preselected a set of clinical metrics to estimate fiber orientations and a predetermined pressure-volume (PPV) curve in a cardiac cycle to predict a series of γ values (Fig. 2a). The predicted gamma values and fiber orientations were used as the input parameters for the FE model. The model calculated volume waveform was compared with the PPV (Fig. 2b). We can see that the predicted γ value (green line) is highest around peak systole, representing the strongest active contraction. Then it gradually decreases to zero in the end of diastole. The FE calculated endocardium volume waveform matches the predetermined volume very well. As it can be seen, the relative error between these curves is minimal (less than 5%). This process was repeated for different sample PV curves, including one derived from a dataset of heart failure patients. The RMSE was computed for each trial and their average was taken as an indicator of the constitutive-based ML model's efficiency. We found that the averaged RMSE is less than 2.00422 for all testing PV curves.

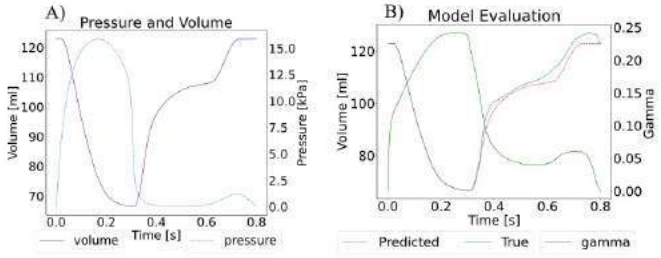

Figure 2: (a) Pressure and volume waveforms of human heart with normal cardiac function (PPV waveform); (b) Model predicted γ values (green line), endocardium volume (solid blue line) and predetermined volume from PPV input (dashed red line).

DISCUSSION

By developing a physics-informed machine learning model, we were able to accurately capture the left ventricular myocardium mechanical response based on a few clinically relevant metrics and prescribed pressure-volume curve. Moreover, our method includes a generation of a sustainable dataset that can be used to train a base ML model capable of selecting a set of epicardium and endocardium fiber orientations and a series of **γ** parameters to represent the contribution of the active contraction. Our model indicates high accuracy for different pressure-volume curves and works well for both idealized and patient-specific geometries of the left ventricle.

The usage of artificial intelligence combined with constitutive-based models allows the autonomously selection of hard to select model parameters. Furthermore, one of the key features that distinguishes machine learning based models is the ability to interactively improve their performance and capabilities when additional data is available. With that in mind, further study will be performed to extend the model to predict detailed deformation of myocardium at different phases in a cardiac cycle.

INTRODUCTION

Ischemic Mitral Regurgitation (IMR) is a significant clinical problem that occurs secondary to post-infarction left ventricular remodeling. In this disease, left ventricular enlargement dilates the valve annulus and displaces the papillary muscles, inhibiting the ability of the leaflets to sufficiently close during ventricular contraction and results in valvular regurgitation. [1]. Complications of IMR are recognized to influence the microstructure of the annulus. The extracellular matrix (VECM) within the annulus consists of collagen, elastin and other supplemental proteins that contribute to the structural integrity of tissue [2]. In case of disease, these proteins are shown to degrade or fragment [2,3] potentially altering the biomechanical strength of tissue.

The biomechanical strength of the annular issue is critical to the surgical correction of IMR. In open-heart surgical techniques, sutures are passed through the annular tissue and used to secure prosthetic annuloplasty rings and replacement valves to the annulus [4]. Although usually successful, reports indicate recurrence of moderate to severe regurgitation in approximately one third of treated patients within 12 months of surgery. A recognized cause of recurrent MR is annuloplasty ring dehiscence, which results from sutures pulling through the annular tissue. This deleterious event is estimated to underlie 13-42% of reoperations for failed annuloplasty repairs [5]. Its consequences are often severe, and can include device migration, embolization, endocarditis, patient morbidity, and mortality.

Dehiscence is governed by a balance between the suture holding strength of the annular tissue and the tension required of the suture to hold the device to the annulus. When the suture force magnitude exceeds the local holding strength of the tissue, device dehiscence can occur. In IMR surgery, larger suture forces are required to constrain the large and dilated annulus to a comparably smaller replacement valve or annuloplasty rings. This in the setting of microstructural changes to the valve annulus, elevate the potential risk for dehiscence.

The forces required to pull out these sutures from the annulus vary with circumferential positions around the annulus [5]. These pullout forces are what determine the suture holding strength (HS) of the annulus. Clinical reports [6] and previous studies [5] have indicated dehiscence to be more common along the posterior annulus. As an effort to further investigate the cause of this observation, our group conducted studies using a mitral annulus from healthy ovine subjects [5]. HS and underlying annular microstructure was evaluated at ten positions around the annulus. It was observed that there was sparse collagen content in the posterior annulus, explaining the low holding strength in that region.

Previous studies have been conducted with healthy specimens; however, the relationship of HS and tissue microstructure in a diseased animal model is necessary to understand device failure in case of IMR.

The objective of the study is to develop an improved understanding of suture holding strength and to investigate underlying structural factors that change the biomechanical behavior of the annulus following IMR.

METHODS

IMR Animal Model. The animals used in this work received care in compliance with the protocols approved by the Institutional Animal Care and Use Committee at the University of Pennsylvania in accordance with the guidelines for humane care [7]. Nine ovine subjects received an inferior left ventricular infarction to produce progressive, chronic IMR. This model has been studied extensively and mimics precisely an inferior infarction described in humans [8-11]. Through a sterile left lateral thoracotomy, snares were placed to occlude permanently the proximal second and third obtuse marginal branches of the circumflex coronary artery. After infarction, the thoracotomy was closed and IMR allowed to progress for an 8-week period prior to heart explantation, holding strength, and microstructural assessments.

Assessment of suture holding strength. The mitral valve annulus and leaflets were excised from IMR ovine hearts and mounted to a custom-built testing plate [5]. This custom plate featured a biaxial traverse, allowing freedom for each suture to be pulled perpendicular to the testing arm. Running sutures with Ford interlocking stitch were used along the outer annulus circumference, and the inner circumference (through the basal regions of the leaflets) to secure the annulus on the test plate. Surgically placed sutures at 10 positions corresponding to different locations circumferentially around the annulus (Figure 1A) were pulled using an 858 MiniBionix II (MTS, Eden Prairire, MN) until the suture tore from the tissue. The test plate was fixed to the lower testing arm, in line with a 100 N load cell (Interface, Scottsdale, AZ) on

the upper arm. The tissue was hydrated periodically throughout testing, with 0.75% saline.

HS was defined as the peak recorded force at the time the suture completely ripped out from the tissue. Data was recorded for all 10 suture positions in a clockwise fashion (left trigone (LT), 11, 1, right trigone (RT), 3, 4, 5, 7, 8 and 9 o'clock)

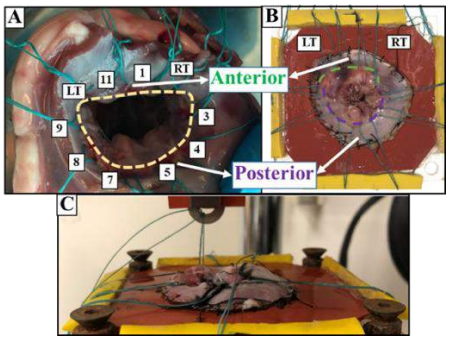

Figure 1: *Ex vivo* mitral annulus excision showing the ten positions around the annulus and setup on custom test plate (A and B). Suture pullout testing shown in C.

Histological analysis of annular microstructure. Following pull out testing, two samples, approximately 3 mm x 3 mm (in the apical-basal and radial directions), were extracted from the LT, 11, 1, RT, 4 and 8 o'clock positions around the annulus. These six representative positions were chosen to represent the anterior, antero-medial, posterior and postero-medial regions. Tissue samples for each position fixed in formalin. Commrcial Van Verhoeff's elastic stain kit (Abcam, Cambridge, UK) was used to visualize, identify and analyze elastin contents in the sample for each position. The stained samples were observed and imaged under a microscope for analysis.

A custom MATLAB (MathWorks, Natick, MA, USA) code was developed to quantify elastin fibers from the microscopic data. The results from the histological analysis were used to compare to both holding strength in the respective positions for each animal.

RESULTS

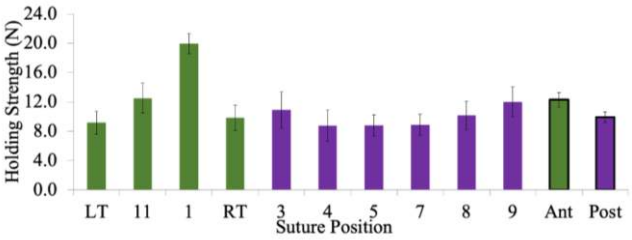

Figure 2: HS in (n=9) diseased subjects at all suture positions. Shown: HS (N). Grouped HS are presented at the right, Left trigone – right trigone, ant (anterior); 3 and 9 o'clock, and 4-8 o'clock, post (posterior).

The average holding strength for all positions in the anterior annulus was observed to be 12.28 N ± 6.02 N, while averaged across all positions along the posterior annulus were 9.94 N ± 5.53 N (Figure 2).

From the elastin histological analysis, the average elastin percentage at the inter-trigonal positions (1 o'clock and 11 o'clock) were observed to be 10% greater than the tested posterior positions (4 o'clock and 8 o'clock). These findings correlate with the lower holding strength observed in the posterior annulus.

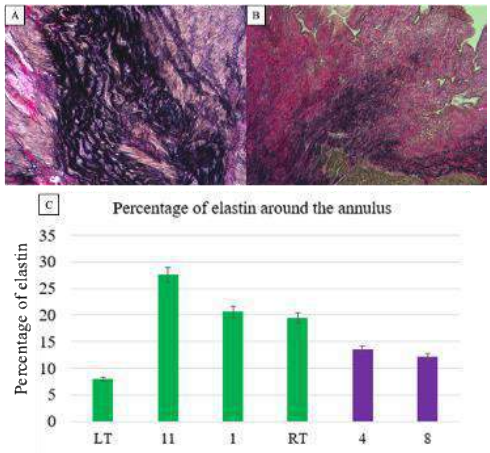

Figure 3: A tissue section taken from the mitral annulus at both the anterior (A) and posterior (B) positions showing elastic fibers (blue/black) embedded in collagen rich (pink) tissue.

DISCUSSION

The posterior annulus exhibited a lower holding strength than the anterior annulus with, the highest holding strength observed at the 11 and 1 o'clock and the lowest at the 3, and 4 o'clock position. The highest holding strength at the inter-trigonal regions is in agreement with prior studies, and could be explained by the higher collagen and elastin content in the anterior annulus [5]. The lowest holding strength positions along the posterior annulus differ from previous investigations in healthy subjects [5]. This could be due to the fact that the infarcted region on the ventricular wall (postero-medial papillary muscle was observed to be closest to the 3, and 4 o'clock region of the annulus. We hypothesize that this ventricular infarct may have contributed to changes in the annular microstructure which led to lower holding strength in that region.

This is the first study to examine the consequences of IMR on both suture holding strength and annular microstructure. Overall, this study aims to investigate the effects of diseased annular tissue on suture holding strength. The current data suggests in that in the diseased tissue region, the holding strength decreases, increasing propensity of suture dehiscence and eventual failure of the device. To understand the basis behind the relationship of cell death due to disease and tissue strength, supplemental histological evidence is being compiled.

COMPUTATIONAL MODELING ON TRANSMURAL DISTRIBUTION OF CORONARY PERFUSION AND MYOCARDIAL WORK

INTRODUCTION

There is a need for intimate balance between the transmural distribution of myocardial demand and supply to maintain normal cardiac function across the heart wall. A mismatch or imbalance between regional myocardial demand and supply is one of the origins of many heart diseases, especially in ischemic heart failure [1]. However, this question is difficult to answer from pure experimental or clinical studies, as in vivo measurements of myocardial blood flow in the deep layer of the heart wall is extremely challenging, and direct measurement of myofiber stress and regional work in the deep layers of the heart wall are currently not amenable to direct observations at the desired resolutions. Besides, there is no model directly considering the interactions among coronary perfusion, cardiac mechanics, and systemic hemodynamics. To address this limitation, a computational framework that couples the systemic circulation consisting of a left ventricular (LV) finite element model (FE) and coronary perfusion in a closed loop manner is developed to investigate the transmural demand (myocardial work)/supply (coronary perfusion) ratio.

METHODS

The computational framework consists of a FE model of the LV and 4 coronary microvascular networks (each network consists 400 vessels) located at different transmural locations across the LV wall (i.e., endocardium, mid-endocardium, mid-epicardium and epicardium) (**Fig. 1a**). The functional relationship between the LV pressure and volume (i.e., $P_{LV} = f(V_{LV}, t)$) is obtained by minimizing a Lagrangian function consisting of myocardial tissue strain energy function and terms associated with the enforcement of constraints on 1) myocardial tissue incompressibility, 2) zero-mean rigid body translation and rotation and 3) cavity volume [2]. The mechanical behavior of the LV is modeled using an active stress formulation, in which the passive and active mechanical behaviors are described by a Fung-type strain energy function and a modified time-varying elastance model, respectively [3]. Coronary flow rate in each vessel of the coronary network is described using a three-element Windkessel model (**Fig. 1b**) consisting of two identical nonlinear resistors and one nonlinear capacitance based on our previous model [4]. Mass conservation is satisfied in the coronary network at each nodal position connecting the vessels, where the number of vessels connected to the node is 3 for a bifurcation and 4 for a trifurcation (**Fig. 1c**). Intramyocardial pressure (IMP), which is the extravascular force applied to the vessel, is prescribed using the local value of the Lagrange multiplier associated with the incompressibility constraint from the FE LV model. We note that the Lagrange multiplier is associated with the hydrostatic pressure of the fluid-like ground matrix in constrained mixture models of the biological tissue, and hence, is assumed here to be the extravascular pressure imposed on the coronary micro-vessels. The FE LV model and coronary arterial network are connected to a lumped parameter representation of the systemic circulation, including the left atrium (LA), proximal peripheral arteries, distal peripheral arteries and peripheral veins each represented by its corresponding electrical analog [4], [5] (**Fig. 1a**). The LA is described by a time-varying elastance model, which relates instantaneous pressure to instantaneous volume.

We first calibrate the model to obtain the waveforms of LV pressure, volume, and strains that are in agreement with those measured in a typical normal human LV or in a large animal under resting conditions. After model calibration, we then vary the parameters from the baseline case to investigate the isolated effects of either the LV's contractility, preload, afterload, or geometry (LV cavity volume and wall thickness) on the LV's chamber pressure, arterial pressure, transmural distribution of IMP, coronary flow, myocardial work and the ratio of myocardial demand and supply.

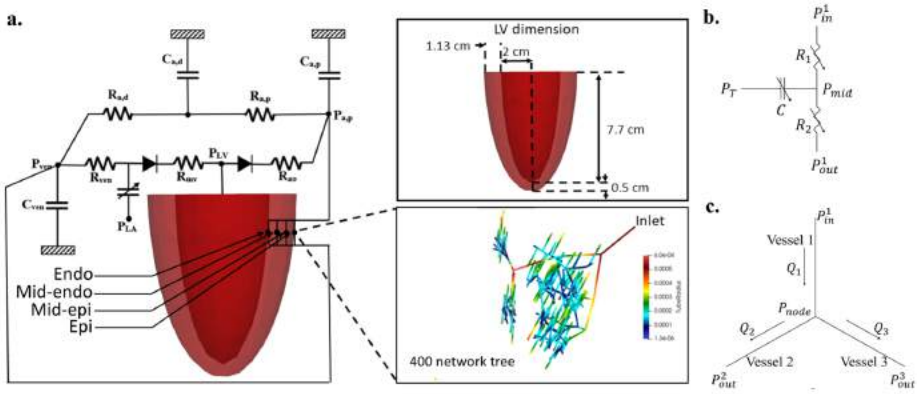

Figure 1a. Schematic of the cardiac-coronary computational framework shows that the LV FE model (with dimension given in the inset) is connected to 4 coronary networks located at different transmural location across the myocardial wall. Each network consists of 400 vessels with different vessel radius (see inset); **b.** Electrical non-linear analog of the segment lumped model; **c.** Single bifurcation three-vessel network.

RESULTS

Waveforms of the pressures in different compartments of the systemic circulation, LV volume, regional IMP, regional coronary flow
