rate $q_{cor,i}$, circumferential strain E_{cc}, longitudinal strain E_{ll}, the ratio of the peak IMP and the peak LV pressure, the ratio of the coronary flow normalized with that at the endocardium, regional myocardial work W_f and regional stress-strain curves $S_{ff} - E_{ff}$ at the transmural locations under control condition are presented (**Fig. 2)**. Peak LV pressure, LV's end-diastolic pressure, systolic arterial pressure and diastolic arterial pressure were 131mmHg, 8mmHg, 130mmHg and 73mmHg, respectively (**Fig. 2a)**. Left ventricular ejection fraction, end-diastolic volume, end-systolic volume were 61%, 110ml and 43ml, respectively (**Fig. 2b**). Intramyocardial pressure waveform was highest in the endocardium and decreased transmurally towards the epicardium (**Fig. 2c**). Except in the epicardial and mid-epi regions, coronary flow rate was largely reduced during systole in the inner layers of the myocardium, and was negative at the endocardium (**Fig. 2d**) since the higher IMP during systole in the endocardium impedes most of the flow. Coronary flow rate in the endocardium during systole (t = 0 – 300ms) is dominated by the effects of IMP. At the onset of diastole (t > 300ms), coronary flow rate increased rapidly as IMP fell faster than the reduction rate in arterial pressure (that controls perfusion pressure). In the epicardial and mid-epi regions, coronary flow rate is dominated by the perfusion pressure during systole. Coronary flow rate in the microvascular networks were, however, largely similar in diastole. Peak E_{cc} and E_{ll} were 26% and 21%, respectively, and their waveforms were in agreement with 3D echo measurements from normal humans (**Fig. 2e** and **2f**). From the endocardium to the epicardium, total coronary flow over a cardiac cycle increased while both myocardial work W_f that is the area of regional stress and strain, and IMP decreased transmurally (**Fig. 2g-2j**). The transmural variation of these quantities is approximately linear. Specifically, IMP was approximately 1.1 times of the LV pressure in the endocardium and decreased to around 0 at the epicardium (**Fig. 2g**), which is consistent with experimental measurements. Total coronary flow was largest in the epicardium and approximately 1.7 times of that in the endocardium, which has the smallest total coronary flow (**Fig. 2h**). This result is largely consistent with experimental measurements. Total myocardial work over a cardiac cycle W_f was approximately 1.7 times higher in the endocardium and midwall regions than that in the epicardium, which has the smallest myocardial work (**Fig. 2i**). The larger value of W_f in the endocardial and mid-wall regions is the result of a higher myofiber stress and strain in these regions compared to that in the epicardium (**Fig. 2j**). The myocardial demand and supply balance across the heart wall under normal condition is represented by the ratio of myocardial work and coronary flow. In the parameter study, myocardial work-perfusion mismatch ratio increases with an increase in LV's contractility, preload, wall thickness or cavity volume, with the ratio increasing more towards the endocardium.

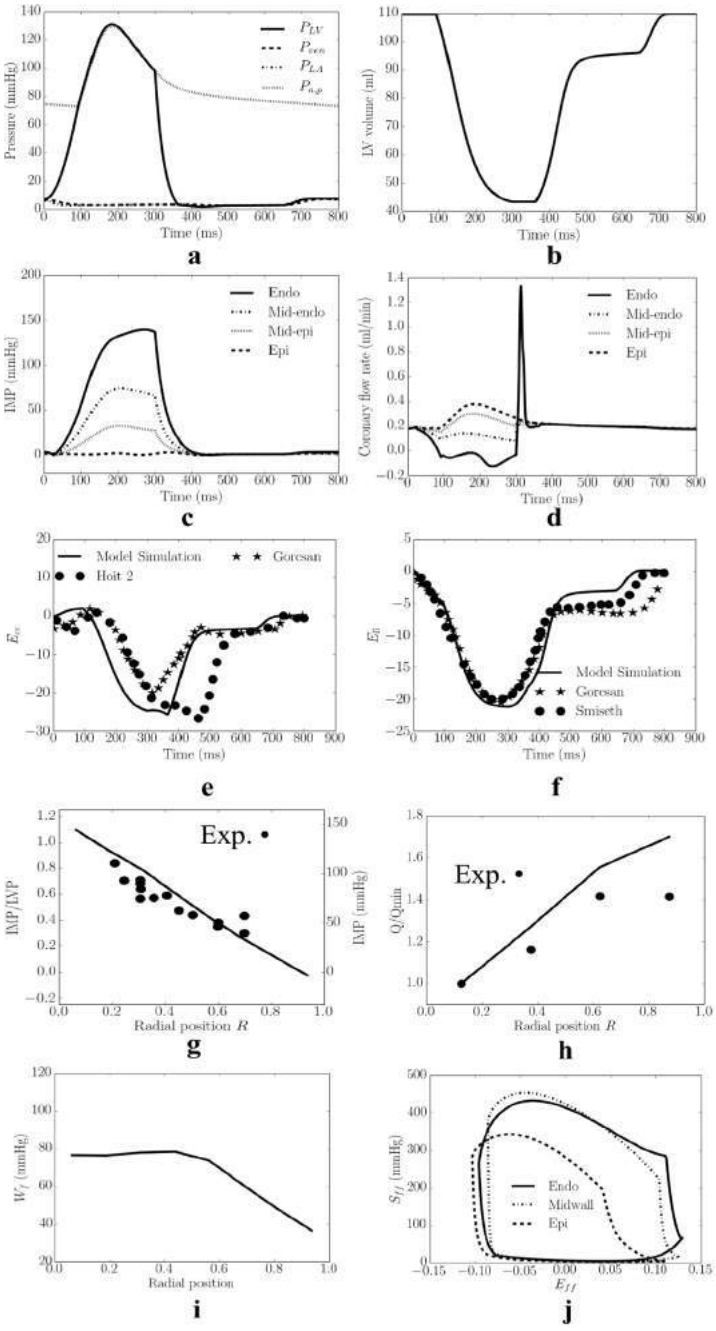

Figure 2a. Pressures; **b.** LV volume; **c.** IMP; **d.** Coronary flow rate; **e.** E_{cc}; **f.** E_{ll} ; E_{cc} and E_{ll} are plotted together with measurements from 3D echocardiography (dots and stars), and were in agreement with clinical measurements . Transmural distribution of **g.** IMP that normalized against LV pressure, is comparable to experimental measurements [6]; **h.** Total coronary flow that is normalized by flow at endocardium, is comparable to the measurements in a canine model under maximal coronary vasodilation [8]; **i.** Work done W_f; **j.** Average $S_{ff} - E_{ff}$ loop at the endocardium, mid-wall and epicardium. • denotes experimental measurements. The radial position R is 0 in the endocardium and 1 in the epicardium.

DISCUSSION

Based on the proposed computational framework, the specific key findings are: **(1)** The model predicted circumferential and longitudinal strains, transmural distribution of IMP and coronary flow under normal condition are able to match the experimental data measured from human and a large animal under resting condition [6]–[8]. **(2)** Transmural distribution of IMP across the LV wall can explain the transmural distribution of passive coronary flow (varying monotonically from endocardium to epicardium) measured experimentally. **(3)** In the parameter study, the model is able to predict the mismatch between myocardial demand and supply, which suggests that endocardium is more vulnerable to ischemia

INTRODUCTION

Sport-related concussion results from single or repetitive biomechanical impacts leading to high-rate head rotational accelerations. Incidence of concussion is higher in contact sports than non-contact sports [1]. This is likely attributable to the increased exposure to head impacts that contact sport athletes sustain during routine participation in practices and games. This provides a higher number of opportunities for high magnitude concussive impacts or the possibility of accumulating changes from repetitive head impacts that contribute to decreased concussion tolerance. Head impact exposure (HIE) refers to the accumulation of head impacts and is often quantified as the number and severity of head impacts on a daily, weekly, or season-long basis. Research involving high school and college football athletes indicated that HIE may play a role in incident concussion. For example, the number of head impacts sustained by individual athletes on the concussion date was higher than on other days [2]. Other studies identified more head impacts prior to concussion in injured athletes than matched controls [3]. However, while those studies focused on concussion occurrence, the effect of HIE on concussion severity remains unclear. HIE can be influenced by factors such as the position of an athlete and if the athlete is participating in a game or practice. Positions such as offensive and defensive linemen have been shown to experience more RHI than others [4]. Other studies found that, during competitions, more RHI are logged than in practices [5]. This study focused on the possible correlation of HIE and concussive impact biomechanics, with the severity of acute clinical outcomes. As HIE and concussive acceleration magnitude increases for an athlete, it was hypothesized that concussive symptom severity would increase.

METHODS

During the 2016-2019 NCAA football competition seasons, a total of 39 concussions were sustained by 37 different athletes enrolled in the Head Impact Measurement Core of the NCAA-DoD Grand Alliance Concussion Assessment, Research and Education (CARE) Consortium Advanced Research Core. All athletes were instrumented with the Head Impact Telemetry (HIT) System (Riddell SRS, Riddell, Rosemont, IL), a helmet-mounted accelerometer array for monitoring impact-associated head accelerations, and completed baseline clinical assessments, including the Sport Concussion Assessment Tool 3 (SCAT3) symptom list, which were then repeated at set timepoints after a diagnosed concussion. The SCAT3 symptom severity score is a standardized tool for assessing post-concussion symptom severity in injured athletes. Twenty-two symptoms are scored with a value from zero (none) to six (severe), giving a maximum symptom severity score of 132. SCAT3 symptom severity scores at the twenty-four-hour post-injury time point were analyzed. The concussions were separated into two groups: lower and higher symptom severity. Based on an empirical assessment of the symptom severity scores, two clusters of data were established: 2-31 and 42-87. There were no symptom severity scores between 31 and 42. HIE and concussive impact accelerations were compared between the two symptom severity groups. HIE was evaluated as the number of recorded head impacts (RHI) over the day and week leading up to injury. Concussive impact accelerations were the peak magnitudes of linear and rotational acceleration from the suspected concussive event. The concussive impact was identified using the following steps. If the player was immediately removed from competition, the concussive impact was identified as the highest magnitude impact in the last few seconds of participation. If the player had delayed concussion report, the suspected concussive impact was

identified through post injury interviews and analysis. If available, the identified head impact was compared to video footage of the event.

RESULTS

Results from 39 concussions in 37 athletes showed that the higher symptom group experienced more HIE (median = 17 RHI, 95% CI [10.8, 20.6]) on the day of injury than their lower symptom counterparts (median = 11 RHI, 95% CI [8.2,13.5]) with no significant difference (p = .109). The higher symptom athletes displayed a larger range of HIE on their day of injury compared to the lower symptom athletes (Fig. 1).

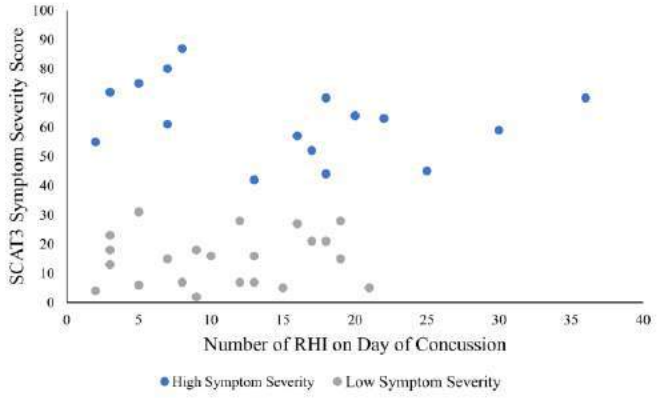

Figure 1. Plot of SCAT3 symptom severity scores versus the number of RHI on day of concussion

Athletes in the higher symptom group did not experience more HIE on the day of injury before the suspected concussive event ($median_{high}$ = 9 RHI, 95% CI [5.2, 12.7], $median_{low}$ = 5 RHI, 95% CI [3.5, 9.0], p = 0.33). For the 31 athletes that also had RHI on the day of injury after their suspected concussive events, the higher and lower symptom groups experienced similar HIE ($median_{high}$= 5 RHI, 95% CI [3.2, 9.9], $median_{low}$ = 5 RHI, 95% CI [3.2, 6.7], p = 0.89). The total number of RHI in the six calendar days prior to injury plus the day of injury ($median_{high}$ = 38 RHI, 95% CI [32.6, 60.8], $median_{low}$ = 40.5 RHI, 95% CI [29.3, 59.9], p = 0.79), and the average ($median_{high}$= 12.9, 95% CI [10.3, 16.5], $median_{low}$ = 11.3, 95% CI [7, 16], p = 0.22) and median ($median_{high}$= 7.5, 95% CI [5.6, 15.7], $median_{low}$ = 11.3, 95% CI [8.6, 16.5], p = 0.2) rates of RHI per session showed no significant difference between the higher and lower symptom groups. Athletes in the higher symptom severity group experienced a longer median symptom resolution time (SRT), $median_{high}$= 9 days (95% CI [7.4, 19.25]) and $median_{low}$ = 6 days (95% CI [5.4, 8.4]), and a longer median time to return to play (RTP), $median_{high}$= 14 days (95% CI [8, 48.6]) and $median_{low}$ = 12 days (95% CI [10.8, 19.2]). There was no apparent correlation between HIE on day of injury and SRT (r=0.168), nor was there a correlation between HIE on day of injury and RTP (r=-0.15). Magnitudes of the concussive linear and rotational accelerations did not show significant variance between the higher and lower symptom groups. Skill players (QB, WR, TE, RB, DB)s, who accounted for 49% of the total population, made up 59% of the concussed players in the lower group, while only accounting for 35% of concussed players in the higher symptom severity group. Skill players, on average, experienced less RHI on the day of injury than other position groups. Competition versus practice environments made no apparent effect in concussion symptom severity; 29% of the concussions in the higher group and 27% of concussions in the lower group occurred during a competition, with the rest of the concussions occurring during a practice. Players concussed during a competition experienced similar HIE (Median = 17 RHI, 95% CI [10.6, 19.2]) to those concussed during practice (Median = 11 RHI, 95% CI [8.9, 15.5]).

DISCUSSION

Head impact exposure was hypothesized to have an influence in the severity of concussion symptoms. The findings of this analysis did not reflect the hypothesized trend. Despite the higher symptom severity group displaying higher median HIE on the day of injury, there was no significant difference between the two populations. Past work found that players who experienced a concussion had more RHI on the day of injury compared to the other practices and competitions where no injury was sustained [2]. Those findings can help guide future work, as the difference in HIE between sessions in which a concussion occurred and sessions in which the athlete left healthy might give insight into the causes of a higher symptom severity score. The lack of significant difference in concussive acceleration magnitudes between the higher and lower groups supports past findings showing their insignificant role in symptom resolution time and time to return to play [6]. This analysis showed a possible correlation between position group and severity of concussion symptoms an athlete may experience. RHI each position group experiences may be the explanation for this trend as skill players are expected to experience less RHI throughout a season based on their roles within a football team [4]. The environment in which a concussion occurred, competition versus practice, showed to have no effect on the symptom severity. This is a surprising trend as athletes concussed during a game had higher median HIE in this analysis, a finding consistent with past studies [5]. As was previously mentioned, the more RHI a player experiences on their day of injury, the higher their respective symptom severity score is expected to be. However, Rowson et al. suggested that individual tolerance plays a large factor in the onset and severity of a concussion [7]. An athlete can have unremarkable HIE and suspected concussive acceleration magnitudes compared to the entire population. However, for the specific athlete the magnitudes they experienced were severe compared to past exposures. Individual tolerance was not explored in this analysis but could possibly explain why the environment does not have an effect, despite more RHI on competition days. More work must be done to quantify the long-term head impact exposure a player experiences throughout a season, and its subsequent role in concussion severity.

INTRODUCTION

Baseball pitching is an action that generates high magnitudes of rotation and torque at the elbow[1]. The repeated application of high magnitude loads can degrade the mechanical strength of the ligaments at the elbow over time and eventually lead to failure by fatigue.

Failure by fatigue has been documented as one of the primary failure mechanisms of ligaments[2]. One such ligament of the elbow is the anterior bundle of the ulnar collateral ligament (AMCL), which has been shown to be the primary support structure of the valgus motion commonly executed during a baseball pitch[3]. Because the AMCL is in a class of tissue commonly susceptible to fatigue failure and is the primary supporter for high-level loading experienced in baseball pitching, its study is needed.

Fatigue failure is a phenomenon that has been studied for a variety of ligaments and tendons in both animal and human specimens. In studies involving cyclic repetition of the Achilles tendon, it was shown how the stiffness of the tissue progressively degrades[4]. In a study involving repetitive cycling of the ACL in simulated jumping motions, it was shown that the ligament can fail at progressively lower loads for larger number of repetitions[5]. However, these fatigue results are often presented for ranges of loading that may fall out of the observational interests of additional studies.

Critical to defining the fatigue characteristics of a material are the fatigue life and fatigue damage evolution behavior. The fatigue life defines how many repetitions under a given load will fail a particular material and the damage evolution defines how this failure is approached. This study seeks to identify both of these nonlinear characteristics for the AMCL in a non-dimensional formulation for the enhanced applicability to a general baseball pitching scenario, based on the maximum valgus pitching-induced stress/stretch of the AMCL.

METHODS

Twenty-two paired cadaveric elbow specimens were used for testing. All specimens were prepared with the removal of all soft tissue surrounding the UCL, leaving only the distal humerus, proximal ulna and UCL. The transverse and posterior bundles of the UCL complex were then transected, leaving the AMCL as the only connecting tissue between the two bones. The ulna and humerus were set into PVC holsters and secured with polyester resin and steel screws. Black optical markers were placed along the length of the AMCL in three distinct columns of equal spacing for the purpose of camera-assisted measurement of deformation.

Two stages of testing were used to understand the fatigue behavior of the AMCL. The first stage was the elastic elongation and failure testing. The second stage was the fatigue failure testing.

In the elastic testing stage, eleven specimens were secured within a materials testing (MTS) machine using a custom fixture that allows for flexion at angles of 0°–120°. The specimens were elongated to prescribed displacements and MATLAB was used to record measurements of force and displacement. Two cameras were used to record the motion. The specimens were then tested to failure at 90°.

In the fatigue testing, eleven contralateral specimens were secured within a custom fatigue testing device. The device allowed the torque-controlled cycling of the specimens in valgus rotation, with the humerus stationary and the ulna/radius in rotation. The magnitude of the torque applied to each specimen M_f (Equation 1), was a proportion, C, of the product of the respective elongation failure load F_f and the capitellum-to-ligament length L_{cap}, measured with calipers.

$$M_f = F_f L_{cap} C \quad (1)$$

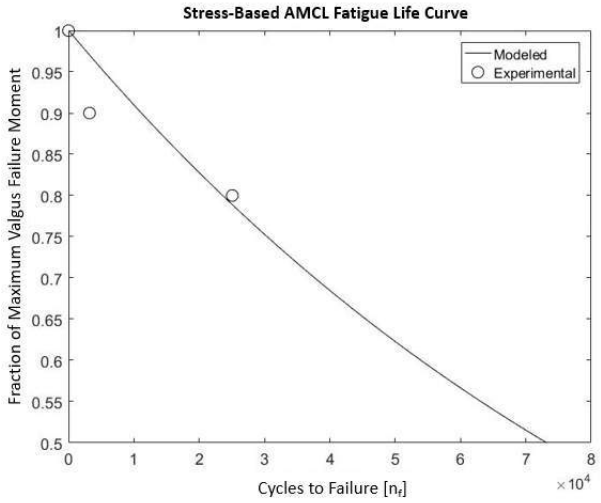

Figure 1: Stress-Based Non-Dimensional AMCL Fatigue Life Curve

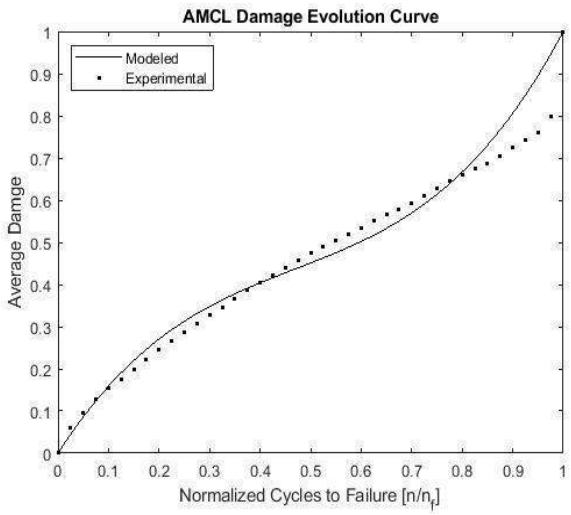

Figure 2: Non-Dimensional Nonlinear AMCL Damage Evolution Curve

Five and six specimens, with magnitudes of C = 0.9 and C = 0.8, were cycled at repeated intervals of 500 valgus cycles until failure was achieved. 500 cycles were chosen to provide enough time for recordings. Saline was manually applied at regular intervals. MATLAB recordings of angular position, torque and cycle number were logged.

RESULTS

For the elongation tests, the average tensile failure load of the AMCL was 595.25 N ± 201.93 N. Using Equation (1), this produced an average value for the theoretical one cycle valgus failure moment of 25.3 Nm ± 8.77 Nm.

For the valgus fatigue experiment, the specimens tested with C = 0.9 and C = 0.8 had an average cycles to failure magnitude of 3211 ± 4721.33 cycles and 25063 ± 30487.58 cycles, respectively.

Two non-dimensional fatigue life curves were generated using the results from the fatigue life test. These were a stress-based curve (Figure 1), where the ordinate gives the respective fraction of the theoretical valgus failure moment M_f. A stretch-based curve was also formulated, where the ordinate is given by the fraction of the experimentally measured average valgus failure stretch. Both data sets were fit with an exponential decay model (Equation 2), where β, γ, and r are constants and n_f is the cycles to failure estimate.

$$S(n) = \beta e^{-\frac{\gamma}{r}n_f} \tag{2}$$

The nonlinear damage evolution curve (Figure 2) was formulated by fitting a cubic model (Equation 3) for the data set representing the average amount of damage D, taken as the relative increase in the maximum angular position, per ratio of current cycles completed n, to total cycle failure life n_f. In Equation (3), A, B, C and E were undetermined constants determined through nonlinear MATLAB regression.

$$D\left(\frac{n}{n_f}\right) = \begin{cases} 0 & \frac{n}{n_f} = 0 \\ A\left(\frac{n}{n_f}\right)^3 + B\left(\frac{n}{n_f}\right)^2 + C\left(\frac{n}{n_f}\right) + E & 0 < \frac{n}{n_f} < 1 \\ 1 & \frac{n}{n_f} = 1 \end{cases} \tag{3}$$

DISCUSSION

The expected trend of increasing cycle life with decreasing valgus torque magnitude was reflected in the results. The high degree of variation in the results can be explained by the complex nature of biological materials, where specimens displayed differing mechanical properties, such as the tensile failure load; and differing geometric qualities, such as the width and thickness.

As expected, the damage accretion curve was nonlinear. As the AMCL is the primary resistor to valgus motion, this curve represents the gradual decrease in the ability of the AMCL to resist the opening of the elbow joint when performing a valgus motion. In the constitutive modeling of the damage behavior of materials[6], this curve describes how the damage variable D, evolves and softens the elastic stress response of the AMCL $\boldsymbol{\sigma_e}$, throughout cycling (Equation 4).

$$\boldsymbol{\sigma} = (1 - D)\boldsymbol{\sigma_e} \tag{4}$$

The non-dimensional formulation of both curves was critical to circumvent the variable characteristics of pitcher-specific pitching properties, such as the magnitude of torque at the elbow. For the same pitch type, different pitchers can generate different torque magnitudes at the elbow and have different resulting fatigue life properties. For any multiple of pitcher-specific torque magnitude, a fatigue life estimate can be made, which then scales the abscissa of the damage evolution curve, providing an estimate of damage for any number of pitches performed.

These estimates of fatigue life and incurred damage, in conjunction with further experimental and computational study, can contribute to the efforts of predicting and mitigating the onset of AMCL fatigue failure in the baseball pitching athlete.

IN AIRWAY EPITHELIAL CELLS, UNJAMMING TRANSITION INVOLVES BASAL CELL ELONGATION AND STRESS FIBER ACCUMULATION

Thien-Khoi N. Phung (1), Jennifer A. Mitchel (1), Michael J. O'Sullivan (1), Jin-Ah Park (1)

INTRODUCTION

The airway epithelium is the first line of defense for external insults such as environmental pollutants or viral infections. Exposure of the airway to these insults causes epithelial injury disrupting the critical barrier integrity that is required to maintain lung homeostasis. After injury, restoration of the disrupted epithelium is initiated by wound healing which requires epithelial cell migration. Migration is traditionally thought to require the epithelial-to-mesenchymal transition (EMT) or partial EMT (pEMT). However, recent work in our lab has revealed a potential alternative mechanism for cell migration, the unjamming transition (UJT) [1]. Unlike in pEMT, during UJT, epithelial markers, cell-cell junctions, and barrier integrity remain intact, while cells become elongated, align into cooperative packs, and migrate collectively [1,2]. UJT has been implicated in various physiological and pathological processes, including airway branching morphogenesis [3,4,13]. However, the role and regulation of UJT in airway epithelial repair and wound healing remain unknown.

Our data indicate that UJT in airway epithelial cells is induced by pathological stimuli linked to lung disease including SO_2 exposure, viral infection, radiation, and mechanical stress. Human bronchial epithelial (HBE) cells grown in air-liquid interface (ALI) culture recapitulate well-differentiated, pseudostratified airway epithelium. Our studies using this system have identified a hallmark of UJT— that cells located at the apical surface elongate and align into cooperative packs [2,4]. However, changes to undifferentiated progenitor (basal) cells located at the basal side have not been studied. Uncovering the role of basal cells may lead to insight into the regulation of UJT. To identify a causal relationship between basal cells and the UJT, we analyzed static images of the mechanically stressed HBE cells— specifically changes to basal cell morphology and the stress fibers within them.

METHODS

Cell Culture

Primary HBE cells isolated from donors with no known lung disease were cultured in transwells first in submerged condition for 4-6 days followed by 14-17 days in ALI in a defined, serum-free media [5]. The cells formed a well-differentiated, pseudostratified epithelium recapitulating the cell architecture and populations of intact human airway. Further details of cell culture are provided in [2].

To induce UJT, cells were exposed to mechanical stress in the form of an apical-to-basal pressure differential of 30 cm H_2O for 3 hours [1]. At 24, 48, and 72 hours after mechanical stress-induced UJT, cells were fixed and stained for F-actin. Two treatment and two control wells were used for each time point. In this study, we examine the cells at a time course across 72 hours because apical cell hallmarks of UJT have been shown to continue evolving over the course of 72 hours [2].

Image Analysis

Five randomly selected fields of view per well were imaged using Zen Blue 2.0 software on a Zeiss Axio Observer Z1 using an apotome module. Across the z-stack from apical to basal-substrate plane, maximum intensity projections were generated at different heights to visualize the apical cell boundaries, basal cell boundaries, and stress fibers (Fig. 1). Cell boundaries were segmented using marker-controlled watershed segmentation in MATLAB. Cell density was quantified as the number of cells per the total cell area. Cell aspect ratio was quantified as the long axis length divided by the short axis from a best fit ellipse to the cell boundary. Stress fibers were segmented using a combination of a tracing algorithm developed by [6] and a fiber reconstruction algorithm developed by [7]. Metrics were quantified and averaged over each field of view. A one-way ANOVA with Bonferroni post hoc test was performed for each metric.

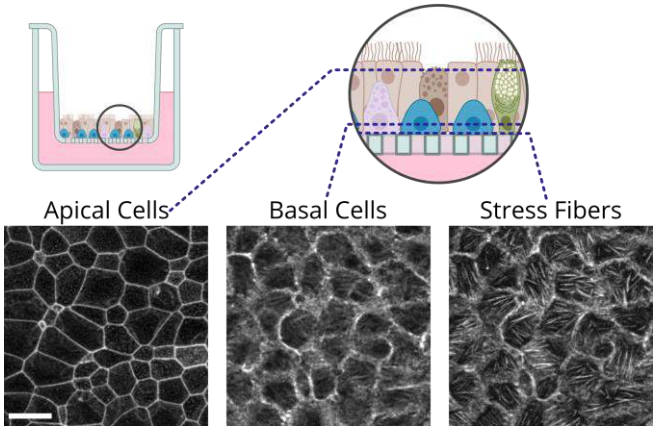

Figure 1: F-actin-stained apical cells, basal cells, and stress fibers were imaged from well-differentiated, pseudostratified human bronchial epithelial cells grown in air-liquid interface culture. Scale bar is 20 µm.

RESULTS

After mechanical stress-induced UJT, apical cells elongated and aligned into cooperative packs similar to our previously published results [2]. The basal cell boundaries were imaged at about 15 µm below the imaging plane of the apical cell boundaries. The basal cell areas increased significantly leading to a decrease in cell density in the field of view (Fig. 2A). The basal cells also significantly elongated as measured by an increase in aspect ratio (Fig. 2B). At the cell-substrate interface about 2 µm below the imaging plane of the basal cells, stress fibers were imaged. Segmented stress fiber lengths significantly increased (Fig. 2C). Total segmented stress fiber length also increased with UJT indicating the accumulation of stress fibers. The increase in basal cell aspect ratio was correlated to stress fiber elongation, $R^2 = 0.81$ (Fig. 2D).

DISCUSSION

In well-differentiated, pseudostratified airway epithelium, apical cell shape changes are a measurable, static hallmarks of UJT [1,2,4]. For the first time, we looked at changes to the basal cells in this layered epithelial system. Basal cells are vital progenitor cells in the human airway epithelium giving rise to and replenishing the specialized differentiated populations including ciliated, goblet, and tuft cells [8-10]. Changes to basal cells have been implicated in pathogenesis of respiratory diseases [11]. From our *in vitro* culture system, mechanical stress-induced UJT decreased the basal cell density and elongated the cell shapes (Fig. 2A and 2B). These data suggest the role of basal cell shape in the UJT.

In monolayer cell culture, cell traction forces have been shown to be regulated by remodeling of stress fibers [12]. Specifically, stress fibers accumulated and aligned in the cells when the monolayer is unjammed. However, the biophysical forces driving migration of the cells in pseudostratified epithelia are not well understood. To determine potential role of stress fibers for UJT in well-differentiated, pseudostratified airway epithelium in ALI culture, we induced UJT and measured accumulation and elongation of stress fibers up to 72 hours after mechanical stress (Fig. 2C). The stress fiber elongation was highly correlated with elongation of the basal cells (Fig. 2D). While it is currently not feasible to measure traction forces in ALI culture, the presence of stress fiber remodeling strongly suggests that basal cells may play a biophysical role in the collective cell migration and apical cell changes observed in the UJT of pseudostratified epithelia. Additionally, basal cells may be an important regulator of the unjamming response to pathological stimuli.

In this study, we presented novel findings demonstrating a positive correlation between basal cell shape elongation and their stress fiber formation in well-differentiated airway epithelium during UJT. Although our results were limited to *in vitro* ALI culture, our data suggest further investigation of the biophysical role of basal cells in regulating collective cell migration seen during epithelial unjamming.

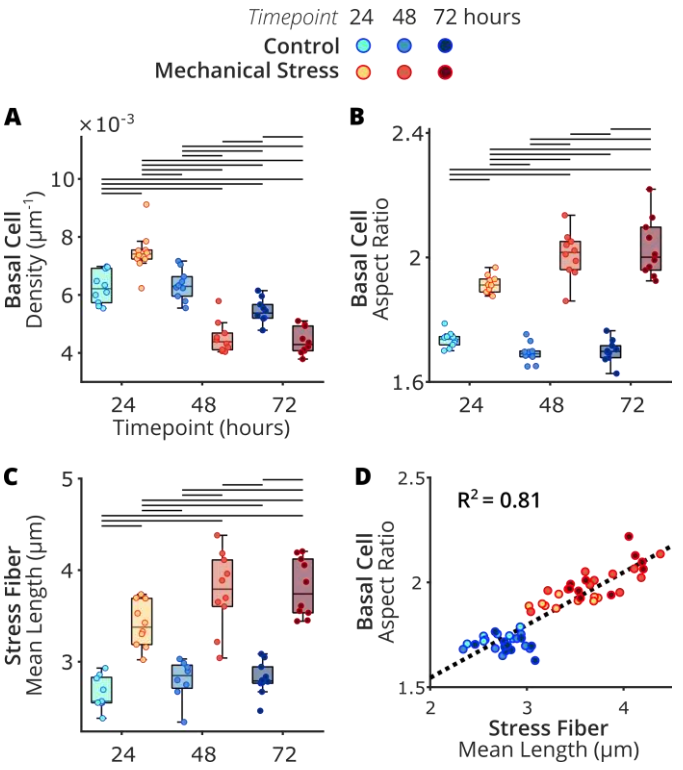

Figure 2: After mechanical stress, (A) basal cell density decreased, (B) cell shapes elongated, and (C) stress fibers elongated. One-way ANOVA with multiple comparisons with significance $p<0.05$. (D) Basal cell elongation was correlated with stress fiber lengthening.

INTRODUCTION

Low back pain may be caused by loading innervated fibrous soft tissues such as the facet capsular ligament (FCL)[1]. Specifically, when axons in these collagenous tissues are stretched past a strain threshold the axon will increase expression of nociceptive signaling molecules[2]. However, the relationship between tissue scale loading, collagen network properties, and expression of signaling molecules remains only partially defined.

Recent in vitro experiments have identified how tissue scale loading affects axonal expression of nociceptive signaling molecules[2,3]. Specifically, co-culture experiments with fibroblasts and dorsal root ganglia in stretched collagen gels have shown that axons increase their expression of substance P when accompanied by low concentrations of fibroblasts relative to fibroblast-free cultures. In contrast, high fibroblast concentrations induce little to no increase in axonal expression of substance P compared to fibroblast-free cultures. Although the specific mechanisms responsible for these differences in expression are unknown, fibroblast forces near axons may cause collagen network heterogeneity[4] thus increasing or decreasing axonal strain.

Since axonal strain is difficult to measure experimentally, a discrete fiber network model has been previously created to determine relationships between collagen fiber density and orientation and axonal strain fields[5]. Therefore, our goal was to determine how collagen network heterogeneity surrounding axons can change the axon strain fields using a discrete fiber network model.

METHODS

To represent the various types of collagen networks that could surround an axon, 3 distinct types of Delaunay networks were created: homogeneous networks, heterogeneous networks with a dense center, and heterogeneous networks with a sparse center. The fiber orientation in all networks was isotropic. Homogeneous networks were created with 9 different global collagen volume fractions that ranged from 0.002 to 0.02. The lowest collagen volume fraction was chosen to match the initial collagen concentration found in a 2mg/ml collagen gel[3], while higher collagen volume fractions are expected to occur due to collagen contraction by fibroblasts[4]. Heterogeneous dense center networks (Fig 1A) were created with a dense region (0.02 collagen volume fraction) in the center of the network and a sparse region (0.002 collagen volume fraction) on the periphery. Heterogeneous sparse center networks (Fig 1A) were created with a sparse region (0.002 collagen volume fraction) in the center of the network and a dense region (0.007 collagen volume fraction) on the periphery. To determine if changing the volume of center region in heterogeneous networks affects axons strain, the radius of the center region was set to one of 4 values (3, 5, 10, or 18µm). All collagen fibers in the networks were modeled as nonlinear elastic fibers with the following force displacement relationship.

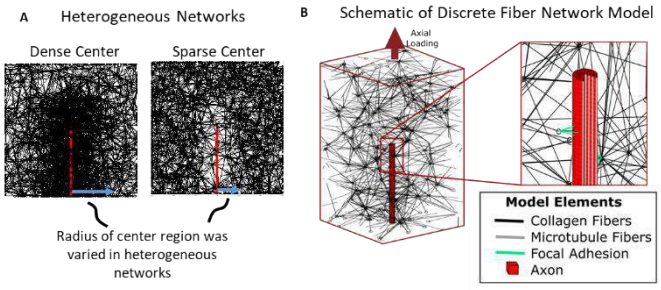

Figure 1: A) Heterogeneous networks showing two distinct network densities. B) Schematic showing the axon embedded in a collagen network.

$$F = \frac{AS}{B\left[\exp\left(\frac{B(\lambda^2-1)}{2}\right)-1\right]},$$

where A, S, and B are set to 43.3MPa, 7854nm^2, and 2.5 respectively. These values were chosen to match previous modeling efforts[5].

Once these networks were created an axon modeled as a composite material was embedded and attached to the center of the network (Fig 1B)[5]. Focal adhesion fibers were used to reduce the effects of point loads on the axon. The axon consisted of microtubules embedded in a linear elastic background modulus. The microtubules were linear elastic with a modulus set to 9.42N/m, which causes the tensile modulus of the axon to match experimental data. The axon background modulus was set to be at much less than the microtubule fibers at 0.433MPa.

Once created, all networks were stretched to 20% axial strain, a strain similar to experiments stretching DRGs embedded in collagen networks[3]. To understand how forces are transmitted through these networks to the axons, we plotted the distribution of forces in each network fiber. To quantify the heterogeneous axon strain fields produced by the networks, the average max principal strain and top 1% of max principal strains were reported.

RESULTS

The distribution of force in each network is dependent on the network architecture. Homogeneous networks have relatively uniform distribution of forces in the fibers throughout the network (Fig 2A). Dense center networks have large forces in fibers on the periphery of the network (Fig 2B). Sparse center networks have large fiber forces in the center of the network (Fig 2C). These fiber force differences may cause changes in the observed axon strain fields.

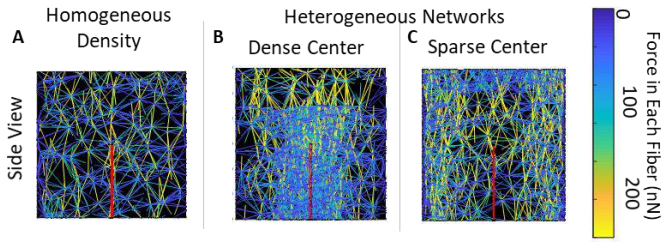

Figure 2: Distribution of fiber forces in networks changes based on the network heterogeneity. A) Homogeneous networks with uniform fiber forces, B) Dense center networks with large fiber forces in periphery, C) Sparse center networks with large fiber forces near the axon.

All axons experience highly heterogeneous strain fields (Fig 3A), but the average and maximum strain in each of these fields is dependent on the network surrounding the axon. Homogeneous networks cause both the average axon strain and the top 1% of axon strains to increase with increasing collagen volume fraction (Fig 3B 3C).

If dense center and sparse center networks are directly compared to homogeneous networks based on their global collagen volume fraction (Figure 3B, 3C), we note differences in the observed strain fields. Specifically, dense center networks increase the average axon strain when compared to homogeneous networks with similar collagen volume fractions. Sparse center networks cause a decrease in the average axon strain when compared to homogeneous networks with similar collagen volume fractions. These differences may be caused by changes in the force transmission from the network boundary to the axon.

DISCUSSION

Heterogeneous networks cause distinct axon strain fields compared to homogeneous networks with similar collagen volume fractions.

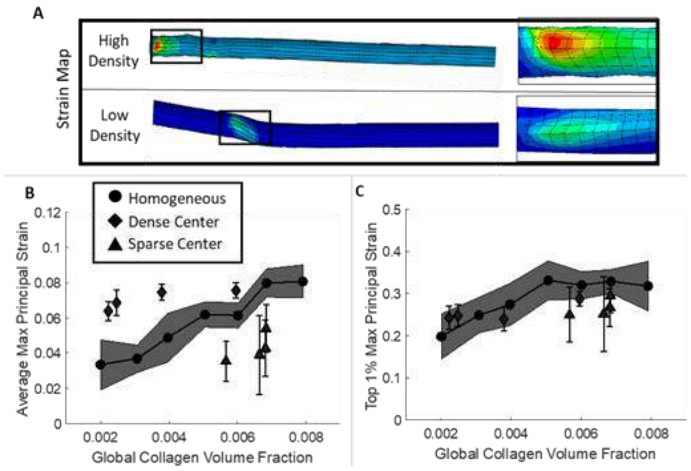

Figure 3: Axon strain fields vary based on network heterogeneity and collagen volume fraction. A) Representative strain maps showing heterogeneous axon max principal strain fields. B) Increasing the collagen volume fraction of homogeneous networks increases the average axon strain. Sparse center networks decrease axon strain, while dense center networks increase axons strains. C) Increasing the collagen volume fraction of networks increases the top 1% of max principal strains. Dense center and sparse center networks cause little to no change in the top 1% of max principal strains on the network.

Interestingly, fiber forces are highest in the sparse regions, but sparse center networks reduced axon strain compared to homogeneous networks. This difference in axon strain may be caused by the large number of fibers transferring force in the peripheral region of the sparse center network and small number of fibers attached to the axon. Since axons tend to grow most readily into regions of low collagen concentration[6], we believe this sparse center network behavior may explain why co-culture experiments with high fibroblast concentrations and DRGs do not cause increased expression of nociceptive signals.

In contrast, the dense center networks show high fiber forces on the network periphery and a large number of fibers attached to each axon. This large number of fibers attached to the axon probably caused the increase in axon strain compared to homogeneous networks with similar collagen volume fractions. Since, aging and disease could cause abnormal collagen formation[7,8], these dense center networks could potentially explain increases in ligament nociceptive signaling.

Local heterogeneity surrounding an axon in a facet capsular ligament can modulate its expression of signaling molecules. Thus, determining the relationships between collagen network heterogeneity, macroscopic loading, and axonal signaling could be critical to understanding pain mechanisms in the spine.

ON THE RELATION BETWEEN 3D AORTIC VALVE INTERSTITIAL CELL SHAPE AND CONTRACTILE BEHAVIOR

INTRODUCTION

Aortic valve interstitial cells (AVICs) reside within all layers of the aortic valve and regulate turnover of the extracellular matrix (ECM). AVICs become activated in times of growth and disease and take on a myofibroblast phenotype and increase their contractility. Cell shape is known to correlate closely with stress-fiber geometry and function and is thus a critical feature of cell biophysical state. Previous studies on the AVIC shape-contraction relation have heavily relied on 2D platforms. In this study, we assess the correlation between 3D AVIC shape and contractile behavior using PEG hydrogel matrices to better understand the relation between AVIC shape and local deformation. This body of work lays the foundation for investigations into intrinsic differences in AVIC contractile function in normal and diseased scenarios.

METHODS

3D Traction Force Microscopy. Porcine AVICs and fluorescent microbeads were seeded within peptide-modified, poly (ethylene glycol) hydrogels for 72 hours before experimentation. The sample was incubated in Tyrode's Salt (normal – N state) for 40 minutes before obtaining an image stack of a single AVIC and surrounding fluorescent microbeads. Afterwards, Cytochalasin D (inactive – I state) was added to elicit cell relaxation through actin depolymerization and a second z-stack of the same FOV was obtained. The image sets were analyzed with our software, FM-track [1], which outputted AVIC surface meshes and bead displacements from the I state to the N state.

AVIC principal curvature distribution. Local curvature on the AVIC surface was computed using a surface patch method [3,4]. We generated a local u-v-n tangent-plane coordinate system on the AVIC surface mesh described by a biquadric surface with the following form:

$$S(u,v) = au^2 + 2buv + cv^2, \tag{1}$$

where u and v are local coordinates on the tangent-plane coordinate system, S is the out of plane coordinate, and a, b, and c are fit constants that are determined for each surface node. The principal curvature k_1 is then computed at each node with the following equation [2,3]:

$$k_1 = a + c + \sqrt{(a-c)^2 + 4b^2}. \tag{2}$$

Representation of AVIC shape using Spherical Harmonics. To more completely describe the global AVIC shape, we utilized spherical harmonics (SPHARM) [5,6]. AVIC surface meshes were subjected to spherical parameterization to create a continuous, uniform mapping from the AVIC surface to the surface of a unit sphere. This results in a one-to-one mapping of the cartesian points on the mesh to a pair of spherical coordinates $[x(\theta,\phi), y(\theta,\phi), z(\theta,\phi)]$. Next, the parameterized surface is fit to a set of SPHARM basis functions Y_l^m where l and m denotes the degree and order of the SPHARM, respectively. The SPHARM expansion takes the form:

$$\mathbf{v}(\theta,\phi) = \sum_{l=0}^{L_{max}} \sum_{m=-l}^{l} \mathbf{c}_l^m Y_l^m(\theta,\phi), \tag{3}$$

where $\mathbf{v}(\theta,\phi) = (x(\theta,\phi), y(\theta,\phi), z(\theta,\phi))^T$, $\mathbf{c}_l^m = (\mathbf{c}_{xl}^m, \mathbf{c}_{yl}^m, \mathbf{c}_{zl}^m)^T$ are the SPHARM coefficients, and $Y_l^m(\theta,\phi)$ is the SPHARM function:

$$Y_l^m(\theta,\phi) = \sqrt{\frac{2l+1(l-m)!}{4\pi(l+m)!}} P_l^m(\cos\theta) e^{im\phi}, \tag{4}$$

where $P_l^m(\cos\theta)$ are the Legendre polynomials represented with the following differential equation:

$$P_l^m(x) = \frac{(-1)^m}{(2^l l!)}(1+x^2)^{\frac{m}{2}}\frac{d^{l+m}}{dx^{l+m}}(x^2-1)^l. \quad (5)$$

A SPHARM software from Shen et al. [6] was adapted to compute the SPHARM coefficients at a user specified maximum degree L_{max}. Power spectra were produced by plotting l,m vs $\mathbf{c}_{\mathrm{xl}}^{\mathrm{m}}, \mathbf{c}_{\mathrm{yl}}^{\mathrm{m}}, \mathbf{c}_{\mathrm{zl}}^{\mathrm{m}}$.

RESULTS

AVIC contractile patterns. AVIC contraction produced a complex displacement field with displacements going away and toward the cell surface (Fig. 1). A prominent axis of contraction was observed along with expansion in the orthogonal direction. The majority of appreciable displacements occurred within 60 um of the AVIC surface.

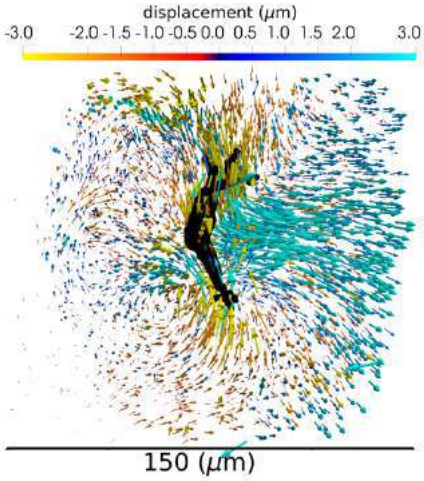

Figure 1: Displacement field produced by AVIC contraction. Displacements that are directed toward the cell surface are represented with warmer colors and negative magnitudes whereas those directed away from the cell surface are represented with cooler colors and positive magnitudes. Vector length is scaled by 3x the magnitude. The AVIC geometry is colored in black.

Curvature-displacement correlation. A statistically significant correlation was observed between curvature and displacement at the nodes of the AVIC surface mesh ($\boldsymbol{\rho} = 0.115$, p-value < 0.001) (Fig. 2). Regions of higher curvature produced larger displacement magnitudes and were localized at the AVIC protrusions.

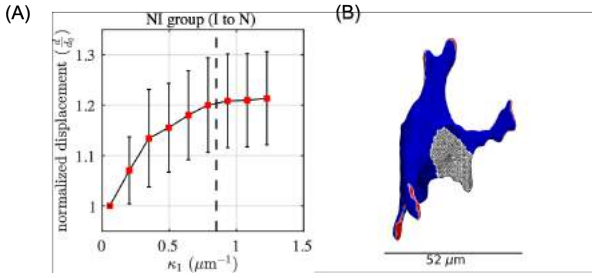

Figure 2: (A) A positive correlation was observed in contractile regions on the cell surface between k_1 and normalized surface displacement. The dashed vertical line denotes the cut-off between regions of high and low curvature. (B) Regions of high (red) and low (blue) curvature mapped onto a representative AVIC. Wireframe denotes expansive regions which were ignored.

SPHARM accurately captures AVIC shape. The AVIC shapes were accurately reproduced with SPHARM (Fig. 3). Increasing the degree of the SPHARM fit resulted in a better representation of the AVIC geometry. A final degree of 47 was used for the fit.

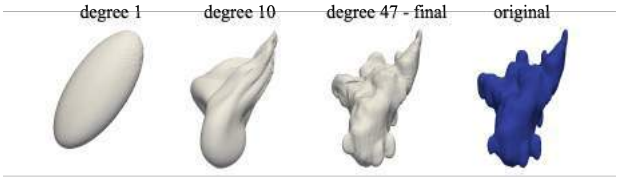

Figure 3: SPHARM representation of an AVIC.

AVIC shape becomes more spherical due to contraction. Power spectra analysis showed that greater SPHARM coefficients were required to fit the I shape than the N shape (Fig. 4). The negative residual of the power spectra, obtained by subtracting the power spectra of the N state by the I state, suggests that AVIC shape is more spherical in the N state than it is in the I state.

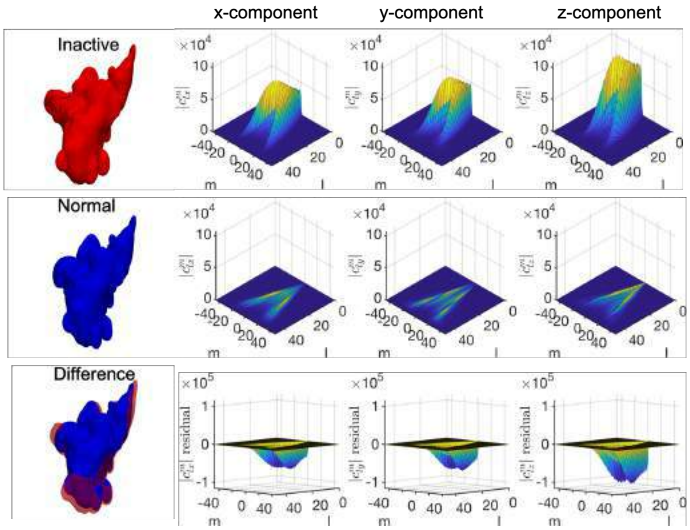

Figure 4: SPHARM fits for each state, the corresponding power spectra, and the difference between the spectra.

DISCUSSION

Here, we present a novel approach to study the 3D relation between AVIC shape and local deformation in high detail. Our findings concur with previous 2D in vitro studies and suggest that in 3D, AVIC shape and function are intimately connected. We successfully reconstructed AVIC shapes with SPHARM at high accuracy and confirm that AVIC shapes become more spherical in a contractile state, which suggests that contraction is mediated by high concentration of stress-fibers localized at cellular protrusions. Future work will involve modeling the sub-cellular components of the AVIC to achieve a mechanistic understanding of the AVIC shape-function relation.

UNDERSTANDING THE EFFECTS OF LONG-DURATION SPACEFLIGHT ON FRACTURE RISK IN THE HUMAN FEMUR USING FINITE ELEMENT MODELING

INTRODUCTION

Long-duration spaceflight has been shown to have significant, lasting effects on the bone strength of astronauts, and to contribute to age-related complications later in life [1]. The microgravity environment of space causes a decrease in daily mechanical loading, which affects bone remodeling, a biological process carried out by cells to maintain bone mass. This results in a decrease in bone density and an increase in damage, which contribute to bone fragility, creating a risk for fracture [2] [3]. However, there is little information pertaining to the timeline of bone loss and subsequent fracture risk. This study used finite element analysis to model the human femur, one of the bones most adversely affected by spaceflight, to simulate the environments of Earth preflight, a six-month mission on the International Space Station (ISS), and one year on Earth postflight. Inferences were then made on when changes in bone density and damage pose the greatest risk for femoral fracture for astronauts after long-duration spaceflight.

METHODS

To model the effects of spaceflight on the adult femur, a three-dimensional bone, finite element model was integrated with a bone remodeling algorithm [4] through a UMAT user subroutine in Abaqus 2020. In the algorithm, remodeling was activated by the level of loading and by repetitive loads that result in damage. It allowed for remodeling to occur simultaneously for both of these cases in different, local areas of the bone. The algorithm calculated changes at each step in time for nine state variables, one of which was the mechanical stimulus (Φ), the forcing function assumed responsible for driving the remodeling process. Measured in cycles per day, it is a function of principal strain (s) and loading cycles (R_L) of n different daily activities, and is calculated using Equation (1).

$$\Phi = \sum_{i=1}^{n} s_i^q R_{Li} \quad (1)$$

The value of the exponent – assumed to be 4, and the initial mechanical stimulus estimated from the strain needed to maintain bone mass, were based on a study by Whalen and Carter [5]. Remodeling by osteoclasts and osteoblasts was activated by stimulus values less than that of the initial value, and by damage in the bone matrix in the form of microcracks assumed to accumulate based on the stimulus in Equation (1). Changes in porosity were determined from the areas of bone resorbed and formed by osteoclasts and osteoblasts, respectively. Elastic modulus was assumed to have a nonlinear relationship with porosity (p), and was calculated using Equation (2) for cortical bone and (3) for trabecular bone.

$$E = 23440(1-p)^{5.74}\ (\text{MPa}) \quad (2)$$

$$E = 14927(1-p)^{1.33}\ (\text{MPa}) \quad (3)$$

In addition to the implementation of the bone remodeling algorithm, loads were applied to the model that mimic joint and muscle forces experienced during daily activities having the greatest influence on strain and remodeling. Muscles included in the model were the gluteus medius, gluteus minimus, vastus lateralis, vastus medialis, psoas, adductor brevis, and adductor longus.

The femur model was used to conduct a quasi-static analysis of an adult femur before, during, and after traveling to the ISS for six months. This was accomplished by modifying the model and algorithm to produce simulations of Earth preflight, six months of spaceflight, and one year of Earth postflight. Data were then collected from each simulation for changes over time in density (determined as a function of porosity) and damage (determined as crack length per area bone) in the two types of bone in the femoral neck: cortical and trabecular.

The first step of this analysis was to bring the model of the femur to a baseline, preflight form, resembling that of a skeletally mature adult. This was accomplished with an Earth baseline simulation. The joint and muscle forces were applied 5,000 cycles per day (per leg), corresponding to a total of 10,000 steps per day – a fair approximation for the active lifestyle of an astronaut [6]. Data were collected for damage and density in both cortical and trabecular bone. The simulation was validated by comparing its results to a previous strain gage study of cadaveric femurs [7] and to density measurements of cortical and trabecular bone samples in the femoral neck [8] [9].

After the Earth baseline was established and validated, time in space was simulated. The joint force and muscle loads used for the Earth baseline model were scaled to 90% of their original values to simulate the microgravity environment of the ISS and the resistance used during exercise in space [10] [11]. A daily step count of 10,000 was used again to account for the extensive amount of exercise performed by crewmembers in space [6] [12]. The simulation was run for six months to match the average mission to the ISS [13], and data were collected upon completion (i.e. immediately upon return from space). The model was validated by comparing its results for the monthly percent change in density to an experiment measuring cortical and trabecular bone loss of the femur in crewmembers making four to six-month flights on the ISS [1].

Upon completion of the six-month space simulation, a final, postflight simulation was produced to again simulate life on Earth. The joint force and muscle loads were scaled back to their original values and the daily step count was maintained at 10,000. This simulation was run for twelve months to provide the most accurate results and extensive understanding of the femur's behavior upon returning to Earth from space and data were then collected for damage and density of cortical and trabecular bone in the femoral neck once every thirty days.

RESULTS

Cortical and trabecular bone in the femoral neck experienced significant changes in damage as a result of spaceflight (Figure 1). In both types of bone, damage increased significantly after six months on the ISS, and continued to increase after returning to Earth without reaching an equilibrium. After spaceflight, damage in cortical bone had increased by nearly 10%. Upon returning to earth, it continued to increase over the twelve months, achieving an overall increase of 60% from the Earth baseline. The damage in trabecular bone increased by nearly 42% after spaceflight and continued to increase on Earth. By the end of the twelve-month, postflight simulation, damage had increased by 190% from the Earth baseline.

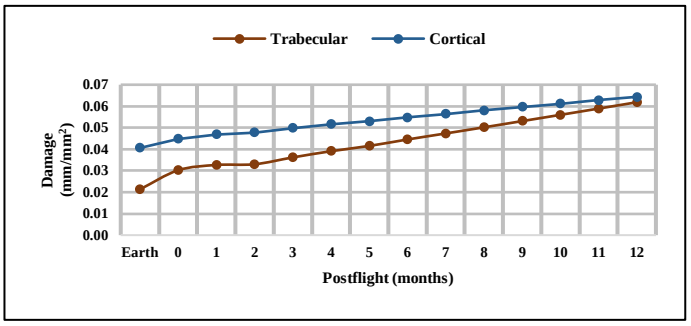

Figure 1: Damage v. Time for Cortical and Trabecular Bone. (0 denotes time immediately after spaceflight)

Changes in density were also seen in both cortical and trabecular bone (Figure 2). The density of cortical bone decreased by approximately 2% after six months of spaceflight. Shortly after returning to Earth, density increased and then leveled off at a value less than that of preflight, remaining at an equilibrium for the remainder of the simulation. Between the Earth baseline and end of the postflight simulation, cortical density experienced an overall decrease of 0.6%. The density of trabecular bone also decreased after spaceflight, but by a much larger magnitude – approximately 18%. At the start of the postflight simulation, density increased slightly, and then leveled off and remained at equilibrium, resulting in an overall decrease of 4%.

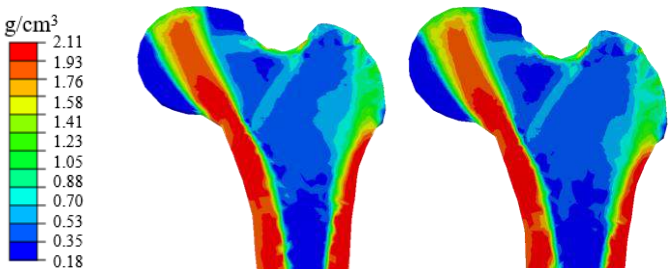

Figure 2: Density After Earth Baseline (left) and Spaceflight (right) Simulations

DISCUSSION

The predicted increases in damage during spaceflight occurred because the microgravity of space resulted in reduced loading altering bone remodeling levels as seen by sharp variations in cellular activity. Although less damage was formed due to the reduced loading, even less damage was removed due to the overall lower activity of the cells, increasing the rate of damage accretion. This suggests that fracture risk is likely to be extremely prominent in the femoral neck and is supported by the fact that naturally, the neck is most prone to fracture due to old age and other medical complications [14]. While the amount of damage required for fracture is unknown, it is reasonable to deduce that higher magnitudes of damage will decrease bone resistance and diminish bone toughness, making it more susceptible to fracture [15].

The higher density loss predicted in trabecular bone was due to the higher accretion rate of damage as well as its naturally high porosity. Because bone loss is the primary effect of long duration spaceflight, it is expected that density will decrease [16]. The greatest decline in density was seen immediately after spaceflight. After returning to Earth, density increased and then oscillated for five months before leveling off. The final predicted value was less than that of preflight, suggesting that bone mass may not recover after one year on Earth. Similar to damage, it is unclear as to what extent density contributes to fracture risk. It is certain however, that loss of bone mass is a risk factor for fracture [17]. Even if a decrease in density is not severe enough to cause fracture immediately upon return from flight, it may lead to health complications later in life [18]. Bone loss may accelerate the onset of osteoporosis, increase its severity, and add to fall risk due to bone fragility in astronauts, long after their time in space.

ACKNOWLEDGEMENTS

The authors are grateful to Christopher Deuel for development of the finite element mesh used in the analysis of this study.

INTRODUCTION

Coronary collateral arteries are clinically important for shunting blood around a stenosis to protect patients against ischemia [1]. While collaterals have been shown to be beneficial, the number, size and configuration of collaterals that are sufficient to restore flow downstream of a stenosis remains unclear. The functional impact of collaterals is difficult to measure in humans because, generally, collaterals are too small to accurately quantify non-invasively.

Studies of collateral formation have succeeded in promoting the growth of collateral arteries in animal models through various cellular and molecular mechanisms with varying degrees of functional impact [2]. While high resolution data of the vessel geometry typically can be obtained, direct measurements of the collateral function in vivo is usually not possible due to limited accessibility and resolution. In addition, it is not possible to precisely control for the number and size of collaterals, which limits the comparisons that can be made. We also see that adult animal models recover poorly after MI compared to postnatal models, but the role of collateral arteries is not well understood.

Consequently, we use an adult and postnatal mouse model with a combination of computational fluid dynamics (CFD) and light-sheet imaging to systematically quantify flow through virtual collateral arteries in response to varying stenosis levels. These models allow us to control the number, size, and location of the collaterals keeping all other modeling parameters fixed. We hypothesize that collateral arteries in the postnatal heart are more effective in recovering flow downstream of a stenosis than in the adult.

METHODS

Adult and postnatal mice hearts were cleared and stained for smooth muscle actin using the iDISCO method [3]. Then, the hearts were placed in a quartz cuvette filled with DBE and imaged using the Lavision Ultramicroscope II light-sheet microscope.

In SimVascular, we constructed 3D subject-specific models of the mouse coronary vasculature from the light sheet imaging data using the standard workflow [4]. Briefly, we created path lines for each vessel (340 vessels) ignoring vessels that were less than 10um in diameter. Circles were used to approximate the cross-section due to some areas of the vasculature appearing collapsed or deformed. Finally, segmentations were lofted and unioned to create a geometric model that was discretized using a commercial meshing module, MeshSim (Simmetrix, Troy, NY).

Virtual collaterals were strategically added to native coronary vasculature to minimize the initial pressure difference of the two points the collateral was connecting. We did this to ensure that collaterals had virtually zero flow when there was no stenosis. We tested 5 levels of stenosis, and 4 different collateral configurations (0, 3, 6, 12) at 3 different diameters (Figure 1). For the postnatal heart, we tested 12 collaterals at 20um.

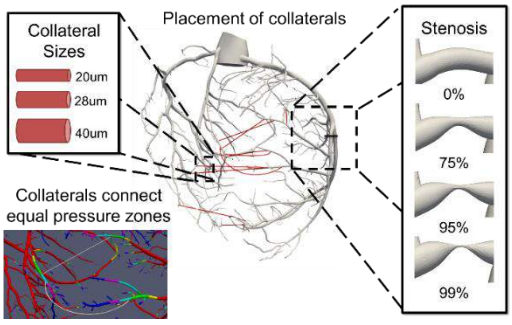

Figure 1: Placement of collaterals.

Pressure and aortic velocity were determined from literature [5]. Using the aortic velocity from literature and the aortic area for each mouse used, a subject-specific pulsatile aortic inflow was applied.

To determine the approximate volume of myocardium each outlet of the coronary model was responsible for perfusing we used a model of the myocardial tissue as the total volume to be perfused and the outlet coordinates as the seed points for the sub-volumes. We used a Voronoi diagram algorithm to assign sub-volumes of the myocardial tissue to each outlet of the coronary model. Resistance boundary conditions were assigned based on these perfusion volumes.

We ran pulsatile flow, rigid wall simulations using a stabilized finite element method in the open-source SimVascular finite element solver svSolver to obtain hemodynamic values, such as pressure, flow, and shear stress [4]. Paraview (Kitware, inc) was used for visualization of the results. Simulations were performed for each collateral configuration and stenosis level (25 cases in total), keeping all other flow parameters and boundary conditions fixed.

RESULTS

To determine the functional recovery for each collateral configuration, we report the total flow at outlets downstream of the stenosis (blue area, Figure 2). Flow downstream of the stenosis decreases non-linearly with stenosis severity with no collaterals (first row, Figure 2). The collateral configurations are ordered from top to bottom based on their functional flow recovery, with 3 collaterals of 40 microns in diameter being the best at stenosis levels greater than 90%.

Flow Recovery Downstream of Stenosis (mm^3/s)

Number of Collaterals	Diameter (um)	Stenosis				
		0%	75%	90%	95%	99%
0	N/A	1.315	1.117	0.685	0.271	0.004
6	20	1.411	1.129	0.731	0.279	0.011
12	20	1.410	1.199	0.719	0.283	0.016
6	28	1.318	1.215	0.699	0.299	0.039
3	40	1.320	1.134	0.711	0.330	0.058

Figure 2: Flow recovery downstream of stenosis. Green, yellow, red colors indicate high, medium, low flow respectively.

To relate the flow recovery with a functional physiological outcome, we estimated the volume of tissue that would be considered "ischemic" based on various thresholds of flow recovery. We found that, for a 99% stenosis, there is a significant reduction in ischemic volume when a very low threshold of 10% flow recovery is used, with 3 collaterals at 40 microns being the optimal configuration (Figure 3).

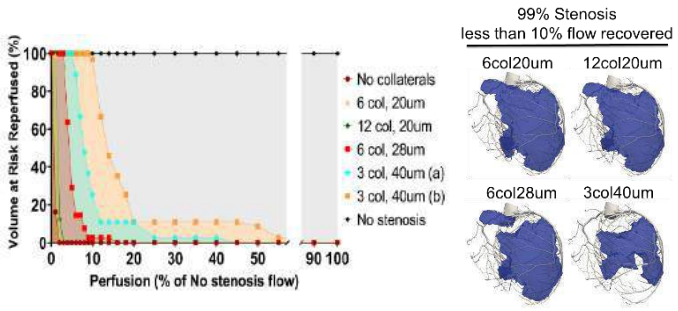

Figure 3: Ischemic volume at 99% stenosis.

In postnatal hearts, collaterals are more numerous and larger than the ones found in the adult after a LCA ligation (Figure 4A). To compare the functional significance of the collateral arteries, we tested the flow recovery downstream of a 99% stenosis in the postnatal coronary vasculature and compared it with the adult. We found that 12 collaterals at 20um in diameter outperformed adult collaterals not only with the same collateral configuration, but even the best possible flow recovery from the adult as indicated by high pressure recovery downstream of the stenosis (Figure 4B).

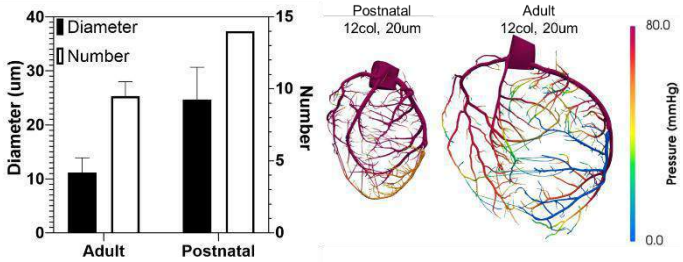

Figure 4: Comparison of adult and postnatal (A) collaterals and (B) pressure recovery downstream of stenosis

DISCUSSION

In this study, we relate the form and function of collaterals by using CFD analysis. This is, to our knowledge, the first time CFD has been used to quantify hemodynamic forces in the adult and postnatal mouse coronary vasculature.

Although we found that fewer, larger collaterals are the most beneficial, that configuration still only recovered about 4% of the unobstructed flow downstream. While we hypothesized that this was due to poor distal pressures, this could also be related to underestimation of pressures at the distal end of the collateral vessels. Future work could address this by accounting for changes in viscosity due to the Fåhræus–Lindqvist effect, which would be relevant at the size of vessels we model [6], however we expect that this would not affect the claims made here regarding the relative functional differences between different collateral configurations and adult vs. postnatal.

In our brief pilot study comparing one collateral configuration between postnatal and adult, we found that collaterals were much more effective, which may be due to higher distal pressures in the postnatal vasculature. We plan to extend the comparisons between adult and postnatal collaterals to include more configurations and detailed volume perfusion differences.

In summary, we present a novel application of CFD analysis to quantify collateral flow in the adult and postnatal mouse coronary vasculature. The findings here suggest the possible benefit of promoting the growth of fewer, larger arteries over many, smaller ones as well as the natural benefit collaterals have in restoring pressure downstream of a stenosis in postnatal hearts. Simulations may also provide mechanical stimulus data to inform mechanobiology studies.

INTRODUCTION

Traumatic brain injury (TBI) is one of the leading causes of morbidity and death worldwide[1]. Mild TBI results in long-term disruption in the brain and a high risk of developing pathology[2]. In sports, repetitive, often sub-concussive, head injuries increase the risk of chronic traumatic encephalopathy (CTE)[3]. During TBI, an increase in intracellular Ca^{2+} is universally seen in all brain cells[4,5]. Using primary astrocytes model, we have previously reported that shear pulse stimulus induces instant Ca^{2+} influx and the response is accumulative[6]. Cells become more responsive when subjected to multiple low magnitude challenges[6]. We speculate that the external forces during TBI may cause lasting changes in the mechanical environments of Ca^{2+} permeable ion channels, resulting in a long-term dysregulation of Ca^{2+} uptakes.

In this study, we have applied repeated shear stimuli, 6, 12, and 24 hrs apart, and measured Ca^{2+} responses in primary rat astrocytes. We show that the Ca^{2+} response to the second stimulus was significantly higher than the first one. The history of shear stimulus affects the later Ca^{2+} response. This cell memory to early mechanical event lasted ~ 18 hrs. Cells responded to repeated shear stimuli with subsequently increases in Ca^{2+} peak values. These results show that the mechanical forces during TBI may cause long-term deformation in cells, and the cell may store TBI information via a mechanical pathway.

METHODS

The entire experiment was conducted using a high-speed microfluidic chip driving by a fast pressure servo[6]. The pressure servo can generate transient shear stress in the microfluidic channel, mimicking shear forces during TBI. The chip consists of a PDMS flow channel of 1 mm x 100 μm x 15 mm on a cover glass. Holes were punched into both ends of channel as fluid inlet and outlet. The shear stress profile in the channel was pre-calibrated using fluorescent beads[6]. Human Fibronectin was applied into microfluidic channel for 30 mins, which was later washed with culture media.

Adult rat astrocytes (ScienCell) were cultured in petri dish to 95% confluency, then trypsinized. The cell suspension solution was centrifuged and perfused into the microchannel. The cells were cultured on the chip in an incubator for 3-4 days until the confluency reached ~95%, in between every 24 hrs media was changed. Prior to experiments, channel was washed with isotonic solution (1 mM $CaCl_2$, 150 mM NaCl, 5 mM KCl, 2 mM $MgCl_2$ and 10 mM HEPES). The saline solution was used for shear experiments. For repeated shear stimuli, after 1st shear, cells were gently washed with culture media and kept in incubator for designed period. A fresh dye was loaded, and the shear experiment repeated following the same protocol.

Intracellular Ca^{2+} was measured using Fluo-4-AM dye (5 μM, Invitrogen). Fluorescence images were acquired using a Zeiss inverted microscope (Axiovert 200M) and a CCD camera. The normalized change in Ca^{2+} intensity was calculated using:

$$\frac{\Delta F}{F_0} = \frac{F - F_0}{F_0} \quad (1)$$

Where F and F_0 are the intensities at time t and 0, respectively. Ca^{2+}intensity was averaged over 10 cells from each channel. Minimal 4 experiments were performed for each condition. Statistical analysis used the standard error of the mean (s.e.m.). Statistical significance was analyzed from two sample t-test. $p < 0.001$ was considered significant.

RESULTS

Using our high-speed programmable microfluidic chips, we applied repeated square shear pulse of 23 dyn/cm^2 and 10 ms duration and measured Ca^{2+} responses. A conditioning shear pulse was applied at time zero and repeated at 6 and 24 hrs for testing. Figure 2a shows

typical Ca^{2+} responses to conditioning (0 hr) and testing stimuli (6, 24 hrs). Cells appeared more susceptible to shear pulse after a conditioning stimulus. Ca^{2+} responses from selected cells under each condition was plotted in Fig. 1b-d. It was observed that Ca^{2+} response to second shear 6 hrs apart was ~ 30% more than that of conditioning one at 0 hr (Fig. 1b, c). Repeated shear pulse at 24 hrs further increased the amplitude of Ca^{2+} response (Fig. 1d). The Ca^{2+} responses consistently increased with repetition, suggesting that cells have long term memory of previous mechanical events.

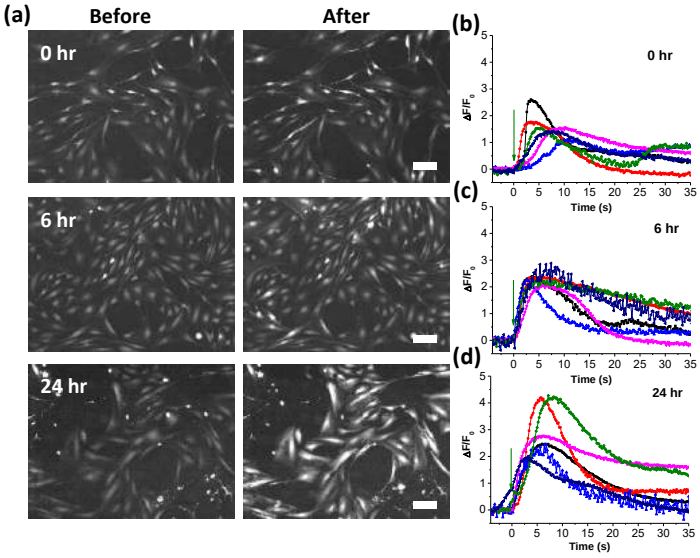

Figure 1. Fluorescence images (a) and time course of Ca^{2+} responses (b-d) to repeated shear pulses at 0, 6, and 24 hrs, showing the responses to repeated stimuli were increased. Each curve was averaged over 10 cells from one experiment. Scale bar = 50 μm.

In controls, cells were not subjected to conditioning stimulus at 0 hr, otherwise was treated the same way (dye loading and imaging), and Ca^{2+} response to testing shear stimuli at 6 and 24 hrs were measured. A comparison between the Ca^{2+} responses with and without conditioning shear stimulus showed that the responses with shear history were consistently higher than the controls (without conditioning shear) (Fig. 2). With conditioning shear, the testing Ca^{2+} intensity at 6 hrs reached to an average of 2.2 (Red curves in figure 3), while without conditioning shear it only reached to 1.55 (Fig. 2a, n = 60). In response to repeated shear at 24 hrs, the response increased to ~3.3 with the conditioning shear, and 2.5 without it (control cells) (Figure. 2c). These results show that cells not only have long term memory of previous mechanical events, but the effect is also accumulative.

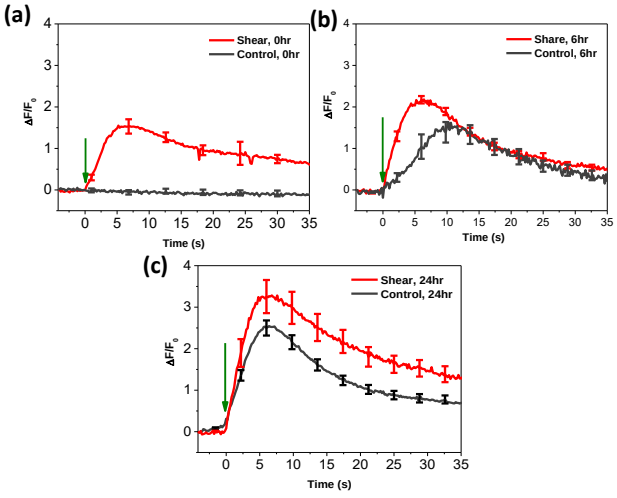

Figure 2. Comparison of Ca^{2+} response with (shear) and without (control) conditioning shear. The conditioning stimulus was applied at 0 hr, test run was conducted at 6 and 24 hrs (n = 60 from 6 runs for each curve). The peak Ca^{2+} value with and without conditioning shear was analyzed using two sample t-test, $p < 10^{-20}$). It shows the response increased significantly with conditioning shear.

To assess the duration of the cell memory, we applied the testing shear stimulus after different time intervals, 6, 12, 18, and 24 hrs. Shear stress of 23 dyn/cm^2 was used for all experiments. We found that longer time interval increased cell sensitivity to the second shear pulse until 18 hrs. For an interval of 6 hrs, the Ca^{2+} intensity in response to second shear pulse was ~50% more than that of first shear pulse. The ratio increased to ~110% for an interval of 18 hrs (Fig. 3a-c). However, the response to shear pulse at 24 hrs showed insignificant difference to the previous one (Fig. 3d). This shows that the limit of memory could be <24 hrs.

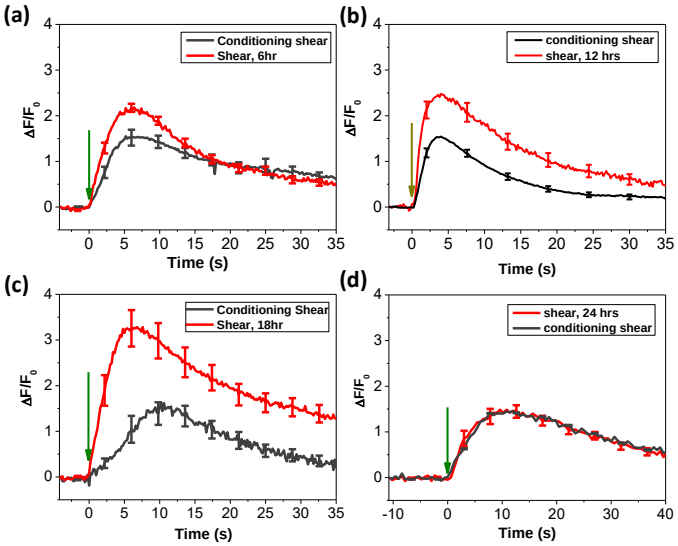

Figure 3. Effect of intervals between stimuli on Ca^{2+} response. The response to conditioning shear at 0 hr (black curves) was compared with testing stimulus at 6 (a), 12 (b), 18 (c), and 24 hrs (d), showing the memory limit is < 24 hrs (n= 50 for each curve).

DISCUSSION

We measured the Ca^{2+} response to repeated shear stress stimuli in astrocytes. We have shown that Ca^{2+} responses to the shear stimulus depend on the stimulus history. The response to subsequent shear stimuli were consistently higher than that to the earlier ones (Fig. 1, 2). The effect of shear stimulus was accumulative. These results show that cells have memory to early mechanical events, and the memory was ~18 hrs (Fig. 3). It is known that TBI causes long-term effects in the brain physiology and pathology. Previous studies have focused primarily on secondary injury that involves biochemical and metabolic dysfunction[7]. Our studies indicate that cells may be able to store TBI information mechanically.

INTRODUCTION

We have developed and implemented a novel machine learning algorithms for accelerating our multiscale modeling on supercomputers [1]. Our multiscale modeling (MSM) is an all-particle based approach that combines Coarse-Grained Molecular Dynamics (CGMD) model to depict the platelet's biophysical properties at the cellular scales [2] and its dynamic interactions coupled with macroscopic flows modeled by a Dissipative Particle Dynamics (DPD) model [3]. Our MSM can be used to describe the platelet activation mechanotransduction process induced by blood flow [2], simulate shear-induced platelet activation with filopodia formation [4, 5], as well as recruitment aggregation of platelets mediated by fibrinogen via the αIIbβ3 receptors [6]. However, the MSM framework, though successfully handling multiphysics problems at diverse spatial scales occurred in multi-components systems, makes the computation task more complex and less efficient on leadership class computers [7]. We thus introduced a novel artificial intelligence (AI)-guided adaptive time stepping (ATS) algorithm that adapts timestep sizes to underlying biophysical dynamics such as combination of our platelet flipping [2, 3] and aggregating [6] models to multi-platelet aggregation at millisecond-long and molecular-accurate resolutions.

In this work, we for the first time present our AI-MSM framework to overcome the major challenges of simulating 3 aggregating platelets with 3-4 aggregated platelets already deposited to the blood vessel walls in the dynamic shear blood flows. The total simulated time duration is approx. 1.2ms. The molecular events including the flow-platelet dynamic interaction, flow-induced mechanotransduction and αIIbβ3-Fg-αIIbβ3 binding and breaking events are all considered in the simulation [4-6]. The timestep sizes are real-time predicted by our trained AI-ATS method [1] without human interventions. During the simulation, we recorded the trajectory of individual platelets and accumulated mapped flow-induced stresses on the platelet membranes for stress analysis.

METHODS

The platelet model has a total of 140,303 particles at which 67,004 for platelet membrane and integrin αIIbβ3 receptors, as well as 32,853 cytoplasm and 40,446 cytoskeleton particles (Fig. 1). The aggregation force field between the receptors of different platelets is modeled as:

$$\boldsymbol{F}_{ij} = D_0\left(e^{-2\alpha(r_{ij}-r_0)} - 2e^{-\alpha(r_{ij}-r_0)}\right)\boldsymbol{e}_{ij} + f^A(t_{ij})\left(1-\frac{r_{ij}}{d_c}\right)\boldsymbol{e}_{ij}$$

where the experimentally-verified parameters are presented in [6].

The spatial CGMD-DPD interface in this MSM is handled by a hybrid force field in [3] where a Lennard-Jones term is used to maintain platelet incompressibility, while a dissipative and random force term to maintain the flow local thermodynamic and exchange momentum to express interactions between the platelet and the flow particles.

The disparity in temporal scales between DPD and CGMD in this MSM is handled by our novel multiple time stepping (MTS) algorithm [8] that utilized varied timestep sizes for different governing functions. Meanwhile, our new AI-guided ATS algorithm [1] is applied on top of this MTS algorithm to enable adaptivity of timestep sizes to underlying dynamics where the AI guides the omission of multiple redundant time steps without scarifying significant accuracy of the dynamics.

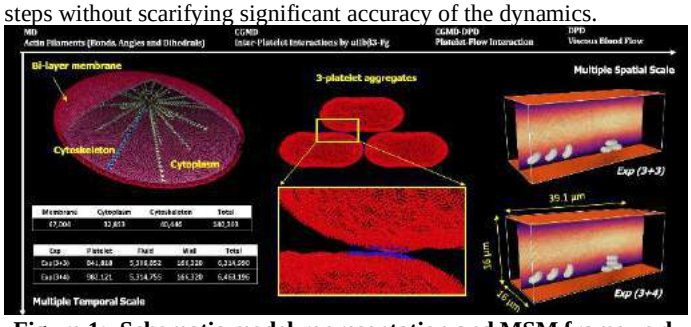

Figure 1: Schematic model representation and MSM framework

RESULTS

Our multiscale model described the biophysical properties of the platelets down to the *nm*-length and *ps*-time scales. Membrane Young's modulus is 31.2 μN/m and shear modulus is 33±9 μN/m. The cytoplasm is modeled by modified Morse potential and its viscosity is 4.1 mPa·s. Actin filament stiffness is 56.3±1.0 pN/nm. [2]

Using this model, we simulated two aggregation numerical experiments: 3 aggregating platelets with 3 and 4 aggregated platelets, as shown in left and right of Fig. 2, named as Exp (3+3) and Exp (3+4) respectively. This simulation studies a microchannel of 39×16×16μm (L×W×H). The pressure-driven Poiseuille flow is modeled with mean velocity of 6 cm/s and flow viscosity of 1.07 dyne/cm^2. During the simulation, our platelet model continuously changes its morphology in response to the dynamic flow stress while flowing and flipping. The aggregated platelets adhered to the blood vessels at the start of simulations. As the flowing platelets approaching, they start to contact the 3-platelet aggregate deposited to the walls. The whole simulated duration is more than 1,250 μs. Fig. 2 shows the velocity magnitude of flowing platelets: initially the flowing platelets flip driven by the flow-induced stresses and there maintains a certain gap between these platelets; after first contacting the aggregated platelets, these flowing platelets are quickly influenced to change their trajectory by climbing up the blood clot in Exp (3+3) and rolling aside in Exp (3+4); after passing the blood clot, these platelets did not firmly aggregate due to the applied strong flow stresses. Clearly, we observed a direct impact of the blood clot size (3 and 4 aggregated platelets) on the dynamics and activities of flowing/aggregating platelets.

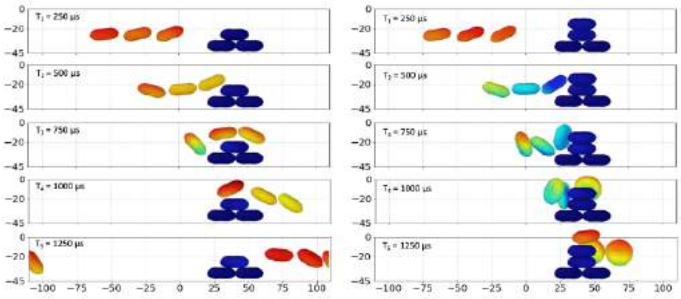

Figure 2: Velocity magnitude distributions on platelet membranes for Exp (3+3) and Exp (3+4) at T = 250, 500, 750, 1000, and 1250 μs

In addition, we studied the accumulated shear stresses on platelet membranes for different cases (Fig 3). We observed that all platelets have larger flow-induced stresses on periphery of their membranes. The flowing platelet has relatively larger flow-induced stress on top/bottom areas than the aggregated platelets as it continues to flip driven by the surrounding flows. The contact region between the aggregated platelets has a relatively smaller flow-induced stresses as this area is hidden from the shear flows. As expected, the bottom platelet (c) has the least flow-induced stresses as it is totally protected by the other two platelets in its front and has no direct contact with the flowing platelets as well. In other words, we can clearly conclude that even under the same flow condition, the relative positions of adhered platelets in a blood clot will lead to a very different accumulated flow-induced stress that may in part respond to different activation states of these adhered platelets [4].

All simulations were conducted on the AiMOS supercomputer using our AI-ATS algorithm on 192 computer nodes, and achieved a speed of 3,077 μs/day using GPUs that are 2.65 times the speed of 1,159 ms/day when using only-CPUs, thus enabling larger-scale, longer simulations.

DISCUSSION

Our approach is the first multiscale numeric method for simulating the platelet flowing, flipping and aggregation under flow that includes bonding and receptors on platelet's membrane. Biophysical properties of a platelet are accurately described down to a nm-length and ps-time scale, and the viscous flow is described at a μm-length and ns-time scale. Platelets are allowed to continuously deform in response to flow stress. In platelet recruitment aggregation, the microscale properties of the receptor-ligand interactions were precisely modeled at molecular scales and correlated well with *in vitro* results, including contact area and detaching force. With this improvement, the aggregation model is able to illustrate the microphenomena that have otherwise been missing.

In addition, our novel AI-ATS method [1] significantly improved the modeling efficiency on leadership-class heterogenous computers and extended our computational capabilities to a billion-scale platelet-fluid system for millisecond-to-second-scale and molecular resolutions.

Ongoing experiments have employed this AI-MSM model to study a second-level aggregation of hundreds of platelets in shear flows for depicting cumulative stress-induced platelet activation (filopodia formation), platelet adhesion to vWF-coated vessels, and activated platelets recruitment aggregation to platelets already adhered to the vessels. Our AI-MSM model can be adopted to other fields, such as drug delivery, by considering the impact of mechanical triggered biochemical events.

INTRODUCTION

The menisci are fibrocartilaginous soft tissues that absorb and distribute 40-70% of loads across the knee joint.[1] Overtime, repetitive physical activity contributes to meniscus degeneration; a retrogressive breakdown of fibrous tissue that affects over half of individuals above 70 years of age.[2] These microstructural changes to the collagen fiber networks increase the risk of multiplanar tears, pain, joint instability, and progression of osteoarthritis.[1] In order to advance prevention and intervention strategies for meniscal degeneration, it is imperative to characterize the wear behavior of whole meniscus to identify loading conditions and activities that cause rapid meniscus wear.

A challenge in characterizing meniscus wear is the lack of an established technology. Pin-on-plate and pendulum systems are common techniques used to measure wear in biological materials[3], however, these methods are limited to small sectioned specimens and are not suitable for whole complex structures. Alternatively, micro-CT and MRI can image whole soft tissue[1], yet these methods are time consuming, costly, and have insufficient resolution to quantify microscale defects[3]. A novel approach to measuring tissue wear is through 3D optical scanning, which creates 3D reconstructions of complex objects. While 3D optical scanning has successfully measured polymer wear in hip implants[4], no study has developed a method to use this technology to measure wear in meniscus, or any soft tissue. The objective of this study was to develop an in vitro method to characterize volumetric wear in whole human meniscus subjected to joint loading.

METHODS

This study was done in two parts. Part I assessed the accuracy of the proposed methodology for measuring wear in meniscus tissue **(Fig 1A)** through a surrogate model. Part II utilized this method to quantify wear in whole human meniscus subjected to physiological loading.

Scanning Procedure. The 3D optical scanner system consisted of a projector, rotary table, and two high-resolution cameras (LMI Technologies) **(Fig 1B)**. 3D renderings were generated for both surrogate model and human meniscus at three different time points: pre-wear, post-wear, and tibia-only. Five sets of eight scans were taken at 45° increments resulting in a full 360° view of the model. All 40 scans were aligned by common geometry and combined via scanning software, FlexScan3D, to generate the 3D renderings. Open-source software, CloudCompare, was used to evaluate volume loss by aligning tibia-menisci to tibia-only rendered models and preforming common geometry subtraction (CGS) **(Fig 1A)**. The defect volume, V_{defect}, was found by aligning the pre- and post-wear menisci and using CGS to isolate the defect **(Fig 1A)**. For the surrogate model, this process was repeated for the varying wear depths, and the percentage error between known volumes and CloudCompare calculated volumes was determined ($100*|V_{defect}-V_{known}|/V_{known}$). An ANOVA test with Tukey post-hoc was performed for the surrogate model to assess error in measuring wear depth. The human meniscus followed the same scanning procedure; however, volume loss due to tribological behavior (in terms of wear and deformation) was recorded.

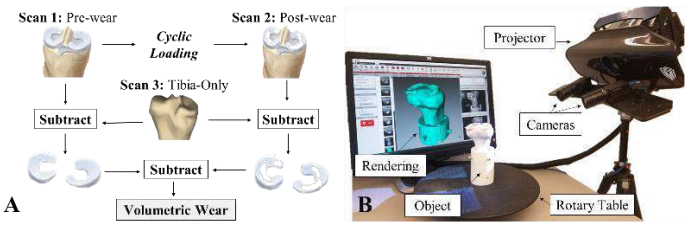

Figure 1. Novel imaging technique to measure tissue wear. A) Flow chart of CGS method, B) 3D scanning setup

Part I: Surrogate. A 3D reconstruction of healthy meniscus (29 yrs, male) was obtained via MR imaging.[5] Both medial and lateral meniscus were 3D printed using polylactic acid material and positioned on a foam replica of a human tibia (Sawbones). Defects in the 3D model were made by applying a wear pattern in meshing software and removing mesh with varying depths of 0.5, 0.025, 0.01, 0.005, and 0 inches to simulate artificially induced wear **(Fig 2A)**. These wear depths corresponded to wear volumes of 412, 206, 79.3, 40.9, and 0 cubic millimeters, respectively. The reference volume, V_{known}, of the 3D defect models was measured using SolidWorks.

Part II: Human. One human cadaveric knee (29 yrs, female) was dissected leaving only menisci and meniscal attachments. The natural reference position of the knee was determined from boney landmarks, mechanical digitizer (Revware Inc), and custom MATLAB code using established Grood-Suntay conventions. Both femur and tibia were potted using Bondo and secured within a custom-made knee fixture **(Fig 3B)** allowing for six degrees of fixed mounting adjustment. Potting alignment was verified through digitizing and kinematic analysis. The potted tibia-meniscus was scanned prior to testing to generate the 'pre-wear' scan **(Fig 1A)**. An Instron E10000 mechanical test system was used to apply combined cyclic axial loading and torsional rotation based on parameters specified by ISO 14243-3 (gait=45%, flexion=10°, axial=2.4 kN, rotation=1.1°). Four loading stages of 250K cycles were run at 2 Hz. Following each stage, the tibia-meniscus was scanned to generate 'post-wear' scans **(Fig 1A)**. After 1 million cycles, the menisci were removed and the 'tibia-only' scan was acquired **(Fig 1A)**.

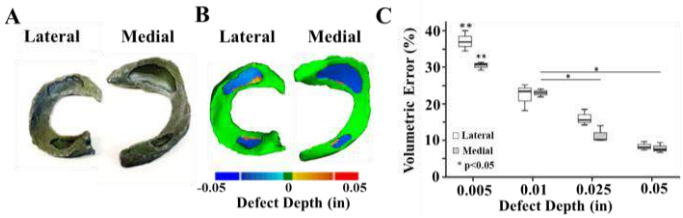

Figure 2. Surrogate: A) real-life, B) color, C) error increases as depth decreases ($p < 0.05$). ** = >all other defect depths ($p < 0.05$)

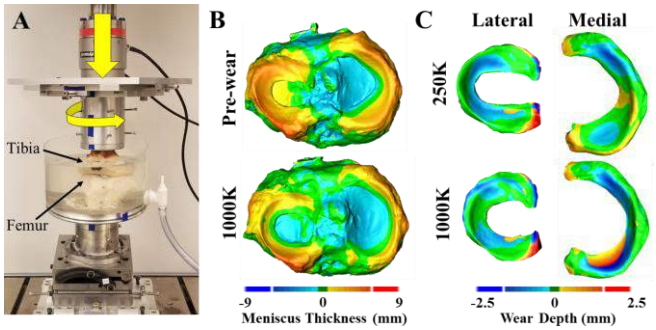

Figure 3. Human: A) Wear testing, Color maps of B) tibia-only to pre-wear and 1000K, and C) pre-wear to 250K and 1000K

RESULTS

Surrogate. Defect patterns were successfully visualized with preservation of detail using the CGS method. The color map shows alignment between two menisci: 0-in control and 0.05-in defect. A tight alignment is indicated by the green regions representing zero difference between the aligned menisci **(Fig 2B)**. The surrogate showed percent error increases as defect depths decrease for both menisci, with errors <7.9% when detecting volumetric changes of 0.4 cm^3 **(Fig 2C)**

Human. Throughout loading, the tibial surface became more prominent **(Fig 3B)** and the inner peripheral regions of the menisci receded **(Fig 3C)**. The CGS method successfully isolated both menisci with overall whole meniscus volume reductions of 52.0% and 31.9% for lateral and medial meniscus, respectively **(Fig 4A)**. Wear volumes increased throughout loading with the lateral meniscus experiencing 25.1% higher wear volume than the medial meniscus **(Fig 4B).**

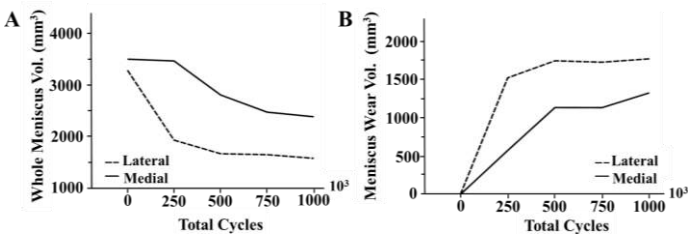

Figure 4. CGS method shows A) whole meniscus volume decreases while B) wear volume increases as the number of cycles increases.

DISCUSSION

For the first time, this study provides a method to characterize in vitro wear in whole human meniscus subjected to physiological loading. Based on our previous work[6], we found that the CGS method we developed has an inherent error of <5% when detecting volumetric changes of 0.4 cm^3 in simple geometry; however, for the complex surrogate analyzed in this study, error increased to <8% **(Fig 2C)**. Using this verified CGS method, we successfully detected and isolated global wear for a human meniscus subjected to joint loading. Wear volumes for both medial and lateral meniscus were shown to increase throughout 1 million cycles of loading. Based on the surrogate analysis, we have confidence that the 42% average measured meniscus volume loss is accurate to within 3%. Additionally, the CGS method yielded average meniscus volumes within +10% of known human meniscus volumes reported from water displacement techniques. This therefore indicates our method can successfully represent whole human meniscus volume.

Colorimetric mapping enabled the detection and visualization of high wear regions in the meniscus structure. A prominent reduction of yellow hue around both menisci from pre- to post-wear **(Fig 3B)** indicates a decrease in meniscus thickness and implies either material loss or hydrostatic deformation. Volume loss mostly occurred in the middle regions of the menisci **(Fig 3C; blue regions)**, matching clinical observations.[7] Additionally, the presence of red regions at 1 million cycles **(Fig 3C)** indicates deviatoric deformation since swelling is unlikely during wear testing. The measured volume loss may therefore be caused by material wear, deformation, or a combination of both.

The CGS method has practical advantages with respect to time, cost, and most importantly, the ability to visualize and quantify meniscus wear and deformation. The method takes 50-125% less time to complete a high-quality 3D model with equipment costs <15 times compared to micro-CT and MRI scanning.[4] Although the absence of synovial lubrication and soft tissue constraints within the joint likely resulted in greater menisci wear than would occur in vivo, the CGS method represents a breakthrough in measuring in vitro volumetric wear under controlled mechanical testing. Therefore, this novel method can provide a fast, accurate, and effective technique to enable researchers to determine meniscal wear rates for specific physiological activities (e.g. running, cutting, stair-climbing) and anatomical variations (e.g. age, BMI, sex) to identify risk factors for whole meniscus degeneration.

INTRODUCTION

Thoracic aortic aneurysms and dissections (TAADs) are severe vascular disorders that can arise due to genetic defects or loss of vessel wall integrity [1]. TAADs are characterized by excessive dilatation of the vessel wall and, in extreme cases, structural failure and rupture of the tissue. These processes inherently depend on the mechanical environment within the vessel and on cellular signaling processes that drive growth and remodeling (G&R) [2]. Vascular smooth muscle cells (VSMCs) are particularly important in vascular G&R given their role in controlling contractility and remodeling of the environment through proliferation and extracellular matrix deposition. In order to study the development and progression of TAADs, we need to understand the interplay between these factors.

In a recent study by Li et al. [3], the authors sought to understand the role of VSMC proliferation on the development and progression of TAADs. To do this, they used a post-natal, conditional, VSMC-specific knock-out (KO) of *Tsc1*, the gene encoding for the mammalian target of rapamycin (mTOR) complex 1 (mTORC1) inhibitor TSC1, and measured the morphological, hemodynamic, and cell signaling changes that occurred. mTOR is responsible for key cellular processes, such as cell growth, protein synthesis, and autophagy [4]. Specifically, mTORC1 is the primary effector of p70 ribosomal S6 kinase (S6K) and eukaryotic initiation factor 4E-binding protein 1 (4EBP1), proteins associated with ribosome synthesis and cell growth. The *Tsc1* KO induced increased activation of mTORC1 in VSMCs and led to higher incidence of TAADs in these KO mice relative to control. Interestingly, the VSMCs in the *Tsc1* mutant mice did not exhibit the characteristics of traditional contractile or synthetic VSMC phenotypes, instead showing decreases in both. The KO mice had significantly lower expression of matrix synthesis transcripts *Eln*, *Fbn1*, and *Col3a1*, as well as decreased elastogenesis, increased susceptibility to elastic fiber damage, and higher expression of matrix metalloproteinase 2 (MMP2). Strikingly, the KO VSMCs expressed high levels of lysosome-related proteins, namely β-catenin, MITF, and LAMP2, and had large numbers of degradative organelles present. These VSMCs notably lacked classic inflammatory cell markers, such as CD45, indicating that they did not undergo dedifferentiation into macrophages. These signaling changes suggested that the VSMCs acquired a novel degradative phenotype in addition to reduced contractile and synthetic capabilities.

The purpose of the current study was to delineate signaling pathways that contribute to the switch of VSMCs from a maintenance phenotype to a degradative phenotype. In order to do so, we constructed a VSMC signaling network model primarily centered on the mTOR pathway and then used it to simulate the *Tsc1* KO and its subsequent phenotypic changes.

METHODS

We built a signaling network model of mTOR signaling in VSMCs by consolidating cell signaling interactions reported in the literature and constructing a system of ordinary differential equations (ODEs) to describe these interactions. The ODEs were based on logic-based Hill-type functions that represent normalized (0-1) activation of each species in the network [5]. For this study, we simulated two conditions: 1) cell signaling in a control VSMC (Baseline) and 2) conditional knock-out of *Tsc1* (KO), in which the maximum activation level of the TSC1/2 species node was set to 0 while keeping all other model parameters constant. For the purpose of tuning the model, we used the steady-state solutions for each model condition to calculate the fold change of species downstream of mTOR (S6K, S6, 4EBP1) and contractile species (AKT, SMMHC, αSMA, SM22). We tuned

model parameters such that these fold changes would fall within one standard deviation of the data reported by Li et al. [4]. We then calculated the fold changes in select synthetic (Col3a1, Elastin, MMP2) and lysosomal species (β-catenin, MITF, LAMP2).

We used our model to describe the phenotypic characteristics in the Baseline and KO conditions. For this purpose, each phenotype (Contractile, Synthetic, and Degradative) is described using a normalized activation, which we calculated as the mean activation of a set of key species. The Contractile phenotype uses SMMHC, αSMA, SM22, and calponin as its primary species. The Synthetic phenotype depends on the levels of Col3a1, Eln, Fbn, and MMP2. The Degradative phenotype is in turn dependent on S6, MMP2, β-catenin, MITF, and LAMP2.

RESULTS

Our VSMC signaling network model consisted of 96 species and 148 reactions. The tuned model used input stress and shear stress values of 0.2404 and Hill-function parameters n = 1.4 and EC50 = 0.52. The weight of cell-surface receptor reactions was set to 0.85 and all downstream reaction weights were set to 1. We tuned the model based on 1) S6K, S6, and 4EBP1 activation at Baseline relative to KO and 2) AKT, SMMHC, αSMA, and SM22 activation at KO relative to Baseline. Our models showed mTOR downstream species relative activations of 0.0334, 0.0128, and 0.0334, respectively, which fall within one standard deviation of the fold changes reported in the experimental data (0.0388 ± 0.0198, 0.0132 ± 0.0040, 0.0498 ± 0.0301, respectively) [Fig. 1a]. The contractile protein species showed relative activations of 0.4294, 0.8005, 0.7617, and 0.7653, respectively, all of which fall within one standard deviation of the reported experimental data relative expression (0.403 ± 0.0324, 0.6912 ± 0.2531, 0.7456 ± 0.0379, 0.7457 ± 0.0599) [Fig. 1b].

Our model was able to capture changes in the synthetic and lysosomal capabilities seen in VSMCs after *Tsc1* disruption. Our model showed reduced levels of synthetic species Col3a1 and Elastin (0.7534 and 0.7986 fold, respectively) in the KO relative to Baseline, while the activation level of MMP2 increased 2.05 fold [Fig. 2a]. In contrast, we saw increased activation levels of β-catenin, MITF, and LAMP2 (1.9596, 4.5341, and 2.5549, respectively) in the KO relative to Baseline, consistent with the increase in lysosomal activity with *Tsc1* disruption [Fig. 2b].

We used our model to describe the phenotypic characteristics in the Baseline and KO conditions based on key species for the Contractile, Synthetic, and Degradative phenotypes. The Baseline condition showed a balance between the Contractile (0.5524) and Synthetic (0.4502) phenotypes and little influence by the Degradative phenotype (0.1419). The KO condition, however, shifted this balance towards a primarily Degradative (0.5308) phenotype, with a decrease in the influence of both the Contractile (0.4202) and Synthetic (0.3096) phenotypes [Fig. 3].

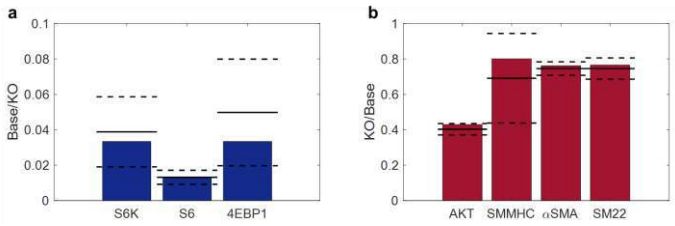

Figure 1: Model relative activation for (a) mTOR downstream species and (b) contractile species fall within 1SD (dashed lines) of the data means (solid lines).

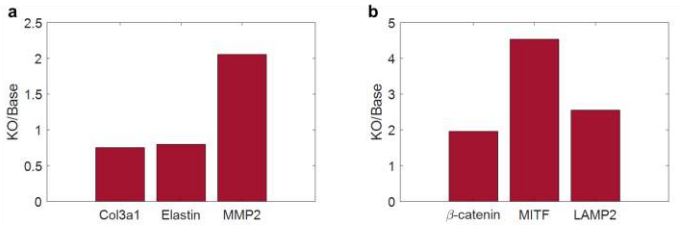

Figure 2: Model relative activations of (a) synthetic and (b) lysosomal species for KO relative to Baseline.

DISCUSSION

One of the key findings by Li et al. [4] was the existence of a degradative phenotype in vascular smooth muscle cells that was previously uncharacterized. This newly-described phenotype challenged the notion that VSMCs operate within a contractile-to-synthetic phenotypic axis. The VSMC signaling network model we presented here recapitulates the phenotypic switch induced by *Tsc1* disruption and captures the signaling changes shown experimentally, specifically increased mTORC1 activity, decreased contractile protein expression, decreased synthetic capabilities, and increased lysosomal activity.

While the simulations presented here used a single network model in isolation, there is potential to use this model in more complex G&R models. Recent work in the Humphrey lab has included coupling a homogenized wall signaling network model to tissue-level constrained mixture G&R modeling [6]. The degradative VSMC network model could also be used in the context of TAAD progression. Eventually, this modeling strategy could be used to simulate the interactions of multiple cell types, such as VSMCs, fibroblasts, and macrophages, and their role in the development and progression of vascular diseases.

CHANGES IN FIBER LEVEL STRAINS & CALCIUM ACTIVITY AFTER EXPOSURE TO BACTERIAL COLLAGENASE IN NEURON COLLAGEN CONSTRUCTS MIMICKING LIGAMENTS SUGGESTS POSSIBLE MECHANISMS FOR PAIN ASSOCIATED WITH JOINT DEGENERATION

INTRODUCTION

Degeneration of and/or pain from the spinal facet can occur naturally with aging [1,2]. The capsular ligament that encloses the facet joints is comprised of type I collagen fibers and is innervated by afferent neurons [3,4]. Changes to the capsular ligament with joint degeneration also alter its biomechanical properties and induce biochemical cascades, leading to the upregulation of proteolytic enzymes that reorganize and further degrade the extracellular matrix [5-7].

Intraarticular injection of bacterial collagenase, which digests type I collagen fibers, in the rat facet induces pain that lasts up to 3 weeks, absent any visible changes to the ligament's structure [8]. Collagenase treatment also alters neuronal activity and upregulates nociceptive mediators [9]. Collagenase digestion of isolated facets causes greater fiber disorganization and altered fiber kinematics during loading than in native tissues [10]. While microlevel mechanics may be involved in the pain response observed in vivo [8], the relationship between fiber level strains and neuronal activity has not been probed.

This study incorporated fluorescent microspheres in our in vitro model simulating the innervated ligament [11,12] in order to define the microlevel strains and neuronal activity generated with digestion by collagenase. Purified bacterial collagenase was applied for 20 minutes, a time known to alter neuronal activity [9,13]. The number of transient calcium events was measured as an indicator of real-time neuronal signaling and to define effects on neuronal activity [14].

METHODS

NCCs (n=5) were fabricated from 2mg/mL collagen solution and dissociated DRG neurons ($3x10^5$cells/mL) from embryonic day 18 rats [11]. The collagen solution was mixed with fluorescent microspheres (40nm dia; 580nm emission; 1:500 dilution; ThermoFisher). A DRG explant was also plated on each gel to provide a reference. After plating, neurons were cultured with neurobasal medium supplemented by 1% GlutaMAX, 2% B-27, 1% fetal bovine serum, and 10ng/mL 2.5S nerve growth factor (ThermoFisher). On day 2 in vitro (DIV2), neurons were transduced with an AAV expressing GCaMP6f in the feeding media (at 1:6000 dilution) which causes them to transiently fluoresce at 488nm with calcium influx [15,16]. At DIV6, collagen (150μL) with the fluorescent beads was added to encapsulate neurons. At DIV9, NCCs were placed on glass-bottomed dishes (MatTek) in 1.2mL of media.

Two groups of gels were exposed to 1mL of either: 37°C 60U activity bacterial collagenase (Worthington Biochemical) (treated; n=3) or the control of feeding media (untreated; 2 gels). A Leica inverted spinning disc confocal microscope imaged NCCs under a 63x oil-immersion objective, with 4 regions of interest (ROIs) for each gel selected to include 4-11 neurons in each ROI. Images were captured before exposure to define reference positions and baseline neuronal activity and at 20mins after exposure. The DRG explant was also imaged at 4X for each gel and timepoint to capture any gel movement. Image series (1024x1024 pixels^2) were taken at 20fps for 60s and analyzed to calculate strains and capture transient calcium events [8,17].

Displacements of the microspheres were tracked with ProAnalyst (Xcitex) and 4-node elements ($n_{treated}$=415; $n_{untreated}$=180) were generated; maximum principal strain (MPS) for each element at 20mins was calculated using LS-DYNA (LSTC) (Fig. 1). Displacement of the explant was also calculated. Average elemental MPS was calculated for each ROI and compared between groups using a Student's t-test.

The custom MATLAB script, FluoroSNNAP, was used to analyze and quantify the number of calcium events for each segmented neuron in each ROI ($n_{treated}$=94; $n_{untreated}$=44) [8,17]. Care was taken to ensure the same neurons were analyzed for both time points. The frequency of calcium events for each neuron was captured by a template-matching

algorithm [14,18]. The proportions of neurons with no or any calcium activity were calculated, as were the proportions with increased, decreased, or unchanged activity after exposure. Neuronal activity was compared between groups and times for each group by Pearson's chi-squared tests. Frequency distributions of calcium events per neuron were also compared with a Kruskal-Wallis non-parametric test.

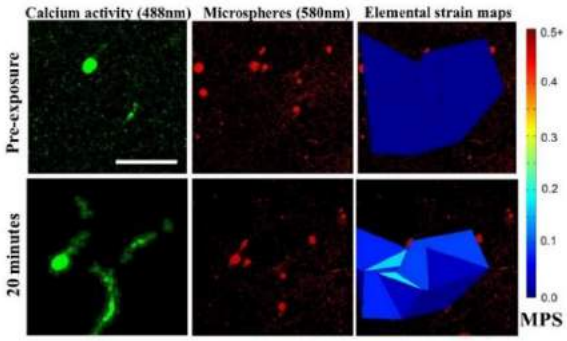

Figure 1: Representative images of a single ROI showing calcium activity (488nm) and microspheres (580nm) at both baseline and 20mins. Also shown are corresponding strains.

RESULTS

Treated NCCs experience strains (10.9±1.6%) nearly twice (p=0.01) those of untreated NCCs exposed to media (5.3±2.6%) (Fig. 1). In contrast, the overall deformation of the gel is not different (p=0.46) between treated (3.5±0.7%) and untreated (2.0±0.9%) cases.

Calcium activity varies with treatment and time (Fig. 2) despite there being similar proportions of inactive neurons in each group before (6.4% in treated; 2.3% in untreated; p=0.34) and after (6.4% in treated; 9.1% in untreated; p=0.57) treatment. Collagenase treatment alters neuron activity at 20mins, with a greater proportion (p=0.03) of neurons exhibiting increased activity (38.3%) compared to those increasing activity in response to media exposure (20.5%) (Fig. 2). Along with that, a greater proportion of neurons decrease (p=0.01) activity after treatment with media (77.3%) than after collagenase exposure (55.3%). These trends are similar for the frequency distributions of calcium events (Fig. 3). Both groups exhibit similar distributions at baseline pre-exposure (p=0.71), and both groups experience a shift to the left at 20mins after exposure, representing overall decreased neuronal activity (p<0.04) (Fig. 3). However, the shift is more pronounced in untreated neurons (p=0.025) than in the collagenase group.

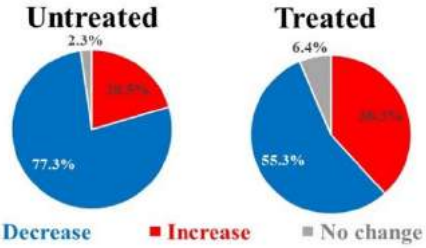

Figure 2: The proportion of neurons with increased activity after collagenase treatment is greater than for media

DISCUSSION

Bacterial collagenase exposure to collagen gels for 20mins generates appreciable microscale strains that can be detected using fluorescent beads embedded in the collagen (Fig. 1). The fact that overall gel deformations are similar across groups (2-4%) and below the collagenase-induced strains (11%) suggests adequate and meaningful measurement resolution in this method. The strains generated by that collagenase exposure are similar to the strains (11.7%) at which anomalous collagen fiber realignment occurs during loading of these same NCCs [12,19]. The similarity of strains and neuronal outcomes suggest collagen degradation may be enough to alter local mechanics of ligaments sufficiently rendering local motions as painful.

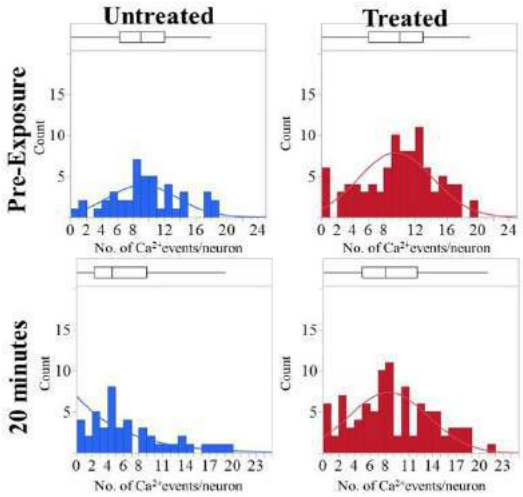

Figure 3: Both groups experience an overall decrease in neuronal signaling with a shift to the left at 20mins. This shift is more pronounced in untreated NCCs with media only.

Both bacterial collagenase and media exposure appear to alter the overall neuronal activity after 20 minutes (Figs. 2 & 3), similar to other reports [8,9]. The increase in firing events in the treated group may provide a mechanism by which those neurons experience local strains large enough to alter their response even absent macroscale deformation [20]. In fact, the strains with collagenase exposure correspond to those inducing upregulation of pERK [12]. The mechanical and biochemical results support microscale mechanics as regulating afferent responses.

Although measurements here were analyzed at the elemental level, mapping local strains to neurons would help to determine the relationships between local strain, neuron activity and even differences between neuronal phenotypes and their responses. Nevertheless, our approach provides a novel experimental platform to study fiber and cellular scale mechanical and functional outcomes.

THE ROLE OF LIGAND DENSITY AND DEGRADABILITY IN HYDORGEL INDUCED BREAST CANCER DORMANCY

C. J. Farino (1), S. Pradhan (1), J.H. Slater (1)

(1) Department of Biomedical Engineering
University of Delaware
Newark, Delaware, United States

INTRODUCTION

While significant advances in cancer treatment have increased survival rate, metastasis persists as the leading cause of cancer associated death. During metastasis, disseminated tumor cells (DTCs) originating from the primary tumor can enter a chemoresistant, dormant state lasting months to decades before returning to an actively proliferative state [1]. However, the underlying mechanisms driving tumor dormancy and reactivation remain elusive.

Towards this goal, we investigated the role tumor microenvironment plays in cancer cell phenotype of four cell lines: the MDA-MB-231 parental line, and three organotropic sublines: BoM-1833 (bone tropic), LM2-4175 (lung tropic), and BrM2a 831 (brain-tropic). Each cell line was encapsulated in three poly (ethylene glycol) (PEG)-based hydrogel formulations composed of a proteolytically degradable PEG, and varying amounts of integrin-ligating RGDS and nondegradable crosslinker N vinyl pyrrolidone (NVP). Dormancy-associated metrics including viability, proliferation, metabolism, morphology, apoptosis, chemoresistance, phosphorylated ERK (p-ERK) and -p38 (p-p38) expression were quantified to classify hydrogel-induced phenotypic state.

METHODS

PEG macromers, PEG-PQ-PEG (PEG-PQ), and PEG-RGDS were synthesized as previously described [2,3]. For cell encapsulation, PEG-PQ was reconstituted in phosphate buffered saline (PBS) to a final concentration of 5% weight/volume (w/v) for all formulations. PEG-RGDS was reconstituted to a final concentration of 10 mM (gel 1), 1 mM (gel 2), or 0 mM (gel 3). Additionally, gel 2 contained 1.0 μL/mL (9.4 mM) NVP. UV-sensitive photocrosslinker, lithium phenyl-2,4,6-trimethylbenzoylphosphinate (LAP) was added to all formulations (3.0 mg/mL (10 mM). Cells cycle was synchronized 48 hr prior to encapsulation using serum-free media. Cells were trypsinized, counted, and re-suspended in pre-polymer solution (10 million cells/mL). Precursor (3 μL) was pipetted, flattened to a height of 500 μm, and photopolymerized by Broad spectrum UV (Blak-Ray flood UV lamp, wavelength: 365 nM, intensity: 10 mW/cm^2). Cell-laden hydrogels were cultured for 15 days with media changes every 4 days.

Hydrogel characterization (compressive modulus, theoretical mesh size, swelling ratio, and degradation) was completed as previously described [2,3]. Dormancy associated metrics were quantified as previously described [2,3]. Briefly, cell viability was measured with a Live/Dead® cell viability kit (Invitrogen), early apoptosis with CF568 Annexin V (Biotium), proliferation via the Click-It® EdU Imaging Kit (Invitrogen), and metabolism via an Alamar Blue assay (Thermo Fisher). For visualizing morphology, cells with fixed, permeabilized, blocked, stained with Alex Fluor 568-F-actin (Invitrogen, 2.6 μg/mL) and counterstained with Hoechst 33342 (10 μg/mL). Drug studies were performed as previously described [3]. For p-ERK and p-38 labeling, cells were fixed, blocked, incubated with the p-p38 primary antibody (1:200), rinsed, and incubated with a secondary goat anti-mouse antibody (IgG-Alexa Fluor 647: 1:500) for 2 hr at room temperature. The protocol was repeated to label cells with the primary p-ERK antibody (1:200) and secondary goat-anti rabbit IgG-Alexa Fluor 488: (1:500) antibody. Hydrogels were counterstained with Hoechst 33342. Expression was measured by quantifying the mean fluorescence intensity of a maximum intensity z-projection. For all imaging, cell-laden hydrogels were placed between two coverslips and fluorescent z-stacks (z-height: 150 μm) were acquired using structured illumination on a Zeiss AxioObserver Z1 inverted fluorescent microscope equipped with a Zeiss Apotome2 imaging system and a Hamamatsu ORCA-Flash 4.0LT camera. FIJI software (NIH).

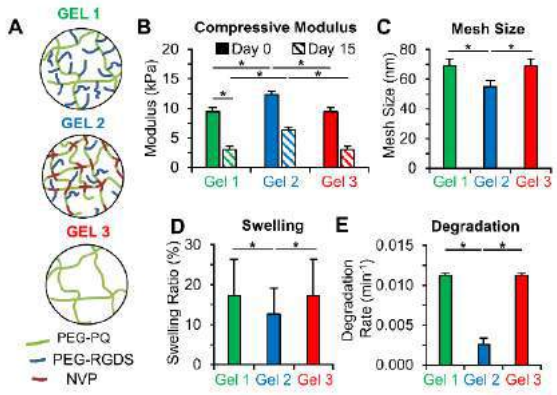

Figure 1: (a) schematic of hydrogel formulations. Quantification of (b) compressive modulus of parental 231 cell laden hydrogels at day 0 (solid) and 15 (striped), (c) swelling ratio, and (e) degradation rate.

RESULTS

To quantify the effect of tuning RGDS and NVP concentrations, elastic modulus of cell-laden hydrogels was measured at day 0 and 15. At day 0, the modulus of hydrogels without NVP (gel 1 and 3) was 9.4 ± 0.8 kPa, while hydrogels with NVP (gel 2) had a modulus of 12.3 ± 0.6 kPa (Fig 1a). NVP incorporation is expected to yield a higher modulus as NVP increases the number of crosslinks. Elastic modulus decreased to 3.0 ± 0.6 kPa (gel 1 and 3), and 6.3 ± 0.5 kPa (gel 2) at day 15, likely due to cell-mediated hydrogel degradation. NVP incorporation also decreased mesh size, swelling, and degradability of gel 2 compared to gel 1 and 3. (Fig 2c-e). Next, we observed how differences in hydrogel composition altered cancer cell phenotype. Parental and organotropic triple negative breast cancer cell lines were individually encapsulated in the three hydrogel formulations for 15 days. First, we measured cell viability at day 0 (6 hr post encapsulation) and 15. In gel 1 and 2 viability remained high at day 15 (>83.3%) for all cell types. In the absence of RGDS, viability dropped to 45.4 ± 3.2% for the parental 231 line in gel 3. Interestingly, viability remained >88.5% for all organotropic cells in gel 3. Temporal changes in viability were quantified by normalizing the number of viable cells at day 15 to the number of viable cells at day 0 (viable cell ratio) (Fig 2). High ligand density and degradability (gel 1) led to a 1.5-1.9-fold increase in the number of viable cells present at day 15. NVP incorporation in gel 2 displayed no significant change in the number viable cells at day 15 compared to day 0 for any cell type. Viable cell density also remained constant for all organotropic cells in gel 3. Quantifying the new number of live cells compared to new number of dead cells at day 15, post day 0 (new live: new dead cell ratio) indicated similar trends (Fig 2).

We also quantified how metabolism, proliferation, and apoptosis changed throughout the culture period. In gel 1, metabolism increased between 5.9-12.5-fold compared to day 0 for all cell types (Fig 2). Additionally, the number of proliferating (EdU^+) cells at day 15 compared to day 0 showed a 3.4-6.1-fold increase. Accordingly, when comparing the number of EdU^+ cells to Annexin V^+ cells at day 15, all cells in gel 1 had significantly more cells undergoing proliferation rather than early apoptosis (Fig 2). In gel 3, all organotropic cells remained a constant state indicated by no significant changes in metabolic activity and the number of proliferating (EdU^+) cells (Fig 2). These cells also indicated a balanced between the number of EdU^+ and Annexin V^+ cells. Furthermore, cells in gel 3 displayed increased drug resistance to doxorubicin and p38 expression, compared to cells in gel 1. Parental cells in gel 3 instead showed decreased metabolic activity, proliferation, and increases apoptosis, alongside increased drug resistance and p38 expression. In gel 2, parental 231s and most organotropic cells displayed a balance in the number of new live and dead cells, metabolic activity, and EdU^+ cells, and increased drug resistance and p38 expression. Interestingly, bone- and brain-tropic cells appeared mostly in clusters, while parental and lung-tropic cells remained as single cells.

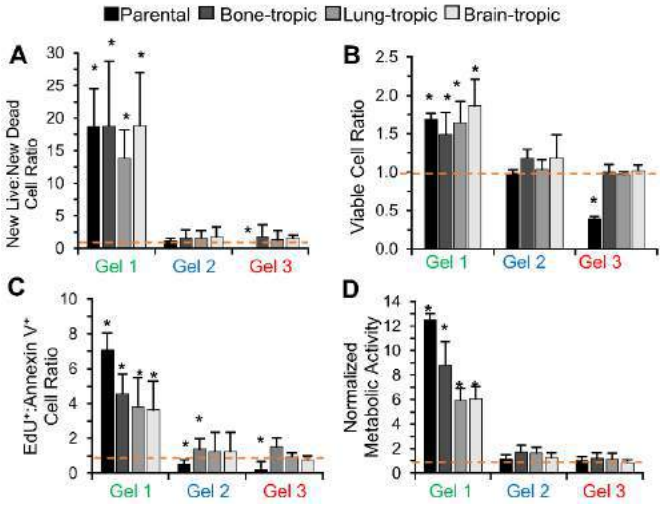

Figure 2: Quantification of (a) the number new live cells compared to new dead cells at day 15, post day 0, (b) the number of viable cells at day 15 normalized to day 0, (c) the number of EdU^+ cells compared to Annexin V^+ cells at day 15, and (d) metabolic activity at day 15 normalized to day 0. * indicates $p<0.05$. n=5. Values represent mean + standard deviation.

DISCUSSION

In this study, we investigated how tuning matrix mechanical and biochemical properties altered cancer cell fate of parental and organotropic 231s. Due to the increases in viable and proliferating cells, metabolic activity, and invasive phenotype, all cells in gel 1 were characterized to be in a growth state. Incorporation of NVP and decreased matrix degradability in gel 2 led to constant viable and EdU^+ cell density, increased chemoresistance, and expression of dormancy marker, p-38. Thus, all cells in gel 2 were in balanced dormancy. Parental and lung-tropic 231s were further characterized as balanced cellular dormancy, while bone- and brain-tropic cells as balanced tumor mass dormancy based on whether cells appeared mostly as single cells or as clusters. Following the same reasoning, organotropic cells in gel 3 were characterized as balanced cellular dormancy. Lastly, in the absence of RGDS, parental 231s were characterized to be in restricted survival dormancy due to its limited viability at in gel 3. Overall, these results show how tuning matrix adhesion and degradability can alter cancer cell fate while simultaneously highlighting how organotropic cells derived from the same parental line can sustain viability in unfavorable conditions. We envision that this this platform may be used in future studies to help identify potential anti-dormancy therapeutic targets for pre-emptive treatment of dormant cancers.

INTRODUCTION

In Canada, approximately one person out of eight dies because of coronary artery disease – the leading cause of death in the world [1]. Coronary arteries play a vital role in the body, supplying the heart with oxygenated blood. However, the buildup of atherosclerotic plaques can narrow the lumen of coronary arteries (stenosis), decreasing blood flow to the heart and ultimately contributing to heart failure. In severe cases, coronary artery bypass graft (CABG) surgery can be performed, using a harvested vessel to create an alternative path for blood to reach the myocardium [2]. After grafting, grafts tend to remodel, and sometimes this process degenerates, leading to a complete occlusion of the graft, known as failure. Unfortunately, despite many advancements, failure remains quite common: 25% of vein grafts fail within two years of CABG surgery, affecting 43% of patients [3]. Significantly, the underlying reasons behind graft failure are still unclear.

Altered blood flow dynamics are already known to be involved in the pathophysiological processes behind vascular remodeling. For example, it is well known that low and oscillatory wall shear stress (WSS) can lead to endothelial dysfunction and the initiation of atherosclerosis [4]. More recent studies have also pointed to the potential role of WSS in graft failure [5]. However, while hemodynamics in grafts and coronary arteries likely play a critical role in explaining CABG failure, this information is difficult to obtain non-invasively, even with the latest imaging modalities. The small caliber of coronary arteries and grafts precludes the in-vivo acquisition of blood velocity, which is needed to calculate WSS.

Previous works in other cardiovascular territories show that computational fluid dynamics (CFD) simulations guided by medical images can potentially address this gap [6]. Patient-specific anatomy obtained through coronary CT angiography can be used to guide CFD simulations to provide quantitative information on the blood flow in coronary arteries and grafts [7]. These non-invasive CFD simulations can also be integrated with flow velocity information obtained from 4D-flow MRI to impose patient-specific boundary conditions and improve accuracy [8]. With CFD simulations, a number of relevant hemodynamic biomarkers such as WSS and oscillatory shear index (OSI) can be obtained non-invasively. Such quantities can provide new insights into the root mechanisms behind CABG failure and potentially lead to better treatment plans.

The main objective of this research is to use patient-specific image-guided CFD simulations in the analysis of CABG remodeling. Specifically, we performed a preliminary investigation on the relation between WSS and OSI calculated one month after surgery, and the degree of graft remodeling measured one year after surgery.

METHODS

This prospective study was performed on a cohort of 4 patients who underwent CABG surgery at the Sunnybrook Health Sciences Centre in Toronto, Canada. The cohort includes 10 grafts, 4 of which were left internal mammary artery (LIMA) grafts, 4 were saphenous vein grafts (SVG), and 2 were radial artery (RA) grafts. Both CT and 4D flow MR imaging were performed 1 month after surgery, to obtain anatomical and flow information, respectively. One year after surgery, CT images were acquired again to assess the extent of graft remodeling.

Three-dimensional anatomical models of the aortic arch and associated branches, coronary arteries, and implanted grafts were reconstructed from CT images using SimVascular (Stanford University, Stanford, California) [9]. The generated reconstructions were used for CFD simulations and for measuring the average diameter in each implanted graft. In order to reach a periodic solution, transient CFD simulations were run for 5 full cardiac cycles. Blood flow rate measured using 4D flow MRI was used as an inlet boundary condition in the

ascending aorta, and a lumped parameter model was used as boundary condition at the outlet of descending aorta, aortic branches, and distal coronary arteries [9].

From the velocity computed with CFD simulations, the WSS and OSI distributions in each graft were computed with SimVascular. Post-processing and visualization of CFD results were performed with ParaView (Kitware, Clifton Park, New York) and MATLAB (MathWorks, Natick, Massachusetts). Wall shear stress was time-averaged over a single cardiac cycle. The ratio between the graft wall area exposed to abnormal WSS (<0.5 Pa [10]) and total graft area was computed. Similarly, the ratio between the graft wall area exposed to abnormal OSI (>0.2 [11]) and the total graft area was also computed.

RESULTS

The plots in Figure 1 compare the average graft diameter found 1 month and 1 year post-surgery. Data points below the black dotted line correspond to a reduction in graft lumen diameter after 1 year. Data points are color-coded by graft type. In Figure 1A, the marker size corresponds to the percent graft area exposed to abnormal WSS, while the marker size in Figure 1B corresponds to the percent graft area exposed to abnormal OSI.

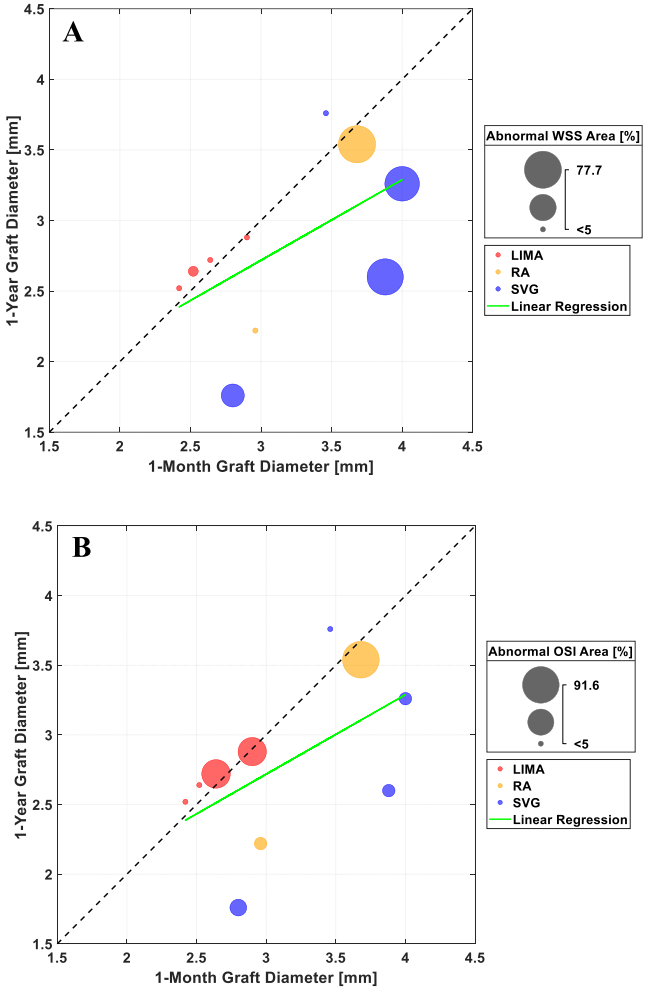

Figure 1: Comparison of average graft lumen diameter between 1 month and 1 year post-surgery. Marker size corresponds to percent graft area exposed to abnormal WSS in (A) and to abnormal OSI in (B).

DISCUSSION

As a whole, the cohort tended towards negative graft remodeling after 1 year, with a linear regression slope of <1. There are also some qualitative differences in the degree of remodeling among the different graft types. None of the LIMA grafts experienced significant remodeling at the 1-year time point, while 3 out of 4 of the SVGs experience a lumen reduction. This observed difference in remodeling for SVG vs. LIMA grafts is consistent with their differential long-term graft patency rates identified in previous studies [12]. The trend for the RA grafts is less clear due to only 2 grafts being included in the analysis.

There are also some qualitative trends between graft remodeling and abnormal WSS area. Figure 1A shows that grafts with lower abnormal WSS area tend to experience less graft remodeling at 1 year than grafts with higher abnormal WSS area. This qualitative observation aligns with what is known about the role of abnormal WSS in vessel remodeling [4]. In particular, we also see that all 4 LIMA grafts have low abnormal WSS area, while 3 out of the 4 SVGs have high abnormal WSS area. This observation seems to align with the clinical observation that LIMA grafts tend to have higher success rate than SVGs [12].

On the other hand, the relationship between abnormal OSI area and graft remodeling is less clear. In Figure 1B, it appears that the grafts with the highest abnormal OSI area did not experience much remodeling at 1 year. The grafts that experienced remodeling were not exposed to much abnormal OSI, while the grafts that did not remodel had mixed exposure to abnormal OSI. Previous studies suggest that abnormal OSI, corresponding to oscillatory WSS, contributes to vascular remodeling [11]. However, others have reported that abnormal OSI alone may not correlate to vascular disease [12]. Our observations regarding the relationship between OSI and bypass graft remodeling are inconclusive.

Overall, the proposed preliminary study revealed some qualitative trends in coronary artery bypass graft remodeling according to graft type and WSS. One limitation of this study is the small sample size, which does not provide enough statistical power to demonstrate significance. Future works will add more patients and grafts to the present study.

SIGNAL TO NOISE RATIO OF POLARIZATION IMAGING PARAMETERS IS DEPENDENT ON LIGHT INTENSITY AND MICROSTRUCTURAL ANISOTROPY OF SOFT TISSUES

INTRODUCTION

Highly aligned collagen fibers serve as the primary load bearing structure in musculoskeletal soft tissues like tendon and ligament. [1] When this organization is disrupted in periods of disease or damage, it leads to aberrant tissue function, pain, and loss of quality of life. For this reason, rapid, accurate visualization of collagen microstructure in these tissues is essential to diagnose tissue dysfunction, better understand disease pathology, and motivate new repair strategies. [1]

Myriad biomedical optics techniques have been used to evaluate collagenous tissue structure, but many of these modalities lack sufficient (1) spatial resolution to probe microstructural length scales, (2) temporal resolution to see dynamic changes in the extracellular matrix, and/or (3) require excision or destructive processing of tissue prior to analysis. [1] Recently, quantitative polarimetry-based techniques have been used across biomedical applications to overcome some of these limitations. [2] These methods employ the intrinsic birefringence of collagen as a source of endogenous contrast, thus increasing the modalities' sensitivity to fiber structures. Additionally, the minimal instrumentation required to implement these techniques lends itself to endoscopic integration, allowing for exploration into more clinically relevant *in vivo* applications. [2]

When moving towards *in vivo* optical imaging, there is an inherent potential constraint on maximal light intensity available due to a need to minimize heat generation from light sources. [3] As such, there is potential for loss in image quality or data integrity if the signal-to-noise ratio of the measurement in question is not sufficiently high. Additionally, during *in vivo* imaging of non-planar tissues, there are local fluxuations of light intensity that could affect the SNR of particular regions of out-of-plane tissue regions more than others. Therefore, understanding how noise propagates in output parameters calculated during polarimetry under low light conditions is essential for successful clinical translation. [5]

Therefore, the objective of this study was to evaluate low-light imposed noise propagation in common polarimetric calculations of degree of linear polarization (DoLP) and angle of polarization (AoP). These measurements provide information about the strength and orientation of collagen fiber alignment, respectively, when imaging biological tissues. To assess the SNR in these metrics, engineered tissue analogs of prescribed anisotropic or isotropic collagen fiber alignment were fabricated and subjected to reflectance quantitative polarized light imaging (rQPLI) across a gradient of incident light intensities during dynamic loading.

METHODS

rQPLI. As described previously, rQPLI utilizes a polarization-sensitive, division-of-focal plane (DoFP) camera to quantify the first three Stokes parameters, and thus the polarization state of light, on a pixelwise basis for the field of view. A circularly polarized light source is mounted 30° angle to the normal above the sample. The DoFP sensor is directly above the sample. (**Figure 1A)** From the Stokes parameters collected for each sample-spanning pixel, the DoLP and AoP can be calculated. This process is repeated framewise during testing to get dynamic measurements of collagen fiber alignment strength and orientation, respectively.

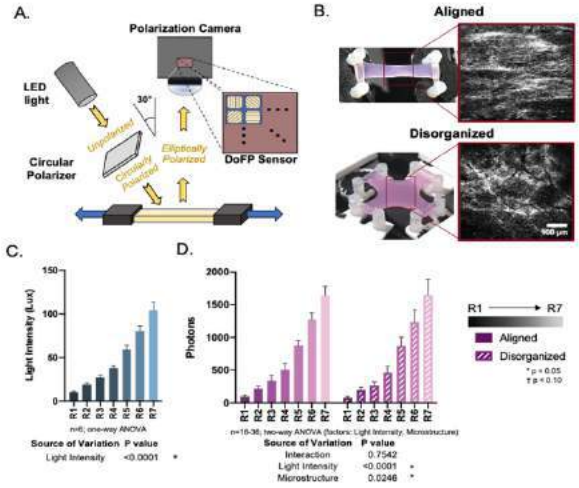

Figure 1. (A) Schematic of rQPLI. **(B)** SHG images indicating anisotropic (Aligned) and isotropic (Disorganized) microstructure of collagen tissue analogs. **(C)** Light intensity measured at plane of sample and **(D)** photons incident on sensor during mechanical testing.

Theoretical Signal-to-Noise Ratio in DoLP and AoP. The theoretical noise within Stokes parameters using DoFP sensors is primarily driven due to photon shot noise and has been previously characterized using standard error propagation techniques. [4] In brief, extending these methods to definitions of the Stokes parameter-derived metrics of DoLP and AoP, the signal-to-noise ratios are defined as:

$$SNR(DoLP) = \frac{DoLP}{\sigma_{DoLP}} = \sqrt{\frac{I}{1+\frac{1}{DoLP^2}}} \quad (1)$$

$$SNR(AoP) = \frac{AoP}{\sigma_{AoP}} = \pi \cdot DoLP \cdot \sqrt{I} \quad (2)$$

where I is the incident light intensity and σ is the noise associated with each polarization parameter.

Tissue Analog Fabrication and Testing. Collagen based tissue analogs of prescribed collagen fiber alignment were generated using previously established methods. [5] Dermal fibroblasts were mixed with Type I collagen and injected into Teflon molds with either a bar- or cruciform-shaped geometry. Rods at the ends of these molds provided static mechanical boundary conditions during 7 days of static culture that stimulated anisotropic (Aligned) or isotropic (Disorganized) collagen fiber alignment in the center of each gel. (**Figure 1B)**

As indicated in Eqs. 1 & 2, the SNR of both DoLP and AoP are dependent on the DoLP of the sample and the intensity of the incident light (I). The baseline DoLP of a sample is determined by its strength of fiber alignment. Creation of tissue analogs with these different microstructures ensured creation of tissues with differing but known baseline DoLP values. To experimentally determine the SNR as a function of changing light intensity, the power of the circularly polarized incident light source was changed to one of seven settings (R1-R7). For each of the prescribed light settings, tissue analogs (n=6-12 per microstructure) were subjected to a mechanical loading protocol (0.1N preload; 10 cycles to 1.25%, 2.5%, 3.75% strain). Samples were cycled at increasing strain amplitudes to assess the ability to discern differing magnitudes of dynamic microstructural realignment due to load in DoLP and AoP at different noise levels (data not shown).

At each light intensity, the average signal and noise were calculated as the mean and standard deviation (STD), respectively, for both DoLP and AoP. Values were calculated for the first 100 frames after preload but before dynamic testing, and then averaged pixelwise within the sample spanning the center region of interest. The ratio of signal (mean) and noise (STD) was then calculated as the SNR for a each sample. Qualitative DoLP and AoP color maps were calculated to visualize signal integrity at each light intensity.

RESULTS

Light Intensity Alteration. Generation of a progressively increasing gradient of light at the plane of the sample was verified via direct luxmeter readings, with values ranging between 10.2 ± 0.9 Lux and 104.0 ± 9.4 Lux from R1 to R7 ($p < 0.05$). (**Figure 1C)** Additionally, a gradient in reflected light onto the sensor after sample interaction was verified by calculating the number of detected photons within the region of interest of the sample ($p < 0.05$); these values ranged between 412.6 ± 110.9 and 7321.4 ± 606.8 photons from R1 to R7 in Aligned samples and between 330.4 ± 78.6 and 7497.1 ± 1049.3 photons from R1 to R7 in Disorganized samples. (**Figure 1D)**

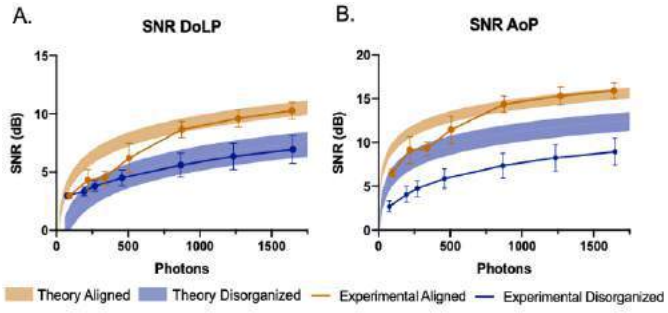

Figure 2. Theoretical solution and experimentally determined signal-to-noise ratio (dB) of **(A)** DoLP and **(B)** AoP. Theoretical bands represent solution to Eq. 1 & 2 at mean ± STD of each microstructure type. Experimental data (n=6-12/microstructure) are mean ± STD.

Theoretical SNR. The baseline DoLP of each microstructure at R7 was considered to be ground truth with which to solve Eqs. 1 and 2 (Aligned 0.28 ± 0.10; Disorganized 0.14 ± 0.03). In these solutions, the higher baseline DoLP resulted in a higher SNR in both AoP and DoLP across all possible light intensities. Additionally, the magnitude of the SNR in AoP is higher across light intensities than that of their respective DoLP SNR counterparts. **(Figure 2)**

Experimental SNR. The SNR of DoLP ranged between 2.97 ± 0.22 dB and 10.25 ± 0.72 dB from R1 to R7 in Aligned and between 2.97 ± 0.23 dB and 6.93 ± 1.21 dB from R1 to R7 in Disorganized. The SNR of AoP ranged between 4.47 ± 0.46 dB and 39.85 ± 7.81 dB from R1 to R7 in Aligned and between 1.88 ± 0.28 dB and 8.28 ± 3.01 dB from R1 to R7 in Disorganized. There was a high degree of congruence between the experimental results and the theoretical solutions, both in magnitude and trend. **(Figure 2)**

DISCUSSION

In this study, the signal-to-noise ratio of DoLP and AoP during rQPLI was explored through imaging of biological tissues of varied anisotropies at graded light intensities. Tissues of known, controlled fiber alignment were fabricated and successfully subjected to a range of incident light intensities resulting in a gradient of photon flux on the surface of the polarization sensor after interaction with the tissues.

Based on the SNR equations of both DoLP and AoP derived from error propagation techniques, we expected SNR to be dependent not only on the incident light intensity, but also the baseline DoLP of the sample. Since the DoLP represents the strength of alignment, this has been shown to be a measurement of the anisotropy of a tissue of interest. [2] Therefore, the SNR of these polarization measurements, and the SNR response as a function of light intensity, should vary based on how aligned a sample is. We confirmed this in both the theoretical solutions to the SNR equations and experimental evaluation of SNR during imaging of biological tissue analogs. The SNR was substantially higher across all light intensities in both DoLP and AoP when imaging the Aligned samples than compared to Disorganized counterparts.

Further, these data show that AoP is more resilient to the noise floor at lower light than DoLP: the magnitude of the SNR AoP is consistently higher both theoretically and experimentally when comparing different microstructures. The DoLP SNR is roughly the same between Aligned and Disorganized at low light intensities (R1-R4, **Figure 2**). At lower light, it is impossible to qualitatively distinguish between microstructures based on the strength of alignment (DoLP) (data not shown) and the signal is effectively lost below the noise floor. This does not occur until much lower lights (R1-R2) when considering the orientation of fibers (AoP).

Overall, these data demonstrate important considerations about SNR when using polarized light to image biological tissues. AoP is more resilient to noise than the DoLP, so it may be of greater use in low light applications like endoscopy, particularly if dynamic range in the sensor of interest is limited. Further, the SNR of DoLP and AoP are both functions of DoLP, and, subsequently, tissue anisotropy. Because of this dependency, low light imaging of highly aligned tissue like tendon may be possible whereas visualization of the disorganized collagen microstructure of other tissues (e.g., skin) might not be visible through noise under the same sensor architecture and conditions of lighting.

AN INVERSE MECHANICS APPROACH TO DETERMINE CHANGES IN THE MECHANICAL HETEROGENEITY OF THE LUMBAR FACET CAPSULAR LIGAMENT

Jill M. Middendorf (1), Victor H. Barocas (1)

(1) Biomedical Engineering
University of Minnesota – Minneapolis
Minneapolis, MN, USA

INTRODUCTION

Recent research has identified a relationship between the lumbar facet capsular ligament (FCL) and sensations of low back pain [1]. This increase in pain may be associated with changes in the mechanical properties of the FCL. Specifically, reduced FCL strength can cause abnormal spinal segment motion [2] or increased strain on axons embedded in the FCL [3], both of which may contribute to low back pain. Global FCL tissue mechanics have been fit to bi-axial force displacement curves [5] providing basic information about FCL mechanical behavior. However, previous work has not determined the heterogeneous mechanical properties of the FCL that could contribute to increased sensations of low back pain.

The FCL has a highly heterogeneous collagen structure [4], but quantification of the mechanics in these heterogeneous regions is unknown. Recent advancements in the use of inverse mechanics methods on soft tissues provide [6,7] an opportunity to directly use experimental data and determine heterogeneous mechanical properties of the FCL. Therefore, to determine differences in FCL mechanical heterogeneity that may cause increased sensations of low back pain, this study coupled experimental data on bi-axially loaded FCLs with an inverse mechanics method.

METHODS

FCLs were obtained from two cadaveric lumbar spines, one with reported low back pain (+LBP) and one with no reported low back pain (-LBP). Prior to dissection, facet joint and IVD health were determined by taking T2 weighted MRI [8]. All scans were performed on a 3T MRI scanner with a Siemens knee coil. The imaging included clinical T2-weighted sequencing in the sagittal plane and the axial plane. We note the articular cartilage in the facet joint of the -LBP spine showed thicker articular cartilage than the facet joint from the +LBP spine (Fig 1). Additionally, both spines contain reduced disc height.

After MRI imaging, the FCL was dissected from the right side of the L3-L4 facet joint in both specimens. Ligaments were cut into approximately a cruciform shape, and then the medial, lateral, interior and superior surfaces were mounted into brackets in a biaxial loading system. A 15-step biaxial loading protocol [6] was applied to the tissue, such that the maximum stretch in both directions was 12%. During loading, videos were taken of the FCL surface, and loads were measured using 6 degree of freedom load cells on each of the 4 loading arms. Once testing was completed, digital image correlation was used to track the

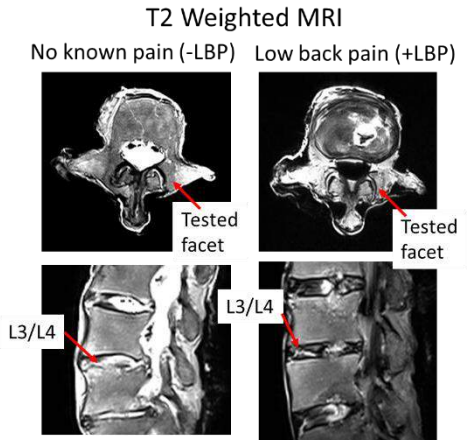

Figure 1: MRI T2 imaging of two different lumbar spines shows variability in the thickness of the facet joint articular cartilage and differences in the IVD height and hydration.

tissue motion and calculate surface strain. These deformation fields were then used partition regions of the FCL into similar and dissimilar regions based on jumps in the deformation gradient, as previously described [7]. Each FCL domain was partitioned until a total of 20 distinct regions were created.

To calculate the local Kelvin moduli of each partitioned region, a previously established generalized anisotropic inverse mechanics (GAIM) approach was used [6,7]. This method solves the weak form of the Cauchy stress balance directly for the mechanical properties of the tissue. The material is assumed to be linear.

RESULTS

Biaxial mechanical testing (Fig 2A) and GAIM analysis reveals differences in the heterogeneous mechanical properties between the two spines. Each FCL exhibits a unique displacement field under the same bi-axial loading scenario (Fig 2B). Visualizations of the maximum Kelvin modulus show large variability across both FCLs (Fig 2C). Quantification of the Kelvin modulus show the FCL from the +LBP spine has a highest average Kelvin modulus (2.1 ± 2.0 MPa, Fig 3A). The Kelvin modulus values for the -LBP spine have a larger relative distribution of values (0.39 ± 0.30MPa, Fig 3A). Interestingly, the +LBP FCL seems to have multiple small regions containing either very large or very low Kelvin Moduli.

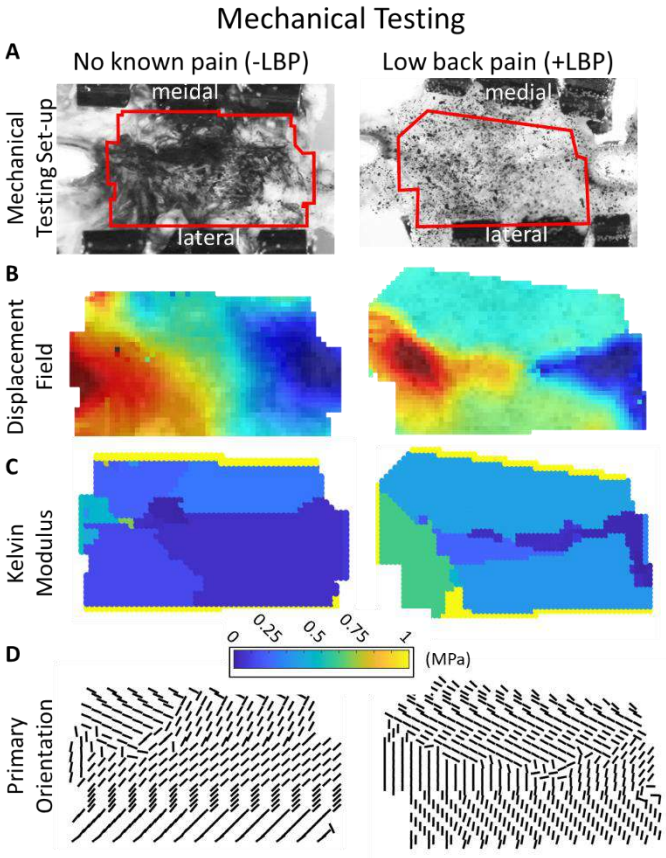

Figure 2: A) Bi-axial testing set-up showing the FCL with a speckle pattern and a region of interest (red). B) Displacement field showing non uniform changes in displacement due to bi-axial loading. C) Kelvin modulus of FCLs show differences in the local mechanical properties. D) The primary orientation of the Kelvin modulus changes between FCLs and between each region in a given FCL.

Finally, the primary orientation of fibers between the two FCL are distinctly different (Fig. 2D). In the -LBP spine, the lumbar FCL's primary mechanical orientation predominately runs 45° from the superior inferior axis (Fig 3B). The +LBP spine has 2 major directions of orientation for the Kelvin modulus. The first is oriented along the medial lateral axis (~90°), while the second major Kelvin orientation is at an angle approximately 150° from the superior inferior axis. Primary orientations in healthy FCLs are expected to occur predominately in the medial lateral axis (90°), so both tested FCLs contain some abnormal changes in the primary orientation.

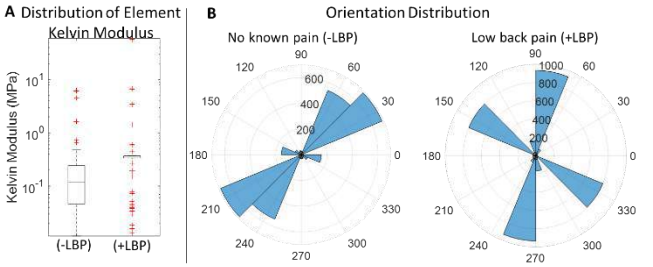

Figure 3: A) Samples from -LBP spines had a larger distribution of Kelvin Moduli. B) The major orientation of Kelvin modulus in FCLs from -LBP spine is about 45° from the medial lateral line, while the orientation of the major Kelvin modulus in the FCL from the +LBP spine is in two different directions.

DISCUSSION

In this study, larger variability in the Kelvin modulus is present in the -LBP spine, while multiple small inclusions of either low or high modulus and a higher average modulus is present in the FCL from the +LBP donor. These differences could affect the axon strain and cause increased expression of nociceptive signaling molecules [3]. Additionally, the changes in fiber orientation between the two FCLs may indicate a process by which collagen fibers change their orientation during disease. These changes could affect both spinal motion and axon strain, which contribute to experienced sensations of low back pain.

Unlike most quantifications of soft tissue material parameters, we did not have to iteratively solve a constitutive model to fit our experimental data [5]. The use of inverse mechanics approaches coupled with an automatic partitioning scheme provides the ability to directly quantify FCL mechanical heterogeneity that may be critical to understanding sensations of pain in the lumbar spine.

SENSITIVITY OF THE SHEAR WAVE SPEED–STRESS RELATIONSHIP TO PROPERTIES OF LIGAMENT-MIMICKING MECHANICAL PHANTOMS

Lesley R. Arant (1), Joshua D. Roth (2, 3)

INTRODUCTION

Shear wave tensiometry has recently emerged as a promising method to non-invasively measure tension in load-bearing soft tissues. The driving principle behind shear wave tensiometry is the linear relationship between axial stress (σ) and shear wave speed (SWS) squared [1]:

$$\sigma = \rho(SWS)^2 - k'\mu \quad (1)$$

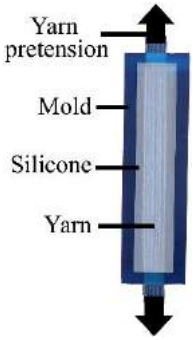
where μ is the unloaded shear modulus, ρ is the tissue density, and k' is a shear correction factor.

Our research group is developing an intraoperative shear wave tensiometer for the initial application of measuring tension in collateral ligaments in vivo during total knee arthroplasty (TKA). To develop our shear wave tensiometer, we are using ligament-mimicking mechanical phantoms as test specimens because they are made of well-characterized engineering materials that have less variability than biological materials. These phantoms have been shown to have similar mechanical properties [2] and SWS squared–stress relationships [3] to collateral ligaments. However, it is unknown whether and to what extent the properties of these phantoms affect the SWS squared–stress relationship. Furthermore, there have been efforts to use shear wave tensiometers to non-invasively detect differences in the structure and mechanical properties of diseased or damaged tendons [4]. To explore the potential of extending this application to ligaments, a preliminary study in ligament-mimicking phantoms would be informative due to their tunable and well-controlled properties.

Accordingly, the objective of this research was to determine the sensitivity of the SWS squared–stress relationship to the structural and mechanical properties of ligament-mimicking mechanical phantoms.

METHODS

We fabricated ligament-mimicking mechanical phantoms by embedding yarn in silicone, with the yarn aligned parallel to the longitudinal axis of the phantom (Figure 1). During molding of the phantoms, we applied a pretension of 10 N to the yarn to remove slack and align the yarn. We fabricated nine phantoms, which varied in the type of silicone and number of yarn strands used in fabrication following a two-factor face-centered central composite design (Figure 1). We chose to vary the elastic modulus of the silicone and the number of yarn strands to model changes in the ground matrix and collagen content of ligaments, respectively, that may result from ligament pathology or healing [5].



Phantom	Silicone Elastic Modulus [kPa]	Number of Yarn Strands
1	24	8
2	152	8
3	261	8
4	24	10
5	152	10
6	261	10
7	24	12
8	152	12
9	261	12

Figure 1: We embedded longitudinally-aligned, pretensioned yarn in silicone to fabricate ligament-mimicking phantoms (left). Nine phantoms were fabricated following a two-factor face-centered central composite design (right).

To replicate the in situ boundary conditions and ligament length available for making measurements, we fabricated a knee model for testing that includes the femur, tibia, and menisci (Figure 2). A custom clamp attached the phantom to the femur, and a roller at the tibial attachment replicated ligament wrapping over the tibia and allowed for the application of low-friction, controlled loads using an electrodynamic testing system. Following preconditioning, we loaded the phantom using a 0 to 200 N ramp at 20 N/s. During loading, a piezoelectric tapper excited shear waves in the phantom by delivering micron-scale taps at a frequency of 10 Hz. Lasers from two laser Doppler vibrometers were spaced 4-5 mm apart on the phantom to track the shear waves. We computed the SWS using a cross-correlation of the two laser signals to find the time delay in wave arrival at the two points (Δt, Figure 2). We measured SWSs during the ramp load in each phantom for five trials.

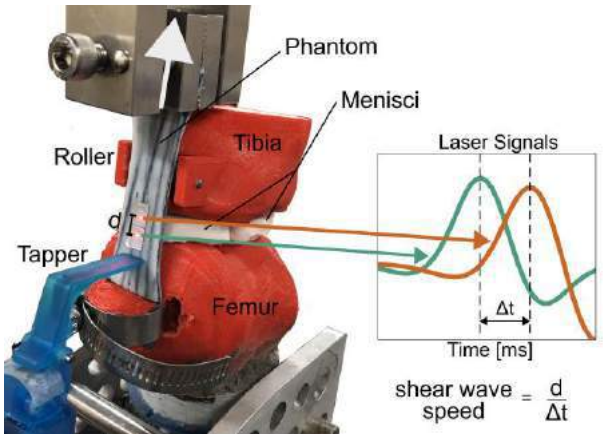


Figure 2: Ligament-mimicking phantoms were placed in a knee model during testing to replicate the in situ boundary conditions.

We extracted the slope, intercept, and R^2 from simple linear regressions between squared SWS (independent) and axial stress (dependent) for each trial of each phantom. We then performed multi-factor regressions to determine the sensitivity of the slope and y-intercept of the SWS squared–stress relationship to phantom properties. The independent variables were the elastic modulus of the silicone and the percentage of the phantom composed of yarn. We chose the latter because we believed yarn content normalized to phantom volume would provide more insight into structure-function relationships than absolute yarn content. We initially fit the models with two-factor interactions, but removed them if they were statistically insignificant ($p > 0.05$).

RESULTS

The axial stress increased linearly with squared SWS for all phantoms (range of R^2 = [0.77, 0.92]). The slope of the SWS squared–stress relationship ranged from 493 to 1304 kg/m^3 across the different phantoms. The multi-factor regression for the slope revealed a significant negative correlation between the yarn percentage and the slope ($p = 0.001$), while the effect of elastic modulus of the silicone was insignificant (Figure 3a). The interaction between the yarn percentage and elastic modulus of the silicone was also significant ($p = 0.046$). The R^2 for this multi-factor regression was 0.26.

The y-intercept of the SWS squared–stress relationship ranged from -764.1 to 13.5 kPa across the different phantoms. In the multi-factor regression for the y-intercept, the interaction term was insignificant, and thus we removed it from the model. The reduced model revealed a significant negative correlation between the elastic modulus of the silicone and the y-intercept ($p = 0.006$), while the yarn percentage was insignificant (Figure 3b). The R^2 for this multi-factor regression with only main effects was 0.18.

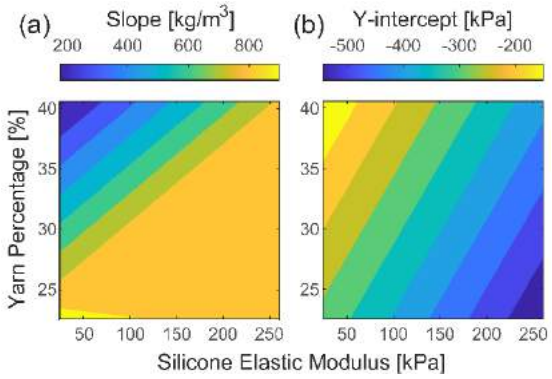

Figure 3: The multi-factor regressions revealed a significant negative relationship between: (a) the yarn percentage and the fitted slopes, and (b) the elastic modulus of the silicone and the fitted y-intercepts.

DISCUSSION

Similar to collateral ligaments [6] and tendons [1], the SWSs in each of the ligament-mimicking phantoms increased linearly with increasing tension. This confirms that the linear relationship between squared SWS and stress holds independent of these fabrication factors.

The slope and y-intercept of the SWS squared–stress relationship were sensitive to properties of the fibrous and isotropic constituents of the phantom, respectively. Since the density is the constant of proportionality between squared SWS and stress (Equation 1), a greater yarn percentage may decrease the slope because yarn has a lower density than silicone. To test the validity of this reasoning, future work will involve repeating this sensitivity analysis with factors that independently alter the density and shear modulus. This should also provide insight into the significant interaction term that was identified in the multi-factor regression model for the slope.

The negative correlation between the elastic modulus of the silicone and the y-intercept is consistent with the structural composition of the phantoms and the analytical model (Equation 1). In transversely isotropic materials with highly aligned fibers, such as ligaments and the phantoms, the transverse shear response is dominated by the isotropic ground matrix [7], for which the shear and elastic moduli are directly proportional. Thus, a higher elastic modulus of the silicone increases the shear modulus of the phantom, which decreases the y-intercept according to the analytical model (Equation 1).

Our results confirm that the properties of the phantoms can be tuned to modulate the SWS squared–stress relationship in a predictable manner. Moving forward, this will allow us to design phantoms that model diseased or damaged ligaments (e.g., contracted and stiffened medial collateral ligaments often encountered in TKA patients [8]). Furthermore, these findings confirm that measurements made using shear wave tensiometry are sensitive to differences in tension, as well as the structural and mechanical properties of the test specimen. This warrants future investigation into the clinical application of shear wave tensiometry to the diagnosis of ligament pathologies.

INTRODUCTION

Radiation cystitis is a rare condition that can develop in cancer patients who have undergone pelvic radiation chemotherapy. This condition can cause symptoms such as painful and frequent urination, decreased bladder capacity, nocturia, and blood in the urine. In severe cases blood clots can block urine flow and increase pressure on the kidneys, leading to renal failure [1]. This condition is rare; the American Cancer Society estimates that in 2018, only 5-10% of pelvic cancer patients undergoing radiation chemotherapy actually developed radiation cystitis [2]. However, for these patients, this disease causes painful and frustrating symptoms that ultimately limit their recovery from cancer.

A mouse model of radiation cystitis has been developed in order to understand the changes to the bladder wall following onset of the disease [3]. This model has shown hypervascularization of the bladder as well as significant fibrosis—i.e. increased collagen fiber deposition. Though the remodeling reported in this animal model can provide insight into the tissue mechanics of the urinary bladder affected by radiation cystitis, further studies must be performed to fully understand the alterations to the mechanical behavior of this remodeled extracellular matrix. Additionally, there are several phases of radiation cystitis: an acute phase occurring weeks after treatment, a latent phase occurring within months to years, and a late phase, which is chronic [1]. Because radiation cystitis has several phases, each with their own defining symptoms and remodeling, it is important to study the mouse model in several stages of recovery following radiation treatment. The goal of this study is to identify changes to the mechanical behavior of the mouse urinary bladder extracellular matrix following onset of radiation cystitis at two timepoints of recovery.

METHODS

A single dose of 40Gy radiation was administered to the bladders of 20 8 week-old C57BL female mice via a small animal radiation research platform. Along with 20 age-matched control mice, their weights and micturition data were recorded on a weekly basis, for either 12 or 24 weeks post-treatment—n = 10 control, 10 irradiated for each recovery time. After either 12 or 24 weeks, the mice were placed into a cage with blotting paper for 4 hours, which allowed for measurement of micturition data. After the 4-hour period, the total number of spots, the average spot size, the total volume of urine, and the size of the primary spot were measured from the blot paper.

Following the micturition study, the mice were euthanized and their bladders were isolated. Each bladder was cut laterally into a ring-shaped tissue sample by removing the dome and lower trigone, which were placed into 10% formalin to later be used for histology. The ring-shaped samples were then decellularized via a 48-hour soak in 1% sodium-dodecyl sulfate to isolate and compare the mechanical behavior of the control and irradiated extracellular matrix [4]. Following decellularization, the samples were mounted onto a uniaxial stretching machine using cotton suture. During testing, the samples were kept in a calcium-free Krebs-Hensleit buffer. Once mounted, the samples were subjected to a 2g preload, which was reapplied between each set of cycles. The full test consisted of 10 cycles of 5% stretch (preconditioning) and 5 cycles each of 10%, 15%, and 20% stretch. Throughout the test, the axial force was measured by a load cell (LSB200, Futek) while the height of the sample was measured by a front-facing camera (Fuji). Pictures of the samples were taken between cycles with the preload from the front and side (using an iPhone) to estimate cross-sectional area for stress calculation. Stress and stretch were calculated using the configuration of the sample following preconditioning (with the preload) as a reference. Following the

mechanical test, the bladder ring was placed into formalin with the dome and trigone for 4 days before being moved into 30% ethanol for storage, embedded in paraffin, and stained with Masson's trichrome to calculate each sample's collagen area fraction.

Finally, the last loading curve of the 20% stretch cycles was fitted to a constitutive model to identify differences between the control and irradiated samples. Currently, only the 12-week time point is completed, but once the second time point is finished, the constitutive model will be used to determine effects of time following radiation to the bladder—i.e. disease recovery or progression. For the constitutive model, we use a Demiray-type strain energy function, W [5] that is isotropic and exponential with two parameters, c and k

$$W = c\left(e^{k(I_1(\boldsymbol{C})-3)} - 1\right)$$

where the strain energy function has the following relation to stress, $\boldsymbol{T}$, and deformation via

$$\boldsymbol{T} = -p\boldsymbol{I} + 2\boldsymbol{F}\frac{\partial W}{\partial \boldsymbol{C}}\boldsymbol{F}$$

For a deformation gradient $\boldsymbol{F}$, Cauchy-Green deformation tensor $\boldsymbol{C}=\boldsymbol{F}^T\boldsymbol{F}$, and a Lagrange multiplier p. The experimental data was fitted to the model by minimizing the normalized root mean square deviation (NRMSD) between the model and experimental stresses (t_{th} and t_{exp}) [6]

$$NRMSD = \frac{1}{t_{exp}^{max}}\sqrt{\frac{\Sigma\left(t_{th} - t_{exp}\right)^2}{n}}$$

for n experimental data points.

RESULTS

As the second time point has not arrived yet, the results will be discussed only in terms of the 12-week time point. Radiation was well-tolerated by the animals as denoted by the irradiated group's body weight maintenance and skin health. The volume of urine from each irradiated mouse in the micturition study was significantly lower than that of the control mice (in total, average, and primary spot size), indicating a decrease in bladder capacity, **Figure 1**. There were no changes to the total number of spots. We are still awaiting histology slides in order to estimate collagen area fraction.

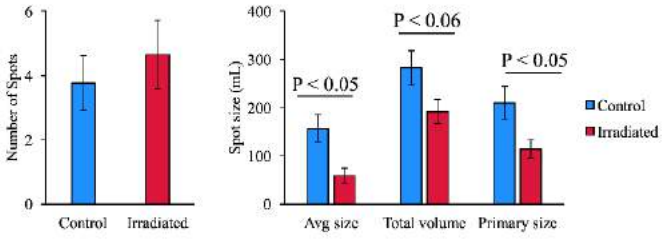

Figure 1. Summary of micturition measurements. No changes in number of urine spots (left), and decreased urine volume (right). Error bars represent standard error.

Mechanical data from one control mouse was not used, as the sample broke early in the test and did not survive the 20% loading. The mechanical data of the remaining samples (n = 9 control, 10 irradiated) showed a stiffening of the urinary bladder extracellular matrix of the irradiated bladders, as compared to the controls. This was noted by a slight left-ward shift of the irradiated experimental data, and a significant increase in one model parameter k (no change in c), **Figure 2**.

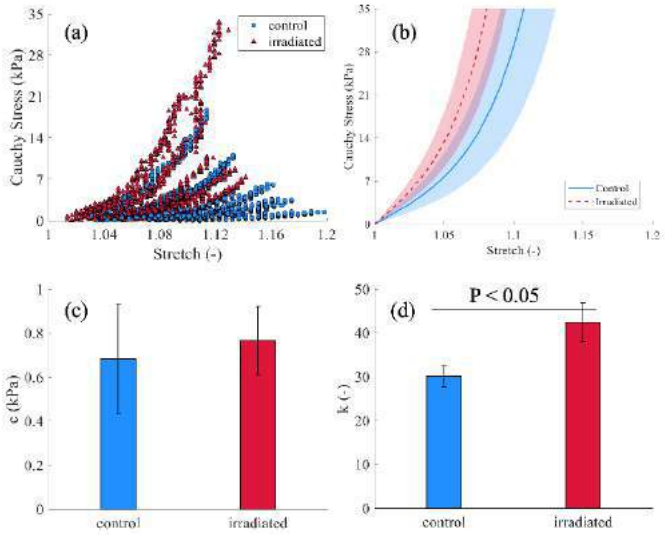

Figure 2. Summary of mechanical measurements. (a) Raw data from all samples, (b) Simulated stretch-stress curves from constitutive model, (c) and (d) constitutive model parameters. Error bars and shaded regions represent standard error.

Following the 24-week time point, we will be able to determine any differences between control and irradiated bladders, but also differences related to either recovery or progression of radiation cystitis.

DISCUSSION

While the radiation was well-tolerated by the mice, there is evidence of the development of radiation cystitis through the diminished bladder capacity, as indicated by the micturition study. The decrease in bladder capacity experienced by these mice is also common in humans who have been diagnosed with radiation cystitis [1]. Though previous studies on this model of radiation cystitis have shown increase collagen area fraction of the bladder [3], our histological analyses are ongoing and we do not yet have values to report.

Following development of radiation cystitis, the extracellular matrices of the irradiated bladders experienced significant stiffening, as was evident in the increased value of parameter k of the constitutive model. Stiffening of the bladder wall of this kind can increase pressure in the bladder, which could pose a threat to renal health and become quite dangerous to radiation cystitis patients. Therefore, it is crucial to understand the changes in bladder wall mechanics and extracellular matrix remodeling related to this disease. To our knowledge, no previous studies have reported changes to the mechanical behavior of the urinary bladder following development of radiation cystitis.

MODELING THE HUMAN LENS CAPSULE WITH IMPLANTED ACCOMMODATIVE INTRACOULAR LENS

Kurt A. Ameku and Ryan M. Pedrigi

Mechanical and Materials Engineering
University of Nebraska-Lincoln
Lincoln, NE, USA

INTRODUCTION

Accommodation is a purely mechanical process of the ocular lens, where the lens changes shape to allow a change in focus from distant to near vision. The prevailing theory behind accommodation is that proposed by Helmholtz [1], who suggested that the accommodated state is achieved through contraction of the ciliary body and release of tension in the zonules that connect it with the lens. In youth, the lens can change the power of the eye by up to 14 D, but this ability declines with age in the development of presbyopia, leaving almost no accommodative ability by 55 years of age. Since presbyopia effects nearly everyone, it is an important problem, yet there are no reliable interventional strategies for its restoration.

A promising approach is replacement of the native lens fibers with an intraocular lens (IOL) that can accommodate (AIOL). Currently, restoration of accommodative ability through implantation of an AIOL has low efficacy—on average, AIOLs only restore ~2.5 D of accommodative power [2] and they suffer from substantially increased rates of visually-debilitating capsule fibrosis mediated by inhabiting lens epithelial cells. Such problems make them questionable for implantation during cataract surgery and a non-option for correction of presbyopia (i.e., the risks far outweigh the benefits).

Improving the efficacy of AIOL designs requires computational tools that can predict their interaction with the remnant accommodative apparatus (i.e., the remnant lens capsule, powered by the attached zonules and ciliary muscle) and assess changes to the homeostatic mechanical environment, which may be an important driver of errant lens epithelial cell behaviors after surgery. Numerous studies have examined the native accommodative apparatus, wherein models were typically 2-D, employed linear elastic material properties, and neglected capsule pre-strain in the accommodated state. We recently developed the first finite element model of the remnant lens capsule with implanted IOL, which employed a fully 3-D approach and the Holzapfel anisotropic hyperelastic material model for the lens capsule. Herein, we extended this model to evaluate the efficacy of an implanted AIOL through comparison to a native lens model and reported data.

METHODS

Material Properties. The lens capsule exhibits nonlinear elastic mechanical behavior with regional variations in anisotropy. To model these complexities, we employed the Holzapfel anisotropic hyperelastic constitutive model, the parameters of which were derived from calibration to our group's previously reported inflation data [3] and other previously reported uniaxial stretch data [4]. Material parameters were assessed as a function of meridional position on the lens capsule and prescribed on an element-to-element basis in the finite element model. The lens capsule was assigned a density of 1.05×10^{-3} g/mm^3 and assumed to be incompressible. The crystalline lens was modeled as two separate linearly elastic sections, an inner nucleus and an outer cortex. Both sections were assigned a Poisson's ratio of 0.49. The nucleus was assigned a Young's Modulus of 3 kPa, while the cortex was assigned a Young's Modulus of 3.7 kPa. The AIOL was modeled after a dual-optic Synchrony IOL with a silicone composition and assigned a Poisson's ratio of 0.48 and Young's Modulus of 25.5 MPa.

Finite Element Analysis. All finite element models were developed in Abaqus Standard 2019. C3D8H 3-D continuum hybrid elements were used to model the AIOL and crystalline lens, while S4R shell elements were used to model the lens capsule. The native lens model was simulated in three steps, one to inflate the capsule until the lens was completely contained within it, a second step to release all loads on the capsule so it contacts the lens and achieves the fully

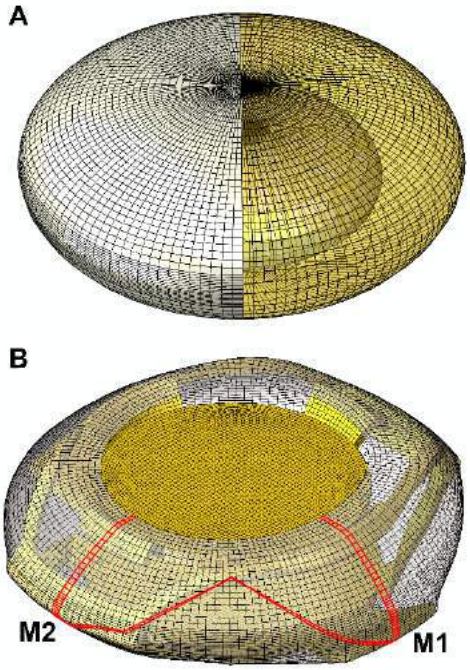

Figure 1: Finite element models of the (A) native lens in the fully accommodated state with the capsule visible on the left and the lens cortex and nucleus visible on the right, and (B) the post-surgical lens capsule with an implanted accommodative IOL in the fully accommodated state with highlighted meridians (M1 and M2) used for radius measurements.

accommodated state (Figure 2A), and a third step to introduce a zonular traction at the equatorial region of the capsule to achieve the fully disaccommodated state (Figure 2B). The post-surgical model was simulated in four steps, one to compress the AIOL and inflate the lens capsule so the whole AIOL was contained within the capsule, a second step to allow the AIOL to unfurl while the capsule was held in place, a third step to release all loads on the capsule to achieve the fully accommodated state (Figure 2C), and the final step to introduce a zonular traction to model the fully disaccommodated state (Figure 2D).

Outputs. Predictions of radius and total thickness were evaluated for the native lens and AIOL models in the fully accommodated and disaccommodated states. Comparisons were also made to the literature.

RESULTS

The model of the native lens *in situ* demonstrated changes in radius and thickness from the accommodated to the disaccommodated state that were comparable to previously reported MRI measurements on 45-year-old human lenses *in vivo*. The radius of the model lens in the fully accommodated state was 4.51 mm and the radius in the fully disaccommodated state was 4.65 mm. These predicted values are similar to empirical values of 4.49 and 4.60 mm, respectively [5]. Likewise, the total thickness of the lens model was 4.14 mm and 4.07 mm in the accommodated and disaccommodated states, respectively, which were similar to empirical values of 4.17 mm and 3.99 mm, respectively [6].

The model of the post-surgical lens capsule with an implanted AIOL demonstrated a significantly different geometry in terms of radius and thickness. Because of the non-axisymmetric design of the AIOL, radius values were measured along two axes where significant contact was made between the capsule and AIOL, labeled M1 and M2 (Figure 1B). In the fully accommodated state, the M1 radius was 4.76 mm, the M2 radius was 4.93 mm, and the total thickness was 2.82 mm. In the

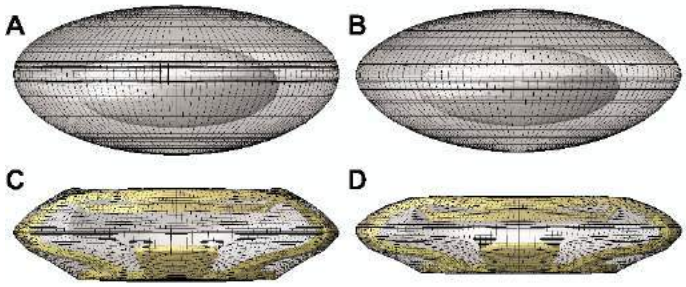

Figure 2: Finite element models of the native lens in the (A) fully accommodated and (B) fully disaccommodated state and the post-surgical lens capsule in the (C) fully accommodated and (D) fully disaccommodated state.

disaccommodated state, the M1 radius was 4.91 mm, the M2 radius was 4.99 mm, and the total thickness was 2.37 mm. This thickness of the AIOL is reasonably close to its intended thickness in the fully disaccommodated state of 2.2 mm [7].

DISCUSSION

Accommodation is a complex process, wherein the mechanical relationships between the ciliary muscle, zonules, and lens determine functionality. This complexity is exacerbated by continuous lens growth and stiffening throughout life, which changes these relationships and ultimately causes presbyopia. The ability to restore accommodative function with reasonable efficacy requires the ability to predict these mechanical relationships with an implanted AIOL. Without mechanical modeling, this task may be out of reach. Indeed, current AIOLs have been hindered by poor performance and the high incidence of capsule fibrosis. To our knowledge, this study reports the first model of the post-surgical lens capsule with an implanted AIOL. The disaccommodated state, which is physiologically induced by relaxation of the ciliary muscle that increases tension in the attached zonules, was incorporated into our model using a traction applied to the equatorial region of the lens capsule. We validated this approach by demonstrating that our native lens model can accurately predict changes in the geometry from the accommodated to the disaccommodated state. We then showed that this model can be extended to assess the functionality of an AIOL, which provides the groundwork for a computational tool that could aid in improving AIOL designs. Although this is an exciting starting point, there is a need for further evaluation of how reported changes in the accommodative apparatus with age, particularly the zonular attachments and ciliary muscle, may impact predicted implant efficacy. Another consideration is the errant cellular response to the procedure. We have previously hypothesized that this fibrotic response is linked to the altered mechanical environment of the lens capsule after cataract surgery. Modeling may be useful in predicting such changes, but this would require growth modeling techniques.

INTRODUCTION

Platelet adhesion to blood vessel walls in shear flow is essential in initiating the blood coagulation cascade and prompting clot formation in prosthetic cardiovascular devices and vascular disease processes. In the adhesion process, platelets undergo complex and rapid receptor-ligand binding such as bond association and breakage. Experimental methods have been improved through enhancing the μm-length and ms-time scale results. We have developed a combined Dissipative Particle Dynamics (DPD) - Coarse Grained Molecular Dynamics (CGMD) multiscale model to depict the platelet's biophysical properties at the cellular scales coupled with macroscopic flows, thus predicting platelet motion under flow conditions.[1] However, sparse and noisy raw image data continues to limit the utility of in vitro measurements in validating such computational models. Accurate biological image analysis coupled with rapidly maturing machine learning techniques enable better identification and registration of platelet morphological changes, which can then be rapidly applied in development and validation of platelet multiscale models.

In this study, we apply a semi-unsupervised learning system (SULS), trained and fine-tuned with shear-based in vitro platelet morphological changes, to overcome the major challenges of moving platelet image analysis, including segmentation, in obtaining high-quality outputs without relying heavily on large volume, high velocity, diverse, and hard-to-produce learnable morphological data. This machine learning (ML)-guided approach was applied to flowing adult and cord platelets to explore whether adhesion dynamics is age-specific and dependent on intracellular calcium. We then adapt a DPD-CGMD deformable platelet model to describe flipping and adhesion of platelets via the GPIbα-von Willebrand factor (vWF) bond under physiological flow conditions.

METHODS

Gel-filtered platelets were prepared from blood drawn from consenting healthy adult volunteers, or umbilical cord blood obtained from neonates whose mothers underwent Caesarean sections, under Stony Brook IRB-approved protocol[2], diluted to 150,000/μl and perfused through 100 μm×1 mm microchannels (μ-Slide VI$^{0.1}$ Luer, ibidi USA, Inc., Madison, WI) pre-coated with 100 μg/ml vWF using a syringe pump (Fig. 1a). Platelets were exposed to a wall shear stress of 30 dyne/cm^2. Adhesion events, defined as platelets flipping or sliding on the vWF-coated surface (Fig. 1), were observed at 100× magnification on a DIC microscope (Ti-E, Nikon, Melville, NY) at 1000 fps (Zyla, Andor Technology Ltd., Belfast, UK). To study the role of intracellular Ca2+ on adhesion, platelets were re pre-treated with 20 μM BAPTA-AM at 37°C for 30 min prior to adhesion experiments.

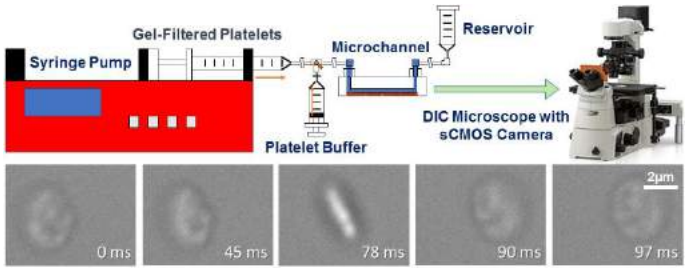

Figure 1: (a) Set-up for adhesion experiments. b) Sequential imaging of platelet adhesion and flipping under flow.

We designed and trained a SULS to extract and classify platelet morphological features from captured images. We selected six agent networks (A-nets) with pre-trained weights for predicting platelet boundaries. A multi-model fusion policy network (P-net) was used to

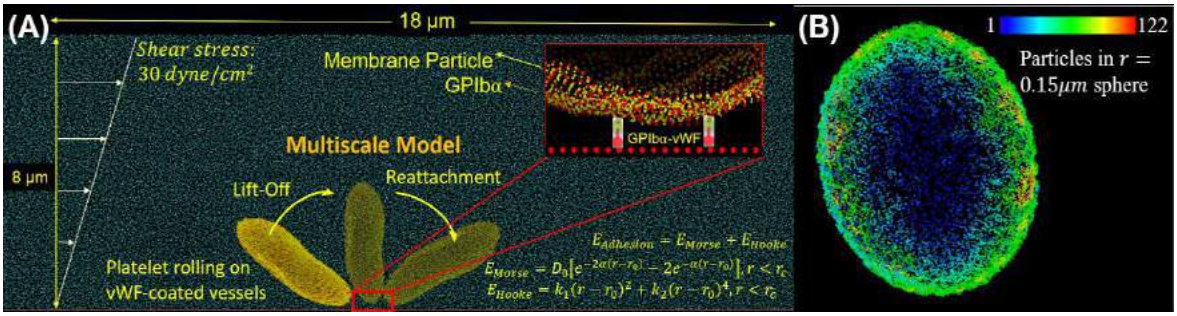

Figure 2. (A) DPD-CGMD multiscale adhesion model schematic. (B) Redistribution of GPIbα receptors.

refine the A-net coarse predictions. Finally, we trained a CNN-based reward network that takes segmentation results from its preceding P-net to produce a scalar score as a quantified indicator for platelet segmentation quality. In vitro platelet adhesion images segmented by the SULS yielded a time series of 2D geometrical data points, which are then input into a mathematical model to calculate platelet major and minor diameters, cross-sectional area, thickness, as well as the platelets' rolling direction. Two periods, Ω_1 and Ω_2, characterizing lift-off and reattachment to the vWF surface during platelet flipping, respectively, were defined. Our observations were compared to models describing such behavior under flow: Jeffery's orbit for (1) rigid ellipsoids and (2) with correction for wall effect.[3] We improved this model by adapting the constant coefficient $\boldsymbol{C}$ as a function of C_1 and C_2, representing the lift-off and reattachment periods, respectively. Constant coefficients within and between adult and cord populations were compared using two-sample t-tests.

We adapted our deformable CGMD multiscale platelet model[1] to describe flipping over vWF in a channel with DPD particles at 30 dyne/cm^2 (Fig. 2A). The platelet's bilayer membrane has a total of 67,004 particles, with 16,751 particles designated as GPIbα receptors, with a density of 585 /μm^2. The vWF, with 506/μm^2 density, is fixed on the blood vessel wall, binds to a platelet GPIbα receptor, and initiates platelet adhesion. The force field between the platelet GPIbα receptor and the vWF ligand is described by a hybrid force field combing Morse and Hooke potentials[4]:

$$E_{Adhesion} = E_{Morse} + E_{Hooke} \quad (1)$$

$$E_{Morse} = D_0\left(e^{-2\alpha(r_{ij}-r_0)} - 2e^{-\alpha(r_{ij}-r_0)}\right) \quad (2)$$

$$E_{Hooke} = k_1(r-r_b)^2 + k_2(r-r_b)^4 \quad (3)$$

We validated our numerical method by correlating simulations and model predictions with in vitro results. In our modeling, we split a whole rotation of an adhered platelet into two periods, wherein disassociation of the GPIbα-vWF bonds in Ω_1 is mimicked and GPIbα-vWF bonds form in Ω_2 as the platelet re-attaches to the vWF-coated wall. In period Ω_1, we adjust the adhesive coefficients of the model to correlate with in vitro measurements. In period Ω_2, we tune the force relaxation distance.

RESULTS

Platelet flipping dynamics at 30 dyne/cm^2 was analyzed from in vitro data using SULS for 2D image segmentation, followed by 3D ellipsoidal reconstruction and calculation of platelet flipping motion. Fig. 3 shows the individual platelet rotation angles for adult (A) and cord (B) platelets, compared with mean rotation angles fit to our modified two-constant Jeffery orbit with constant correction for wall effect. Our observations confirmed two asymmetrical periods, Ω_1 and Ω_2, defining the lift-off and reattachment phases of flipping, for both adult and cord platelets. Cord platelets (C_1=66.81±7.72, C_2=55.54±5.98) flip non-significantly faster than adult platelets (C_1= 70.47±3.54, C_2=59.37±3.23, p>0.05). However, Ω_1 is significantly longer than Ω_2 for both adult and cord platelets (p<0.05). Chelating intracellular calcium in cord platelets with 20 μM BAPTA-AM further reduced these constants (C_1=46.67±20.10, C_2=36.27±11.40), with a corresponding 1.16-fold increase in peak rotational speed (Fig. 3C).

Our initial CGMD-DPD adhesion model indicates that k_1 = 60 and k_2 = 50 can reproduce adult platelet dynamics at 30 dyne/cm^2 prior to GPIbα-vWF breakage during Ω_1. We modified the GPIbα receptor distribution in our CGMD model based on the curvature of the platelet (Fig. 2B), and ongoing simulations are evaluating the effect of this redistribution on GPIbα-vWF bond numbers, forces, and platelet-vWF contact area during both Ω_1 and Ω_2.

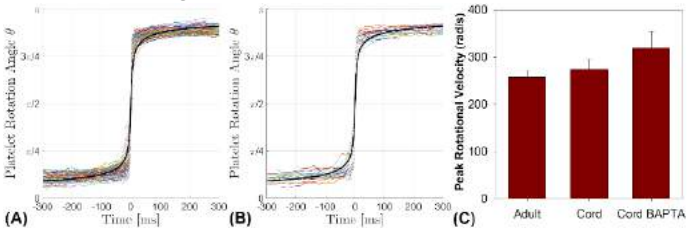

Figure 3. (A) Adult (n=70) and (B) cord (n=21) platelet rotation during adhesion. (C) Peak rotational velocities for adult, cord, and 20 μM BAPTA-AM-treated cord platelets (n=3).

DISCUSSION

We successfully adapted a ML-guided framework that integrates SULS with high-framerate and resolution DIC microscopy for accurate segmentation of flowing and flipping platelets undergoing adhesion. This method provides a critical connection between our experiments and multiscale platelet adhesion models by anticipating dynamics that cannot be captured in vitro. We were able to confirm the heterogeneity of platelet motion during initial adhesion, which is present for platelets from both adult and umbilical cord blood. Furthermore, we show that cord platelets potentially flip faster on vWF-coated surfaces, a phenomenon that is dependent on intracellular calcium. Ongoing multiscale simulations are using our ML-guided segmented platelet images as the ground truth, and we are studying the effect of GPIbα redistribution on flow-mediated adhesion dynamics on vWF. In future studies, the SULS framework will be extended to synthesize large-volume data to build a comprehensive database which can be used to identify physiologically significant platelet dynamics in activation, aggregation, and adhesion. We expect our approach to be adopted by other fields to rapidly and objectively quantify dynamic morphological changes from large datasets.

INTRODUCTION

The optic nerve head (ONH) in the posterior eye experiences a complex and dynamic biomechanical environment under both physiological and pathological conditions. The ONH is the site of remodeling and/or retinal ganglion cell axon loss in several ocular pathologies, including glaucoma, idiopathic intracranial hypertension (IIH), nonarteritic anterior ischemic optic neuropathy (NAION), and spaceflight-associated neuro-ocular syndrome (SANS) [1,2,3,4]. These pathological conditions are often related to changes in mechanical loads, namely intraocular pressure (IOP), intracranial pressure (ICP), or choroidal volume. However, it is poorly understood how these mechanical loads influence deformation of individual tissue regions within the ONH. Further, it is known that ostensibly pathological loads do not invariably lead to clinical pathology. For example, not all subjects with elevated IOP (30 mmHg) develop glaucoma. This indicates that, even at pathological loading levels, there is likely a range of ONH deformations that lie within a physiological range, possibly due to the natural variability in tissue material properties.

Here, we use finite element modeling to study how physiological and pathophysiological levels of IOP, ICP, and choroidal swelling influence ONH deformation, with specific focus on understanding how variation in tissue material properties lead to variations in ONH deformation.

METHODS

We used our existing geometric model of the eye and finite element approach [5]. In brief, our posterior eye model includes the sclera, peripapillary sclera, annular ring, pia mater, dura mater, laminar cribrosa, prelaminar neural tissue (PLNT), choroid, Bruch's membrane, and optic nerve (Fig 1). The pia mater, dura mater and optic nerve were extended posteriorly 10 mm from the ONH. We also included a single central retinal vessel to approximate the effects of mean arterial blood pressure. We incorporated an anatomically realistic choroid based on OCT scans and average choroidal thickness measurements from the literature at specific distances from the ONH [6].

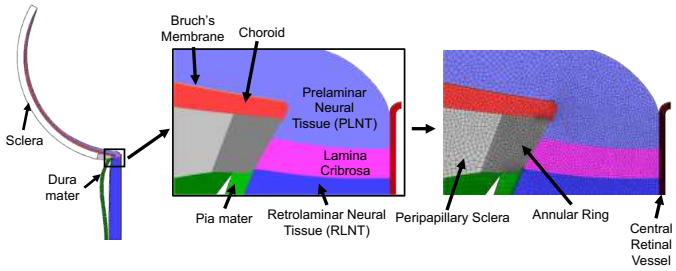

Figure 1: Geometric model of the entire posterior eye (left), zoom of the ONH (center) highlighting each tissue component in the model, and meshed geometry (right).

The model was meshed using Gmsh, and FEBio was used as the finite element solver [7,8]. We assumed axisymmetry, implemented (due to constraints of the FEBio solver) by using a 3° wedge about an axis of symmetry passing though the central retinal vessel. The PLNT, lamina cribrosa, optic nerve, central retinal vessel, and Bruch's membrane were modeled as isotropic linear-elastic. The choroid was treated as a mixture material consisting of a linear-elastic solid capable of swelling based on Donnan equilibrium. This simple approach allowed us to control the degree of choroidal volume change (e.g. swelling) without requiring us to account for the complex geometry of the vascular bed. All other tissues were modeled as neo-Hookean solids with embedded collagen fibers, distributed according to a von Mises distribution. The material properties for each tissue (e.g. Young's

modulus, Poisson ratio, coefficients for collagen fibers) were based on previously reported values [5].

Our baseline condition represented an individual in the upright position: IOP=15 mmHg, ICP=0 mmHg, mean arterial pressure=57 mmHg, and no choroidal swelling (0 uL). We then applied physiological loading conditions including choroidal swelling occurring over a cardiac cycle (ΔV = 2.2 and 14.2 uL), IOP=19 mmHg, which represents normal diurnal variation (ΔIOP = 4 mmHg), and an ICP=10 mmHg, which represents the ICP in a supine position [4,9]. We also examined supra-physiologic, or "pathologic", loading conditions including choroidal swelling (ΔV = 32 and 50 uL), Elevated IOP (30 mmHg), and Elevated ICP (20 mmHg) [4,5,6]. Variation in the tissue material properties at each loading condition were based on an established approach [5,9]. Our outcome measures were the peak 1st and 3rd principal strains (95th percentile and 5th percentile) in the PLNT, lamina cribrosa, and retrolaminar neural tissue (RLNT) relative to our baseline condition.

RESULTS

Peak tensile and compressive strains changed substantially as tissue material properties were varied under physiological and supra-physiological loading conditions (Fig 2 & Fig 3). Under supra-physiological, or pathological, conditions there was a wider range of strains relative to those expected to occur due to physiological choroidal swelling, IOP and ICP

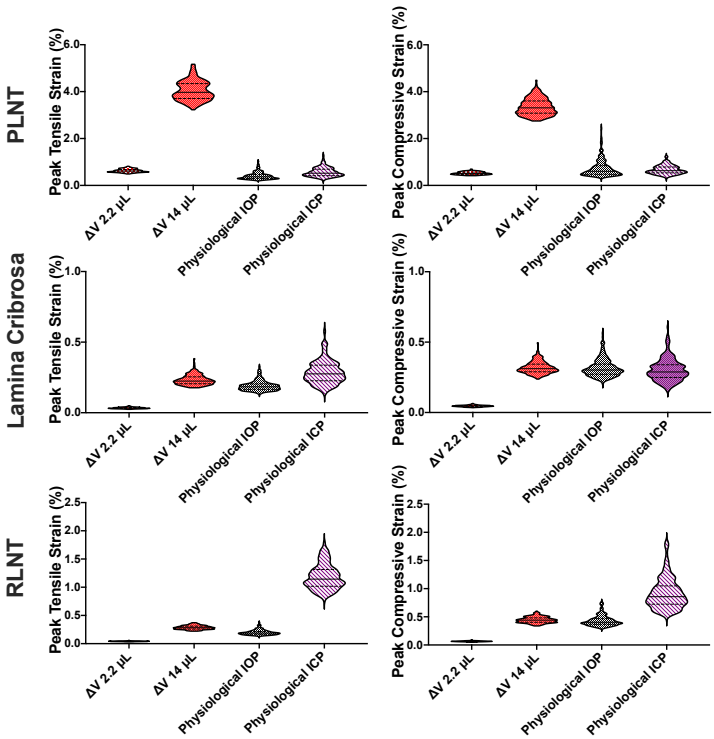

Figure 2: Violin plots of the peak tensile (left) and compressive (right) strains estimated to occur at each physiological condition due to variations in material properties (200 simulations per loading condition). All strain distributions were significantly different within each tissue region (p<0.001).

In the PLNT, median peak strains and the range of peak strains caused by choroidal swelling were significantly greater than those caused by IOP or ICP elevation. Within the lamina cribrosa, elevated IOP caused the highest compressive peak strains; however, choroidal swelling of 50 uL lead to analogous levels of peak tensile strains. Elevated ICP caused major changes in the peak strains in the RLNT.

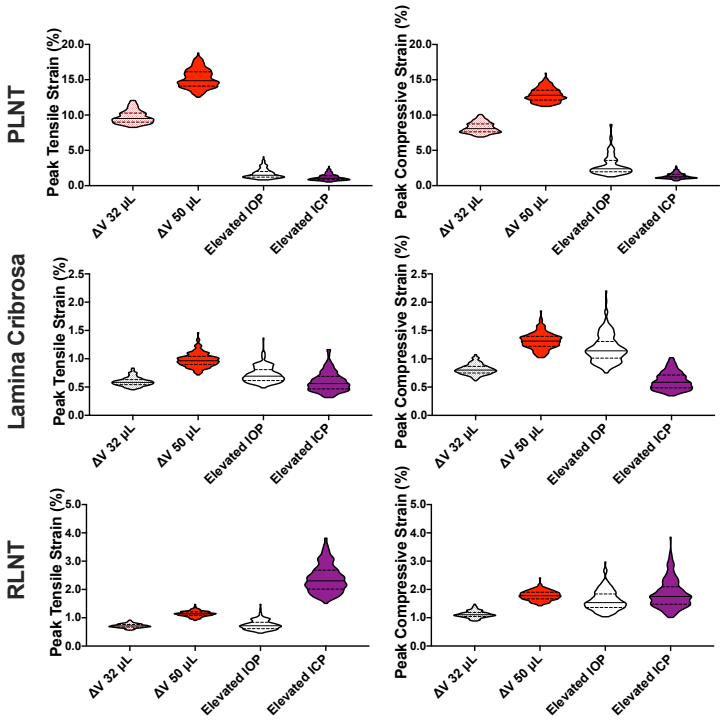

Figure 3: Violin plots of the peak tensile (left) and compressive (right) strains estimated to occur at each supra-physiological condition due to variations in material properties (200 simulations per loading condition). All strain distributions were significantly different within each tissue region (p<0.001).

DISCUSSION

This work is consistent with the hypothesis that certain tissue biomechanical material properties are risk factors for developing ocular pathology, even under physiological (normal) loads. Further, the influence of choroidal swelling on ONH biomechanics is likely underappreciated and deserves further study. While these results are limited to consideration of acute effects, we expect that chronic loading may activate local mechanosensitive cells and result in tissue remodeling.

POST-STRETCH RECOVERY OF VASCULAR SMOOTH MUSCLE CELLS IS STRAIN RATE DEPENDENT

Samuel F. Boland (1), Patrick W. Alford (1)

(1) Department of Biomedical Engineering
University of Minnesota – Twin Cities
Minneapolis, MN, USA

INTRODUCTION

During a traumatic brain injury (TBI) event the cerebral vasculature can experience strain rates of up to 1000 s^{-1}. Vascular smooth muscle cells (VSMCs), which encircle blood vessels and modulate blood flow through the cerebral vasculature, experience contractile deficiencies and phenotypic changes in response to mechanical loading characteristic of TBI.[1] Loss of VSMC function may contribute to the development of neurodegenerative diseases such as Alzheimer's disease.[2] Though VSMC function and gene expression have previously been linked to applied stretch[3,4], our understanding of VSMC response to rate of mechanical injury is still fundamentally lacking. Here, we characterize how physiological and trauma-like strain rate loading modifies the contractile properties of VSMCs using traction force microscopy (TFM) and cellular micro-biaxial stretching (CμBS).

METHODS

Substrate Fabrication and Cell Culture. Polyacrylimide (PA) gels of 13.5 kPa stiffness doped with fluorescent microspheres were synthesized onto PDMS membranes using previously described methods.[3] A layer of patterned 32 x 128 μm^2 fibronectin islands was stamped onto the top surface of the PA gel facilitate cell adhesion to the substrate and control cell area. Human umbilical artery VSMCs (Lonza) between passages 5-7 were seeded onto the gel constructs, after which they adhered to the patterned fibronectin. The VSMCs were cultured overnight in supplemented Medium-199 (Gibco) and incubated at 37 °C and 5% CO_2. 24 hours before imaging, the cell culture medium was replaced with a supplemented growth serum-free Medium-199 to induce a contractile phenotype in the cells.

Imaging and Strain Application. The constructs were mounted in a custom-designed CμBS apparatus and the elastomer membranes were stretched to 15% strain at rates of 0.025, 0.1, or 1.0 mm/s (**Fig. 1A**). Following stretch, the constructs were imaged at 40X using a confocal microscope to obtain traction images. VSMCs were imaged once per second in a time-lapse, with the stretch time and imaging time totaling 5 minutes for each condition. For example, for the 0.025 mm/s case, the time to stretch to 15% strain is 2 minutes and cells are imaged for 3 minutes after 15% strain is achieved. Brightfield images were taken of VSMCs at the first timepoint and fluorescent images were taken of the respective underlying bead layer in the PA gel at every timepoint. Constructs were then returned to 0% strain and the same imaging protocol was performed. Three cycles of stretch were performed on each construct. The cells were then lysed with SDS and

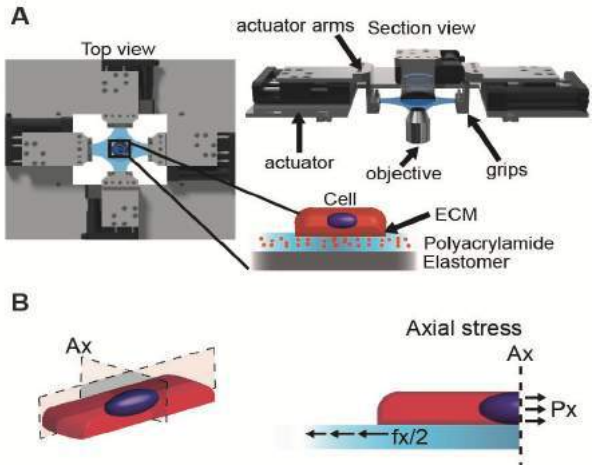

Figure 1: **A**. Schematic of CμBS apparatus. **B**. Calculation of axial PK1 stresses in a single cell. Figure adapted from Win et al.[3]

the bead layer of the gel was imaged again at the location of each cell at 0% and 15% strain. The fluorescent images of the gel layers with the adhered cells were paired with the respective images of the gels without the cells to perform traction calculations.

Traction Calculation. Displacement of the beads due to cellular contraction was tracked and measured using a particle image velocimetry (PIV) ImageJ plugin between paired images with and without the adhered VSMCs.[5] Using the displacement data with the material properties of the PA gel, traction stress vectors throughout the area occupied by the cell were calculated using an unconstrained Fourier transform traction cytometry (FTTC) ImageJ plugin with a filtering regularization factor of 1E-9.[6] Each vector in a specified region of the image was represented by

$$\boldsymbol{T^n} = {T_x}^n \boldsymbol{e_x} + {T_y}^n \boldsymbol{e_y} \quad (1)$$

in which $\boldsymbol{e_x}$ and $\boldsymbol{e_y}$ are the unit vectors along the x and y directions, respectively. From the traction vector field, total force vectors $\boldsymbol{f^n}$ were calculated by

$$\boldsymbol{f^n} = -{T_x}^n a^n \boldsymbol{e_x} - {T_y}^n a^n \boldsymbol{e_y} \quad (2)$$

in which n is the discrete surface and a is the area of the surface. Total force across the cell was calculated by

$$2f_i = \sum_n \frac{{f_i}^n {r_i}^n}{|{r_i}^n|} \quad (3)$$

where r_i is the x or y component of the position vector r^n that maps the surface to the center of the cell such that

$$\boldsymbol{r^n} = {r_x}^n \boldsymbol{e_x} + {r_y}^n \boldsymbol{e_y} \quad (4)$$

From the total force components f_i, x and y components of the First Piola-Kirchoff (PK1) stress P_i of the cell was calculated by

$$P_i = \frac{f_i}{A_i} \quad (5)$$

in which A_i is the axial undeformed cross-sectional area of the patterned VSMC (**Fig. 1B**).

RESULTS

Single cell stress relaxation experiments were performed to investigate how rate of strain impacts VSMC mechanical response immediately following stretch. Representative bright field images and stress maps are shown for a cell stretched at 0.1 s^{-1} for five time points (**Fig. 2A**). Cells were strained according to the protocol described in the methods (**Fig. 2B**).

For cells exposed to a step-change in strain, post-stretch mechanics depended on strain rate during stretch (**Fig. 2C**). Cells that were stretched to 15% strain at a higher rate of 1 s^{-1} demonstrated a comparatively low stress immediately following stretch. Stress decayed exponentially to the pre-stretch value. Cells that were stretched to 15% strain at a lower rate of 0.001 s^{-1} demonstrated a comparatively higher stress immediately after stretch. Stress decayed to a lower value but did not approach the pre-stretch value and remained higher than the stress relaxation plots for faster strain rates. Following compression back to the original configuration, stress recovery behavior was nearly identical for all cells regardless of strain rate. This pattern repeated with increasing cycles.

DISCUSSION

Our results indicate that VSMC stress relaxation behavior depends on strain rate. We found that VSMCs stretched at a higher strain rate exhibit consistently lower contraction stress than cells stretched at a lower strain rate. This implies a strain rate dependency in VSMC stress relaxation that is not captured in conventional models of viscoelasticity. In upcoming experiments, we will propose a new model to more accurately capture VSMC stress relaxation following stretch at high strain rates.

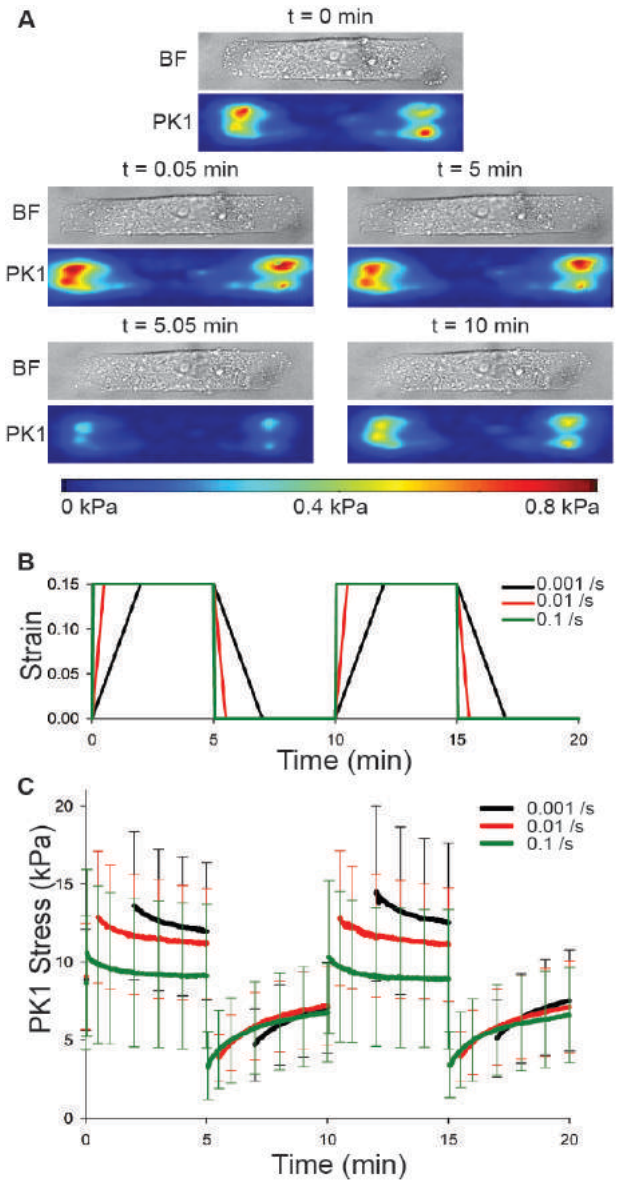

Figure 2: A. Bright field images of VSMC stretched at 0.1 s^{-1} with corresponding PK1 stress map for five time points: t=0 min (prior to stretch), t=0.05 min (immediately after stretch), t=5 min (end of stretched period), t=5.05 min (immediately after compression to original configuration), and t=10 min (end of cycle).. **B.** Strain protocol for stretching and time-lapse periods. **C.** PK1 stress relaxation time lapse for VSMCs stretched to 15% strain at 3 strain rates. n = 18, 16, and 22 for strain rates 0.001, 0.01, and 1.0 s^{-1}, respectively.

INTRODUCTION

Upon short-pulsed laser irradiation, plasmonic metallic nanoparticles convert light energy into thermal energy and heat up surrounding medium. This sudden heating leads to the thermal expansion in medium and pressure transients known as photoacoustic (PA) effect. PA effect has been developed as imaging tools for noninvasive diagnosis of disease. PA imaging can reach deeper into tissue than optical imaging techniques because light is only used for generating heat not for imaging. Comapred with conventional PA agents such as dye molecules, plasmonic nanoparticles have tunable plasmon resonance and good photostablity. These unique properties make plasmonic nanoparticles be promising contrast agents for PA imaging. Furthermore, the surface engineering of plasmonic nanoparticles, such as coating with polyethylene glycol [1], polymers [2], and inorganic materials [3] can provide advantages, including improved biocompatibility, increased thermal and colloidal stability, and surface functionalization.

Among many coating materials, the silica coating on gold nanoparticles has demonstrated good potential for PA signal enhancemnet [4,5]. Although experimental results were promising, the mechanism of the PA enhancement by thin silica coating of gold nanoparticles is still far from completing. One hypothesize is that silica coatings can change the heat transfer process on the interface of nanoparticle and medium resulting in PA improvement. Although qualitivily describing the experimental observation, this theory remains unresolved and lacks detail. Here, for the first time, we provide a theoretical model to explain how the interfacial heat transfer affects the PA generation with the silica coating in presence. We use experimental method and numerical simulation to investigate two effects on photoacoustic enhancement of silica coating on gold nanosphere, namely the particle structure and the laser duration.

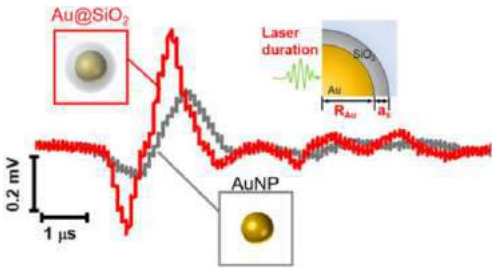

Figure 1. Representative photoacoustic (PA) signal of the silica coated gold nanoparticle (Au@SiO_2) and the bare gold nanoparticle (AuNP). Two important aspects are investigated in this study including laser duration (picosecond vs nanosecond), nanoparticle structure including gold core size (R_{Au}), and silica shell thickness (a_s)

METHOD

Synthesis of nanoparticle: Gold nanoparticles (AuNPs, 15 nm diameter) were synthesized by Turkevich method [6]. AuNPs larger than 15 nm were synthesized by method previously reported [7]. Au@SiO_2 was prepared by following the procedure described by Liz-Marzán et al. [8]. The size of Au core and silica shell thickness (a_s) was determined by JEOL 1400 Transmission electron microscope (TEM).

Photoacoustic signal measurement: To measure the PA signal, samples are diluted to 0.5 OD at 532 nm and loaded in a dialysis cassette. A pulsed picosecond laser (532 nm, full width half maximum (FWHM) = 28 ps) or a pulsed nanosecond laser (532 nm, FWHM = 6 ns) was used to generate PA signal. The PA signal was detected an ultrasound transducer with the central frequency at 0.5 MHz.

Numerical simulation: The numerical simulation was conducted in COMSOL 5.3 software. The PA quantum yield ($\boldsymbol{\phi_{PA}}$) is defined as the ratio of the emitted ultrasound energy ($E_{acoustic}$) to the absorbed photon energy (E_{optic}) from a single nanoparticle and can be calculated by Eq. 1,

$$\phi_{PA} = \frac{E_{acoustic}}{E_{optic}} = \frac{\iint {}^{p^2}/_{R}\, dSdt}{\int \sigma_a I dt} \quad (1)$$

where p is acoustic pressure, R is the acoustic impedance of water, σ_a is the absorption cross section of nanoparticle and I is laser intensity. The area S encloses a large spherical volume containing the nanoparticle [9].

RESULTS

First, we experimentally investigated the effect of particle geometry and laser duration on PA generation. The silica coating is uniformly distributed on the surface of gold and has well-defined thickness (a_s, Fig. 2A). Comparing with the bare AuNP with a diameter of 15 nm, the 1.9 nm silica coating enhances the PA signal more than 100% under ps laser (Fig. 1). The PA enhancement decreases gradually with the shell thickness (Fig. 2B). Importantly, no noticeable PA enhancement by silica coating was observed under the nanosecond laser irradiation. Next, the effect of Au core size on silica coating induced PA enhancement is investigated. Strong PA enhancement can be observed from Au@SiO_2 with 30 nm and 90 nm Au core under picosecond laser. Interestingly, the PA amplification by silica coating only appears when the silica shell thickness is in a certain range. For the 15 nm gold core, the enhancement was observed within a narrow range of shell thickness from 2 ~5 nm. The range for PA enhancement is 5 ~ 10 nm and 3~20 nm for 30 nm and 90 nm Au core, respectively. In the case of 90 nm core, the range is wider than for smaller core AuNPs. The silica thickness range for the signal amplification was wider as the size of the core particle increased.

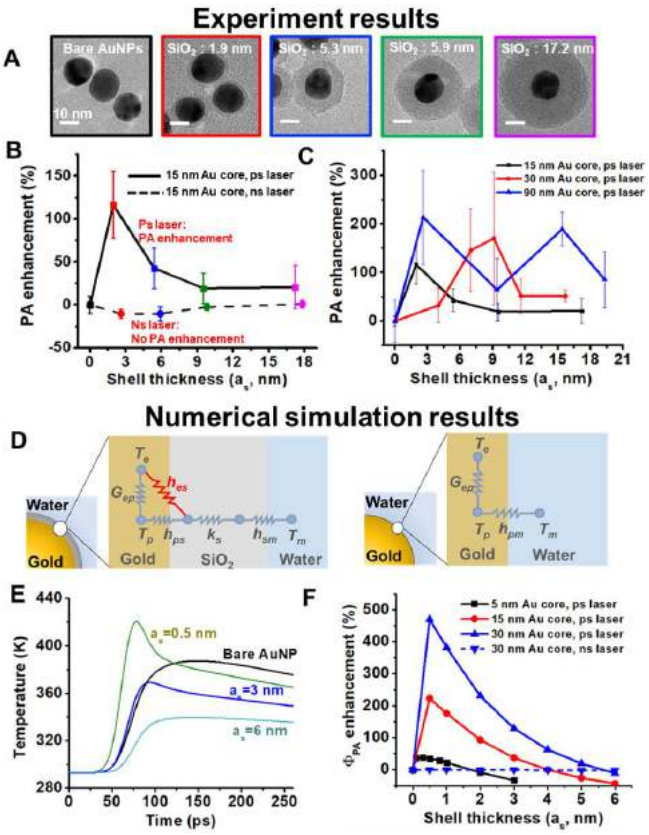

Figure 2. Experiment and numerical simulation results. (A) representative transmission electron microscopy images of bare gold nanoparticles (AuNP) and silica coated gold nanoparticles (Au@SiO_2). (B) Effect of laser duration on PA enhancement. (C) Effect of Au core size on PA enhancement. (D) Schematic of heat transfer model for Au@SiO_2 and AuNP. (E) Temperature of water on the surface of the particle with different silica shell thickness. (F) The enhancement of the PA quantum yield ($\boldsymbol{\phi_{PA}}$) for Au@SiO_2 with different gold core size and silica shell thickness. The silica coating does not enhance PA quantum yield under ns laser.

Second, we numerically investigated the effect of silica coating on PA generation of AuNPs. For Au@SiO_2, besides the phononic heat transfer between gold and silica, the energy will directly be transported from gold electrons to silica phonons (h_{es}, Fig. 2A). This additional transport mechanism enhances the heating rate of adjacent medium under the ps laser irradiation. On the other hand, the interface electron-phonon coupling is absent for the bare AuNP. Compared to the bare AuNP with a diameter of 30 nm, the temperature of water on the particle surface raises faster when a thin silica shell is in presence (a_s<3, Fig. 2E). The enhanced heating rate of water leads to a significant increase of acoustic signal. The PA enhancement is highly dependent on the particle geometry (Fig. 2F). In general, thin silica coatings enhance the PA generation more than thick silica coatings. Furthermore, large Au cores allow larger PA enhancement than smaller Au cores. Importantly, the PA enhancement by silica coating only occurs for ps laser while no obvious enhancement for ns laser. This is because that the direct energy transport through gold electrons to silica phonons is only significant under ps laser pulse in the ps time scale and can be neglected in ns time scale. The numerical simulation results agree with our experimental observations. This indicates that the electron-phonon coupling on gold and silica interface is responsible for PA enhancement by silica coating under ps laser pulse.

DISCUSSION

We systematically studied the effect of the nanoparticle structures and laser duration on photoacoustic signal generation. We observed that silica coating can enhance PA signal by 2 folds compared to bare AuNP under picosecond laser while the signal is unchanged under nanosecond laser. In addition, the core size affects the range of silica thickness range where PA signal is enhanced. These experiment results agree with our theoretical model and suggest that energy transport channel between gold electron and silica phonon contributes to PA enhancement under picosecond laser. This study is an important step towards a better understanding of PA signal generation of plasmonic nanoparticles. For the first time, a clear mechanism was provided to explain the PA enhancement by silica coating on plasmonic nanoparticles and will find many biomedical applications.

SUBSTRATE STIFFNESS REGULATES ECM GENE EXPRESSION, AND SIZE OF CELL AND NUCLEUS OF FIBROBLASTS

Brijesh Kumar Verma[1], Aritra Chatterjee[1], Paturu Kondaiah[2] and Namrata Gundiah[1,3]
1. Centre for Biosystems Science and Engineering, 2. Molecular Reproduction, Development and Genetics and 3. Mechanical Engineering,
Indian Institute of Science, Bangalore, 560012, India.

INTRODUCTION

Fibroblasts are mesenchymal in origin and among the most common cell types in the stroma [1]. They are involved in the maintenance of the extracellular matrix (ECM), and synthesize a diverse array of proteins including collagen and proteoglycans; fibronectin; laminins; metalloproteinases (MMPs), among others [2]. Adherent fibroblasts are sensitive to changes in their biochemical and mechanical milieu [3], and induce remodeling of the ECM in skin, lung, heart, kidney, liver and other organs [4,5] in response to these stimuli. Changes to the ECM layout and composition often occurs either through degradation or crosslinking of ECM proteins [6]. Pro-inflammatory cytokines and growth factors, such as Transforming growth factors (TGFs), platelet derived growth factor (PDGF) and tumor necrosis factor (TNF), regulate these behaviors [7]. Maladaptive tissue remodelling requires a switch from inflammatory to pro-fibrotic pathways, thereby triggering fibrosis[8,9]. We work on the preliminary hypothesis that variations in the underlying substrate stiffness result in morphological changes to the cell cytoskeleton and nucleus which alter gene expression levels related to ECM remodeling.

RESULTS

Fig. 1a, shows confocal images of HMF3s cells cultured on substrates of different stiffnesses. Cell areas were significantly smaller on lower substrate stiffness (10:1, 20:1 and 40:1) as compared to tissue culture dish (Fig. 1b). We also found similar observation with regards to nuclear area (Fig.1c). The expression of MMP2, Collagens 1 and III, and TGF-β1was reduced when cultured on 10:1, 20:1 and 40:1 substrate as compared to tissue culture dish. GAPDH expression served as control (Fig.1d). These data suggest that changes in cell and nuclear morphologies of HMF3s cells and ECM associated gene expressions are regulated by changes in substrate stiffness.

METHODS

Substrates of different stiffnesses were prepared by mixing silicone elastomers (Sylgard® 184, Dow Corning) with the cross-linker in different stoichiometric weight ratios of 10:1 (1.58±0.188 MPa), 20:1 (351±24 KPa) and 40:1 (41.89±4.09 KPa)[10.] Substrates were treated with plasma for 2 minutes, followed by incubation with 40 μg/ml of fibronectin (FN) for 1 hour at 37°C, and washed twice with phosphate buffer saline (PBS). Immortalized human mammary fibroblasts (HMF3s)[16], grown in DMEM media supplemented with 10 % fetal calf serum, were cultured on the substrates for 24 hours. Gene expression analysis was performed by RT-PCR. Cellular and nuclear morphologies were analyzed using confocal imaging.

DISCUSSION

Our study provides important insights on the effects of substrate stiffness in combination with changes to the overall cellular and nuclear morphologies that result in ECM associated gene expressions. These results provide useful mechanistic understanding of the ECM remodeling with substrate stiffness changes associated with tissue fibrosis. These finding may be useful in developing a pro-fibrotic molecule in mitigating and facilitating tissue repair due to injuries.

INTRODUCTION

In the past 30 years, percutaneous therapies for the treatment of congenital heart disease have advanced immensely, however, with the limited investment from industry there is a lack of devices specifically designed for the treatment of congenital heart disease in paediatric patients [1]. There is currently a clear clinical need in the area of stenting for paediatric patients, whereby currently commercially available adult stents are often required to be used off-label for paediatric patients that may lead to suboptimal outcomes [1,2]. The increasingly widespread use of CT and/or MR imaging for pre-surgical assessment, and the emergence of additive manufacturing processes such as 3D printing, could enable bespoke devices to be produced efficiently and cost effectively.

In recent years, research has been carried out into the development of 3D printed metallic stents in an attempt to overcome the disadvantages of the conventional stent manufacturing techniques where stents are laser cut from a tube [3],[4]. Additive manufacturing of metallic stents has the potential to eliminate these challenges in both production and treatment leading the way to 3D printing specialised and unique stent designs. A recent study by Demir & Previtali [3] investigated SLM of cobalt-chromium stents for cardiovascular stenting. That study outlined the need for a selective laser melted stent to be self-supporting and rules on creating such a geometry. This ensures there is no unnecessary damage to the stent in removing supports post-printing. These rules state that struts should be (i) maintained at angles greater than 45° to the horizontal, (ii) have overhangs less than 1mm, and gaps greater than 0.3mm. However, these design rules lead to restrictions in the design of stents available through additive manufacturing. Further to this, Finite Element (FE) models have been used to predict the performance of medical devices [5,7] and can be used to optimise these devices for specific patient anatomies.

The objective of this study is to demonstrate the feasibility of producing patient-specific 3D printed stents for paediatric patients with congenital vascular defects, to investigate the stent designs available through 3D printing, to assess their performance using a combination of FE modelling and experimental bench testing and design an optimised stent for a given paediatric patient.

METHODS

CT Reconstruction: Computer tomography (CT) images of the aortic arch of a paediatric patient with an aortic coarctation, necessitating the placement of a stent were obtained and used to develop 3D models of the coarctation. The aorta geometry is extracted via image segmentation using 3D Slicer [4], a skin surface of the vessel is constructed with ANSYS Spaceclaim (2019 ANSYS. Inc) and a volumetric hexahedral mesh representation of the geometry is finally generated with ANSA-BETA Pre-Processer (BETA CAE Systems, Luzern, Switzerland).

Patient-Specific Silicone Model: Preform (Formlabs Inc., MA, USA) was then used to generate a 3D printed model in elastic resin with varying thickness using a Form 2 Printer (Formlabs Inc., MA, USA). The relationship between the stiffness of the elastic resin and its thickness was investigated by printing 20 mm tubes of different thicknesses and pressurizing them to 80 mmHg and 120 mmHg using a FISO pump and pressure sensor and measuring the change in strain. This was then compared to porcine arterial tissue.

Patient-Specific Stent Design and Processing: A Simple Honeycomb (SH) and a Novel Design (ND) stent geometries were designed based on patient dimensions and design criteria for additive manufacturing based on [5]. These stents were then printed using the ReaLizer Selective Laser Melting (SLM) printer (Realizer GmbH) using Titanium powders. After printing, some of the stents were etched

to reduce the stent strut thickness and improve the surface finish. The samples were immersed into etching solution containing hydrofluoric and nitric acid ((HF: HNO3: H2O = 1:2:3) for approximately 12 minutes and then transferred into distilled water for 5 minutes and rinsed with ethanol. Half of the SH designs were etched, and all three of the ND designs were etched. The finished stent designs can be seen in Figure 2.

Stent Testing: Once printed, these stents were implanted into the patient-specific geometry and underwent an experimental crush test using an Instron 3366 (Instron., MA, USA).

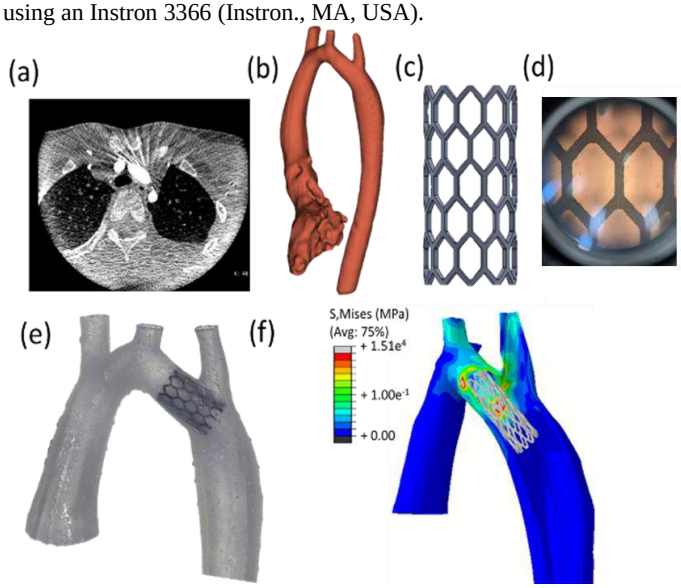

Figure 1. (a) CT scan of a paediatric patient with an aortic coarctation (b) patient-specific model of the aorta (c) STL of stent geometry (d) Stereoscopic image of SLM printed stent geometry (e) our SLM printed stent in the elastic model of the patient-specific aortic root (f) FE model of stent deployment into patient specific geometry.

FE Crush Test: Prior to the experimental crush test measurements of the strut width and thickness of each stent were taken using a stereoscopic microscope. Based on these as etched and as printed measurements the stents were recreated in Solidworks (Dassault Systemes Solidworks Corp, MA, USA). Stents were then prepared for meshing and meshed using Ansys Spaceclaim (2019 ANSYS. Inc) and ANSA BETA (BETA CAE Systems, Luzern, Switzerland) respectively. A FE model was created in ABAQUS and used to replicate the experimental crush test. Using an inverse FE approach the experimental and FE crush tests were compared to calibrate the material properties of the printed and etched stents.

Patient Specific Finite Element Model: Using the generated mesh of the patient's aortic arch from CT images an FE model was used to simulate stent deployment into an isotropic hyperelastic model of the patient specific geometry. This was achieved by crimping the stent inward radially using a cylindrical part (crimper). Hard normal contact with a coefficient of friction of 0.8 was applied between the stent and the crimper [6]. The top and bottom edges of the aortic arch were constrained using displacement boundary conditions in the longitudinal and circumferential directions. The stent was uncrimped and hard normal, frictionless contact was applied between the stent and the aorta [7]. Different stent designs pre- and post-etching were deployed into the patient specific anatomy to analyse and compare stent performance.

RESULTS

Strain measurements from pressurised printed vessels found that the elastic model of the patient-specific aorta demonstrated higher stiffness than native arteries, however, such 3D printed models are a valuable pre-surgical planning tool and offers a means of validation for FE models.

Etching stents was found to reduce the stent strut width and thickness. Alongside this, stent surface finish was improved post-etching. Furthermore, it was found that combining novel designs with etching allows for open stent designs to be printed without the need for additional supports. Such techniques can allow for a greater range of 3D printed stent designs to treat specific patient needs.

Calibration of the stent material properties found that non-etched stents had lower Young's moduli. This is attributed to the fact that increased surface roughness led to overestimation in the stent width and thickness from stereoscopic measurement therefore, led to an overestimation in the stent performance in the FE model.

The patient specific model found changes in stent design combined with etching can reduce aortic stress with minimal loss in lumen gain.

DISCUSSION

This study demonstrates the feasibility of this in-vivo imaging to product development pipeline that will enable patient-specific stents to be produced for varying anatomies to achieve optimum device performance.

INTRODUCTION

Our overarching aim is to facilitate mechanistic understanding of visceral nociception by leveraging multiscale models bridging the intra-tissue mechanics within the colorectum and mechanical neural encoding by sensory nerve endings. Mechanotransduction of colorectal distension/stretch plays a critical role in evoking visceral nociception [1]. The colorectum displays strong microstructural hierarchy through the wall thickness, consisting of two major fibrous layers: the inner mucosal-submucosal composite and the outer serosal-muscular composite. We previously conducted mechanical [2,3] and imaging [2-4] experiments to quantify the biomechanics and morphology of the colorectum. Our recent imaging study [4] revealed concentrated collagen in the submucosa relative to other distinct layers, implying that the submucosa serves a specific mechanical role. Furthermore, this mechanical heterogeneity in the colorectum determines the microscale stresses/strains around afferent endings embedded within the collagen-rich regions undergoing noxious mechanical stimuli. We previously separated the colorectal wall into inner and outer composite layers, completed mechanical testing, and fitted constitutive models assuming two layers [5]. In this study we aimed to improve model fidelity, particularly the through-thickness heterogeneity of the colorectum, via a novel three-layered model. We quantified the layer thicknesses and determined parameters for constitutive models of the mucosa and submucosa from three longitudinal locations (colonic, intermediate, and rectal), using nonlinear optimization to fit our mechanical tests [2,3]. We implemented the constitutive equations and created three-layered, 3-D finite element models using FEBio (U. of Utah) [5,6], and simulated three mechanical stimuli commonly used in experiments to study visceral nociception in colorectum *ex vivo*, i.e. circumferential stretching (C. stretch), probing, and shearing [7]. Our models capture the biomechanical heterogeneity in three distinct through-thickness layers and highlight the differential roles of sensory nerve endings in different regions of the colorectum in visceral mechanotransduction.

METHODS

Imaging and Mechanical Testing of Colorectum. We recently conducted nonlinear imaging via second harmonic generation (SHG) to quantify the thickness of each distinct through-thickness layer of mouse colorectum (colonic, intermediate, and rectal), as well as the morphology of the dispersed collagen fibers [4]. The submucosal layer had the largest collagen content with the greatest average diameter of fibers, and presented two principal orientations of alignment. Collagen fibers in muscular layers aligned with the longitudinal and circumferential muscle fibers. In contrast, the mucosa showed no principal orientation of alignment for these fibers. We also performed biaxial extension tests both on bulk composite mouse colorectum and the separated layers of inner and outer composite which provided data for constitutive modeling [2,3]. We identified residual stresses by quantifying the reference configuration of the bulk composite and the separated configurations of inner and outer composites.

Constitutive Modeling and Model Fitting. To model the layers of the colorectum we used the strain-energy function [6,8]

$$\Psi = \mu(I_1 - 3) + \int_\Omega \rho(\mathbf{M}) \frac{k_1}{2k_2}\{\exp[k_2(I_4 - 1)^2] - 1\}\mathcal{H}(I_4 - 1)\mathrm{d}\Omega\,, \quad (1)$$

where μ is the shear modulus of the matrix, $I_1 = \mathrm{tr}\,\mathbf{C}$ where $\mathbf{C}$ is the right Cauchy-Green tensor, k_1 is a stress-like material parameter, k_2 is a dimensionless parameter, $I_4 = \mathbf{M}\cdot\mathbf{CM}$, and $\rho(\mathbf{M})$ is an orientation distribution function characterizing the network of fibers $\mathbf{M}$ with $1/4\int_\Omega \rho(\mathbf{M})\mathrm{d}\Omega = 1$. For the mucosal layer in which collagen fibers showed no principal orientation, we used only the neo-Hookean portion of (1). Guided by our biomechanical and image-based data [2-4], we

established a three-layered square patch of mucosa-submucosa-muscular composite (7.0×7.0 mm^2) which we meshed with eight-node hexahedral elements [6]. To capture the kinematics of the biaxial extension test, we wrote the invariants I_1 and I_4 as

$$I_1 = \lambda_c^2 + \lambda_a^2 + \lambda_r^2 , \quad I_4 = \lambda_c^2 \cos^2\alpha + \lambda_a^2 \sin^2\alpha , \qquad (2)$$

where λ_c, λ_a, and λ_r were the measured principal stretches in the circumferential, axial, and radial directions, respectively; we identified α, representing the angle between the fiber orientation and the circumferential direction, from our SHG imaging data [4]. Consequently, we obtained four parameters (μ,k_1,k_2,α) for the submucosa and one parameter (μ) for the mucosa.

Modeling of Ex Vivo Mechanical Stimuli. We established a three-layered (mucosal, submucosal, and muscular) square patch of colorectum (8.0×8.0 mm^2) (**Fig. 1**) [7]. Specifically, we modeled mechanical stimulation from: (1) homogeneous, circumferential stretch by fixing one edge of the patch and linearly increasing the circumferential displacements, **Fig. 1(a)**; (2) perpendicular probing by applying a cylindrical probe to the mucosa surface including a sliding contact between the surfaces, **Fig. 1(b)**; and (3) mucosal stroking in shear tests by sliding a soft block along the mucosal surface, **Fig. 1(c)**. In cases 2 and 3 we pinned the colorectum flat on a silicone foundation (10.0×10.0 mm^2) by using a tied contact between the interfacing surfaces, consistent with the prior *ex vivo* experimental conditions [7]. We again meshed these models with eight-node hexahedral elements. We included residual stresses between submucosa and muscular layers in the initial configurations using the pre-stretch algorithm in FEBio [6].

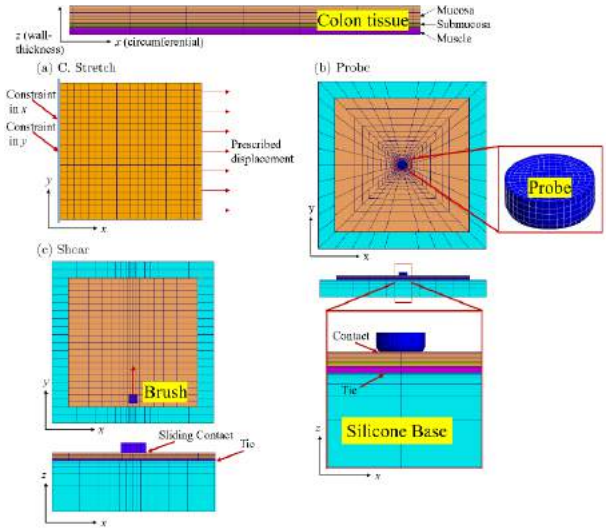

Figure 1: Finite element modeling of mechanical stimuli to the colorectum: (a) circumferential stretch, (b) probe, and (c) shear.

RESULTS

Validating the Constitutive Model. **Figure 2** presents the comparisons between the simulated biaxial extension (finite element models of bulk colorectal patch) versus the experiment data, and **Table 1** summarizes the resulting model parameters for the mucosa and the submucosa along the length of the colon. The relative error is less than 12%. In **Fig. 2**, EXP, FE, cir, and ax are abbreviations for experimental, finite element, circumferential, and axial, respectively.

Modeling of Mechanical Stimuli. **Figure 3** presents the through-thickness distributions of maximum shear stresses in response to three different mechanical stimuli, i.e. circumferential stretching, probing, and shearing. A normalized depth of 0 represents the bottom surface of the muscular layer while 1 represents the top surface of mucosa layer.

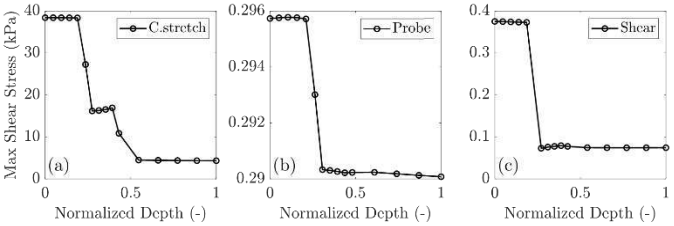

Fig. 3: Maximum shear stresses through the thickness of the colorectum: (a) circumferential stretch, (b) probe, and (c) shear.

DISCUSSION

Combining our experimental data, i.e. the collagen distributions acquired via SHG and the mechanical responses quantified with biaxial extension testing, we improved the fidelity of our computational model of the colorectum by incorporating three layers, i.e., mucosal, submucosal, and muscular layers. Our fitted model shows strong mechanical heterogeneity thought the thickness of the colorectal wall, and indicates that the relatively thin submucosa is the principal load-bearing structure within the colorectum, owing largely to the concentrated, well-aligned network of collagen. The two families of fibers form a dispersed network in the submucosa that informs the micromechanical environment therein, and which is heavily innervated by sensory nerve endings. We compared the maximum shear stresses through the thickness of the colorectum undergoing three experimental mechanical stimuli [8]. Our finite element simulations of intra-tissue stresses/strains within the three-layered colorectum will inform multiscale models exploring the local stress/strain stimuli affecting the individual afferent endings, and ultimately facilitate a mechanistic understanding of visceral nociception and pain.

CROSSLINKS AND TOUGHNESS OF GELATIN HYDROGELS FOR TISSUE ENGINEERING

Anshul Shrivastava[1], Namrata Gundiah[1]

(1) Mechanical Engineering, Indian Institute of Science, Bangalore, 560012, India

INTRODUCTION

Hydrogels are soft materials which can be engineered to mimic the mechanical properties of biological tissues. Gelatin is a promising scaffold material for tissue engineering applications for tissues such as cornea, arteries, etc[1]. Gelatin, though a soft material which is abundantly present, displays failure characteristics of brittle materials which is a severe limitation when used in tissue engineering [2]. We hypothesized that increasing the crosslinks in gelatin will increase the modulus of the gel, measured using monotonic compression, and also improve the fracture properties. Cavitation rheology is a promising method used for the local assessment of the failure behaviors of soft materials and involves the use of needles to initiate cracks of known dimensions in the gel [1][3]. Unstable bubble growth occurs when pressure inside reaches a critical value, related to the Young's modulus of the material, and the initial size of the defect which is associated with a critical pressure due to pressure drop [4]. The objective of this study is to crosslink gelatin gels and measure the failure characteristics using cavitation rheology.

METHODS

We dissolved 0.05 gm/ml of bovine gelatin Type-B powder (Sigma Aldrich, India) in distilled water at 50° C to obtain a clear solution. A 1% v/v of glutaraldehyde (Sigma Aldrich, India, 25% stock) was added as a crosslinking agent which exploits the large number of functional side groups. The uncured mixture was poured into a cylindrical mold of 16 mm diameter and 20 mm height made using polydimethylsiloxane (PDMS, Sylgard ®184, Dow Corning). Gels were cured at 4° C for 6 hours and were soaked in 0.1 M glycine solution to block additional glutaraldehyde action. Specimens were stored in distilled water overnight prior to mechanical tests [2].

The imine bonds in gelatin were crosslinked by placing the gelatin samples in 10ml of 150 mM phosphate buffer (pH = 7.4) and treated with 1% (w/v) $NaBH_4$ solution in 1 mM NaOH at 4° C. This ratio was used to give a substrate: reagent ratio of 30:1 (w/w). The reaction mixture was kept for incubation, with occasional stirring, for 1 hour and washed twice with distilled water after 1 hour to stop the action of $NaBH_4$ [5].

Monotonic compression tests were performed on a Bose Electroforce® 3200 (Bose Corp., USA) instrument equipped with two parallel compression platens. Hydrogel specimens were preloaded to 5 grams and preconditioned for 30 cycles of 10% compressive strain at 0.05Hz to obtain a repeatable material response. Following preconditioning, samples were compressed at a rate of $0.01s^{-1}$ until either the maximum displacement limit of the instrument was reached, or the gels failed catastrophically. Compressive moduli were calculated using the stress-strain data upto 4% strain [2].

Blunt needles with different gauge sizes (CML Supply) were inserted into the gel samples for the cavitation experiments. A syringe pump (model NE1000, New Era Pump Systems) with 20ml syringe was used to introduce an air bubble into the gelatin sample at the rate of 2000 μL/min. A pressure sensor (Honeywell, ASDXAVX015PGAA5) was attached to the outlet of the syringe with the help of a three-way connector, to record the pressure readings inside the cavity in gel. Real time pressure was recorded with the help of Arduino UNO board and the results viewed and analyzed using MATLAB (2020b).

RESULTS

The monotonic compression tests on gelatin gels treated with $NaBH_4$ showed stiffer mechanical response as compared to control gelatin samples that were untreated (Fig. 1a). The schematic of the cavitation rheology experiment is shown in Fig. 1(b) which was used to quantify failure of hydrogels. Fig. 1(c) shows a sequence of high speed videographs of the bubble inflation in the hydrogel which resulted in gel fracture. Variation of pressure with time inside the cavity is shown which clearly shows a sharp drop in pressure. This point occurs upon reaching a critical value of pressure due to rapid growth of the bubble which results in macroscopic rupture of the control hydrogels (Fig. 1d). Ongoing studies are aimed at characterizing the failure of cross-linked gelatin gels to assess improvement in the toughness of the materials which make them attractive for tissue engineering applications.

DISCUSSION

This study aims to provide insights on the role of collagen crosslinks on the mechanical properties of the hydrogels. We aim to use cavitation rheology experiments to assess the fracture toughness of gelatin hydrogels cross-linked using $NaBH_4$. These results will be extended to quantify the toughness of the cornea in keratoconus which is associated with the degradation and disintegration of collagen. These changes result in a progressive change in stiffness of the corneal tissue and corresponding change in the curvature of the cornea leading to progressive loss in vision. Collagen cross-linking chemicals, including riboflavin and UV treatment, will be used to alter the tissue properties in future studies. Cavitation rheology methods developed in this study will be used to quantify the efficacy of such treatment methods in altering the toughness of the corneal tissues.

ACKNOWLEDGEMENTS

We gratefully acknowledges the Department of Biotechnology (BBI2) for project support. We are thankful to Achu Byju who did the pilot cavitation experiments and high speed videography on gelatin failure reported in this study.

INTRODUCTION

The tricuspid valve (TV) has often been referred to as the *forgotten heart valve* due to the predominant research focus on the mitral valve and aortic valve within the left side of the heart. However, there has been a shift in attention towards the TV in the past 5 years, focusing primarily on advances in our current understanding of the TV pathologies and improved clinical remedies. Despite the recent advancements, little effort has been devoted to determining the appropriate strain energy density function (SEDF) for the TV leaflets. Typically, a SEDF form is first selected and then fit to available data from planar biaxial mechanical characterizations to determine the model parameters. The resulting SEDF and optimal model parameters often provide a good fit to the experimental data, but *would another SEDF form better represent the mechanical behaviors and directional coupling of the TV leaflets*? This question remains to be answered and has notable implications in predictive modeling of the TV function.

Humphrey *et al.* (1990) [1] previously outlined an experimental technique to determine an appropriate SEDF for hyperelastic transversely isotropic materials using constant invariant protocols. This theory-driven experimental framework has provided promising SEDFs for the left ventricular myocardium tissue [1], the mitral valve leaflets [2], and the jugular vein-derived valves [3]; however, it remains to be investigated for the TV leaflets. The objective of our work is, thus, to determine an appropriate SEDF for the TV leaflets using experimental data acquired from constant invariant experimental characterizations.

METHODS

Theoretical Background: We first assume the TV leaflet is a transversely isotropic material, which can be modeled by a SEDF W that is a function of the first and fourth invariants of $\mathbf{C}=\mathbf{F}^T\mathbf{F}$, i.e., $I_1 = tr\mathbf{C}$ and $I_4 = \mathbf{N}\cdot(\mathbf{CN}) = \lambda^2$, where $\mathbf{F}$ is the deformation gradient tensor, and $\mathbf{N}$ is the unit vector defining the preferred collagen fiber orientation associated with fiber stretch λ. The Cauchy stress $\boldsymbol{\sigma}$ of the material is then computed as

$$\boldsymbol{\sigma} = -p\mathbf{I} + 2W_{,1}\mathbf{B} + W_{,4}\mathbf{F}\cdot\mathbf{N}\otimes\mathbf{N}\cdot\mathbf{F}^T, \tag{1}$$

where $p=2W_{,1}(\lambda_1\lambda_2)^{-2}$ is the penalty term to enforce incompressibility (i.e., $det\mathbf{F}=1$), $\mathbf{I}$ is the identity tensor, $W_{,1}=\partial W/\partial I_1$, and $W_{,1}=\partial W/\partial I_4$. Rearranging the non-zero components of $\boldsymbol{\sigma}$ (i.e., σ_{11} and σ_{22}), we arrive at the following relationships for $W_{,1}$ and $W_{,4}$

$$W_{,1} = \frac{1}{2}\sigma_{22}\xi_2^{-1} \text{ and } W_{,4} = \frac{1}{2\lambda_1^2}\left(\sigma_{11} - \sigma_{22}\xi_1\xi_2^{-1}\right), \tag{2}$$

where $\xi_1 = \lambda_1^2 - (\lambda_1\lambda_2)^{-2}$ and $\xi_2 = \lambda_2^2 - (\lambda_1\lambda_2)^{-2}$. The relationships provided in Eq. (2) can determine $W_{,1}$ and $W_{,4}$ for any planar biaxial data with minimal shear (i.e., $F_{12}=F_{21}=0$).

Constant Invariant-Based Mechanical Characterizations: Equation 2 enables us to determine the values of $W_{,1}$ and $W_{,4}$ for any planar biaxial configuration. However, carefully designed constant invariant protocols are necessary to decouple the contributions from I_1 and I_4. If we ensure $I_4= \lambda_1^2$, constant I_4 protocols can be simply achieved by maintaining a constant value of λ_1 while λ_2 is varied. On the other hand, the complex nature of $I_1 = tr\mathbf{C} = \lambda_1 + \lambda_2 + (\lambda_1\lambda_2)^{-1}$ requires more sophisticated loading paths to maintain a constant value for I_1. For example, given an arbitrary value of λ_1 and a target value for I_1, the required value of λ_2 is

$$2\lambda_2^2 = (I_1 - \lambda_1^2) \pm \sqrt{(I_1 - \lambda_1^2)^2 - 4/\lambda_1^2}. \tag{3}$$

A similar relationship can be established for λ_1. These relationships then guide the displacement paths for the constant I_1 protocols.

Tissue Preparation and Mechanical Characterization: Ten frozen porcine hearts (n=10) were acquired from a regional tissue vendor (Animal Technologies, Inc., Tyler, TX), dethawed, and dissected to obtain the three TV leaflets. The preferred fiber orientation of the leaflet

was first quantified using our in-house polarized spatial frequency domain imaging (pSFDI) apparatus (**Fig. 1a**). Details of this system can be found in [4]. Then, an 8x8 mm specimen was dissected from the leaflet with the *x*-axis of the specimen approximately aligned with the median collagen fiber orientation determined via pSFDI analysis (**Fig. 1b**). Finally, the specimen was mounted to a commercial biaxial tester (CellScale BioTester, Canada) with an effective testing size of 6x6 mm for the subsequent characterizations (**Fig. 1c**).

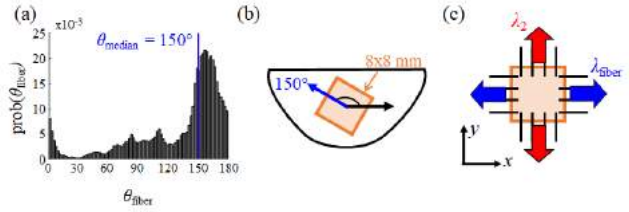

Figure 1. (a) Collagen fiber orientation distribution to inform the (b) excised specimen's orientation. (c) The TV leaflet specimen mounted to the system with the fibers aligned in the *x*-axis.

The TV leaflet specimens underwent eight cycles of force-controlled equibiaxial preconditioning to the approximate *in vivo* forces estimated using the tissue thicknesses and the Laplace's law. The post-preconditioning configurations were taken to be the stress-free reference configurations. Each specimen was then subjected to the comprehensive constant invariant protocols as outlined above. The linear actuator displacements and load cell readings were recorded at 10 Hz throughout the testing. Data from the unloading portion of the last cycle were used to compute the tissue stresses and stretches. Finally, the experimental data was fit with a 3rd-order polynomial surrogate function (**Fig. 2**) to minimize the influence of noise in the subsequent analyses.

SEDFs and Model Fitting: Two general SEDF function forms were fit to the acquired experimental data. The first was a polynomial form:

$$W = \sum_{i=0}^{n}\sum_{j=0}^{n} C_{ij}(I_1-3)^i(I_4-1)^j, \tag{4}$$

whereas the second SEDF was an exponential form

$$W = C_0(I_1-3) + \exp\left(\sum_{i=0}^{n}\sum_{j=0}^{n} C_{ij}(I_1-3)^i(I_4-1)^j\right) - 1. \tag{5}$$

In the above equations, C_0 and C_{ij} are the model parameters, and n denotes the model order. This study considered n=3 for the polynomial SEDF in Eq. (4), and n=2 and n=3 for the exponential SEDF in Eq. (5).

The SEDFs in Eq. (4) and Eq. (5) were fit to the surrogate function curves using nonlinear least squares regression. The fitting was repeated 10 times for each leaflet due to the expected large parameter covariance.

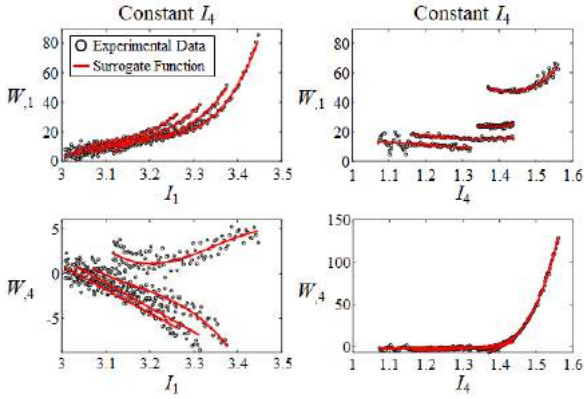

Figure 2. Representative experimental results for one TV leaflet.

Evaluation of the SEDF Forms: The optimal parameters and the corresponding residuals were analyzed to evaluate the candidate SEDFs suitability for the TV leaflets. First, the residuals (i.e., fitting errors) for the three models were compared to understand which form best fits the experimental data. Then, the Hessian **H** of the objective function was calculated using the model parameter set with the lowest residual value for each specimen. The determinant of the Hessian, more commonly known as the D-optimality criterion [5], was calculated to understand the variance of all the model parameters.

RESULTS

Comparison of the SEDF Residual Distributions: The residual values summarized in **Table 1** clearly show the differences in model performance between the polynomial SEDF in Eq. (4) and the exponential SEDF in Eq. (5). In particular, the exponential SEDFs provide noticeably lower residual values compared to the polynomial residual. However, the two exponential SEDFs (i.e., n=2 and n=3) provide similarly excellent fits to the experimental data.

Table 1. Residual values (median ± 0.5*IQR) for the three SEDFs.

Polynomial (n=3)	Exponential (n=3)	Exponential (n=2)
12.64 ± 7.14 kPa	2.99 ± 1.36 kPa	3.33 ± 1.39 kPa

Analyzing the *D*-Optimality Criterion: The *D*-optimality criterion was used to understand the variance in the determined model parameters. **Table 2** summarizes the criterion values for representative leaflet samples, considering the three SEDFs. Larger values of the *D*-optimality criterion, i.e., *det***H**, are indicative of less variance in the model parameters. Thus, it is evident that both exponential SEDFs lead to less variance in the model parameters, with the 2nd-order exponential SEDF outperforming the 3rd-order exponential SEDF.

Table 2. *D*-optimality criterion for three representative TV leaflet samples. AL: anterior leaflet, PL: posterior leaflet, SL: septal leaflet.

	Polynomial (n=3)	Exponential (n=3)	Exponential (n=2)
AL	4.55	$1.7\text{x}10^{18}$	$\mathbf{1.03\text{x}10^{24}}$
PL	4.55	$7.26\text{x}10^{8}$	$\mathbf{6.30\text{x}10^{19}}$
SL	4.55	$6.94\text{x}10^{12}$	$\mathbf{1.77\text{x}10^{22}}$

DISCUSSION

This study has provided the assessment, *first of its kind*, of candidate SEDFs for the TV leaflets using a constant invariant experimental approach. Our results highlighted that the exponential SEDF is likely more suitable than the polynomial counterpart based on the residuals; however, the 2nd- and 3rd-order exponential SEDFs provided similar performance. The commonly-adopted *D*-optimality criterion further elucidated that the 2nd-order exponential SEDF result in less variance in the determined model parameters. Ideally, the reduction in variance would provide a more robust optimization, but this remains to be further investigated. As an extension of this work, we plan to explore the capabilities of the SEDF forms considering different combinations of model parameters beyond those presented herein. The resulting SEDF will then be fit to typical planar biaxial mechanical data and used in *in-silico* computational models of the TV function.

INTRODUCTION

Endovascular grafting has steadily become a more viable option for patients with aortic aneurysm or dissection [1], [2]. Commercially available stent-grafts are stiff fabric tubes reinforced by wire mesh. Companies and researchers alike are interested in improving upon this design, but most efforts have been dedicated to adding fenestrations for placement in the juxtarenal aorta or the aortic arch [3], [4]. An often-overlooked challenge is that the high stiffness of the device reduces aortic compliance in patients already suffering the effects of high arterial stiffness [5], [6]. Aortic stiffness has independent predictive power for both cardiovascular and all-cause mortality, making it an important parameter to consider when assessing treatment options [7].

We have done proof-of-concept studies on a novel double-walled stent-graft (DWSG), using compressibility of a thin gas layer to introduce compliance [8]. The design balances increasing compliance with minimizing flow disturbance from the reduced lumen area. In the current study, optimization of the longitudinal gas layer profile was conducted to identify designs that best satisfy these competing objectives of increased compliance and minimized flow disturbance.

METHODS

The DWSG gas layer shape was optimized using a multiobjective genetic algorithm through the Platypus optimization package [9] in Python. The objective functions were evaluated with computational fluid dynamics (CFD) simulations [10]. The key components of the routine are described in the sections below.

Model Generation: Although CFD simulations were conducted in 3D, the gas layer profile was axisymmetric, defined by a series of points in the r-z plane (Fig. 1a). The relationship between gas layer volume and DWSG performance was characterized earlier [8], so the present CFD models used a rigid lumen based on the DWSG profile (Fig. 1b).

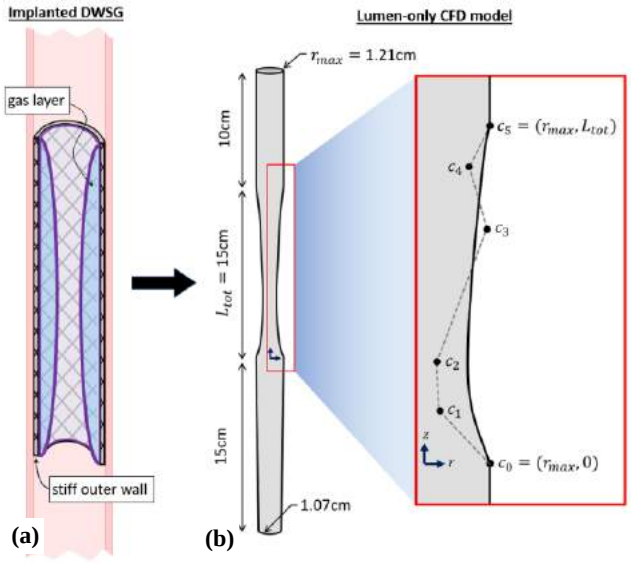

Figure 1: (a) Diagram of the DWSG placed within the descending aorta. (b) Model of the implanted DWSG used for CFD simulations. The DWSG gas layer dictates the profile of the lumen in that region, given by a Bézier curve.

A six-point Bézier curve was used to generate a wide range of profiles by moving the four central control points. The first and last control points were fixed to maintain an overall DWSG length of $L_{tot} = 15cm$ and outer radius of $r_{max} = 1.21cm$. For CFD, the DWSG was placed within a straight segment of the aorta, with 10cm of descending aorta upstream of the device and 15cm of abdominal aorta downstream.

For a given set of control points, a Python script was used to create a file defining the outer wall of the model domain. Using the SimVascular Python API, this contour group file was translated into a 3D model and then a tetrahedral mesh. The mesh was generated with elements approximately 0.3cm long and three boundary layer rings forming a 0.27cm thick region from the wall. To overcome meshing failure, which occurred when the model was very narrow in the DWSG region, the program would automatically attempt to mesh with a second set of parameters with two boundary layer rings in a 0.21cm region.

CFD Simulations: Unsteady flow simulations were conducted to evaluate the impact of each gas layer profile on the hemodynamics in the aorta. Periodic flow for the descending aorta [11] was applied at the inlet of the model, and an RCR boundary condition was applied at the outlet, with parameters taken from Brown et al. [12] Simulations were run for 3 cardiac cycles with a time step of 0.01s, with data collected only from the final cycle.

Optimization Objectives: The optimization was conducted with objectives to minimize: (1) lumen area at the DWSG site, (2) oscillatory shear index (OSI), and (3) mesh area with low time-averaged wall shear stress (TAWSS). Lumen area was a surrogate for gas volume – more gas within the DWSG directly translates to increased compliance. High OSI and low TAWSS are both common measures for atherosclerotic risk [13], so both were evaluated for the unstented regions of the domain. The root mean square (rms) value of OSI and the normalized surface area of the mesh exhibiting $TAWSS < 2\ dyn/cm^2$ were minimized [14]. Restrictive requirements for the system, such as maximum TAWSS not exceeding 200 dyn/cm^2 [15] and the gas layer profile remaining within the bounds of the surrounding vessel wall, were enforced as constraints.

Implementation: The NSGA-II algorithm was implemented through Platypus with a population of 100 individuals. The optimizer called a script that executed a series of Python programs to sequentially generate a new mesh, run the simulation, convert results from the final cycle, and finally evaluate the objective functions and constraints. The simulations were parallelized to four processors on the local machine. Nondominated solutions, which are candidates to lie upon the pareto front, were found via the *ParetoFront()* function in MATLAB [16].

RESULTS

Data were retrieved after the optimizer had completed 564 iterations, or more than 5 evolutionary generations of the algorithm. Figure 2 shows the evaluated objectives over the solution space along with selected gas layer profiles. The lumen volume ranges from 17 to 54 mL, or 25-78% of the total available volume in that region. A strong positive correlation was seen between low TAWSS area and OSI (OSI_{rms}), clearly visible in the 2D projection of the results (Fig. 2, bottom). All of the nondominated solutions showed a gradual tapering of the radius from both the inlet and outlet of the DWSG, leading to the triangular profile depicted in the bottom-right image of Fig. 2.

DISCUSSION

These results show that the shape of the DWSG gas layer has significant impact on local hemodynamics, even for a fixed gas volume. The strong correlation between the two objectives quantifying flow disturbance suggests that future optimization studies may be simplified by replacing those objectives with a single combined value such as relative residence time [17]. Because the flow-based objectives were evaluated only for the unstented regions of the domain, the most optimal designs tended to make the transition between vessel and stent as gradual as possible, leading to sharp discontinuities in the gas layer profile. This behavior can be avoided by including the stented region when evaluating flow behavior. After incorporating the adjustments described here, the next-generation framework will be used to identify a set of optimal potential DWSG designs, which then can be investigated more thoroughly with fluid-structure interaction simulations.

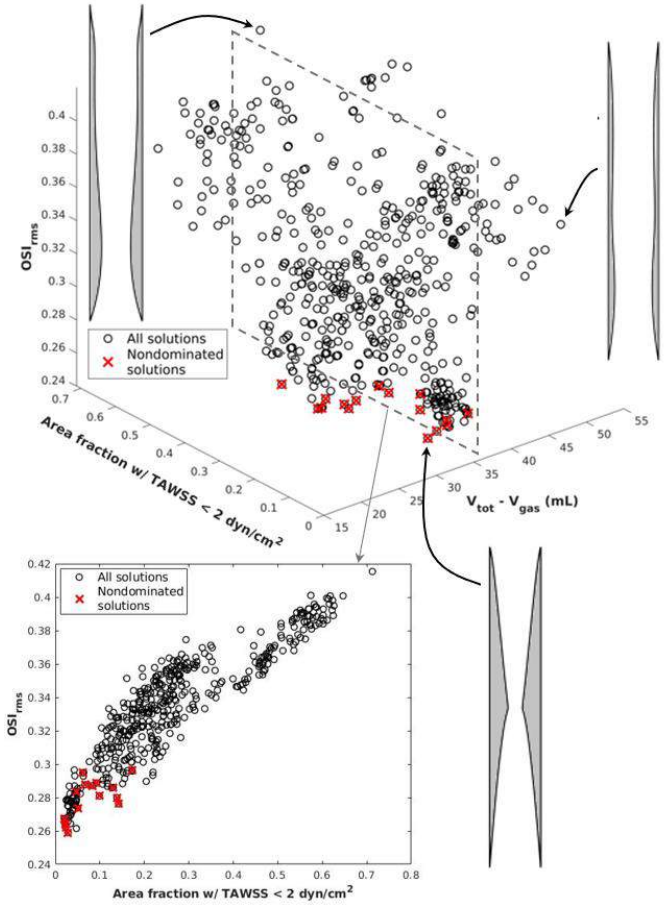

Figure 2: (Top) 3D plot of objectives; nondominated solutions highlighted with an 'x'. Examples of 3 gas layer profiles are shown. (Bottom) The same data in 2D, showing the co-dependence of two objectives: OSI and low TAWSS area.

TUNING SHEAR WAVE TENSIOMETRY TO IMPROVE SUBJECT SPECIFICITY IN ACHILLES TENDON LOADING MEASUREMENTS DURING WALKING

Stephanie G. Cone (1), Dylan G. Schmitz (1), Darryl G. Thelen (1)

INTRODUCTION

Human motion analysis is a well-established approach for characterizing the joint kinetics that drive an individual's walking pattern [1]. Joint kinetics in turned are often used to infer the timing and magnitude of muscle-tendon forces and joint contact forces [2]. However, redundancies in the musculoskeletal system make it challenging to infer tissue loads from joint level metrics, particularly during swing phase. This challenge highlights the need for a more direct approach to assess muscle-tendon tissue loads during walking.

Shear wave tensiometry is a noninvasive method for assessing tissue loads by exciting and measuring shear waves [3]. A shear wave tensiometer consists of a mechanical tapper that excites a shear wave, and two accelerometers that record the arrival of the wave at downstream locations. Shear wave speed is calculated as the inter-accelerometer distance over wave travel time. A tensioned beam model provides a constitutive relationship directly relating wave speed to tensile load [3]. Indeed, prior studies show that Achilles tendon wave speed closely tracks net ankle torque during stance, but not during swing when tendon load arises from passive stretch [3]. While healthy subjects generally exhibit similar Achilles tendon wave speed patterns during walking [3], there is unexplained variability in wave speed magnitudes. Such inter-subject variability may arise, in part, from design factors and anatomical variability. In this work, we investigated the sensitivity of wave speed metrics to tap excitation patterns across a range of healthy young adults. The first objective was to investigate the dependence of Achilles tendon wave speeds on mechanical tap duration. The second objective was to perform a preliminary assessment of the relationship between tendon wave speed and select anatomical geometry metrics.

METHODS

In a study approved by the University of Wisconsin Institutional Review Board, 16 subjects (8M/8F, 23.5 ± 3.9 years, 71.8 ± 11.2 kg, 1.75 ± 0.10 m) were recruited. A shear wave tensiometer, consisting of a piezoelectric-actuated tapper and two miniature accelerometers (8 mm apart), was secured over each subject's right Achilles tendon. The subject performed a continuous walking trial at 1.34 m/s. Trials consisted of 10 second intervals of pulse wave (50 Hz) taps with varying duty cycles (0.5, 1, 2, and 10 ms pulse durations). Each condition was performed in triplicate in a randomized order. Subjects then stood with their instrumented ankle on a force plate, and static trials of shear wave tensiometry with each pulse duration were collected with 0%, 25%, 50%, 75%, and 100% body weight on the involved limb (Fig. 1).

Transverse B-mode ultrasound images (Verasonics Vantage 64LE) of the Achilles tendon were collected. Imaging was done in a prone position with the ankle passively held in 0° of dorsiflexion.

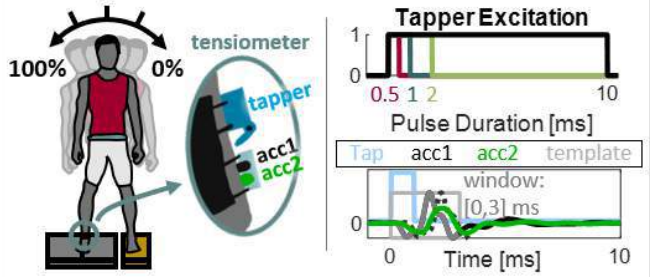

Figure 1: Static loading test methods (left), tap excitation patterns for different pulse durations and wave speed analysis (right).

Shear wave speed was calculated for each tap event. For each tap, wave travel time was computed by finding the time delay that maximized the normalized cross-correlation of accelerometer signals over a 3 ms window following tap onset [3] (Fig. 1). Wave speed signals were re-sampled to 101 points over each gait cycle, and then ensemble

averaged over all gait cycles for each tap duration. Parameters of interest (minimum stance wave speed, maximum push-off wave speed, average standard deviation) were calculated. Repeated measures anova was used to ascertain the effects of tap duration on wave speed metrics ($p<0.05$).

Ultrasound images were used to measure the Achilles tendon thickness and the cross-sectional area (CSA) between the accelerometer locations (Fig. 1). Simple linear regression was used to assess the relationship between peak wave speeds and anatomical metrics.

RESULTS

Pulse duration had a significant effect on the magnitude of shear wave speeds during both stance ($p<0.01$) and swing phase ($p<0.01$). Pulse duration did not have a significant effect on the standard deviation either at peak wave speed ($p=0.42$) or averaged across the gait cycle ($p=0.07$). Additionally, pulse duration had a significant effect on the magnitude of shear wave speeds measured during static loading ranging from 0% to 100% body weight ($p<0.01$), but there was no significant effect of pulse duration on the goodness of fit between calculated tendon load and percent body weight ($p=0.30$).

Table 1: Maximum shear wave speeds and standard deviations averaged across gait for each tap length. Bold represents $p<0.05$.

Tap Pulse Length (ms)	Maximum Push-off Shear Wave Speed (m/s)	Average Standard Deviation (m/s)
0.5	58.6	1.3
1	60.2	0.8
2	59.1	0.9
10	**66.9**	0.9

During walking, the magnitude of shear wave speeds varied by as much as 14% between cases at max push-off across pulse durations averaged across subjects (Table 1). These values were significantly higher with 10 ms pulse durations compared to all other cases ($p<0.01$). At minimum wave speed levels in both stance and swing, 10 ms pulses yielded significantly higher wave speeds compared to other cases by 13% and 11%, respectively ($p<0.01$). At maximum speeds during swing, 2 ms pulses yielded 18% higher wave speeds than other cases ($p<0.01$) (Fig. 2).

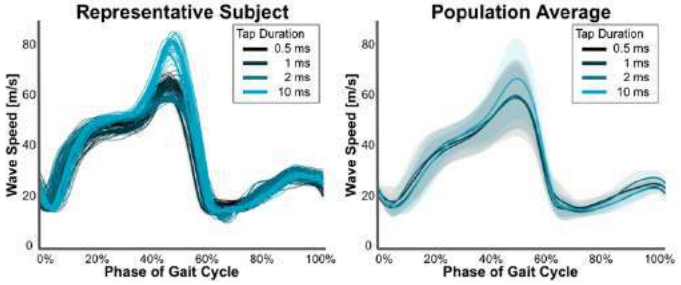

Figure 2: Pulse duration has a significant effect on the overall magnitudes wave speeds in a single subject (left, individual strides) and averaged across subjects (right, mean ± standard deviation).

In static standing trials across loading levels, pulse duration again had a significant effect on shear wave speed magnitudes ($p<0.01$) but not on wave speed variability within a trial ($p=0.30$). Across pulse duration cases, increasing loading led to significant increases in shear wave speeds ($p<0.01$). These increases were on the scale of 55% to 75% increases in shear wave speed as subjects shifted their weight from the non-instrumented to the instrumented limb.

Some significant correlations emerged from the pilot investigation of shear wave speeds and anatomical metrics. Notably, peak wave speed during push-off for the 1 ms pulse was positively correlated with height ($p=0.03$), body weight ($p=0.04$), and anterior-posterior tendon depth ($p=0.04$) (Fig. 3). Similar trends were observed for the other pulse durations (0.5, 2, 5), but did not reach the 0.05 significance level.

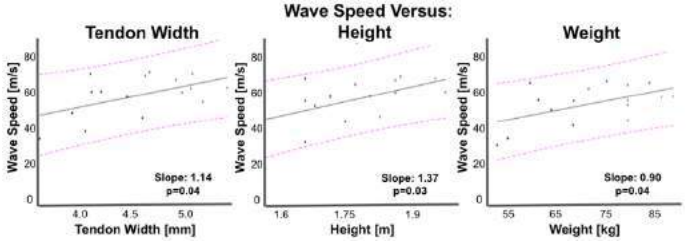

Figure 3: Peak wave speed increased with increasing tendon anterior-posterior depth, height, and weight.

DISCUSSION

This study illuminates the effects that excitation can have on measured tendon wave speeds. Our tensiometer used a transient wave speed measurement approach, in which an impulsive tap is used to induce and measure group wave propagation speed. We varied tap duration which alters the transient wave appearing in the post-tap analysis window (Fig. 1). Tap duration had a non-significant effect on repeatability of the wave speed metrics, though there was a trend for greater variability with the shortest (0.5 ms) duration pulse. This could be a signal-to-noise ratio effect. The shortest impulse doesn't allow for full excitation of the piezoelectric stack we used, hence produced a smaller amplitude wave than pulses under 1 ms.

Wave speed magnitudes were significantly dependent on pulse duration with the longest pulse producing significantly higher peak wave speeds in push-off. This is likely due to the analysis window (3ms) being shorter than the pulse (5 or 10ms) duration. As such, the analysis for the long pulse did not include both the push and release events, which were considered in the shorter duration pulses (Fig. 1). Not including the release event likely alters frequencies inherent to the wave, affecting the wave speed when dispersion is present [4].

There were some intriguing relationships between anthropometry and wave speed that emerged. Notably, peak wave speeds increased with subject height, mass, and tendon size. This may simply reflect the direct dependence between tendon load and wave speed, as propulsion demands increase with body size. The dependence of wave speed on tendon geometry could arise from dispersion effects. Specifically, wave length is greater than the tendon thickness, resulting in guided wave behavior that depends on the relative thickness of tissue layers. Further analysis via computational models and physical experiments are needed to better understand these complex dispersion effects.

This work extends the promising use of shear wave tensiometry to gauge tendon loading during movement. We showed that repeatable results can be obtained with different wave excitation patterns, but that the absolute wave speed is dependent on the duration of excitation and subject anatomy. These observations are important for establishing shear wave tensiometry as a valid sensor of subject-specific tendon loading during locomotion.

MULTISCALE MODEL OF HEART GROWTH DURING PREGNANCY: INTEGRATING MECHANICAL AND HORMONAL SIGNALING

INTRODUCTION

Pregnancy stands at the interface of mechanics and biology. Significant mechanical and hormonal changes occur during pregnancy as the growing fetus continuously loads the maternal organs. In response to these changes, maternal soft tissues undergo dramatic growth and remodeling to support the mother and baby for a healthy pregnancy. We focus here on the maternal left ventricle (LV), which increases its cardiac output by 45% [1] and increases in mass by approximately 30% [2] over nine months of pregnancy, only to regress to the nonpregnant size by 3-6 months after delivery. Cardiovascular conditions and heart failure together account for more than 25% of pregnancy-related deaths in the United States. Therefore, there is a critical need to understand how pregnancy hormones and hemodynamic changes interact to affect heart growth during pregnancy. Thus, the objective of this work was to develop a multiscale cardiac growth model that incorporates these interactions.

Towards this objective, we present a novel multiscale cardiac growth model. We coupled a cell-signaling network model of cell-level hypertrophy to an organ-level compartmental growth model of the rat heart and circulation. We first calibrated this multiscale model to LV growth due to experimental volume overload (VO) and infusion of hormones. We then validated the ability of this model to capture interactions between combinations of 2 inputs. Finally, we simulated pregnancy-induced changes in hormones and hemodynamics to predict heart growth during pregnancy.

METHODS

To simulate the influences of hormones and stretch on cell-level hypertrophy, we built an intracellular signaling network model for pregnancy-induced cardiomyocyte hypertrophy (Fig.1A) using previously published methods [3]. This network model consisted of 4 key inputs: the pregnancy hormones progesterone (*P4*) and estrogen (*E2*); Angiotensin 2 (*AngII*), a hormone elevated during both volume overload and pregnancy; and the mechanical signal, *Stretch*. These inputs interacted with each other and nine other intermediate species through 24 reactions. We used normalized Hill-type ordinary differential equations to model signaling reactions. The activity level of each species was represented as a value between 0 and 1, where 0 indicates no signaling activity and 1 represents maximal activation. We based the reactions on a previously published network model of cardiomyocyte hypertrophy by Ryall et al. [3] and adjusted crosstalk interactions to match phosphorylation data from *in vitro* experiments where cardiomyocytes were treated with P4, E2, and/or AngII.

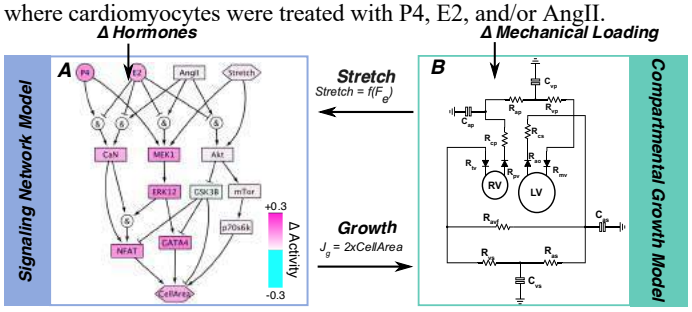

Figure 1: Multiscale cardiac growth model for pregnancy. A) Intracellular signaling network model of cardiomyocyte growth is coupled to a B) compartmental growth model. Growth predicted by the network model is fed into the compartmental model as a growth stretch. Elastic stretches calculated by the compartmental model are fed into the network model to close the loop.

To simulate organ-level heart growth, we modified a previously published compartmental growth model of the canine heart coupled to

a lumped-parameter circuit representation of the circulation [4] (Fig.1B). We used allometric scaling to re-parameterize this model from canine to rat [5]. We then optimized circulatory parameters to match average experimental hemodynamics and reported stretches experienced by the LV during baseline and acute VO states [6]. We used a kinematic growth framework within the compartmental model based on previously published methods [4]. In this framework, the total stretch (F_{tot}) is a product of the growth stretch (F_g) and elastic stretch (F_e): $F_{tot}=F_e*F_g$. We calculated F_g from the signaling network model output, *CellArea,* as $J_g=2*CellArea$, where $J_g=\det(F_g)$. We then input the maximum elastic fiber stretch, $\max(F_{e,f})$, predicted by the compartmental model into the signaling network model input, *Stretch*, as $Stretch=m_{stretch}*\max(F_{e,f})+b_{stretch}$, closing the loop between the two models (Fig.1). Here, $m_{stretch}$ and $b_{stretch}$ are linear transfer function parameters we optimized in the calibration steps outlined below.

We first calibrated the multiscale model parameters by matching the individual effects of VO, AngII, E2, and P4 on heart growth. Next, we simulated the combination of VO+E2 and AngII+E2 to validate the model representation of interactions between inputs. Finally, we simulated pregnancy-induced changes in the hormones and hemodynamics to predict heart growth during pregnancy.

RESULTS

We were able to calibrate the multiscale model to match reported changes in LV mass due to VO in rats and experimental infusion of AngII in rats, E2 in rats, and P4 in mice (Fig. 2). Specifically, we optimized linear transfer function parameters that map hormone concentrations [ug/ml or pg/ml] and $\max(F_{e,f})$ to the appropriate normalized network model inputs for *AngII*, *E2*, *P4*, and *Stretch*. When we simulated the combinations of VO+E2 and AngII+E2, the model correctly predicted attenuated growth as reported in rats [7] and mice [8]. VO+E2 resulted in 4% attenuation in LV mass compared to VO alone, while AngII+E2 resulted in 12% attenuation of LV mass compared to AngII alone.

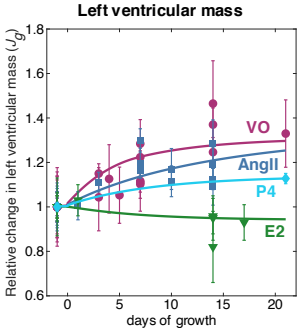

Figure 2: Calibrating the multiscale model. Symbols represent experimental data from volume overload (VO), angiotensin 2 (AngII) infusion, progesterone (P4) infusion, and estrogen (E2) infusion. Solid lines represent model match to data for each experimental condition.

Next, we used the model to simulate pregnancy in rats. We implemented reported changes in circulating concentrations of E2, P4, and AngII from rats during pregnancy for the hormonal inputs. In the circulatory model, we specified the heart rate (*HR*) and systemic resistance (*Ras*) changes calculated from the reported mean arterial pressure (*MAP*), stroke volume (*SV*), and *HR*. To simulate the increase in total blood volume during pregnancy, we allowed stressed blood volume (*SBV*) to change at each growth step to match the reported increase in end-diastolic diameter during pregnancy. When we incorporated pregnancy hormones and these circulation parameter changes, the calibrated multiscale model was able to predict growth (Fig. 3B) and hemodynamic changes that were in good agreement with the experimental data. When we examined the predicted network response for the pregnancy simulation, cell-level growth was primarily driven by species downstream of *P4*. Surprisingly, the network *Stretch* did not increase significantly (Fig.3A), leading to no significant changes in the downstream pathways (Akt, GSK3B, p70s6k).

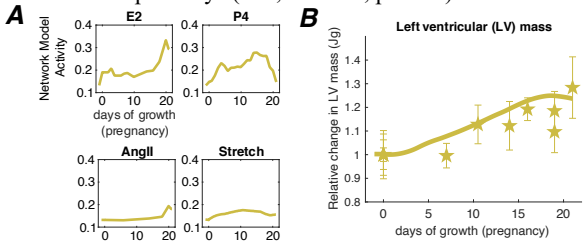

Figure 3: Model predictions for pregnancy. A) activity of input nodes for the network model. B) Solid line demonstrates the predicted relative change in left ventricular mass during pregnancy. Symbols represent experimental data from pregnant rats.

DISCUSSION

The objective of this work was to develop a multiscale cardiac growth model that incorporates hormonal and mechanical signaling for simulating heart growth during pregnancy. We coupled an intracellular signaling network model of cell-level growth to an organ-level compartmental mechanical growth model. We calibrated this model to reported heart growth in response to VO and infusion of AngII, E2, and P4 and validated the interactions between VO+E2 and AngII+E2. When we predicted heart growth during pregnancy by implementing appropriate hormonal and hemodynamic changes, the model produced growth predictions in good agreement with experimental data.

One striking result was the relatively constant level of Stretch throughout pregnancy predicted by the model (Fig. 3A). In this model, the change in network *Stretch* is a function of elastic stretch (F_e), which is dependent on the rate at which LV end-diastolic volume (EDV) increases compared to the rate of ventricular growth. In the model, the rise in P4 during early pregnancy leads to growth that tracks with the increase in EDV as *SBV* gradually increases throughout pregnancy. These results suggest that progesterone stimulation could account for much of the pregnancy-induced heart growth in rats, particularly in the early stages of pregnancy.

An advantage of this model is the ability to validate predictions across multiple length scales from intracellular signaling to organ-level growth. Future work will focus on expanding our network model to incorporate more signaling pathways and validating network model predictions against data. In particular, a better understanding of how *P4* and *Stretch* interact is necessary. An *in vivo* experiment of VO+P4 could provide valuable insights into how Stretch and P4 interact to affect heart growth and intracellular signaling.

COMPUTATIONAL ANALYSIS OF CORONARY PERFUSION IN HEART FAILURE WITH PRESERVED EJECTION FRACTION

Yuexing Sun, Lei Fan, Lik Chuan Lee

Department of Mechanical Engineering
Michigan State University
East Lansing, Michigan, USA

INTRODUCTION

Heart failure with preserved ejection fraction (HFpEF) is a syndrome that accounts for about 50% of heart failure patients [1]. There is, however, no effective treatment for HFpEF. The lack of effective treatment may be partly due to the fact that the mechanisms of the HFpEF are complex and have not been fully elucidated. Specifically, how HFpEF affects the left ventricle (LV) mechanics and coronary perfusion, as well as their interaction remains unclear. This question is difficult to answer from pure experimental and clinical studies since it is impossible to isolate the effects of each confounding factor in HFpEF. In order to overcome this limitation, a computational model that strongly couples the systemic circulation, LV and coronary perfusion with flow regulation in a closed loop system is developed. A key novelty of the model is that myocardial supply and demand are tightly coupled based on a linear relationship between the vasodilator signal F_{meta} and the LV pressure-volume loop area (PVA).

METHODS

The circulatory system is modeled using a closed loop framework consisting of five compartments, namely, LV, left atrium (LA), peripheral proximal and distal arteries, coronary artery and venous networks (**Fig 1(a)**) [2]. The LV and LA are described using a time-varying elastance model that relates instantaneous pressure to instantaneous volume. Coronary flow network consisting of 400 vessels is strongly coupled with the systemic circulation and the LV. Flow in each vessel of the network is described by a three-element Windkessel model that consists of two nonlinear resistors and one parallel capacitance (**Fig 1(b)**) [3]. Intramyocardial pressure (IMP), which is applied to each vessel, is defined as a combination of two mechanisms including time-varying elasticity and ventricular cavity-induced extracellular pressure. Specifically, $IMP = \alpha E_{es} e(t) + \beta P_{LV}$, where α and β are prescribed parameters, P_{LV} is the LV cavity pressure, E_{es} is the maximal chamber elastance of the LV, $e(t)$ is the time-varying elastance function. Flow regulation that includes the myogenic, shear, and flow regulation responses is taken into account in model. Vessel radius under regulated condition can be expressed as $R_{reg} = R_p - A\Delta R_m$, where R_p is the passive vessel radius (under fully dilated condition), ΔR_m is the myogenic activation based on transvascular pressure, and A is the total activation level given as $A = (1 - F_\tau)(1 - F_{meta})$. The total activation A depends on the shear signal F_τ and vasodilator signal F_{meta}. Here, F_{meta} is updated based on a prescribed $F_{meta} - PVA$ relationship, where F_{meta} varies from 0 to 1 linearly with PVA (**Fig 1(c)**), and is saturated when F_{meta} = 1. The gradient of the $F_{meta} - PVA$ linear relationship is controlled by a parameter. The vessel is fully constricted at maximum myogenic response ($F_{meta} = 0$) and fully dilated with the minimum myogenic response ($F_{meta} = 1$).

The model is first calibrated to match the clinical measurements of healthy subjects. These measurements include the blood pressure, LV end systolic pressure (LVESP), LV end diastolic pressure (LVEDP), LV end systolic volume (LVESV), LV end diastolic volume (LVEDV), ratio of E and A waves of the mitral valve flow rate (E/A ratio), LV ejection fraction (LVEF) and total coronary flow over one cardiac cycle under both passive and regulated conditions. The calibrated model is then applied to simulate HFpEF by adjusting parameters that are deemed to change with the condition (e.g., maximal chamber elasticity and LV relaxation) to match clinical measurements in HFpEF patients. The gradient of the $F_{meta} - PVA$ relationship is also determined from these measurements. All simulations are run with a heart rate of 75 bpm for several cardiac cycles until a steady periodic behavior is reached.

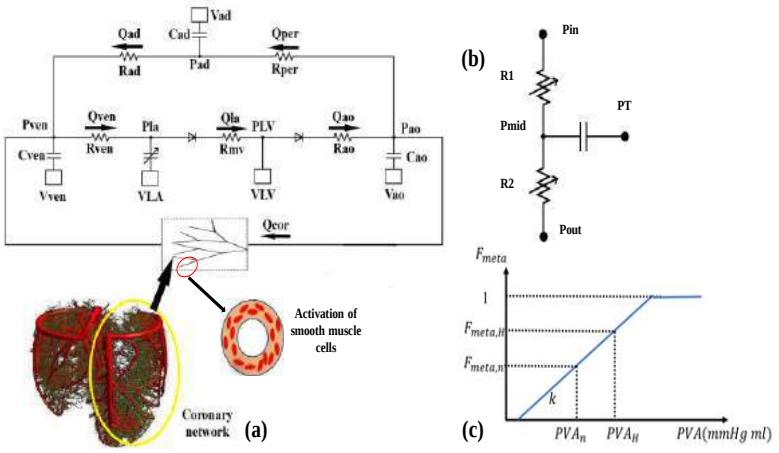

Figure 1(a): Schematic of the LV modeling framework and coronary network; **(b)**: three-element Windkessel model; **(c)**: $F_{meta} - PVA$ relationship.

RESULTS

In the normal case, the calibrated model predicted LVESP, LVEDP, systolic blood pressure (SBP), diastolic blood pressure (DBP), LVESV, LVEDV, LVEF, E/A ratio, and total coronary flow under passive and regulated conditions to be 96mmHg, 13mmHg, 108mmHg, 71mmHg, 42mL, 108mL, 60%, 2.05, 3.15mL and 1.31mL. These values are in agreement with the clinical measurements of healthy subjects, which are in the range of 84-160mmHg, 3-12mmHg, <120mmHg, <80mmHg, 40-54mL, 69-162mL, >45%, 1.4-2.6, 2.144-4.224mL, 0.784-1.9mL, respectively [4]. In order to simulate HFpEF, both maximal chamber elastance E_{es} and relaxation time are increased (based on clinical studies) [5]. Systemic resistances and compliance are also adjusted (to reflect an increase in afterload in HFpEF). In the HFpEF simulation, the model predicted LVEDP, SBP, DBP, LVESV, LVEDV, LVEF, E/A ratio, and total coronary flow under passive and regulated conditions are, 27mmHg, 148mmHg, 84mmHg, 37mL, 103mL, 64%, 0.89, 3.03mL and 1.44mL, matching with the clinical measurements under HFpEF condition, which are 17-31mmHg, 60-90mmHg, 145-165mmHg, 31-59mL, 84-135mL, 53.7-65%, 1.4-2.6, 2.064-4.016mL and 1.056-1.88mL, respectively [6][7]. Since IMP is controlled by LV pressure, the increased LV pressure in HFpEF causes IMP to increase (**Fig 2(a), (e)**), which impedes coronary flow and slows the flow rate in coronary network. Model prediction of E/A ratio is also decreased in HFpEF (**Fig 2(b), (f)**), where the increased A peak is caused by a slow myocardial relaxation rate. In HFpEF, LVEF remains close to a normal value but the heart has less blood inside during the diastolic phase since the LVEDV is slightly reduced compared to normal (**Fig 2(c), (g)**). Comparing the coronary flow rate under passive and regulated conditions from normal to HFpEF cases (**Fig 2(e), (h)**), their values are close to each other. Coronary flow rate in HFpEF, however, is lower in the diastolic phase and higher in systolic phase and the resultant coronary flow reserve (CFR) is lower in HFpEF (2.16) than in normal (2.35). The vessel is fully dilated under passive condition with $F_{meta} = 1$ for both normal and HFpEF cases, but the vasodilator signal is larger in HFpEF ($F_{meta} = 0.55$) than in normal ($F_{meta} = 0.35$) due to the PVA change based on the prescribed relationship, where less myogenic activation applied on the coronary networks, suggesting that the conditions in HFpEF requires more dilation of the vessel.

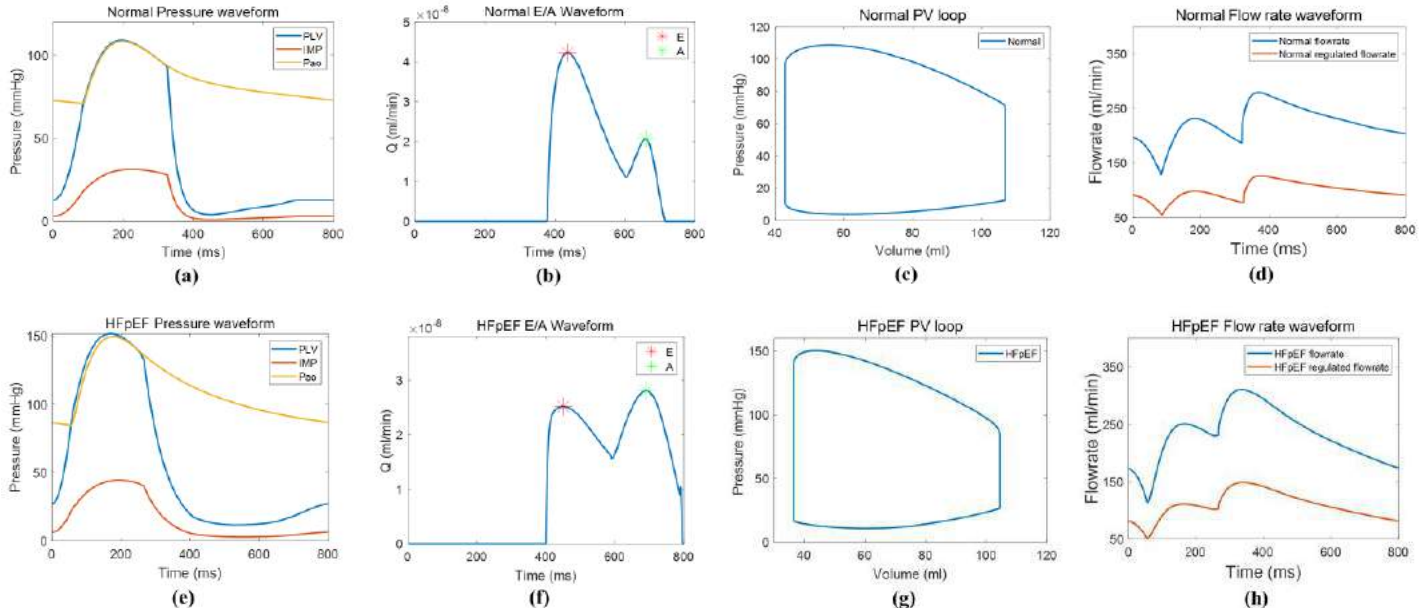

Figure 2(a): LV pressure, arterial pressure, and IMPs waveform under normal condition; **(b)**: E/A ratio of mitral valve flow rate under normal condition; **(c)**: LV pressure volume loop under normal condition; **(d)**: Normal flow rate under passive and regulated conditions; **(e)**: LV pressure, arterial pressure, and IMPs waveform under HFpEF condition; **(f)**: E/A ratio of mitral valve flow rate under HFpEF condition; **(g)**: LV pressure volume loop under HFpEF condition; **(h)**: HFpEF flow rate under passive and regulated conditions.

DISCUSSION

We have developed model coupling LV mechanics and coronary perfusion that is able to quantitatively reproduce clinical measurements in normal and HFpEF patients. The key findings of this study are **1)** from normal to HFpEF, the conspicuously increased LV pressure during the systolic phase led a larger increase of perfusion pressure than that of IMP, which rise more flow rate in systolic. **2)** The vasodilator signal F_{meta} is larger in HFpEF patients than that of the healthy subjects. This results that the vessels are required to be more dilated to accommodate the increase in PVA in HFpEF, which contributes to the slight reduction in CFR. In contrast to previous models [8], we have, for the first time, take into account the coupling between myocardial demand and supply by prescribing a direction relationship between PVA and the vasodilator signal.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a minimally invasive procedure that does not require an open-heart surgery. Thus, THVR has been recommended for patients with high surgical mortality risk. The most recent data from clinical trials indicate that TAVR can be extended to patients at intermediate and low risk [1,2]. Unfortunately, THVR faces similar failure mechanisms as bioprosthetic valves where calcification and valvular degeneration are some of the ongoing challenges. The lack of long-term durability data on TAVR further reveals the critical need for improving the design of transcatheter aortic valves (TAV) [3].

Polymeric heart valves show great potential for use in TAVR due to their tunability and cost-effectiveness. Furthermore, enhancing polymers has shown to further improve their durability, hemocompatibility, and hemodynamic properties [4]. TAV with leaflets made of an interpenetrating polymeric network of hyaluronan (HA) and linearly low-density polyethylene (LLDPE) have been shown to be hemocompatible with good hemodynamic performance [5,6]. The objective of this study is to develop a new process of forming the HA-LLDPE TAV that involves a combination of finite element analysis (FEA) and vacuuming forming. The goal is to create a cost-effective fabrication method without sacrificing the performance of the HA-LLDPE TAV.

METHODS

Design optimization. The shape of the cusps was determined via FEA (Abaqus Explicit). Their height and geometry along the fixed edges were predetermined based on an ongoing parametric study. To obtain the desired curvatures and shape of the three leaflets, a mechanical load of 100 mmHg was applied on the aortic side of the predetermined model. The boundary conditions are fixed edges on the outer side of the cusps. In the initial state, the cusps had a cylindrical shape like a tubular film; they were thin (80 um), almost incompressible (Poisson Ratio = 0.45), and linearly elastic with a Young' modulus of 20 MPa. The low modulus creates a compliant material that, when placed under the applied load, causes the cusps obtain the idealized shape that minimizes the stresses for the given loading. The final geometry was exported into a CAD software (Solidworks), and it was used to create a mold for valve fabrication.

Leaflet Fabrication & Valve Assembly. The valve frames (26 mm ID) were 3D printed (uPrint SE Plus, Stratasys) Acrylonitrile butadiene styrene (ABS). The leaflets were shaped using a vacuum forming machine (Formech 300XQ). Briefly, a mold of the idealized leaflet geometry from the design optimization study above was 3D printed. The mold was amounted on the forming machine, which briefly heated a flat LLDPE film (2045G, 80 um thick) for varying durations. Once the polymer sheet is soft, a vacuum is applied and the mold was pressed against the heated LLDPE to obtain the leaflet geometry from the mold. The thermoformed leaflets were then glued onto the valve frames for the in vitro experiment.

Hemodynamic Analysis. The assembled valves were placed in an in vitro model and tested under pulsatile aortic flow conditions. A water-glycerin mixture (40:60 v/v) was used as the blood analog. The aortic pressure, pulsatile rate, and cardiac output were 80/120 mmHg, 60 beats per minute (bpm), and 5 L/min, respectively. The ventricular and aortic pressures were recorded via catheter transducers (Millar Mikro-Tip). The mean pressure gradient (mPG), peak pressure gradient (pPG), effective orifice area (EOA), and the regurgitation fraction (RF) were calculated. Data was averaged over 60 cardiac cycles, and analyzed as described elsewhere [6].

RESULTS

Figure 1 shows the contour plot of the maximum principal strain (left) of the three cusps, which look almost identical. The strain concentration appears highest near the fixed edge. It lowers with decreasing distance along the radial direction towards the coaptation region. The leaflets deformed least near the free edge where the three cusps are seen compressed against each other. The right image shows an example of thermoformed leaflets assembled into a valve. The clear

LLDPE shaped leaflets are seen in the center of the assembly. The yellow portion is the 3D printed ABS frame.

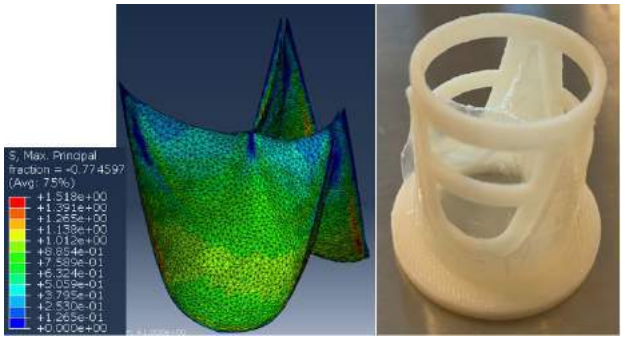

Figure 1: The left image shows idealized shape of the leaflet cusps from the FEM study. Strain unit are dimensionless. The assembled valve is shown on the right side.

Figure 2 shows the results of thermoforming the LLDPE for different durations. The longer durations created more refined shapes of the cusps from the LLDPE film. Shorter heating times, such as 15 and 10 seconds, were not long enough to create the 3D shaped leaflets. The flat LLDPE was also heated to 60 seconds (s) (not shown), and those leaflets were also assembled into a valve.

Figure 2: From left to right, LLDPE films that were thermoformed under different durations of 50, 40, 30, 20, 19, 18, 15, and 10 seconds.

The hemodynamic results are shown in table 1. The EOA does not seem to vary noticeably across all the valves. There is a correlation between heating time and pPG. The TAV with the longest (60 s) and shortest (18 s) heating durations appears to have the most paravalvular leakage with RF of 53.80±0.69 and 36.05±0.71, respectively. The same can be concluded for mPG, which are 11.8 ±0.43 and 9.45±0.26 for 60 and 18 s.

Table 1: Data from the pulsatile flow study showing TAV with LLDPE leaflets heated for 60, 30, 20, and 18 seconds during thermoforming.

Duration (s)	mPG (mmHg)		pPG (mmHg)		EOA		(RF) (%)	
	mean	std	mean	std	mean	std	mean	std
60	11.8	0.43	19.0	0.74	1.76	0.04	53.8	0.69
30	8.77	0.28	13.2	0.24	1.72	0.06	14.4	0.85
20	8.39	0.34	14.6	0.28	1.80	0.07	13.9	0.79
18	9.45	0.26	12.7	0.41	1.69	0.04	36.1	0.71

DISCUSSION

The results show that TAV can be easily assembled through thermoforming. The data also present interesting patterns. For example, long heating time created the 3D shape that may improve the kinematics, but heating too long could lead to a rigid material which could comprise the leaflet kinematics. This may explain why the mPG and pPG increase with longer heating during vacuum forming. Although further improvement is required, the performance of thermoformed TAV is already comparable to FDA approved TAV. For the SAPIEN 3 (Edwards Lifesciences) of the same size, mean EOA is 1.74±0.35 cm^2 with an mPG of 10.59±3.88 mmHg. For the Evolut R (Medtronic) of the same size, mean EOA is 1.69±0.40 cm2 with an mPG of 7.53±2.65 mmHg [7].

Future work will involve more FEA to optimize the shape of the leaflets. The vacuum forming method will be further explored through a series of parametric studies varying the duration, heat, and possibly different grades and thicknesses of LLDPE. Perhaps a parametric study that to analyze the deformation gradient of LLDPE will reveal the localized deformation of the polymer. This would help show the material behavior under heat and further improve the fabrication process. An accelerated wear test will help verify the durability of the thermoformed TAV. Future studies will also include HA-LLDPE IPN formation testing of the thermoformed leaflets and developing a metal stent frame for the novel heart valve.

INTRODUCTION

It is well established that certain types of physical exercises can serve as a therapeutic treatment to minimize bone loss and decrease the risk of bone fracture [1, 2]. Exercise plays a crucial role in maintaining the skeleton because bone is sensitive to the mechanical forces experienced during physical exercise [3]. Because many molecular and cellular features of mammalian bone are conserved in the zebrafish (Danio rerio) skeleton, such as the major categories of tissues and cells [4, 5], the zebrafish has received increased attention as a vertebrate model in the field of exercise physiology [6] . Furthermore, previous swimming experiments in water tunnels support a role for exercise in increased bone growth and density in adult zebrafish [7].

In humans, the effect of exercise on the skeleton depends on how the skeleton is loaded [2, 3]. This is also true in zebrafish, where results depend on an array of unstandardized swimming parameters (e.g. speed, test duration, number of swimming bouts). For example, swimming exercise studies have reported effects in the growth of the vertebral bodies, with increases in bone volume, mineralization, and the number of bone-forming osteoblasts in zebrafish [7] but has also been shown to induce vertebral lordosis with a dose-response pattern [8]. Further, zebrafish swimming experiments have been conducted in a range of different water tunnel designs, often with uncharacterized fluid flow fields that are assumed to be laminar and thus parabolic [9–12]. Previous work has shown that zebrafish larvae tend to take advantage of this, where they cling to the wall of the test section using their mouth to maintain their position in areas of little to no flow [11]. To address these shortcomings, we designed, built, and characterized a water tunnel with a uniform flow field and small boundary layers near the walls to decrease variability in the experimental outcomes (Figure 1). Additionally, we designed a computer-controlled pump system that allows different types of flow waveforms to be tested. To test our design, we investigate the role of increased swimming speeds on zebrafish bone remodeling.

METHODS

We integrated wind tunnel design methodologies into our testing apparatus to delay boundary layer growth. To achieve uniform flow, a conditioning chamber and a contraction nozzle was incorporated into the design of the water channel. Using established design guidelines [13], the wall curvature, contraction ratio, and the contraction length were carefully chosen. A fifth order polynomial was chosen for the contraction nozzle's wall curvature:

$$Y(X) = H_i - (H_i - H_e)[6(X')^5 - 15(X')^4 + 10(X')^3] \qquad (1)$$

where X'=X/L and L is the contraction length. When aiming for a laminar boundary layer at low Reynolds numbers, minimal boundary layer separation and reasonable flow uniformity at the contraction outlet, this wall shape performed better than those based on third order polynomial, seventh order polynomial, or matched cubics [13]. To drive the flow, our design can either be pump driven or gravity driven to allow for higher speeds if desired. A variety of waveforms can be generated using a computer program we wrote in the LabVIEW software. A voltage signal is exported from a National Instruments data acquisition card and used to control a Watson-Marlow 530U peristaltic pump. The pump propels the water into the water channel and the flow rate at the inlet of the inlet is monitored with a Transonic Systems, Inc. ultrasound flow meter as a feedback control. The testing chamber cross sectional dimensions are 30 mm x 30 mm by a length of 150 mm to allow simultaneous testing of 15-20 juvenile zebrafish (~1 month), enabling high-throughput measurements.

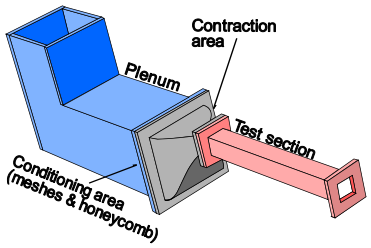

Figure 1: Water channel schematic highlighting the conditioning system (blue), contraction cone (grey) and test section (red).

Water channel experiments are described briefly: 30 days post fertilization (dpf) juvenile zebrafish are exposed to 6h of exercise per day for 7 days with flow rates beginning at 1 body length/sec and increasing by 10% every day. Control fish remain in holding tanks of a similar volume with no flow. For every experiment, increased swimming and control fish are full siblings. Exercise begins with 3h of swimming, followed by 1h of rest, then by another 3h of swimming. Fish are fed a combination diet of newly hatched Artemia and Gemma Micro 300 1h before the first exercise period, during the 1h rest period (test group only), and after the second swimming bout. The night before the experiment, fish are exposed to a green fluorescent bone dye (calcein) to label fish's bones on day 0. After 7 days of swimming, the bones were labeled once more with a red fluorescent bone dye (alizarin red) to label the fish's bones on day 8. The difference in area or length of particular bones is used to assess growth rates

RESULTS

After 7 days of swimming, the growth in 4 superficial bones that represent distinct functional units of the skeleton was calculated: (1) the opercle (OP), which protects the gills and acts in respiration; (2) the cleithrum (CL), which supports the pectoral fin musculature and is involved in stabilization of the body axis; (3) the caudal fin rays (FR), which comprise the caudal fin and are involved in propulsion; and (4) the 3rd infraorbital (ORB), which lines and supports the eye socket. The orb was included as a negative control, as growth in this bone was not expected to be influenced by increased swimming. We found accelerated bone growth in the experimental group compared to the control group in the FR by 19.8%, CL by 43%, and OP by 16%. The negative control, the ORB did not experience a difference in growth (Figure 2). Thus, our water channel can be used to elicit differences in bone growth in a relatively brief period.

DISCUSSION

The design of our water tunnel provided a near uniform flow field that allows for experiments where fish swim for the duration of the experiment. Turbulent flow theory was used to ensure an isotropic and homogeneous flow field void of velocity gradients. Traditional swim studies that utilize laminar flow can be problematic for researchers. This type of velocity profile is parabolic, with zero velocity at the walls and a maximum velocity at the center, and thus zebrafish will experience different velocities and drag forces depending on distance from the test section's wall, adding variability in experimental results. The design of our water tunnel provided a uniform flow field absent of velocity gradients, except at the wall where a very thin boundary layer was present. One minor issue is that the flow rate is limited to 2 L/min (~3 BL/s for juveniles, SL=1.2cm) with the current pump-driven set up, which means some types of experiments are unable to be performed. For example, sprint tests are limited as the critical swimming speed of an adult zebrafish is 18 BL/s [14]. To achieve higher flow rates, the water channel can be driven by using gravity instead. Using our design, we investigated the role of increased swimming speeds on zebrafish bone remodeling. Our preliminary proof-of-concept study resulted in increased bone volume after 7 days. These results show our carefully designed and built water tunnel provides a well-controlled environment where the effects of mechanical forces on skeleton remodeling can be further elucidated.

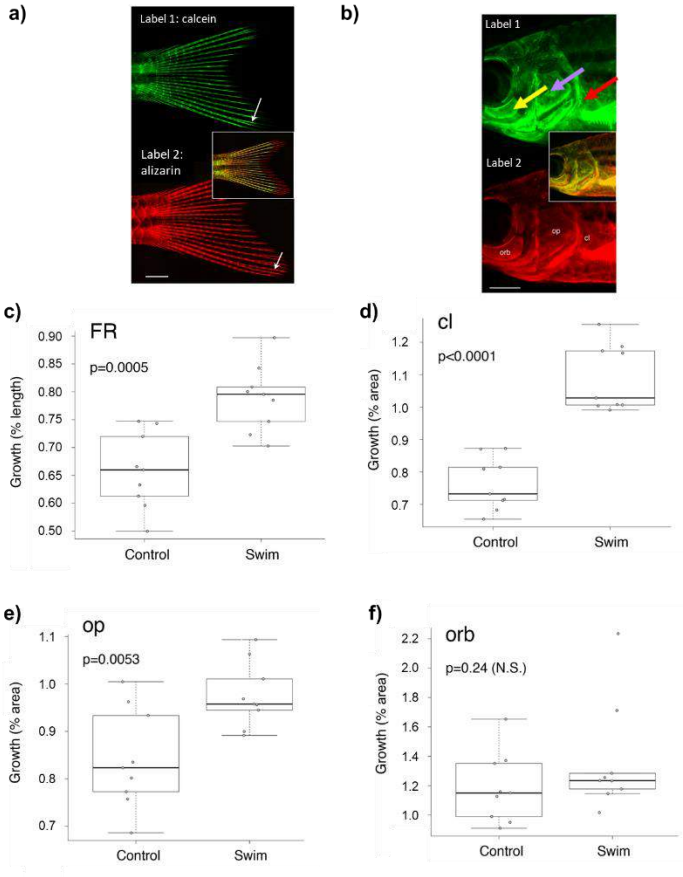

Figure 2: Swim training leads to expanded bone formation in the caudal fin ray (a, c), cleithrum (red arrow b, d), and opercle (purple arrow b, e). There were no differences between groups in the negative control (yellow arrow b, f). Scale bar = 100 µm.

MAXIMUM VENTRICULAR WALL LOADING COINCIDES WITH PERIVENTRICULAR WHITE MATTER HYPERINTENSITY LOCATIONS

Valery L. Visser (1,2), Andreia Caçoilo (2), Johannes Weickenmeier (2)

INTRODUCTION

White matter hyperintensities (WMH) are bright appearing lesions in white matter tissue on T2-weighted or fluid attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI) scans. The prevalence of these lesions strongly increases with age, and has been shown to correlate with cognitive decline and neurodegenerative diseases [1–3]. Even though WMHs are associated with characteristic pathological tissue changes and are commonly observed in elderly, their etiology remains unclear. WMHs are grouped based on their anatomical location into either periventricular WMHs (pWMHs) which are located adjacent to the lateral ventricles (LVs) or deep WMHs (dWMHs) located in diffuse white matter regions throughout the brain [4,5]. Both types of WMH are typically associated with the accumulation of fluid in brain tissue, which induces the hyperintense signal on MRI scans [6]. The interstitial fluid damages surrounding tissue and leads to neuroinflammation and neurodegeneration. This process worsens over time and promotes WMH volume growth. In this study, we pose that the onset location of pWMH originates from ventricular wall failure which causes cerebrospinal fluid (CSF) to leak into adjacent brain tissue [3,7]. Normally, the ependyma, a single layer of cells forming a tight barrier between brain tissue and LVs, prevents CSF to diffuse into the brain tissue [8]. However, after damage of the ependyma this function might be disturbed [9]. Several histological and pathological studies have posed this hypothesis, but none of them has successfully explained what mechanism is responsible for the damage of the ependymal tissue [5,6,9]. Here, we hypothesize that hemodynamically driven LV expansion generates mechanical loading of the ependymal wall, which induces mechanical fatigue in the tight connections between the ependymal cells that line the LVs. This fatigue is thought to induce detachment of the cell-cell connections in the ependyma causing denudation of the LV wall and fluid accumulation in the periventricular space which initiates the onset of pWMH. We use a finite element modeling approach to determine the location of maximum ventricular wall loading and demonstrate that their location matches pWMH locations.

METHODS

From the NYU Langone Alzheimer's Center medical image database, we selected eight healthy subjects (four female, four male) aged 65 through 79. We used FLAIR images of each subject and chose

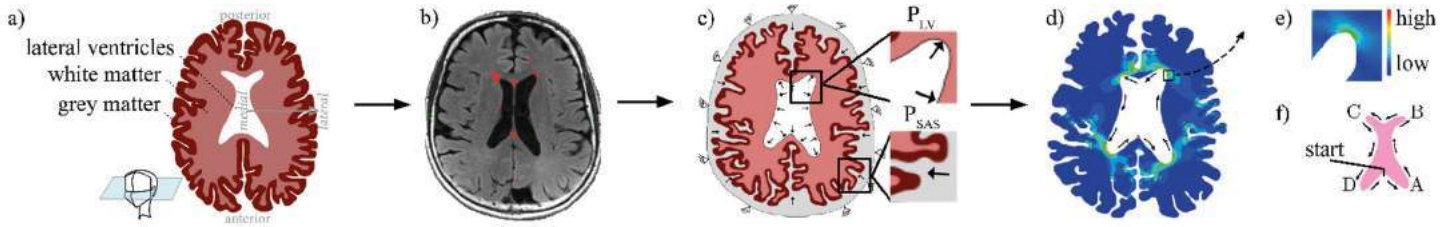

Figure 1: a) Anatomy of axial brain slice, b) FLAIR brain scan with WMH segmentation, c) Boundary conditions 2D FE model, with magnification of pressure in LV and pressure in SAS, d) representative figure of stretch in brain tissue at peak pressure, e) close up of stretch in LV horn, f) parametrization of the location along ventricular wall.

an axial slice that shows a representative cross section of the LV for segmentation using the software Simpleware ScanIP (Synopsis, Mountain View, CA). As shown in Figure 1c, our 2D finite element models differentiate between LV, white matter, gray matter, and CSF. We then imported the meshes into the finite element software Abaqus (Dassault Systèmes, Providence, RI) in order to prescribe Dirichlet and traction boundary conditions. Specifically, a normal pressure of 20 Pa was applied to the wall of the LV, and a normal pressure of 2 Pa to the tissue-CSF interface in the subarachnoid space (SAS) [10]. Grey and white matter tissue was modelled as an Ogden-type hyperelastic material with a Young's modulus of 1 and 2 kPa, respectively. We evaluated our simulations with respect to *maximum* and *minimum principal strain* along the LV, see Figure 1d-e. We further calculated the scalar product between the direction of the maximum principal Green Lagrange (GL) strain and the vector tangential to the LV wall in order to identify regions were cell stretch coincides with maximum GL strain. Finally, we compare the spatial distribution of our measures with WMH location extracted from each subject's WMH mask.

RESULTS

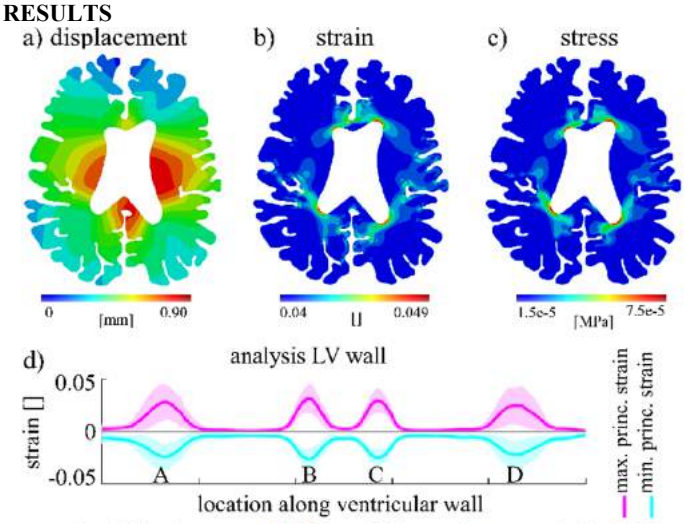

Figure 2: a) Displacement field [mm], b) maximum principal GL strain [-] and c) Von Mises stress [MPa] in one of the models, and d) Mean ± std of the maximum and minimum principal GL strain along LV wall for all eight models [-].

We show in Figure 2 that the LV wall displaces up to 0.9 mm and experiences stretches of up to 5%. From Figures 2b–d it can be derived that strain and stress localize in LV horns. Figure 2d also indicates that max. and min. principal strain show peak values in the anterior (points B and C) and posterior horns (points A and D) for all 8 models.

Figure 3a (3b is a magnification) shows the vector field of the maximum and minimum principal strain directions. From the scalar product between maximum principal strain direction and the vector tangent to the ventricular wall, we show in Figure 3c, that (i) maximum strain projection is predominantly tangential to the wall and that (ii) pWMHs co-localize where maximum principal strain is tangent to the ventricular wall; this is primarily observed in the anterior and posterior horns.

DISCUSSION

The modelling pipeline developed in this study is able to convert MRI scans to patient-specific models to simulate LV expansion. The displacement and strain fields observed in our models are similar to previously reported values for LV wall displacement by amplified MRI studies [10]. This indicates that the model is able to make physiological predictions of stress and strain distributions in the brain tissue due to hemodynamically driven LV expansion.

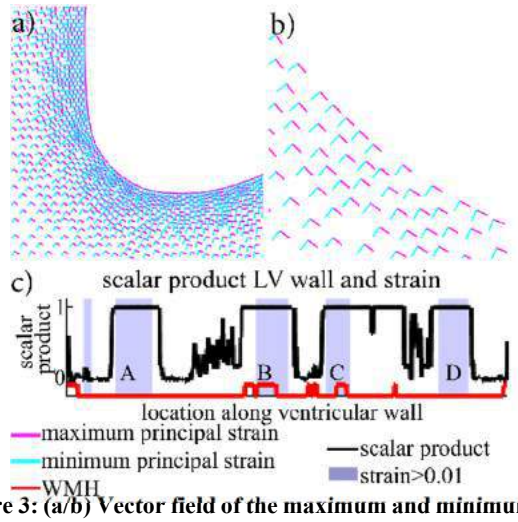

Figure 3: (a/b) Vector field of the maximum and minimum principal strain directions in a representative LV horn; (c) scalar product between maximum principal strain direction and tangent vector of LV wall and pWMH as a function of LV wall location.

The tissue deformation results in peak strains and stresses around the horns of the LV. Analysis of strain along the LV wall shows peak strains coinciding with WMHs found on FLAIR scans. Further analysis of the strains occurring in the ependyma shows that the maximum principal strain is tangential to the LV wall. The local strain state is representative of a cell loading state where cell-cell connections are under tension and cells are compressed. Ependymal cells are considered to be stretched thin which leads to their progressive failure and scar formation of the ependymal wall, as shown in Figure 4. Previous studies have shown that loss of cell-cell connections in the ependyma triggers denudation [11]. This would lead to failure of the tight-barrier function of the ependyma and the onset of pWMH.

This indicates that the locations which have high strains tangential to the LV wall are most prone to develop pWMH. Therefore, strains in ependymal cells could be used to predict the onset location of pWMH. Future studies could analyze how pWMHs grow over time by modeling tissue softening via a constitutive tissue damage model. This could be used to make prognoses of patient specific pWMH development.

INTRODUCTION

Computational fluid dynamics (CFD) is rapidly gaining ground as a non-invasive way to study blood flow in the cardiovascular system [1]. In the context of cerebral aneurysms, recent studies have shown that the properties of the algorithm used to solve Navier-Stokes equations are as important as the temporal and spatial resolution to obtain accurate hemodynamic predictions [2,3]. For cardiovascular CFD simulations, finite-elements (FEM) algorithms with stabilization schemes, such as streamline upwind Petrov–Galerkin (SUPG) [4], are typically used, due to their robustness, proven track record, and availability in commercial CFD software. While stabilization maximizes numerical robustness, it introduces additional numerical dissipation. We refer to these algorithms as "regular fidelity". This type of algorithm is also used in SimVascular, a comprehensive and open-source suite dedicated to cardiovascular CFD analysis [4].

More recently, it has been shown that more sophisticated algorithms to solve Navier-Stokes equations could offer compelling advantages. In cerebral aneurysms, it was shown that a high order and minimally dissipative FEM solver could attain high accuracy with a temporal and spatial mesh quite coarser than regular-fidelity schemes [2,5]. Furthermore, the high-fidelity approach was able to reveal high-frequency flow instabilities that were suppressed by the regular fidelity approach but may have clinical significance for predicting rupture. We refer to this latter class of algorithms as "high fidelity".

The objective of this study is to compare regular and high-fidelity algorithms in the context of the hemodynamic analysis of the aorta and surrounding branches. The hypothesis is that a high-fidelity approach may offer computational advantages for this type of analysis, which is computationally demanding due to the large caliber of the aorta and the presence of complex flow patterns caused by the relatively high Reynolds number.

METHODS

The study considered the prediction of blood flow in the aorta and supra-aortic branches of a patient admitted to the Sunnybrook Health Sciences Centre (Toronto, Canada) for coronary artery bypass graft surgery. A three-dimensional model was reconstructed from CT images using SimVascular [4]. Blood velocity was acquired in-vivo with 4D-flow MRI and used to set patient-specific boundary conditions to the CFD simulation. The shape of the simulated model is shown in figure 1. At the inlet of the ascending aorta, a pulsatile flow rate was imposed, with a Poiseuille-like velocity profile in the cross-section, and a temporal profile derived from 4D-flow MRI data. As boundary conditions at the outlets, a Windkessel RCR model was used where resistance and capacitance values were calculated based on average aortic pressure and MRI-derived flow rates. Vessel walls were assumed to be rigid to keep computational costs at affordable levels. Blood viscosity and density were assumed to be 0.04 g/(cm·s) and 1.06 g/cm^3, respectively.

Pulsatile flows in the aortic branches were simulated using both the high-fidelity second-order solver Oasis [5], and the regular-fidelity first-order solver available in SimVascular. Four cardiac cycles were simulated to assure that initial transients are washed out and simulation results have converged. All simulations were performed on the SciNet Niagara cluster, using four computing nodes for a total of 160 cores. Various combinations of solver type, mesh resolution, and temporal resolution were tested. Three levels of spatial resolutions (coarse, medium, and fine) were tested using SimVascular. For Oasis, three levels of spatial resolution and three time resolutions (time step of 1ms, 0.5ms, and 0.1ms) were tested, for a total of 9 Oasis scenarios.

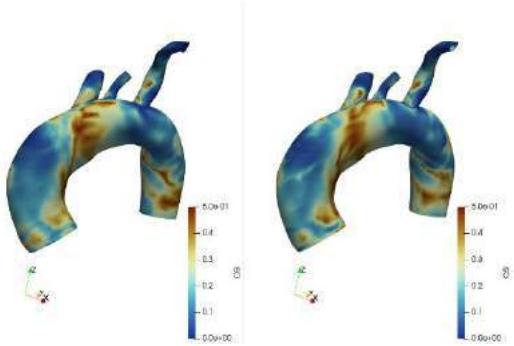

Figure 1: OSI computed by SimVascular (left) and Oasis (right).

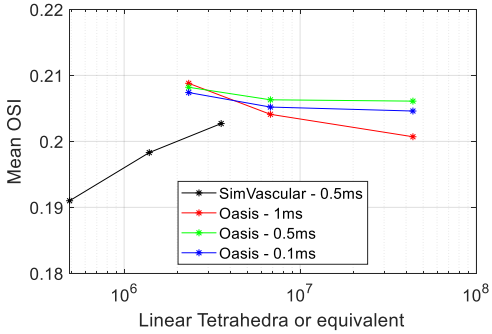

Figure 2: Mean oscillatory shear index vs. number of linear elements of the mesh (or equivalent).

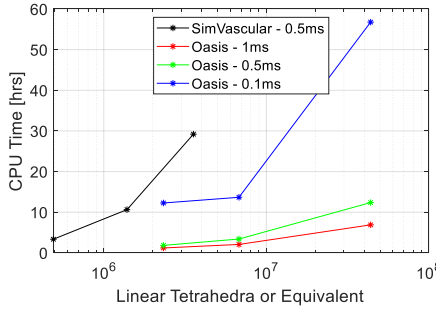

Figure 3: CPU time vs number of linear elements (or equivalent)

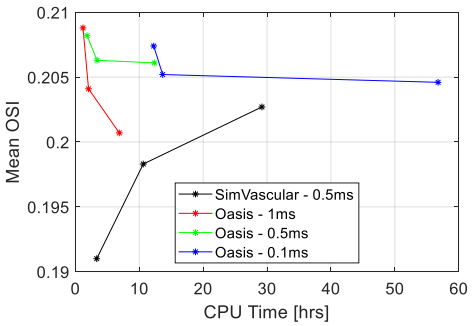

Figure 4: Mean OSI vs. CPU time.

RESULTS

Several hemodynamics indicators were computed to evaluate the simulation results, including mean wall shear stress (WSS), and oscillatory shear index (OSI). Figure 1 compares the mean OSI averaged over the 4th cardiac cycle by SimVascular and Oasis, obtained with the fine mesh and a 0.5-ms time step for both solvers. Figure 2 presents the mean OSI values over the entire model and time-averaged over the fourth cardiac cycle, for all the 12 scenarios examined. Figure 3 shows the CPU time consumed by these simulations as a function of the number of linear tetrahedral elements or equivalent. Since second-order elements were used in Oasis, the number of equivalent linear elements was set to eight times the number of mesh elements. Figure 4 depicts mean OSI as a function of CPU time directly. In figures 2 to 4, each line corresponds to a different combination of solver type and time step. The three points on each line, from left to right, correspond to the three spatial resolution levels (coarse, medium, and fine).

DISCUSSION

From figure 1, it can be seen that the simulation results of OSI given by the two solvers are comparable and agree with each other in terms of general patterns. Similarity is also observed when comparing time-averaged WSS. In figure 2, the mean OSI results of the Oasis solver showed a better converging behavior as mesh refines, compared to SimVascular results which have not yet converged within a 5% tolerance. It is also noted that the coarse temporal resolution setting (1 ms step) may be insufficient for the finest mesh, since its OSI results still show some variation. Figure 3 shows that the high-fidelity solver Oasis generally requires a lower amount of CPU time compared to the regular-fidelity strategy.

By comparing the OSI values vs CPU time in figure 4, it becomes clearer the advantage that a high-fidelity strategy can offer in terms of accuracy and computational efficiency. For the comparison, we take the OSI result of 0.204 obtained with Oasis with the finest settings as the reference result (rightmost point in Fig. 4). We see that the high-fidelity solver Oasis, with any combination of temporal and spatial resolution, yields an OSI prediction within ±2.5% of the reference. On the other hand, the regular-fidelity solver produces an OSI within ±2.5% of the reference value only with the finest spatial mesh, which requires 29 hours of CPU time, compared to the 3.4 hours required by the high-fidelity solver with the same temporal resolution (0.5 ms) and medium spatial resolution. We also observe that the high-fidelity solver delivers a fair OSI estimate even with the coarsest temporal and spatial meshes, while requiring only ~1 h of CPU time.

In conclusion, our study shows that high-fidelity CFD solvers can offer superior accuracy and efficiency in the hemodynamic analysis of large vessels such as the aorta. On par of accuracy, the high-fidelity solver Oasis was shown to reduce CPU time by about eight times compared to a regular-fidelity approach. Furthermore, the high-fidelity strategy seemed able to produce good estimates of hemodynamic indices even with relatively coarse meshes and limited CPU time, an appealing feature for clinical translation.

INTRODUCTION

In the United States, more than 54 million people over the age of 50 suffer from osteoporosis or low bone mass,[1] which contributes to an increase in fracture risk. Clinically, fracture risk and osteoporosis are predicted by measuring bone mineral density (BMD). However, fracture risk is not only dependent on BMD, but also bone quality.[2] Patton et al. showed that bone stiffness highly correlates with bone strength, but this relationship varies with sex and age.[3] While both osteoporosis and low bone mass are moderately heritable,[4] little is known about how bone quality and stiffness are genetically regulated.

The micro-architecture of cortical bone is comprised of a porous and highly connected system of intracortical pores, called lacunae, and microchannels, called canaliculi. This system is known to be highly diverse between different bones,[5] but how this system is regulated is still being investigated. It has been shown that higher lacunar density correlates with lower microcrack density,[6] showing the importance of bone properties across length scales.

The goal of this study was to investigate how bone parameters correlate across different length scales and if these properties are genetically modulated. To do this, we analyzed whole-bone and lacunar morphological properties of eight genetically diverse mouse strains and correlated these bone properties to each other and bone stiffness. We hypothesized that bone properties vary between mouse strain and correlate across length scales.

METHODS

Mice. Female and male mice (n = 67) were received from Jackson Laboratory (Jax) at 8 wks and aged in our animal facilities until skeletally mature (22 wks). Mice were sacrificed with CO_2. The eight mouse strains (A/J, C57BL/6J, 129S1/SvImJ, NOD/ShiLtJ, NZO/HlLtJ, CAST/EiJ, PWK/PhJ, and WSB/EiJ) were chosen because they cover 90% of the genetic variation in mice and were used by Jax as the founders for the Diversity Outbred population.

Whole-Bone Morphology. The right tibial diaphysis was scanned on a Scanco vivaCT 40 at 10.5 µm resolution. Total area, bone area, medullary area, cortical thickness, tissue mineral density, polar moment of inertia, and 3D offset of a 1.05 mm long region centered 5 mm proximal to the tibiofibular junction (TFJ) were quantified.

Lacunar Morphology. The left tibia was cut approximately 5 mm proximal to the TFJ and 2 mm distal to the TFJ. A 0.5 mm region was scanned on a Zeiss Xradia Versa 520 X-ray Microscope (XRM) 4 mm proximal to the TFJ, centered halfway between endocortical and periosteal surfaces at the posterial-lateral apex. Scanning parameters were as follows: 40 kV, 3 W, 1601 projections, 20x objective, bin = 2, 4800-5000 projection intensity (7-8 sec exposure), nominal resolution of 0.54 µm. Bones were segmented, filtered, and analyzed using Dragonfly for total lacunar volume, total vessel volume, and individual lacunar properties.

Stiffness Analysis. The right tibia was exposed and cleaned, and a single-element strain gauge was glued to the antero-medial surface 5 mm proximal to the TFJ. The right tibia was axially compressed on a material testing machine (Dynamight 8841) at a peak-to-peak force ranging from 2-10N for 12 cycles at 4 Hz with 3 minutes of rest between each force. The corresponding mechanical strain was measured (LabView), and the force needed to induce a strain of 1500 µε was calculated from the force-strain regression as a proxy of tibial stiffness.

Statistics. Results of cortical bone morphology and stiffness analysis were analyzed using two-factor ANOVA to investigate (mouse) strain and sex effects, and sex-strain interactions. A correlation matrix (Pearson r) of all parameters was created to investigate the relationship between bone properties and bone stiffness.

RESULTS

Most whole-bone parameters vary significantly with (mouse) strain and sex plus have significant strain-sex interaction (Fig 1). Bone properties correlate across length scales with bones with larger area correlating to larger lacunae and more densely spaced lacunae (Fig 3).

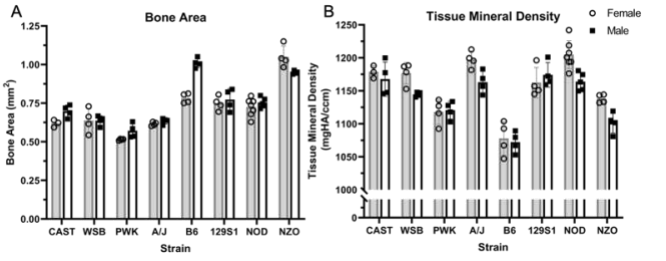

Figure 1: Both bone geometry (A) and composition (B) vary between strain, sex, and have a strain-sex interaction.

On average, 4370 lacunae were analyzed per bone, with the lacunae occupying 0.8-2.4% of the total analyzed bone volume. The lacunar number density (Lc.N/TV) varies from 46,700/mm^3 for A/J males to 84,500/mm^3 for 129S1 female (57% difference). Total porosity (lacunar plus vessel porosity) (Fig 2A) varies significantly between mouse strain, sex, and has a sex-strain interaction. Lacunar volume density and vessel volume density are moderately correlated (r = 0.54) while lacunar number density is independent of vessel volume (Fig 3).

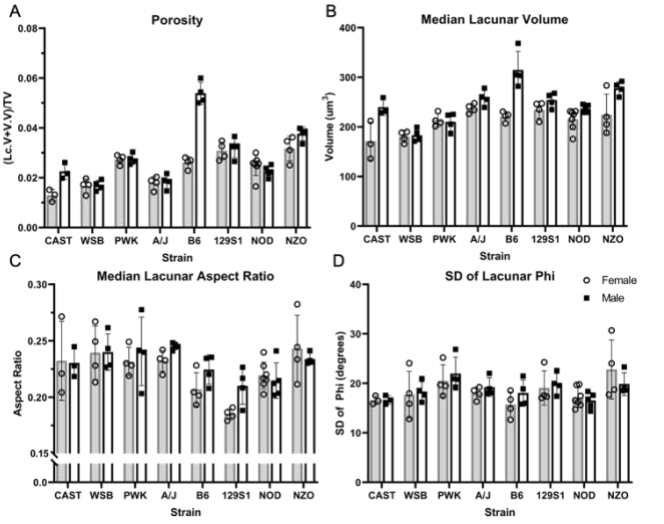

Figure 2: Total porosity (A) varies with mouse strain, sex, and has a strain-sex interaction. (B) Median lacunar volume (size) varies with mouse strain, sex, and has a strain-sex interaction. (C) Median aspect ratio (shape) and (D) SD (standard deviation) of phi (orientation) both vary with mouse strain.

Lacunar size (volume), shape (aspect ratio), and orientation (SD of phi) all vary with mouse strain (Fig 2). The variation of median lacunar volume between strains is sex dependent (Fig 2B). Median lacunar volume is moderately positively correlated with total lacunar volume density (r = 0.65). Shape and orientation are moderately correlated (r = 0.45), with more elongated lacunae (smaller aspect ratio) being more aligned to the loading axis (smaller SD of phi) (Fig 3).

The force to engender and equal strain (1500 με) was calculated and compared as a proxy measurement of stiffness, with stiffer bones requiring more force. Force varies significantly between mouse strains and was moderately correlated with bone size, bone curvature, lacunar size, and lacunar porosity measurements (Fig 3).

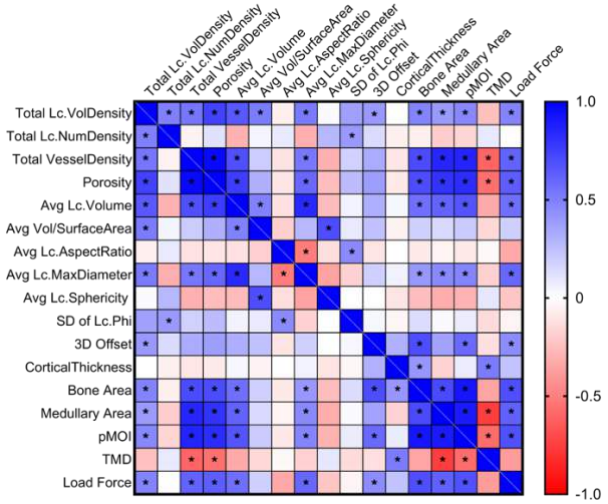

Figure 3: Correlation of Pearson r coefficients for all measurements. * denotes p < 0.001.

DISCUSSION

We showed that bone architecture, at both the whole-bone level and lacunar level, and bone stiffness vary with mouse strain, implicating a genetic contribution. Additionally, we showed that bone properties correlate across length scales with larger bones (higher bone area) having larger lacunae (higher median lacunar volume).

Bone micro-architecture also influences whole-bone tissue mineral density (TMD). Bones with higher porosity and specifically higher vessel volume density, have lower TMD. Therefore, the bone between the pores may have the same mineral density, but when measured at a larger length scale the apparent density is diminished. Therefore, lower TMD measurement in bone may imply more vasculature and not reduced mineralization.

Bones with higher total lacunar volume density tend to have larger lacunae on average, implying an increase in volume density is mainly explained by larger individual lacunae rather than more lacunae. Additionally, as lacunar volume increases, lacunar number density slightly decreases (r = -0.3, p = 0.012), supporting the idea that each lacuna "supports" a certain volume of cortical bone.

Bone micro-architecture also correlates to bone stiffness. Despite lower TMD, bones with higher porosity are stiffer. Larger bones, which also tend to have larger lacunae, are also stiffer. This implies bone size and shape across length scales contribute to bone stiffness and possible fracture risk.

We have shown that bone properties correlate between length scales, and that cortical bone properties vary with genetic background, motivating future studies to investigate the gene loci modulating these relationships.

OCULAR BIOMECHANICS DUE TO THE GROUND BLAST REINFORCEMENT OF AN IMPROVISED EXPLOSIVE DEVICE AT VARIOUS HEIGHTS

A Karimi (1), R Razaghi (2), CA Girkin (1), JC Downs (1)

(2) Research Department, Heel of Scene Ltd., Tokyo, Japan

INTRODUCTION

Although the eyes comprise approximately 0.27% of the total body surface area and only 0.1% of the erect frontal profile, eye injuries are found in 10-13% of all combat casualties. Combat eye injuries are often due to unexpected improvised explosive devices (IED), homemade bombs constructed and deployed in ways other than in conventional military action. More than 24,000 injuries to American service members in the military action have been reported (1), and ocular injuries due to IEDs are responsible for ~ 5-13% (2, 3), 29% (4), and 72% (5) of battlefield casualties in prior reports. It is important for ophthalmologists, particularly those working in urban trauma centers, to have knowledge of the mechanisms and spectrum of injury from various IED blast injury patterns (6). However, investigating ocular injuries from IED blasts is difficult experimentally due to complicated experimental setups and variations in the weight, angle, distance of the IED from the victim, and other factors. The finite element (FE) method can be used to estimate the injury to the eye computationally . FE analyses can be used to simulate ocular tissue deformations, stress and strain from IED blast at various IED weights, heights, and angles, which is difficult to achieve experimentally. IEDs are typically placed off the ground to more severe injure the victim through ground blast reinforcement (GBR). However, there is still a paucity of knowledge about the role of the IED height from the ground on ocular biomechanics; and how the GBR can amplify the severity of injury.

METHODS

This study was aimed to establish a 3D fluid structure interaction model of the eye, skull, air, soil, and IED, using a multi-material, arbitrary coupled load blast enhanced and Eulerian-Lagrangian approach to estimate the stresses and deformations in the human eye connective tissues (Fig. 1). An eye-specific FE model of the human eye, including a detailed optic nerve head, was constructed and a generic anterior segment was added. The eye was then incorporated into a 3D FE model of the human skull and the gap between the orbital bone and the eye was filled with extraocular tissue. The skull-eye FE model was then subjected to an IED explosion (IED's weight=2kg) from the front in a way that the blast pressure from the IED hits the frontal bone of the skull. Two different blast formulations, (a) spherical air burst with no amplification (GBR) of the initial shock wave due to interaction with the ground surface; and (b) a hemispherical surface blast from an IED located on or near the ground surface, with GBR, were used to simulate the IED explosion. In the latter case, the initial blast wave is immediately reflected and reinforced by the ground to produce a hemispherical reflected wave from the point of the blast. This reflected wave merges with the initial incident wave, producing overpressures, which are as much as four to eightfold (6) greater than those produced by the initial blast wave alone (7). The simulations were done for a period of 20 ms, much longer than prior studies, which allowed us to simulate the tertiary injury (victim's head translation due to the blast loading) in addition to the full loading of the primary injury. Furthermore, a longer simulation time allowed us to simulate the merging of the GBR and the bomb blast overpressure itself, which finally led to a stronger overpressure in the eye. Prior studies simulated the blast out to ~ 1.6 ms.

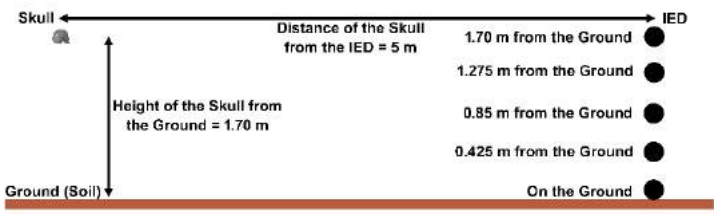

Figure 1: The FSI model of the skull, eye globe, IED, air, and soil. The IED was placed 5 m from the victim at five different heights from the ground. After the explosion, the blast wave from the bomb and its reflection from the ground hit the frontal bone of the skull.

RESULTS

The results revealed that the blast wave from the GBR reached the skull prior to the IED blast itself (Fig. 2).

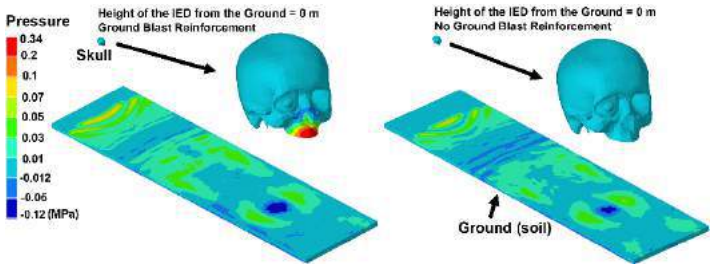

Figure 2: The contours of pressure distribution in the ground (soil) and skull-eye model. The skull-eye model is magnified for each model to better visualize the pressure distribution in the victim.

The GBR also reached the skull ~ 0.6 ms earlier when the IED was on the ground compared to when the IED was at the height of 1.70 m from the ground. The highest and lowest intraocular pressures (IOP) of ~ 17,000 and ~ 15,000 mmHg were observed for the IED heights of 1.70 and 0 m from the ground, respectively, considering the GBR. However, the IOP of ~ 9,000 mmHg was observed when the role of the GBR is ignored, regardless of the IED height from the ground (Fig. 3). The deformation in the apex of the cornea was higher when considering GBR (~ 0.75 cm) compared to the case with no GBR (~ 0.65 cm); no considerable deformation difference was observed at different IED heights from the ground. When the role of the GBR was ignored, the results showed almost the same patterns and magnitudes of stresses and deformations in the skull and eye regardless of the height of the IED from the ground, suggesting the GBR plays a crucial role in ocular blast simulations. Within 1.6 ms after the blast, our results revealed the IOP elevation of 2730 and 1670 mmHg with and without GBR, respectively, which is within the reported ranges of 2625 mmHg (8), 3150 mmHg (9), and 1739±307 mmHg (10). This is consistent with the experimental study on porcine eyes under blast loading by Alphonse (11).

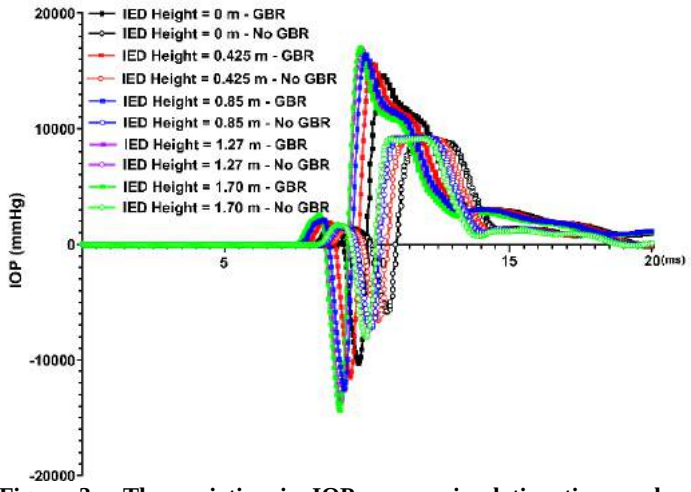

Figure 3: The variation in IOP versus simulation time under various IED heights from the ground as well as ground blast reinforcement.

DISCUSSION

In the cases of the Boston Marathon bombing and the Fertilizer Plant explosion in West, Texas in 2013, blasts were at ground level, and yet they still resulted 13.4% and 14.2% ocular injury rates, respectively (12). This suggests the important role of the IED height from the ground in ocular injury. Our results also showed the importance of the GBR in ocular injury assessment (Fig. 2), as GBR reached skull-eye model prior to the incident IED blast pressure itself. Our results revealed that when the IED was placed on the ground, it took longer for the GBR to reach to the skull compared to when the IED was at the height of 1.70 m. We were able to simulate these differences in the blast wave GBR (7), which is likely important since as it has been shown that the GBR can increase the blast energy by as much as four to eightfold (6). In addition, increasing the height of the IED from the ground led to an increased pressure in the eye and a reduction in the time that took the GBR to reach to the head. This is in agreement with the literature, as IEDs are typically placed at a substantial heights from the ground (*e.g.*, at the height of the vehicle) so as to cause fatal injury (13). This study shows the importance of the IED height and ground blast reinforcement in blast injury assessment using a modified detonation formulation and a multi-material arbitrary coupled load blast enhanced and Eulerian-Lagrangian algorithm, and lays the groundwork for providing ophthalmologists and military medical experts with valuable simulations of IED effects.

INTRODUCTION

The mechanical and geometric characteristics of a vehicle's interior contribute to the biomechanics associated with a collision. Specifically, in regard to low speed rear-end collisions, the mechanical properties of the seat play a significant role in the resulting biomechanical response of an occupant. The MAthematical DYnamic MOdeling (MADYMO) software suite provides the capability to simulate such vehicle-specific conditions and corresponding occupant kinematics.

A methodology for analyzing low-speed rear-end collisions using subject-specific simulations has previously been presented [1]. The current study expands upon this methodology to account for the mechanical properties of the vehicle seat. The Insurance Institute for Highway Safety (IIHS) conducts seat rating tests on new vehicles in order to assess the efficacy of seats/headrests in mitigating cervical spine injuries during rear-end impacts. Seat parameters, such as the stiffness of the seat cushions [2,3], seat back stiffness, seat back energy return, cushion energy return, and friction [4], may have an impact on the biomechanical environment experienced by an occupant involved in a rear-end collision.

The objective of the current study was to determine a method for validating a vehicle-specific seat model for studying low speed rear-end collision occupant dynamics. The seat parameters were determined by optimizing computational head and pelvis accelerations to those observed during controlled, physical, rear-end impact sled tests. We hypothesized that utilization of the validated seat properties would allow for accurate computational predictions of occupant head and pelvis acceleration for a range of severities when compared with published physical testing.

METHODS

Seat Validation. The IIHS Dynamic Seat Rating test for the 2013 Honda Accord (SER12031) was utilized to visually construct a seat in MADYMO using a series of ellipsoids and connecting joints. A digital anthropomorphic test device (ATD), specifically a Hybrid III 50th percentile dummy model (Tass International version 2020.1), was placed in the digital environment and positioned to match the precise position of the BioRID II ATD in the sled test (Figure 1). The test acceleration pulse (with a change in velocity, or Delta-V, of 15.6 kph) was taken directly from the IIHS sled test documentation and applied to the MADYMO model. The IIHS also documented the final deflection of the seatback joint along with accelerations of the head and pelvis, and the maximum seatback deflection was determined from the IIHS sled test video. The model seat parameters were based on the seat foam stiffness properties from Cruise et al. (2020) [2] and seatback joint stiffness functions from a Honda Passport in Molino (1998) [4] as a baseline. These properties were iteratively optimized based on the seatback angle and computational ATD head/pelvis accelerations (Figure 2). Optimization of the seatback joint stiffness was conducted by scaling the load vs. displacement functions, as well as adjusting the seat back energy return until the seatback angular position reached the maximum deflection determined from the video and the final angular position recorded in the controlled rear-end collision sled test. The baseline seat foam load vs. displacement functions were scaled, and cushion energy return properties were varied to align the peak timing and peak magnitude of both the head and pelvis accelerations. The friction between the dummy and the seat and the head rest joint damping coefficient were modulated in order to match the computational and physical head kinematics.

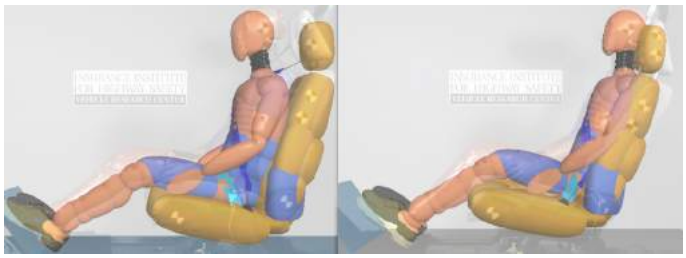

Figure 1: MADYMO seat model overlaid on IIHS test video frames.

Prediction of Varying Severity Impacts. Once the model seat properties were determined, the model was then tested against a previously published rear-end collision testing series [5,6]. This testing consisted of four low- to moderate – speed (Delta-V's ranging from 5.6 kph to 19.5 kph), full-scale, collinear rear-end crash tests [5, 6]. The tests utilized two 2014 Honda Accords which were occupied by restrained and instrumented Hybrid III 50th percentile male ATDs. The crash pulses from this series of testing are reported by Crosby et al.

(2019) [5] and the occupant dynamics results are reported by Toney-Bolger et al. (2019) [6]. Collision acceleration pulses were applied to the vehicle system in MADYMO [5]. Peak resultant linear head acceleration and dynamic pelvis accelerations were compared between the MADYMO simulation and the full-scale testing [6].

RESULTS

Seat Validation. The MADYMO validation simulations matched the results of the IIHS physical sled test in both seat dynamics and ATD kinematics. The IIHS test seat reached a maximum deflection and a final deformed deflection of 4.1 and 1.9 degrees, respectively, as a result of the 15.6 kph rear-end collision. This was the same deflection recorded in the MADYMO simulation. A comparison of the MADYMO ATD pelvis and head acceleration to those of the IIHS test accelerations are depicted in Figure 2. This demonstrates the validation of the computational vehicle specific MADYMO kinetics to those found in the IIHS rear-end sled test, with regards to acceleration magnitude, timing, and duration.

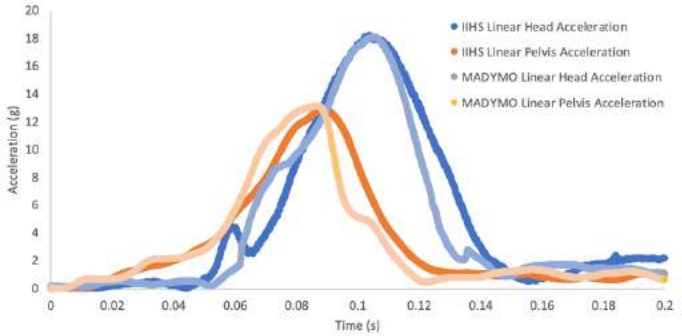

Figure 2: Head and pelvic acceleration comparison between IIHS test and MADYMO validation.

Prediction of Varying Severity Impacts. The peak head accelerations for each physical test of the rear-end test series and MADYMO simulation are compared in Table 1. A graphical comparison of pelvis accelerations are shown in Figure 3. MADYMO predicted peak head accelerations within 3 g's or less of the physical tests for all severities of 13.2 kph and below. However, the peak head acceleration predicted by MADYMO for the 19.5 kph run was 9 g's less than the peak head acceleration experienced by the ATD in the physical test.

Table 1: Head acceleration comparison between Toney-Bolger, M. et al. (2019) rear-end test series and the MADYMO.

Test Series Run – Delta-V	Peak Head Acceleration – Physical Tests	MADYMO Simulation
L1 – 5.6 [kph]	7.9	8.8
L2 – 9.0 [kph]	13.5	12.2
L3- 13.2 [kph]	22.2	19.2
L4 – 19.5 [kph]	28.0	19.0

DISCUSSION

This data demonstrates the efficacy of utilizing standardized crash testing to determine dynamic seat properties for constructing vehicle-specific models of low-speed rear-end collisions in MADYMO. When testing these vehicle-specific seat properties against a published rear-end collision series, the model accurately predicted resultant head and pelvis acceleration at or below the Delta-V of which the validation was performed (5.6 kph to 15.6 kph).

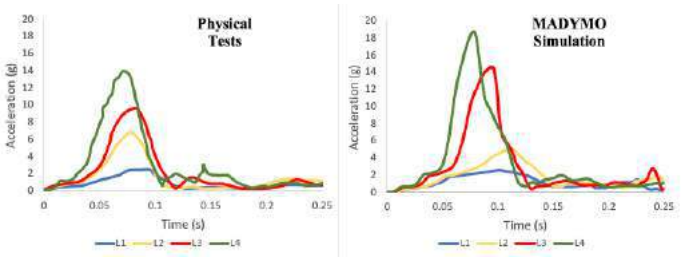

Figure 3: Pelvis acceleration comparison between Toney-Bolger, M. et al. (2019) (Left) rear-end test series and the MADYMO (Right).

A previously presented study outlined a methodology for building a *subject*-specific MADYMO model [1]. In short, the subject driver was imaged using a Faro Focus 3D laser scanner and a scaled ATD was aligned with the 3D laser scan. The methodology presented in the current study can be utilized in conjunction with this previously presented subject-specific methodology in order to create a robust model that incorporates both vehicle and subject-specific geometry and dynamic mechanical properties. These methodologies can be utilized for evaluating real-world collisions that may be less characteristic of generalized testing performed for collinear rear-end collisions with a normally seated driver.

While accurate at lower impact severities, the model overpredicted resultant pelvis accelerations and underpredicted resultant head accelerations at the maximum severity tested (19.5kph Delta-V). This likely occurred because the primary seat properties of a real-world seat differ between low- and mid-speed rear-end collisions due to the excessive amounts of seat cushion penetration and seat back joint deformation experienced at high speeds. While this study is considered successful at validating low-speed rear-end collisions, more severe rear-end collisions likely require additional parameters to account for the non-linear nature of the dynamic seat stiffness characteristics.

While the current study demonstrated the efficacy of a seat-specific model in accurately predicting dummy accelerations, future studies will test the ability of the model to predict kinetic parameters, particularly in the cervical and lumbar spine. Furthermore, in addition to the scalable dummy model used in the present study, MADYMO offers scalable human models [7]. The MADYMO manual indicates that the human models have improved biofidelity in comparison to the dummy models and can be utilized in a wider range of loading conditions. Future work will utilize the human models for a comparison with the current ATD model.

INTRODUCTION

Osteoporosis and low bone mass are estimated by the National Osteoporosis Foundation [1] to affect more than half the U.S. adult population. Predictions indicate that by 2025 fractures due to osteoporosis will cost $25.3 billion per year [2]. Understanding mechanotransduction, the process that transduces bone mechanical strain into biological signals affecting bone remodeling could improve therapeutic methods for reducing the impact of osteoporosis [3]. In particular, it is not known how strain at the microscopic level affects the biological response of individual osteocytes, which are viewed as the mechanosensitive cells. This research tests the hypothesis that osteocytes detect bone strain directly from the strain in the bone matrix, which would mean osteocytes in regions with the highest bone strain would be the ones most likely to respond to loading.

Osteocytic response to loading as measured by increased activation of Wnt/β-catenin signaling pathway was observed to be heterogeneous at the microscopic scale [4]. Preliminary finite element analyses suggest that including lacunae in models of bone loading results in heterogeneous strain distribution[4]. This study aims to find correlations between local bone strain and β-catenin activity in individual osteocytes. This information could be used to develop therapies and medical devices designed to increase strain in regions that will more effectively increase bone formation.

To that end, multi-plexed 3D confocal imaging experiments were performed using stains that allow the lacunocanalicular spaces, osteocyte membranes, and activation of osteocyte β-catenin signaling to be identified in the same bone specimen. The images from these experiments were used to produce models of bone loading for each sample and ascertain where β-catenin activity is strongest.

METHODS

FITC was used to label the lacunocanalicular network (LCN), DiI to label osteocyte cell membranes, and DDAOG, a LacZ substrate, to indicate β-catenin signaling activity in TOPGAL mice.

The tibiae of TOPGAL mice (9 mo male) were loaded with 9.25 N for 100 cycles at 2 Hz to stimulate β-catenin signaling in the osteocytes. The mice were rested for one hour, then sacrificed. Harvested bones were incubated overnight at 37°C in 30 μM DDAOG in X-Gal buffer solution. Transverse sections of the bone were then incubated at RT in 1% FITC in ethanol overnight, rinsed, and incubated in 100 μM DiI in ethanol overnight. Samples were rinsed, polished, and mounted with Permount.

3D confocal fluorescence imaging at 40x with 12-bit depth was used to collect signal from each stain, using 488, 594, and 633 nm laser excitation. The image stacks were imported into the Materialise® Innovation Suite [5] for creation of 3D finite element models, and to calculate osteocyte volume (based on DiI imaging) and total DDAO signal intensity (as a measure of β-catenin activation) for each osteocyte. Relative β-catenin activity was represented by DDAO intensity/Osteocyte volume. The FITC model was inverted to form a volume mesh of the bone matrix for strain analysis.

RESULTS

The image in *Figure 2* shows that the three dyes were clearly distinguished. The LCN fluid space, filled with FITC, is shown in green. The osteocytes labeled with DiI are shown in blue (cyan where signal is colocalized with FITC). DDAO is shown in red (pink or purple where colocalized with other dyes), indicating osteocytes with active β-catening signaling. DDAO was also apparent in a wide-field microscope where activated osteocytes look blue. Resolution is inadequate to

distinguish dendrites from canaliculi. Since regions where DiI dominates must be within the LCN, the LCN and osteocyte signals were combined for modeling the LCN. The LCN model from this image contains about 1.4 million nodes and 5.1 million tet4 elements.

DISCUSSION

The emission spectra for the three dyes, FITC, DiI, and DDAO are shown in *Figure 2*. The 633 nm laser does not excite FITC or DiI, allowing the DDAO label for β-catenin signaling to be distinguished from the other stains. The DDAO signal intensity is a relative measure of osteocyte β-catenin signaling activation[6] when compared with other osteocytes in the same image. DiI can be excited by a 543 nm or 594 nm laser, but to avoid bleed through from FITC, the 594 nm laser was chosen. If any DDAO signal is collected with the DiI signal, it is of no consequence since DDAO is contained within the osteocytes that DiI labels. FITC can also easily be distinguished by selecting an emission range of wavelengths shorter than DiI emissions.

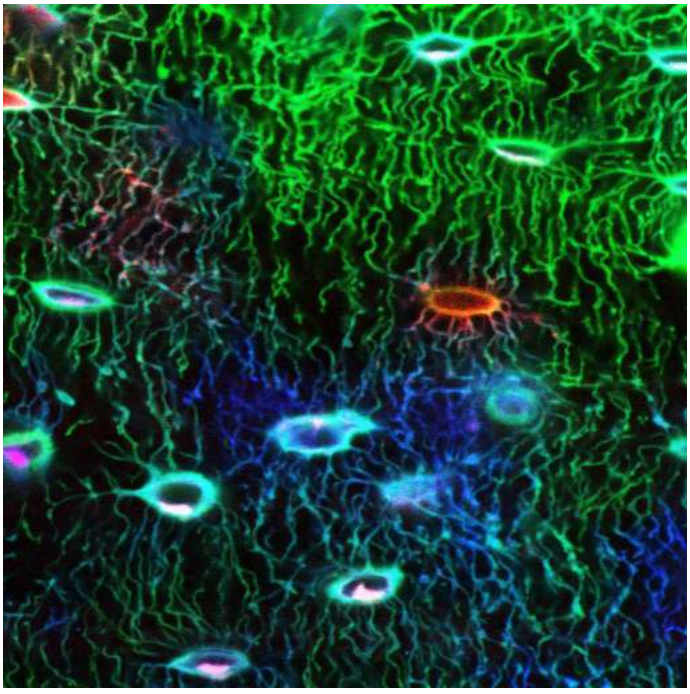

Figure 2: *Confocal fluorescence image of TOPGAL mouse tibia after loading. Green is FITC in the lacunocanalicular extracellular space. Blue is DiI labeling the cell membranes. Red is DDAO in cells with active β-catenin signaling. Notice the heterogeneity of β-catenin signaling activity.*

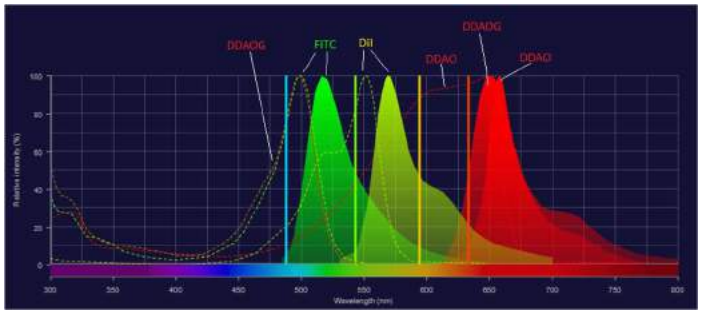

Figure 2:*Spectral graphs for FITC, DiI, and DDAOG/DDAO. The dyes are distinguished from one another by imaging each separately with the 488, 594, and 633 nm lasers. Bleed-through of DDAO signal into the DiI signal is of minimal concern since DDAO is contained within the osteocyte membranes, and the DiI signal is being used for volume measurements only.*

The collected image shown in *Figure 2* demonstrates that the three dyes are compatible when used in combination. Furthermore, the expected heterogeneity of β-catenin signaling in the osteocytes is clearly demonstrated by the different distributions and intensities of DDAO within labeled osteocytes.

An FE model of this image has been constructed to predict the strain distribution. Comparison of the DDAO intensity (β-catenin activation) in and osteocyte and the local strain distribution will provide insight as to whether mechanotransduction is occurring in the immediate vicinity of bone under the highest strains or if it may be due to another phenomenon such as fluid flow shear stress across the cell membranes, which is related more to the volume and architecture of the LCN that affect fluid flow rates.

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a complex cardiovascular disease characterized by an increase in pulmonary arterial (PA) pressure. Progressive PAH leads to impaired ventricular-vascular coupling and right ventricle (RV) hypertrophy. Pulmonary vascular stiffness (PVS) of the proximal PAs has been recently recognized as an immediate marker of the disease progression [1]. Also, several clinical studies have suggested that PVS is correlated with the mortality of PAH patients [2]. Vascular remodeling in PAH, typically through a mechano-regulatory process, is the direct cause of PVS elevation in both large proximal and small distal PAs. Smooth muscle cell (SMC) hypertrophy and proliferation as well as extracellular matrix (ECM) accumulation such as collagen and elastin have been recognized as common features of PAH remodeling [3]. Due to an increase in the mass of these tissue constituents, the PA wall becomes thicker and stiffer. To investigate the remodeling processes in the large proximal PA due to PAH, we developed a patient-specific computational modeling framework based on the constrained-mixture theory [4]. Specifically, we investigate how an elevation of the mean pulmonary arterial pressure (mPAP) in PAH affects vascular homeostasis. We show that the stress-mediated model predicts an increase in mass production rate, thicker arterial wall and stiffer PA with elevated mPAP.

METHODS

Clinical data and finite element (FE) modeling. Data from a female patient (16 y/o) diagnosed with idiopathic PAH was acquired. Specifically, pressure waveforms in the pulmonary circulation were measured by invasive right heart catheterization. Magnetic resonance images (MRI) were also performed were also performed to acquire the PA anatomy which was used to build the geometric model with CRIMSON [5]. The PA wall was modeled as a membrane structure and the material domain was meshed triangular elements in 3D space (**Figure 1**).

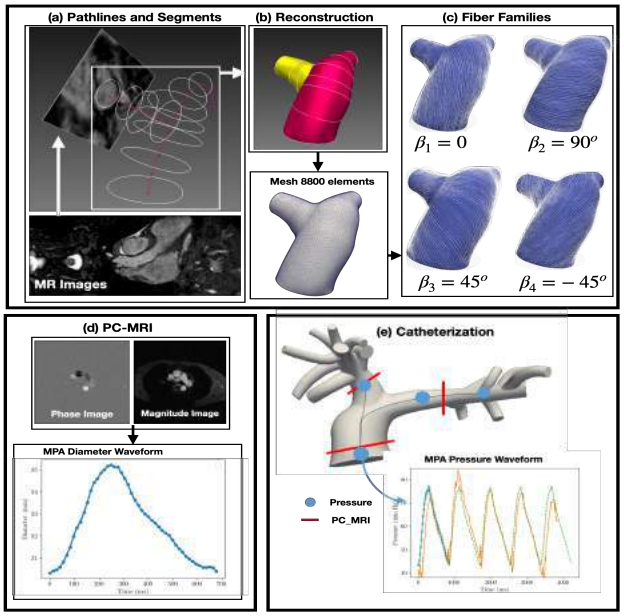

Figure 1: (a-c) Anatomical reconstruction, FE mesh and fiber data. (d-e) Catheterization and waveforms acquirement.

Constrained mixture model of vascular growth. The PA wall was modeled as a mixture of the tissue constituents, which are constrained to deform together. Mechanical contributions of the three primary tissue

structural constituents are considered. These constituents are, namely, collagen fibers ($\alpha = k$) and SMC ($\alpha = m$) whose passive behavior is described by a Holzapfel-type model, as well as elastin $\alpha = e$ that is modeled as a Neo-Hookean solid. Employing the rule of mixture, the collective stored energy function at each G&R timepoint s is given as

$$w^{\alpha}(s) = M^{\alpha}(0)Q(s)\Psi^{\alpha}\left(\mathbf{C}^{\alpha}_{n(0)}(s)\right) + \int_0^s m^{\alpha}(\tau)q^{\alpha}(s-\tau)\Psi^{\alpha}\left(\mathbf{C}^{\alpha}_{n(\tau)}(s)\right)d\tau, \quad (1)$$

where M^{α} and m^{α} are the mass and mass production rate per unit area of the constituent α synthesize at time τ, respectively. $\mathbf{C}^{\alpha}_{n(\tau)}(s)$ is the right stretch tensor of the fiber from its natural stress-free configuration synthesized at time τ that has survived up to time s.

Evolution of constituents' mass. Mass production rate of constituent α is modulated by the deviation from the homeostatic value of its stress:

$$m^{\alpha}(s) = \frac{M^{\alpha}(s)}{M^{\alpha}(0)}\left[k^{\alpha}_{g}(\sigma^{\alpha}(s) - \sigma^{\alpha}_{h}) + m_{basal}\right], \quad (2)$$

where k^{α}_{g} is the non-negative rate parameter governing the constituent stress-driven mass production. k^{α}_{g} scales the production of fibers by cells in response to changes in homeostatic deviation. To have a sensitivity analysis, we picked values in the range of $k^{k}_{g} = k^{m}_{g} =$ 0.5~1.25 for both collagen fibers and SMC and a case of unregulated SMC mass turnover and $k^{k}_{g} = 1.0$.

RESULTS

Simulation was performed by imposing a constant mean pressure of 46.7 mmHg for a 450 days period to reach homeostasis in the PA, following which pressure is then elevated to 56.0 mmHg. The total simulated duration is 800 days (**Fig. 2(a)**). For the first 450 days, the turnover rate and mass density of collagen and SMC reached mass equilibrium (**Fig. 2(b,c)**). The resultant MPA wall thickness also reached homeostasis during this period (**Fig. 2(a), Table 1**). With a 20% increase in PA's pressure at day 450, mass production in collagen fibers and SMC is increased and its rate of increase is controlled by the factor k_g. For the range of k_g considered here, the wall is thickened by 29%-48% (**Fig. 2(a)**) and the PA overall mass is increased by 46%-102% (**Fig. 2(c)**). The larger the regulation factor, the larger the mass of SMC that is produced (**Fig. 2(b,c)**). Collagen mass increase, however, was not affected by k_g (**Fig. 2(b,c)**). When SMC turnover is not regulated, more collagen is produced in comparison to the case where the both constituents are mediated by stress (**Fig 2(b,c)**). Larger local stresses and thickness can be found at the bifurcation points. These quantities are highest at the MPA, followed by LPA and RPA (**Fig. 3**).

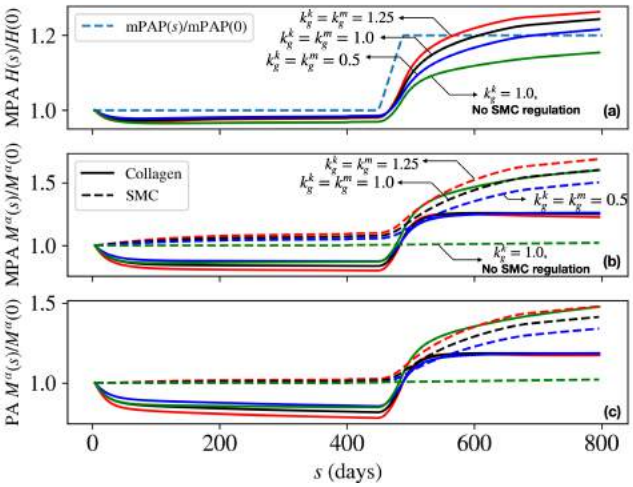

Figure 2: (a) The MPA wall thickness; (b) MPA, (c) PA collagen (-) mass and SMC mass (--).

Mass	Day 450				Day 800			
	MPA	LPA	RPA	PA	MPA	LPA	RPA	PA
Collagen (mg/mm^2)	0.189	0.1516	0.148	0.183	0.283	0.204	0.221	0.265
SMC (mg/mm^2)	0.294	0.284	0.247	0.273	0.442	0.423	0.353	0.384
Thickness (mm)	0.854	0.794	0.729	0.822	1.08	0.977	0.901	1.01

Table 1: Collagen and SMC mass and MPA wall thickness, (0-450)-days 46.7 mmHg and (450-800)-days 56.0 mmHg mPAP.

DISCUSSION

Pressure elevation in the PA causes higher collagen and SMC turnover, mass accumulation, that in turn, produces a thicker arterial wall. An increase in collagen is a common feature of PAH. This increase may be due to adventitial fibroblast activities [3]. Although SMC proliferation is less observed in small animals [6], it is, however, reported to play a role in the remodeling process in larger animals due to the presence of multiple phenotypically distinct SMC populations in the medial layer [7].

The stress-induced growth is controlled by the regulatory factor k_g [4], which affects the SMC growth more significantly. This is because the circumferentially oriented fibers and constituents bear a more significant portion of the additional load. Since SMCs are fully oriented in the circumferential direction (only 10% of collagen fibers are aligned circumferentially) [7], we expect a larger accumulation of SMC in the G&R process (**Fig. 2(c,d)**). Conversely, when SMC is not regulated, the amount of collagen accumulation increases drastically to compensate the absence of SMC response to the pressure elevation (**Fig. 2(b,c)**). A limitation of this study is that elastin was not regulated, even though there are studies indicating altered elastin content factor, e.g. growth [6], fragmentation [3] and no adaptation [9]. There is a need for further studies to have better insight in the role of elastin especially in age-sensitive pediatric PAH which will be a future plan of this work.

INTRODUCTION

Umbilical vessels maintain blood flow from the developing mammalian fetus to the placenta throughout gestation [1]. The umbilical vein carries oxygen-rich blood from the placenta to the portal vein and to the inferior vena cava through the ductus venosus, and deoxygenated blood is returned from the internal iliac arteries to the placenta through the umbilical arteries. During this time, it is essential that both sets of vessels maintain patency to allow for normal growth of the fetus [2]. However, shortly after birth, the lumen of the umbilical artery closes rapidly, while the umbilical vein remains patent, which allows for placental transfusion that increases fetal hematocrit [3].

In clinical practice, umbilical venous closure can be caused by clamping of the umbilical cord within a few seconds of birth, though recent studies have found several advantages to delayed cord clamping [4]. Our recent work has shown a natural mechanism that allows for umbilical artery closure, absent in the umbilical vein, that is preserved across many mammalian species [5]. The thick inner layer of the umbilical artery is rich in glycosaminoglycans (GAGs), while circumferentially oriented, contractile smooth muscle cells form the outer layer. Strong contraction by the smooth muscle cells at birth causes circumferential buckling of the inner layer, which protrudes into the lumen and prevents blood from returning to the placenta. Although the vein includes some GAGs in an inner layer and contractile smooth muscle cells, it does not buckle in the same manner as the artery.

We previously developed a computational model of buckling in the umbilical artery to understand the feasibility of the proposed mechanism for closure [5]. Herein, we utilize this model to understand how the structural differences between the umbilical artery and vein can inhibit closure. Parametric studies were performed to assess volume changes in the different layers. Additionally, bifurcation simulations were performed to identify structural effects on buckling.

METHODS

The umbilical vessels were both modeled as thick-walled, bi-layered cylinders with a GAG-rich inner layer and an outer layer including ground matrix, collagenous extracellular matrix (ECM), and contractile smooth muscle cells (Fig. 1A). Stored energy densities for

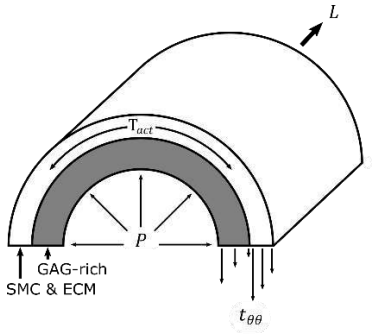

Figure 1. (A) Schematic drawings of the computational model with loading pressure P, axial load L, and active stress contribution T_{act}. Note the GAG-rich inner layer and SMC- and matrix-rich outer layer, which together give rise to the overall biomechanical behavior. Circumferential stress $t_{\theta\theta}$ varies pointwise in each layer.

the GAGs and ground matrix were neoHookean, and the collagenous matrix and smooth muscle cells were given Fung-like exponential forms. Material parameters were fit from biaxial mechanical testing data for the umbilical arteries [5]. As the vessels were observed to exude fluid during contraction, swelling and deswelling were accounted for by prescribing the ratio of the deformed to original volume v/V, and its effect on the stress distribution was enforced via a Lagrange multiplier

[6]. Contraction of the smooth muscle cells was modeled using a Rachev-type active stress in the circumferential component of the Cauchy stress [7]. Vessels were simulated with luminal pressurization and axial extension in a quasi-equilibrated state; the linear momentum balance equations were solved to identify the loaded configuration.

Buckling of the vessels was modeled with an incremental approach to the deformation, where a small perturbation was applied to the finite deformation and the incremental equilibrium equations were then solved to identify bifurcations [8]. A sinusoidal form for the incremental displacements was assumed, which allowed for simplification of the incremental equilibrium equations to a single fourth order ordinary differential equation, which, along with boundary conditions, allowed for a solution using the compound matrix method [9].

RESULTS

To understand better the distinct structures and functions of the umbilical arteries and veins, we modified the structural assumptions used to model the umbilical artery to be like those observed for the umbilical vein. As the loss of volume during contractile testing of the umbilical veins appeared to be greater than the entire volume of their thin GAG-rich inner layer, volume must have also been lost from the layer containing smooth muscle cells and matrix [5]. Therefore, we compared parametric studies where volume changes were constrained to one layer or homogenous across both layers (Fig. 2A and B). In the case with volume loss from the inner layer alone, a decrease in volume ($v/V < 1$) led to a lower active stress required to constrict the vessel, while increases in volume ($v/V > 1$) increased the active stress required for closure. However, with the volume changes occurring across both layers, the trends observed with volume changes in the inner layer alone generally reversed, with smaller lumens at higher values of swelling for all values of active stress.

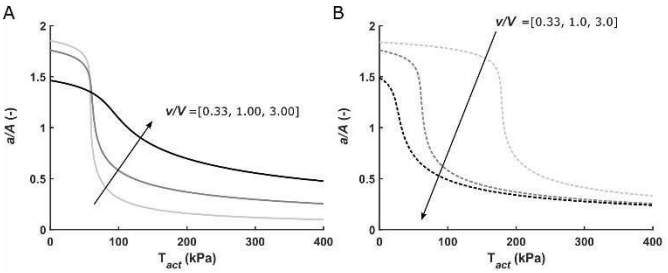

Figure 2. (A) Normalized inner radius a/A as a function of the active stress parameter T_{act} for different fixed values of volume change in the inner layer and (B) for fixed values of volume change in both layers. Arrows depict increasing volume.

We similarly examined the effects of volume changes across both layers on the buckling behavior. When examining the critical value of T_{act} for a vessel with volume changes in both layers, we found that the trends observed for volume changes in the inner layer alone remained the same, with a decrease in volume leading to a decreased active stress required for buckling and increased active stress required for an increase in volume. However, the critical values of T_{act} were lower for swelling in both layers and higher for shrinkage in both layers than in comparable cases for the inner layer alone, that is volume changes in both layers had a larger effect than changes in the inner layer alone. For $v/V = 0.5$, which was observed experimentally for the umbilical artery, the value of T_{act} was increased by nearly 2-fold for volume changes spread across both layers versus in the inner layer alone (Fig. 3A). This is likely because the mean circumferential stress $t_{\theta\theta}$ in the inner layer is less negative when volume is lost from both layers (Fig. 3B), which necessitates additional contraction to generate large enough compressive stress to cause buckling.

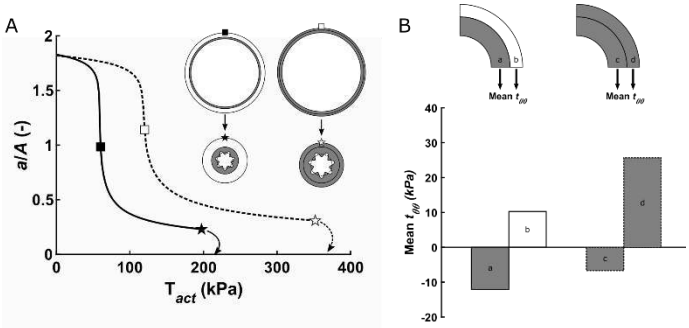

Figure 3. (A) Normalized inner radius a/A as a function of the active stress parameter T_{act} to the critical buckling point for decreased volume of the inner layer alone (solid line) and decreased volume of both layers (dashed line). Inflection points (solid square and open square) and critical points (solid star and open star) are marked and visualized in the corresponding schematics with shading corresponding to volume loss. (B) Mean circumferential stress $t_{\theta\theta}$ across the umbilical vessel wall for varying volume changes for a fixed value of active stress $T_{act} = 200$ kPa: (a) and (b) show circumferential stress for shrinkage of the inner layer alone with $v/V = 0.5$ while (c) and (d) show shrinkage in both layers.

DISCUSSION

Maintaining umbilical vessel patency throughout gestation is critical for ensuring the normal growth and development of mammalian fetuses. The presence of a GAG-rich inner layer, which is generally considered to convey compressive stiffness [10], in both the artery and vein indicates a role during gestation for preventing early narrowing. Indeed, reduction of the stiffness of the inner layer generally reduces the active stress required to reduce the lumen size. However, for buckling to take place, compressive stresses must build within the layer. In the umbilical vein, the propensity for volume losses to occur across both layers reduces the inner layer compressive stresses, which then inhibits buckling (Fig. 3B). Furthermore, stresses are increased in the outer layer of the umbilical vein as additional active stress is required to continue to narrow the lumen. These biomechanical differences arise as a result of the difference in GAG content and are mediated by the differential expression of proteoglycans and proteoglycanases between the vessels [5]. This mechanism provides for a natural method to prevent exsanguination of the newborn, and its ubiquity across mammalian species suggests an evolved role in supporting fetal health.

INTRODUCTION

Biomechanical models provide a reasonable and relatively inexpensive avenue to analyze spinal pathology. Subject-specific data for such models are obtained from a full-body CT or MRI in supine or prone position [1]. Clinical imaging records, however, do not offer such coherent data of spine and muscle geometry for modelling, as they generally consist of standing x-ray of the entire spine and a supine MRI of only the pathological spinal levels. Hence, there is a need to obtain spinal geometry and muscle line-of-action in positions that is reflect anatomy of the patient's clinical symptom for accurate modeling. Additionally, biomechanical muscle parameters such as cross-sectional area (CSA) and moment-arms measured from imaging modalities, in most cases, are not perpendicular to the scan slices [2] (Fig. 1 A). Hence, they must be corrected to be appropriately used in models.

With an aim to address these literature gaps, our objectives were: i) To develop and validate a method for estimating subject-specific sagittal spinal geometry in different postures (supine, flexion and sitting) from data (vertebral body center (VBC) positions) in a given reference posture (standing) ii) To obtain line-of-actions for two paraspinal muscles-erector spinae and transversospinalis in those postures, and iii) To correct for the cosine between the MRI axial scan plane and dominant fiber line-of-action for muscle parameters (CSA and moment-arm).

METHODS

Imaging

Thoracic Spines of six healthy participants (age 26±6 years, BMI 24±3 kg/m^2) were imaged (0.5T vertical MROpen, Paramed Italy) in four postures (supine, standing, 30° forward flexion, and sitting). VBCs from T1 to T10 were located on sagittal MR images and the intra-rater repeatability was assessed (Fig. 1A). Two muscles— erector spinae and transversospinalis were manually segmented (good/excellent segmentation repeatability [3]) on axial MR images. Muscle parameters, CSA, anterior-posterior (A-P) and medial-lateral (M-L) distances from VBC were computed for each muscle (Fig. 1 D). The unit normal to the MR slice plane was also computed for all postures.

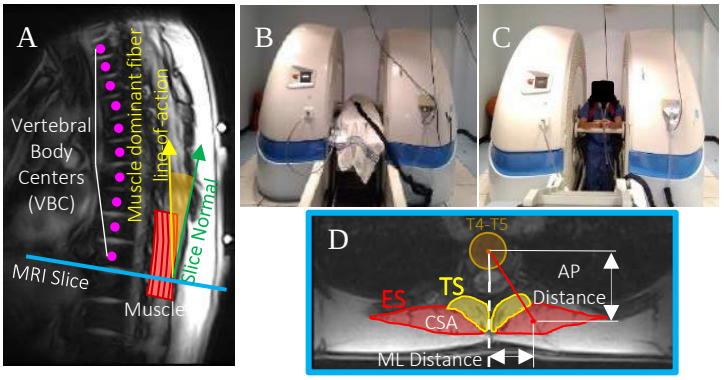

Figure 1: A) Illustration showing direction of muscle line-of-action and scan plane normal. T1 to T10 vertebral body center (VBC) are marked. MROpen image acquisition in B) Supine and C) Standing. D) Illustration to show CSA, anterior-posterior (AP) and mediolateral (ML) distances marked for erector spinae (ES) and transversospinalis (TS) on an axial MR image.

Modelling and Estimation of Sagittal Spine Geometry

Sagittal spine curvature (represented by VBCs) was approximated using a circular arc spline passing through C1, T1, T12 and S1 (Fig. 2 A). The system is constrained such that it has 9 degrees-of-freedom. Assuming the system is hinged at S1, the geometry in any desired posture (supine, flexion, sitting) was be estimated by altering the arc angles, θ (kyphosis and lordosis) and arc lengths (assumed to be constant) of the three segments in the that posture. This data was be obtained from clinical measurements (Cobb Angle), literature and estimations. Furthermore, the position of VBCs in the estimated posture was obtained by normalization with the reference posture (standing).

Validation of the Estimated Spinal Geometry

The VBCs in each estimated posture were rigidly registered to the corresponding MRI data of the thoracic spine, which is the ground truth data, using coherent point drift method [4] (Fig. 2 B).

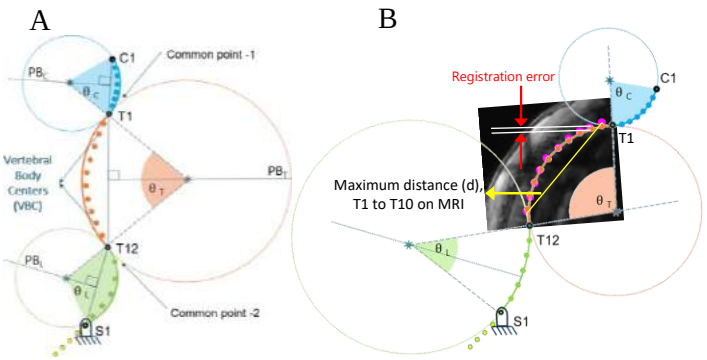

Figure 2: Illustration showing: A) geometric construct of sagittal spinal curvature in the reference posture (standing) B) estimated spine geometry in flexion, rigidly registered to ground truth data (T1 to T10 VBC marked on MRI in flexion) showing registration error. Subscript notations C, T and L refer to cervical, thoracic, and lumbar spine.

Computation of Muscle Line-of-Action and Correction parameter

A generic thoracolumbar model [5] was registered to thus estimated VBCs in different postures in a 3D modelling platform, Artisynth [6]. The dominant muscle fiber line-of-action of erector spinae and transversospinalis for each posture was estimated as the direction vector from the point of origin to insertion. Next, the raw CSA, A-P and M-L distance data obtained from MR images were converted to anatomical CSA and true A-P and M-L distances using the mathematical approach suggested by McGill et al. [7].

RESULTS

Repeatability of Marking T1-T10 VBC on Sagittal MR Images

The intra-rater repeatability for identifying and marking VBCs on MRI scans was found to be excellent (average intraclass correlation coefficient, ICC (3,1) = 0.98).

Goodness of Spinal Posture Estimation

The average maximum registration error between the estimated VBCs and the ground truth data (VBCs marked on MRI) was found to be small (~3.5 mm for supine). The maximum RMSE value for registration (normalized by the maximum distance between T1 and T10 on MR images) was found to be as low as 5.1% (for sitting) (Table. 1).

Table 1: Error assessments (standard deviation) for registration of the VBCs in three estimated postures to corresponding VBCs marked on the sagittal MR images. Max error=Maximum error between corresponding VBCs (mm), Max distance=Distance between two farthest MRI VBC markers (T1 and T10) (mm), RMSE= Root mean square error.

Posture	Max error (mm)	Max distance (d) (mm)	$\frac{\mathbf{RMSE}}{\boldsymbol{D}} * \mathbf{100}$ (%)
Supine	3.5 (0.5)	120.8 (6.7)	2.9 (0.9)
Flexion	3.1 (0.8)	117.8 (9.8)	3.2 (1.3)
Sitting	3.0 (0.5)	111.8 (6.0)	5.1 (1.2)

Corrected Muscle CSA and Distances

The correction factor reduced the muscle parameters (~5% for ES and ~25% for TS) when compared to raw MRI data. While the erector spinae showed most reduction in the flexion, the transversospinalis showed greater decrease in its values for supine (Fig. 3).

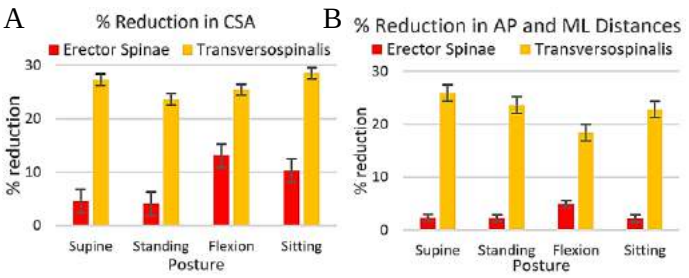

Figure 3: Average (±SD) percentage reduction in magnitudes of A) CSA, B) mean of AP and ML distances, after applying correction factor for MRI slice normal and muscle line-of-action.

DISCUSSION

The spinal curvature, among other factors, is one of the most important parameters for the evaluation of spinal deformities [8]. Although a number of methods exists for quantitative evaluation of sagittal spinal geometry [9], none of these techniques allow for estimations of spinal curvature in different positions from clinically measured parameters (Cobb Angle). Our method is simple, reliable, computationally inexpensive, and easily digitizable for clinical images. Furthermore, the model could be easily modified for different spine geometries by not only changing the number of arcs used to estimate each segment but also the locations of inflection points (T1 and T12 are used in this study). Furthermore, our method could find applications in characterizing spinal deformities not just in the sagittal plane but also in the coronal plane.

Another novelty of this work is reporting trunk muscle properties for postures other than supine. Application of the correction factor demonstrated greater reduction in the parameter values of the transversospinalis than the erector spinae. This is because, transversospinalis is short and obliquely placed to the trunk axis, while the erector spinae, is a long cylindrical muscle spanning several thoracic levels and is usually parallel to the trunk axis in most postures.

Additionally, moment-arm is a sensitive variable in biomechanical models, especially for spinal muscles due to its small magnitude. Small changes in its value could produce large changes in predicted muscle forces. Furthermore, image-based moment-arm data across multiple vertebral levels reported in our study could be used to model the muscle path along the trunk [10]. Overall, our data contributes to the growing literature of trunk geometry evaluation and makes subject-specific biomechanical modelling of the spine clinically more relevant.

INTRODUCTION

The pulmonary valve (PV) anatomically separates the pulmonary artery and the right ventricle, segregating the deoxygenated blood from reaching the pulmonary artery. The PV consists of three cusps attached at the pulmonary root that open and coapt, governing the unidirectional flow of deoxygenated blood into the pulmonary artery, where it can be reoxygenated by the lungs. Collagen, the microstructural component that provides structural integrity to the PV cusps, is vital to tissue's mechanical properties and organ-level function. When the structural integrity of the PV cusps begins to fail (e.g., stenosis), the mechanical properties of the cusps are affected, negating full coaptation, resulting in the retrograde of blood into the right ventricle – a condition known as pulmonic insufficiency. Understanding the relationship between the collagen-dominant microstructure and the tissue mechanics of the PV cusps will not only elucidate the underlying pathology, but also provide the constitutive relations necessary to inform multiscale computational models for improving the treatment of PV disease [1].

Previous investigations of the collagen-dominant microstructure in the PV cusps relied primarily on pressurization systems in conjunction with *destructive* optical imaging techniques [2]. Although these studies yielded valuable relationship between pressure loading and collagen microstructure, those destructive imaging methods require the use of chemical fixatives, limiting their ability to examine the load-dependent collagen fiber architectural changes within *the same tissue specimen*. To overcome this limitation, we employed our in-house opto-mechanical system, capable of observing the realignment and reorientation of collagen fibers under varying biaxial mechanical loads [3], to quantify the load-dependent collagen architecture changes for the PV cusps.

METHODS

Tissue Preparation & Mechanical Testing: Fresh porcine hearts (n=12) were obtained from a local USDA-approved abattoir. Each heart was dissected, and the three PV cusps (i.e., the anterior cusp - *PVAC*, left cusp - *PVLC*, and right cusp- *PVRC*) were extracted. Each extracted cusp was mounted to a commercial biaxial testing system (BioTester – CellScale, Canada) via BioRake tines that penetrate the tissue, creating an effective testing region of 6.5x6.5mm (**Fig. 1a-b**). Fiducial markers were placed on the center region of each tissue specimen to quantify the tissue strain via a digital image correlation (DIC) technique in conjunction with a single bilinear finite element [3]. Pre-conditioning was performed on each specimen with six loading/unloading cycles, prior to biaxial mechanical testing, to return the tissue microstructure to its *in vivo* configuration. After pre-preconditioning, mechanical testing was performed consisting of seven biaxial tension protocols with a target stress of 240 kPa (T_C:T_R=1:1, 1:0.75, 1:0.5, 1:0.25, 0.75:1, 0.5:1, and 0.25:1).

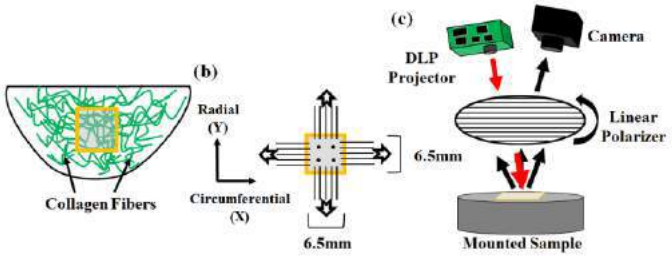

Figure 1. (a) Schematic of a PV cusp, (b) mounted of the tissue to the biaxial mechanical testing system, and (c) examined quantifications of collagen fiber architecture via our in-house collagen imaging system.

pSFDI-based Collagen Microstructural Quantification: Following our developed protocol [3], collagen fiber quantifications were performed utilizing our in-house polarized spatial frequency domain imaging (pSFDI) device integrated with biaxial testing (**Fig. 1c**). In

brief, each tissue was imaged at mounting, after precondition, and at the intermediate and peak loading points of various biaxial tension protocols. Each specimen was imaged to capture the reflected light intensity responses through a rotating linear polarizer (Thorlabs Inc., Newton, NJ, US) at 37 distinct polarization states ranging from 0° to 180°, with a 5° step size. Imaging processing permits the ability to observe the collagen fiber orientation angle θ_{fiber} and the degree of optical anisotropy (DOA) – a metric utilized to quantify the alignment of the collagen fiber architecture – at each individual observed pixel.

RESULTS

Biaxial Mechanical Properties: A non-linear stress-strain relationship was observed for each specimen, exhibiting a low-stress toe region that transitions into high-stress, stiffer region. The high-stress portion of this relationship occurred at a larger stretch for the radial direction then that of the circumferential direction, highlighting the mechanical directional-dependence of collagen fiber architecture in the PV cusps (**Fig. 2a-b)**. For all equibiaxial and non-equibiaxial mechanical loading protocols, the PV cusps displayed greater extensibility in the radial direction, with a much stiffer response shown by the circumferential direction, previously observed heart valve tissues (**Fig. 2c-d**) [3].

Load-Dependent Changes in Collagen Fiber Architecture: Using pSFDI, microstructural reorientation was observed, which exhibits initial collagen fiber orientation in the *radial* direction in the center of the tissue, while displaying *circumferentially*-dominant fibers towards the bottom left of the specimen (**Fig. 2a**).

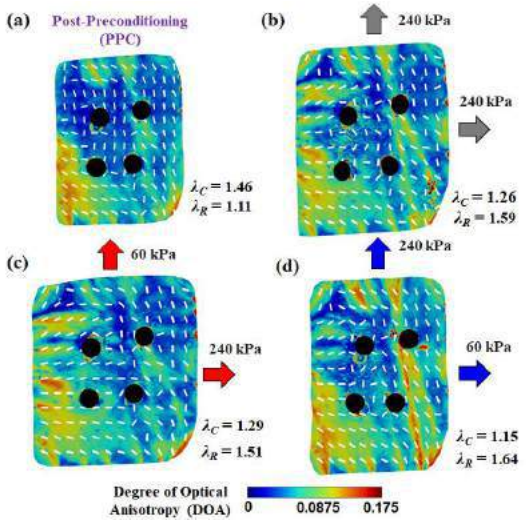

Figure 2. Quantified collagen fiber orientation angle θ_{fiber} (denoted by the white vector plots) and mechanical stretch λ, and degree of optical anisotropy (DOA): **(a)** post preconditioning, and **(b-d)** under various biaxial tensions.

Specifically, under equibiaxial loading, the collagen fiber orientation shifted by 25.9% towards the *radial* direction (**Fig. 2b, Table 1**), whereas under circumferentially-dominant loading, the collagen fiber architecture in the center of tissue shifted in the *circumferential* direction by 28.3% (**Fig. 2c, Table 1**), whereas the radially-dominant loading resulted in a 15.2% shift towards the dominant loading, i.e., *radial*, direction (**Fig. 2d, Table 1**).

Table 1. Percentage changes in the quantified collagen fiber orientation (mean ± SEM) between the mounting configuration and various biaxial loading points for a representative PVLC specimen.

Mount.	PPC	T_C:T_R=0.25:1	T_C:T_R=1:0.25	T_C:T_R=1:1
—	12.5±0.1%	15.2±0.08%	28.3±0.1%	25.9±0.09%

Collagen Fiber Realignment under Equibiaxial Tension: Increasing membrane tension exhibited on the tissue in the equibiaxial state resulted in greater alignment among the collagen fiber architectures. When observing the alignment of the collagen fibers within the mounted configuration (Loading Point 1) yielded DOA values ranging from 0 to 0.04 (**Fig. 3a**). As the membrane tension applied to the tissue increases to $0.3T_{Max}$, greater collagen fiber alignment occurs with DOA values within a range of 0.0875 and 0.1 (**Fig. 3b**). The maximum membrane tension applied (T_{Max}) allowed greater alignment across the entire tissue, although yielding similar DOA values to Loading Point 2 (**Fig. 3c**).

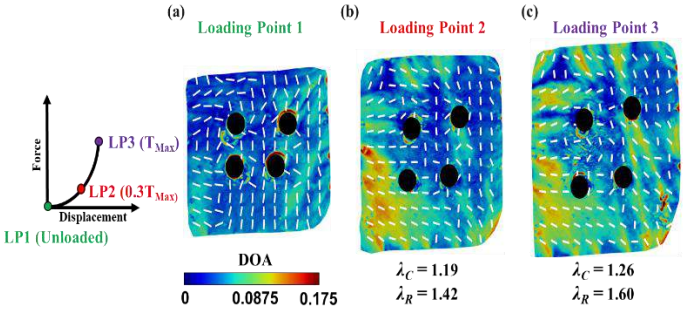

Figure 3. Measured collagen fiber orientation angle (θ_{fiber}) and DOA: (a) mounting configuration, (b) $0.3T_{Max}$ tension, and (c) T_{Max} subjected to the same specimen along the force-displacement curve.

DISCUSSION

This investigation, which is the *first of its kind*, further elucidates the interconnected relationship between the tissue-level mechanics and the load-dependent collagen fiber architecture within PV cusps. Previous studies have relied on destructive imaging techniques to understand the dynamic collagen fiber microstructure within PV specimens, requiring the fixation of tissues under a pressurized load. This approach offers the ability to observe the realignment and reorientation of the collagen-dominant microstructure within the *same specimen*, and allows a systematic examination of the trends across multiple specimens. Employing a non-destructive, opto-mechanical approach allows for the dynamic microstructural changes to be captured within the same tissue, providing novel information regarding the tissue microstructure's ability to adapt to various mechanically-loaded states.

The microstructural-mechanical relationship observed in this study provides unique information that can be implemented into fiber-based constitutive models, establishing the link between local microstructural changes and bulk-tissue mechanical loading [4]. These constitutive models rely on experimental observation that are collected due to the large variations in pressure exhibited on the PV cusps during the cardiac cycle. This combined approach to inform computational models permits future investigations of collagen microstructures of other heart valve, improving the understanding of the collagen-dominant microstructure in response to physiological loading. These potential future computational developments can help elucidate disease pathology and improve the understanding of tissue-engineered prostheses [5].

INTRODUCTION

Coronary artery disease (CAD) often manifests as lesions in the vessel that obstruct blood flow. Percutaneous treatments of CAD involve balloon angioplasty in a predilatation procedure, often followed by stenting of the vessel. Bifurcation lesions, which make up 20% of all percutaneous treatments, are highly complex, and current treatments may cause restenosis [1-3].

Current efforts in improving treatment is including development of tapered balloons in bifurcation lesions [4]. However, tapered balloons are not readily available, and any customization of these balloons are expensive and time consuming to procure. Therefore, the ability to manufacture custom balloon shapes quickly and relatively inexpensively at regional facilities or central locations with access to fast shipping options is needed. In this study, a custom balloon forming machine was developed for immediate and inexpensive balloon creation.

METHODS

The balloon forming machine uses a burst of pressurized air to expand a sealed section of tubing to the desired balloon shape. The sealed section of tubing is in CAD treatment device industry referred to as a "parison".

Parisons were cut to 120mm in length from polyethylene terephthalate (PET) tubing with 0.132" OD and 0.1" ID. Cyanoacrylate glue was used to attach a luer lock to one end of the parison and to seal the other end.

The balloon forming machine's main structure was two halves of an aluminum block (50mm x 50mm x 100mm) that formed a housing for a custom cylindrical mold. Four additional holes were bored to allow space for four 250W cartridge heaters. A sheet of carbon insulation surrounded the block, and a C-clamp was used to hold the two halves of the block together.

The four cartridge heaters were attached to a custom 120V proportional-integral-derivative (PID) controller box using a MyPin TA4 PID (Mypin Electrical Co., Zhongshan, Guangdong, China) to control temperature, with one cartridge heater also containing a thermocouple for sensing temperature. The temperature was assumed to be similar in all heating rods. The custom cylindrical mold was 3-D printed from stereolithography resin to form the desired balloon contour. Two stoppers were created from stereolithography resin and were inserted in the mold to form the desired shape of the balloon ends. The schematic outline of the balloon forming machine is shown in Figure 1.

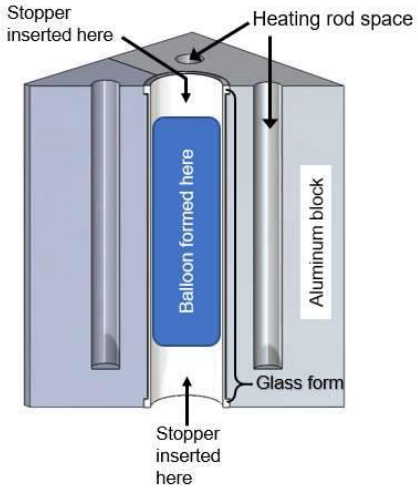

Figure 1: Cross sectional schematic outline of balloon forming machine

To form the balloons, the machine was assembled as shown in Figure 2.

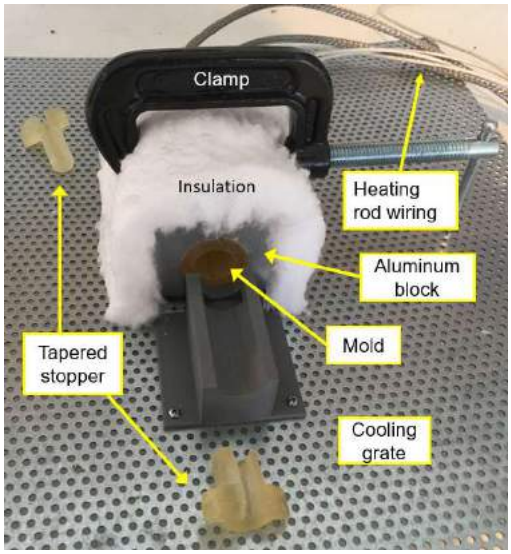

Figure 2: Complete balloon forming machine showing the tapered stoppers that fit inside the glass form.

The system was heated to the desired temperature, and the temperature of the inside wall of the glass form was confirmed with a separate thermometer. The temperature of the interior glass form wall was typically 10-15 C below the temperature settings for the heating rods. Next, the parison was attached to an air compressor via luer lock. The stoppers were inserted into both ends of the glass form mold followed by the insertion of the parison. The parison was heated for 30 seconds, then the air lock on the air compressor was manually opened to form the balloon by inflating the parison. Once inflated, the air lock was closed, and the newly formed balloon was removed from the balloon forming machine and allowed to cool in room temperature air. Additionally, the stoppers were removed and dipped in water to cool before reinserting and forming the next balloon.

In this study, N=104 balloons were made using variations of temperature and pressure. Heating time was kept constant at 30 seconds, and expansion time was 1-2 seconds; both being similar to values indicated in the literature and preliminary testing [5]. Pressure was varied between 55-115 PSI and temperature was in groups of 100 C, 110 C, 120 C, and 130 C.

For ease of handling, balloon dimensions used were much larger than balloons typically used in coronary arteries. The target size for these larger balloons was a diameter of 16mm and a length of 53mm. These values were chosen based on industry balloons created at similar size and shape (10004013EB, Nordson Medical, Westlake, Ohio). Additionally double wall thickness, which is the thickness of the deflated balloon, was targeted to be 0.051-0.061 mm (2-2.4mil). A balloon was considered successful if it exhibited no punctures, was within 20% of intended diameter, and length was greater than 45mm, the length of stent models being used in the lab. An additional criterion called "skew ratio" was created to account for bowing effects observed in balloon formation. The skew ratio calculation was conducted by photographing the balloon with any bowing effect clearly shown. Parallel lines were added to form a box around the balloon. The skew diameter was the width of the box, and the skew ratio is the comparison of the skew diameter to the average diameter of the balloon.

RESULTS

An example of a successful balloon creation is shown in Figure 3.

Figure 3: Completed balloon

104 parisons were used in this study. From the balloons created, a chi-squared test was conducted to determine if pressure, temperature, or a combination of both were significant factors towards balloon creation success. The results from the test are shown in Table 1.

Table 1: Results of Chi-Square Test

Source	G^2	P-value
Temperature	0.479	0.489
Pressure	4.545	0.033*
Temperature and Pressure	7.096	0.008*

A p-value of 0.05 or lower was considered significant. All tests were run using JMP (SAS Institute, Cary, NC).

Pressure alone and pressure and temperature in combination were identified as significant factors towards balloon creation success with p-values less than 0.05. Temperature alone is not a significant factor.

DISCUSSION

For this study, a custom balloon forming machine was created. The balloon forming machine was tested and demonstrates the ability to create viable balloons. Pressure and temperature were both shown to impact balloon creation success, showing that both factors need careful consideration. Temperature alone was not a significant variable for balloon success, which is perhaps due to the temperature chosen being just above glass transition temperature of PET plastic while remaining well below the melting point [6]. The significance of pressure alone seems to correspond to successful balloon creation occurring between 60-85 PSI, though pressures between 55-115 PSI were tested. The significance of both combined indicates an interdependence between pressure and temperature for successful balloon creation.

Future work will involve further optimization of the balloon forming machine. Stretching of balloons during creation is one technique used in industry, which may contribute towards the creation of thin-walled balloons. Additionally, automating parts of the balloon creation process may contribute to less variability in balloon creation.

ANALYSIS of HEMODYNAMICS in ANEURYSM BLEBS with THIN and ATHEROSCLEROTIC WALLS

Seyedeh Fatemeh Salimi Ashkezari (1), Fernando Mut (1), Juan R. Cebral (1)

(1) Bioengineering Department

Fairfax, VA, USA

INTRODUCTION

Many intracranial aneurysms (IAs) have well-defined secondary structures or daughter sacs known as blebs [1]. The presence of blebs is considered a risk factor for rupture [2] and is one of the few aneurysm-specific factors used in aneurysm scoring scales [3, 4].

Blebs can have an effect on the wall stress as well as the local hemodynamics. Mechanisms responsible for bleb development and evolution are not fully understood. Previous studies have shown that aneurysm walls can be extremely heterogeneous. They can have thin translucent regions or thick atherosclerotic walls [5, 6].They can have collagen fiber distributions with unidirectional or bidirectional orientations, and thick wavy fibers or thin fragmented fibers [7]. All of these structural characteristics can affect the strength of the wall and the distribution of intramural stresses [7].

In this study we investigated the relationship between aneurysm blebs with different wall characteristics and their local hemodynamic environment.

METHODS

A total of 32 intracranial aneurysms harboring 41 blebs treated with microsurgical clipping and with available intra-operative videos where the blebs were visible were selected from our database [1]. All these aneurysms were imaged prior to surgery with 3D rotational angiography (3DRA) or computed tomographic angiography (CTA).

Using previously described methods [8], patient-specific vascular models were constructed from 3D images. Blebs have been visually identified and interactively marked on the vascular models for all aneurysms in this database as detailed in [1].

In order to characterize the local hemodynamic conditions at bleb sites prior to their formation, the bleb regions were first projected to the model with virtually removed blebs and then hemodynamic variables were calculated over these regions.

Intra-operative videos were inspected to characterize bleb walls. Blebs that had been previously marked on the 3D vascular models were visually identified in the intra-operative videos. These blebs were classified as: (1) ‘thin’ translucent walls as those with a red appearance, (2) ‘atherosclerotic’ walls as those with a white (hyperplastic) or yellow (fatty) appearance, or (3) ‘unremarkable’ walls as those with a pinkish coloration similar to normal arteries [6].

The blebs identified in each aneurysm were characterized by computing several variables related to strength of the flow stream within the bleb and distribution (magnitude, heterogeneity, oscillations) of the wall shear stress (WSS) distribution over the bleb surface. Hemodynamic variables were computed using the same tools and techniques previously used to characterize the hemodynamics in the entire aneurysm [9].

Hemodynamic characteristics of 'thin' and 'atherosclerotic' blebs were compared using the non-parametric two-sample unpaired Wilcoxon (Mann–Whitney) test. For this purpose, bleb hemodynamic variables were first normalized with their average value over the entire aneurysm. All statistical analyses were performed in R, and differences were considered significant if $P<0.05$.

RESULTS

Average flow characteristics of ‘thin’ and ‘atherosclerotic’ blebs are presented and compared in table 1. This corresponds to 22 thin and 19 atherosclerotic blebs visible in intra-operative videos. Based on these results, maximum oscillatory shear index (OSI) tended to be larger in atherosclerotic blebs ($P=0.0941$) but this association was not significant.

Table 1: Comparison of (normalized) hemodynamic characteristics (prior to virtual bleb removal) of thin (red) blebs and atherosclerotic (white/yellow) blebs.

Characteristic	Variable	Bleb Wall Type		P value
		Thin (Red)	Atherosclerotic (White/Yellow)	
Flow Strength	VEL	0.46 ± 0.41	0.36 ± 0.41	0.3572
	VO	0.89 ± 0.64	0.57 ± 0.54	0.1481
	SR	1.02 ± 0.72	0.65 ± 0.57	0.1271
WSS Distribution	WSS	0.63 ± 0.47	0.47 ± 0.54	0.1557
	OSI(max)	0.38 ± 0.33	0.54 ± 0.29	0.0941
	RRT	1.84 ± 1.64	2.45 ± 1.42	0.1026
	WSSGRAD	0.93 ± 0.65	0.66 ± 0.40	0.1801
	GON	0.99 ± 0.54	0.92 ± 0.41	0.6321

In order to further explore this trend, a subset of aneurysms with multiple blebs of both kinds, thin and atherosclerotic (n=8), was analyzed by computing the ratio of values of thin over atherosclerotic blebs of the same aneurysm, and compared them against one using one-sample Wilcoxon tests. This analysis as presented in table 2 confirmed that thin blebs had lower OSI (ratio OSI=0.38, P=0.0156) than atherosclerotic blebs of the same aneurysm. The WSS tended to be higher (ratio WSS=4.74, P=0.0781) but this association was not significant. An illustrative example is presented in figure 1.

Table 2: Ratio of hemodynamic parameters of thin over atherosclerotic blebs of the same aneurysm. Values are mean ± standard deviation. Significant differences are marked with a "*".

Characteristic	Variable	Ratio (thin/atherosclerotic)	P value
Flow Strength	VEL	4.42 ± 7.64	0.4609
	VO	3.96 ± 4.31	0.1094
	SR	3.78 ± 4.04	0.1094
WSS Distribution	WSS	4.74 ± 5.71	0.0781
	OSI(max)	0.38 ± 0.39	0.0156*
	RRT	0.98 ± 1.57	0.7422
	WSSGRAD	4.40 ± 4.38	0.1094
	GON	1.40 ± 1.95	0.1484

DISCUSSION

Previous observations have led to the common belief that blebs form in regions of slow recirculating flow and that aneurysms rupture at blebs [10]. Conversely, other studies have proposed that blebs could also form at or in the vicinity of flow impingement regions associated with localized high WSS [11]. Moreover, a recent study suggested that blebs are more common in aneurysms exposed to flow conditions characterized by stronger flows and higher WSS compared with aneurysms where blebs did not form [1].

However, in all previous studies, all blebs have been grouped together without distinguishing different kinds of blebs. Therefore, while the conclusions of these studies as well as the common beliefs about blebs may be true for some blebs, they may not be true in general.

Our study has shown blebs with different wall characteristics as reflected in their visual appearance; thin translucent blebs seen red in videos, and atherosclerotic, usually thick-walled, blebs seen white or yellow in videos. The different visual appearances suggest different remodeling processes have led to distinct local wall structures.

In addition, our study found thin red blebs may form in regions exposed to strong flows, flow impingement, and large WSS spatial gradients, while atherosclerotic blebs may form in regions of slow flow and low and oscillatory WSS.

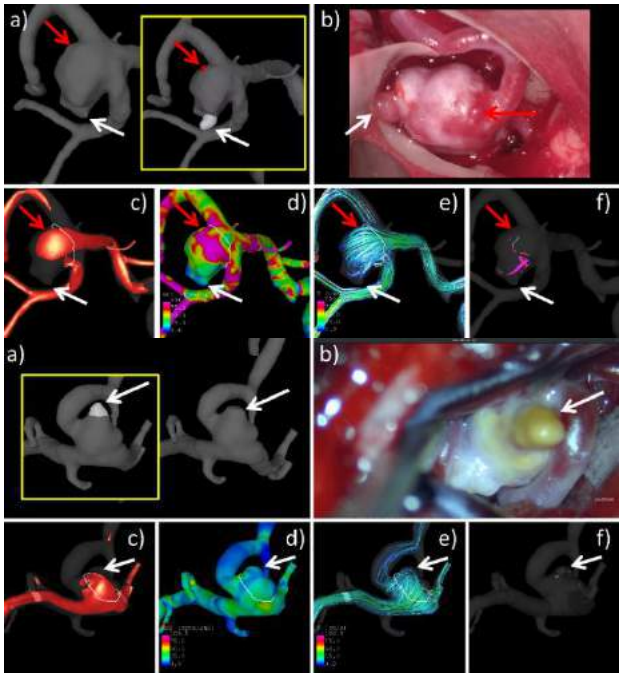

Figure 1. Example of an aneurysm (Top): with a thin bleb (red) and a slightly hyperplastic (white) bleb. (Bottom): with an atherosclerotic (white) bleb. a) anatomical model with blebs removed, b) blebs observed in intra-operative video, c) visualization of inflow stream, d) WSS distribution, e) flow pattern visualized with streamlines, and f) flow structure visualized with vortex corelines. All flow visualizations correspond to peak systole. Arrows point to the regions of bleb formation.

The results and observations of our study suggest that different mechanisms of wall remodeling and degradation in response to locally high- and low-flow conditions may be at play simultaneously in intracranial aneurysms and may be responsible for the development and evolution of blebs with different wall structures.

The trends and hypotheses proposed in this study should be confirmed and further studied with larger datasets. Nevertheless, it is important to highlight the main message of this study, namely that not all blebs are the same and their distinguishing characteristics should be taken into consideration when studying the mechanisms of wall degeneration and when evaluating aneurysms clinically to decide on immediate treatment or conservative observation.

INTRODUCTION

Past studies have shown that dentin/adhesive interface is the most vulnerable region for the failure of dental composite restorations [1]. Phase separation, sub-optimal polymerization, water sorption, diffusion of bacteria, and hydrolytic/enzymatic degradation have all been attributed to the failure of the dental adhesive [2]. As the adhesive infiltrates through the wet dentin, it undergoes phase separation into hydrophobic and hydrophilic-rich phases [2]. The cross-linker in the dental adhesive which is hydrophobic in nature accumulates into the hydrophobic-rich phase. This indicates that the hydrophilic-rich phase of the adhesive possesses poor cross-linking density. Moreover, the photosensitizer in the adhesive, camphorquinone is also hydrophobic in nature and resides mostly into the hydrophobic-rich phase, causing poor photopolymerization of this phase [3]. Sub-optimal polymerization and poor cross-linking density in this phase accelerates water sorption and diffusion of bacteria/enzyme which ultimately leads to the failure of this region. It has been proposed that incorporation of water-compatible cross-linker in addition to the current popular hydrophobic cross-linker, will improve the clinical lifetime of composite restorations significantly [3].

In this study, computer-aided molecular design (CAMD) has been employed to design candidate water-compatible crosslinkers for dental adhesive application. The properties based on which the cross-linker was designed were octanol water partition coefficient and degree of conversion.

Computer-aided molecular design (CAMD) utilizes quantitative structure property relationships (QSPRs) and optimization algorithm to propose candidate molecules with optimal properties. QSPRs are mathematical relationships between molecular descriptors and properties [4]. CAMD consists of forward and inverse problems. In the forward problem, a model building set is created which consists of relevant molecules, and properties of interest are determined for these molecules. The structure of the molecules in the model building set is then described quantitatively using the descriptors. Quantitative structure property relationships (QSPRs) are determined by linear regression. In the inverse problem, molecule groups are created which have both ends open for bonding. These groups can be put together to form new molecules. The structure of the newly formed molecule can be optimized for target properties using stochastic optimization algorithm. This method has been used successfully in the past to design hydrophilic photosensitizer for dental application, solvents, catalysts, excipients, polymer etc. [4]. CAMD is a time efficient and inexpensive method which can be used to understand molecular structures with optimal properties for an application.

METHODS

Octanol water partition coefficient and degree of conversion were the properties of interest. Octanol water partition coefficient was selected to tune the hydrophilicity of the cross-linker, and the degree of conversion ensured that the polymerization was substantial giving mechanical strength and providing an intact barrier at the interface. Table 1 and 2 exhibits the cross-linkers that formed the model building set for the octanol water partition coefficient and degree of conversion respectively. The experimental values were obtained from literature. Topological descriptors, connectivity and valence connectivity indices were used to quantitatively describe the molecules in the model building set. Correlations (QSPRs) between the topological descriptors and the properties were obtained by linear regression using the leaps package in the statistical software R. For the degree of conversion connectivity and valence connectivity indices only until first order were used to carry out the regression. The linear regression model with high correlation coefficient was chosen for each property. The predictability of each

selected model was studied by the leave-one-out method. Cross-validation was carried out using the DAAG package in the statistical software R. The predictive squared correlation, Q^2 was calculated to understand the predictive ability of the selected models.

Table 1: Crosslinker molecules in the model building set for logP

Crosslinker	logP	Reference
Tetraethylene glycol diacrylate (TTEGDA)	0.484	[5]
Tryethylene glycol diacrylate (TREGDA)	0.7	[5]
Diethylene glycol dimethacrylate (DEGDMA)	0.81	[6]
Diethylene glycol diacrylate (DEGDA)	0.84	[5]
1,3-propanediol diacrylate (PDDA)	0.946	[5]
Triethylene Glycoldimethacrylate (TEGDMA)	0.96	[7]
Pentaerythritol tetra acrylate (PETA)	2.227	[5]
Neopentyl glycol diacrylate (NPGDA)	2.5	[5]
Hexamethylene glycol diacrylate (HMGDA)	3.08	[5]
(1-methylethylidene) bis (4,1-phenyleneoxy) (1-methyl-2,1-ethanediyl) diacrylate (XDA)	6.1	[5]

Molecular groups with both ends open for bonding were generated based on the molecules in the model building set. These formed the building blocks for generating new molecules. A maximum of six groups were chosen to generate a crosslinker molecule from 42 groups. Properties of the newly generated molecules were determined from the QSPRs. Candidate crosslinker molecule with properties close to the target values were obtained by using the stochastic optimization algorithm, Tabu search. The objective function minimizes the difference between the target property value and that obtained from the corresponding QSPR. Optimization framework proposed by Roughton et al. was modified to perform this task [4]. The optimization formulation is given by the equations below:

$$Minimize\ s = \sum_M \frac{1}{P_M^{Scale}} \left| P_M - P_M^{Target} \right| \quad (1)$$

$$P_M = f_M(\chi) \quad (2)$$

$$\chi = g(a_{i,j}, w_i) \quad (3)$$

$$h_c(a_{i,j}, w_i) \geq 0 \quad (4)$$

Where P_M is the QSPR for M^{th} property, $f_M(\chi)$ is the function to calculate descriptors, χ are the descriptors from the function g, $a_{i,j}$ and w_i are adjacency matrix and identity vector, h_c is structural constraint, P_M^{Target} is the target value of the M^{th} property, P_M^{Scale} is the scaling factor for the M^{th} property, s is the objective function

RESULTS

Equations 5 and 6 exhibits the QSPR for the properties logP and degree of conversion (DC) respectively. The correlation coefficient (R^2) and the predictive correlation coefficient (Q^2) both were greater than 0.95 for logP and DC. Therefore, both the experimental data have a good fit with the respective model, and both have a good predictive ability. The structure of two candidate crosslinker from CAMD is shown in Figure 1. Table 3 summarizes the target values of the properties and the corresponding values for the candidate molecules. It can be seen that the new molecules possessed properties very close to the target values. The logP of the candidate molecules was much lower than that for BisGMA, indicating that these candidate molecules were much more hydrophilic in nature compared to BisGMA. These crosslinkers have approximately 80% DC, showing that they can undergo substantial photopolymerization.

$$\log P = 3.7643 - 1.4099(^1\chi) + 5.4157(^3\chi^v) \quad (5)$$

$$DC = 79.31366 - 0.57471(^1\chi) \quad (6)$$

Table 2: Crosslinker molecules in the model building set for degree of conversion (DC)

Crosslinker	DC	Reference
Urethane dimethacrylate (UDMA)	70.9	[8]
Triethyleneglycol dimethacrylate (TEGDMA)	74.4	[8]
Trimethylol-propane mono allyl ether dimethacrylate (TMPEDMA)	72.6	[8]
1,1,1-tri-[4-(methacryloxyethylaminocarbonyloxy)-phenyl]ethane (MPE)	64	[8]
2,2-bis[4(2-hydroxy-3-methacryloyloxy-propyloxy)-phenyl] (BisGMA)	69.3	[8]

Table 3: Properties of the candidate water-compatible crosslinker

	log P	DC	Objective value
Target	0.80	80%	0.000
Candidate 1	0.80	76%	0.052
Candidate 2	0.76	76%	0.067

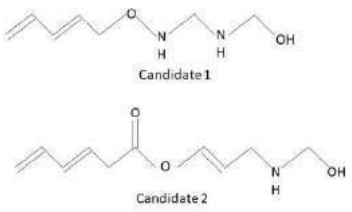

Figure 1. Structure of two candidate crosslinkers

DISCUSSION

Local optimal solutions were obtained by solving the optimization problem related to the structure of dental crosslinkers by using Tabu Search. Molecular structure of two best solutions are proposed here. Both structures have secondary amine group in addition to -C-O-C-. Since both candidates have low octanol water partition coefficient compared to BisGMA they will accumulate in the hydrophilic-rich phase of the dental adhesive in higher concentration, enhancing the crosslinking density. This will reduce the detrimental impact of degradation, water sorption etc., and will improve the clinical lifetime of dental restorations significantly.

INTRODUCTION

The Cumulative Strain Damage Measure (CSDM) is one of the most reported and widely used brain injury metrics based on results from computational models. The CSDM metric was theorized as a metric for brain injury in the mid 1990s by Bandak and Dimasi [1], [2]. The CSDM is commonly reported as a peak scalar value with no information relating to the spatial or temporal accumulation of strain resulting from linear and angular kinematics of the head. Similarly, the Maximum Principal Strain (MPS) is reported as a scalar peak value rather than describing the spatial and temporal details of strain accumulation in the brain [3], [4]. Alternative brain injury metrics focus on the product of maximum principal strain and strain rate or more localized axonal strains [5]. None of the above metrics account for the spatial and temporal accumulation of strain in the brain resulting from the linear and angular head kinematics. The purpose of this study was to describe preliminary efforts to understand the spatial and temporal accumulation of strain in the brain by investigating the time-history of CSDM response for anatomical regions specified in two finite element models of the brain.

METHODS

Computational simulations were performed using both the Simulated Injury Monitor (SIMon) head model and version 5 of the Global Human Body Model Consortium (GHBMCv5) head and neck [3], [6]. The SIMon model is symmetric about the midsagittal plane and includes deformable solid elements for the left and right cerebrum, cerebellum, brain stem, ventricles, and cerebral spinal fluid. The GHBMCv5 model is symmetric about the midsagittal plane and includes deformable solid elements for the left and right cerebrum, cerebellum, lateral ventr[7]icles, corpus callosum, thalamus, and brain stem. The cerebrum parts for the GHBMCv5 are further divided into gray and white matter (Figure 1). The GHBMCv5 model is generally stiffer than the SIMon model (Table 1).

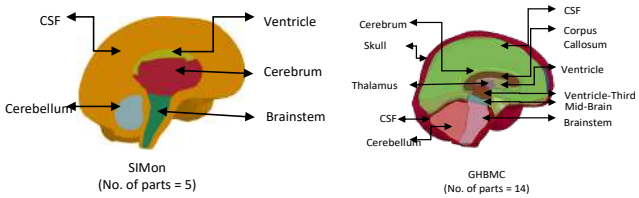

Figure 1: Model overview of the SIMon (left) and GHBMCv5 (right) computational models.

Table 1: Summary of computational model material properties.

	Density (kg/m^3)	Bulk Modulus (GPa)	Go (GPa)	Ginf (GPa)	beta
SIMon*	1040	0.558	1.7e-6	9.3e-7	16.95
GHBMCv5*	1060	2.19	6e-6 to 1.2e-5	1.2e-6 to 2.4e-6	0.0125

*** Model material properties reported for deformable regions of interest. GHBMCv5 shear modulus reported as a range of values for multiple regions.**

Both models were run using LS-DYNA (Livermore Software Technology Corporation, Livermore, CA). CSDM was calculated as the volume fraction of elements within each subpart exceeding a specified strain threshold. For the present analysis, the CSDM threshold was 0.15.

CSDM(15) has been used to validate the second generation SIMon Model. The CSDM was calculated (eq. 1) for each part in the modified model and the original model. Linear and rotational accelerations from experiments were applied at the head center of gravity.

$$CSDM = \frac{Volume\ of\ elements\ >\ Strain\ Threshold}{Total\ Volume} \quad (1)$$

Experimental tests were performed with a rigid arm pendulum striking a helmeted head-neck system. The headform used for all tests was the Facial and Ocular CountermeasUres for Safety (FOCUS) headform [7]. The FOCUS headform is an anthropomorphic test device (ATD) based on anthropometry representative of male military aviators. The FOCUS headform was mounted to a H-III neck and fitted with an Advanced Combat Helmet (ACH) for all tests. Care was taken to ensure that the helmet's bottom rim (near the earcup) was parallel with the Frankfurt plane and was symmetric about the midsagittal plane.. The Frankfurt plane of the head was maintained in a horizontal position for all tests. Impacts from tests conducted at two sites around the helmet, front and left side, are reported for an impact velocity of 6 m/s.

RESULTS

The peak CSDM(15) for the whole brain occurs well after the impact event, indicating that the modeled brain response is slower developing than the impact. CSDM(15) was negligible at the time of the peak resultant acceleration (Table 2) while it reaches between 20% (front impacts) and 40% (side impacts) of the maximum CSDM(15) by the time the rotational velocity peaks.

Table 2: CSDM(15) at peak resultant acceleration (PRA) and peak rotational velocity (PRV) as a percentage of the maximum CSDM(15).

	%Max CSDM(15) at PRA		%Max CSDM(15) at PRV*		Maximum CSDM(15)	
	SIMon	GHBMC	SIMon	GHBMC	SIMon	GHBMC
Front	0%	0%	17%	12%	0.247	0.319
Side	1%	0%	39%	34%	0.399	0.334

*** PRV is reported about Y-axis for front impacts and X-axis for side impacts**

In addition to observing that the whole brain CSDM(15) occurs well after the peak resultant acceleration and peak rotational velocity peak, it was seen in the GHBMCv5 model that the accumulation of strain occurs at different time scales depending on the depth of the brain structures (Figure 2).

DISCUSSION

The present study showed the temporal and spatial brain strain development using two computational models. Both models show similar spatial and temporal strain responses; however, the anatomical accuracy and detail limited the number of additional analyses that could be completed.

The accumulation of strain in different brain regions over time is one potential method to understand further the effects of head impact exposure and the potential effectiveness of protective gear (e.g., helmets). Injury response is dependent on the time of exposure, as evidenced by the incorporation of airbags in motor vehicles reducing the injury rate by lengthening the exposure.

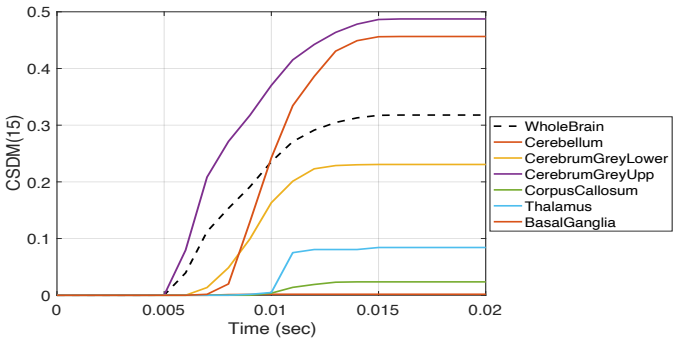

Figure 2: CSDM(15) versus time for multiple GHBMCv5 regions of interest. Figure illustrates the delayed accumulation of strain in the deeper brain structures (e.g., corpus callosum) compared with the surface brain structures (e.g., cerebrum).

Similarly, helmets are intended to extend the time of exposure to reduce the amount of energy transferred to the head. However, while the increased exposure time often results in a reduction in injury, it may also shift the location of the injury. An example of this is the inclusion of knee-bolster airbags in motor vehicles. Rather than eliminating knee-thigh-hip injuries, the airbags shifted the injuries from the knee (at point of impact) to the hip (following mass recruitment allowed by the extended exposure time). This same effect is likely seen in brain response [8]; however, limitations in FE model design (anatomical accuracy), and exposures have limited further investigation in this area using modern models. It is well known that the functional responses of various components of the brain have differing implications from a neurological perspective. Hence, it is important to evaluate at a local/regional/component level, any shift in the location of peak injury metrics with the inclusion of the temporal variable. This study has provided some insights into this aspect of TBI.

The presented study shows the temporal and spatial relationship between exposure (kinematics) and strain response (via CSDM) for a helmeted headform under military-specific exposures. Future work will investigate this relationship further using updated FE models as well as additional kinematic parameters of exposure (e.g., peak severity, length of exposure, total energy, etc.) through parametric analyses.

INTRODUCTION

During last decades, endovascular aneurysm repair (EVAR) has emerged as the treatment-of-choice for elective and ruptured abdominal aortic aneurysms (AAAs). The evolution of EVAR has brought improvements in efficiency, outcomes, and procedural success. However, the re-intervention rate has been shown to be more common in EVAR than open repair [1].

Computational Fluid Dynamics (CFD) simulations are lately used to identify the hemodynamic impact of endograft installation. The post-EVAR morphology of the lumen, determined by the stent-graft system, could favor regions where disturbed hemodynamics might develop. The initiation of thrombus, immediately after implantation or after months, can be triggered in regions where low wall shear stresses (WSS) prevail [2]. The study of thrombosis in endografts is a high research priority according to the Vascular Surgery Society practice guidelines on the care of AAAs [3].

The current study deals with the post-EVAR flow conditions in 4 stent-graft systems with different design, material and type of fixation. The devices under consideration are: AFX (Endologix, Irvine, California), Endurant (Medtronic, Minneapolis, Minnesota), Excluder (Gore, Newark, Delaware) and Nellix (Endologix, Irvine, California). An endograft-specific approach is applied, analyzing flow statistics based on a sample of patients in each endograft group [4].

METHODS

The cases were EVAR-treated patients with fusiform type of AAA and no signs of diseased common iliac arteries. The preoperative and one-month after EVAR computed tomography (CT) scans of 32 cases (8 cases per endograft group) were used as the raw material for the computational analysis. All patients were on optimal medical treatment (single antiplatelet, statin and hypertension medication) and no event during the early post-operative period was recorded. The screening protocol and the specifications of the CT scanner can be found in [5, 6]. All subjects gave informed consent for the use of their screening data.

Initially, the preoperative CT scans were processed and the following morphological characteristics were calculated using 3mensio (Pie Medical Imaging BV, Maastricht, The Netherlands): neck length, neck diameter, suprarenal and infrarenal angle, aorta length, right and left iliac length, right and left iliac diameter, neck diameter to right iliac diameter, neck diameter to left iliac diameter. The preoperative morphology of the AAAs did not vary significantly between the groups as proven by ANOVA tests in all studied morphological characteristics [4].

Modelling: The methodology involves the reconstruction of postoperative medical imaging data, 3D model refinement, computational mesh generation, CFD simulations, post-processing and statistical analysis, all carried out in a range of commercial and open-source software [5-7]. The 3D postoperative lumen models represent in practice the post-implantation spatial configuration of the endografts (Figure 1). The wall was considered as rigid without thickness or material properties. The computational grids had sufficient resolution to capture complex blood flow dynamics [5-7]. Blood was modeled as a Newtonian fluid with density, $\rho = 1050$ Kg/m^3, and kinematic viscosity, $\nu = 3.2\times10\text{-}6$ m^2/s. A literature-based physiological pulse pressure condition was applied at the inlet and flow rate at the outlets.

Regions of interest (ROI): The zone surrounding the bifurcation of the device: the surface before (1) and after (2) the bifurcation specifically (Figure 1).

Hemodynamic properties: velocity, WSS and helicity. Specifically, i) maximum, ii) maximum WSS on at peak systole, and iii) mean helicity at mid diastole.

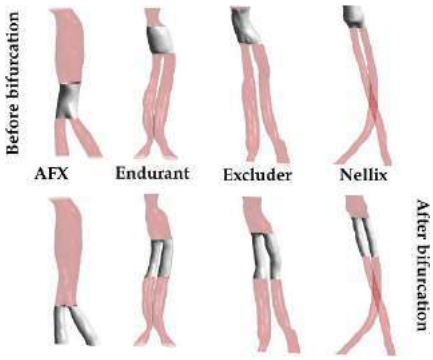

Figure 1: Indicative models and the ROI.

Statistical analysis: Between- and in-group statistical analysis using one-way-ANOVA and t-tests, with $p<0.05$ determining statistical significance.

RESULTS

The velocity is expectedly higher after the bifurcation, as blood flows in smaller diameters. According to Figure 2, the higher blood velocity, in both ROIs, was recorded for Nellix cases, with statistically significant deviation from the AFX ($p=0.03$), Endurant ($p\ll0.01$) and Excluder ($p=0.03$) ones, particularly in the region before the bifurcation. Endurant, on the other hand, is associated with the lowest blood velocity among the endograft groups, before and after bifurcation. The mean value of maximum blood velocity was approximately equal in AFX and Excluder groups before the bifurcation, while after the flow separation, AFX induces the second highest velocity value with Excluder following in the third position.

The highest WSS value was found in Nellix group, before and after the bifurcation (Figure 2). There was a statistical deviation between the Nellix and Endurant groups ($p=0.03$) in terms of maximum WSS before blood flow separation. The order of the endografts in terms of max. WSS is: Nellix, in the first place, followed by AFX and Excluder, while the lowest values were attained in Endurant cases.

Regarding helicity results, the AFX and Nellix follow a different trend than Endurant and Excluder (Figure 2). Specifically, AFX and Nellix exhibit higher mean helicity after the blood stream separation than before while the reverse was evident in the rest 2 endograft groups. In total, the highest helicity value, either before or after the bifurcation, was found for Endurant, followed by Excluder, and Nellix – AFX that are remarkably close in terms of helicity.

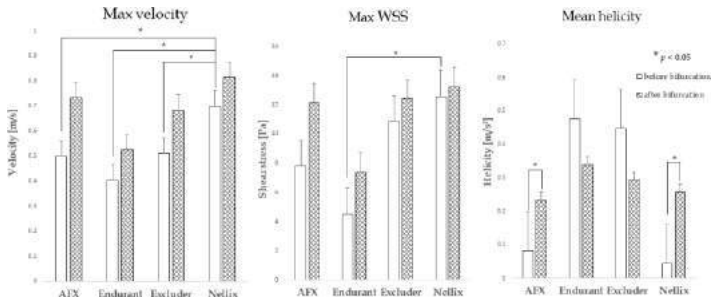

Figure 2: Mean and standard error values of the hemodynamic indexes (velocity, WSS, helicity) in both regions of interest in the 4 endograft groups.

DISCUSSION

The commercial endografts inherently differ in technical specifications and are associated with variable frequency of postoperative adverse events, justifying the need for endograft-specific analysis. Nevertheless, an endovascular device can reduce sac pressure, mechanical stress, pulsatile wall motion, but increased drag forces have also been detected on the device [6]. The material and the design of an endovascular along with the morphology of the AAA are parameters that determine the positioning of the stent-graft inside the aneurysmal sac and the local hemodynamics in large extend.

According to the results, the Nellix distinguishes from the rest devices in terms of velocity and WSS. The special design of Nellix, exploiting the endovascular sealing technology, seems to have a prevalent effect on blood flow. Endurant and Excluder, which incorporate a main body section that bifurcates high in the aneurysmal sac, seem to preserve high-intensity helicity before the flow division. However, the two devices, despite the similar structure, induce distinct blood flow environment in terms of velocity and WSS that might be attributed to their dissimilar material and stent configuration [7, 8]. The AFX device has its main fixation point on the iliac bifurcation such that the post-EVAR lumen morphology resembles physiological anatomy. Previous work has shown that AFX achieves restoration of blood flow indices to physiological levels [5]. In present study, AFX was associated with lower blood helicity values than Endurant and Excluder. It is of interest that similar results occurred for the AFX and Nellix devices regarding helicity, both presenting low helicity before the bifurcation increasing afterwards.

Boersen et al. [9] compared three endografts, Endurant, AFX, and Nellix, visualizing flow with laser particle imaging velocimetry. They suggested that the different stent designs did not influence suprarenal flow. In our study, we found similar results with highest values of velocity and WSS being noted in the Nellix cases, despite not accounting for the suprarenal area. Even, after the flow division, the trend of the results was preserved; Nellix induced the highest velocity and WSS, closely followed by Excluder and AFX.

Loss of limb patency varies between the endografts used in the present study, ranging from 3.4% for the Endurant to 1.1% for the Excluder. Demanget et al. [10] investigated the mechanical performance of 8 different graft limbs without, interferingly, finding significant differences in graft limb complication rates between. More data are needed to affirm whether the differences in flow dynamics found in the present study, may be translated in different graft properties, affecting the clinical outcome. Despite the differences found between the endografts, we must note that the clinical experience with all four devices has demonstrated good results at least during early and mid-term period. The in-stent flow dynamics could reveal the long-term durability of an endovascular device suggesting new ways for the development of complication-resistant stent graft systems.

INTRODUCTION

The Fontan operation provides life-saving palliation for children born with a variety of congenital heart defects including tricuspid atresia, mitral atresia, and hypoplastic left heart syndrome. In the Fontan circulation, the inferior vena cava (IVC) and superior vena cava (SVC) are diverted directly to the pulmonary arteries, bypassing the morphological right ventricle so that the systemic and pulmonary circulations are in series with a single functional left ventricle. Patients who have undergone the procedure are increasingly living into adulthood, but many may face heart failure with elevated central venous pressure. The only treatment option for so-called failing Fontans is heart transplantation; however, many are ineligible due to organ failure or other complications. In addition, Fontan patients are more likely to face subsequent right-heart failure after transplantation due to elevated pulmonary vascular resistance.

The Fontan Circulation Assist Device (FCAD) is under development as a destination therapy for failing Fontan patients. *In vivo* evaluation of the pump detailed in Cysyk et al. [1] indicates favorable performance in a sheep model. However, geometric details of the pump anastomosis, such as anastomotic angle onto the aorta, can impact the pump's performance. The purpose of this computational fluid dynamics (CFD) study is to evaluate two surgical options for the FCAD anastomosis to the pulmonary arteries.

METHODS

One MRI-derived patient-specific anatomy, acquired from the Children's Hospital of Philadelphia, is used in the current study. This anatomy is of a 17-year-old girl with an offset total cavopulmonary connection (TCPC). Raw MRI data was used to reconstruct a three-dimensional model of the patient's Fontan conduit, depicted in Figure 1 along with the two surgical anastomosis options considered. Included in the clinical MRI data are the mean flow rates in each of the IVC, SVC, and the left and right pulmonary arteries (LPA and RPA).

Simulations were performed on three separate models. The first model was a simple reconstruction of the patient-specific anatomy. Simulations were also performed of two surgical options for the anastomosis of the pump outlet to the pulmonary arteries. The first was a simple t-junction, whereby the outlet of the pump connected directly to the central pulmonary artery. The second surgical option, the so-called y-graft, directs flow individually to each pulmonary artery through a bifurcated graft. Such a bifurcated graft has previously been shown to improve the energy efficiency and flow distribution of a TCPC conduit [2]. The computational domain in the pulmonary arteries was removed before the presence of any branching.

CFD simulations were performed in OpenFOAM, using a modified version of pisoFoam, a built-in transient, incompressible, low-Mach Navier-Stokes solver. Simulations were run with a Newtonian constitutive model, with a blood density of ρ=1060 kg/m^3 and a kinematic viscosity ν=4.4×10^{-6} m^2/s. To approximately recreate pulsatile flow through the Fontan conduit, the boundary conditions at the IVC and SVC prescribe a sinusoidal flow rate with a period of 1 second, equivalent to a heart rate of 60 beats per minute. The mean flow rates are prescribed based on MRI data. The anastomosis simulations used velocity data from a precursor FCAD simulation for the inlet boundary condition.

Pressures at the pulmonary arteries used a three-element windkessel model, whereby the outlet pressure (p) and flow rates (Q) were linked according to Equation 1. Each lung had its own value of C (capacitance), R (resistance), and Z (proximal resistance) prescribed to match the left-right flow split observed in the MRI.

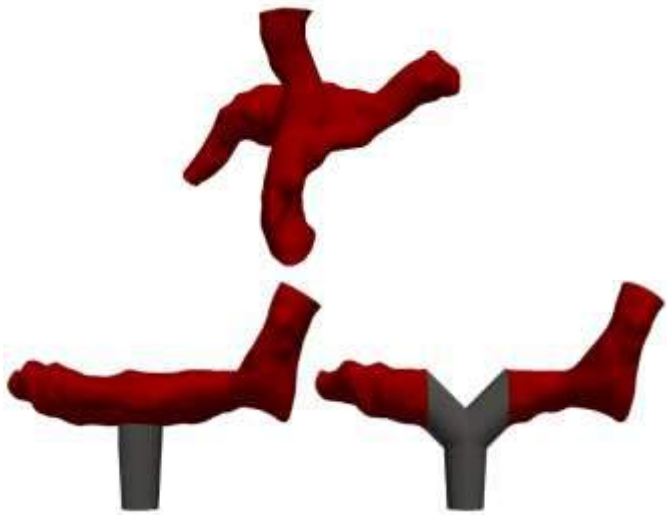

Figure 1. Basic TCPC anatomy (top), and surgical anastomosis options (bottom); t-junction (bottom-left) and y-graft (bottom-right).

$$\frac{dp}{dt} + \frac{p}{RC} = \frac{Q}{C}\left(1 + \frac{Z}{R}\right) + Z\frac{dQ}{dt} \quad (1)$$

All three cases were run on three increasingly fine grids to evaluate grid convergence and provide uncertainty bands by grid convergence index [3] for comparing results. All simulations ran for a start-up time of 4 seconds, and averaging was performed over a subsequent 3 seconds.

RESULTS

The three geometries are evaluated based on several fluid-dynamic metrics, and explicit comparisons are presented between the t-junction and y-graft. Results and statistical significance of difference between t-junction and y-graft are given in Table 1.

Table 1. Fluid-dynamic performance of the three investigated geometries.

	Base	t-junction	y-graft	% reduce Y over T	p-value
E (mW)	14.3	46.8	35.7	23.8%	< 0.0001
$\boldsymbol{\Delta P}$ (mmHg)	2.6	5.0	3.8	25.5%	< 0.0001
$\boldsymbol{A_{OSI}}$ (cm^2)	9.23	6.56	3.30	49.6%	< 0.0001
$\boldsymbol{A_{WSR}}$ (cm^2)	9.98	2.77	1.83	33.9%	< 0.0001
$\boldsymbol{t_r}$ (sec)	2.76	2.41	2.37	1.9%	0.19

In Table 1, E is the rate of energy dissipation, ΔP is the mean pressure drop between the inlets and outlets of the computational domain, A_{OSI} is the area exposed to an oscillatory shear index (OSI) ≥ 0.25, A_{WSR} is the area exposed to a wall shear rate (WSR) less than 200 s^{-1}, and t_r is the maximum residence time in the domain.

DISCUSSION

The primary function of the FCAD is to provide adequate flow to the lungs by overcoming pulmonary hypertension and to reduce central venous pressure, a ubiquitous morbidity in the failing Fontan. Both goals benefit from an energy-efficient placement of the pump, just as previous work has shown more efficient Fontan revisions improve patient outcomes [4]. Both energy loss by viscous dissipation and pressure drop are measures of this efficiency, both of which show significantly better performance in the y-graft as compared to the t-junction. As shown in Figure 2, the impinging jet at the posterior wall of the central pulmonary artery is a significant source of energy loss in the t-junction anatomy, which the y-graft does not suffer from.

Though it is anticipated that the FCAD will improve pulmonary blood flow and central venous pressure, the addition of foreign blood-contacting material is expected to create a thrombosis risk. Hypothetical patients receiving an FCAD would necessarily undergo lifetime anticoagulation therapy, but the fluid dynamics also play a role in thrombosis risk. Thrombosis in this case is primarily a concern of flow stagnation and insufficient washing of adhered platelets by wall shear stress. Although the y-graft shows improvement in area with wall shear rate less than 200 s^{-1}, there is no statistically significant difference in maximum residence time.

The introduction of non-physiological flow patterns in the vicinity of blood vessels creates a risk of vascular injury. The y-graft shows a marked improvement in area with critical OSI. This is primarily due to the lack of impinging jet on the native vessel.

In summary, the y-graft shows improved hemodynamic performance over the t-junction in metrics related to efficiency, thrombosis risk, and vessel damage, and may be a good candidate for connecting the FCAD to the pulmonary arteries.

INTRODUCTION

Low back pain is among the top five causes of disability globally [1]. The spinal facet joint is a common source of pain in the neck and low back [2,3]. Repeated loading of joints and their soft tissues can cause repetitive strain injuries and pain, and have a prevalence as high as 22-40% [4,5]. While effects of cyclic and repeated facet loading have been defined for the cervical spine [6,7], little is known about the lumbar facet's response to repeated subfailure loading.

The mechanical response of the spinal facet capsular ligament, like other ligaments, is rate dependent [8]. The facet capsule is primarily comprised of a collagen network [9] and has nerve fibers innervating it [10]. Because collagen networks are viscoelastic and axonal injury has been shown to be rate dependent [11], defining the rate-dependent response of the facet capsule is important for defining relevant pathophysiological mechanisms related to injury and pain.

The goal of this study was to define the effects of repeated loading and a subfailure ramp-and-hold on the lumbar facet capsular ligament's multiscale tissue and collagen fiber alignment responses. The L4/L5 facet capsule of the rat underwent cyclic tension-compression loading to 0.2mm, which is 10% of failure conditions, has been shown to be non-painful in vivo, and to not produce changes in the cervical facet capsular ligament's structure and collagen organization [6,12,13].

METHODS

Lumbar spines (L3-S1) were harvested from male Sprague-Dawley and Holtzman rats (n=3; 360-405gm) according to IACUC-approved procedures [14,15]. The superficial soft tissue was removed to specifically isolate and expose the bilateral L4/L5 facet joints and their capsular ligaments; the *in situ* length of each joint was measured with microcalipers [16,17].

Single facet joints (n=5) underwent mechanical testing using a customized test frame mounted in an Instron 5865 [12,14,15]. Each sample's *in situ* joint position was re-established as the reference gauge length at the start of each test (Fig. 1A). Each sample first underwent 30 cycles of distraction/compression to 0.2mm at 0.4mm/s [18], followed by an additional ramp to 0.2mm at 0.4mm/s with a hold for 90sec (Fig. 1B). Force and displacement data were acquired at 50Hz and filtered [19]. To determine when, during the hold period, the force stabilized, the time when the rate of force change was smaller than twice the resolution of the load cell was calculated (FR0). Quantitative polarized light imaging was integrated with the mechanical set-up and used to acquire collagen fiber alignment maps throughout testing [19]. In particular, the circular variance (CV) was calculated using those data for each sample at: the unloaded reference (ref), first distraction (Cycle

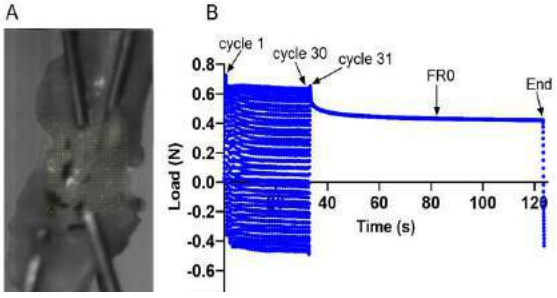

Figure 1: (A) Isolated facet capsule in test set-up showing forceps coupling it to the Instron. (B) Representative load response with each relevant analysis point: cycles 1, 30, and 31, force rate reaching zero (FR0), and the end of the hold.

1), last distraction of the cycling (Cycle 30), peak of the ramp (Cycle 31), FR0, and at the end of the 90sec hold (End) (Fig. 1).

The peak tensile force, peak compressive force, and stiffness were compared between Cycle 1 and Cycle 31. Stiffness was calculated as the slope of the positive portion (tensile) of the loading curve for each cycle. In addition, loads at FR0 and End were also compared to Cycle 31 using separate paired t-tests. CV values were similarly compared between reference and each of those events using separate paired t-tests.

RESULTS

Cyclic loading alters the capsular ligament's mechanical response. The peak tensile force at Cycle 31 (0.59±0.16N) is significantly lower (p=0.0032) than the peak tensile force at Cycle 1 (0.67±0.17N) (Fig. 2). Similarly, the maximum compressive force at Cycle 31 (0.40±0.20N) is larger (p=0.009) than the maximum compressive force from the first Cycle 1 (0.29±0.14N). The stiffness also changes with cyclic loading. The stiffness at Cycle 31 (4.86±1.59N/mm) is significantly larger (p=0.01) than the stiffness at Cycle 1 (3.22±0.8N/mm). During the hold, the force stabilizes after 53.1±7.24sec, decreasing significantly (p=0.0002) by 33.9% to 0.39±0.12N from the peak load at Cycle 31.

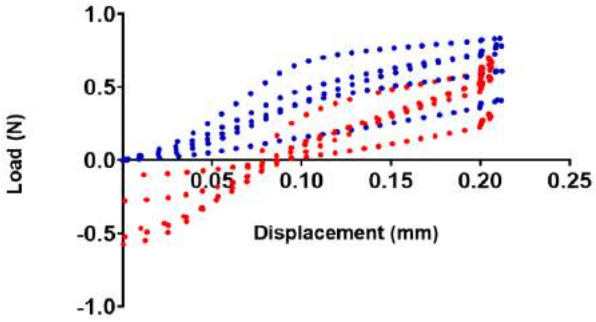

Figure 2: Load-displacement responses for all samples for each of Cycle 1 (blue) and Cycle 31 (red) showing the decrease in peak tensile load and increased stiffness between cycles.

Polarized light data were only available for 4 of the samples but show that one distraction is enough to change the CV (Fig. 3). A single distraction of 0.2mm (Cycle 1; 0.2378±0.0102) significantly (p=0.006) alters CV compared to the reference (0.2289±0.0122) with fiber alignment becoming less organized with increasing CV (Fig. 3). The CV is further increased (p=0.0029) by Cycle 31 (0.2428±0.0107) (Fig. 3). The CV at both the time when force stabilizes (FR0; 0.2438±0.0096) and the end of the hold (End; 0.2473±0.0118) are both significantly different (p<0.0065) from the CV for the unloaded condition (reference). While the CV at End (0.2473±0.0118) is significantly different from that at the peak of Cycle 31 (p=0.0425), the CV at FR0 is not different from either the peak Cycle 31 or at End.

DISCUSSION

The distraction magnitude selected for cyclic loading and the subsequent ramp falls within the toe region of the tensile loading curve for the cervical facet joint loaded to failure [12,15]. Since the collagen fibers in the facet capsular ligament are crimped and overall do not have a preferential orientation, cyclic loading, even at low levels, can reorient and even align fibers in the direction of loading [13,20]. Of note,

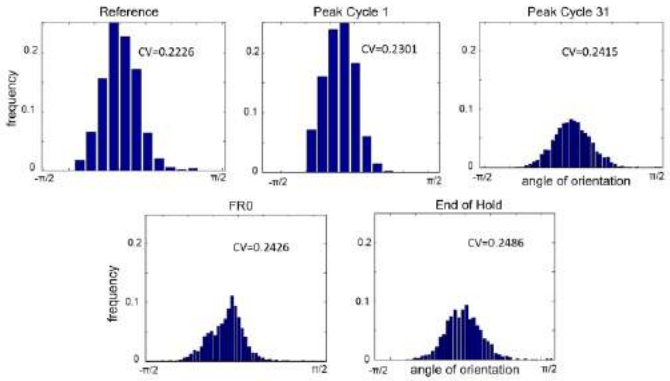

Figure 3: CV (Rat 2LHS) at reference, Cycle 1, Cycle 31, FR0, and the End of the hold, showing changes in fiber alignment

the change in CV after even one cycle at 0.2mm occurs at a lower distraction magnitude than when anomalous realignment of the collagen fibers is detected (0.34-0.68mm) for the rat cervical facet capsule [17]. In addition to varied anatomical levels, differences in sample preparation may account for these discrepancies. These data also indicate that further microstructural changes occur in the collagen network throughout the range of cyclic loading and also during force-relaxation (Fig. 3). Though additional studies are needed to better understand the spatial changes in each test paradigm, the changes in microstructure after cyclic loading are not surprising because repeated distraction of the facet capsule, even below the pain threshold, has been shown to alter capsular mechanics along with pain production [6]. While that repeated loading induced strains that were greater (~8-10%) than those estimated in this study (5%), microstructural changes due to cyclic loading are also supported here by the decrease in load and increase in stiffness (Figs. 1 & 2).

Measuring the local strains along with fiber micromechanics will help to better define and understand this tissues response to its varied loading experienced in the lumbar spine under normal and pathological conditions. Furthermore, defining the rate-dependent response of the facet capsule to mechanical loading will be useful to help refine and develop more realistic computational models of the spinal tissues and ligaments more broadly.

ROLE OF COHERENT STRUCTURES IN AIRFLOW MEDIATED INFECTIOUS DISEASE SPREAD WITH EXPIRATORY PARTICLES

Sara S. Meschi (1), Amirhossein Arzani (1)

(1) Department of Mechanical Engineering
Northern Arizona University
Flagstaff, AZ, USA

INTRODUCTION

Inhalation and contact with virus-laden droplets and aerosols are the main transmission routes of infectious diseases, including COVID-19. Droplets and droplet-nuclei carrying pathogens expelled from the infected person's nose and mouth during expiratory activities transmit the virus to the recipients by coming into contact with their respiratory and eye mucosa [1].

A complex sequence of flow-mediated occurrences, from the formation of infectious droplets, airborne particles, and multi-phase turbulent jets to deposition of the virus on target tissues, makes the disease transmission possible. Thus, the study of the flow physics of respiratory phenomena will lead us toward effective protective solutions. Since the start of the COVID-19 pandemic, a large number of computational and experimental studies have been done to help scientist with understanding the spread of SARS-CoV-2 laden droplets and aerosols in various environmental conditions in terms of ventilation, the distance of the infected person and the recipient, and the type of expiratory event (coughing, sneezing, talking, breathing, singing, etc.) [2]. Studies showed that the expelled content from the nose and mouth contains a multi-phase turbulent gas that carries droplets with a size range of 2-700 μm. Droplets larger than a critical size fall and contaminate surfaces, but smaller droplets evaporate and turn into infectious aerosols, which can stay suspended in the air for hours. Also, it is demonstrated that this multi-phase gas cloud can travel up to 23 to 27 ft depending on environmental and physiological factors, transporting the droplets along with it, which in comparison to the social distancing recommendation (6 ft) is much longer [3].

Considering the above points, it is clear that our understandings of the spread of COVID-19 still have to be evolved, and there are many unanswered questions that remained in the path of establishing more efficient protection guidelines. Additionally, most studies have focused on violent expiratory airflow events such as coughing/sneezing and near-body breathing has received less attention. In this study, we are trying to find out if there is a relationship between the flow topology of the expelled gas cloud from the mouth of the patient and the trajectory of the virus-laden particle traveling toward the recipient. For answering this question, we have employed computational fluid dynamic (CFD) to obtain the flow data during the breathing of two individuals in a confined space. We demonstrate how the Lagrangian coherent structures (LCS) formed in the flow around the two individuals can determine bio-aerosols' destination in the expelled turbulent airflow.

METHODS

A cylindrical confined environment with a diameter of 3 m and height equals 1.5 m is constructed. The heads of the human models are simplified as spheres with a diameter equal to 240 mm to avoid computational complications and are placed 650 mm from each other at the center of the cylinder. Also, the mouth of each model has a diameter of 20 mm. The mesh consisted of 7.3M tetrahedral elements with local refinement between the head models and is generated by the ANSYS Meshing 2019 R3 (ANSYS Inc., Canonsburg, PA) (Fig.1). Pulsatile breathing waveforms are prescribed at both models' mouths with a peak velocity of 2.4 m/s. Two sets of simulations are performed with inlet waveforms with opposite phases (one inhaling and one exhaling) and with inlet waveforms at the same phase (both exhaling and inhaling synchronously) for 5.5 seconds. No-slip boundary condition is prescribed for the model ceiling, floor, and head.

Flow velocity data were obtained using the FEniCS-based open-source finite-element solver Oasis and employing the Large Eddy Simulation (LES) model for solving the turbulent airflow generated by the respiratory events.

Calculation of Finite-time Lyapunov exponent (FTLE) can lead us toward the material surfaces known as LCS. These structures act as transport barriers and have been used in previous studies for investigating the chaotic flow behavior [4]. In this study, we calculated the repelling and attracting LCS, by forward and backward particle integration, respectively. Integrations are performed for integration time lengths of T = 0.2 and 0.5 seconds.

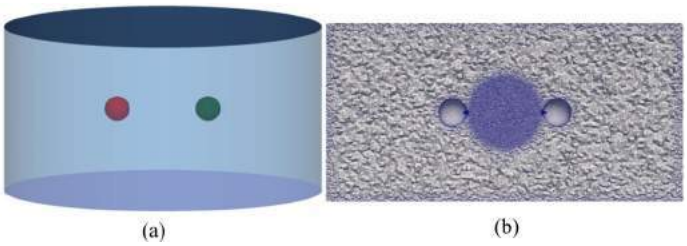

Figure 1: (a) Computational domain consisted of two spheres depicting the human heads. (b) Mesh details in the domain and mesh refinement around the models' mouths.

Furthermore, particle transport was studied by simulating the pathogen-laden droplet nuclei as massless tracers as well as inertial droplets. Approximately 130,000 particles are uniformly seeded at one of the inlets (disease source). Lagrangian particle tracking of tracers is used for tiny aerosols and the Maxey-Riley equation [5] with appropriate force terms for droplets is solved for inertial droplets.

RESULTS

The results of forward and backward FTLE field calculations and the tracers' visualization in the domain are presented in this section. Representative results of the FTLE field calculations for case 1: one person at the exhaling phase and the other one at the inhaling phase and case 2: both human models are exhaling at the same time are shown in Fig. 2 and Fig. 3, respectively.

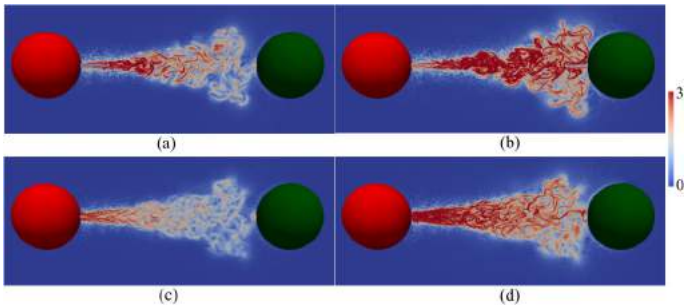

Figure 2: The FTLE field is shown while red model is exhaling and green model is inhaling. Backward FTLE: (a) T=0.2s (b) T=0.5s, Forward FTLE: (c) T=0.2s (d) T=0.5s

For each case, the results for forward and backward integration are presented for integration time of 0.2 s and 0.5 s. The red lines in forward and backward calculations are representatives of repelling and attracting LCS. Furthermore, the tracer/aerosol tracking results along with the corresponding forward FTLE field maps for both simulation cases are shown in Fig. 4, demonstrating the correlation of tracers spread pattern and the Lagrangian coherent structures formed in the turbulent flow around the models' heads.

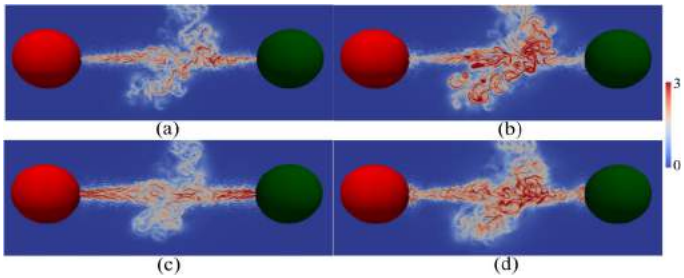

Figure 3: The FTLE field is shown while both models are exhaling. Backward FTLE: Backward FTLE: (a) T=0.2s (b) T=0.5s, Forward FTLE: (c) T=0.2s (d) T=0.5s

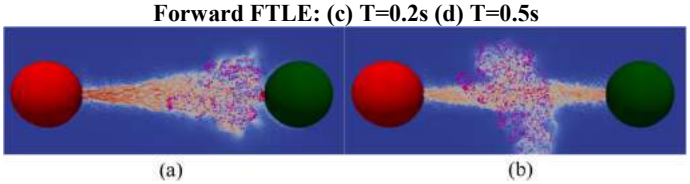

Figure 4: Tracer tracking results shown along with the corresponding FTLE field map calculated forward in time with T=0.5s. Tracers are displayed as massless spheres in magenta.

DISCUSSION

In this study, we have presented a new approach to the investigation of COVID-19 flow physics. We demonstrated that the flow topology of the expelled turbulent gas during breathing carrying expiratory droplets could determine virus-contaminated aerosols fate. This study aims to better understand the spread pattern of virus-laden droplets and aerosols generated by close-contact events such as breathing and talking. We have also performed inertial droplet transport and calculated the corresponding inertial Lagrangian coherent structures (ILCS) [6] to demonstrate the complexity in their trajectory (results not shown). Finally, talking simulations are currently underway and we expect to study the flow topology of small aerosols and large droplets generated in talking using LCS and ILCS, respectively. If we understand how coherent flow patterns influence droplet transport, we can control their spread by modifying airflow. Our proposed framework provides the means to investigate such airflow-mediated protection strategies.

INTRODUCTION

Right ventricle (RV) failure contributes significantly to the mortality and morbidity in a variety of cardiovascular disease including pulmonary hypertension, congenital heart disease and heart failure with preserved ejection fraction [1]. The prevalence and clinical significance of RV failure in pediatric and adult patients require a better characterization of this ventricle, including the mechanical changes during cardiac development and maturation. To date, it is unknown how the RV biomechanics alter in post-natal period, when the left and right ventricles start to adapt to different mechanical loads.

The **goal** of the study was to investigate the differences in the passive viscoelastic behavior of the RV between healthy adolescent and fully matured adult sheep. It is documented that the ovine reach sexual maturity at ~6-9 months old [2], whereas other organs like the orthopedic system mature at ~3 years old. Since the full maturation involves multiple organ systems and lasts until 3-4 years old, we **hypothesize** that the RV passive viscoelastic behavior changes during maturation from adolescence to adulthood. To test the hypothesis, *ex vivo* biaxial tensile tests and stress relaxation were performed in adolescent and fully matured adult ovine hearts and the differences in RV passive viscoelastic properties were examined.

METHODS

Fresh ovine hearts (n=3 for 36+ months old and n=4 for 6-8 months old) were obtained with no known cardiovascular diseases from unrelated studies and from the local abattoir, respectively. Within 4~30 hours after harvest, the hearts were placed in cardioplegic solution (CPS) on ice or at 4°C. Prior to the mechanical tests, the tissues were sliced and cut into 3-4 mm thick, 25 mm x 25 mm square samples, and then placed in CPS combined with the 30 mM of 2,3-butanedione monoxime (BDM) solution at body temperature (26-37°C) for at least 10 minutes to ensure that cardiomyocytes were relaxed. The samples were preloaded by approximately 0.1 N and underwent 15 cycles of equibiaxial stretch at the speed of 8 mm/s for preconditioning. Then, cyclic equibiaxial mechanical tests (at 0.02Hz and 1Hz) and stress relaxation (at strain of 9, 12 and 15%) were performed. The outflow tract direction was marked as the longitudinal direction (0°). All samples underwent a maximum displacement of 4 mm to cover the physiological strain range. Deformations of graphite powder speckled samples were tracked with a camera (Nikon, Tokyo, Japan) and the strains were derived by digital image correlation using in-house Matlab codes. Biaxial stretch forces were obtained by 250 lb load cells (Honeywell Sensotec, Columbus, OH).

Cauchy stress (σ) and Green's strain (ε) were calculated from the last cycle of stress-strain data. From the hysteresis loop, the elastic moduli (E) at low and high strain ranges (slopes of the two straight trend lines) of the loading curve (Fig. 1), the transition stress (intersection point of these two lines) of both loading and unloading curves, and the stored energy (W_s) (Fig. 1) were calculated as elasticity measurement. The dissipated energy (W_d), loop width (a) (Fig. 1), and damping calculated as $W_d/(W_d+W_s)$ were derived as viscosity measurement. From the stress relaxation data, the relaxation rates derived from the logarithmic plots at all strains were used to determine the type of the tissue viscoelastic behavior, where a non-linear viscoelastic behavior is indicated if the relaxation curves from multiple magnitudes of input strains are not parallel [3]. Data were presented as mean ± SEM. Student's t-test was performed and $p \leq 0.05$ was considered significant.

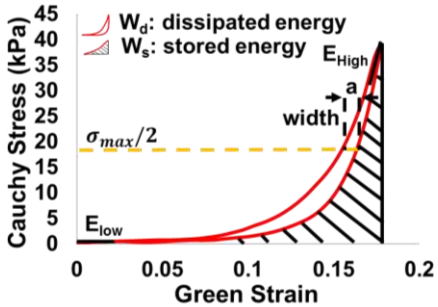

Fig. 1 Various viscoelastic parameters derived from the experimental stress-strain hysteresis loop.

RESULTS

Different frequency-dependent viscoelastic behavior between the adolescent and adult RVs. We firstly compared the viscoelastic behavior of the RV at two frequencies (quasi-static vs. physiological frequency). We found that in both directions, the high-strain E (E_{High}) decreased or tended to decrease as frequency increased, and the two age groups showed similar behavior. But the trends in low-strain E (E_{Low}) were different in these groups: the adult RV tended to stiffen as frequency increased, whereas the adolescent RV showed no frequency-dependent change (Fig. 2A-B). From the viscosity measurement, we found that in both directions, the adolescent RV had higher viscosity with increased frequency, whereas the adult RV had only a mild similar trend in loop width in the circumferential direction (Fig. 2C-D). Our results suggest that adolescent RV had different frequency-dependent viscoelastic behavior than the adult RV.

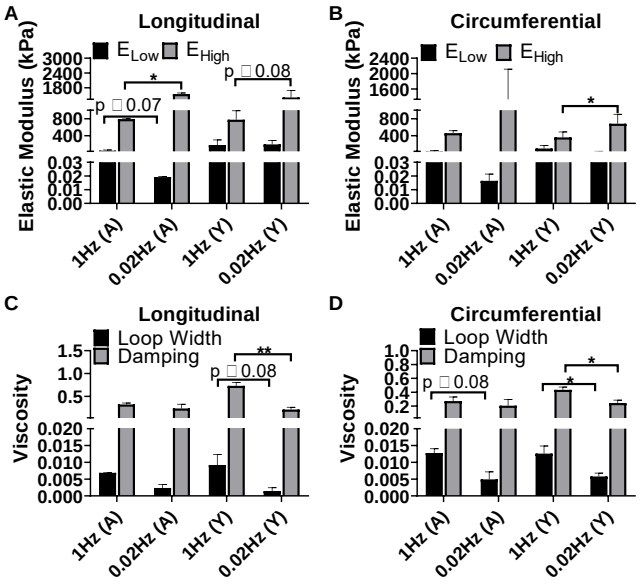

Fig. 2 RV frequency-dependent viscoelastic properties in the longitudinal (L) and circumferential (C) directions from the adult (A) and young (Y) adolescent RVs. (A&B) Local RV elastic moduli at low and high strains; (C&D) RV viscosity measured by loop width and damping. *p<0.05 and **p<0.01.

Different anisotropic viscoelastic behavior between the adolescent and adult RVs. We then further examined the anisotropic viscoelastic behavior of the RV at 1Hz, which mimics the heart rate of sheep. We used storage energy (Ws) to quantify overall RV stiffness and found that with maturation, the RV had increased Ws in both directions, and the increase was significant in longitudinal direction (Fig. 3A). Furthermore, compared to the adult RV, the young adolescent RV exhibit significant anisotropy with larger Ws in the circumferential direction (Fig. 3A). The same trends were observed in the transition stress from the unloading curve (data not shown), another indicator of overall stiffness. As for the viscosity, we found that with maturation the RV became less viscous in both directions, and the decrease was significant in the longitudinal direction (Fig. 3B). Furthermore, compared with the adult RV, the adolescent RV tended to show anisotropic viscous behavior with higher viscosity in the longitudinal direction (Fig. 3B). Overall, our results suggest that after birth, the RV became stiffer and less viscous and was less anisotropic during the cardiac maturation.

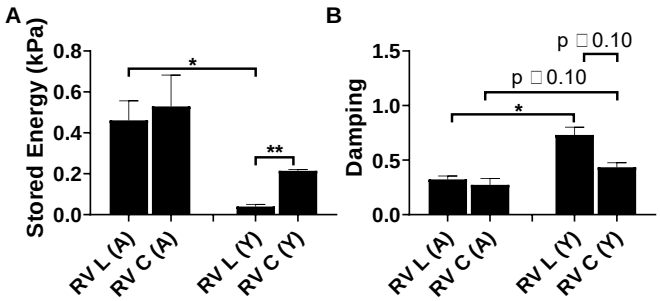

Fig. 3 RV elastic (A) and viscous (B) properties measured in longitudinal (L) and circumferential (C) directions from the adult (A) and young (Y) adolescent RVs (1Hz). *p<0.05 and **p<0.01.

Nonlinear viscoelastic behavior of RV in both age groups. From the stress relaxation data, we observed that the RV exhibited nonlinear viscoelastic behavior in both directions and at both ages (data not shown). This suggests that aging or maturation does not alter the type of RV viscoelastic behavior.

DISCUSSION

Before birth, the RV and left ventricle (LV) are similarly loaded and present similar morphology (e.g. wall thickness). The adaptation of RV after birth is very different than the LV due to the low pressure, low vascular resistance of the pulmonary circulation. But the post-natal cardiac maturation in terms of RV biomechanics is not well known. This study is the first to investigate the changes of RV passive viscoelastic properties between adolescent and fully matured adult sheep. From the pilot data, we found that the adolescent RV showed more pronounced frequency-dependent viscoelastic behavior than the adult RV. Moreover, when examining the viscoelasticity at physiologically relevant frequency (1Hz), we found that the RV became stiffer and less viscous and was less anisotropic during maturation. These age-dependent changes were significant in the longitudinal direction. Myocardial stiffening with aging was reported previously in old adults [4], but the evidence during cardiac maturation is less noted. The main extracellular matrix (ECM) protein in fetal heart is fibronectin, and collagen starts to accumulate after birth and with aging. The age-dependent stiffening may thus be a result of gradual deposition of collagen. But we cannot rule out the role of cardiomyocyte (CM) which stiffens with aging as well [5]. Since microtubules and titin are known to contribute to CM viscoelasticity [6-7], we also speculate that changes in these cellular components during CM maturation lead to increased stiffness and reduced viscosity of RV (as observed here). Such change may be advantageous to enhance RV pumping efficiency. How exactly the ECM deposition and CM adaptation in the RV lead to the viscoelastic changes needs to be further investigated. It also remains unclear whether the changes are unique in the RV. Further study will recruit more hearts and perform biological examinations to fully understand the RV viscoelastic behavior change with maturation. Our study will enhance the understanding of RV biomechanics in pediatric and adult subjects and assist to develop age-dependent RV therapies.

INTRODUCTION

Transparent "Window to the Brain" (WttB) cranial implants made from a biocompatible ceramic, nanocrystalline yttria-stabilized zirconia, were recently reported. These reports demonstrated chronic brain imaging across the implants in mice using optical coherence tomography (OCT) [1] and laser speckle imaging [2]. However, optical properties of these transparent cranial implants are neither completely characterized nor completely understood. In this study, we measure the group refractive index of the implant using a swept source OCT system with a spectral range of 136 nm centered at 1300 nm, over a narrow range of temperatures at which the implant may be used during imaging or therapy (20°C – 43°C).

METHODS

The transparent 8 mol% YO1.5 nc-YSZ WttB implant used in this study was fabricated from a precursor yttria-stabilized zirconia nanopowder and densified into a bulk ceramic via Current-Activated Pressure-Assisted Densification (CAPAD) as described previously [3]. The densified sample was polished with diamond slurries to reduce light scattering by the implant surfaces and thus increase transparency. The implant sample was imaged and analyzed using a swept-source OCT system with a mode-locked laser (Axsun, Billerica MA) with central wavelength emission at 1300 nm, 136 nm sweep and an A-scan-rate of 100 kHz. A pixel in the depth dimension was determined to correspond to a real thickness in air of 6.19 µm. The OCT imaging head was placed over a glass dish containing a 100 µm thick coverslip spacer with hole in the center and secured in place with epoxy. The refractive index of the coverslip spacer (made of borosilicate glass) is 1.504 at central wavelength of OCT at 1.31 µm. The glass dish was placed atop a temperature adjustable plate on a tilt and z-stage, allowing for the dish to be positioned with normal incidence to the OCT beam (Figure 1).

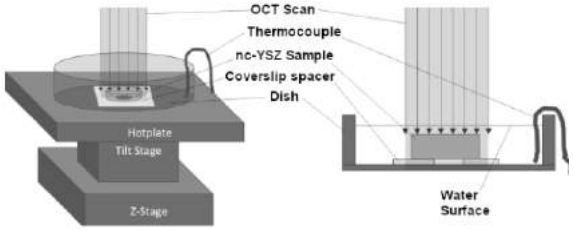

Figure 1: Experimental setup for OCT imaging of nc-YSZ.

A baseline image was acquired, showing the vertical height of the dish and spacer when imaged in air (Figure 2A). Next, the nc-YSZ sample was carefully placed atop the spacer, and water was slowly added to submerge the sample. A thermocouple was used to measure the water temperature as 20.8°C. A room temperature (RT) image was acquired, showing the apparent displacement of the spacer and dish due to non-unity group refractive index of water (at locations F & G) or due to the nc-YSZ and water (at locations A, B, C, D & E) (Figure 2B). The water temperature was increased by heating the temperature adjustable plate to 38°C (near body temperature) (Figure 2C), and then to 43.2°C (the upper limit at which the implant can be used in vivo) (Figure 2D).

The first method of analysis (Method 1) used Image J to quantify distances within the image (in microns and pixels). At locations of interest (A, B, C, D, E, F & G in Figure 2), distances were measured from the top of the image to the following features: top surface of spacer, bottom of dish, top and bottom surfaces of nc-YSZ sample, and surface of water (see colored arrows in Figure 2). From these measurements, and group refractive index values of water at 20.8°C, 38°C, and 43.2°C (1.337, 1.339, and 1.340, respectively), it is possible to separate the total displacement in the image Δ_{total} into apparent displacement $\Delta_{apparent}$ of the dish bottom and/or spacer (due to non-unity

group refractive index of water and nc-YSZ) and the real displacement Δ_{real} of the setup (due to compression and/or expansion of the temperature adjustable plate).

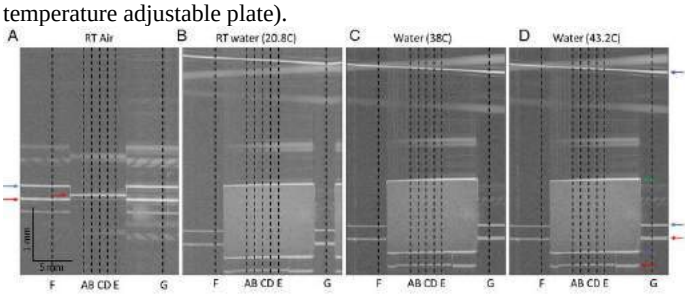

Figure 2: OCT B-Scans of nc-YSZ sample. (A) Dish and spacer in air at room temperature, (B) nc-YSZ sample atop spacer and dish in water at room temperature (20.8°C), (C) nc-YSZ in water at 38°C, (D) nc-YSZ in water at 43.2°C. Horizontal arrows highlight relevant surfaces (red = dish; blue = spacer top/nc-YSZ bottom; green = nc-YSZ top; purple = water surface).

First, the real displacement Δ_{real} of the setup at each temperature is found using the total displacement Δ_{total} of the spacer relative to the baseline image at locations F & G, where $\Delta_{apparent}$ is caused by n_{gwater} only. Subtracting these real displacements from the total displacement Δ_{total} in the images yields the apparent displacement within the image. To calculate the group refractive index of nc-YSZ from the apparent displacement, the method is the same as that used to compute real displacement Δ_{real}, except it is applied at locations A, B, C, D & E, where the apparent displacement $\Delta_{apparent}$ is due to non-unity group refractive index of water and nc-YSZ, using Equation 1:

$$\Delta_{apparent} = (T_{water} - d_{water}) + (T_{nc-YSZ} - d_{nc-YSZ}) = \left(T_{water} - \frac{T_{water}}{n_{g_{water}}}\right) + \left(T_{nc-YSZ} - \frac{T_{nc-YSZ}}{n_{g_{nc-YSZ}}}\right) \quad (1)$$

where T = optical thickness, d = real thickness, and n_g = group refractive index.

The second method of analysis (Method 2) uses the spectral phase function to calculate group refractive index and chromatic dispersion [4]. The spectral phase function describes the relationship between the optical frequencies in the OCT pulse and the difference in phase for each frequency returning from the top and bottom surfaces of the nc-YSZ sample. The spectral phase function may be written as a Taylor series expanded about the central OCT optical frequency, Equation 2:

$$\Phi(\nu) = \Phi^{(0)} + \Phi^{(1)}(\nu_0)(\nu - \nu_0)' + \frac{1}{2}\Phi^{(2)}(\nu_0)(\nu - \nu_0)'' + \frac{1}{6}\Phi^{(3)}(\nu_0)(\nu - \nu_0)''' + \ldots \quad (2)$$

where Φ is phase, ν is optical frequency, ν_0 is the central OCT optical frequency, $\Phi^{(0)}$ is a common phase shift, $\Phi^{(1)}(\nu_0)$ is the group delay (GD), $\Phi^{(2)}(\nu_0)$ is the group delay dispersion (GDD), and higher order terms are higher order dispersion. The group delay of each interface corresponds to the actual optical path length difference between the interface and the OCT reference arm. A subtraction of these GDs for the top and bottom interfaces corresponds to the distance the light experienced within the sample ($T = n_g \cdot d$). Fitting the phase vs. optical frequency data acquired by OCT with a polynomial curve can approximate the spectral phase function. 4th order polynomial fits of the optical phase vs frequency data were performed in MATLAB, and the 1st order terms of these fits give the GD.

RESULTS

Group refractive index of nc-YSZ was determined at each location and each temperature using the image-based analysis (Method 1), shown in Table 1. This method also allowed for determination of real sample thickness $d_{nc\text{-}YSZ}$ at each location and temperature, using the optical thickness T divided by the group refractive index n_g along with a calibration factor of 6.19 microns per pixel in the OCT image. This method is based on whole pixels, and an error analysis shows that the measurement has a 2% error.

Table 1: Group refractive index of nc-YSZ by Method 1:

$ng_{nc\text{-}YSZ}$	20.8°C	38°C	43.2°C
A	2.159	2.159	2.168
B	2.164	2.150	2.165
C	2.176	2.164	2.159
D	2.176	2.174	2.159
E	2.181	2.173	2.176
Average	2.171	2.164	2.165

Next, group delay (GD) of the nc-YSZ sample was obtained using the spectral phase function approach (Method 2). From GD, group refractive index n_g can be calculated using Equation 3 and sample thickness values $d_{nc\text{-}YSZ}$ obtained from Method 1:

$$ng = \frac{GD \cdot c}{4\pi \cdot d} \quad (3)$$

where c = 2.998e+8 m/s. Group refractive index values calculated using Equation 3 are shown in Table 2. Because this method uses sample thickness values determined from Method 1, it also has a 2% error in the calculated values of group refractive index, or an error of ~0.043.

Table 2: Group refractive index of nc-YSZ by Methods 1 and 2:

$ng_{nc\text{-}YSZ}$	20.8°C	38°C	43.2°C
A	2.165	2.156	2.218
B	2.162	2.208	2.202
C	2.182	2.186	2.209
D	2.196	2.196	2.167
E	2.147	2.194	2.202
Average	2.170	2.188	2.200

DISCUSSION

Nc-YSZ cranial implant windows have a group refractive index of 2.1-2.2 for OCT imaging with a spectral range of 136 nm centered at 1300 nm at normal working implant temperatures (20°C-43°C). This is important to consider when interpreting OCT images of underlying brain tissue. Because OCT is a time-based imaging technique, on-axis dimensions in reconstructed OCT images depend on time-of-flight of the OCT pulse. When imaging across the WttB implant with a group refractive index of ~2.1, the implant appears 2.1 times its mechanical thickness, and displaces other features beneath the window downward in the image.

INTRODUCTION

Characterization of material parameters of very soft meso-scale biological tissues is required to understand the cardiovascular biomechanics and governing internal dynamics of a rapidly remodeling vessels. From the mechanobiological perspective, evolution of vessel stiffness and bulk properties of soft tissue can give insights in disease models [1] and predicting in vivo growth and remodeling (G&R) response [2]. G&R is associated with changes in key microstructural constituents like collagen and elastin fibers. Although many techniques have been proposed to determine material properties, determination of the parameters in micro-scale under external stresses in the 0.1-1 kPa range remains a challenging task [3]. A standard approach is through force-displacement measurements, such as the indentation or pipette-aspiration, which are easy to apply for mature vessels, but require careful tool designs. Both methods provide a wide range of stress-strain variation, which is useful to extract mechanical characteristics of the tissue. Tissue aspiration is amiable to simple analytical approximations even for the large strain regimes encountered in very soft gel-like materials.

The aim of this work is to determine the material properties of pharyngeal aortic arch vessels during a critical period of early embryonic development. Present study complements the previous research efforts to describe the properties of embryonic vascular system, which is concentrated on the embryonic heart tube formation and ventricle material properties[4].

METHODS

Measurements are performed in early chick-embryo model at two consecutive Hamburger-Hamilton (HH) stages HH18 (n=4) and HH24 (n=3). Extracted aortic arches (Arch IV – percussor of ascending aorta) are treated with PBS solution. The micro pipette aspiration of the domain is performed by a negatively pressurized glass pipette (WPI Inc, FL, USA) with Rp=30μm tip radius. The cross-sectional tomography of investigated domain during micro pipette aspiration is imaged via cine optical coherence tomography (OCT). We track the pressure displacement data from the calibrated OCT device (Figure 1A). The y- location along the axis of symmetry is a function of the local stretch ratio [5]. Hence, an experimental stretch ratio (λ) for the axis of symmetry is defined by normalizing the aspirated length (L) to the pipette radius $\left(\frac{Rp+L}{Rp}\right)$. The ΔP versus λ curves are fitted to experimental data using the axial Cauchy stress, the incompressibility assumption, and an exponential material law:

$$\Delta P = C * a * \left(\lambda^2 - \frac{1}{\lambda}\right) * \exp\left(a * \left(\lambda^2 + \frac{2}{\lambda} - 3\right)\right) \quad (\mathbf{1})$$

Where, C (mmHg) and a (-) are material parameters [5].

We use an iterative inverse finite element (FE) approach to compute the tissue mechanical properties. Therefore, the best-fit material parameter is found by minimizing the standard error between the FE model estimation and the fitted exponential curve to the experimental measurements. In the model, vacuum

pressure is applied gradually inside the pipette and frictional contact condition are assumed between the pipette and the tissue. The mesh convergence is tested by means of the saturation of Cauchy stress (σ_{yy}) in the specified mesh to achieve less than 5% change in the results (Figure 1B).

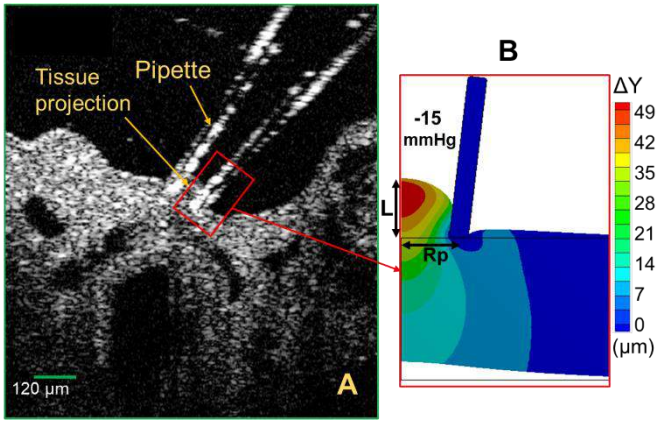

Figure 1: (A) OCT image of the curved aortic arch segment after aspiration *in ovo* (vacuum pressure= -15 mmHg). **(B)** Corresponding simulation from the quasi-static computational finite element model. Directional deformation in Y direction after aspiration is plotted for the embryonic stage HH18.

The goodness of fit is evaluated using the R-squared value. Data are presented as the mean ± standard deviation (Figure 2). The effective modulus, $M= C*a$, is assumed as a stiffness metric for two parameter exponential models [6]. Statistical comparisons between HH18 and HH24 are performed with *t*-test, $*p<0.05$ for n=3.

RESULTS

In the analytical model (Figure 2), statistical tests indicate that the mean value of parameter a increases significantly from a = 0.068± 0.013 (-) at HH18 to a = 0.260±0.014 (-) at HH24 (p= 0.0075). However, effective modulus does not show significant change by M=0.775±0.191(mmHg) at HH18 to M=0.684 ±0.173 (mmHg) at HH24 (p= 0.73).

Optimized neo-Hookean material parameter computed from the FE model are obtained with a standard error < 9%. Assuming incompressible tissue (ϑ=0.49), the optimized initial shear modulus increases from µ=51Pa at HH18 to µ=93 Pa at HH24.

DISCUSSION

Significant changes in the exponential nonlinearity characteristic of embryonic tissue is observed from HH18 to HH24. These differences can be quantified through the load-to-stretch ratio curve (Figure 2) through significant tangential slope increase in the high stretch (λ > 2) region. Stiffening of the stress-strain curve is associated with collagen fiber recruitment in developing vessel wall, in which the fibers straighten with stretch to become recruited and contribute to the local stiffening of the tissue [7]. It can be concluded that significant increase in the non-linearity parameter (a) is due to collagen fiber accumulation in the tissue from HH18 to HH24 [8].The initial shear modulus increases ≈1.8 fold from HH18 to HH24 in the Neo-Hookean material model to capture the stress-strain curve at HH24.

Here, our interpretation for nonlinearity increase in mechanical response of the tissue is increase in collagenous content of tissue, this in agreement with our recent study on embryonic aortic arch microstructure [9] in which the material properties were estimated through loaded and unloaded vessel configurations. However, considering the entire deformation characteristics, effective tissue stiffness (M) in HH24 remains at the same level as HH18. This can be due to the dynamic changes in extra cellular matrix contents in tissue which compensates the stiffness elevation due to collagen fiber accumulation and maintain the effective stiffness of the tissue in the same level.

Our experimental framework is applicable to microscopic tissue systems where extraction of the measurement domain is challenging, or non-invasive in vivo data is desired as in the present application.

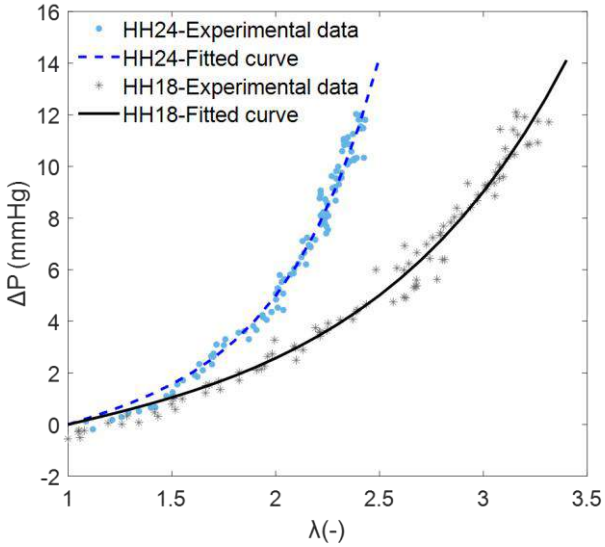

Figure 2: Representative curves that show experimental pressure versus experimental stretch ratio data obtained from aspiration test for samples at HH18 and HH24.

INTRODUCTION

Pectus excavatum is a common deformity classified by a depression of the anterior chest wall. Pectus excavatum is the most prevalent chest wall deformity in children, constituting over 88% of all chest wall deformities [1]. This deformity has been recognized to have a higher prevalence among males than females [2]. Pectus excavatum can be diagnosed as early as infancy, and most patients present no adverse effects of the deformity until adolescence. As the child experiences growth spurts, they may report symptoms such as decreased exercise tolerance, chest pain, and shortness of breath [2]. It is also common for self-image problems to be associated with pectus excavatum, as the chest can be visibly sunken inwards and lead to a more hunched over posture. To prevent further complications in adulthood, this chest deformity is often surgically repaired during adolescence. Current surgical methods include the Nuss Procedure and the Ravitch procedure [3]. The Ravitch procedure is typically seen in adults and involves cutting the cartilage, manually elevating the sternum before fixing it in place with plates and screws. The Nuss procedure, the most popular procedure in general and for adolescents, involves insertion of a metal bar below the depressed sternum to raise it to a more normal position. However, most cases of the deformity are not uniform in their type and severity, which can make surgical methods challenging. This study aims to create thoracic models of more severe representative adolescent pectus excavatum patients that can be used in surgical planning and device design for chest wall reconstruction.

METHODS

Chest computed tomography (CT) scans of pectus excavatum patients ranging in age from 12-16 were mined from Wake Forest Baptist Health medical records by querying patients with ICD diagnosis codes for pectus excavatum and CPT codes for CT scans covering the chest region. Mined CT scans were acquired from the clinical PACS system. From the 49 scans mined, 7 female and 30 male subjects were selected that had sufficient scan quality. In order to quantify severity of the deformity, measurement tools in TeraRecon (Durham, NC, USA) were used to collect thoracic dimensions and calculate a Haller Index and Correction Index for each subject. Haller Index characterizes the internal dimensions of the thorax and is calculated by dividing the maximal transverse diameter of the chest by the narrowest anterior-posterior (AP) length of chest (Figure 1) [4]. The minimum anterior-posterior distance was measured from the anterior aspect of the spine to the posterior aspect of the sternum. Correction Index represents the percentage of chest depth to be corrected and is computed by dividing the difference of the minimum and maximum anterior-posterior distance by the maximum anterior-posterior distance (Figure 1) [5]. The Haller Index (HI) measurements were used to classify each subject's pectus excavatum deformity as mild (HI 2.0-3.2), moderate (HI 3.2-3.5), or severe (HI > 3.5) [3]. Although, Haller Index was the primary measurement used for classification, the Correction Index measurements provided additional validation of severity and were included to enhance the database of thoracic measurements on the pectus excavatum adolescent subjects.

Based on these data, a severe representative female and male adolescent subject were chosen to create two thoracic models. Severe cases of the deformity were preferred in order to better understand the extent to which pectus excavatum influences all relevant anatomical structures. A more severe case of the defect causes greater impact on other anatomy, such as compression of the lungs or deviation of normal rib morphology. Three-dimensional (3D) models of the entire thoracic region were generated from the CT scans using semi-automated image segmentation in Mimics 23.0 (Materialise, Leuven, BE). All

components of the models were separated to allow for ease of adjustment to the models in subject-specific surgical planning and virtual testing of surgical device designs.

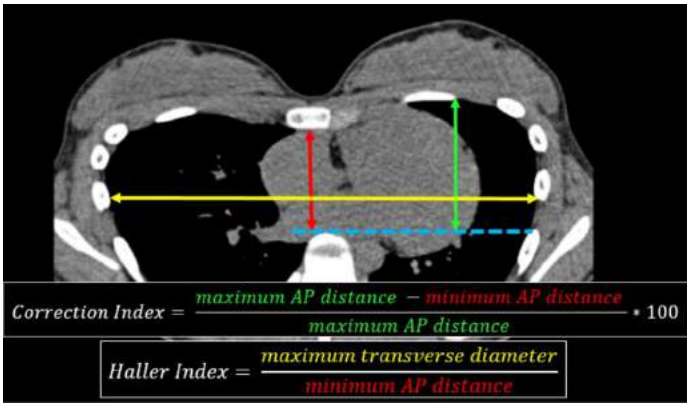

Figure 1: Diagram of Haller Index and Correction Index calculations to characterize severity of pectus excavatum deformity in the axial view of a computed tomography scan.

RESULTS

Of the 37 adolescents analyzed with pectus excavatum, 15 were classified as mild cases, 7 as moderate cases, and 15 as severe cases (Figure 2). The severities were relatively evenly distributed among the male and female subjects. Among male adolescents, pectus excavatum severity was mostly mild (43%, n=13) or severe (40%, n=12), with very few moderate (17%, n=5) cases. Among female adolescents, pectus excavatum severity was mostly severe (43%, n=3), with equal amounts of mild (29%, n=2) and moderate (29%, n=2) cases.

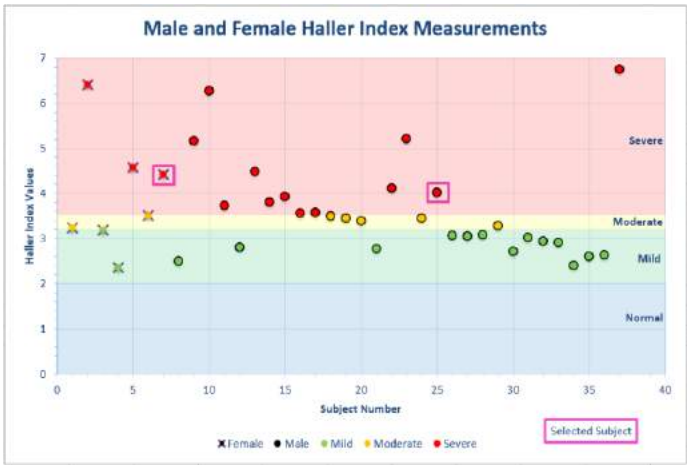

Figure 2: Distribution of Haller Index measurements for the 37 adolescents analyzed with subjects selected for modeling indicated by pink boxes.

From these 37 adolescents, a representative male (age 13) and female (age 15) with severe pectus excavatum deformity was chosen for 3D reconstruction modeling, with Haller Index measurements of 4.02 and 4.43, respectively. 3D reconstructions for the two subjects included models of the individual ribs, sternum, thoracic spine, costal cartilage, lungs, heart, liver, spleen, kidneys, and abdominal cavity (Figure 3).

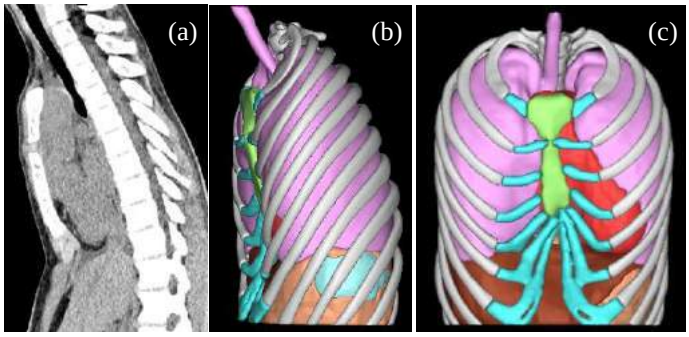

Figure 3: (3a) Original subject CT scan. Completed 15 year old female thoracic model in (3b) lateral view and (3c) anterior view.

DISCUSSION

Medical imaging data were used to characterize pectus excavatum severity and create a male and female thoracic model representative of severe cases of the deformity. The data used in this study is not representative of the entire population with pectus excavatum, but reflective of our hospital's population of these patients with CT scans available. The number of female subjects was very limited, which may be a result of the higher prevalence of the deformity among the male population. Also, this study is limited to subjects 12-16 years of age and does not include any pectus excavatum adult patients or pediatric patients younger than age 12. Of the data available, it can be suggested that adolescent patients with pectus excavatum in our hospital system are more likely to exhibit mild or severe cases of the deformity. This could indicate that moderate cases are less common since they may often progress to severe cases. However, more data is required to conclude definitively.

While the data used in this study may not represent the broader adolescent population with this chest wall deformity, the generated models are clinically valuable because they serve as a tool to inform surgical planning techniques and improve device design for chest wall reconstructions of pectus excavatum on a subject-specific basis. The models representative of severe deformation provide more insight on the range of possible anatomies that may need to be corrected, and helps clinicians both explicitly and intuitively in their assessment of possible solutions with regards to surgical repair. These models can be used to virtually test different device designs for surgical implants and tools used in pectus excavatum chest wall reconstructive surgery.

INTRODUCTION

The primary function of the anterior cruciate ligament (ACL) is transmitting tensile forces between the femur and tibia for stabilizing the knee joint. Recent reports focused on medial and lateral fibers, or fan-like extension and mid-substance fibers [2, 3]. Previous anatomical observation reports suggested that the fan-like extension fibers (FLEF) play a role like an anchor and the mid-substance fibers (MSF) transmit tensile force flexibly for changing direction according to the knee position [3], and another report indicated that the failure load of the ACL dramatically drops after transection of FLEF [4]. In addition, the biomechanical investigation indicated that the proximal part of the MSF mainly resists the anterior drawer force [5]. However, these reports did not address the mechanical functions of these fibers under physiological loading conditions and the relationship between the function and magnitude of the loading. Therefore, the objective of the present study was to determine the relationship between the mechanical function of the FLEF and MSF of the ACL, and the magnitude of the anterior drawer force using the robot testing system.

METHODS

A 6-DOF robotic testing system (FR-2010, Technology Service, Japan, Fig.1, [6]) was used to apply loads to knee joints with respect to the knee joint coordinate system [7, 8]. Porcine cadaveric knees (n=3) were used. The knees were dissected down to the joint capsule and fixed to the robotic testing system. The anterior drawer test was performed up to 200 N at maximum extension. During the test, the anterior-posterior (AP) DOF was translated under displacement control at a rate of 0.1 mm/s while all the DOFs except the AP and flexion-extension DOFs were set under force control with prescribed force/moment at zero. The test were repeated at 30, 60 and 90 degrees of knee flexion in intact, fan-like extension fiber transected (FLEFT) and mid-substance fiber transected (MSFT) states. In the present study, the FLEF and MSF were identified based on the femoral attachment region of the ACL referring to the previous report [4] (Fig.2). Anterior tibial translation and *in situ* forces [6] of both FLEF and MSF during the tests were determined at the 50, 100, 150 and 200N of the anterior drawer force application.

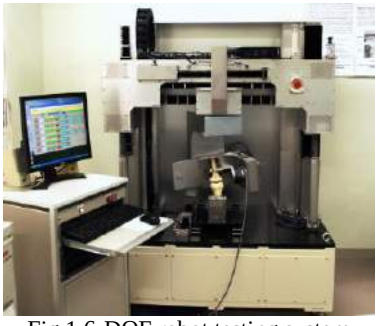

Fig.1 6-DOF robot testing system

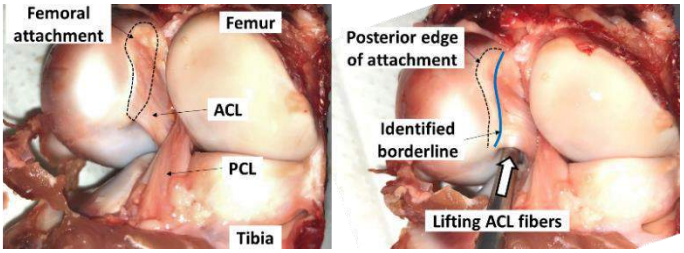

Fig.2 Identifying the borderline (blue line) for dividing the ACL into fan-like extension and mid-substance fibers by lifting the ACL fiber and finding the mid-substance region

RESULTS

At 200 N of the anterior drawer force application, the anterior tibial translation slightly increased after the FLEF transection, the anterior translation was dramatically increased after the MSF transection in all flexion angles (Fig.3). In situ forces of the FLEF at the 200 N of anterior drawer force application were smaller than those in the MSF in all flexion angles.

In maximum extension and 30 degrees of flexion, the *in situ* force of the FLEF gradually increased with the increase of anterior drawer force, and the *in situ* force of the MSF rapidly increased after anterior drawer force application (Fig.4). In 30 and 60 degrees of flexion, the FLEF rapidly responded after anterior drawer force application (Fig.5). The *in situ* force of the MSF rapidly increased at 100 N of the anterior drawer force application and became larger than those in the FLEF.

DISCUSSION

The present study determined the mechanical function of the FLEF and MSF of the ACL in response to more physiological loading and indicated load- and position-dependent function of both fibers.

In maximum extension and 30 degrees of flexion, the MSF rapidly responded to the anterior drawer force application. As the MSF is shorter than the FLEF, the tensile force was assumed to be transmitted earlier in the MSF while the *in situ* force of the FLEF gradually increased in response to anterior drawer force.

The previous study indicated that the FLEF is an important structure for the prevention of structural failure [4], while they were less functional with the increase of the magnitude of anterior drawer force up to 200N. This suggests that 200 N of the anterior force is still *in vitro* load taking the failure load of the ACL into account, and that the MSF is more functional than the FLEF under such a small amount of the loading condition. In other words, the FLEF is afunctional compared to the MSF in the early phase of the load application to the knee. On the other hand, the MSF consists of a lower stiffness structure than those of the FLEF [10, 11]. This suggests that the FLEF consisting of high stiffness structure mainly resists the load under greater loading condition like sports activity, while the MSF of low stiffness allows large deformation.

In 60 degrees of flexion, the FLEF rapidly responded to the anterior drawer force application. This suggests that the FLEF becomes more functional in the flexed knee at early phase of anterior drawer force application, as the femoral attachment of the ACL rotates according to the knee flexion.

CONCLUSIONS

(1) ACL has a site-dependent function, and the function of each site is activated depending on the magnitude of the force.
(2) The site-dependent functions are dependent on the knee flexion angle, as well.

INTRODUCTION

To quantify the risk of Traumatic Brain Injury (TBI) and mild TBI (mTBI), brain strain, particularly maximum principal strain (MPS), is found to be a good predictor for brain injury and assorted pathology and is widely used in mTBI research[1,2]. To quickly evaluate brain injury, many brain injury criteria (BIC) have been developed to approximately quantify brain injury and are often evaluated by the brain strain calculated based on FE modeling. These BIC use different rotational parameters of impact kinematics in the calculation, such as the peak values of angular acceleration.

However, the contribution of different rotational parameters in the calculation of brain strain is not well understood. In addition to the kinematics in their original maximum values, the underlying relationship between the kinematics and MPS may also be high-order. The combination of multiple rotational parameters under mathematical transformations, and the contribution of different parameter components such as angular velocity in different directions in the evaluation of brain strain remain to be further studied. To better develop BIC based on rotational kinematics, we need to systematically study the predictive power of different rotational parameters.

In this study, 5 datasets from various head impact subtypes are used for analysis. With multiple statistical interpretation techniques, we study the predictive power of multiple rotational parameters in the linear regression models of 95% MPS (MPS95). Three aspects of features are focused in this study: the derivative order of the angular kinematics (angular velocity, angular acceleration, angular jerk), the components in three spatial directions and the magnitude, and the power of the kinematics (square root, quadratic, cubic, etc.)

METHODS

The datasets in this study includes 2130 simulated head impacts from a validated finite element model (FEM)[3,4] (dataset HM), 184 college football[5](dataset CF1), 118 college football head impacts[6] (dataset CF2), 457 mixed martial arts (MMA)[2](dataset MMA), 53 reconstructed head impacts by National Football League (NFL) [7] (dataset NFL), 48 car crash dummy head impacts from NHTSA[8] (dataset NHTSA) and 272 numerically reconstructed head impacts in National Association for Stock Car Auto Racing (NASCAR).

To build the regression models of MPS95, various features were extracted. As linear acceleration has been proven to contribute significantly less to MPS compared to angular velocity[9], only angular-velocity-based features are used in our analysis. We extracted features that may contribute to the regression based on three different aspects. 1) derivative order: we took the zero-order, first-order and second-order derivative of angular velocity. 2) spatial component and magnitude: the components of the rotational parameters derived from the components in three spatial directions, which is defined using the right-hand rule. The magnitude of the rotational parameters was also calculated to be the fourth component. 3) power order: power of 1, 0.5, 2, 3, 4, 5, and 6 of those features were calculated and added to the feature set respectively.

Ordinary Least Squares (OLS) was used to build the linear regression models to quantify the contributions of features to MPS95. The OLS model captures the most direct and explicit predicting effect of a feature, and thus is considered the most suitable model in this situation where the purpose of the study is to understand the most directly related features in the prediction. To analyze the relative feature importance from linear models considering the linear correlation among features, four statistical interpretation methods that focus on different perspective of interpreting predictive power were used: zero-order correlation coefficients[10], structure coefficients[11], commonality analysis[12] and dominance analysis[13].

RESULTS

Predictive power of different derivative orders: The predictive power of three factors of derivative orders were analyzed using the four methods mentioned above. According to both zero-order correlation coefficients and structure coefficients, on all datasets but dataset MMA, the first-order features (angular acceleration) were the most predictive features while the second-order features (angular jerk) were the least predictive features ($p < 0.05$). On dataset MMA, both statistical methods showed zero-order features (angular velocity) were the most predictive ($p < 0.05$). Commonality analysis showed that the common information of all three factors had the highest predictive power on datasets HM, CF1, CF2 and NASCAR. On dataset MMA, the common information of zero-order features and first-order features had the highest predictive power. The dominance analysis showed that on dataset HM, CF1, CF2, and NASCAR, the first-order features dominated in every level, and on dataset MMA, the zero-order features dominated in every level.

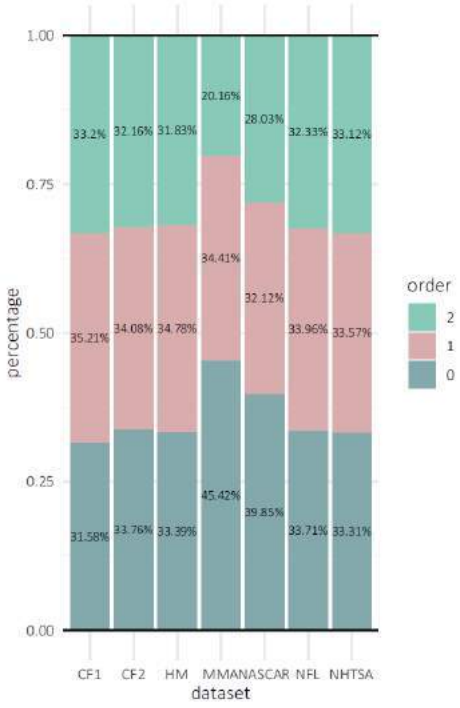

Figure 1. Stacked bar plots of normalized mean R^2 contribution of kinematic factors of 3 different derivative orders in the regression of MPS95 using zero-order correlation coefficients.

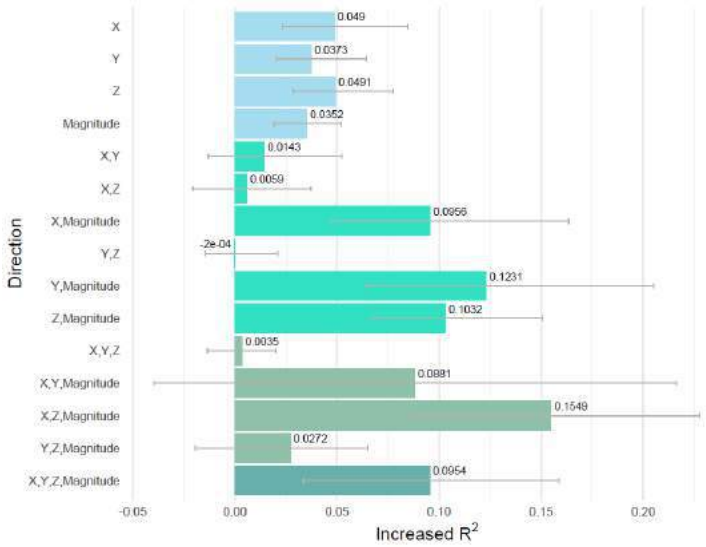

Figure 2. Commonality analysis results for unique or common information of different predictors in the regression of MPS95 from features of 4 different components on dataset MMA.

Predictive power of different kinematic components: The same interpretation methods were used to analyze the four kinematic components: the three spatial directions and the magnitude. According to both zero-order correlation coefficients and structure coefficients, on all datasets but dataset NHTSA, magnitude features were the most predictive features ($p<0.05$). Zero-order correlation coefficients showed the features of z-axis component were the most predictive on dataset NHTSA ($p<0.05$). This result was not statistically significant according to structure coefficients ($p=0.17$). Commonality analysis showed the predictive power varied with different datasets. On dataset HM, the common information of features from y-axis and the magnitude showed the highest predictive power. On dataset CF1 and CF2, the common information of features from x-axis, y-axis, z-axis and the magnitude were the most predictive. On dataset MMA, the common information of features from x-axis, z-axis, and the magnitude was the most predictive. Dominance analysis showed that magnitude features dominated in most levels of analyses with an exception on dataset MMA, where x-axis features dominated over other features on level 3.

Predictive power of different power orders: In the power order analysis, both the zero-order correlation coefficients and the structure coefficients showed that, on all datasets except NHTSA, the first-order-powered features were the most predictive features ($p < 0.05$), while the square-root-features were the most predictive feature on dataset NHTSA ($p < 0.05$). The power orders smaller than 3 were significantly more predictive than the remaining power orders. Besides the power order of 0.5, 1, and 2, as the power order increases, the features showed gradually decreasing predictive power in the regression. According to the results of commonality analysis, the common information of all factors had the highest predictive power, which indicates that changing the power of features does not provide new information in the regression. The dominance analysis showed that the first-order-powered features generally showed dominance, with exceptions on dataset MMA and dataset NASCAR where different factors showed dominance on different levels, which indicates that the predictive power of different factors were not clearly ranked on dataset MMA and dataset NASCAR.

DISCUSSION

This study applied four statistical interpretation methods to analyze the regression of MPS95 to evaluate the predictive power of different factors of rotational parameters of head impact kinematics. In terms of the predictive power among factors when viewed individually (the direct effect defined by Budescu[14]), the zero-order correlation coefficients and structure coefficients manifest that the following kinematic factors generally show the highest predictive power: 1) features based on the first derivative order of angular velocity (angular acceleration), 2) features based on the magnitude of the kinematics and 3) features of power order 1. These findings were generally supported by the dominance analysis in which these three factors dominated in most levels of analyses. Based on the findings in this study, in terms of the feature engineering of brain injury criteria, new mathematical forms can be designed and validated to evaluate the brain injury risk in a more accurate manner. For instance, the brain injury criteria can take into consideration both angular acceleration and angular velocity[9], the magnitude as well as the components in different spatial directions[15], and the first-order-powered and also the square-rooted math forms for better risk evaluation in a wider range of head impacts. In addition to the diagnostic and risk-evaluation development, upon understanding the most predictive features in the head impact kinematics, better concussion-prevention technologies can be developed with focus laid on the features predictive of high brain strain. For instance, in the design process of protective equipment such as the football helmets[16], the peaks of the angular acceleration magnitude can be the metric to guide the design most appropriately.

INTRODUCTION

Magnetic Resonance Elastography (MRE) is a developing imaging technique that enables non-invasive estimation of tissue mechanical properties through the combination of magnetic resonance imaging (MRI) and mechanically induced shear waves in the tissue [1]. During MRE imaging of smaller and stiffer tissues, the shear wavelength should not surpass the size of the region of interest (ROI). In other words, enough data having adequate temporal resolution needs to be collected in a single period of cyclic harmonic loading to avoid aliasing. For instance, performing MRE on a small tissue such as the intervertebral disc (IVD) requires the targeting of shear wavefields to maximize the signal-to-noise ratio (SNR) in the ROI [2,3]. Although increased actuation frequency allows placement of shorter wavelengths in a given ROI which can cause an increase in SNR, challenges with attenuation caused multi-driver units to be investigated [4-7]. With multi-driver units, it is aimed to illuminate the ROI in a more uniform fashion through constructive wave interference [6]. Also, past efforts have utilized manual placement of drivers for brain MRE [8], but for more targeted tissue movement, control of driver positioning is needed.

This work details the design and evaluation of an active MRE driver positioning system for image guided MRE that is targeted to be used for the assessment of disc degeneration in the lumbar region in vivo non-invasively. Application of MRE imaging to identifying the degeneration level of the intervertebral disc (IVD) has been performed by multiple research groups primarily on excised IVD tissue [9-11]. The proposed system in this work combines positioning control with MRE actuation and is shown in Figure 1.

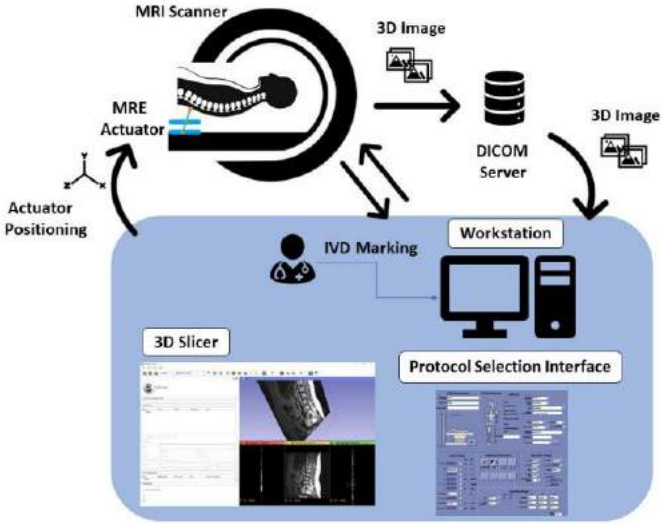

Figure 1: Process flow: Marking of the targeted ROI by MR technician. Image data transfer from DICOM server to local workstation. Bi-directional communication between the local workstation and linear positioners of the parallel stage mechanism. Actuator positioning to the target location through visual servoing.

METHODS

Mechanical Design: A fixed platform was made from two parallel stages distanced by rectangular pillars in between. Both in lower and upper stages, identical carriers were used to provide motion along the y-axis [12]. On top of these y-axis carriers, carriers providing motion along the x-axis were situated (see Fig. 2a). Low surface friction rods

*Contributed Equally

were used as carrier guides. Inside the x-axis carriers, a ring-shaped volume was left empty for contrast agent to be injected. Furthermore, at the center of these x-axis carriers custom cut spherical ball joints were placed. The linear positioning of all the carriers was performed by hydraulic manipulators (syringe-tube-syringe system). As the mechanical vibration source, an MR compatible piezo actuator (APA150M-NM, Cedrat Technologies) was used. This actuator is attached to the tip of a rod which passes through the upper spherical ball joint. The other end of the rod piece was coupled with a syringe that serves as the 5th DOF linear positioner. Inside this rod, a fiducial marker was placed closer to its tip in which the piezo actuator was attached. While the upper spherical ball joint serves as a guide for this rod piece, the lower spherical ball joint holds the syringe tube casing.

Imaging Protocol: A morphological scan was performed to acquire the position and orientation of the piezo actuator attached to the rod piece. Imaging parameters for this 3D morphological scan were acquisition matrix: 96 x 48, TE/TR: 1.26/520.29ms, FOV: 100 mm, flip angle: 38, and slice thickness: 1.6 mm. While performing MRE imaging, the MRE sequence provided TTL triggering was used to drive the piezo actuator in sync with the motion encoding gradients. MRE data was acquired for 19 slices with 3D motion encoding gradients using an echo planar spin echo 2D pulse sequence [13] in the axial plane with the following imaging parameters: acquisition matrix: 96 × 48, TE/TR: 59/2541.4ms, FOV: 240 mm, flip angle: 90, 8 phase offsets, slice thickness: 2 mm, gradient amplitude: 40 mT/m, mechanical vibration frequency: 60 Hz. The experiments were performed on a 3-Tesla Siemens Skyra scanner.

Phantom Preparation: A Knox gelatin phantom was prepared to evaluate the positioning mechanism. Three disc-shaped phantoms made from 100ml-Knox:500ml-water mixture was placed inside of a 35ml-Knox:500ml-water mixture. A plastic pipette was passed through the disc shaped phantoms to hold them in place. During the preparation of both mixtures, Knox dissolved in water was heated in microwave for 80 seconds and then placed in vacuum chamber for 30 seconds before being poured into molds.

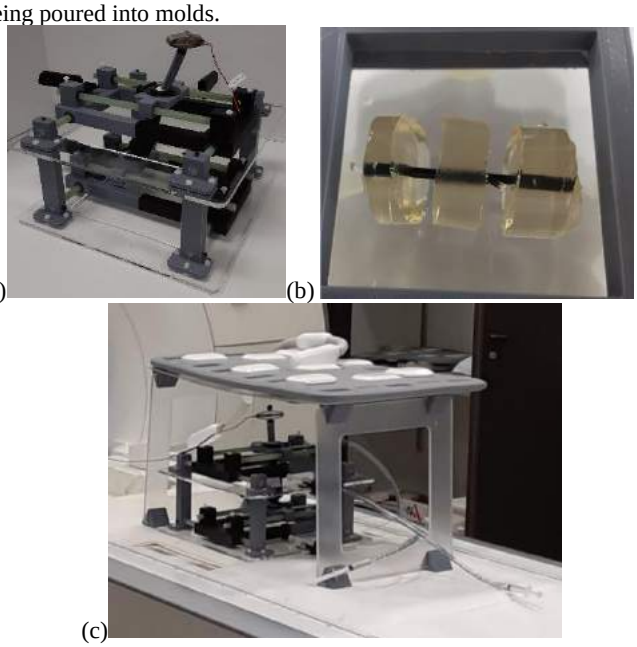

Figure 2: (a) Parallel stage mechanism. (b) IVD mimicking phantom. (c) The whole setup including the hydraulic manipulators. Underneath the body coil, a phantom holder was positioned in which the IVD mimicking phantom resides.

RESULTS

Manual positioning of the piezo actuator was performed by using the hydraulic manipulators (see Fig. 2c). For mechanical wave delivery, a 3D printed rod extension attached to the tip of the piezo actuator was brought in contact with the IVD-mimicking phantom's surface. Wave propagation fields were captured under different harmonic loading angles during MRE imaging (see Fig. 3e-f). The angle of loading for each configuration shown in Figure 3 was calculated through a custom written Python script in 3D Slicer. The harmonic loading angles were 88°, 83°, and 88° with respect to the IVD mimicking phantom's surface (see Fig. 3a-c). The absolute maximum/minimum amplitudes were ±5 microns in all experiments.

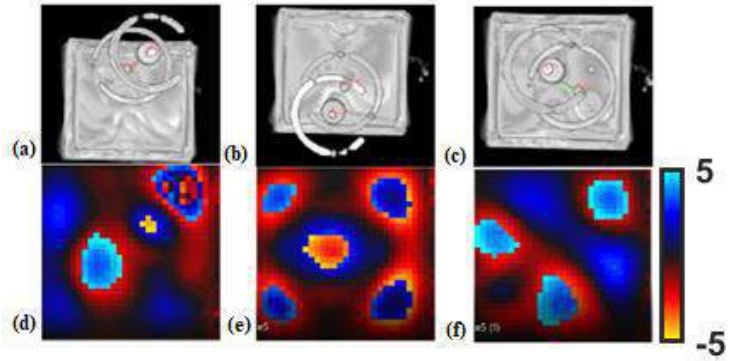

Figure 3: Displacement fields and associated robot configurations for harmonic loading under (a) 88°, (b) 83°, and (c) 88°.

DISCUSSION

Currently elastography imaging of the IVD is not widely available clinically due to limitations of current MRE actuator positioning methods. In this study we have shown that harmonic loading angle has an influence on the acquired wave field data in a phantom model. Our initial prototype's performance will be further evaluated based on the stiffness maps and the propagating wave field profiles acquired of an excised IVD volume. Stiffness maps and wave field profiles can be used to pre-diagnose the onset of a possible tearing on the annulus fibrosus region of an IVD. By having this knowledge at the early stages of degenerative disc disease, precautions can be taken to avoid progression of the disease at early stages. This can prevent a person to go through extensive surgeries in the future.

MEASURING THE ANISOTROPIC MECHANICAL PROPERTIES OF SINGLE NEONATAL MOUSE CARDIAC MYOCYTES

INTRODUCTION

Congenital heart defects and subsequent surgical interventions alter the loading conditions on the heart muscle.[1] Biomechanical models of congenital heart defects are useful for understanding disease progression and aiding clinicians in planning treatment. In order to formulate the most predictive tissue and organ level biomechanical models, the mechanical properties of the individual components must also be elucidated. In order to fully understand the mechanical properties of the heart, the mechanical properties of cardiac myocytes, the force generating cells in the heart muscle, must also be characterized. Cardiac myocytes play an important role in remodeling of the heart muscle and are sensitive to mechanical stimuli.[2-3] As cardiac myocytes exist in a dynamic mechanical environment and have a highly organized cytoskeletal architecture, there is a need to understand how complex mechanical loading conditions influence the cell's anisotropic mechanical properties. Here, we measure the stress-strain behavior of cardiac myocytes in response to complex loads.

METHODS

Substrate Fabrication and Cell Culture. Neonatal mouse ventricular myocytes (NMVMs) were isolated from one-day-old mouse pups using standard methods.[4] As previously described,[5] NMVMs were micropatterned with elongated architecture (aspect ratio 7:1 and an area of ~2250 μm^2) on fluorescent-bead-doped polyacrylamide (PA) gel with a Young's modulus of 13.5 kPa (Fig. 1a-b).

Cellular Micro-Biaxial Stretching (CμBS). CμBS experiments were performed using a custom-built microscope-mounted device to perform traction force microscopy (TFM) experiments on cells exposed to biaxial stretching (Fig. 1c). Three types of straining protocols were applied to the micropatterned NMVMs: axial tension, axial compression, and transverse tension where the axial direction is parallel to the short axis of the cell and the transverse direction is parallel to the short axis of the cell (Fig. 1d). Strains were evaluated in 5% increments to a maximum of 15% for all protocols. NMVMs were paced at 1 Hz using an Ionoptix MyoPacer to induce contraction. High temporal resolution (100 Hz) images of the fluorescent bead layer were acquired to capture the full contraction of the cell and used to calculate traction forces of the cardiac myocytes at each applied strain (Fig. 3e).

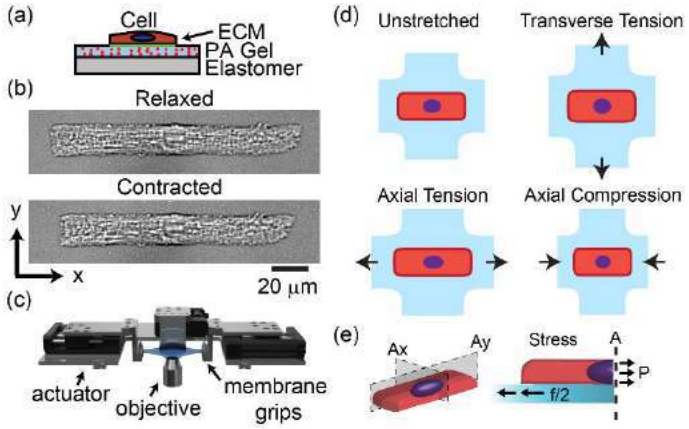

Figure 1: Cellular microbiaxial stretching device and methods for measuring cell stress. (a) Schematic of cell patterned on PA gel,[5] (b) Representative images of a contracting micropatterned NMVM, (c) CμBS device,[5] (d) Schematic of a cell under axial tensile, axial compressive, and transverse tensile strains, (e) Relationship between traction stress, cross-sectional area, and PK1 stress.

Traction forces at each stretch were calculated using standard methods.[5] The first Piola-Kirchhoff (PK1) stresses, represented by $P_x = f_x/(2A_x)$ and $P_y = f_y/(2A_y)$, where f is the traction force and A is the cell cross-sectional area, were calculated at the mid-plane of the cell using the total tensile force and the undeformed cross-sectional area of the cell (Fig. 1c). The PK1 stress was converted to Cauchy stress (σ) by multiplying the PK1 stress by the stretch ratio, λ. The cross-sectional areas of micropatterned NMVMs were estimated to be A_x = 19 μm^2 and A_y = 131 μm^2.[6] Sarcomere spacing during stretching was measured using a fast Fourier transform (FFT) on bright field images of the contracting NMVMs in which the sarcomere structures are visible.

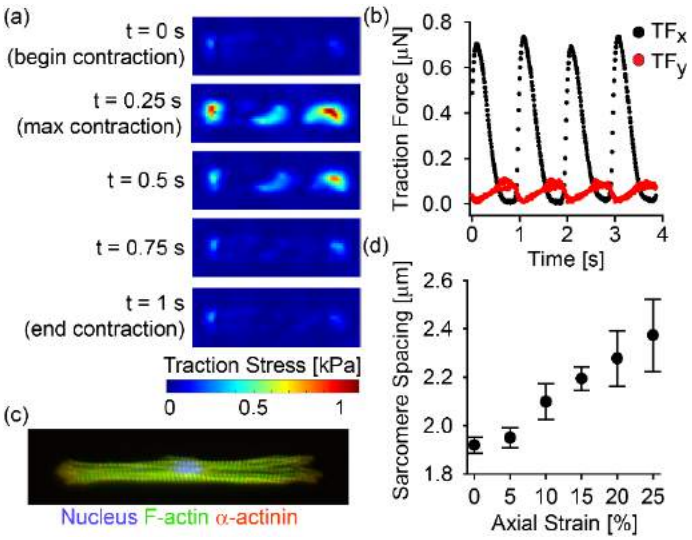

Figure 2: NMVMs are compatible for use with CμBS. (a) Traction stress heat maps during contraction, (b) Trace of the traction forces in a micropatterned NMVM, (c) NMVM stained for nuclei, F-actin and α-actinin, (d) Sarcomere spacing of cardiac myocytes under axial tensile strain.

RESULTS

Traction force of the NMVMs during contraction was measured and was greatest along the long axis of the cell (Fig. 2a-b), which is consistent with the underlying sarcomeric architecture (Fig. 2c). Using FFT, the sarcomere spacing prior to stretch was measured to be ~1.97 μm, which is consistent with measurements from fluorescently stained cells (Fig. 2c) and literature values.[7] When the NMVMs were exposed axial tensile strains, the spacing between sarcomere subunits increased with stretch (Fig. 2d).

In the axial direction, the NMVMs were exposed to tensile or compressive strains using CμBS (Fig. 3a) and the axial Cauchy stress (σ_x) (Fig. 3b) and transverse Cauchy stress (σ_y) (Fig. 3c) were calculated at each deformation. The passive stress was defined as the stress in the cell when the cell is not contracting and the active stress is defined as the difference in cell stress between the fully contracted and non-contracted states. Under axial tensile strains, the active σ_x initially increases with increasing strain before decreasing at the maximum applied strain. Under axial compression, the active σ_x decreased as the cell was compressed. This is consistent with previous understanding of the length-tension relationship observed in striated muscle cells. The passive stress and the stress along the short axis of the cell, σ_y, remained relatively unchanged under both axial tension and compression compared to the active stress in the long axis. Under transverse tensile strains (Fig. 3d), the active σ_x decreased slightly with increasing strains while the passive σ_x was relatively unchanged (Fig. 3e). Both the passive and active σ_y remained relatively unchanged with increasing strains (Fig. 3f).

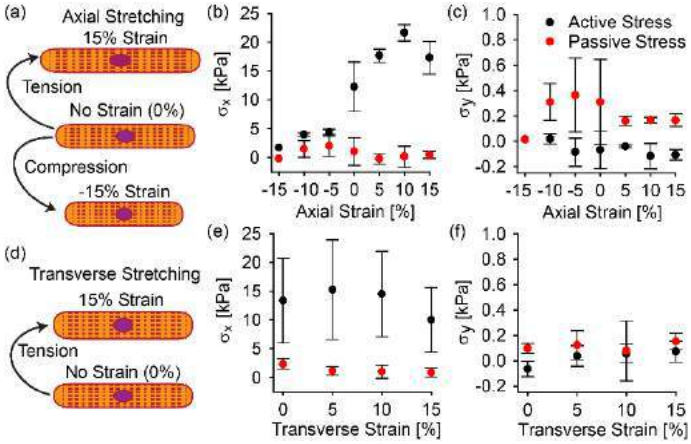

Figure 3: Cauchy stress (σ) measurements in NMVMs under complex loads. Axial Stretching (a-c). (a) Schematic of axial tension and compression, (b) Active and passive σ_x along the long axis of the cell, (b) Active and passive σ_y along the short axis of the cell. Transverse Stretching (d-e). (d) Schematic of transverse tension, (c) Active and passive σ_x along the long axis of the cell, (d) Active and passive σ_y along the short axis of the cell.

DISCUSSION

There is a need to fully characterize the anisotropic mechanical properties of cardiac myocytes in order to develop the best tissue and organ level biomechanical models of the heart. In this study, we used CμBS to measure the stress-strain behavior of NMVMs under complex loads. We found that in the axial direction, the stress-strain behavior is similar to what is described by the length-tension relationship of striated muscle in which changing the sarcomere spacing from an ideal distance decreases the force the cell is able to generate.[8] Additionally, we found that strains applied in the transverse direction also altered cell stress as the active stress appeared to decrease with applied tensile strain. This could be due to inhibiting the interactions of the acto-myosin lattice in the micropatterned cells similar to the axial stretching. Future work will expand the types of stretches performed to include transverse compression and equi-biaxial tension and formulation of a mathematical model to describe the contraction of the cardiac myocytes. Overall, our results suggest that complex loads affect the functional contractility of NMVMs.

INTRODUCTION

Patients with cam femoroacetabular impingement (FAI) morphology are prone to chondrolabral injuries, which often progress to osteoarthritis (OA) [1]. The mechanical factors responsible for initiating and progressing chondrolabral injuries in these patients are not well understood. Additionally, while labral repair is commonly performed during surgical correction of cam morphology, the isolated mechanical effect of labral repair on the labrum and surrounding cartilage is unknown. Using patient-specific finite element (FE) analysis, we asked the following questions: 1) Does cam morphology pose a higher risk of damage to cartilage due to higher stresses and strains, compared to a radiographically normal hip? 2) Do common chondrolabral damage scenarios, including delamination, delamination with rupture of the chondrolabral junction (CLJ), and presence of a chondral defect, experience elevated stress and strain around the damage? 3) How does labral repair affect stresses and strains in the context of the aforementioned chondrolabral damage scenarios?

METHODS

We selected a patient with cam FAI who was representative of a cohort of seven patients in a previous study [2]. The selected patient was a 25-year-old, 90 kg, BMI 24 kg/m^2 male with cam morphology characterized by an alpha angle (AA) of 78°, lateral center edge angle (LCEA) of 28°, Tonnis angle of 7°, femoral neck shaft angle (FNSA) of 131°, no crossover sign, and subspine type I. We selected a control participant from the cohort with similar demographics (male, 23-year-old, 81 kg, BMI 24 kg/m^2) having normal morphology with an AA of 37°, with an LCEA of 27°, Tonnis angle of 7°, FNSA of 130°, no crossover sign, and subspine type I. Patient-specific FE models were created of the cartilage and labrum and meshed with quadratic tetrahedral elements (Figure 1A). The cartilage and labrum were represented as inhomogeneous, biphasic, anisotropic materials. A strain-dependent, anisotropic permeability was used to represent the physiological permeability characteristics of articular cartilage. The mechanical contribution of the collagen fibrils was represented by a continuous fibril distribution constitutive model, which varied in primary orientation through the thickness of the cartilage layers. Material coefficients were set according to a previous study of cartilage mechanics in the hip [3]. Patient-specific kinematics representing one cycle of gait were applied to the patient models. For each scenario analyzed, contact area, contact stress, tensile strain, and shear stress were recorded over the gait cycle and compared.

For the cam FAI model, additional FE models were created to represent delamination, delamination with CLJ rupture, and a full-thickness defect. For each case, a labral tear and labral repair were simulated. The size and location of damage was assigned based on reported clinical prevalence [1].

RESULTS

The cam FAI hip experienced higher magnitudes of all variables compared to the normal hip, and the location of all maximum dependent variables shifted anterosuperiorly. (Fig 1B-D).

Compared to the intact FAI case, the damage cases experienced a more even stress distribution, with 8-10% increases in contact area during heel-strike (Figure 1E). Contact stress during heel-strike for the intact FAI case was concentrated at the CLJ and experienced a peak of 12.3 MPa. The contact stress shifted posteroinferior and, contrary to our expectations, decreased substantially for all damage cases with a peak ranging from 7.5-8.0 MPa, also during heel-strike (Figure 1F, left). Tensile strain and shear stress followed similar trends to contact stress in both location and magnitude, and all damage scenarios followed the same trend; thus, the delamination case was used as a representative

scenario in Figure 1F. Labral repair only marginally affected the cartilage, but subtle increases in contact stress were observed near the CLJ and on the labrum (Figure 1F, right).

DISCUSSION

Our results suggest that patients with cam FAI morphology may be susceptible to chondrolabral damage due to concentrated stress and strain conditions in the anterosuperior region. Shear stress had the largest difference in peak variables between cases, while contact stress and tensile strain also increased for the FAI hip. Shear stress has been implicated as the cause of delamination, which is commonly observed in the anterosuperior location on the CLJ – coincident with the location of peak shear stress predicted in our study. Notably, this result was found without contact or direct impingement between the cam bump and acetabular rim. This finding suggests that, for some patients, chondrolabral damage in the FAI hip could occur due to morphologic femoral and acetabular differences in the central compartment regardless of whether osseous impingement occurs.

Contrary to our hypothesis that varied degrees of chondrolabral damage would result in elevated stress and strain around the damage region, all simulated damage conditions redistributed the load more evenly across the joint compared to intact cartilage in the FAI hip. The redistribution of load seen in damage cases, which increased contact area and decreased contact stress, shifted pressure away from the damage zone. The high shear stress in the intact joint suggest that it is predisposed to damage, but the damage cases relieve that disposition. Regardless of the damage condition, the distribution of contact area during heel-strike also decreased peak strain and shear stresses in the cartilage and labrum. All damage cases experienced concentrations of tensile strain and shear stress around the damage location, but the magnitude may not be high enough to progress damage alone. Larger damage size or other activities may also cause further instability around the damage zone, leading to higher strain conditions. It is also worth noting that the shift in peak stress may cause additional damage in the posteroinferior location. Posteroinferior injuries secondary to anterosuperior damage are reported for patients with femoroacetabular syndrome and were first described by Beck et al in 2005 [4].

Labral repair with delamination shifted peak concentrations of tensile strain from the damage zone border to the CLJ. The repair may cause increased risk for further damage at this location, such as progression to rupture of the CLJ. Additionally, the repaired labrum may be more strained by the repair and cause subsequent labral damage.

It is worth noting that even though we used representative cam FAI patients based on radiographic measurements and average damage data to capture general differences in the groups, further studies including more patients would add confidence to our results. While the patients that we included in this study had similar acetabular morphology and are not dysplastic, differences in acetabular morphology may affect results. Specifically, damage to and around the labrum may have a significantly different effect in borderline dysplastic patients with FAI.

INTRODUCTION

Osteoarthritis of the acromioclavicular (AC) joint has been said to be a common source of shoulder pain, and is said to be the most common source in patients over the age of 50, with over 50% of the patients showing radiographic signs of degenerative arthritis [1,2]. The pain associated with AC osteoarthritis is thought to be caused by irritation of the subacromial bursa when the AC joint becomes inflamed or had protruding osteophytes and the cross body adduction (CBA) test is a current clinical diagnosis of this pathology [3]. However, recently, another test has been proposed—the Reverse Shoulder Internal Rotation test—that involves placing the hand behind the back, abbreviated HBB for short.

In a clinical setting, it was observed that some patients test negative under the CBA test and positive under the HBB test. These patients were later found to have osteoarthritis of the AC joint through imaging or arthroscopic means. The purpose of this study is to investigate the biomechanics of these two positions in order to determine if the HBB test is a better one.

METHODS

The Zygote Solid 3D Male Homan Anatomy model by ZYGOTE (American Fork, UT) was used to construct a 3D CAD model of an adult 50th percentile male shoulder and chest cavity [4]. This model was created as a SolidWorks file, Dassault Systèmes (Vélizy-Villacoublay, France) [5]. This model was then imported into MSC.ADAMS, Adam View 2017 by MSC Software (Newport Beach, CA) in order to model and study the dynamics of the shoulder in three specified positions – standard anatomical, CBA, and HBB [6]. The model includes the clavicle, scapula, humerus, and the rib cage. The radius and ulna were combined as a single rigid body. Similarly, the 27 bones of the hand were considered as one segment.

Three revolute joints were used to model the glenohumeral joint allowing rotations around three different axes. A spherical joint was used to model the elbow joint. In order to move from one position to another, these six rotations were identified.

Nine springs were used to model five ligaments, with stiffness identified from the literature [7]. Three muscle forces were introduced into the model for the CBA position and two for the HBB position. In order to account for the complexity of the contact constraints of the scapulothoracic contact, normal to the tangent springs were introduced in order to allow scapular motion along the curvature of the thorax.

The shortest distance between the distal clavicle and the acromion process of the scapula was calculated as an indicator of the intensity of the stress at the articulating surfaces, which would indicate the presence of osteoarthritis at the AC joint.

RESULTS

Table 1 shows the seven rotations at the glenohumeral, elbow, and wrist joints that were used to position the skeleton in the CBA position, and the six rotations that were used at the same joints to position the skeleton into the HBB position; both moving from the anatomical position. Figure 1 depicts the skeleton at both final resting positions.

Table 1: Rotations used to position the skeleton in both the CBA and HBB positions

	CBA			HBB		
Step	Angle	Joint	Rotation	Angle	Joint	Rotation
1	90°	GH	Internal Humeral	90°	GH	Internal Humeral
2	100°	GH	Flexion	45°	GH	Extension
3	65°	Wrist	Pronation	20°	GH	Adduction
4	24°	GH	Adduction	40°	Elbow	Pronation
5	90°	Elbow	Flexion	90°	Wrist	Pronation
6	18°	Elbow	Superior	120°	Elbow	Flexion
7	15°	Wrist	Radial Deviation	-	-	-

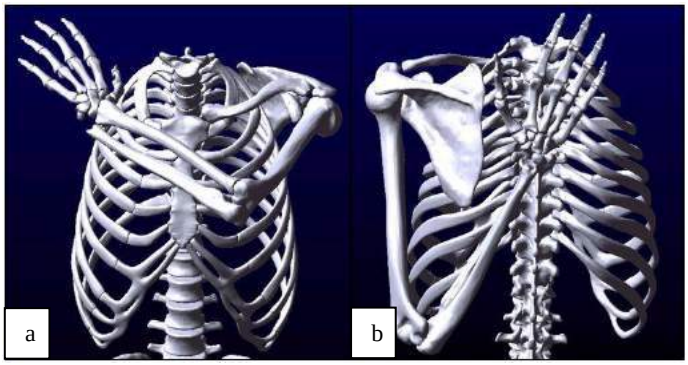

Figure 1: Final resting positions of the (a) Cross Body Adduction (anterior view) and (b) Hand Behind the Back (posterior view) tests.

The shortest distances between the distal clavicle and acromion process of the scapula for these two positions were obtained interactively using MSC.ADAMS and are listed in Table 2. This table also includes the shortest distance in the anatomical position obtained from the literature [8] as well as using MSC.ADAMS and using SolidWorks.

Table 2: Minimum distances between the distal clavicle and acromion process of the scapula.

Source	Distance (mm)
Literature [8]	3.31
Anatomical (SW)	3.14
Anatomical (ADAMS)	3.16
CBA (ADAMS)	2.86
HBB (ADAMS)	1.51

DISCUSSION

Table 2 shows that the acromion process of the scapula moves to different locations relative to the clavicle. With CBA decreasing the distance between the distal clavicle and the acromion process by 0.30 mm there is an indication that the stress level at the joint increases, thus causing irritation of the subacromial bursa. It is then understandable that this is the current method of clinically diagnosing osteoarthritis of the AC joint.

Additionally, Table 2 shows that the spacing at the AC joint is decreased by 1.65 mm from the standard anatomical position in the HBB position, indicating that this is also a valid test for osteoarthritis of the AC joint. Due to the over 5x greater reduction in space, the HBB position may be argued that it is a better test to diagnose earlier stages of osteoarthritis at the AC joint because of the higher degree of irritation that it places upon the subacromial bursa.

In order to validate this anatomical model, the creations of both a kinematic model and a Finite Element Method (FEM) model are needed to complete the three model validation trifecta. The kinematic model would focus upon the placement of the end-effector—the patient's palm—and define the mathematical models that describe the arm's motion regardless of forces or torques—i.e. the muscles and ligaments [9]. Whereas the FEM model would build upon this anatomical model through quantifying the stress at the articulating surfaces as well as the stresses placed upon the ligaments and muscles to ensure that these values stay within their specified reasonable ranges.

INTRODUCTION

The use of manual micropipettes has been associated with a high prevalence of upper extremity and work-related musculoskeletal disorders in laboratory workers [1]. This may be due to a combination of repetitive motions during pipetting and the amplification of forces from the thumb tip to the basilar thumb joint [2] that lead to tendonitis, carpal tunnel syndrome, other musculoskeletal injuries, and may increase risk of osteoarthritis (OA). These pathologies cause substantial physical pain/discomfort, increase health care costs, and cause employees to miss time at work. An investigation into ergonomic pipette design could help to reduce these musculoskeletal pathologies and their consequent negative impacts.

Several methods could be used to investigate the effects of pipetting on the joints in the thumb. These include using a thin-film force sensor underneath the thumb and a kinematic analysis of the motion of the thumb's joints, used in conjunction with computational hand models to predict muscle forces, and tendon displacement [2-4]. While these may be useful in for comparison of movement and muscle forces, this approach requires numerous boundary condition assumptions and assumptions that allow estimation of muscle activation or force distributions. Also, these methods cannot capture nuances of how design features (such as texture) may affect muscle coordination and forces. One method to investigate the effects of pipette design on stresses within joints is through MRI-based modeling. This offers a non-invasive *in vivo* approach to estimate forces, contact pressures, contact area and location(s), and tissue stresses in joints during functional activities. Additionally, MRI-based modeling allows for the use of subject-specific geometries in place of generic geometries and minimizes assumptions for model boundary and loading conditions. This is accomplished through the collection of lower resolution loaded scans (i.e. during simulated pipetting) and higher resolution unloaded scans (i.e. with a relaxed hand) for finite element model building, and image registration to obtain displacement boundary conditions [5-6]. The creation of a MRI-compatible pipette simulator would enable MRI-based modeling of the basilar thumb joint to investigate the effects of different design features on joint forces, contact pressures, and contact area/location(s) within this highly susceptible joint.

OVERALL SYSTEM DESIGN

MRI-compatibility, modularity, and the reproducibility of experimental conditions were primary objectives for the design of the pipette simulator. Ferromagnetic substances could not be included due to safety concerns, and other metals were excluded to avoid image distortion. Therefore, plastic materials were most appropriate, and additive manufacturing allowed straightforward fabrication of the parts (and multiple versions to be tested). Modularity was required so that various different design features could be easily interchanged for testing.

Figure 1. Disassembled pipette simulator

Reproducibility of experimental conditions requires high sensitivity for the sensor and low friction (resistance) in moving parts, so we can assure that the research participants are applying a consistent force.

To achieve modularity, the pipette simulator was divided into multiple parts: a button to be pushed by the thumb, a carbon fiber plunger/rod to transfer force through a handle, an o-ring on the far end of the rod (to prevent the rod and button from falling out of the handle), a two-piece spherical base, and a pneumatic rubber bulb inside the base (Figures 1 & 2). The two parts of the spherical base can be fastened together using plastic nuts and bolts. Each handle set (with button and push-rod) can be screwed onto the spherical base (with rubber bulb).

Figure 2. Fully assembled pipette simulator

The rubber bulb was attached via plastic connectors and tubing to a pneumatic pressure system with pressure regulator to assure consistent pre-pressure (before the pipette plunger is pushed) and a precision pressure transducer. This system provided consistent resistance to plunger depression with minimal friction and a precision of 0.001 psi. Early experiments with plastic and glass syringe designs had substantial friction which increased the force to move the piston from a static position and decreased force to hold the syringe pressure at a fixed level. This behavior was apparent even with lubricants. Other earlier designs experimented with plastic springs within the handle, but these could not provide accurate feedback on the force applied. The aforementioned pressure transducer provides data to the investigators and to the research subject. A custom LabVIEW code provides visual feedback to the subject and allows them to attain and hold the pressure near a specified target during the MRI scan (Figure 3). This also helps assure experimental conditions are consistent across subjects. In addition, subjects wore an MRI-compatible wrist brace with 20º wrist extension, to assure consistent hand/wrist position (and thus more consistent data overall) between subjects.

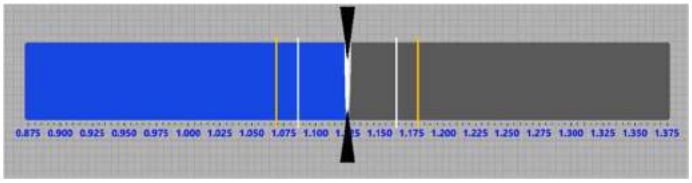

Figure 3. LabVIEW screen visible to the subject during testing.

PIPETTE FEATURES TO EVALUATE

Using 3-D printing, any number of shape parameters and features of the simulated micropipette handle can be easily created and evaluated. Early experiments will examine overall micropipette size (diameter) and the effect of a finger hook/stop on the basilar thumb joint forces required to perform the simulated pipetting task. Future studies could consider additional features, such as cross-sectional shape, stroke length for the plunger, and even texture of the micropipette surface, to determine how these features affect the force and contact mechanics in the basilar thumb joint.

DISCUSSION

The proposed pipette system has been fabricated, tested, and used in a preliminary human subjects study (Figure 4). The system performed consistently through the tests. Changing the handle/features between scans was quick and simple. It is our hope that these studies will identify key design features that can be optimized to reduce risk of overuse injuries and/or osteoarthritis.

FATIGUE LOADING OF MOUSE ACHILLES TENDON EXPLANTS DOES NOT INDUCE COLLAGEN DENATURATION

Krishna Pedaprolu (1), Spencer E. Szczesny (1,2)

Hershey, Pennsylvania, USA

INTRODUCTION

Tendon overuse (i.e., fatigue loading) is a common cause of injury[1] that results from progressive accumulation of structural tissue damage[2-4] and a reduction in mechanical properties.[2] In order to prevent injury and restore proper tendon function, it is necessary to understand the specific damage mechanisms that are generated by tendon fatigue loading. At a microscopic level, collagen fiber disorganization, kinking, and delamination are seen with fatigue loading[2,5]. At the molecular level, studies show that fatigue induces collagen denaturation in various tendon types, including rat tail tendons[7] and flexor carpi ulnaris tendons.[7-8] Studies of bovine forelimb tendons demonstrate that extensor tendons also experience collagen denaturation during fatigue loading; however, flexor tendons do not, which suggests energy storing tendons are resistant to fatigue damage.[5] Still, it is unknown whether other energy storing tendons (e.g., Achilles tendon) also exhibit a resistance to molecular damage. Since mouse Achilles tendons show similar signs of degeneration with overuse compared to humans[9], the objective of this study was to investigate whether collagen denaturation occurs within mouse Achilles tendon explants during fatigue loading. This information will identify whether degeneration due to fatigue loading is due to tissue damage in the form of collagen denaturation.

METHODS

Mechanical testing:

Three Achilles tendons were extracted from euthanized C57BL/6 mice from an approved IACUC study. The cross-sectional areas of the tendons were determined by a non-contact laser transducer. Mechanical testing of the tendons was performed in culture medium (low glucose DMEM, 1% penicillin and streptomycin, 200 mM Glutamax, 25 mM HEPES, 1 mM magnesium ascorbyl phosphate) at 30°C using a custom bioreactor. The bioreactor applied a cyclical load of 2 MPa (16.8% of the ultimate tensile strength) at 0.5 Hz by offloading hanging weights attached to each sample via a motorized table (**Fig.1**). The samples were loaded until failure.

As a positive control for collagen denaturation, three flexor carpi ulnaris (FCU) tendons were extracted from freshly frozen Long Evans rats from another approved IACUC study. Similar to mouse Achilles tendons, FCUs were cyclically loaded to 20% of the ultimate tensile strength (9 MPa) at 1 Hz either until failure or 158,430 cycles at room temperature in PBS. One of the fatigued FCU samples did not fail after 158,430 cycles. Finally, one mouse Achilles and one rat FCU was gripped in the bioreactor and was statically loaded at a minimal stress value (~0.06 MPa) to act as negative controls.

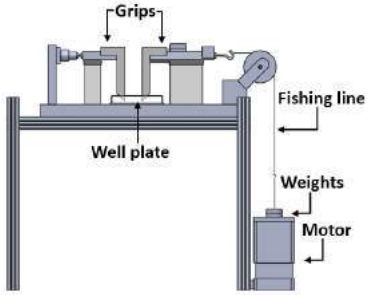

Fig.1. Schematic of the bioreactor design: The bioreactor applies cyclic load to gripped tendon explants by offloading weights from a motorized table

Imaging:

Static controls and fatigue-loaded samples were cryosectioned at a thickness of 20 μm. The sections were stained with fluorescein tagged collagen hybridizing peptide (CHP) at a concentration of 10 μM

overnight at 4°C (3Helix Inc). CHP is a probe that specifically binds to denatured collagen.[10] The sections were washed three times for 10 minutes each with distilled water. Background signal from fatigue loaded samples was removed by using the fluorescence levels of corresponding static samples as a threshold. Percentage area of collagen denaturation was calculated as a ratio of the area of positive signal in to the total area of the tendon section.

Statistical analysis:
A t-test with Welch's correction was used to compare percent area of collagen denaturation between rat FCU and mouse Achilles sections.

RESULTS

Rat FCUs showed significant CHP staining above the threshold intensity value determined from its static control. However, mouse Achilles tendons exhibited minimal CHP staining. The percentage area of collagen denaturation was statistically different between the two tendons. (**Fig. 2**) (p=0.05)

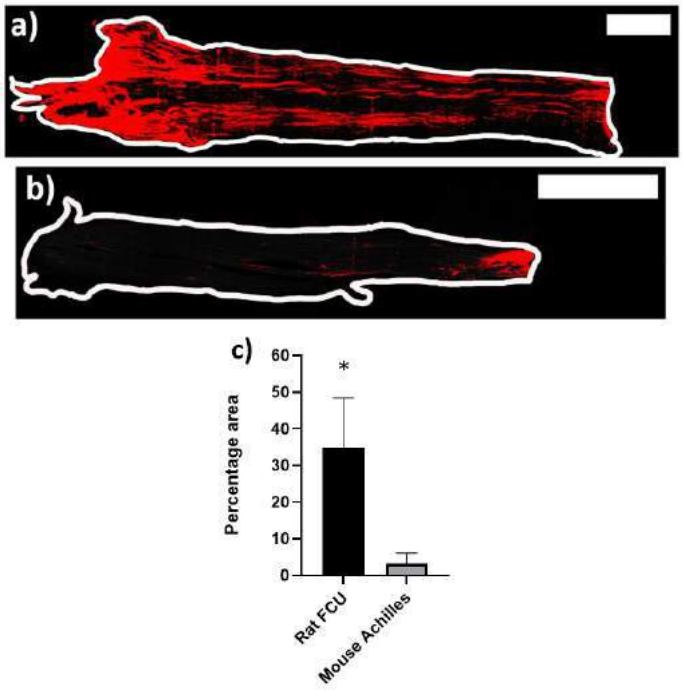

Figure 2 Collagen denaturation via CHP staining. Representative images of thresholded fatigue ruptured (a) rat FCU and (b) mouse Achilles tendons. (c) The percentage of collagen denaturation is higher in rat FCU than mouse Achilles tendons (* p=0.05). Scale bar: 1 mm.

DISCUSSION

We demonstrated that under a similar magnitude of fatigue loading (approximately 20% of the ultimate tensile strength), rat FCUs exhibited significant collagen denaturation in the form of CHP staining, but mouse Achilles tendons show minimal staining. This is in agreement with previous studies demonstrating that energy storing bovine superficial digital flexor tendons (SDFT) do not undergo collagen denaturation when they are cyclically loaded[5] and individual fibrils of such tendons do not show CHP staining when subjected to tensile rupture[11]. While collagen molecules do denature in response to fatigue loading of other flexor tendons, including the FCU in this study and the flexor digitorum longus[6], this may be because these flexor tendons serve different functions than the Achilles tendon and SDFT. Still, our findings confirm that not all tendons, even the same type, will undergo damage the same way. Additionally, our findings suggest that degenerative changes observed with overuse[9] are potentially not due to tissue damage in the form of collagen denaturation.

A limitation to this study is that an explant model does not perfectly replicate in vivo overuse. While a maximums stress of 2 MPa at roughly 20% of the tendon ultimate tensile strength is representative of physiologic loading[12], it is possible that the true in vivo stresses are higher. Additionally, preliminary data show that this level of loading maintained cellular viability, suggesting that tendon cells tolerated the cyclic loading. Future studies will investigate the effect of higher loads on collagen denaturation. Since Achilles tendons are one of the most physiologically relevant tissues to study, these results will help researchers choose an appropriate model to study tendinopathy and determine if degenerative catabolic cellular changes seen in tendinopathic tissues can happen independent of collagen denaturation.

INTRODUCTION

Macroscale and microscale injury regularly occur in the human knee joint resulting from complex and/or compound motions such as flexion, extension, and rotation, particularly under impact [1]. We previously demonstrated that low-energy mechanical impacts to articular cartilage, usually considered non-injurious, can in fact cause microscale cracks in the collagen network of visually pristine human cartilage [2]. Therein we defined collagen-network microcracks as fractures in the collagen network that are no wider than the diameter of chondrocyte lacunae (<30 μm). Such seemingly minute mechanical trauma may disrupt the microstructure of the extracellular matrix (ECM), altering the critical load-bearing capabilities and fluid retention properties of cartilage. We then quantified the extent to which microcracks initiate and propagate in collagen networks of cartilage during mechanical loading representative of normal activities [3].

Overall we aim to establish therapeutics to slow, stop, or even heal microcrack growth during cyclic loading, and thus minimize the possibility of subsequent cartilage and joint pathologies. Crosslinking of collagen can improve the mechanical stiffness of (especially monomeric) networks through several mechanisms, cf. [4]. Genipin is a well-established cross-linker for proteins and studies confirm that it can improve the mechanical strength of collagen networks [5]. While genipin cannot repair large (mm-scale) fissures [6], its ability to repair micron-scale fissures in collagen remains unknown. In this study we aimed to determine the effects of genipin as a preventative treatment: (1) to mitigate the initiation of microcracks under mechanical impacts; and (2) to mitigate the propagation of microcracks under cyclic compression (and specifically the effects of number and timing of genipin treatments). We hypothesized that treatments with genipin will interrupt initiation and progression of damage in the networks of collagen in cartilage, and thus potentially lead to new treatments.

METHODS

Mechanical Tests and Images via SHG. In total we tested 49 full-thickness, cylindrical osteochondral plugs (specimens) of 3 mm diameter. We pooled specimens from the lateral and medial femoral condyles, and assigned them to one of four different genipin treatment (dosing) groups, which included two time points: (A) before low-energy impact (2.5 mJ/mm^3) and (B) before unconfined cyclic compressions (10% of reference thickness at 1.44 Hz for 12,000 cycles), of either 0 mM (denoted –) or 11 mM (+) of genipin. Our control group (n=10) underwent the same mechanical treatments but no treatment with genipin (and subsequent crosslinking) [3]. We impacted all specimens with the same impact energy density and imaged them via Second Harmonic Generation (SHG) (Zeiss LSM 510, Oberkochen, DE) in Phosphate Buffered Saline (pH 7.4) at three time points, see **Fig. 1**.

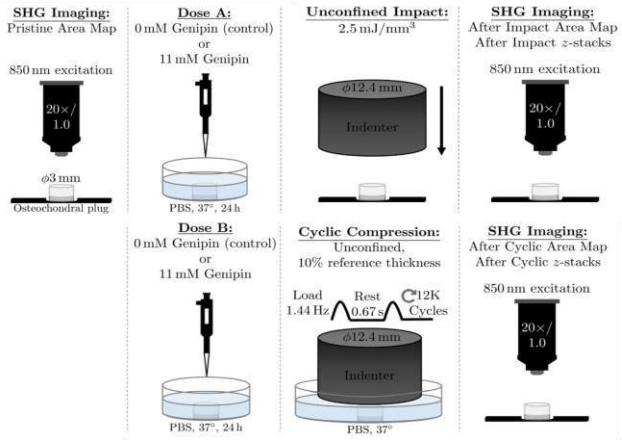

Figure 1: Schematic summary of our experimental protocol.

Analyses of Images. We used Fiji's Grid/Collection stitching plugin to generate images of the full circular cross section at a resolution of 1.2 μm/pixel. Using only the 3 × 3 tile grid centered on the main axis of the cylinder (to avoid edge effects), independent observers measured the length, width, depth, and principal angle (relative to the split-line direction) of each microcrack, cf. [3]. We calculated the length, width, depth, and orientation of all microcracks from both post-impact (PI) and post-cyclic (PC) compression phases of the mechanical experiment, and when possible, used the specific morphologies and orientations to track microcracks between the last two phases.

Statistical Analyses. We used separate mixed regression modeling to evaluate the effects of genipin treatment on microcrack density, and on the length, width, and depth of the microcracks over the course of the experiment. We included genipin treatment (dose) as a fixed effect and the thickness of each cartilage specimen as a covariate. We used post-hoc tests to evaluate differences among treatment combinations. To probe microcrack propagation, we analyzed our data from the tracked microcracks over the course of the experiment using the same mixed-model regressions, but with specimen included as an additional random factor. We completed all statistical analyses using SAS 9.4 (SAS Institute, Inc., Cary, NC) with a significance level $P < 0.05$.

RESULTS

We confirmed that our protocol successfully cross-linked the network of collagen. After 24 hours of incubation, the cartilage transformed from its normal white and glossy state to a dark color produced as genipin reacts with the amino groups. We imaged both treated and untreated specimens via Raman Spectroscopy and confirmed a characteristic fluorescence at 785 nm in only the treated specimens, thus confirming microstructural changes.

Genipin did not have a significant effect on the density and width of microcracks initiated under low-energy impacts, see **Figs. 2(a), (c)**. We did find statistically significant differences in the lengths and depths of microcracks initiated under low-energy impacts, see **Figs. 2(b), (d)**. Microcracks initiated in specimens treated with genipin tended to be longer and penetrate deeper into the cartilage specimens.

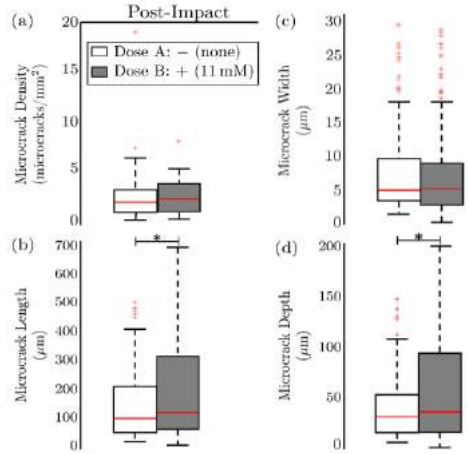

Figure 2: Microcrack Initiation under low-energy impact, untreated (white) vs. treated (gray) specimens. Box plots of the median (red lines) and interquartile ranges (black lines): (a) density, (b) length, (c) width, and (d) depth of microcracks.

Genipin had a significant effect on some aspects of microcrack propagation under cyclic, unconfined compression, see **Fig. 3**. Two treatments of genipin caused significantly greater propagation of microcracks (both longer and wider) than a single treatment of genipin, see **Figs. 3(a), (b)**. A single treatment of genipin did not have a statistically significant effect, but consistently resulted in marginally less propagation. Treatment with genipin had no effect on the depth of microcracks during cyclic, unconfined compression.

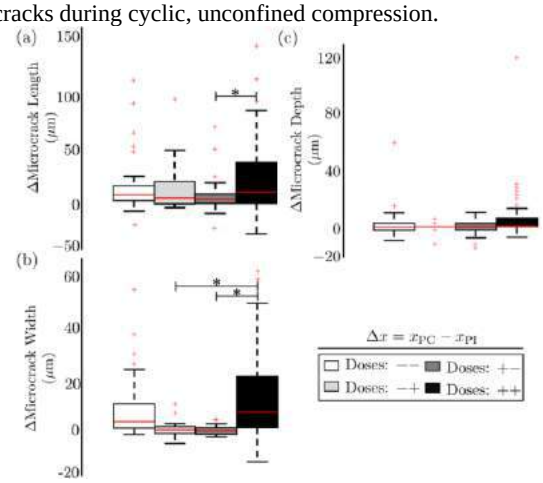

Figure 3: Microcrack Propagation post-impact to post-cyclic, unconfined compression, comparison of untreated (white), and treated (before impact = light gray, before cyclic compression = medium gray, before both = dark gray) specimens. Box plots of the median (red lines) and interquartile ranges (black lines): (a) length, (b) width, and (d) depth of microcracks.

DISCUSSION

In this study, we induced microscale damage to the network of collagen (i.e. collagen network microcracks) using low-energy impacts to cylindrical specimens of cartilage, and propagated these microcracks in unconfined, cyclic compression. The initiation and propagation of microcracks may deteriorate the mechanical function of cartilage and characterize pathogenesis of osteoarthritis, and may suggest therapeutic targets for future studies [3].

Our results do not support our hypothesis that treatments with genipin will improve the damage resistance of cartilage. In the dosing scheme that we tested genipin was not an effective treatment for preventing or repairing damage to the network of collagen in cartilage. Studies show that genipin can enhance the mechanical properties of collagen networks, particularly in engineering constructs. Specifically, genipin treatments to cartilage significantly increased stiffness in specimens treated with 10 mM for 24 hours [5]. In our study, the increased stiffness likely caused a reduction in ductility, which caused the cartilage to be less resistant to damage under impacts. Since crosslinking with genipin did not prevent microcrack initiation, the additional cross-links among collagen fibrils created by treatment with genipin were insufficient to prevent rupture of fibrils. Adding a second treatment of genipin further exacerbated the damage, suggesting that the stiffness may have further increased following the second treatment. While increased stiffness may be desirable in some engineering applications, it may be accompanied by reduced material toughness.

INTRODUCTION

Breast cancer-related lymphedema (BCRL) is a chronic and debilitating condition, characterized by an incurable swelling of the arm. Over 70% of patients have surgery during breast cancer treatment, which typically involves removal of at least one lymph node (LN) from the axilla. The removal of LNs disrupts drainage of lymph from the arm, which can lead to permanent swelling. The current standard of care is a management strategy at best, consisting of complete decongestive therapy. While such therapy may help prevent worsening of symptoms, it is only useful in some patients. Autologous lymph node transfer (ALNT) transplants lymph nodes from the groin to the axilla to assist in lymph flow restoration; however, such a specialized procedure is time-consuming and expensive. Improved treatments are necessary to reestablish lymph flow in the affected arm.

We have developed a novel lymph node prosthetic, Faciliflow, that is implanted at the time of breast cancer surgery to prevent the onset of edema. Faciliflow combines physiologically inspired fluid mechanical characteristics in conjunction with a localized release of Vascular Endothelial Growth Factor-C (VEGFC) to encourage lymphatic vessel regrowth. Afferent lymphatic vessels often divide into multiple parallel vessels as they approach the lymph node to decrease the downstream flow resistance to each contracting lymphatic vessel. Similarly, Faciliflow has multiple parallel channels, which encourages both continued interstitial flow and lymphatic vessel regrowth through the implant.

The aim of this study was to demonstrate that Faciliflow enables lymphatic vessel regeneration and reconnection after LN excision.

METHOD

Faciliflow was implanted in rats (n=20), following a modified methodology of Schindewolffs et al. [1], where ALNT is substituted with Faciliflow implantation. This initial Faciliflow design consisted of three parallel channels (Fig. 1A), fabricated through injection molding of medical grade polyurethane (Polymermedics Ltd., St. Astell, United Kingdom). The LNs of one limb of the rat were removed prior to device implantation. At the time of implantation, 6.67μg of exogenous VEGFC was injected intradermally. Vessel reconnections were verified using fluorescent imaging (indocyanine green, or ICG) after 28 days, 2 months, and 4 months. Histology of the implant and surrounding vessels was conducted after sacrifice at 4 months.

Following the *in vivo* investigation in rats, the Faciliflow implant was redesigned to improve ease of use during surgery and to optimize VEGFC release kinetics. Computational fluid dynamics (CFD) modelling (COMSOL Multiphysics 5.3, Burlington, USA) was used to assess Faciliflow 2.0 and investigate the release kinetics of VEGFC over 90 days. The VEGFC release profile was verified experimentally using ELISA to quantify the VEGFC concentration at discrete time intervals.

RESULTS

Successful reconnection of the lymphatic vessels was observed by ICG in 6 of 11 rats in which the correct orientation of the implant was maintained (Fig. 1B). This means that the implant channels remained in the same direction as the afferent and efferent vessels of the excised nodes. This success rate is comparable to that reported by Schindewolffs et al. [1] where rats were treated with ALNT and 6.67μg of VEGFC (55% vs. 53%). The rats implanted with Faciliflow device had a significantly higher success rate than those rats treated with ALNT and a saline-only injection (p=0.01, Fisher's exact test) [1]. The implants in 8 additional rats did not maintain their correct orientation after implantation, with vessel reconnection observed in only one animal. This observation emphasizes that successful vessel reconnection is more easily achieved when the correct channel orientation is

maintained. Histological examination of the tissue after animal sacrifice confirmed the presence of lymphatic vessels, with positive staining of LYVE-1 close to the implant surface (Fig. 1C). One rat died before study completion.

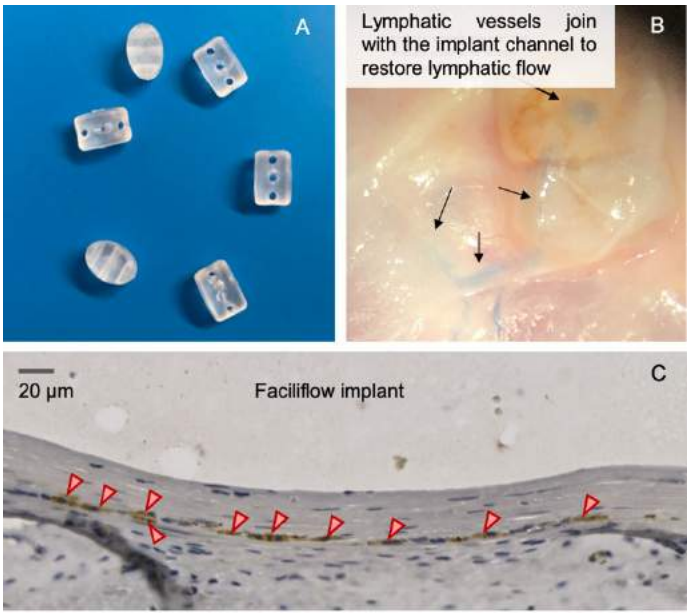

Figure 1: (A) The three-channel design of Faciliflow 1.0 implanted in rats; (B) Successful re-anastomosis of the lymphatic vessels to the implant by ICG in a rat; (C) Histological image indicating positive staining for LYVE-1, confirming presence of lymphatic vessels close to implant surface (indicated by the red arrows).

To prevent Faciliflow from moving after implantation, and thus losing its correct channel orientation, suture tabs were incorporated in the second design iteration of the device, Faciliflow 2.0. This will provide increased device stability and prevent the device from rotating or tilting. In addition, the number of parallel channels was increased to 6, allowing for additional hydrogel volume to be injected and a higher overall VEGFC concentration. CFD modelling indicated a VEGFC release profile of 0.6ng/day per mg of microspheres resulted in a growth factor concentration just below the target therapeutic threshold of 100ng/ml [2]. A rapid initial increase in VEGFC concentration was observed, peaking at approximately 100ng/ml on day 5.5 (Fig. 2). This was followed by a decrease in peak VEGFC concentration of approximately 50% (Fig. 2), which was sustained for the remaining duration of the 90-day simulation period. Experiments are ongoing to verify the VEGFC concentration profile using ELISA.

DISCUSSION

The preliminary *in vivo* investigation in rats demonstrated the efficacy of the Faciliflow implant, with a similar success rate to rats treated with an ALNT and bolus VEGFC injection. However, when the implant did not maintain its correct orientation, lymphatic vessel reconnection was limited to only 1 of 8 rats. This finding confirmed the importance of channel orientation to direct interstitial flow within the channels of the device. It was found by Goldman et al. [3] that VEGFC is more effective in the presence of interstitial flow. Increased lymphatic vessel growth was observed in a mouse tail model with interstitial flow than versus mice with reduced or inhibited flow, after a 4µg dosage of exogenous VEGFC. Therefore, maintaining correct channel orientation in the implant is critical to ensure the therapeutic efficacy of the eluted VEGFC. As a result of these findings and in consultation with clinicians, suture tabs have been added on the lateral sides at the base of the implant, minimizing potential flow disturbances in the vicinity of the channels. The suture tabs provide increased stability and robustness when anchoring the implant.

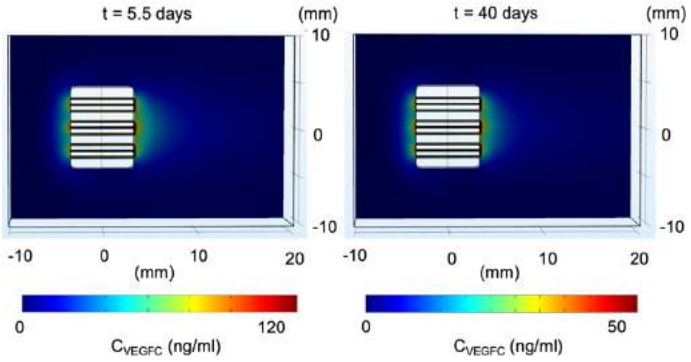

Figure 2: VEGFC concentration at 5.5 days and 40 days after simulated implantation.

The combination of *in silico* modelling and *in vitro* testing allows for a robust evaluation of Faciliflow 2.0 without an immediate need of additional *in vivo* trials. In order to optimize the release of VEGFC from the implant, a dual-release supply of VEGFC is proposed, where the channels of the implant are filled with a type I collagen hydrogel. For short-term release of the lymphatic growth factor, VEGFC is directly incorporated in the hydrogel, with VEGFC-encapsulated PLGA microspheres in the hydrogel for long-term elution. This will allow a therapeutic concentration of growth factor for up to four months. Work is ongoing to quantify the VEGFC concentration over time released from the device, with both free VEGFC and VEGFC encapsulated microspheres, by ELISA.

Secondary lymphedema, surgically induced at the time of breast cancer treatment, is a debilitating condition leaving affected patients with painful arm swelling, chronic infections, and limited treatment options. Faciliflow has the potential to eliminate the risk of BCRL at the time of surgery and improve patient livelihood post-cancer diagnosis.

INTRODUCTION

Glaucoma is an optic neuropathy and the leading cause of irreversible blindness worldwide. The biomechanics of the optic nerve head (ONH) are a key aspect of the pathogenesis of glaucomatous optic neuropathy [1]; however, there is limited information about the mechanical behavior of the ONH tissue.

Due to their high water-content and biopolymeric structure, many soft tissues behave differently under static vs. dynamic loading (i.e., viscoelasticity). We hypothesized that the ONH also shows viscoelastic behavior, which can be described using mixture theory. A previous study from our lab showed a dependence on loading-rate in the biomechanical response of porcine and murine ONHs [2]; however, no studies report the ONH's viscoelastic properties and underlying structural mechanisms per se. Therefore, our objective was to assess the viscoelastic mechanical properties of the porcine ONH using ex vivo micromechanical testing coupled with biphasic mixture modeling.

METHODS

Animal tissue samples: Eyes were harvested from freshly sacrificed mature female pigs (c. 5 months old). The ONH was dissected from the eye globe within a few hours to 24 hours postmortem (Fig. 1A & B), and from each ONH four samples were isolated using a 1 mm surgical biopsy punch (Fig. 1C). The diameter of each sample (n=13) was then measured using brightfield microscopy (diameter = 1.101 ± 0.043 mm; Fig 1D) followed by mechanical testing (Fig 1E; see below). During all steps of the experiment, hydration was maintained by immersion in phosphate buffered saline (PBS).

Micromechanical testing: We tested the ONH samples using a micromechanical testing device (Microtester; CellScale, ON, Canada), in a 37 °C PBS bath. Samples were subjected to an incremental creep protocol in unconfined compression. They were preconditioned by loading to 200 μN (tare-load) over 60 sec, immediately unloaded to zero force at the same rate, and then loaded to tare-load once more and kept at that force level for 1 minute. The reference height ($h_0 = 0.555 \pm 0.152$ mm) of the tissue was calculated by averaging the distance between the compression plates from the final 20 sec of the last hold at tare-load (Fig.1 E). The incremental creep protocol was imposed as four cycles of loading to 524, 1047, 1470, and 2094 μN, which approximately corresponds to physiological IOPs of 5, 10, 15, and 20 mmHg. At each force level the sample was held for 5 min, and following the fourth creep cycle, the sample was unloaded to the tare-load level over 4 minute and held there for 1 minute.

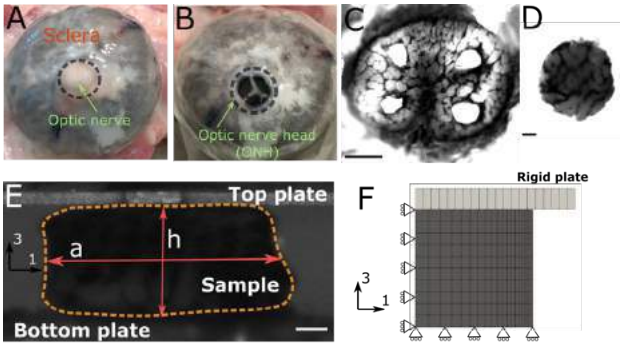

Fig. 1: The experimental procedure used in this study; (A) posterior segment of the eyeball; (B) the optic nerve is removed flush to the scleral surface; from a tangential slice of each ONH (C; bar = 1mm) four samples (D; bar = 0.1mm) are punched out. The sample is tested using a micromechanical tester (E), and the height (h) and width (a) of the sample are measured throughout the test (bar = 0.1mm). (F) An axisymmetric finite element model is used to model the mechanical response of the ONH.

Image analysis and strain calculation: To calculate the axial and lateral strains of the tissue, we used image analysis. During the test, images of the sample were recorded using a CCD camera (Fig. 1E). The images were digitally segmented to obtain a binary mask of the sample, after which we calculated the height of the sample (h) as the distance between the two plates and the width (a) by dividing the area of the binary mask by h. The normal strain in both axial and lateral directions was calculated as $\epsilon_{axial}=h/h_0-1$, and $\epsilon_{lateral}=a/a_0-1$, where h_0 and a_0 were the reference height and width, respectively. We also calculated the apparent Poisson's ratio as $\nu_{app}=-\epsilon_{lateral}/\epsilon_{axial}$.

Finite element model: We used a finite element model with a homogenous constitutive material formulation to model the ONH's mechanical response. Based on the average diameter and height of the experiment samples, we generated an axisymmetric geometry in FEBio (v3.1, febio.org) with linear hexahedral elements (height = 0.55 mm, radius = 0.55, angle = 1°; Fig. 1E). To model compression of the sample with the rigid plate, we used a sliding elastic contact formulation [3]. The tissue was treated as a biphasic poroelastic (solid content 0.22[4]) material with compressible neo-Hookean matrix (matrix material parameters: Young's modulus = E_{NH}, Poisson's ratio = ν_{NH}, and isotropic reference hydraulic permeability = k).

Data fitting: To calculate the model parameters $\{E_{NH}, \nu_{NH}, k\}$, we used multi-start optimization (MSO) [5]. The cost function was designed to fit the axial and lateral strains simultaneously, as:

$$f = \sqrt{\sum_{i=1}^{N} \frac{\left(\epsilon^i_{axial} - \epsilon^i_{axial,0}\right)^2 + \left(\epsilon^i_{lateral} - \epsilon^i_{lateral,0}\right)^2}{2N}} \quad (1)$$

where $\epsilon_{axial.0}$ and $\epsilon_{lateral.0}$ are the experimental axial and lateral strains, respectively. The index i stands for the uniform resampling intervals, which split the time of the test into one hundred equal segments (i.e., N=100).

A constrained nonlinear least squares algorithm was used to perform the optimization (interior-point, *fmincon,* Matlab), where the bounds of the model parameter values were $\{E_{NH}, \nu_{NH}, k\}_{min}$={0.1 kPa, 0, 10^{-4} mm^4/(N.sec)} and $\{E_{NH}, \nu_{NH}, k\}_{max}$={100 kPa, 0.49, 1 mm^4/(N.sec)}. We conducted MSO with 100 random initial guesses, generated using Latin hypercube resampling. The criteria for accepting a fit was as the root mean square of errors (RMSE) of both ϵ_{axial} and $\epsilon_{lateral}$ fits to be less than their respective maximum experimental standard deviation.

RESULTS

The incremental creep protocol showed the expected increasing compressive axial strain as compressive force increased (Fig. 2A). A similar tensile behavior was observed in the lateral strain (Fig. 2A). The peak strain in the axial and lateral directions were -0.29 ± 0.18 (mean ± standard deviation), and 0.13 ± 0.12, respectively. This resulted in an average ν_{app} of 0.41 ± 0.14, which was approximately constant throughout the test (Fig. 2B).

The model successfully fit the experiments in both axial and lateral direction. Out of 100 initial guesses 94 resulted in fits that matched the fit criteria (see summary in Table 1). We used the median response to generate a summary of the fits (dashed lines, Fig.2 A & B). During the incremental creep cycles both the axial and lateral strains, as well as the apparent Poisson's ratio, closely matched between experiment and calculation; however, during the unloading phase (after minute 24) the fits were less accurate.

Table 1: Summary of the model parameter values for the fits.

	E_{NH}[kPa]	ν_{NH}	k [mm^4/(N.sec)]	k [m^4/(N.sec)]
Median	4.26	0.26	5.60×10^{-2}	5.60×10^{-14}
Min.	3.51	0.10	6.19×10^{-4}	6.19×10^{-16}
Max.	4.74	0.33	1.13×10^{-1}	1.13×10^{-13}

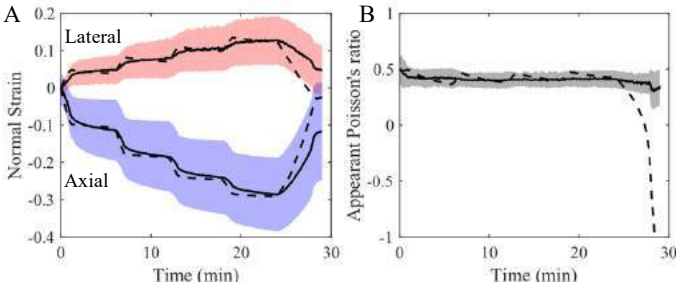

Fig. 2: (A) Axial and lateral strains vs. time, and (B) apparent Poisson's ratio vs. time. The solid line and shaded area show the experimentally determine mean ± 95% confidence intervals. Dashed lines are results of data fitting.

DISCUSSION

We successfully assessed the poroelastic mechanical properties of the porcine ONH using micromechanical testing and biphasic mixture modeling. Our results provide a Young's modulus of 4.26 [3.51, 4.74] kPa (median [min., max.]; Table 1), which closely matches a previous report on the porcine ONH Young's modulus (3.05 kPa [2]), and another study on the human lamina cribrosa (17.2 kPa [6]). Although previous studies assumed incompressibility ([2], [6]), we showed that the ONH is compressible, with a matrix Poisson's ratio ν_{NH} of 0.26 [0.10, 0.33], which was smaller than the apparent Poisson's ratio (Fig. 2B). This difference indicates the role of the fluid component of the ONH in its mechanical properties.

Notably, to the best of the authors' knowledge, for the first time we report the hydraulic permeability of the porcine ONH (k = 5.60×10^{-14} m^4/(N.sec)). A previous study from our lab reported the average k of porcine peripapillary sclera (ppSC), an anatomically adjacent tissue, as being in a similar range but somewhat smaller ($k = 0.86\times10^{-14}$ m^4/(N.sec) [7]). The same study also provided the compressive stiffness as 10 kPa, which is larger than the stiffness we found for the ONH. These differences are consistent with the higher fibrous collagen content of the ppSC compared to the ONH.

Our study was subject to some limitations. As simplifying and practical considerations, we treated the ONH as an isotropic material with non-spatially-varying permeability; however, addition of further modeling considerations, such as strain-dependent permeability, would improve the fidelity of the model. Further, we used an elastic contact to model compression by the rigid plate, which performed well during the loading phases of the mechanical test; however, it was not successful during unloading (Fig. 2), when it is possible that other forms of contact forces are at play, e.g., microscale local fluid pressurization.

In conclusion, this study provides a framework for explaining ONH mechanical behavior using biphasic mixture theory, and the material properties reported herein can be used as benchmarks for future studies aimed at understanding the pathogenesis and role of mechanobiology in glaucomatous optic neuropathy.

INTRODUCTION

In 2019, 1 in 10 babies born in the United States was born prematurely [1]. Preterm birth (PTB), which is delivery at a gestational age of fewer than 37 weeks, places infants at an increased risk of many short- and long-term health complications, such as breathing problems, gastrointestinal problems, and cerebral palsy [1,2]. There is currently no accurate method to predict PTB, and current PTB prevention strategies have had little impact on lowering PTB rates [3,4]. A significant barrier to improving PTB prediction and prevention is the pervasive lack of knowledge on normal function and evolution of the human uterus and cervix throughout gestation, making it difficult to demarcate cases that are not normal [3]. Compounding these obstacles is the challenge of conducting in vivo research on pregnant patients. Therefore, this research aims to build computational modeling tools to assess the biomechanical environment of pregnancy and its effect on birthing outcomes. In this work, we use patient-specific parametric computational models to investigate how maternal anatomy affects the uterus and cervix loading in term pregnancies.

The mechanics of pregnancy has been studied previously using computational models. For the most part, these models have used geometry derived from MRI and 3D ultrasound [5,6]. These high-fidelity models provide a wealth of information for a few patients, but since MRIs and 3D ultrasounds are costly to obtain and not commonplace in prenatal care, they are not a viable basis for capturing pregnancy anatomy on a larger scale. To overcome this issue, a method to build parameterized patient-specific models of pregnant anatomy from 2D ultrasound images, which are standard in obstetrics, has been developed and implemented into a longitudinal study of pregnant maternal anatomy [7,8]. This research aims to utilize the existing parametric modeling methods to investigate how maternal geometry impacts the distribution of load throughout gestation. Finite element analysis (FEA) is carried out for pregnant patients with a low-risk for PTB at four time points during pregnancy. The stretch and stress in the uterus and cervix are examined. The FEA results from these models will be used to establish normal patterns of stretch and stress in pregnancies at low-risk for PTB, and in future work will be compared to patients at high-risk for PTB.

METHODS

Trained sonographers took ultrasounds of healthy pregnant patients at four gestational ages (8-14, 14-16, 22-24, 32-34 weeks), and solid models of the uterus and cervix were built using the method described in Louwagie et al. [8]. In Solidworks (Dassault Systemes, Vélizy-Villacoublay, France), the solid modeling process was expanded to include the separation of the cervix from the uterus, and a fetal membrane and supporting abdomen were added. Quarter model geometries were used to decrease computational time, and the resultant solid meshed in Hypermesh (Altair Engineering Inc., Troy, MI). The fetal membrane was meshed with quadratic hexahedral elements, and the cervix, uterus, and abdomen were meshed with quadratic tetrahedral elements. FEBio Studio (v1.1.0) was used for FEA, and the meshed geometry was imported into it [9].

Within FEBio, the material properties, boundary conditions, and contacts were defined. The patients were assumed to have *normal* cervical stiffnesses at each gestational age, where cervical properties were determined using inverse FEA of *in-vivo* cervical aspiration data [10] assuming the cervix is a passive fiber composite material [11]. The uterine tissue was modeled as a passive fiber composite material based on tensile tests of pregnant uterine tissue [12]. The abdominal tissue was considered to be nearly incompressible neo-Hookean. The fetal membrane was modeled as a transversely isotropic fiber-based material with a compressible neo-Hookean ground substance based on existing

literature [13]. The boundary conditions applied were as follows: fetal membranes sliding on the uterine wall and cervix, the uterus tied to the abdomen, the cervix sliding along the abdomen and vaginal canal, and the entire model fixed along the outside surface. A gestational intrauterine pressure was applied to the inner membrane surface [14]. An example of the model setup is shown in figure 1. Patterns of stretch and stress in the uterus and cervix were analyzed, locations of maximum stretch and stress observed, and comparisons made between maternal geometry and FEA results.

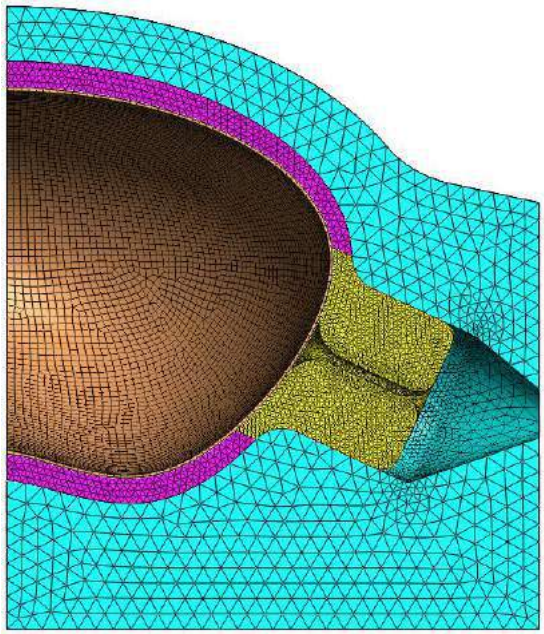

Figure 1: Example of meshed quarter model, including the fetal membrane, uterus, cervix, and supporting abdomen material. Viewed in the sagittal plane.

RESULTS

Model simulation is ongoing for this research. Therefore, we can make limited comparisons between different geometries. In work done thus far, several patterns regarding strain in the uterus and cervix have arisen. In the first trimester and early second trimester, the 1st principal Lagrange strain is most significant at the internal os (opening of the cervical canal into the uterus). Near the end of the second trimester and in the third trimester, the 1st principal Lagrange is similar in magnitude to the uterocervical junction and the internal os. However, the main direction of the 1st principal Lagrange strain changes as pregnancy progresses. In the first trimester, it is in the circumferential throughout the cervix. However, as pregnancy progresses, 1st principal strain is increasingly aligned radially from the internal os, especially near the uterocervical junction. This pattern suggests that, in term pregnancies, there is a progressive shift of loading that the uterus and cervix undergo, where pregnancy advancement brings about the cervix being stretch open and pushed out from the uterus. The 3rd principal Lagrange strain shows the greatest compression of tissue throughout the uterus and at the internal os. As pregnancy progresses, more compression is observed at the uterocervical junction. This pattern makes sense, as the thickness of the lower uterus segment decreases throughout pregnancy [8].

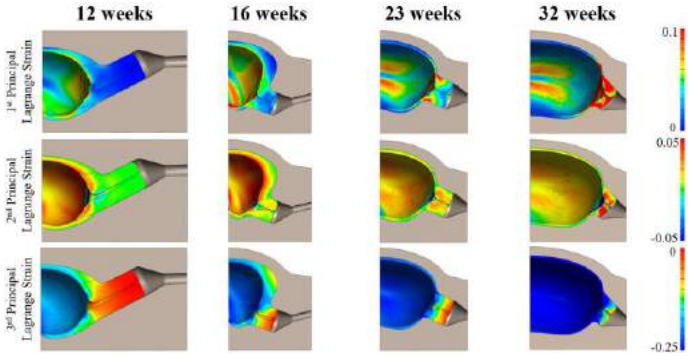

Figure 2: 1st, 2nd, and 3rd principal Lagrange strain heat maps for one patient at 12 weeks, 16 weeks, 23 weeks, and 32 weeks. Models are not to scale.

DISCUSSION

This research shows the evolution of loading patterns in the uterus and cervix throughout pregnancies that will ultimately deliver at term. Thus far, loading has been characterized by a shift in principal strain from being aligned circumferentially throughout the cervix to also be radially aligned from the internal os. This suggests a possible a mode through which the cervix is stretched as pregnancy progresses. Further work will explore how different geometries affect loading in the uterus and cervix.

This study's primary limitations are that the geometries used are derived from measurements already in a loaded configuration, so our reference configurations are not in a stress-free state. Additionally, patient-specific tissue properties and intrauterine pressure are unknown, and we cannot compare our results to in vivo loading results. This means that ultimately, the numerical results' magnitude will not provide an actual measurement of stress and strain for individuals throughout gestation. However, it will provide data on how maternal geometry affects loading on the uterus and cervix during pregnancy and supply a workflow in which patient-specific parameters can be added in future studies.

INTRODUCTION

Motion preservation devices have become increasingly popular in the treatment of spinal pathologies that require biomechanical support following removal of the degenerated tissue [1-3]. As these devices continue to be developed to treat multiple adjacent diseased spinal levels, i.e., using multiple disc prostheses or placing a disc prosthesis adjacent to a fused level, biomechanical data that supports these established surgical methods are needed. The objective was to determine the stability of four cervical disc prostheses tested under low endurance multidirectional loading conditions in a cadaveric cervical spine model.

METHODS

16 (C4-C5) and 16 (C6-C7) functional spinal units (FSUs) were dissected from eight male and eight female cadaveric cervical spines with an average age of 55.9 +/- 9.7 years. Three FSUs were not usable due to poor tissue quality which reduced the sample size to 29 FSUs. Four cervical total disc replacement (TDR) prostheses that had a similar ball and socket type articulation mechanism but varying endplate fixation features were tested (Figure 1): 1. A clinically used and FDA approved single central keel (SCK), 2. Low profile teeth (LPT) with domed endplate shape to allow a better fit in case of concave vertebral endplate, 3. Tripod keel (TK), and 4. Small single keel (SSK). A minimum sample size of 6 implants per prosthesis type was used.

Each specimen was mounted in a robotic testing platform (Figure 2) and tested with a coupled eccentric loading (CEL) protocol that moved the instrumented specimens through a sequence of combined motions of flexion or extension coupled with right and left axial rotation. A compressive load of 50N was applied to the upper mounting pot directly above the midline of the disc implant. End limits of motion were established for load limits of 1.5Nm in flexion, extension and axial rotation resulting in a total applied moment of 2.25Nm. If the specimen reached a total of 15degrees in flexion or extension, or 10 degrees in axial rotation, the corresponding moment value at the end range of motion was used which prevented the resultant target moment from being exceeded. Each specimen was then cyclically tested 2000 times at a rate of 2.5deg/s. Anteroposterior endplate migration of both the upper and lower implant components was measured after 20, 250, 500, 1000, 1500, and 2000 cycles.

Single Central Keel (SCK | Low Profile Teeth | Tripod Keel (TK) | Small Single Keel

Figure 1: Cervical Total Disc Replacement Prostheses.

Implant migration was analyzed by using a digital Vanier caliper set (with 1micron accuracy) to measure the offset distance between a fixed reference plate attached to the front surface of the mounting pot and the outer front face of both upper and lower implant components. Tests were stopped if implant component migration exceeded 3mm or endplate fracture was observed, and migrations less than 0.3mm were defined as clinically stable. A one-way repeated measures ANOVA with a Student Newman-Keuls test was used to compare differences.

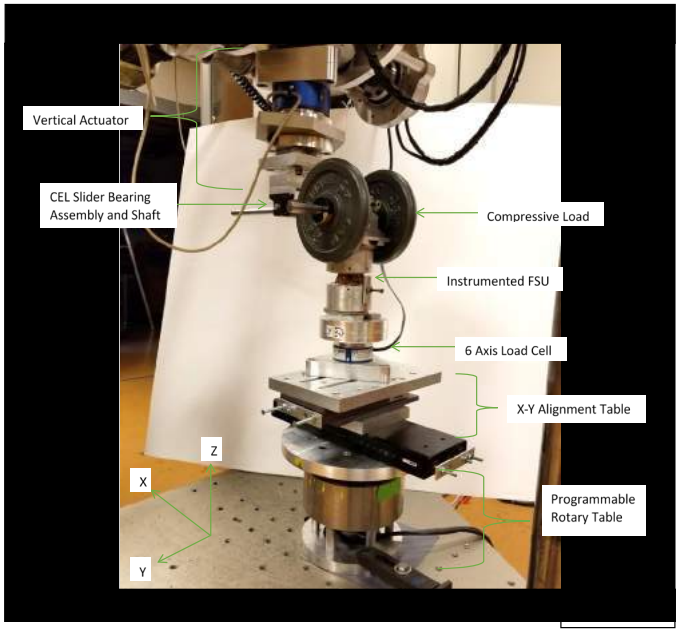

Figure 2: Experimental Setup for Multidirectional Test.

RESULTS

The mean and standard deviations of the combined (flexion plus extension) sagittal plane range of motion or the combined (left plus right) axial motion of the four TDR devices are shown in Figure 3. No statistical differences were found between the ranges of motion (ROM). The anterior-posterior migration of the upper and lower components of the disc prostheses are shown in Figure 4. All but one of the specimen migration values were below 0.3mm. Upper prosthesis component migration ranged between 0.02mm and 0.08mm and between 0.01mm and 0.04mm for the lower components. No significant differences occurred between the upper components or the lower prosthesis components of any implant type.

DISCUSSION

A human cadaveric cervical spine model was used to determine the biomechanical stability properties of four cervical TDR prostheses. Three low profile endplate fixation designs currently in the investigational phase of FDA clearance were found to provide comparable ranges of coupled movements to an existing clinically used and FDA approved central-based keel design. The three investigational prostheses also remained as stable as the FDA approved device following low cyclic testing. More cervical TDR prostheses, having different endplate fixation design features, provides spine surgeons with more options to accommodate anatomical constraints (i.e., varying endplate profiles and shapes) and/or treating multilevel adjacent spinal diseases.

INTRODUCTION

As of 2017, approximately 25,000 patients died as a result of heart valve disease (HVD) in the United States annually [1]. For patients with HVD, the native valve presents with severe regurgitation or calcification, increasing the demands on the heart. The primary treatment option for compromised heart valves is to receive either a mechanical or bioprosthetic heart valve replacement. However, 30% of patients with HVD are unable to receive these surgical options due to severe comorbidities and/or age [2]. Transcatheter aortic valve replacements (TAVRs) are a novel approach to treat HVD and are growing in popularity due to their minimally invasive approach, gaining approval in 2019 for low-risk patients [3]. However, despite the increase in interest for TAVR use, the long-term durability is unknown.

To demonstrate heart valve durability for market approval, the U.S. Food and Drug Administration mandates that valves be tested in an accelerated wear tester (AWT) in accordance with ISO:5840. ISO:5840 only specifies biological valves be cycled for at least 200 million cycles while applying a transvalvular pressure, commonly 100 mmHg, across a closed valve for 5% of the cycle [4]. However, no testing frequency is ever specified, which may contribute to differences observed between *in vivo* and AWT cycling. With an increase in testing frequency, porcine heart valve tissue demonstrates a decrease in leaflet stress relaxation. This produces a higher average preload than what is observed *in vivo* [5]. A higher preload could produce a harsher environment with high stresses sustained over the cycle, underestimating the life span of the valve. Alternatively, with a reduced range of stress fluctuations, the durability of the valve may be overestimated. Therefore, this study aims to better understand the influence of frequency within an AWT environment on TAVR motion and fluid dynamics using enface imaging and high-speed particle image velocimetry (HSPIV).

METHODS

To determine the effect of frequency on TAVR valve motion and fluid dynamics, a TAVR was mounted in an Electroforce® Durapulse™ AWT (TA Instruments, New Castle, DE) externally modified for optical access to the valve. The AWT consisted of a proximal chamber, valve holder, distal chamber, and pressure transducers at the base of each chamber (Utah Medical Products, Inc., Midvale, UT) (Figure 1). The AWT head was mounted on a Bose linear motor which developed the ISO:5840 compliant pressure loading conditions at three frequencies (10, 15, and 20 Hz). To provide visual access to the near valve fluid mechanics, the valve stent was trimmed between the upright supports to create windows and was fixed to a custom mount to prevent migration. The Durapulse™ cycled the TAVR in a blood analog comprised of glycerin and saline solution with a density of 1.13 g/ml and a viscosity of 3.99 cP to match the asymptotic viscosity of 40% hematocrit blood.

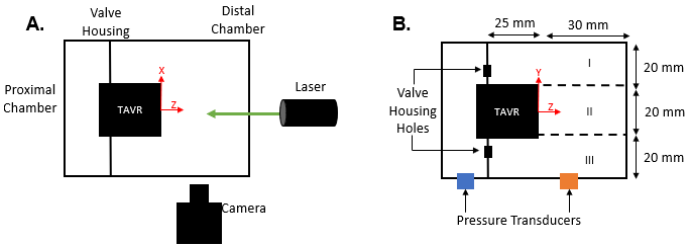

Figure 1: A. HSPIV experimental set-up with the Durapulse, high speed camera and laser. B. Side view schematic of the three regions of interest imaged with HSPIV, with pressure transducers and holes in the valve housing for fluid recirculation indicated.

To quantify the valve motion, the geometric orifice area (GOA) and flow rate was determined using enface imaging. The Phantom Miro-Lab 110 high-speed camera (Vision Research, Wayne, NJ) was mounted to visualize the valve opening and closing behavior. Image contrast was improved with an external light source behind the proximal chamber. Insight 4G (TSI, Inc., Shoreview MN) acquired ten images every 9% of the cycle for each frequency. Images were processed in MATLAB using the workflow shown in Figure 2. The flow rate (Q, ml/s) at each point in the cycle was approximated as a function of the average transvalvular pressure (ΔP, mmHg), fluid density (ρ, g/cm^3), and GOA (cm^2) as shown in Equation 1.

$$Q = 51.6 * \sqrt{\frac{\Delta P}{\rho}} * GOA \qquad (1)$$

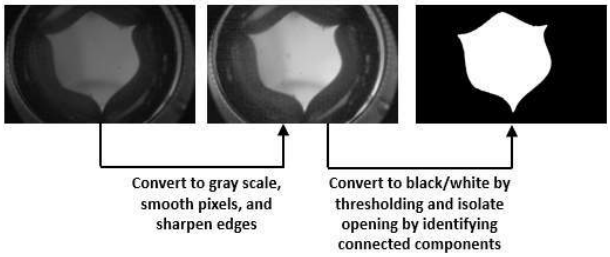

Figure 2: Workflow to process raw valve images in MATLAB to calculate the GOA.

To measure the fluid dynamics, a high-speed camera was mounted to visualize the side of the Durapulse^{TM} chamber (Figure 1B). Three regions were imaged due to large differences in velocity magnitude: Region I above the TAVR, Region II downstream of the TAVR, Region III below the TAVR (Figure 1B). A high-speed Terra PIV laser (Continuum, San Jose, CA) illuminated vertical planes every 1 mm in the x-direction from -10 mm to +5 mm to quantify AWT flow. Two HSPIV data sets were captured: an averaged and an instantaneous set. The averaged set captured 1000 image pairs every 9% of the cardiac cycle to compare between frequencies. The instantaneous set rapidly captured images to visualize random eddies that may develop. Velocity contour plots and streamlines for the averaged and instantaneous data were plotted with Tecplot360 (Tecplot, Bellevue, WA).

RESULTS

For all frequencies, the TAVR opened at the start of the cycle, reached a maximum GOA at 36% of the cycle, and closed until the following cycle. However, differences were observed in GOA and how much the valve leaflets were able to coapt. At 10 Hz, the valve obtained a maximum GOA of 1.54 ± 0.03 cm^2 and a flow rate of 17.13 ± 0.29 L/min (Figure 3A). The 15 Hz valve achieved a maximum GOA of 1.10 ± 0.01 cm^2 and a flow rate of 11.43 ± 0.13 L/min (Figure 3B). Finally, the 20 Hz condition produced a maximum GOA of 0.91 ± 0.02 cm^2 and a flow rate of 8.81 ± 0.15 L/min (Figure 3C).

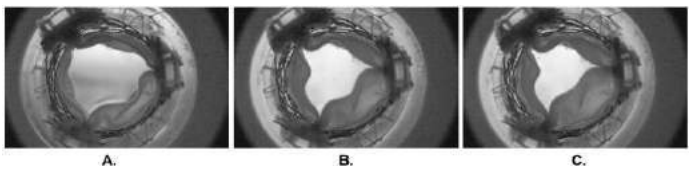

Figure 3: TAVR orifice at 36% of the cycle for A. 10 Hz, B. 15 Hz, and C. 20 Hz.

Additionally, during diastole, leaflet coaptation varied (Figure 4). At 10 Hz, the coapted leaflets curved back on themselves, and the valve was closed for approximately 41% of the 100 ms cycle. For 15 Hz the valve coapted along the entire leaflet, and the valve was closed for approximately 31% of the 66.6 ms cycle. At 20 Hz, the valve leaflets never completely coapted over the 50 ms cycle and opened as soon as the leaflets touched.

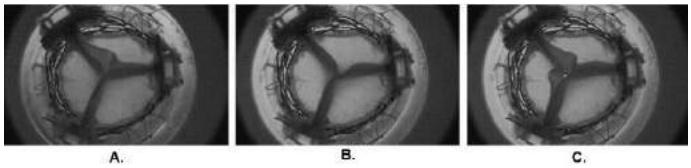

Figure 4: TAVR leaflet coaptation at 90% of the cycle for A. 10 Hz, B. 15 Hz, and C. 20 Hz.

During systole, a jet emerged from the valve and achieved a maximum velocity magnitude at 36% of the cycle for each frequency. As the valve closed, a large recirculation appeared at the base of the valve and dissipated downstream of the valve as the next cycle started. The maximum velocity observed during 36% of the cycle was 0.90 m/s at 10 Hz, 0.66 m/s at 15 Hz, and 0.47 m/s at 20 Hz. During diastole, the jet dissipated further downstream of the valve at lower frequencies.

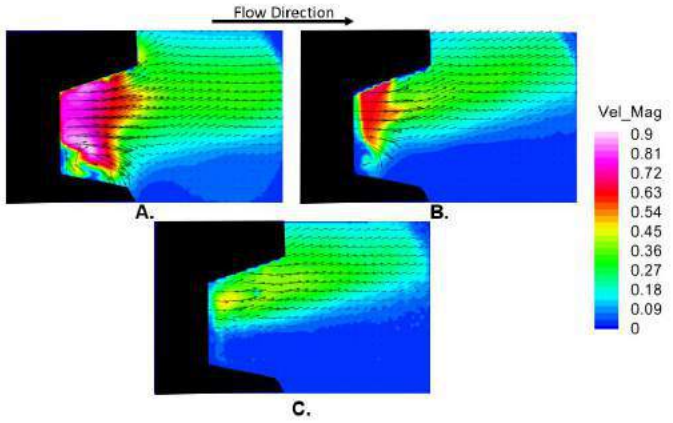

Figure 5: HSPIV data of the maximum jet exiting the TAVR in m/s during 36% of the cycle for A. 10 Hz, B. 15 Hz, and C. 20 Hz.

DISCUSSION

This study demonstrated different valve behavior with increasing frequency. With increasing frequency, the TAVR motion demonstrated a decrease in orifice area and flow rate during peak systole. During diastole, the valve remained closed longer and coapted better at lower frequencies. The fluid mechanics showed a greater jet velocity magnitude during systole and greater dissipation during diastole at the lowest frequency. Therefore, ISO:5840 should specify an AWT frequency due to clear differences in valve loading conditions.

INTRODUCTION

There is an unmet clinical need for small diameter (<6 mm diameter) synthetic vascular grafts. There is strong evidence that the presence of an endothelial cell (EC) layer due to EC migration or endothelial progenitor cell (EPC) capture, known collectively as endothelialization, on the graft luminal surface could increase long term patency of synthetic vascular grafts by inhibiting intimal hyperplasia, the predominant failure mechanism, and by reducing thrombogenicity through an anti-coagulant and anti-inflammatory EC phenotype. ECs attach to surfaces through peptide bonds between the activated N-terminus of various integrins employed by the cell and binding sites on adsorbed proteins or functional groups on the material surface. Researchers in the field of small diameter synthetic vascular graft materials have tried many clever strategies to induce integrin binding on their materials by generating a biofunctional surfaces to recruit EPCs and ECs, which has proven effective in promoting *in situ* endothelialization. However, the molecules typically used to capture and promote the growth of EPCs and ECs are generally expensive, difficult to functionalize on new materials, and lack structural stability, capturing specificity, and biological functionalities which together have limited their applications and clinical potential and wide-spread adoption as platform materials.

Evidence is mounting that nanoscale surface roughness also promotes activation of integrins, and that microscale surface topography can determine the migration propensity and inflammatory phenotype of ECs. Recently our lab has shown that treating a hydrogel graft material poly(vinyl-alcohol) (PVA) with reactive ion plasma (RIP) can increase the attachment and proliferation of EPCs on PVA and reduces both platelet accumulation and fibrin deposition in a clinically relevant model of thrombosis[1]. However, the exact mechanisms of attachment, including which integrins are employed in a given milieu and in response to what substrate properties remains unclear.

Different RIP treatment formulations impart these surface modifications to varying degrees. For example, physical etches such Argon-based RIP treatments introduce more nanoscale roughness than O_2 RIP treatments whereas N_2 RIP treatments impart more surface reactive chemistry than Ar or O_2 treatments at the same power. We have shown that each RIP formulation results in different EPC affinities and that after aging RIP-treated PVA some, but not all, of the surface nitrogen introduced by the RIP degrades after 240 days in storage but the surface topography completely disappears and EPCs no longer adhere or proliferate. We have shown that RIP treatments introduce functional groups such as amines, amides, and carbonyls that we hypothesize allow ECs to attach to the luminal surface of the PVA. Recent data also suggests that there might be a role for the increased surface roughness of RIP-treated PVA in inducing cellular substructures such at filopodia which are necessary for ECs to attach and migrate. Decoupling the effects of surface chemistry and surface roughness by leveraging the differential degradation kinetics of surface reactive chemical groups and nanotopography introduced by RIP treatment would provide an easily adoptable platform to answer longstanding questions about the relative importance of surface chemistry and topography in cell attachment, migration, and proliferation including which integrins are employed in each process and whether specific integrins are typically employed by an EC at the site of cellular substructures such as lamellipodia.

METHODS

Dry PVA films were treated with reactive ion plasma (RIP) using O2, N2, or Ar gas at powers of 50 W or 100 W for 5 minutes. Surface roughness was quantified using Atomic Force Microscopy (AFM),

surface chemistry was determined using X-ray Photoelctron Spectroscopy (XPS) within 14 days or at 240 days after RIP treatment. Endothelial colony forming cells (ECFCs) were isolated from a peripheral venous blood draw. All cells were used between passage numbers 3–4 to seed 8 mm diameter RIP-treated PVA samples and cultured in a standard incubator at 37 °C and 5% CO2. ECFCs were seeded at 100,000 cells per well in 48 well plate. Cells were grown for 48 hours, rinsed and quantified using Quant-iT Picogreen reagent (ThermoFisher, Waltham, MA).

RESULTS

Untreated PVA indicated no surface reactive chemistry, quantified through the atomic percentage of surface nitrogen, and a roughness quotient (R_q) of 6.8 nm. After treating PVA with 100 W Ar RIP the atomic surface nitrogen increased to 2.1% and the roughness quotient increased an order of magnitude to 73.1 nm. After storage for 240 days at standard temperature and pressure the surface nitrogen was measured to be 2.5% and the roughness quotient decreased to a baseline value of 9.6 nm (Figure 1). Importantly, ECFCs (EPC derivatives) adhered on the newly modified PVA surface, but did not adhere to the surface after it was stored for 240 days and allowed to degrade.

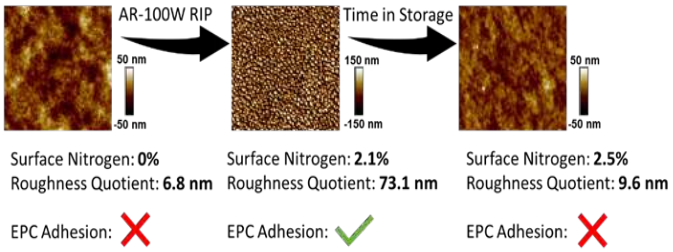

Figure 1: RIP-treating PVA imparts surface roughness and reactive surface chemistry, indicated as the atomic percent nitrogen, onto PVA which corresponds with the adhesion and proliferation of Endothelial Colony Forming Cells. However, after storing RIP-treated samples for 240 days, the surface topography disappears and EPCs no longer adhere, while the surface nitrogen mostly remains.

The roughness quotient (R_q) of RIP treated PVA depends not only on treatment gas and power, but also storage time after treatment. For the RIP treatments at a power of 50 W the roughness quotient was 10.7 nm, 64 nm, and 57.4 nm for O_2, N_2, and Ar gases respectively which increased from the untreated PVA control value of 6.2 nm. For the RIP treatments at a higher power of 100 W, the roughness quotient was 92.4 nm, 69.2 nm, and 73.1 nm for O_2, N_2, and Ar gases respectively. After storage at standard temperature and pressure for 240 days, the R_q for 50 W O_2, N_2, and Ar RIP treatments were 8 nm, 5.8 nm, and 36.7 nm respectively, while the values for 100 W O_2, N_2, and Ar RIP treatments after storage were 15.5 nm, 7.1 nm, and 9.6 nm respectively (Table 1).

Table 1: Roughness quotient (R_q) of PVA films less than 14 days after RIP treatment and 240 after RIP treatment.

Roughness Quotient (R_q)

	<14 days		240 days	
Plasma Treatment	50W	100W	50W	100W
Oxygen	10.7	92.4	8	15.5
Nitrogen	64	69.2	5.8	7.1
Argon	57.4	73.1	36.7	9.6
Untreated		6.2		

DISCUSSION

Aging of RIP-treated PVA samples resulted in a significant decrease in surface roughness, with most samples *relaxing* to the baseline value for PVA, which was never exposed to RIP. Aging of samples tended to have the same effect on the surface nitrogen content, but not to the same degree (data not shown). These results indicate that RIP-treated PVA can be used as a platform to study the attachment and other behaviors of ECs by treating materials with different RIP treatments and allowing each to age until the desired surface properties are obtained. With known underlying surface topography and/or surface chemistry, immunofluorescent imaging and antibody blocking assays can be utilized to determine the specific integrins used by ECs or EPCs in EC behavior. While biofunctional surfaces to recruit EPCs and ECs, have proven effective in promoting *in situ* endothelialization, molecules typically used to capture and promote the growth of EPCs and ECs are generally expensive, difficult to functionalize on new materials, and lack structural stability, capturing specificity, and biological functionalities. Utilizing RIP, which is an inexpensive and widely adopted high-throughput manufacturing technology which is ubiquitous in modern academic, clinical, and industrial laboratories to study the mechanisms of endothelialization of vascular graft biomaterials dramatically increases the utility and potential as a platform system. The system can ultimately be used to increase endothelialization of vascular grafts *in vivo*, which would increase their long-term patency, but might also be used to study the effect of modern medical device sterilization, which often involves RIP, on *in vivo* pathologies and device failure.

INTRODUCTION

Digital volume correlation (DVC) is a widely used technique to extract the deformation between two image volumes. An increasingly popular way for obtaining volumes of soft tissues, such as eyes, skin and blood vessels, is optical coherence tomography (OCT). The combination of DVC and OCT has thus emerged as a powerful way to characterize the biomechanics of soft tissues **[1-4]**.

We present a new DVC method that overcomes three major challenges to obtaining accurate deformations between OCT volumes. First, because of differences in relative acquisition position and orientation between imaging sessions, OCT volumes acquired at different times often exhibit both deformations and rigid body motion. Rigid body motion increases DVC search area, decreasing computational efficiency. Large rotations reduce correlation **[5]**, affecting the measurement accuracy. Second, OCT image contrast decreases and noise increases with depth. Poor contrast and high speckle noise decrease the convergence of the popular 3D inverse-compositional Gaussian Newton (IC-GN) **[6]**, heavily reducing the DVC measurement accuracy. Third, interpreting the DVC results requires considering simultaneously various aspects of the process, such as local image quality and correlation coefficient. The technique we present overcomes these issues by using a combination of rigid body motion correction, sub-voxel point selection, and a novel scalar measure of "confidence". We demonstrate the technique with optic nerve head images.

METHODS

Rigid body motion correction: A semi-automatic pre-registration technique combining manual operation and automatic phase correlation **[7]** was implemented to correct the rigid-body motion of the tissue in the OCT volumes, especially the rotation angle. An interactive software with a user interface was developed to help 1) monitor the rigid-body motion correction process and 2) manually adjust the position and orientation of the deformed volume to register the reference volume. Manual operation is required if there is a large rotation of the tissue between the two volumes as the large rotation will decorrelate them and may fail an automatic correction. During manual operation, the error tolerance of rotation angles in the X, Y, and Z directions was relatively large: about 2 degrees, decreasing demands on the operator. Thereafter, phase correlation was used to further correct the rigid body motion automatically by maximizing the correlation coefficient in the Fourier domain.

Sub-voxel point selection applied if the 3D IC-GN iteration fails to converge: Commonly, the DVC search process consisted of two steps, a voxel-accuracy coarse search and a sub-voxel registration using 3D IC-GN iteration, among which the latter determined the accuracy of corresponding points searched. To ensure sub-voxel accuracy despite low contrast and high noise, if 3D IC-GN fails to converge, we select the sub-voxel corresponding point when the 2-norm incremental deformation parameter $\|\Delta\mathbf{p}\|$ was minimal; $\|\Delta\mathbf{p}\|$ of each iteration was recorded; $\|\Delta\mathbf{p}\|$ is expressed as,

$$\|\Delta\mathbf{p}\| = [\Delta u^2 + \Delta v^2 + \Delta w^2 + (M\Delta u_x)^2 + \left(M\Delta u_y\right)^2 + (M\Delta u_z)^2 + (M\Delta v_x)^2 + \left(M\Delta v_y\right)^2 + (M\Delta v_z)^2 + (M\Delta w_x)^2 + \left(M\Delta w_y\right)^2 + (M\Delta w_z)^2]^{\mathbf{1/2}} \quad (1)$$

where $\mathbf{p}$ is the deformation parameter: $\mathbf{p} = \{u, v, w, u_x, u_y, u_z, v_x, v_y, v_z, w_x, w_y, w_z\}$. Δ is the incremental operator. M is the half size of subvolume.

Confidence definition: Conventionally, the correlation coefficient $Corr = 1 - C_{ZNSSD}/2$ is assumed directly to reflect the confidence of a tracked point (C_{ZNSSD} represents the coefficient of zero-normalized sum

of square difference **[8]**); with a larger *Corr* indicating higher reliability. However, in practice, this is not sufficient for a reliable result. A point in a region of low contrast may have a large *Corr* without a good result. Average voxel intensity gradient (*AVIG*) is a good indicator of image contrast; a larger *AVIG* **[9]** generally means a higher contrast. We combined both *Corr* and *AVIG* to define a confidence *Conf* of the measured data as follows:

If $Corr_i > T_{corr}$ (a threshold, herein set to 0.7) or $Corr_i < T_{corr}$ & $AVIG_i < Const$:

$$Conf_i = Corr_i \times \left(\frac{AVIG_i}{Const}\right)^2 \quad (2)$$

Otherwise,

$$Conf_i = Corr_i \quad (3)$$

where $Const$ is a constant and set as $\overline{AVIG} \times 0.65$. ($\overline{AVIG}$ denotes the average $AVIG$ of all the reference subvolumes). i is the subvolume number. Greater *Conf* indicates higher reliability. *Conf* can be used to guide the search path of DVC and weigh the points for calculating strain, leading to increased robustness and higher accuracy of DVC measurements.

Test method: We used an OCT volume of the optic nerve head of a non-human primate (NHP) acquired using a Heidelberg Engineering Spectralis system. To test the effectiveness of the pre-registration method, we applied an artificial "synthetic" rigid body motion to the volume (translation vector: [-3.2, 1.8, 9.3] voxels; rotation angle [5.3°, -5.8°, -14.4°]). The pre-registration technique was then used to correct the preset rigid body motion. We compared the presented DVC method with the conventional method by measuring the preset 1) rigid sub-voxel translations ($u = v = w$ = 0.2, 0.4, 0.6, and 0.8 voxels, respectively.) and 2) strained deformation ($[u_x, v_y, w_z]$ = [-0.04, -0.04, 0.1] and [0.04, 0.04, -0.1]; $[u_x, v_y, w_z]$ = [-0.04, -0.04, 0.1] and [0.04, 0.04, -0.1].) In both cases, two rigid body motions were also respectively applied: a translation of [2.6, -3.4, 4.6] voxels (same to both cases); and rotation angles of [2.5°, -3.3°, 3.8°] and [-5.1°, -6.4°, 7.3°], respectively. *u*, *v*, *w* denoted the displacement in the X, Y, and Z directions, respectively; u_x, v_y, w_z were the strains in the three directions. To better mimic real OCT imaging, we also added speckle noise with a standard deviation of 0.05 to the artificially deformed volumes.

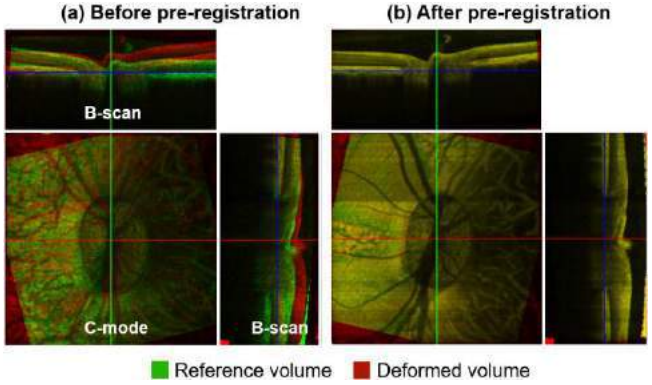

Figure 1. Artificial rigid body motion correction using the presented pre-registration technique. The OCT images are from a NHP optic nerve head. (a) Shown are overlays of the reference volume and the one with artificial rigid body motion before pre-registration; (b) Overlay after pre-registration. The overlays appear yellow if the two volumes register well, and green or red if they do not.

RESULTS

The reference ONH volume registered well with the one with artificial rigid body motion after applying the pre-registration technique (Fig. 1), validating its effectiveness. Absolute differences between the measured rigid body motion and the preset one was a translation of (0.2, 0.2, 0.3) voxels and the rotation angle of (0.25°, 0.26°, 0.36°). For the displacement and strain error comparison (Fig. 2), the presented DVC method had a displacement error of 0.05 voxels, with a strain error under 0.003; whereas, the conventional DVC method exhibited substantially higher displacement error (0.18 voxels) and strain error (more than 0.015). For the rigid body motion with larger rotation angle, the conventional method failed, while the proposed method's accuracy was not affected.

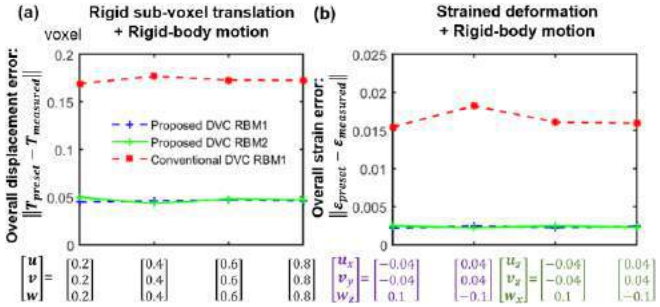

Figure 2. Accuracy comparison between the presented DVC method and a conventional DVC method on displacement and strain measurement accuracy. Two kinds of rigid-body motion (RBM1 and RBM2) are accounted. RBM1: $[T_x, T_y, T_z, \theta_x, \theta_y, \theta_z]$ = [2.6, -3.4, 4.6, 2.5°, -3.3°, 3.8°]; RBM2: $[T_x, T_y, T_z, \theta_x, \theta_y, \theta_z]$ = [2.6, -3.4, 4.6, -5.1°, -6.4°, 7.3°]. (a) The overall displacement errors. (b) The overall strain errors. For RBM2, the conventional DVC method failed, hence, its results were not shown.

DISCUSSION

We developed an improved DVC method that overcomes three important challenges of conventional DVC. We have demonstrated that this method works despite large rigid body motion, ensuring the sub-voxel accuracy even if the convergence of 3D IC-GN iteration fails. Finally, we have defined a novel confidence measure that is a more comprehensive measure of reliability. We have demonstrated that the new DVC method achieves significantly higher accuracy in computing displacements and strains than the conventional method when analyzing OCTs of the NHP optic nerve head.

INTRODUCTION

Complex geometries such as stenoses can cause turbulence in arterial blood flow. A stenosis is a narrowing of the artery wall, which can cause heart attacks and strokes. Many numerical and experimental studies have been utilized to characterize the turbulence in an arterial geometry. Blood is a non-Newtonian fluid with shear thinning behavior at a lower shear rate and Newtonian behavior at a higher shear rate [1]. Because of this blood behavior, our group has focused on examining the assumption of blood as a Newtonian fluid at higher shear rates with particular emphasis on the impact of the transition to turbulence. This work has revealed a delay (i.e., a slightly higher critical Reynolds number) for whole blood than the Newtonian analog fluid in the transition to turbulence in a straight pipe under steady flow conditions [1]. Similar results were obtained for flow downstream of a stenosis, both experimentally [2,3] and numerically [4]. The stenosis experiments were conducted using a rigid flow model, and it is unclear if the fluid-solid interaction of a flexible wall would alter these results. The present study was conducted to investigate the impact of a flexible wall downstream of a stenosis on the transition to turbulence of blood by measuring wall vibration as an indicator of the level of turbulence.

METHODS

The flow circuit was temperature and flow rate controlled (Figure 1). A centrifugal pump [D] (Sarns Disposable Centrifugal Pump 7850) drove the test fluid from the reservoir [A]. The test fluid was cooled when passing through four glass heat exchangers [B]. The coolant fluid used came from a chiller [J] (RTE-110, Neslab), which was kept at 27ºC and was driven by another pump [G]. The test fluid was warmed using a coil heater [C]. The flow rate and heating/cooling was voltage controlled by three switching DC Power Supplies (BK Precision 1685B, Yorba Linda, CA) based on the feedback of measurements of the temperature and flowrate using an immersion thermistor probe [I] (DP25-TH-A & OL-703, OMEGA Engineering, INC., Stamford, CT), and a transit time ultrasonic flowmeter [H] (TS410 and ME6 PXN, Transonic Systems In., Ithaca, NY), respectively. The data was acquired for 3s with a sampling rate of 250 kHz using a data acquisition of 1.25MS/s (NI USB-6259, National Instrument). Downstream the 5% eccentric stenosis with 75% are reduction geometry [E], a flexible latex tube of length 130mm, inner diameter 6.35mm, and outer diameter 7.94mm [F] (McMaster-Carr, Elmhurst, IL) was used. The circuit flow was located inside an insulated chamber to ensure body-temperature control.

A laser Doppler vibrometer (LDV) was used to measure the velocity of the latex tube downstream of the stenosis. The LDV laser beam was passed through a hole in the insulated chamber. The wall vibration measurement was conducted at three locations downstream of the stenosis: 5D, 10D, and 15D (D-diameter) in the latex tube. In these locations, Polytech A-RET-T010 reflective tape (Polytec, Inc., Dexter, MI) was used to reflect the laser beam. The vibration measurement was acquired data for 3s and 12s with a sampling rate 250kHz. The vibration measurement was conducted at Reynolds numbers: 0, 200, 300, 350, 400, 450, 500, 550, 600, 650, 700, and 750. A total of five experiments were conducted (across all of these Re) with whole porcine blood as well as a water-glycerin mixture. For the whole porcine blood, a mixture of 3.8g of NaCl (Sigma-Aldrich, St. Louis, MO) and 100 ml of distilled water was added for every 900 ml of blood. The water-glycerin mixture had a ratio of 500:460 by volume.

The flowmeter was calibrated using a stopwatch and a 250ml graduated cylinder. The viscosity (at 37ºC and 1000 s^{-1}) and density (at 37ºC) were measured using a rheometer and a scale with a 25ml graduated cylinder, respectively, to define the actual Reynolds number. For the data postprocessing, the amplitude spectrum was calculated by

multiplying the fast Fourier transform by its complex conjugate and then square rooting it. A root mean square was also calculated after a low pass filtering for frequencies above 200Hz.

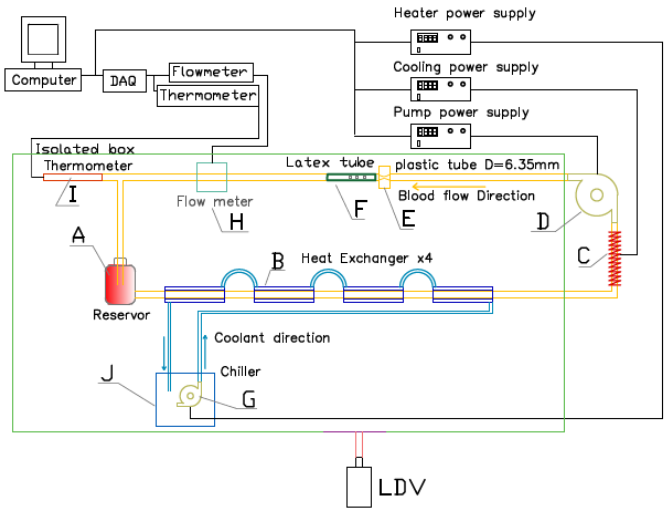

Figure 1: Flow experiment diagram

RESULTS

The average wall root mean square (RMS) velocity for the five samples of blood and water-glycerin are shown in Figure 2. The average wall velocity RMS for blood was slightly smaller than that for water-glycerin. The curves of blood and water-glycerin wall velocity RMS have a similar shape. Their curves rise gradually with an inflection point occurring approximately at Reynolds number ~ 350-500. Most of the measurements had frequencies between 15-19Hz, which is close to the natural frequency obtained by a bump test on the flexible tube when filled with the water-glycerin mixture (19Hz).

DISCUSSION

The results show that whole blood had a similar wall vibration as the Newtonian fluid (water-glycerin) during the transition to turbulence under steady flow within a flexible tube downstream of a 5% eccentric stenosis with a 75% area reduction. This suggests that there is no delay in the transition to turbulence for blood compared to water-glycerin. Blood and water-glycerin had a similar curve pattern for each measurement location near the critical Reynolds number (Re_{cr}~ 350-500) found by Casey and Yao in their rigid wall stenosis model [2,3]. However, they were able to identify a delay in the transition to turbulence by measuring the flow velocity fluctuations using a pulsated Doppler ultrasound probe with a rigid wall model. Yao found a delay of approximately 20% for blood compared to water-glycerin. Yao's experimental study showed Re_{cr}= 473±43 vs. Re_{cr}= 395±20 for blood and water-glycerin, respectively. Casey's results showed that the minimum Re_{cr} for blood was ~ 350-500 and for water-glycerin was ~250.

Note that the measurement of wall vibration is an indirect way to verifying the level of turbulence in the flow, and it was chosen due to the structural sealing limitations for the use of a Doppler ultrasound probe that may affect the wall motion. Thus, it may not have sufficient sensitivity to observe the delay in transition observed by Casey and Yao [2,3]. Nevertheless, the results from our study show that rheology has minimal impact on the wall vibration during the transition to turbulence. The consistency of vibration frequencies clearly indicates wall resonance phenomena, albeit at frequencies lower than expected in vivo. Further research using a more direct measurement of fluid velocity is required to fully understand the impact of a flexible wall on the transition to turbulence, even for simple fluids.

INTRODUCTION

Concussions occur at a relatively high rate among soccer players, and research suggests that female players may be more susceptible to brain injury than their male counterparts [1]. In addition to concussion, there is increasing concern about the potential consequences of repetitive subconcussive impacts. Although concussions are most likely to occur during player-to-player collisions, the majority of head impacts in soccer are intentional headers [1,2]. Head impact sensors that have been previously used to quantify head impact exposure in soccer may be prone to error resulting from poor coupling with the skull [3]. This has made comparisons across levels of play difficult to adequately assess, and few studies to date have attempted to simultaneously measure head impact exposure in two or more levels of play with the same sensor [4,5]. Further understanding of how head impacts differ across age groups is necessary to inform safety regulations in the sport. Additionally, accurate kinematic measurements are necessary to drive finite element brain models, which have been previously used to estimate tissue-level strain in sport-related impacts [6]. Evaluating the tissue-level strain response of the brain to headers experienced in an on-field setting can help identify factors associated with the biomechanics of repetitive head impacts which, in turn, can inform our understanding of how those impacts relate to neurological deficits and concussion risk. The objective of this study was to evaluate and compare head kinematics and the corresponding tissue-level brain strain of intentional headers across youth and collegiate female soccer players.

METHODS

Soccer players from one U15 girls' team and one National Collegiate Athletic Association Division 1 women's team were recruited to participate in this study over one competitive season. Each participant was instrumented with a previously-validated mouthpiece sensor that contained a tri-axial accelerometer and gyroscope [7]. Kinematic data and time-synchronized video were collected during each game and practice. Sensors were configured to collect 60 milliseconds (ms) of linear acceleration and angular velocity data (15 ms pre-trigger and 45 ms post-trigger) at sampling frequencies of 4,681 Hz and 800 Hz, respectively, when the linear acceleration exceeded 3.5 g (youth) or 5 g (collegiate) for at least 3 ms. Recorded events were processed and transformed to the head center of gravity (CG). Recorded events were video-verified using a custom MATLAB (MathWorks, Natick, MA) graphical user interface that semi-automatically paired event timestamps with corresponding video times. The ball delivery method of each verified header was defined as the method in which the ball was delivered to the player prior to the header and included kicks, throws, and headers (i.e., the player received the ball from another header).

The head kinematics measured from the mouthpiece sensors were used to drive the atlas-based brain model (ABM) [8]. For each header, the measured linear acceleration was numerically integrated to obtain the linear velocity at the head CG. The measured rotational velocity and the calculated linear velocity were applied to the head CG of the model. The maximum principal strain (MPS) in each element was used to calculate two strain-based metrics: the maximum value of the 95th percentile MPS time history curve (MPS95) and the area under the cumulative strain damage measure curve (CSDM area) [6]. Mixed effect models were used to compare head kinematics and strain-based metrics by level of play. Session type and ball delivery method were included in the model as covariates. Because of their right-skewedness, all dependent variables were log-transformed before analysis and back transformed to report the mean and 95% confidence intervals. Statistical analysis was completed in SAS (version 9.4, SAS Institute Inc., Cary, NC).

RESULTS

Six youth girls' and 13 collegiate women's soccer players participated in the study. A total of 567 film-verified headers (n=309 youth, n=258 collegiate) were collected over 88 practices (n=34 youth, n=54 collegiate) and 38 games (n=19 youth, n=20 collegiate). None of the recorded headers resulted in a clinically diagnosed concussion. The mean peak resultant linear acceleration, rotational velocity, rotational acceleration, MPS95, and CSDM area of all 567 headers were 16.3 g, 6.97 rad/s, 1.53 krad/s^2, 0.0649, and 4.50, respectively. Pairwise comparisons of mean head kinematics and strain by level of play and associated summary statistics are provided in Table 1. Compared to youth players, headers experienced by collegiate players had greater mean and 95th percentile peak linear acceleration, peak rotational velocity, peak rotational acceleration, MPS95, and CSDM area.

Median	6.22	2.60
95th Percentile	11.6	5.78

DISCUSSION

Collegiate soccer players experienced higher kinematic magnitudes and greater tissue-level brain responses during headers than youth soccer players. The mean linear acceleration, rotational acceleration, rotational velocity, MPS95, and CSDM area were approximately 61%, 88%, 51%, 64%, and 67% greater among the collegiate players compared to the youth players, respectively. The comparison of head kinematics described herein adds to the limited knowledge regarding differences in soccer head impacts experienced across levels of play. The characterizations of brain tissue strain are, to the authors' knowledge, the first comparisons of the brain's response to headers experienced at different levels of play during normal soccer participation.

The increased head kinematics observed in collegiate players compared to youth players in the present study is consistent with two previous studies which observed greater magnitude head impacts among players at higher levels of play. Chrisman et al. reported greater head impact exposure over one month of play among U14 soccer players compared to U12 players [4]. The U14 female players in the study experienced a greater number of head impacts higher than 15 g compared to U12 players (87 vs. 0). McCuen et al. reported that female collegiate soccer players experienced head impacts with slightly greater mean peak linear acceleration (39.3 g vs. 37.6 g) but no significant difference in mean peak rotational acceleration (6.43 krad/s^2 vs. 6.53 krad/s^2) compared to female high school soccer players [5]. Differences in reported mean kinematic magnitudes between studies may, in part, be due to the improved accuracy of the mouthpiece sensors and film verification used in the current study compared with other types of head kinematic measurement devices [3].

The current study contributes to the limited research on the mechanical response of the brain to intentional soccer headers. Kuo et al. evaluated MPS during 14 intentional soccer headers delivered via a ball launcher at 7.0 m/s using the KTH brain model [9]. The resulting median MPS value of 8.5% is similar to our reported median MPS95 of the collegiate headers (8.8%). Allison simulated 111 on-field intentional headers with the Global Human Body Models Consortium head model using kinematic data recorded with the GForce Tracker wireless headband sensor [10]. Interestingly, one of Allison's simulated headers resulted in a concussion and was associated with an MPS value of approximately 18.6%. Four headers in the current study (all from collegiate athletes) had MPS95 values that exceeded that of the concussive impact reported by Allison, but none of them were associated with a diagnosed concussion.

This study was limited by factors associated with the mouthpiece devices, on-field data collection, and the finite element model. First, the devices were configured at different threshold values for the youth (3.5 g along any axis) and collegiate players (5 g along any axis). The youth threshold was lower because previous work found over 40% of youth soccer impacts measured below 5 g [11]. Secondly, the headers recorded during games are biased toward a subset of players who participated in the study. Four of the six youth players and three of 13 collegiate players recorded a header during a game. Thirdly, although the ABM possesses high anatomical accuracy, the model includes several simplifying assumptions [8]. Finally, the ABM was developed from the International Consortium for Brain Mapping brain atlas of adult brains and may not accurately represent brains of the youth participants.

INTRODUCTION

The adult human brain has a unique structure and morphology, similar to fingerprints. The complex surface topology of the highly folded cortex, the outermost layer of the brain, consists of asymmetrical outer gyral ridges and inner sulci valleys which emerge during the third trimester of gestation. Although the mechanism of cortical folding is still under investigation, a combination of mechanical and biological factors is thought to affect the buckling of the cortical sheet. Specifically, cellular processes and mechanical forces generated during growth have been shown to lead to consistent regional variations in cortical thickness between gyri and sulci, with gyri being significantly thicker than sulci, both within humans [1-4] and in primates [5]. In this study, we want to investigate how this variation differs across the convoluted surface of the brain beyond just gyri and sulci. This is highly relevant to public health as neurological disorders such as Autism Spectrum Disorder (ASD) [6] and schizophrenia [7] are known to be associated with regional abnormal folding patterns and mean cortical thickness differences of the cortex. Quantification of the typical and atypical folding patterns of the cortex on a local scale, in addition to the regional, is extremely important in order to (1) better understand the causes of diverging folding shapes which are linked to atypical and neuro-typical development of the brain, (2) capture the true variation of cortical folding patterns without loss of valuable local information, and (3) be able to early and objectively diagnose neurological disorders by identifying accurate and reliable biomarkers before clinical symptoms evolve. In this study, we developed an open-source computational toolbox to investigate cortical thickness variations on a local scale (at ~40k points) in order to understand how this varies with the morphology of the folded cortex. The toolbox takes in any cortical surface mesh as an input and calculates the surface measures (curvature, thickness, depth and area) spatially on a local scale (point-wise).

METHODS

The structural MRI of typically developed (TD) human subjects are obtained from a publicly available imaging data set [8]. The outer cortical sheet, i.e. pial surface of the cortex, and the inner cortical sheet, i.e. white surface, are reconstructed from cross-sectional MR images by using an automated open-source neuroimaging pipeline, Freesurfer [9], which outputs a piecewise cortical mesh for both surfaces.

The accuracy of the quantitative surface measures depends on a uniform, smooth mesh, while the original meshes are irregular and uneven. Therefore, we decimated and smoothed both meshes with a user-defined target reduction and smoothing value (Fig. 1). The simplified and uniform surface mesh preserves the original surface topology and geometry for robustness of the calculations. Then, by utilizing the principles of discrete differential geometry, we calculated the curvature measures (mean curvature (H), Gaussian curvature (K), principal curvatures (PCs), Shape Index (SI)), cortical thickness, and sulcal depth at each vertex using our computational pipeline, which will be shared publicly in the future for the use of other researchers. Moreover, we calculated the total folding index (FI) and the total intrinsic curvature index (ICI) for sulcal and gyral regions of the cortex separately. Here, instead of using to an automatic cortical parcellation scheme to distinguish gyral and sulcal regions, such as the Destriuex atlas, we investigated the cortex in its entirety to explore the thickness variations at local scales including the tangential (in-plane) bends of the gyri and sulci. These bends of the cortex have not received much attention previously, but based on our finding that folding directly leads to cortical thickness variations, we expect to observe thickness variations within these folds as well. We attributed convex shaped vertices (negatively signed PCs) as gyral, concave shaped vertices (positively signed PCs) as sulcal and saddle shaped vertices (negatively signed K/oppositely signed PCs) as tangential folds of the cortex.

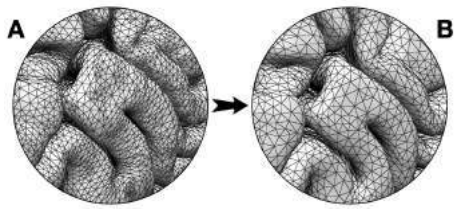

Fig. 1: Representative piecewise mesh of the pial surface. (a) Irregular, dense mesh (b) Simplified, more uniform mesh.

RESULTS

We present the cortical thickness variations throughout the cortex as a Gaussian kernel density distribution with respect to the local morphology identified by the curvature measures (Fig. 2, right). The mean curvature is successful in delineating the gyral and sulcal folds of the cortex (Fig. 2B), while negative Gaussian curvature is an effective measure to highlight the tangential folds (in-plane bends) of the cortex (Fig. 2C). It is important to note that, as it is not possible to distinguish convex from concave by using only the Gaussian curvature, we used principal curvatures additionally to demonstrate the thickness variations of convex (gyral) and concave (sulcal) folds (Fig. 2B-right). Finally, we found that Shape Index by itself is capable of distinguishing gyral, sulcal, and tangential folds of the cortex in a spectrum from cup to cap (Fig. 2D) [10]. From this investigation, we found that gyral folds are consistently thicker than tangential folds and that sulcal folds are the thinnest throughout the cortex.

DISCUSSION

The development of the cortex entails an extensive folding process which engenders characteristic gyral, sulcal and tangential cortical folding patterns and also appears to result in systematic cortical thickness variations throughout the cortex both radially (from sulcus to gyrus) and circumferentially (in-plane folds). In this study, we present the well-organized relationship between the curvature of the cortex and cortical thickness at individual points. Throughout the cortex, the point-wise cortical thickness distribution reveals a continuous spectrum from gyral peaks to sulcal pits, including the tangential folds as well. The curvature measures presented here are useful to investigate these systematic variations.

As part of our future work, we will extend the capabilities of our computational toolbox to extract vertices belonging to outer and inner parts of the tangential folds using the curvature measures presented here or a combination of them. This will allow us to further investigate cortical thickness variations from outer to inner tangential folds of gyri and sulci. Furthermore, we aim to build on recent advances in high-resolution MR imaging [11] and computational neuroimaging tools to investigate the relationship between the local shape (identified by the curvature) and thickness on a laminar scale from gyri to sulci and from inner to outer in tangential folds (in-plane bends). This investigation might not only provide additional insight to understand the consistent relationship between curvature and thickness of the laminar layers but also the role of laminar and major cortical thicknesses in typical development and in abnormal cortical folding seen in neurological disorders such as the ASD.

INTRODUCTION

Analysis of three-dimensional (3D) geometry is critical to a wide range of studies in many different disciplines. The proliferation of 3D imaging devices such as magnetic resonance imaging (MRI) and computerized tomography (CT), once out of reach for many researchers, has increased the need for efficient and effective tools with which to perform analysis. Often, particularly within biological studies, samples require support or conditioning from specialized hardware. Examples of such hardware include mounting hardware, pressurized containers, and manipulators. Depending upon the goals of the study, this hardware must frequently be removed from the resulting 3D image dataset prior to further analysis. The most common technique for this relies on removing regions that fall above or below a pixel intensity threshold. Not uncommonly however, situations arise where the contrast between the region of interest and adjacent hardware features is quite low. This generally leads to difficulty with intensity based removal approaches as they tend to under-remove the unwanted areas and more importantly can remove portions of the region of interest. If, however, the specific 3D shapes of the hardware features are already known, it can be removed based purely on geometry. The following presents a new and novel approach for the semi-automatic removal of known-geometry components from a 3D dataset represented by using a 2D image stack.

METHODS

STL File: The algorithm is summarized in Figure 1. Hardware geometry is first input in the form of a binary STL (standard tessellation language) file, which represents the solids as a mesh of triangular facets with associated edges and vertices. Additional inputs include the bottom and topmost image numbers in which the hardware elements are visible, the inter-image spacing and the locations of three (or more) fiducial points. Fiducial points are ideally modeled into the hardware itself in such a way as to allow easy, precise identification.

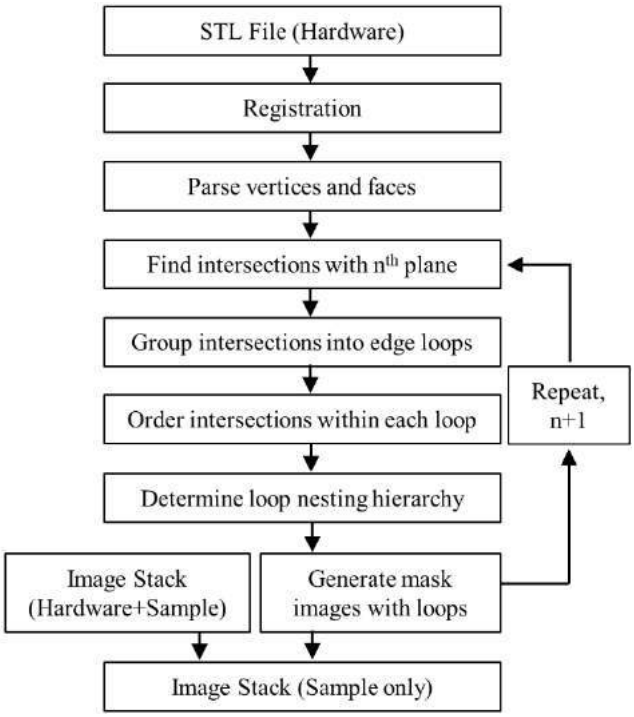

Figure 1 – Flowchart representation of the overall hardware removal process

Registration: A rigid-body transformation is conducted so as to register the three hardware fiducial points (whose positions with respect to one another are known) with their positions within the image stack. The necessary rotation and translation matrices are found through singular value decomposition [1], while scaling is determined from fiducial point-to-point distances.

Find Intersections: A plane is constructed such that it is coincident with the bottom-most image in which hardware is visible. The vertex coordinates from the STL file are parsed into separate faces and associated edges. These faces are evaluated to determine which ones intersect or cross the plane. If the plane is crossed, then the intersection points along the face's edges that cross are found. Any vertices or edges that lie along the plane are also found. All the intersections with the plane, for all STL faces, are compiled into an array.

Group and Order Intersections: These intersections trace out the edges of the model formed by a cross sectional cut taken at the plane. In the event that the hardware element has several branches or internal features, such as holes, then the multiple edges will all be represented by the points within the intersections array. In order to separate the intersection points into individual edge "loops", a connectivity thresholding approach is employed to segment the intersections, whereby all points within a pre-defined radius of an arbitrary base point are considered to occupy the same loop. All similarly "connected" points are grouped until no additional points fall within the connectivity radius, at which point the process is repeated for a new loop. The now grouped intersections must next be ordered within the individual loop arrays such that they would present the smooth, cross-sectional outline of the model if connected in a connect-the-dots manner. This is accomplished through a "nearest neighbor" approach, though other methods may be suitable, such as a traveling-salesman solver [2].

Determine Hierarchy and Generate Masks: Once all loop arrays have been ordered appropriately, the loop hierarchy, or whether the loop represents an interior or exterior edge, must be determined. This may be done by checking whether an arbitrary member from each loop is inside the polygon formed from each of the other ordered loops. The now appropriately ordered sets of intersection points are used to generate polygonal masks that are applied to a template image which is of equal size and resolution to those of the image stack. Mask regions are flood filled white or black according to their hierarchy.

The above procedure is repeated for a new image plane, offset from the first by the data image stack inter-image spacing. This continues until the image plane height matches the uppermost image which displays the hardware to be removed. Masks are finally multiplied pixel-wise by the original images to remove the hardware from the data set.

Mitral Valve Clamp Case Study: A case study was conducted using a portion of a previously described [3] 3D printed, customizable annulus clamp that is utilized in mitral valve scanning studies. The clamp was scanned with a Nikon TH 225 ST CT system with a beam energy and current of 180 kV and 174 µA respectively. An isotropic 32-micron resolution was used. Following reconstruction, the dataset consisted of 1622 images with a pixel depth of 16-bit and a size of 2000x2000 pixels, giving a total dataset size of approximately 12 gigabytes. The clamp piece was mounted atop Styrofoam, which is weakly visible to x-ray, resulting it an isolated clamp against a black field within the resultant image stack. The above described algorithm was performed using the clamp STL and scan imagery, using a Dell XPS 9570 with 16 GB memory, 6 cores and GTX 1050Ti graphics card.

RESULTS

Application of the algorithm to the clamp scan removed more than 96% of the clamp, as measured by the number of pixels before and after removal with an intensity greater than 40,000 (out of 65,536). Total computational time for removal of the 1190 mounting-hardware-containing images was approximately 15 minutes. An example mask, along with its corresponding original image and multiplied result, are shown in Figure 2.

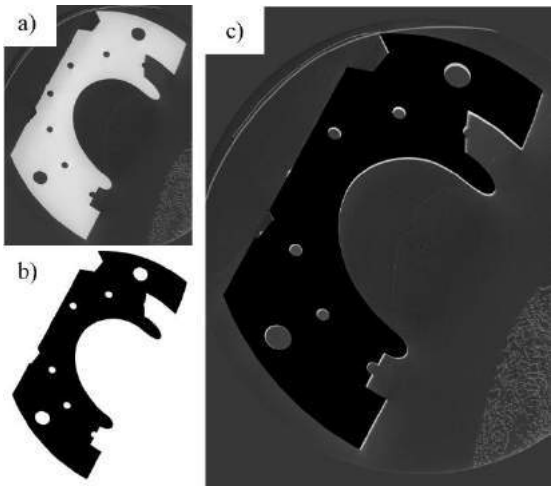

Figure 2 – Example images of a) original image, b) corresponding mask and c) pixel-wise multiplication result showing nearly full hardware removal of scanned mitral clamp

DISCUSSION

The above-described method has been shown to be effective for removing known-geometry hardware elements from imagery. The error preventing total removal was mostly due to imperfect registration with the three fiducial points; this will be improved by using more points. Although the time required to process the image data was relatively short, this can be improved by increasing the number of cores, ram, and graphics on the computation system. In circumstances where low/no contrast is present between mounting hardware and adjacent sample, which would render ineffective many intensity thresholding methods such as Otsu's Method [4], geometry-based removal may well be the only viable option for subtraction of hardware. Another major advantage of this approach over others, such as volume-based subtraction [5], is the vastly reduced computational load. This is primarily due to the image-by-image manner in which masks are generated and applied to the data image stack. Rather than loading into memory the entire dataset, which can often exceed 10Gb for high resolution scans, and then performing operations on each voxel, only a small fraction of the total dataset should be loaded and analyzed at a time with this method.

INTRODUCTION

Motion preservation devices have become increasingly popular in the treatment of spinal pathologies that require biomechanical support following removal of the degenerated tissue [1-3]. As these devices continue to be developed to treat multiple adjacent diseased spinal levels, i.e., using multiple disc prostheses or placing a disc prosthesis adjacent to a fused level, biomechanical data that supports these established surgical methods are needed. The objective was to determine the stability of four cervical disc prostheses tested under low endurance multidirectional loading conditions in a cadaveric cervical spine model.

METHODS

16 (C4-C5) and 16 (C6-C7) functional spinal units (FSUs) were dissected from eight male and eight female cadaveric cervical spines with an average age of 55.9 +/- 9.7 years. Three FSUs were not usable due to poor tissue quality which reduced the sample size to 29 FSUs. Four cervical total disc replacement (TDR) prostheses that had a similar ball and socket type articulation mechanism but varying endplate fixation features were tested (Figure 1): 1. A clinically used and FDA approved single central keel (SCK), 2. Low profile teeth (LPT) with domed endplate shape to allow a better fit in case of concave vertebral endplate, 3. Tripod keel (TK), and 4. Small single keel (SSK). A minimum sample size of 6 implants per prosthesis type was used.

Each specimen was mounted in a robotic testing platform (Figure 2) and tested with a coupled eccentric loading (CEL) protocol that moved the instrumented specimens through a sequence of combined motions of flexion or extension coupled with right and left axial rotation. A compressive load of 50N was applied to the upper mounting pot directly above the midline of the disc implant. End limits of motion were established for load limits of 1.5Nm in flexion, extension and axial rotation resulting in a total applied moment of 2.25Nm. If the specimen reached a total of 15degrees in flexion or extension, or 10 degrees in axial rotation, the corresponding moment value at the end range of motion was used which prevented the resultant target moment from being exceeded. Each specimen was then cyclically tested 2000 times at a rate of 2.5deg/s. Anteroposterior endplate migration of both the upper and lower implant components was measured after 20, 250, 500, 1000, 1500, and 2000 cycles.

Single Central Keel (SCK | Low Profile Teeth | Tripod Keel (TK) | Small Single Keel

Figure 1: Cervical Total Disc Replacement Prostheses.

Implant migration was analyzed by using a digital Vanier caliper set (with 1micron accuracy) to measure the offset distance between a fixed reference plate attached to the front surface of the mounting pot and the outer front face of both upper and lower implant components. Tests were stopped if implant component migration exceeded 3mm or endplate fracture was observed, and migrations less than 0.3mm were defined as clinically stable. A one-way repeated measures ANOVA with a Student Newman-Keuls test was used to compare differences.

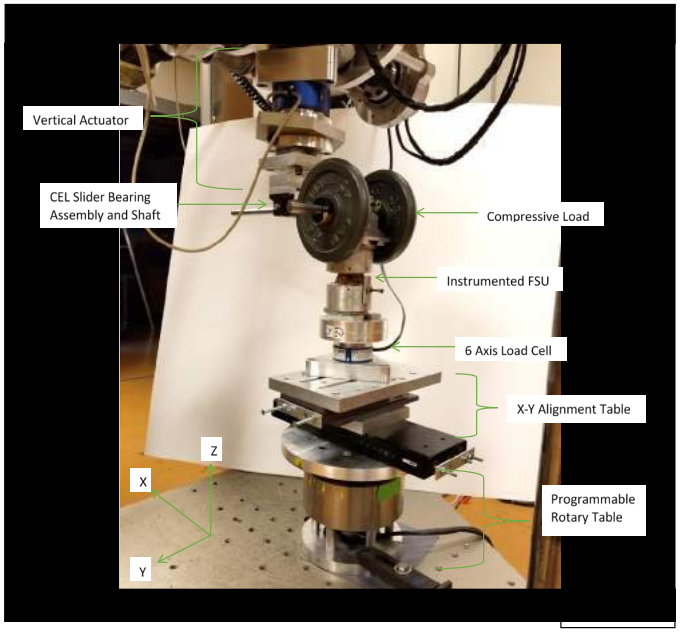

Figure 2: Experimental Setup for Multidirectional Test.

RESULTS

The mean and standard deviations of the combined (flexion plus extension) sagittal plane range of motion or the combined (left plus right) axial motion of the four TDR devices are shown in Figure 3. No statistical differences were found between the ranges of motion (ROM). The anterior-posterior migration of the upper and lower components of the disc prostheses are shown in Figure 4. All but one of the specimen migration values were below 0.3mm. Upper prosthesis component migration ranged between 0.02mm and 0.08mm and between 0.01mm and 0.04mm for the lower components. No significant differences occurred between the upper components or the lower prosthesis components of any implant type.

DISCUSSION

A human cadaveric cervical spine model was used to determine the biomechanical stability properties of four cervical TDR prostheses. Three low profile endplate fixation designs currently in the investigational phase of FDA clearance were found to provide comparable ranges of coupled movements to an existing clinically used and FDA approved central-based keel design. The three investigational prostheses also remained as stable as the FDA approved device following low cyclic testing. More cervical TDR prostheses, having different endplate fixation design features, provides spine surgeons with more options to accommodate anatomical constraints (i.e., varying endplate profiles and shapes) and/or treating multilevel adjacent spinal diseases.

INTRODUCTION

Current methods for achieving immediate endplate fixation with cervical total disc replacement (TDR) prostheses include the use of keels or spiked teeth. Non-physiologic push-out or expulsion tests are typically used to measure the distraction force and mechanical work required to expulse the device [1]. The objective of this study was to determine the failure work and load required to expulse the upper and lower components of the four different cervical prostheses after undergoing multi-directional cyclic testing. Endplate configurations included single central keel, tripod keel, and spiked teeth.

METHODS

16 (C4-C5) and 16 (C6-C7) functional spinal units (FSUs) were dissected from eight male and eight female cadaveric cervical spines with an average age of 55.9 +/- 9.7 years. Three FSUs were not usable due to poor tissue quality which reduced the sample size to 29 FSUs. Four cervical total disc replacement (TDR) prostheses that had a similar ball and socket type articulation mechanism but varying endplate fixation features were tested (Figure 1): 1. A clinically used and FDA approved single central keel (SCK), 2. Low profile teeth (LPT) with domed endplate shape to allow a better fit in case of concave vertebral endplate, 3. Tripod keel (TK), and 4. Small single keel (SSK). A minimum sample size of 6 implants per prosthesis type were used. Each instrumented cervical FSU was mounted in a robotic testing platform and cycle 2000 times under combined flexion/extension (up to 1.5Nm) and right/left axial rotation (up to 1.5Nm) at a rate of 2.5deg/s. Following cyclic testing, specimens were disarticulated through the disc space, separated into upper and lower segments, and remounted with different fixtures for expulsion testing (Fig. 1). A custom shear expulsion tool was used to apply a 50N compressive load to the top surface of the implant (Figs. 2 and 3), followed by a downward shear force to the backside of the implant until it was fully expulsed. Shear expulsion force and distraction-displacement were measured and combined to calculate Expulsion Work (area under curve) and Resistive Stiffness (slope of curve) (Fig. 4). Peak Expulsion Force was also obtained. Normality of the expulsion data was tested using the Shapiro-Wilk test (p=0.05). If normality failed, a non-parametric Kruskal-Wallis test with Bonferroni correction was used. An additional test was done to compare the shear expulsion parameters between the upper and lower components of the same implant type. A similar normality test as above was used. If normality failed, a (2 tailed) Mann Whitney test was used.

Figure 2. Shear Expulsion Test Setup. a) Custom shear explusion tool, b) Shear expulsion tool mounted to the upper test assembly, and c) FSU mounted in multi-axis vice with the top surface of disc implant parallel to the shear expulsion tool.

a) b)

Figure 3: Expulsion Protocol. a) Side view showing expulsion tool aligned overtop with the top surface of the disc implant. b) Front view of expulsion tool placed over TDR prosthesis. The shear expulsion tool was displaced downward pushing against the back edge of the prosthesis until the device was fully expulsed.

RESULTS

Mean and standard deviations for Peak Expulsion Forces were 69(41)N, 62(21)N, 110(71)N and 78(36)N, Expulsion Work were 321(225)Nmm, 399(161)Nmm, 463(305)Nmm, and 296(149)Nmm, and Resistive Stiffness were 81(61)N/mm, 44(42)Nmm, 163(207)Nmm, and 150(149)Nmm (Fig. 5). No significant differences occurred between implant types for any of expulsion data. Further, no significant differences were found between the upper and lower components of any implant type except for the Expulsion Work term of the traditional central keel device ($p=0.037$).

DISCUSSION

Using a human cadaveric cervical spine model, the fixation strength of four different cervical TDR prostheses was analyzed. The fundamental premise of the study was to highlight the acute biomechanical fixation properties of prosthetic endplate designs. The findings from the study do not reflect the long-term biological response of osseointegration. Three of the endplate fixation designs studied are currently in the investigational phase of FDA clearance and were found to provide comparable immediate holding strength to an existing clinically used and FDA approved central-based keel design.

INFLUENCE OF PHYSIOLOGICALLY INFORMATIVE AVERAGE CONTACT STRESSES ON CARTILAGES' TRIBOLOGICAL REHYDRATION

Shamimur R. Akanda (1), Meghan E. Kupratis (2), David L. Burris (1,2), Christopher Price (2,1)

(1) Mechanical Engineering
University of Delaware

INTRODUCTION: Articular cartilage, the remarkable bearing tissue of our joints, can maintain very low coefficients of friction ($\mu<.005$) over millions of annual articulation cycles. Cartilages' phenomenal lubricity arises out of its biphasic structure, which allows it to generate very high levels of interstitial fluid pressure and fluid load support (FLS >90%), shielding the tissue from rapidly applied stresses, and promoting interstitial lubrication.[1] This behavior allows well-hydrated articular cartilage to support rapidly applied peak stresses as high as 20 MPa, which are an order of magnitude higher than its compressive modulus (0.5-1 MPa), without compromising tissue integrity or lubricity.[2]

However, when cartilage is subject to quasi-static loading, it experiences loss of FLS and interstitial lubrication due to time-dependent fluid exudation. As a result, overall articular cartilage function is dictated not by the peak stresses it is subject to but by the average contact stresses it experiences.[3] Within mammalian joints, average contact stresses range from 0.1 - 2.0MPa.[4] As a result of these non-trivial average pressures, cartilage function would be rapidly compromised in our joints if a mechanism for recovering load-induced interstitial hydration and FLS loss did not exist. Fortunately, studies in intact joints suggest that articulation serves as a driver of this requisite fluid recovery,[5] with a number of fluid recovery mechanisms, including free swelling upon contact uncovering/exposure or nominal unloading, having been put forth as potential mediators of fluid recovery, and thus, overall function.

Recently, our team has identified a novel fluid recovery mechanism, termed 'tribological rehydration',[6] that is driven by pure sliding, meaning that it supports the active recovery of cartilage interstitial fluid and FLS without the need for contact migration, unloading, or uncovering. Discovered when we re-interrogated the high-speed sliding behavior of the convergent stationary contact area (cSCA),[6] tribological rehydration represents a competitive process between load-induced fluid exudation and sliding—or hydrodynamic—driven fluid recovery. When hydrodynamic driven fluid recovery exceeds that of pressure-driven exudation, cSCA explants experience the reversal and recovery of interstitial hydration, tissue compression/strain, FLS, and interstitial lubrication loss, and the maintenance of phenomenal lubricity on the benchtop. From these behaviors, it becomes apparent that a critically important influencer of tribological rehydration, and of overall cartilage function, is applied contact stress, with high applied stresses likely contributing to the suppression of sliding-induced tribological rehydration. However, to date, studies utilizing the cSCA have been restricted to a rather small range of applied stresses (<0.3MPa; in bovine tissues).[7] The goal of the present work is to explore the influence of elevated contact stresses on the high-speed sliding behavior of cSCA cartilage using ovine (sheep) stifle explants, which because of their smaller geometry (radius of curvature) enable the application of higher contact stresses using our tribometer.

METHODS: 12 mm diameter osteochondral explants (n = 16) were harvested from previously frozen ovine femoral condyles and stored in 1X PBS at 4°C for no more than 48hrs before tribology test. Tribological rehydration was characterized under six compressive loads (1, 2, 4, 6, 7, and 8N) in a custom reciprocating tribometer[6,8] via a protocol consisted of 20 minutes of compression followed by 10 minutes of sliding at 80mm/s (Figure 1). Samples were 'free swelled' for 30 minutes between each subsequent load level. Compression and friction force/coefficient were recorded throughout.[8] Load dependent contact area was determined optically at the conclusion of the tribology tests.[6] Start- and end-of-sliding compressions and frictions, recovered compression, start- and end-of-static exudation rates and start-of-sliding recovery rate were determined as described previously.[8] Mixed model analysis was

used to quantify tribomechanical parameters as a function of load and stress.

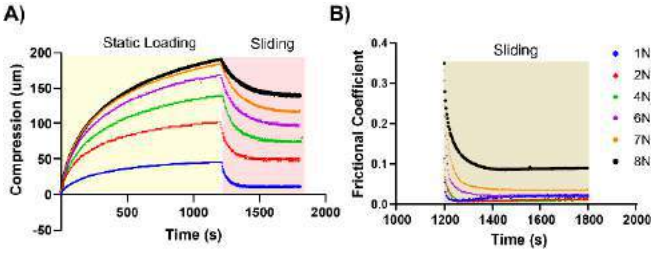

Figure 1: A) Compression and B) Friction traces illustrating the response of a representative ovine cSCA explant to high-speed sliding under six different applied loads.

RESULTS: In the cSCA, both tissue compressions and friction coefficients at the start of sliding and end of sliding increased with increasing loads (Figure 1). The relationship between recovered compression, measured as the difference between start-of-sliding and end-of-sliding compression, and applied load (Figure 2A) was complex, taking the shape of an inverted 'U' that could be fitted with a second-order quadratic equation ($y = ax+bx^2$; Figure 2A). At high sliding speed compression recovery was minimal at low applied loads due to nominal load-induced compression, but these small compressions were almost fully recovered. Compression recovery then increased with moderate applied loads, reaching their peak (34-79um) at intermediate loads (4-8N). Most explants experienced subsequent decreases in compression recovery at higher loads, with one specimen exhibiting zero and/or negative recovered compression (i.e., net exudation) at the highest applied loads. Both start- and end-of-sliding exudation rates increased in proportion to applied load (negative slopes; Figure 2C), whereas fluid recovery rate tended to decrease with increasing load.

When plotted against compressive stress, an inverted 'U' shaped relationship between compression recovery and applied stress was again

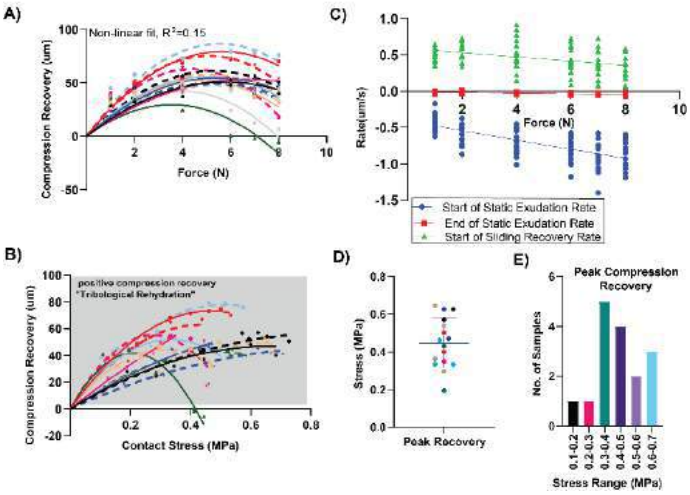

Figure 2: Compression recovery as a function of applied A) Load and B) Stress. C) Fluid exudation and recovery rates plotted against applied load. D&E) Compressive stresses at which each specimen exhibited peak compression recovery magnitudes.

observed (Figure 2B), with peak compression recovery (i.e., maximum tribological rehydration) being observed at a mean compressive stress of 0.45 MPa (ranging from 0.2-0.7 MPa, Figure 2D&E).

Apart from a few explants, all specimens showed qualitatively similar friction vs. applied load and friction vs. applied stress behaviors. While 'initial' start-of-sliding, and 'equilibrium' end-of-sliding friction coefficients increased in proportion to applied loads/stresses (Figure 3 A-B) nearly all cSCA specimens experienced rather rapid reductions in friction upon the initiation of high-speed sliding (i.e., friction recovery/suppression observed; Fig. 1C); apart from two explants at their highest contact stresses.

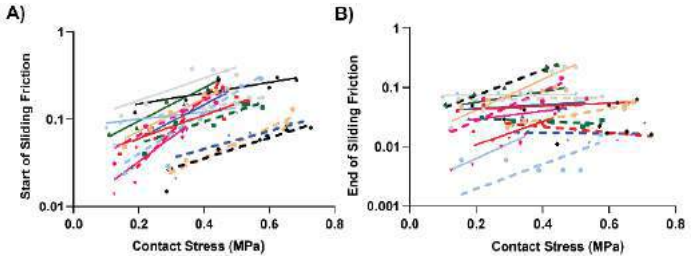

Figure 3: A) Start-of-sliding, and B) End-of-sliding friction coefficients as a function of applied stress in the cSCA under high-speed sliding (80mm/s).

DISCUSSION: Sliding-induced tribological rehydration, which represents a potent means of articulation-induced cartilage functional recovery (i.e., compression/strain & lubricity) is underpinned by competitive processes; pressure-induced fluid exudation (which increases with stress) and sliding-driven rehydration (which we assume largely constant for a given sliding speed).[7] Here, we demonstrate that sliding-induced compression recovery (in ovine cSCA explants) is highly contact stress dependent, illuminating several fundamental behaviors of articular cartilage, as well as limitations of the tissue.

At relatively low contact stresses (<0.2MPa), high-speed sliding (80mm/s) effectively recovered most, if not all cartilage compression due to prior static loading. Peak compression recovery occurred at intermediate stresses (mean = 0.45MPa, range 0.2-0.7MPa), followed by clear suppression of tribological rehydration effectiveness at higher contact stresses. Negative/zero compression recovery magnitude at high contact stress was only observed in one specimen (~0.4-0.5MPa); due to limitations with our tribometer's max loading capacity (≤8N). However, based upon extrapolation, we predict similar 'defeat' of tribological rehydration at stresses ≥1MPa more globally. It is interesting that the contact stresses that generate the best tribological rehydration behaviors overlap with the compressive modulus of cartilage (0.5-1MPa);[2] we are presently investigating if predicted relationships exist between cartilage's material properties and sliding-induced tribological rehydration behaviors.

It is also noteworthy that compression recovery, which is required for recovering interstitial rehydration and lubrication, is quite robust in the face of the spatiotemporally averaged contact stresses mammalian joints typically experience *in vivo* (0.1 to 2.0 MPa). However, this also highlights a potential concern. Because cartilage's tribomechanical behaviors are dictated by average applied contact stresses (as opposed to transient peak stresses),[3] there is the concern that modern socio-demographic increases in both body mass and overall inactivity represent significantly concerning and detrimental stressors to the overall tribomechanical function and health of our joints, even in the face of articulation mediated rehydration mechanisms.

DAMAGE MODELING OF THE HUMAN MENISCUS: VALIDATING FINITE ELEMENT MODELS WITH DIGITAL IMAGE CORRELATION

Derek Q. Nesbitt, Trevor J. Lujan

Mechanical & Biomedical Engineering
Boise State University
Boise, Idaho, United States

INTRODUCTION

Meniscus tears are one of the most common orthopedic injuries, with more than a half-million surgeries performed annually in the U.S.[1] The healing capacity of meniscus becomes diminished with age,[2] and surgical interventions to remove damaged tissue increase the likelihood of osteoarthritis.[3,4] With the lack of effective treatment options to fully restore meniscus function, preventing meniscus tear injuries is of utmost importance to combat osteoarthritis. The design of preventive therapies can be improved by computational tools like finite element analysis (FEA) to predict tears, similar to what has been done to inform treatments of aortic aneurysms.[5] One way that FEA can be effectively used to predict material failure, is by using Continuum Damage Mechanics (CDM) to model material weakening due to the onset of damage. However, the validation of an appropriate constitutive framework requires model comparisons to experimental data.[6] Our previous experimental work in human meniscus tracked the progression of surface strains in the tear region using high-speed video and digital image correlation (DIC), enabling the onset and progression of material damage to be measured at specific points of interest on the stress-strain curve.[7] This localized data can be used to validate that the appropriate failure behavior is being captured by a predictive CDM model[8], increasing the probability that the model is truly representing physiological behavior.

O**bjective.** The objectives of this work are to (1) fit a CDM model to the anisotropic tensile stress-stretch behavior of human meniscus and (2) validate that the model predicts the localized planar strains in the tear region as measured by DIC. Our hypothesis is that a CDM model using the maximum normal Lagrange strain failure criteria will reproduce the magnitude of the normal strains in the tear region at yield and ultimate strength, while closely matching the stress-stretch profile during quasi-static tensile tests.

METHODS

All models were developed, run, and analyzed using FEBio studio.[9] Model parameters were calibrated to our previous quasi-static tensile tests on the posterior side of the lateral meniscus from five different donors (<40 yrs).[7] Two fiber orientations were analyzed in order to capture the anisotropic character of the human meniscus, with samples from each of the five donors tested along the primary circumferential fiber axis (n=5 longitudinal) and normal to the primary circumferential fiber axis (n=5 transverse).

Mesh and Geometry. A $1/8^{th}$ symmetric dogbone shaped coupon was modeled to reduce computational effort, with geometry determined by the average dimensions of coupons tested in our previous study. The coupon had a clamp to gauge width ratio of 2:1, with a constant 0.5 mm wide gauge section. Longitudinal models were 5.67 mm long with a 2.5mm gauge length. Transverse models were 4.47 mm long with a 1.5mm gauge length. The clamp was modeled as a rigid body with an irrotational sliding elastic tension contact at the top of the gauge width of the coupon. The models were meshed with a 10 x 4 x 2 element 3D hexahedral mesh.

Model Formulation and Optimization. The selected model was a Veronda-Westmann ground substance[10] reinforced by a transversely isotropic fiber matrix.[11] The damage evolution was modeled using a quintic polynomial cumulative distribution function using the maximum normal Lagrange strain as the failure criteria. Ground substance parameters were fit first by optimizing the model to transverse data in the linear elastic region prior to ultimate tensile strength (UTS; Figure 1B). This was done since the fiber matrix does not contribute to the stress when stretched in this direction. The fiber matrix parameters were then fit to data in the linear elastic region prior to UTS in the longitudinal data (Figure 1A). Material parameters were optimized with the Levenberg-Marquardt algorithm in FEBio. Specimen specific

damage parameters were then fit manually to each transverse and longitudinal test by adjusting damage parameters until stress dipped near UTS.

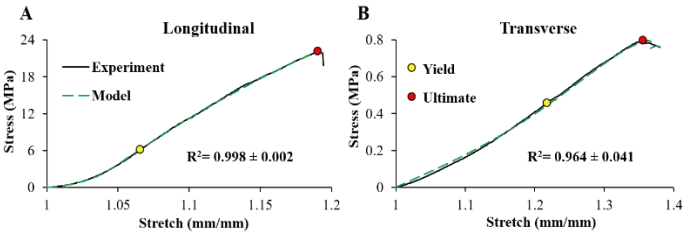

Figure 1: Representative curve fit of model to experimental data for A) longitudinal and B) transverse.

Analysis. Stress-stretch data was output by FEBio and compared to experimental data. Strain from the critical stress element of the model was compared to the tear region strain measured experimentally using DIC at yield and ultimate strength (Figure 3). This element was selected as the element that reached the damage threshold first.

Statistics. Model quality-of-fit to experimental data was determined by calculating the Root Mean Square Error (RMSE) of the stress-stretch data. Experimental and model strain data were compared at yield and UTS using a one-way ANOVA ($p<0.05$).

RESULTS

The average RMSE of model fits to experimental stress-stretch data was 0.01 ± 0.01 and 0.03 ± 0.01 for transverse and longitudinal models, respectively. Both transverse and longitudinal models greatly under predicted the experimental tear region strain, with the model giving a 73% and 40% reduction in strain magnitude at ultimate strength for transverse and longitudinal models, respectively. Additionally the models under predicted the tear region strain at yield strength with approximately 50% reduction in strain magnitude for both longitudinal and transverse models (Figure 2). The average tear region strain was significantly different than the experimentally measured values at both UTS and yield for the longitudinal model ($p < 0.05$), but not for the transverse models (p=0.20 at ultimate and p= 0.33 at yield) (Figure 2).

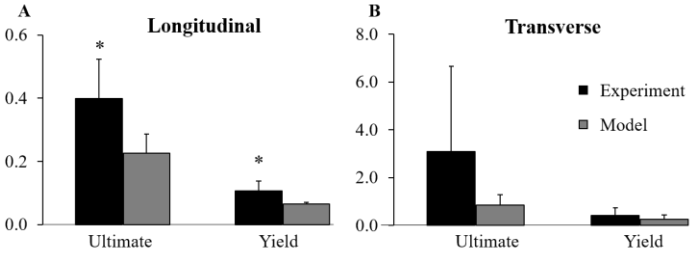

Figure 2: Comparison of the average local strain between experiment and model for A) longitudinal and B) transverse test series. *Significantly greater then model output.

The location of the critical stress element and concentration of greatest strain was the same element in the fillet region for all longitudinal models (Figure 3A). This location of failure initiation is similar to the fillet region type failures seen in 45% of longitudinal coupons from our previous study (Figure 3B).[7] The transverse models failed in the gauge region (Figure 3C), perpendicular to the loading axis, similar to the failures seen in nearly all transverse coupons from our previous experimental study (Figure 3D).

DISCUSSION

This is the first study to successfully model the anisotropic tensile behavior of the human meniscus. It is also the first study to attempt to validate a finite element model for human meniscus using DIC assisted quasi-static tensile experiments. While this model was successful at replicating the general location of failure initiation (Fig. 3), our model was unsuccessful at reproducing the magnitude of the normal strain in the tear region at either yield or UTS (Fig. 2).

The quality of the model fit to experimental stress-stretch data suggests that a Veronda-Westmann ground substance reinforced with a transversely isotropic fiber matrix is an appropriate model formulation for human meniscus. The quintic polynomial cumulative distribution function using maximum normal strain was also successful at re-creating the strain-softening. This is a reduction in modulus with increasing strain, often associated with the onset of damage[12] (Figure 1). However, the inability to reproduce the normal strains in the tear region suggests that our implementation of damage is inadequate for this application. This under prediction of strain indicates that the model tear region is being spread out over a wider area then seen experimentally. Strain concentrations may be improved with changes to the damage evolution model itself, or with a greater mesh density.

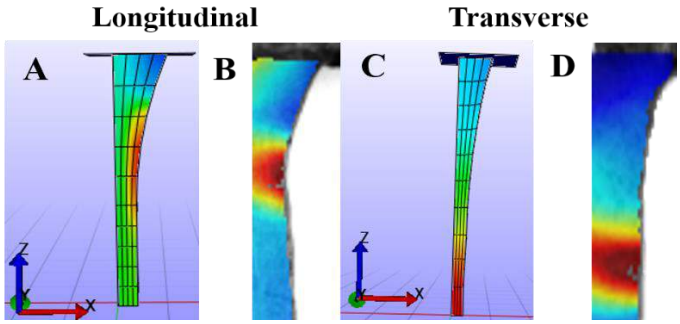

Figure 3: Representative normal strain concentration colormaps comparing the A) longitudinal model to B) experimental, as well as comparing the C) transverse model to D) experimental.

The mesh density used in this study was very coarse to promote model strain-softening, while avoiding the premature model failures due to regions of highly concentrated damage seen with finer mesh resolutions. Strain energy regularization techniques[13] could spread the damage out in a finer mesh to prevent premature failures, while promoting strain-softening. However, by calculating damage from a spatially averaged value as done in regularization, strains could be artificially spread out over this region. This could exacerbate the under prediction of the critical local strains, negating the utility of using a finer mesh resolution while significantly increasing computation time.

In conclusion, this was the first study to model the anisotropic tensile behavior in human meniscus, and to use experimentally measured tear region strain data in attempt to validate a CDM model. Though model improvements need to be made, this study serves to inform model formulation for the human meniscus moving forward.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a minimally invasive treatment for patients with severe symptomatic aortic stenosis [1]. TAVR has historically been reserved for patients deemed to be at intermediate to high-risk for open-heart surgery. In these patients, the valves demonstrated sufficient performance and durability for the remaining life of the patient. Regulatory agencies however have recently expanded indications of TAVR to a low-risk patient population [2]. With these procedures being conducted in a younger patient population, increasing concerns exist for patients outliving the functional lifespan and durability of the valves [3].

Structural valve degeneration such as leaflet deterioration or tearing is a known temporal failure mode of bioprosthetic heart valves. The unique aspects of TAVR technology that include device crimping, asymmetric valve expansion, leaflet/tissue characteristics and valve design factors are recognized to play a role in valve structural damage and affect long-term durability. Leaflet design factors of shorter leaflet length and thinner leaflet material have been shown to improve the valve flow performance [4,5], however the influence of these factors on the leaflet deformation is unknown. The objective of this study was to investigate the effects of TAVR valve leaflet length and material on the leaflet strain as a surrogate measure of valve loading and durability.

METHODS

Creation of transcatheter heart valve designs

Three transcatheter heart valve (THV) models were manufactured with varying leaflet length (15 mm vs 12 mm) and leaflet material (bovine pericardium vs porcine pericardium).

Bovine and porcine pericardium (BP and PP respectively) were treated with 0.6% glutaraldehyde in phosphate buffered saline for approximately 36 hours. The leaflets were laser-cut from uniform sections of treated pericardium using a leaflet template designed for each model, and the leaflets were sewn unto the valve frame. Each valve frame was designed in SolidWorks (Dassault Systemes, Waltham, MA), with locations to account for the native valve leaflet, THV leaflet length, and suture holes.

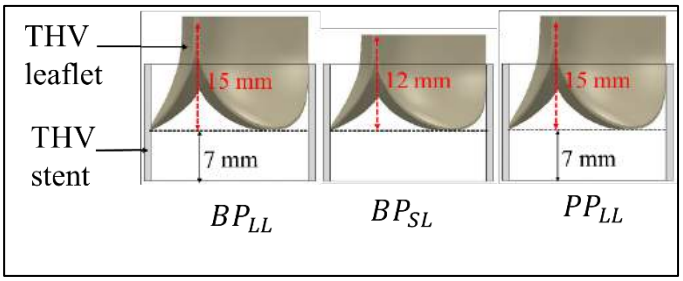

Figure 1. Schematic of THV designs. BP/PP represent bovine and porcine pericardium respectively, and LL/SL represent long and short leaflet length respectively.

In vitro testing of THV designs

Dual camera stereo-photogrammetry was used to measure the *in vitro* THV leaflet strains as demonstrated successfully in previous studies[6]. Tissue marking dye (Richard-Allan Scientific, San Diego, CA) was used to create an array of 56 markers, each approximately 1 x 1 mm^2 on one leaflet for each THV model. Each model was mounted in an idealized, rigid, acrylic aortic chamber and evaluated in a left heart simulator tuned for normotensive flow conditions. All testing was conducted using 3.5 cSt water glycerine at 37°C as the working fluid, mean arterial pressure of 100 mmHg, 5 L/min cardiac output and 70 beats/min heart rate.

The marker positions were tracked throughout the cardiac cycle using two high-speed A504k cameras (Basler Corp, Exton,

PA) and XCAP video acquisition software (EPIX Inc., Buffalo Grove, IL) to record dynamic motion of the leaflets at 200 Hz. Cameras were positioned on tripods approximately 45° relative to each other with the valve as a vertex. External illumination and the camera lenses were adjusted to provide maximum contrast between the markers and the leaflet for both cameras. After image acquisition, image calibration was conducted using a 10 mm steel cube positioned within the volume that was previously occupied by the TAV leaflets such that each camera could image 7 of the cube's corners. A 3D-coordinate system between the two cameras was defined using direct linear transformation.

The displacement and major principal strains in the commissure, coaptation and belly regions between peak systole and mid diastole for THV models were computed over one cardiac cycle using a custom MATLAB code (R2020a, Mathworks, Natick, MA). To assess the influence of leaflet length, displacement and strain fields between BP_{LL} and BP_{SL} were compared in the coaptation region only; and to assess the influence of leaflet material, the displacement and strain fields in the commissure, coaptation and belly regions between BP_{LL} and PP_{LL} were compared.

RESULTS

The results summarized in **Figure 2** and **Table 1** highlight the regional variations in displacement and major principal strain across THV leaflets.

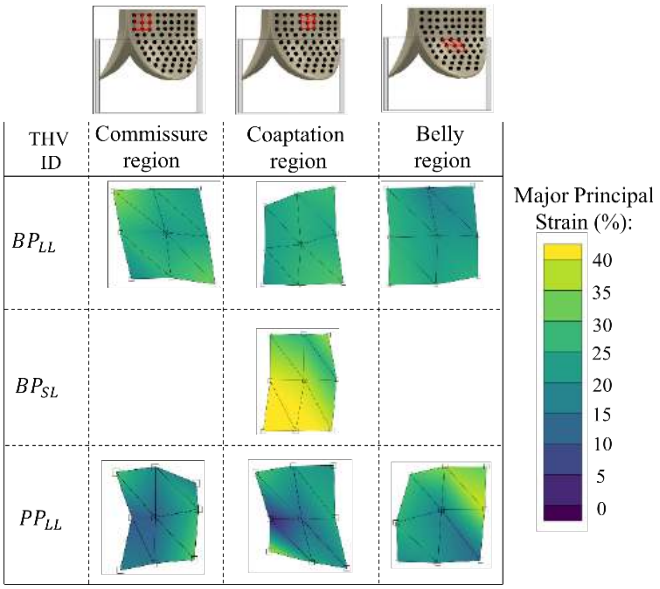

Figure 2. Major principal strain distribution across THV leaflets. BP/PP represent bovine and porcine pericardium respectively, and LL/SL represent long and short leaflet length respectively.

The BP_{LL} valve experienced the highest displacement in the belly region, and highest strain in the commissure region. Comparing the coaptation regions of BP_{LL} and BP_{SL}, BP_{SL} experienced greater displacement and strain. The PP_{LL} valve experienced the highest displacement and strain in the belly region. Comparing BP_{LL} and PP_{LL}, the commissure region of BP_{LL} experienced greater strains than the PP_{LL} valve, however, the coaptation and belly region of PP_{LL} experienced greater strain than the BP_{LL} valve. All three regions of the PP_{LL} valve experienced greater displacements than BP_{LL}. Overall, the coaptation region of BP_{SL} experienced the highest displacement and strain compared to any other model and region.

Table 1. Displacement and strain summary for each THV model at mid diastole.

THV ID	Region	Maximum displacement (mm)	Maximum principal strain (%)
BP_{LL}	Commissure	5.53	33.8
	Coaptation	5.52	29.6
	Belly	9.05	28.5
BP_{SL}	Coaptation	22.2	43.1
PP_{LL}	Commissure	7.80	30.5
	Coaptation	7.70	36.7
	Belly	9.27	37.5

DISCUSSION

The high strains observed in the coaptation region of the shorter leaflet length THV design compared to the longer leaflet length THV designs were due to the larger displacement needed to fully close the valve in diastole. With reduced coaptation length and area in a short leaflet length THV design, the leaflets undergo excessive bending to create a seal and prevent backflow under diastolic pressure. This bending results in higher strains in the coaptation and potentially the belly regions of the leaflet which overtime may lead to premature tissue degeneration. The observations of increased strains in the belly region of the porcine-based THV design compared to the bovine-based THV indicate greater deformations in the porcine-based models, which could be due to the reduced tissue thickness. This reduced thickness could amplify the leaflet stress and its distribution. The increased mechanical stress on THV leaflets may lead to accelerated tissue degeneration and diminished long-term valve durability [7]. As TAVR manufacturers seek to advance device designs, leaflet design characteristics should be optimized for hemodynamics and structural characteristics to ensure further improvement of patient outcomes and long-term durability.

INTRODUCTION

Finite element (FE) human body models (HBMs) are used to simulate various events (vehicle crash, sports impacts, etc.) and research human injury probability. Studies have shown that posture greatly influences the predicted injury[1,2]. HBMs have been developed in standard postures, such as a seated occupant or standing pedestrian, and are repositioned to different postures depending on the application. Repositioning simulations naturally cause deviations from the baseline, which can negatively affect subsequent simulations. The amount of deviation in the HBM can be quantified by measuring aspects of the model, such as contact penetrations. This has become more important with the emergence of autonomous vehicles and the potential for occupants to be in non-traditional seating postures.

A contact penetration occurs when there is an overlap between a node and the shell thickness of an interacting surface; this can be either a node overlapping a segment or two segments overlapping. Repositioning simulations can generate contact penetrations that may persist as initial penetrations in subsequent simulations depending on the contact settings invoked. When running simulations using a model with initial penetrations, the solver attempts to remove all penetrations during the first cycle by applying nodal forces. These forces can be large enough to develop non-physical stresses and strains, which may compromise model stability. Though models can be set to ignore initial penetrations and the solver will not attempt to initially correct penetrations, the presence of initial penetrations also effects the reliability and repeatability across multiple hardware and software combinations[3]. To develop reliable and reproducible results, the effects of repositioning on HBMs must be better understood and quantified. The objective of this study was to quantify how HBM repositioning parameters affect contact penetrations in a state-of-the-art HBM.

METHODS

The chosen model, THUMS v4.1 (Toyota Motor Corporation and Toyota Central R&D Labs, Aichi, Japan), was repositioned using Primer v. 17.0 (Oasys Software, London, United Kingdom) into 4 different realistic postures using volunteer and naturalistic driver and passenger data [UMTRI CITATIONS]. The 4 postures (Figure 1) were selected to cover realistic driver and passenger positions, a full range of positions, and extreme positions that challenged the robustness of the HBM.

Figure 1: The 4 end-state postures used in the study. From left to right: 23º upright posture, relaxed driver, normal driver, and 53º reclined occupant.

For each posture, the model was repositioned over three different Posture Adjustment Times (PATs) of 50ms, 100ms, and 150ms with 3 different levels of mass scaling 1x, 1.5x, and 2.0x of baseline for a total of 36 different combinations of repositioning parameters (4x3x3=36). Mass scaling is a method by which mass is added to the model in order to achieve a greater time step, resulting in a reduction of the simulation computational time.

After the PAT, the model was given 50ms to stabilize while contact penetrations were extracted every 10 ms (+0, +10, +20, +30, +40, and +50 ms). The effects of mass scaling, simulation time, and stabilization time on contact penetrations were assessed using t-tests run using JMP Pro 14.0 (SAS, Cary, NC, USA). All simulations were run using LS-

Dyna R11.0 (Ansys/LST, Canonsburg, PA, USA) using 44 cores on the Wake Forest DEAC computational cluster.

A method to evaluate the presence of contact penetrations in a FE model was developed. This method used Python v. 3.7 to automate the extraction of contact penetrations measured using LS-PrePost v. 4.8.2 (Ansys/LST, Canonsburg, PA, USA). Measurements were obtained using the built-in contact check feature of LS-PrePost and reported as vector components. After calculating the magnitude of each penetration, a threshold value of 0.036 mm, or 1 percent of the average length of the elements in the HBM, was applied. All penetrations below the threshold value were disregarded, as they were not likely to have a significant impact on the model's quality. Reports on the remaining penetrations in the model were output as the total number of penetrations, the total depth of all the penetrations, and the 95th percentile penetration depth.

RESULTS

Contact penetration data were measured as the change from the baseline THUMS model and averaged across all 4 postures for each set of repositioning parameters. Figures 2-4 show the results as three-dimensional bar charts for the total number of penetrations, cumulative depth of penetration, and 95th percentile penetration depth, respectively. Here, 0 ms refers to the end of the PAT, with 10 ms increments plotted thereafter. The 3x3 bar grid shows each of the 9 PAT and mass scaling configurations. The bold time axis labels refer to the stabilization time and the non-bold labels refer to the PAT.

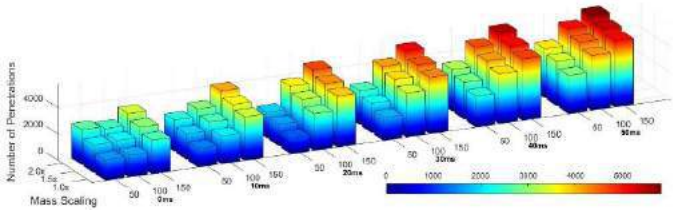

Figure 2: Total number of penetrations for each simulation.

The number of penetrations in the model increased with simulation time ($p<0.001$) and stabilization time (Figure 2), the lone exception being that the number of penetrations in the 50ms simulations decrease from +0 to +20ms of stabilization time. We hypothesize this was due a rebounding of soft tissues from the aggressive motion induced through repositioning the model in a short timeframe. The increase with mass scaling was not statistically significant ($p>0.2$).

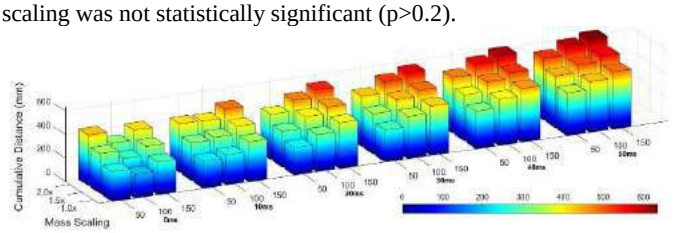

Figure 3: Total depth of all the penetrations for each simulation.

The cumulative penetration depth followed the same trends and exceptions as the total number of penetrations (Figure 3). Mass scaling also caused an increase in cumulative penetration distance for 1.0x to 1.5x ($p=0.002$) and 1.5x to 2.0x ($p=0.006$). Additionally, at +0 ms stabilization time the depth of penetrations for the 50ms simulations was larger than both the 100 and 150 ms PAT simulations.

The decrease in 95th percentile penetration depth grew with simulation time increased (Figure 4). As PAT increased, 95th percentile depth decreased, meaning that, while there were more penetrations, they were very small and receded with time. Mass scaling did not have a consistent effect on the 95th percentile penetration depth.

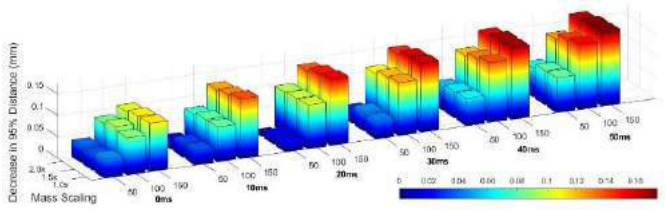

Figure 4: The decrease from baseline in 95th percentile penetration depth for each simulation.

DISCUSSION

The repositioning simulations reviewed here were developed for a larger study that aimed to determine best practices for HBM repositioning. Contact penetrations were just one of the indicators of model quality used for the greater novel study. The repositioning method affects the development of contact penetrations[4], which was seen in this study. It was found that the number of contact penetrations increased with increased simulation time and stabilization time. However, it should be noted that, while penetration count increased, the proportion of small to large penetrations increased shifting the distribution leftward during stabilization. Penetrations with a depth less than the threshold value were ignored, as they were not likely to have a significant impact on model quality. Traditionally, the contact penetrations developed in this process may lead to instability in the simulation. Contact penetrations can be removed manually or upon initialization, however, the practice that leads to the fewest and smallest penetrations should be used. The simulation was set to ignore initial penetrations for the repositioning simulations in this study. Determining the repositioning parameters that produce the fewest contact penetrations will save users a significant amount of time and effort and may serve as the first step to determining standards for repositioning practices. The growing prevalence of HBMs within the injury biomechanics community indicates their impending use in regulatory settings. As such, standard practices should be explored with the goal of reaching a broad consensus.

The results of this study are limited due to a focus on one HBM (THUMS) and a single output measure, contact penetrations. To fully understand the problem other parameters, such as mesh quality, need to be considered. These parameters are being examined in the broader research effort by our group. The strengths of this study are that wide ranges of realistic postures including large ranges of movement and were directly informed by volunteer and naturalistic occupant data were covered. Additionally, many combinations of HBM repositioning parameters were tested. Further work should investigate the initial reduction in contact penetrations of 50 ms simulations. This study found that the number of contact penetrations increase with simulation time and stabilization time while proportion of small to large penetrations increased during stabilization.

INTRODUCTION

As researchers in the fields of biomechanics and biophysics expand beyond pure fluid and solid mechanics analyses, modeling solute transport and chemical reactions is becoming increasingly necessary in different applications such as cardiovascular mechanics, respiratory mechanics, and mechanobiology, among many others. For example, finite element codes that include solute transport have been used to model thrombosis formation [1], charged solutes in cartilage [2], and drug delivery [3]. Ideally, an open-source FE code that offers both fluid mechanics and solute transport capabilities would be readily available to further facilitate verification and replication of results. However there are few such open-source software, resulting in many biomechanics researchers utilizing their own in-house codes or commercial codes, which may not be sufficiently specialized for all applications.

To model reactive solute transport, the convection-diffusion-reaction (CDR) equation is typically included as one of the governing equations. However, the CDR equation does not converge well when using the standard Galerkin residual method, particularly in high Peclet number flows where convection is dominant. Generally, under physiological conditions, solute transport poses more numerical challenges than fluid flow, as the Peclet number is usually greater than ~10^8 while the Reynolds number is ~10^3. Various methods to overcome this difficulty were proposed, such as upwinding methods [4], discontinuity capturing methods [3], and characteristic methods [5]. Researchers have also considered only steady analyses, or reduced the Peclet number to verify that the solution remains valid [6].

In this study, we formulated a new computational fluid dynamics (CFD) solute formulation derived from mixture theory [7], which was then implemented into FEBio (febio.org) [8], a free and open-source finite element software specialized for modeling biological tissues. Using mixture theory, we coupled solute transport with our previously developed CFD solver [9]. Our CFD-solutes formulation does not require stabilization methods and includes terms typically omitted from the CDR equation, such as body forces for the solutes, and osmotic effects, which include solvent transport driven by solute transport.

METHODS

Our previous CFD formulation assumed that the fluid was compressible and viscous, circumventing the need for upwinding stabilization methods. It used the fluid dilatation as a state variable, from which the pressure may be calculated [9]. Using mixture theory as a framework for the current formulation [7], we accommodate any number of distinct solute species, and include diffusion, convection, chemical reactions, osmotic effects, body forces, and frictional drag between the solvent and the solutes. The solute constituents are assumed to be dilute and intrinsically incompressible, and their respective inertia terms are neglected. The fluid momentum balance is

$$\rho^f \frac{D^f \boldsymbol{v}^f}{Dt} = -\mathrm{grad}\tilde{p} + \mathrm{div}\,\boldsymbol{\tau} + \rho^f \boldsymbol{b}^f + \sum_\gamma \tilde{\kappa}^\gamma(-R\theta\,\mathrm{grad}\tilde{c}^\gamma + M^\gamma \tilde{c}^\gamma \boldsymbol{b}^\gamma) \qquad (1)$$

where ρ^f is the fluid density, $\boldsymbol{v}^f$ is the fluid velocity, $\tilde{p}$ is the effective fluid pressure, $\boldsymbol{\tau}$ is the viscous fluid stress, γ represents each of the solute species, $\boldsymbol{b}^f$ and $\boldsymbol{b}^\gamma$ are the body forces acting on the fluid and solute γ respectively, $\tilde{\kappa}^\gamma$ is the partition coefficient of γ, R is the universal gas constant, θ is the absolute temperature, $\tilde{c}^\gamma$ is the effective concentration of γ, and M^γ is the molar mass of γ. $\frac{D^f \boldsymbol{v}^f}{Dt}$ is the material time derivative following the fluid. The mixture mass balance is

$$\frac{D^f J^f}{Dt} = J^f\left(\mathrm{div}\boldsymbol{v}^f - \hat{\zeta}\sum_\gamma v^\gamma \frac{M^\gamma}{\rho_T^\gamma}\right) \qquad (2)$$

where J^f is the fluid dilatation such that $\rho^f = \rho_r^f / J^f$ where ρ_r^f is the referential fluid density. $\hat{\zeta}$ is the molar production rate of a chemical

reaction, ν^γ is the net stoichiometric coefficient of γ, and ρ_T^γ is the true density of γ. The solute mass balance is

$$\nu^\gamma \hat{\zeta} = \frac{\partial\, \tilde{\kappa}^\gamma \tilde{c}^\gamma}{\partial t} + \mathrm{div}\boldsymbol{j}^\gamma \tag{3}$$

where $\boldsymbol{j}^\gamma$ is the solute flux of γ, given by

$$\boldsymbol{j}^\gamma = d_0^\gamma \left(-\mathrm{grad}\tilde{c}^\gamma + \frac{M^\gamma}{R\theta}\tilde{c}^\gamma \boldsymbol{b}^\gamma\right) + \tilde{c}^\gamma \boldsymbol{v}^f \tag{4}$$

Here, d_0^γ is the free diffusivity of γ. $\tilde{p}$ only depends on J^f according to an equation of state, such as $\tilde{p} = K\left(1 - J^f\right)$ where K is the fluid bulk modulus. The actual concentration is $c^\gamma = \tilde{\kappa}^\gamma \tilde{c}^\gamma$ and the actual pressure is $p = \tilde{p} + R\theta\Phi\sum_\gamma c^\gamma$, where Φ is the osmotic coefficient. This formulation was implemented in FEBio by obtaining the virtual work integrals from Eqs. 1, 2, and 3, linearizing and discretizing them with respect to the nodal degrees of freedom ($\boldsymbol{v}^f$, J^f, and $\tilde{c}^\gamma$'s), and then solving using Newton's method.

RESULTS

The FEBio CFD solutes solver was verified with a variety of test problems. 1D problems were created to ensure that all aspects of the formulation behaved as expected. Here we show the flow past a block in a narrow channel [9], where we are now also prescribing a solute concentration ($\tilde{c}^\gamma = 0.001$ mM) at the inlet in addition to the fluid velocity ($v^f = 1$ m/s). At the outlet, we prescribe $p = 0$ as well as backflow stabilization for the solute and fluid [9], where for the solute, $\tilde{c}^\gamma$ from the previous time point is prescribed in the presence of backflow. The Peclet number is ~10^3. Results at different times for the fluid velocity and concentration are shown in Figure 1. Even with the presence of vortex shedding and backflow at the outlet, the solute flow converged properly in the presence of convection and diffusion.

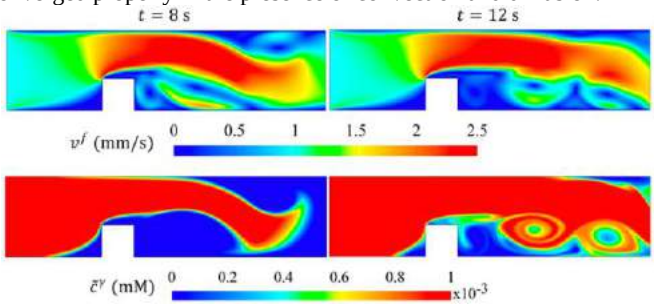

Figure 1: CFD solute flow past a block problem. Both fluid velocity and concentration are shown at different times.

In the next example, we tested the flow of different sized solute species, taking gravitational effects into account. This problem is a simple simulation of a person talking, breathing, or coughing with saliva droplets expelled into a larger domain. The solvent is assumed to be air at 25 °C with three different droplet sizes with properties Table 1.

Table 1: Properties of each of the water droplet solute species

R (μm)	d_0^γ (m²/s)	M^γ (kg/nmol)	$\tilde{c}_0^\gamma$ (pM)	τ_{sed} (s)
1	1.18×10^{-11}	2.51	5.57×10^{-9}	2130
15	7.84×10^{-13}	8490	8.35×10^{-9}	9.44
30	3.92×10^{-13}	67900	5.57×10^{-9}	2.36

The free diffusivity and expected sedimentation time, τ_{sed}, were calculated using Stokes' law using the following equations [10],

$$d_0^\gamma = \frac{k_b T}{6\pi\eta R} \tag{5}$$

$$\tau_{sed} = \frac{k_b T z_0}{d_0^\gamma m g} = \phi\frac{z_0}{R^2} \tag{6}$$

where $k_b T$ is the thermal energy, η is fluid viscosity, R is droplet radius, z_0 is domain height, $m = 4\pi R^3\rho/3$ is droplet mass, g is the gravitational constant, and $\phi = 0.85\times10^{-8}$ m s is a numerical pre-factor. Evaporation effects were ignored. The initial concentration, $\tilde{c}_0^\gamma$, was calculated from size distribution data of expiratory droplets at the mouth opening [11]. The sedimentation time calculated from Eq. 6 was verified separately for different sized droplets in FEBio. Inlet velocity was calculated from respiratory flow values from a ventilator. The Peclet number reached values up to ~10^{11}. Results are shown in Figure 2, where droplet expiration occurred in the first second within a square domain of length 0.5 m (such that $z_0 = 0.25$ m). As expected, for larger solutes, sedimentation dominated over convection.

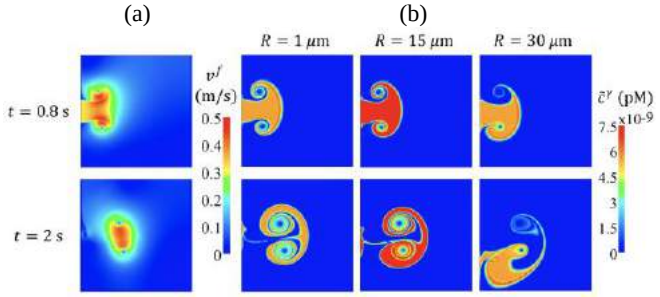

Figure 2: Different sized droplets expelled into a larger domain. (a) The fluid velocity and (b) solute concentrations are shown at two different times for three distinct droplet sizes.

DISCUSSION

In this study, a novel CFD-solutes formulation was implemented in the finite element code FEBio. It was derived from first principles using a mixture framework and is distinct from standard formulations that employed the CDR equation. This new formulation allows for diffusion, convection, chemical reactions, osmotic effects, body forces, and frictional drag between the solvent and the solutes without the need for stabilization methods. The solver behaves as expected in examples shown in Figures 1 and 2. In particular, the second example has potential implications for research in disease transmission and safety protocols, particularly for respiratory infections like COVID-19. More extensive verification and validation problems will be tested, particularly those with chemical reactions. In the future, we will also accommodate charged solutes to account for electrochemical effects. Later, we plan to couple this formulation with our biphasic fluid-structure interaction formulation [12], with the aim of developing a fully general multiphasic-FSI solver that includes all of the features in this study as well as porous media mechanics and fluid-structure interactions.

A HYBRID DISCRETE-CONTINUUM MULTISCALE KINEMATIC GROWTH MODEL

Minneapolis, MN, USA

INTRODUCTION

The evolution of biological tissues as they grow and adapt remains of vital importance for understanding disease states from aortic aneurysm to low back pain. Understanding how cells, as the active component of tissues, modulate their environment through the manipulation, addition, and removal of constituents is significant, not only from the aspect of understanding disease progression, but also for creating therapeutics such as tissue-engineered grafts.

Past work in the field of computational modeling of growth and remodeling in biological tissues has focused primarily on the continuum-level tissue growth[1–5]. These models remove the discrete nature of fiber networks with interconnected cells, and instead focus on determining an average behavior for the system. Continuum-level constrained mixture theory presents a valuable tool for understanding tissue growth, yet there exists an entirely different length scale over which the key changes in growth and remodeling actually take place.

Thus, we propose a hybrid discrete-continuum framework where we utilize discrete-fiber networks applying growth laws directly to the fibers and analyzing the growth of the material from the fiber level up through the application of kinematic growth and a fitted continuum-material response. This technique allows us to directly gather discrete information from the fiber network including fiber radii, lengths, and alignment as the remodeling process unfolds.

METHODS

Fiber Network Model: For the following simulations, we utilize a periodic Delaunay network of one fiber type, in this case, collagen, and use the helical fiber constitutive model of Freed & Doehring[6] to model the lockout behavior of the fibers with constitutive model parameters giving transition stretch of 1.145 and a lockout modulus of 20MPa.

After the boundaries have been subjected to an arbitrary deformation gradient tensor, we solve the network nodal positions at equilibrium using Newton's method. We then calculate the network stress using volume averaging as:

$$\sigma_{ij} = \frac{1}{V}\int_{\Omega} \sigma^m n_i^m n_j^m dV = \frac{1}{V}\sum_{m=1}^{M} \sigma^m n_i^m n_j^m V^m = \frac{1}{V}\sum_{m=1}^{M} f^m l^m n_i^m n_j^m \quad (1)$$

where σ_{ij} is the network averaged Cauchy stress, V is the network volume, σ^m is the fiber stress of fiber, m, n_i^m is the fiber direction vector, f^m is fiber force, and l^m is the fiber current length.

The collagen fibers are further allowed to remodel to approach a target stress state. We use the simple first-order remodeling law, given below, that couples fiber radius changes to fiber lengthening. In this model, collagen remodels according to:

$$\frac{dR}{dt} = \frac{1}{\tau}\left(\frac{\sigma^m}{\sigma_\infty^m} - 1\right); \frac{dL}{dt} = k\left(\frac{dR}{dt}\right) \quad (2a; 2b)$$

where R is the fiber radius, t is time, τ is the remodeling rate constant, σ_∞^m is the target homeostatic fiber stress, L is fiber unloaded length, and k is a constant relating the fiber radius change to the fiber length change. In our model, we use $\tau = 72h$, $\sigma_\infty = 2kPa$, and $k = 120$.

Finite Element Model: To describe kinematic growth, the deformation of a body ($\mathbf{F}$) is defined as the product of the elastic deformation ($\mathbf{F}^e$) and the growth ($\mathbf{F}^g$) at time t = T relative to the reference state at t = 0 and is given by $\mathbf{F} = \mathbf{F}^e\mathbf{F}^g$. Inherent to this decomposition of the deformation into an elastic and growth component is the requirement that the body after growth be compatible (i.e. $\nabla \cdot \sigma = 0$). Thus, even with no *external* load it is possible that $F \neq F^g$, an observation from which arises the residual stress found in many tissues. To solve this compatibility condition, we use *FEBio Studio 1.2*[7] utilizing the *Prestrain* plugin[8].

Hybrid Model Coupling: The fiber network simulations are coupled to the FE simulation by prescribing one fiber network to each element in the FE mesh. The network constitutive behavior is then used in the FE simulation to determine local deformation and stress for each element,

which is fed into the network model allowing the fibers to remodel, adjusting the rest state and changing the constitutive properties. Thus, the fiber network model is coupled to the finite element simulations using (1) Mechanical response of the fiber network and (2) Total growth of the fiber network.

In order to solve the mechanics in the finite element simulations, we use a constitutive model of the HGO-type[9]

$$W = c_1(I_1 - 3) + \frac{K}{2}(ln\ (J))^2 + \sum_{i=1}^{3} \frac{c_2^i}{2c_3^i}\left[exp\ \left(c_3^i(I_4^i - 1)^2\right) - 1\right] \quad (3)$$

where W is strain energy density, c_1 is the modulus of the ground matrix, $I_1 = tr(C_{ij})$ is the first strain invariant of the right Cauchy-Green tensor $C_{ij} = F_{iM}F_{jM}$, K is the bulk modulus, c_2^i is the fiber modulus of family i, c_3^i captures the nonlinearity of fiber family i, $I_4^i = C_{ij}N_iN_j$ is the fourth strain invariant C where N is the fiber direction vector.

The growth tensor is determined by remodeling under load, then removing the load and re-equilibrating the network to determine the new reference configuration. The result, $\mathbf{F}^g$, is combined with constitutive response and the compatibility equation is solved using *FEBio*. We then compute the deformation for the next remodeling iteration.

Model Validation: We recreated the controlled mechano-adaptation of fibroblasts in a collagen gel cruciform[10]. We looked at three scenarios: 1. Initial cruciform geometry (Fig. 1A) to remodeled with arms fixed (Fig. 1B), 2. Remodeled with arms fixed (Fig. 1B), then increase force by 20% in x and remodel (Fig. 1C), and 3. Remodeled with arms fixed (Fig. 1B), then decrease force by 20% in x and remodel (Fig. 1D).

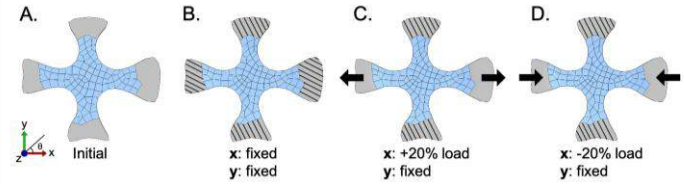

Figure 1: A.) Unconstrained cruciform, B.) Fully constrained cruciform followed by C.) uniaxial stretch of +20% baseline force or by D.) uniaxial compression of 20% baseline force.

RESULTS

To validate our remodeling approach, we compared results to Eichinger and Paukner et al. for grip force with a 20% increase or a 20% decrease in force at hour 28 as shown in Fig. 2 A and B respectively.

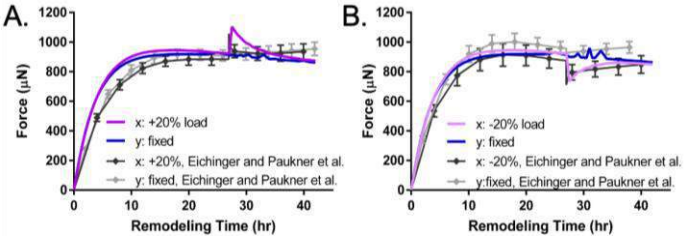

Figure 2: Measured cruciform grip loads over 42 hours with A.) a 20% increase in or B.) a 20% decrease in grip load at 28 hrs.

We further monitored individual elements and networks (Fig. 3). The residual stress in the constrained sample is shown in Fig. 3A and E immediately prior to the 20% load increase (Fig. 3B) or 20% load decrease (Fig. 3F). We also monitored the fiber network directly during remodeling. The network fiber orientations are shown in Fig. 3D and Fig. 3H for 20% increase and 20% in load, respectively. The fiber radii and lengths for networks located in each region (left/right arms, top/bottom arms, and center region) are shown in Fig. 4.

DISCUSSION

Our model recapitulated remodeling of a fixed-arm cruciform (Fig. 2A/B up to 27h). The homeostatic state in the 20% increase in load is more rapidly recovered than the 20% decrease in load in the experiment, which is not captured in our model (Fig. 2A/B after 27h). Our model accurately captures the decay rate, but not the addition rate, likely a result of different time-dependencies in collagen decay and addition.

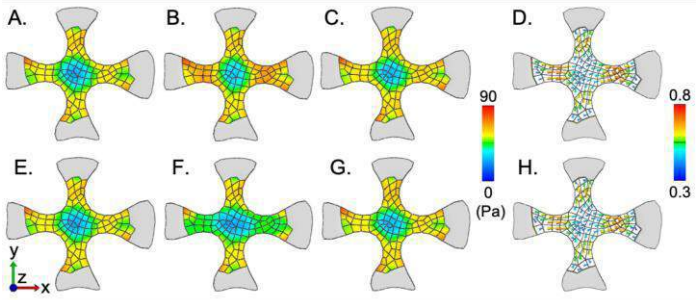

Figure 3: The 1st principal stress at remodeling time of A.) 27h, B.) 28h and C.) 42h with 20% increase in load at hour 28, and the 1st principal stress at time E.) 27h, F.) 28h, and G.) 42h with 20% decrease in load at hour 28. Principal in-plane fiber orientation (theta) at hour 42 for D.) 20% increase in load and H.) 20% decrease in load. Color bar indicates strength of alignment (maximum Eigenvalue of the orientation tensor).

Our allows insight one could not get from continuum-based approaches. We see that the orientations are relatively insensitive to the load changes (Fig 3D/H), which is evidenced by the relatively small differences seen in fiber lengths and radii relative to the +/- 20% load cases (Fig. 4). We do, however, see significant differences from the initial state to the remodeled fixed state (Fig. 4 light blue vs. dark blue bars) where the fibers shorten over time and the radii decrease.

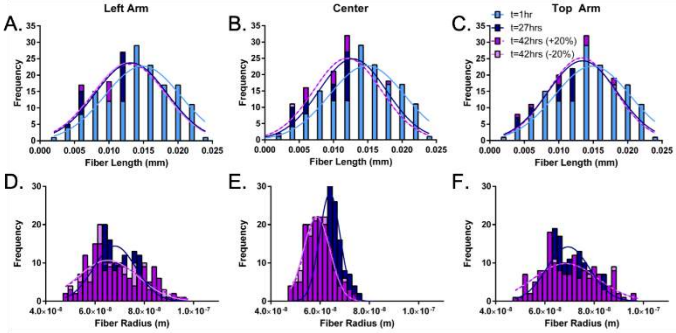

Figure 4: Length of every network fiber within a representative element shown for the A.) left arm, B.) center, and C.) top arm of the cruciform at 1, 27 and 42 hrs of remodeling. Similarly, fiber radii are shown for the D.) left arm, E.) center, and F.) top arm at 27 and 42hrs. The initial fiber radius for all fibers was 8.0 x 10^{-8} m.

This framework demonstrates the ability to capture many macroscopic observables while observing micro-scale phenomena. This framework has applications in many multiscale problems, particularly those that involve the cellular microenvironment such as pain transduction, cellular mechano-adaptation, and the cancer tumor microenvironment.

INTRODUCTION

The sarcomere is considered the basic contractile unit of striated muscle, however, the actual process responsible for generating force within the sarcomere is the cross-bridge cycle, which involves interactions between a single myosin head and an actin filament. During each cycle, myosin ATPase hydrolyzes one ATP molecule, whose energy is converted into mechanical work (shortening of the sarcomere) during the power stroke. Because each cross-bridge cycle relies on the hydrolysis of one ATP molecule, it follows ATP availability plays an integral role in the potential force generated by each sarcomere, and thus the muscle tissue as a whole. However, existing models of sarcomere contraction do not explicitly consider the free energy contributions of the concentrations of ATP and its hydrolysis products, ADP and inorganic phosphate (P_i), in the states of the cross-bridge cycle at which they are interacting with the actomyosin complex [1-3]. As a result, these models are incapable of simulating the myosin duty ratio as a function of intracellular concentrations of ATP, ADP, and P_i, and therefore cannot predict the rates of ATP consumption needed to produce and maintain certain contractile forces [4,5]. Consequently, existing models are lacking in their ability to dynamically vary ATP concentration to simulate pathological conditions such as hypoxia, i.e. low-oxygen conditions, where tissue may struggle to generate the necessary ATP to maintain the contractile stress required for proper function [1-3].

We therefore aimed to develop a model with a more physiologically relevant distribution of free energy between the various states of the cross-bridge cycle to allow for closer examination of the effects of oxygen presence and ATP availability on sarcomere force generation and maintenance. The construction of such a model will enable an analysis of experimental data that will provide information on ATP consumption for various force generation profiles. Moreover, such a model can include predictions of contractile stress at varying levels of hypoxia and overall ATP utilization required to generate and maintain desired stress levels.

METHODS

The equations that govern the dynamics of the model were formulated analytically. The stochasticity of the cross-bridge cycles was reproduced via Monte Carlo simulations. Random numbers for the Monte Carlo algorithm were generated using MATLAB's internal *rand()* function. The mechanical force balances at each node of the sarcomere model were solved by a system of linear equations. At the end of each time step during a simulation, the mechanical equilibrium of the model, and more specifically the location of each node within the lattice, was calculated using MATLAB's internal system of linear equations solver. In **Fig. 1**, the a_Z and m_M nodes indicate the Z-line and M-line respectively. k_a, k_m, k_{xb}, k_T, and k_e represent the spring constants for the linear spring elements of the actin filament, myosin filament, myosin head/cross-bridge, titin, and the external spring respectively. The dashed red line labeled m_M' indicates a displacement of the M-line that may occur as a result of a contraction i.e. a power-stroke occurring within the system. The contractile force output of the half sarcomere could then be calculated based on the displacement of the M-line from a fixed-point external to the sarcomere (**Fig. 1**).

RESULTS

Model Formulation We developed a stochastic-mechanical half-sarcomere model to predict the amount of ATP required by striated muscle to maintain a specific level of functional force output. The half-sarcomere was modeled as a series of elastic spring elements combined with the biokinetics involved in actin-myosin force generation (**Fig. 1**).

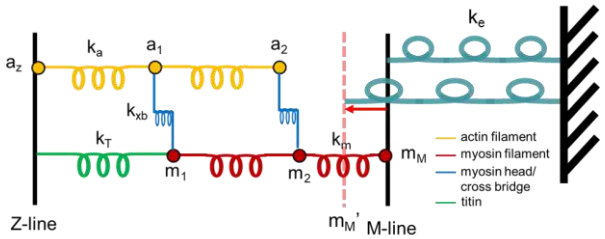

Fig. 1 Schematic of 4-Node Sarcomere Model; 2 actin (a_1 and a_2) and 2 myosin (m_1 and m_2).

The spring elements are connected at nodes, each representing either an actin binding location (on thin filament) or myosin head (on thick filament). Cross-bridges formed between the two filaments were represented by an additional linear spring element between the two attached nodes of the thick and thin filaments.

The stochastic nature of the 3-state cross-bridge cycle and calcium regulation of actin filament availability was modeled using a Monte Carlo algorithm. Actin filament availability governed the number of myosin heads that will bind during contraction and contraction strength. The cross-bridge cycle's states included in the model were (1) unbound myosin head state, (2) bound, pre-power stroke state, and (3) bound, post-power stroke state (**Fig. 2**). Rate constants of transitions from state i to state j are denoted by k_{ij}, which were calculated by defining the free energies of each cross-bridge state (equations 1-4) and the corresponding equilibrium constants K_{ij} (equation 5). Traveling through each cycle required an addition of an ATP from the environment, thus we defined state 1' as the reset energy baseline for each new cross-bridge cycle (equation 4).

$$G_1 = 0 \quad (1)$$

$$G_2 = \Delta G_{bind} + \frac{1}{2}k_{xb}x^2 \quad (2)$$

$$G_3 = \Delta G_{bind} + \Delta G_{stroke} - \Delta G^*_{\text{D,Pi rel.}} + \frac{1}{2}k_{xb}(x+d)^2 + k_B T ln\left(\frac{[ADP][P]}{[ADP]^*[P]^*}\right) \quad (3)$$

$$G_{1'} = -\Delta G^*_{hydr.} - k_B T ln\left(\frac{[ATP]/[ATP]^*}{([ADP]/[ADP]^*)([P]/[P]^*)}\right) \quad (4)$$

$$K_{ij}(x) = \frac{k_{ij}(x)}{k_{ji}(x)} = exp\left(\frac{1}{k_B T}\left(G_i(x) - G_j(x)\right)\right) \quad (5)$$

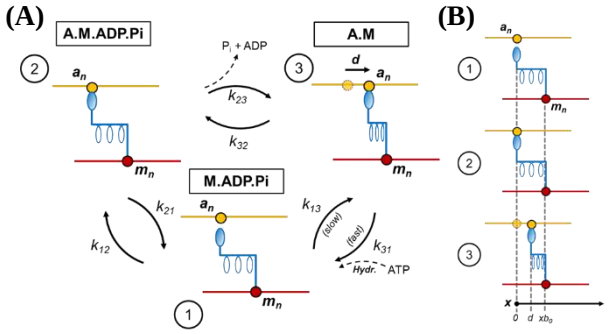

Fig. 2 (A) Schematic of 3-state Cross-Bridge Cycle. (B) Schematic of the change in displacement between a myosin node and actin node during a cross-bridge cycle

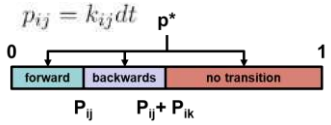

Fig. 3 The p* value determines the state transition chosen for each cross-bridge.

After state transitions are defined by the Monte Carlo algorithm, we assumed mechanical equilibrium is achieved rapidly relative to the time taken to transition between states. Probabilities of state transitions occurring are calculated as the product of the rate constant and time step (**Fig. 3**). Thus, the position of each node within the lattice was calculated by solving a detailed force balance at each node. The formulation of the model is flexible enough to allow for the addition of more actin binding sites (actin nodes) and cross-bridges (myosin nodes).

Simulation Results The model is flexible enough to be modified in accordance with different aspects of the physiology being simulated, and the free energies define fitting parameters that can be adjusted based on experimental data that can be used for validation (for example, ΔG_{bind} and ΔG_{stroke}). Outputs of the model include cardiac force generated at various levels of ATP availability and overall ATP utilization. ATPase activity is quantified by tracking state 3 to state 1 transitions during each simulation. The model is capable of demonstrating the expected step-wise manner of ATP utilization (**Fig. 4**).

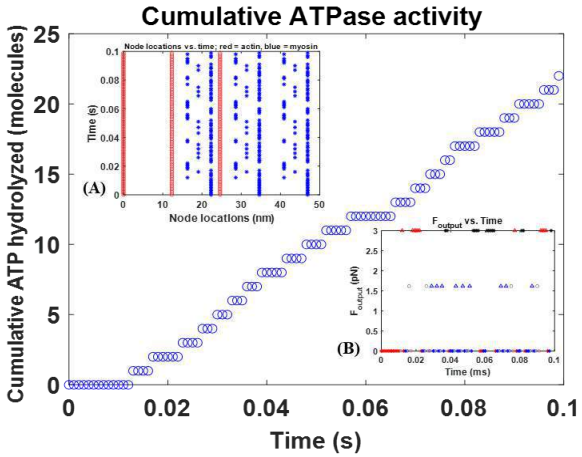

Fig. 4 Cumulative ATP utilization example. (Inset A) Location of actin and myosin nodes during simulation. (Inset B) Force output of the sarcomere and corresponding cross-bridge states of the 4-node system.

DISCUSSION

The results demonstrate that our model is capable of simulating the relationship between ATP availability and sarcomere force generation, which is an important output to investigate the relationship between mitochondrial function, oxidative phosphorylation, and overall cardiac output. Additionally, because ATP utilization persisted even while maintaining certain levels of force, our model is a good representation of the cross-bridge cycling that occurs even when a constant force is applied to a static system. This formulation of this model allows the flexibility to add more nodes and the placement of half-sarcomeres adjacent to each other to simulate larger sarcomeric lattices. Beyond the desired outputs of cardiac stress values at various levels of ATP availability and overall ATP utilization, cardiac stress generation in response to other conditions such as preload and shortening velocity will also be investigated using this model.

INTRODUCTION

Right ventricle (RV) dysfunction is common in the advanced stage of pulmonary hypertension, and RV failure is a useful predictor of mortality in these patients [1]. It has been noted that the RV becomes stiffer and more anisotropic with pressure overload [2-4]. We have previously shown that local delivery of mesenchymal stromal cells (MSCs) to failing RVs improved the organ despite persistent pressure overload, suggesting a therapeutic effect of MSCs likely due to the paracrine effects [5]. However, if and how the therapeutic effects are altered by the mechanical environment of the diseased RV is unclear.

It is evident from previous *in vitro* studies that MSC behavior and function depend on substrate stiffness, including the proangiogenic paracrine effect. However, those investigations are limited to a narrow stiffness range (0.5-88 kPa) that does not encompass the range of RV tissue stiffness obtained *ex vivo* [6-8]. Therefore, it remains unknown how MSCs respond to substrate stiffness and anisotropy that mimic RV tissue. We hypothesize that a soft and anisotropic matrix causes an increase in the proangiogenic potential of MSCs. To test the hypothesis, a new class of nanofiber scaffolds was fabricated to mimic healthy and diseased RVs. Then, the effect of the scaffolds' stiffness and anisotropy on MSC angiogenesis function was studied.

METHODS

To fabricate scaffolds, 6% or 12% w/v polyester urethane urea (PEUU) [9] was dissolved in hexafluoro-2-propanol and then electrospun into fibrous scaffolds using a custom electrospinning apparatus with a rotating mandrel (diameter: 7.46 cm). The concentration of PEUU was varied (6 versus 12%) to induce changes in stiffness, and the mandrel speed was varied (100 versus 890 rpm) for production of isotropic and anisotropic fibrous scaffolds (Table 1). Scanning electron microscopy (SEM) was performed to determine the fiber orientations using an ImageJ plugin, and histograms were plotted. The average and standard deviation of fiber angles were determined from three image regions per sample. The elastic moduli (EM) of the scaffolds (n=3 per group) along the fiber and cross-fiber directions were obtained by in-house biaxial testing after 24 hr of phosphate buffered saline soak. Human bone marrow MSCs (hMSCs) at passage 5 were cultured in 24-well plates at 10,000 cells/cm^2 on the sterilized scaffolds. Human vascular endothelial growth factor (VEGF) expression in the condition medium (CM) was determined by ELISA (Invitrogen) after 48 hr culture. DAPI staining elucidated cell counts. Data are presented as mean ± SEM. Unpaired Student's t-test was used to compare between groups and $p<0.05$ was considered statistically significant.

Table 1: Key parameters to adjust scaffold stiffness and anisotropy.

Group	Key spinning parameters
Soft & Isotropic	6% PEUU, 100 rpm
Soft & Anisotropic	6% PEUU, 890 rpm
Stiff & Anisotropic	12% PEUU, 890 rpm

RESULTS

We engineered three groups of scaffolds: a) soft & isotropic PEUU, b) soft & anisotropic PEUU, and c) stiff & anisotropic PEUU. Mechanical tests showed that the soft scaffold groups had significantly lower elastic moduli (EM, $p<0.05$) than the stiff group (Fig. 1), which mimicked the stiffness of healthy and diseased RVs, respectively.

Next, we quantified the scaffold fiber orientation and derived an anisotropy index as the ratio of the EM in the fiber direction to the EM in the cross-fiber direction. The histograms of the fiber orientations showed an even distribution of fiber angles in the isotropic group and

more aligned fibers in the other two anisotropic groups (Fig. 2A-C). The average fiber angles were 0.3±52°, -5.4±45° and -6.4±34° for the soft & isotropic group a, soft & anisotropic group b and stiff & anisotropic group c, respectively. The anisotropic index data showed comparable EM in both directions (ratio ~ 1) in the isotropic group and significantly higher ratio of EM in the other two anisotropic groups (Fig. 2D).

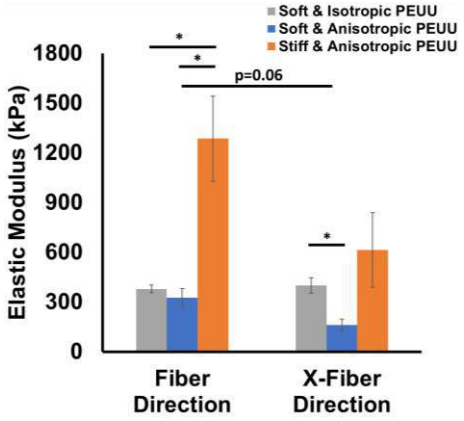

Figure 1: Elastic moduli of the three scaffold groups in the fiber and cross-fiber (X-fiber) directions. *p<0.05.

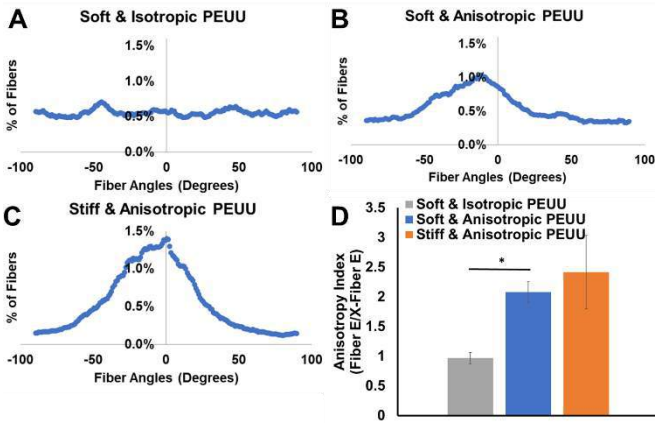

Figure 2: (A-C) Histograms of fiber orientation in the three PEUU scaffolds. (D) Anisotropy indices of the three scaffolds. *p<0.05.

After 48 hr of culture, we found the highest VEGF expression in CM of hMSCs cultured on the soft & anisotropic scaffold (group b). However, when normalized by cell counts, the stiff & anisotropic scaffold (group c) had the highest VEGF production per cell due to the lowest number of cells. Moreover, in the two soft groups, the anisotropic scaffold (group b) had higher production of VEGF per cell (Fig. 3).

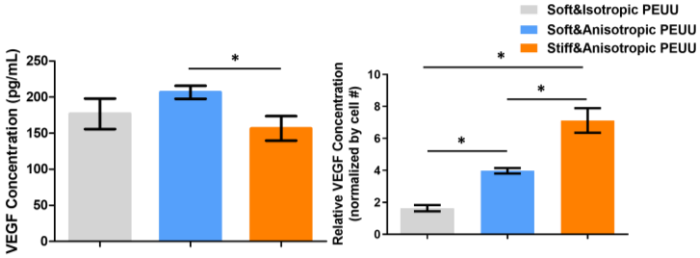

Figure 3: VEGF total concentrations in condition medium (left) and concentration normalized by cell numbers (right) in the three scaffold groups. *p<0.05.

DISCUSSION

In the present study, three different PEUU scaffold groups were engineered with different combinations of stiffness and fiber alignment – soft & isotropic, soft & anisotropic and stiff & anisotropic. The soft and stiff groups had significantly different EM, mimicking that of native healthy and diseased RV tissue. The anisotropy indices from the mechanical tests as well as fiber angle measurements from SEM showed that varying mandrel speed allowed for the production of isotropic or anisotropic scaffolds. Unlike the hydrogel matrix, the cardiac tissue is mechanically anisotropic and the diseased RV had increased anisotropy. Therefore, these electrospun scaffold groups serve as an *in vitro* platform to delineate the effect of stiffness or anisotropy on cells.

To investigate the mechanically regulated MSC proangiogenic function, we first examined the expression of VEGF, a key protein involved in angiogenesis. Our results revealed the highest VEGF production in MSCs cultured on the soft & anisotropic group. We further observed the lowest number of cells in the stiff & anisotropic group (data not shown), which is consistent with prior reports of reduced MSC proliferation on stiffer substrates [10]. The increased anisotropy also led to reduced cells as observed in the two soft groups (data not shown). As a result, when the VEGF production was normalized by cell counts, interestingly, the MSCs cultured on the stiff & anisotropic group showed the highest VEGF production per cell, indicating that higher stiffness promotes VEGF expression. On the other hand, between the two soft groups, the anisotropic group had higher VEGF expression per cell, suggesting that larger anisotropy also promotes VEGF expression. The promotion of MSC angiogenic function by fiber alignment was similarly reported by Su et al. using polycaprolactone (PCL) electrospun scaffolds (with much higher EM), although the scaffold stiffness was not measured and taken into consideration of this paracrine effect [11].

The overall VEGF production is determined by both cell number and production rate per cell. Although the increased stiffness or anisotropy enhanced the VEGF production per cell, they limited cell growth and thus the combined effects led to a maximal VEGF production in the soft & anisotropic group. We speculate that like smooth muscle cells whose contractile and synthetic (proliferative) phenotypes do not co-exist [12], the MSCs with limited proliferation may present higher proangiogenic profiles. Further examination on MSC proliferation, secretion of other growth factors in these groups and at a longer culture period will be needed to confirm our speculation.

In conclusion, the differences among the three scaffold groups showed that the MSC VEGF production was stiffness and anisotropy dependent. Our results suggest that the substrate mechanics similar to healthy RV (soft & anisotropic) may provide the best mechanical environment for MSC proangiogenic function. In general, the mechanical property of the substrate should be a key consideration to optimize MSC paracrine function and therapeutic effect for RV failure.

INTRODUCTION

Prolonged inactivity during work hours is a major factor that leads to various health issues in office workers. Office workers can spend as much as ten to eleven hours in a seated posture, causing prolonged physical inactivity [1]. This can lead to health risks such as poor metabolism, type-two diabetes, and obesity [2]. Kyphotic postures assumed during sitting have been known as a risk factor of intravertebral disc degeneration [3]. Extended times in the seated posture have also been linked to reduced blood flow and blood pooling in the legs [4].

Research indicates that breaks in prolonged sitting reduce these health risks in office workers [2]. Standing desks promote movement, however, keeping workers motivated to use the height adjustable desk has been a challenge because once the novelty of the height adjustable desk wears off, usage diminishes [5]. Also, many individuals find the standing posture problematic. Larger loads through the legs and feet during prolonged standing has been associated with musculoskeletal disorders, pain, and discomfort of the feet and legs [6]. Prolonged standing has also been known to cause blood pooling and swelling in lower legs [7].

Due to the drawbacks of the seated and standing positions, there is a need for other positions which can provide changes in body posture without subjecting the legs to large loads, yet, achieving some of the benefits of standing. The goal of this study was (a) to compare the pelvic tilt, torso openness (a measure of lumbar curvature), and ground reaction forces between seated posture, a new type of mid-seated posture and standing posture (b) to investigate the blood perfusion during posture change from seated to mid-seated as well as mid-seated to standing position (termed, dynamic motions).

METHODS

Twenty consenting participants (ten males and ten females) were recruited in this university approved research study. An 11-camera motion capture system, a six-axis force plate and a laser doppler perfusion monitoring system were used to obtain measurements. Reflective markers were attached on toe, lateral malleolus, lateral epicondyle, greater trochanter, glenohumeral joint, left and right anterior superior iliac spines (ASISs), and left and right posterior superior iliac spines (PSISs). A marker pod with four markers was attached to the sternum. Two rectangular openings were made in the backrest of the chair that allowed the markers on the PSISs to be visible while in the seated and mid-seated postures. The perfusion data was collected on the right lower leg of the participant.

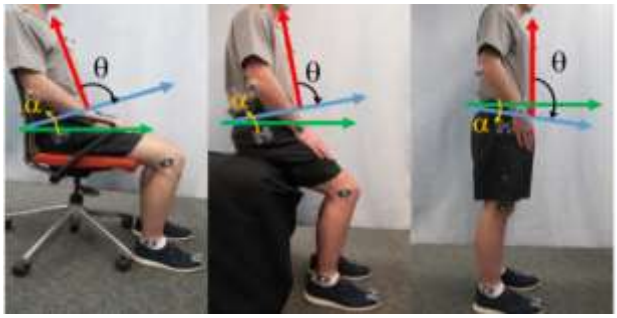

Figure 1 Vector overlay diagram of pelvic tilt angle and openness angle in seated, mid-seated and standing postures. The angle between pelvis plane (blue) and horizontal (green) provides pelvic tilt (α) and the angle between pelvis plane and torso (red) produces the openness angle (θ)

The participants were asked to conduct office tasks (typing and mousing) while assuming three different postures within an hour test period. The postures were: seated, mid-seated, and standing. The mid-seated posture was with a slightly bent knee, in an elevated chair with their feet on the ground (Figure 1). Marker position and force data were collected for every posture and blood perfusion was collected during transitions between seated to mid-seated and mid-seated to standing postures. Pelvic tilt (angle between the pelvic plane and horizontal) and openness angle (angle between the thorax and pelvis) were calculated for all postures. A repeated measures ANOVA followed by a Tukey post-hoc test was used to compare each of the following measures across the three postures: joint angles, ground reaction force and blood perfusion.

RESULTS

The average vertical ground reaction force expressed as the percent of body weight in mid-seated posture (16.41% BW) was larger than in the seated (12.55%) but smaller than in standing (96.54%). The difference in vertical ground reaction was statistically significant across all three postures. The anterior posterior ground reaction forces were largest in the seated posture (1.64%) followed by mid-seated (1.44%) and standing postures (0.03%). The differences in anterior-posterior ground reaction force between the seated and mid-seated postures were not statistically significant ($p=0.4934$). However, there were significant differences ($p<0.001$) between the mid-seated and standing postures as well as seated and standing postures. The medial lateral ground reaction forces were less than 1 percent of body weight in all three postures.

The average pelvic tilt and openness angle during all three postures are presented in Table 1. Both angle values during mid-seated posture were between that of seated and standing postures. The difference in both pelvic tilt and openness were significant for all three pairwise comparisons.

Table 1 Average joint angles and standard deviations in degrees across the subject pool for each posture

Posture	Seated	Mid-seated	Standing
Pelvic Tilt	15.3 (6.6)	6.3 (6.6)	-8.4 (7.6)
Openness Angle	96.7 15.7)	102.1 (14.0)	116.5 (17.1)

The average blood perfusions for the three postures are presented in Table 2. There was no statically significant difference in blood perfusion for three postures (p value for seated vs. mid-seated = 0.6402, p value for mid-seated vs standing= 0.5180, p value for seated vs standing = 0.1238).

Table 2 Average blood perfusion and standard deviation in perfusion unit (PU) across the subject pool for each posture

Posture	Blood Perfusion in PU
Seated	17.2 (9.5)
Mid-seated	15.6 (11.4)
Standing	13.7 (11.9)

An example of the time trace for blood perfusion during the dynamic posture change from seated to mid-seated position is presented in Figure 2. Blood perfusion for both dynamic motions increased to a maximum value during the motion, and after the participant stopped moving, dropped to near the initial value. However, the blood perfusion values did not return to the initial perfusion value immediately after the movement.

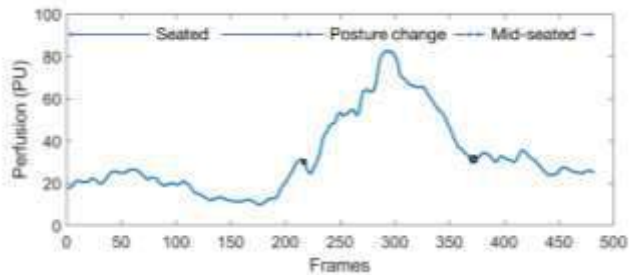

Figure 2 An example of the typical trends seen in blood perfusion during the dynamic movement from seated to mid-seated posture. The blood perfusion increased to maximum during motion then decreased, but not to the same value as before the movement

DISCUSSION

The goal of this study was to investigate the pelvic tilt, openness angle, ground reaction forces and blood perfusion across three working postures.

The difference in the pelvic tilt and openness angles among the three postures suggest that the change in posture permitted additional body movements, especially the pelvis. It is interesting to note that while in the mid-seated posture, the pelvis articulated a point halfway between the seated and standing postures. This is seen as a benefit for this new posture. An increased openness angle is another measure that confirms lumbar articulation is occurring in the mid-seated posture, even though the person is still in a chair. Previous research has shown that a larger openness angle is correlated to an increased lordotic lumbar curvature [8]. This change in lumbar curvature is a positive as posture changes promote blood flow and nutrient transport to the intervertebral discs [9].

Change in posture from seated to mid-seated and mid-seated to standing increased the blood perfusion, which reduces one of the biggest issues for office workers- blood pooling. The blood perfusion data indicated that during the motion, the blood flow increased, and it remained larger than the initial value for a time after the motion. The duration for increased perfusion varied and was subject dependent.

The ground reaction force data indicated that the anterior-posterior or shear loads were smaller in the mid-seated posture than sitting. As expected, the mid-seated posture resulted in smaller vertical loads than the standing posture.

To summarize, the mid-seated posture provided a pelvic orientation and lumbar posture closer to that of standing, while subjecting the legs to a lower vertical loads than in standing. Changing postures from seated to mid-seated as well as from mid-seated to standing increased the blood flow as well as provided motion to the joints. The use of mid-seated posture as an additional working posture could reduce health issues in the office workers.

INTRODUCTION

Aviation safety standards are articulated by the Federal Aviation Administration (FAA) and are used by aircraft manufacturer in the testing of their equipment. In recent decade, there has been increase interest among airline industries to install seats at an oblique orientation to the centerline of the aircraft, in order to maximize seating density and increase comfort. For this novel seating configuration, the current FAA standard only allow seat installation angles ranging from 18º-45º for oblique-facing and 80º-100º for side-facing. However, the existing safety standard in the commercial passenger aircraft were developed based on fore- or aft-facing seats and pure side-facing seats.

The oblique seating configuration put forth unique safety challenges, since the occupant kinematics and loading during emergency landing scenario differ from the traditional fore- or aft-facings and side-facing seats. The human body tolerance to injury in restrained oblique dynamic loading is also unknown and likely different than for pure frontal or pure side loading. Limited work has been done to understand the injury and response of an occupant seated on the aircraft seats installed at different orientation relative to aircraft centerline.

Recently, a series of whole-body Post-Mortem Human Surrogate (PMHS) sled tests were conducted with the aim to assess the gross occupant kinematics and evaluate potential injuries in oblique loading configurations [1]. The test used a survivable crash pulse defined by the FAA [2]. In this test series, two installation angles were investigated, that set the seat centerline at 30° and 45° to primary loading vector. From this testing, multiple injuries were seen throughout the body. However, the complete transection of the vertebral column at L5/S1 level was noteworthy. The authors concluded that these injuries were a combined multi-axial bending and tension. Although, the PMHS tests have shed light on our knowledge of the spinal distraction injury mechanisms, the segment level loads and moments associated with the failure is required for better evaluation of oblique seats in the aircraft environment.

The preliminary test results underscore the need for additional cadaver tests, but physical testing comes with high cost, large data scatter and difficulty in instrumentation. As an alternative, computational modeling can overcome the limitation of physical tests. One such modeling approach was performed in this study using a 75-year-old 50th percentile male Global Human Body Model Consortium (GHBMC) model, with the aim to validate against previous whole-body PMHS oblique impact sled tests and to assess the response and injuries occurring in the lumbar region. The validated model was then simulated with different seating orientations to study the influence of seat configuration on the occupant response.

METHODS

The 75-year-old model was originally developed for automotive crashworthiness applications [3]. The selection of this model was appropriate, as such the actual test used for model validation had male specimens with the age of 65 years and above. The previously conducted PMHS tests comprised of seven instrumented whole-body sled tests, characterized by peak sled acceleration, seat orientation, pelvis restraint, leg constraint, knee angle and presence or absence of armrest. For the purpose of validation in this computational study, a whole-body PMHS test performed with the specimen positioned on a seat installed at 45° orientation relative to the loading vector. In this condition, the specimen's pelvis was restrained using a body-centered belt and traditional lap-belt. Also, the legs were constrained at the thigh and tibiae. The test was performed with no armrest and had a peak sled acceleration of 16 g over 145 ms.

Similar seating and boundary conditions were implemented in the current computational study. Figure 1 shows the simulation setup and the surrogate orientation relative to the primary loading vector. All simulations were completed using LS DYNA 971_R4.2. The model biofidelity was based on the resultant acceleration and angular velocity measured at T6, T12 and S1 levels along the spinal column and was assessed using CORA (CORrelation and Analysis) rating [4]. The test-reported tensile injuries of the spine were validated in the model by measuring the intervertebral distance and comparing the maximum value against the spinal injury threshold obtained from isolated spine tests in tension loading [5]. Parametric simulations were performed with varied seating orientation ranging from 0° to 90° with 15° increment in the angle.

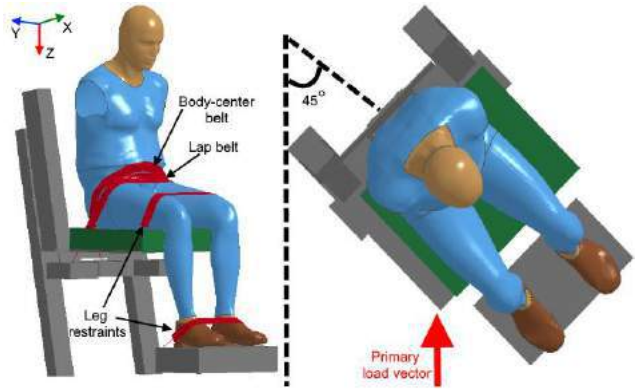

Figure 1: Simulation setup

RESULTS

The overall CORA score ranged from 0.567 to 0.702. The model predicted spinal and pelvis failure locations were consistent with the test reported injury locations. The parametric analysis showed a linear trend among the spine axial loads measured at L5 and T12 levels and it decreased with increase in the seat installation angle. The peak bending moments measured at T12 and L5 levels are shown in Figures 2A and 2B.

It can be observed from the L5 moment plots that the peak lateral moments increased linearly with increase in installation angle, while the peak flexion moments decreased linearly with increase in installation angle. With respect to T12, the peak lateral moments were constant across the installation angle, while the Y moment reversed its bending direction from flexion to extension at 45° orientation onwards. Additionally, the T12 peak moments were relative lower compare to the moments measured at L5 level. This implies the susceptible nature of the lower lumbar spine in aircraft environment.

DISCUSSION/CONCLUSION

The study aimed to evaluate the biofidelity and assess the lumbar spine response to different seat orientation relative to the primary loading vector. The overall biofidelity score for the spinal column ranged from 0.567 to 0.702. The parametric simulations showed a linear trend among the spinal loads with R^2>0.9. The axial force decreases with increase in seat installation angle, consistent with previous modeling study [6]. Additionally, the current study also measured the lateral and forward bending moments, which showed a trend with respect to seat installation angle. The initial data from this study put forth the necessity to develop new lumbar spine injury criterion, comprising of bending moments and axial force for obliquely positioned seats.

Occupant loading in far-side crashes is generally longer in duration than nearside and, hence, more similar to an aircraft emergency pulse, although at a lower delta V. The far-side PMHS studies were performed at 90 and 60 degrees [7, 8]. These studies evaluated gross kinematic of the occupant, with specific interest in head excursion relative to impact direction. Head excursions from the present study matched better with these studies. However, no data was available to compare the model predicted lumbar spine moment.

The preliminary modeling provides the effect of seat orientation on the lumbar spine loads and moments, which will be helpful in designing aircraft seats and countermeasure techniques. The limitation does exist in the current study with respect to the spine model. The selected GHBMC version lacks 3D discs between the lumbar segments, instead they were connected using 1D beam element. Efforts are ongoing to simulate the latest GHBMC with well-developed spine model to evaluate the spine response to FAA crash pulse.

INTRODUCTION

During standing, the lumbar spine experiences compressive and anterior shear forces. Consequently, the resulting flexion moment causes sagittal imbalance. In order to restore sagittal balance, the posterior muscles of the spine (i.e. posterior chain) must generate sufficient extension. Thus, realistic loading conditions to simulate standing should involve application of posterior muscles to offset the flexion moment that results during standing.

Prior spinal finite element (FE) studies utilize a compressive follower load to represent standing [1,2]. These studies result in no facet contact and inherently cause sagittal balance. While phenomenologically accurate, the lack of appropriate lines of action of muscle force may not represent the load sharing between the disc and facets. Further, these biomechanical models do not provide the ability to investigate alterations in posterior chain strength with respect to the stresses experienced by the disc and facets.

Therefore, the objective of the current study was to establish a set of FE loading conditions that includes the inertial contributions of the upper body as well as the counteracting posterior chain of muscles. We hypothesized that the application of the posterior Erector Spinae (ES) muscles will result in spinal kinematics and disc pressure consistent with experimental studies involving compressive follower loads while also experiencing facet contact forces.

METHODS

A previously developed and validated finite element model of a lumbar motion segment was utilized for the current study [3]. A Three-Dimensional Static Strength Prediction Program (3DSSPP, University of Michigan) was used to determine the loading conditions for the model. Four 3DSSPP analyses were conducted to determine the upper body weight and predicted ES force during an upright standing posture for adult males of heights and weights consistent with a 5th percentile, 50th percentile, and 95th percentile male. An additional run was conducted to represent the male volunteer in a previously published *in vivo* study with a height and weight of 66 inches and 154 pounds, respectively [4].

Axial compression representative of body weight above the L4-5 motion segment, as determined by the 3DSSPP analyses, was applied 15 mm anterior of the center of the L4 superior bony endplate to simulate standing [5]. The inferior bony endplate of L5 was fixed rigidly in space. A surface-to-surface contact was established between the L4 and L5 posterior elements. The ES was simulated by attaching bi-lateral force elements between the spinous processes approximately 5.5 cm posterior of the joint center. The amount of ES force applied for each scenario was based on the results of the 3DSSPP analysis. Table 1 depicts the upper body weight and ES force applied to the FEM (Finite Element Model) for each of the four scenarios. Figure 1 shows the FEM. The lordotic angle, i.e. intersegmental rotations (ISR), facet joint reaction forces, and disc pressures were recorded.

Table 1: Loading conditions for each scenario.

	Wilke 1999	5th Male	50th Male	95th Male
Upper BW	280 N	209 N	347 N	489 N
ES Force	53 N	80 N	116 N	156 N

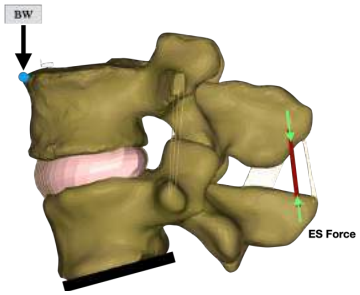

Figure 1: Lateral view of the L4-5 motion segment FEM depicting the boundary conditions utilized to simulate standing.

RESULTS

The 3DSSPP predicted ES muscle loads consistent with *in vitro* data. Specifically, the *in vitro* data demonstrated an estimated ES muscle load of 100 N during standing [6]. The average ES muscle loads predicted by 3DSSPP for all scenarios in the current study was 101 N. For each scenario, results of the current FE study showed peak intervertebral disc pressures and ISRs between L4 and L5 that were consistent with *in vitro* data [4,7-11] (Figure 2 and Figure 3). The peak *in silica* disc pressures were 0.42, 0.26, 0.45, and 0.65 MPa for the 154-lb male, 5th male, 50th male, and 95th male scenarios, respectively. The peak disc pressures agreed well with the *in vivo* data, which showed disc pressures ranging from 0.27 to 0.76 MPa during standing. The ISRs between L4 and L5 also agreed well with *in vivo* data. Wood 1996 demonstrated ISR during standing in the range of 8.8° to 25.6° and Lin 1994 demonstrated ISR during standing of 12.2°±4.4°. The current study resulted in ISRs of 12.6°, 10.6°, 12.2°, and 13.6°, for the 154-lb male, 5th male, 50th male, and 95th male scenarios, respectively.

The facet joints came into contact in all four scenarios. The total facet contact force was 384, 392, 578, and 789 N for the 5th male, 50th male, and 95th male scenarios, respectively. The largest facet contact force was seen in the 95th-percentile male scenario, where the ES muscle load was the largest, while the smallest facet contact force was seen in the Wilke scenario, where the ES muscle load was the smallest (Figure 4).

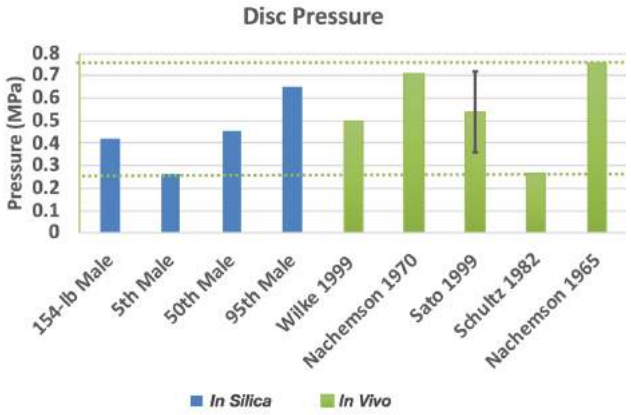

Figure 2: Peak *in silica* disc pressures during standing for each scenario compared to *in vivo* data.

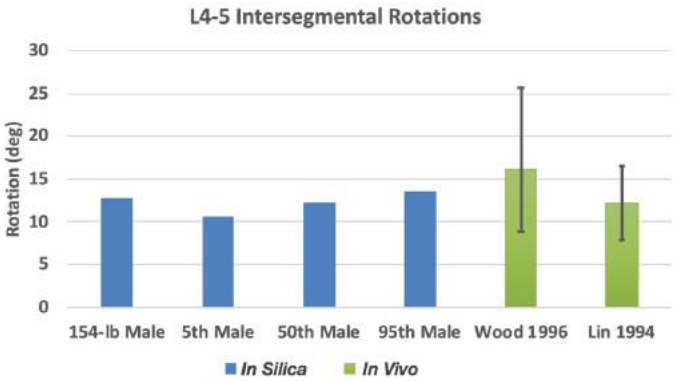

Figure 3: *In silica* L4-5 intersegmental rotations for each scenario compared to *in vivo* data.

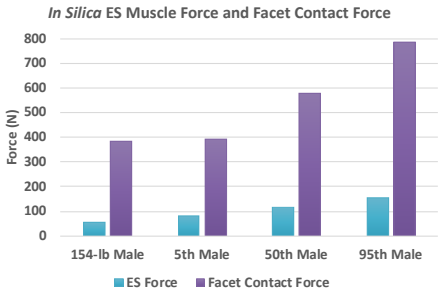

Figure 4: *In silica* ES muscle loads and total facet contact forces for each scenario.

DISCUSSION

The loading conditions for standing utilized in the current study correlate well with published *in vitro* and *in vivo* data. Further, the results demonstrate that the application of upper body weight in conjunction with an offsetting posterior ES muscle load result in disc pressures and intersegmental rotations consistent with published *in vivo* data.

The results of our study confirmed the hypothesis that the application of ES muscle load would result in spinal kinematics and disc pressures consistent with experimental studies while also experiencing facet contact. There was a linear correlation ($R^2 = 0.9407$) between ES muscle load and facet contact reaction force. It is not surprising that greater ES muscle loads resulted in increased facet joint reaction forces. Prior studies in the literature have demonstrated increased facet loads with increased extension moment, which is generated by the activation of the posterior extensor muscles, i.e. ES muscles [12,13].

While the use of a follower load to simulate standing may have undeniable applications, those loading conditions are not fully representative of physiological spinal loads. Studies that have utilized a follower load have resulted in disc pressures and intersegmental rotations that were consistent with *in vivo* data. However, utilizing a follower load does not consider the effects of appropriate muscle action and neglects the contribution of the facets in load sharing, and therefore, has limited clinical application in scenarios where physiological loading conditions are required.

Utilizing loading conditions that mimic physiological spinal loads during standing has many clinical applications. Specifically, the current FEM provides a platform for future studies that involve investigations into the relationship between posterior lumbar muscle strength, facet contact, and disc health. The current model is limited to a single lumbar motion segment and future studies should involve utilizing a full lumbar FE spine to establish physiological loading conditions applicable to the whole lumbar spine. However, we predict that the physiological loading conditions demonstrated in this study will remain applicable to the whole lumbar spine.

INTRODUCTION

An accurate failure metric plays a critical role for noninvasive assessment of patient-specific rupture/dissection risk of ascending thoracic aortic aneurysm (ATAA). Previously, isotropic material failure metrics were often adopted in biomechanical risk assessment of aortic aneurysms. However, experimental studies [1,2] have revealed that the aortic wall strengths in the circumferential and axial directions are significantly different. Hence, to incorporate direction-dependent failure properties, an anisotropic failure metric needs to be developed and applied.

Patient-specific failure properties (i.e., aortic wall strengths) can only be accurately determined using invasive and destructive tests, and these tests, obviously, cannot be performed for *in vivo* patients whose ATAAs are still intact. Some studies suggested to use deterministic approaches to estimate failure properties [3,4]. However, since the large variability of aortic wall strengths was not considered in the deterministic approaches, the predictive capability is limited.

In this study, we developed a novel probabilistic and anisotropic failure metric for ATAA risk assessment. Uniaxial failure tests were performed using aortic tissue samples from 84 ATAA patients, from which a two-dimensional (2D) joint probability distribution of the anisotropic wall strengths was obtained. Subsequently, an anisotropic failure probability (FP) based on the Tsai-Hill (TH) failure theory was developed from the probability distribution of the circumferential and axial strengths. Using computed aortic wall stresses, the novel FP metric can be used to estimate the risk of an individual ATAA patient. For method validation, "ground-truth" risks of additional 41 ATAA patients were numerically computed from finite element analysis (FEA) using CT images and matching tissue testing data. Using the "ground-truth" data, different risk assessment methods and failure metrics were compared and assessed.

METHODS

Aortic Tissue Samples and CT Image Data. In this study, surgically resected human aortic tissues of 98 ATAA patients (72 males, 26 females, age: 62.57 ± 12.42 years) were obtained from the Emory Saint Joseph's Hospital, GA with IRB approval. In addition, we obtained surgically resected aortic tissue samples and matching CT images of 27 ATAA patients in a previous study [5] from the Yale-New Haven Hospital, CT.

The cohort of 125 (98+27) ATAA patients was divided into two groups: (1) 84 patients without CT images; and (2) 41 patients with CT images (including 27 patients from our previous study [5]). Group 1 was used for method development; and Group 2 was used to compute the "ground-truth" risks for method validation. Hence, there is no overlapping between the two groups.

Uniaxial Tests and Failure Criterion. Uniaxial tensile tests were then performed using the 98 ATAA tissue samples. For each ATAA patient, circumferential and axial specimens were obtained and subjected to uniaxial tensile tests until failure, from which circumferential and axial strengths were extracted.

In this study, the TH criterion was used for modeling failure properties of the aortic tissues. The TH model has demonstrated a good fitting capability with off-axis tension test data of aortic tissues.

Probabilistic and Anisotropic Failure Probability (FP). The anisotropic probabilistic failure metric is developed in the following steps: (1) estimating the joint probability density function (PDF) of the TH model parameters (circumferential strength and axial strength) from uniaxial testing data of Group 1 by using kernel density estimation (KDE); (2) evaluating the KDE-estimated PDFs by performing goodness-of-fit tests using the estimated joint PDF and marginal PDFs; (3) deriving PDF of the TH failure metric, by using the method of random variable transformation (a.k.a. the technique of changing

variables); and (4) calculating the failure probability (FP) using numerical integration.

Validation Using Patient Data in Group 2. In this study, "ground-truth" risks of additional 41 ATAA patients (Group 2) were computationally estimated using matching CT images and tissue testing data from individual patients. Uniaxial failure tests and planar biaxial tests were performed for patients in Group 2 to obtain failure properties and hyperelastic properties, respectively. To estimate ATAA risk, patient-specific geometries were numerically inflated until rupture in FEA using patient-specific hyperelastic and failure properties. For a particular patient, the pressure rupture risk (PRR) [5] is used to quantify the risk revealed by the patient-specific FEA (to compute stresses) and the patient-specific TH model (to determine failure). Using the estimated "ground-truth" data, the following risk assessment methods and failure metrics were compared and assessed: 1) maximum diameter criterion; 2) maximum FP failure metric at systolic blood pressure; 3) maximum TH failure metric at systolic blood pressure using typical deterministic value of circumferential and axial strengths; 4) maximum FP failure metric at elevated pressure (1.5 systolic); and 5) maximum deterministic TH failure metric at 1.5 systolic pressure. Due to static determinacy [6], patient-specific hyperelastic properties are not needed in methods 2) and 3). Patient-specific hyperelastic properties were used in methods 4) and 5). These methods were used to classify high (PRR≥0.6) and low risk (PRR<0.6) patients. The receiver operating characteristic (ROC) curves were used to evaluate the discriminative power of the methods.

RESULTS

FP Metric. The FP metric was developed from failure property data of 84 patients. The value of FP represents the probability of failure. FP can be visualized on a 2D plot of circumferential and axial stresses. In Figure 1, 2D contour plots of FP are generated using representative shear stress $\tau_{\theta z}$ values.

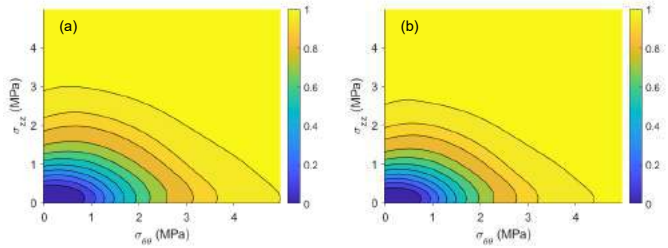

Figure 1. 2D FP contour in the circumferential and axial stress plane ($\sigma_{\theta\theta} - \sigma_{zz}$) with shear stress $\tau_{\theta z}$ (a) 0 and (b) $300kPa$.

Validation. Probabilistic FP and deterministic TH metrics of the 41 ATAA patients (Group 2) were computed by using the patient-specific geometries and blood pressures. Using the maximum diameter criterion, no statistical significance was found between the high and low risk groups (p=0.1677). Difference between high and low risk groups is significant using the maximum FP at systole (p=0.0117), while p=0.0099 when the same method is used with TH. Using patient-specific hyperelastic properties and the maximum TH under elevated pressure, the p-value is low (p=0.0017). The most significant difference was found for FP under elevated pressure (p=0.0001). ROC curves are shown in Figure 2 for failure metrics evaluated at systolic pressure (Figure 2(a)) and 1.5 systolic pressure (Figure 2(b), using patient-specific hyperelastic properties). The plots are generated using false positive rate (FPR) versus true positive rate (TPR). The area under the ROC curve (AUC) is 0.5489 for the diameter criterion. Using the FP and TH under systolic pressure, AUCs are 0.8448 and 0.8017, respectively. Under elevated pressure (1.5 systolic pressure), the AUCs are 0.8621 and 0.8362 for FP and TH, respectively. The results indicate that the probabilistic metric FP has a better discriminative power comparing to the deterministic metric TH.

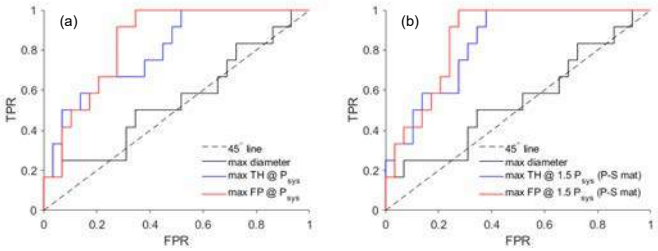

Figure 2. ROC curves of diameter criterion, probabilistic (FP) and deterministic (TH) failure metrics. (a) FP and TH under systolic pressure; (b) FP and TH under 1.5 systolic pressure.

DISCUSSION

In this study, a novel failure metric is developed based on a probabilistic modeling framework, which can be adopted for other types of materials. By employing the TH model, anisotropic failure properties are embedded in FP. Comparing to the deterministic TH metric, FP incorporates uncertainties of wall strengths, i.e., the distribution of the circumferential and axial wall strengths in the ATAA population. With more tissue failure testing data collected, FP can be updated and improved, e.g., a conditional FP can be built based on patient-specific information (age, gender, family history). Using reconstrued risk data, this study demonstrated that the performance of FP metric is superior to the deterministic TH metric with representative failure parameters. To our best knowledge, this is the first study that develops a probabilistic and anisotropic failure metric for aortic aneurysm risk assessment.

Using the estimated risk of the 41 patients, we found that the biomechanical failure metrics (TH and FP) have more discriminative power than the maximum diameter criterion. Using patient-specific hyperelastic properties and FP, the highest AUC is achieved by FP under elevated pressure, which highlights the potential benefit of identifying patient-specific hyperelastic properties for risk assessment. When patient-specific hyperelastic properties are not available, FP can be evaluated on image-derived geometries using static determinacy [6] without the need of patient-specific hyperelastic properties.

In this study, an ideal scenario was assumed, in which the wall thickness can be accurately measured from MRI or high-resolution CT scans. Hence, AUC of the failure metrics could be close to the upper limits. Using an uncertainty quantification (UQ) framework, the wall thickness, which is the input to the FE simulations, can treated as a source of uncertainties. We have recently developed a deep learning model [7] as a fast and accurate surrogate of FE simulation, which can replicate the results of FE simulations instantaneously. To incorporate uncertainties originated from FE inputs such as wall thickness into FP, the DL model can be used to accelerate the UQ framework.

INTRODUCTION

Helmets are an essential piece of equipment for protection against mild traumatic brain injuries (mTBIs) and other head injuries in sporting activities. The Canadian Journal of Public Health has called mTBIs a "silent epidemic" in Canada. The occurrence of mTBIs has increased by an annual percentage change of 9.6% across all age groups in Canada between 2005 and 2014 [1]. Improving the way a helmet protects the wearer from mTBIs can decrease the occurrence of these injuries.

A mTBI is usually caused by a kinematic impact to the head or upper body, with which there are significant strains in the tissue cells of the brain that may cause damage. Impact severity can be qualified by average maximum principal strain (MPS) and cumulative strain damage measure (CSDM) values, such as $CSDM_{25}$ which is calculated by dividing the volume of elements of MPS over 0.25 by the total volume of the elements in a model. In this case, these elements are finite modelling elements that exist within the Global Human Body Models Consortium (GHBMC) human brain finite element model.

This study intends to specify which kinematic input metric or combination is best able to predict accurate MPS and $CSDM_{25}$ values. We explored various ways to predict these values with an artificial neural network, and how changing the training and test database sizes of the artificial neural network affected the results of the artificial neural network's MPS and $CSDM_{25}$ predictions.

METHODS

The data used in this study was originally collected by *Levy el al.*, in which six helmets were assessed a Hockey STAR rating via experimental tests. [2]. In total, each of the six helmets labelled A to F, were put through an average of 112 tests, resulting in 672 tests in total [2]. The kinematic data of each helmet impact, linear acceleration, rotational acceleration and rotational velocity was collected [2]. Using a custom MATLAB script, LS-DYNA, and LS-PrePost, the MPS and $CSDM_{25}$ values were calculated. Incidence STAR values were output, and subsequently Hockey STAR values were calculated.

The Multilayer Perceptron procedure within SPSS Statistics was used to produce a predictive artificial neural network (ANN) model for which kinematic data was most accurate in predicting real MPS and $CSDM_{25}$ values from the collected data. Different combinations of kinematic inputs were used as covariates. Combinations were tested with a random subset of data used for training and the remainder for testing. The ANN-predicted MPS and $CSDM_{25}$ values were plotted against the actual MPS and $CSDM_{25}$ values from simulations. An R-squared value was generated in Microsoft Excel. The R-squared value of each combination tested was used as the comparator for which combination of kinematic inputs was most accurate, and the combinations were ranked in order.

The ANN was subjected to a sensitivity analysis. This evaluated how sensitive the results generated by the ANN were to different test and training subset breakdowns and showed how well the ANN could predict average MPS and $CSDM_{25}$ values for helmets excluded from the ANN testing and training process. Two test and training subset breakdowns were examined. One divided the data set 70% for training and 30% for testing, and the other 80% training and 20% testing. Over a second series of tests, certain permeations of helmets were excluded from the Multilayer Perceptron ANN creation process. The remaining helmets that were included were used to create the ANN. The created ANN was then used to predict the MPS and $CSDM_{25}$ values for the helmets that were excluded based on the network created from the included helmets. The predicted results were then plotted in Excel against the actual results. Sets of one, two and three helmets were excluded to see if the quality of the prediction dropped below a threshold R-squared value of 0.95.

RESULTS

Fifteen combinations of covariates were used in the analysis. This analysis was completed using 70% of the dataset as a training set and 30% as a testing set. The five strongest correlated kinetic input variable combinations are shown in Table 1. Definitions for the kinematic inputs used in Table 1 are explained in Table 2.

Table 1: Five Strongest Correlated Kinetic Input Variable Combinations, Ranked by R-Squared Value

Case Number	Associated Kinematic Input Variable Combination	R-Squared Value
Case 15	$\boldsymbol{LinA_{x,y,z}} + \boldsymbol{RotV_{x,y,z}} + \boldsymbol{RotA_{x,y,z}}$ + **RPLV** + **RPRV** + **RPRA**	0.988
Case 7	$\boldsymbol{LinA_{x,y,z}} + \boldsymbol{RotV_{x,y,z}} + \boldsymbol{RotA_{x,y,z}}$	0.985
Case 4	$\boldsymbol{LinA_{x,y,z}} + \boldsymbol{RotV_{x,y,z}}$	0.978
Case 5	$\boldsymbol{RotV_{x,y,z}} + \boldsymbol{RotA_{x,y,z}}$	0.955
Case 14	**RPLV** + **RPRV** + **RPRA**	0.955

Table 2: Kinematic Input Variable Definitions

Short Form	Kinematic Input Variable
$LinA_X$, $LinA_Y$, $LinA_Z$	Linear Acceleration in X, Y, and Z Planes
$RotV_X$, $RotV_Y$, $RotV_Z$	Rotational Velocity in X, Y, and Z Planes
$RotA_X$, $RotA_Y$, $RotA_Z$	Rotational Acceleration in X, Y, and Z Planes
RPLA	Resultant Peak Linear Acceleration
RPRV	Resultant Peak Rotational Velocity
RPRA	Resultant Peak Rotational Acceleration

Case 15, which had the greatest number of kinematic inputs, was the variable combination with the highest R-squared value, and subsequently is the best predictor of both average MPS and $CSDM_{25}$ values.

Figure 1 shows how the R-squared value trends as a greater number of helmets are excluded from the ANN generation process.

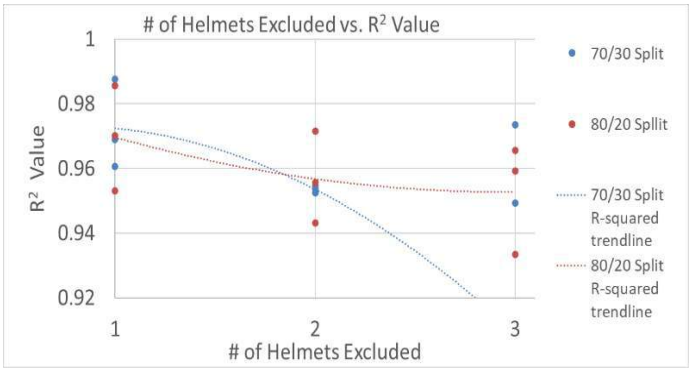

Figure 1: Number of Helmets excluded versus resultant ANN R-Squared Value

DISCUSSION

The prediction combination of kinematic variable inputs with the highest R-squared correlation value was Case 15, which was expected as it contains all twelve potential kinematic input variables. The next three highest cases all contained rotational velocity, which aligns with the current scientific consensus that rotational velocity should be given higher weight than linear or rotational acceleration and is a better predictor of brain strain than other kinematic inputs. The data shows that when rotational velocity is not included in the set of kinematic inputs to the ANN, the ANN's prediction ability decreases significantly.

A kinematic input variable combination of only the peak rotational velocity, linear and rotational accelerations was considered in Case 14. This combination was found to be an unexpectedly efficient way of predicting MPS and $CSDM_{25}$ values. By utilizing the peak kinematic values in the ANN creation, there is a 75% reduction in the amount of data variables that must be collected from the accelerometer, as compared to Case 15. This reduction comes from the kinematic input combination only requiring peak values. The results of using this combination show that high quality predictions of MPS and $CSDM_{25}$ values can still be made with fewer overall data variables collected from each individual test, which may be useful if testing is scaled up significantly.

As more helmets were excluded, the ANN was created based on less data. Consequently, the training and testing sets were smaller and the ANNs ability to accurately predict MPS and $CSDM_{25}$ values was expected to decrease. As the number of helmets involved was decreased from one to three, the R-squared values did decrease, but one half of the trials that were conducted with three helmets excluded still had R-squared values that were greater than 0.95, indicating a high degree of correlation was still possible.

Of the six helmets that data was collected for, three helmets, labelled A, B and C, had good Hockey STAR ratings. The other three helmets, labelled D, E and F, had poor Hockey STAR ratings. A good Hockey STAR rating, for the purposes of this study, was defined as a rating that is less than 6. A poor Hockey STAR rating, for the purposes of this study, was defined as a rating that is greater than 8. None of the six helmets that were assessed had Hockey STAR ratings between 6 and 8. It was determined that using only the helmets with a good Hockey STAR rating or using only helmets with a poor Hockey STAR rating to predict MPS and $CSDM_{25}$ values would result in a less precise prediction than a mixture of good and poor Hockey STAR rated helmets. This was particularly noticeable when there was less data to train and test the ANN that will be used for prediction (e.g. when the data of only three helmets was used).

Having more test data and testing a greater number of helmets would further reduce the error in the ANN prediction process. Having a greater selection of helmets would allow more exclusion and prediction options. Additionally, it was noted that when comparing predicted versus actual MPS and $CSDM_{25}$ values, there were gaps between clusters of data because there were no actual MPS and $CSDM_{25}$ values available for those ranges. The location of these gaps varied for each helmet. Eliminating these gaps and having a more equal spread of data would also further reduce the overall error.

In conclusion, as long as an appropriate training and data exclusion strategy is selected to ensure accuracy, ANNs are an effective tool to use in the study and prediction of brain strain, and in predicting the risk of mTBI occurrence.

INTRODUCTION

Inadequate inclusion of females in medical research has been a matter of concern for a long time. In 1993, the US National Institute of Health (NIH) Revitalization Act was issued, which mandated the inclusion of women in federally supported phase III clinical trials and appropriate reporting of sex effects [1]. Though these policies increased the number of female clinical-research participants, sex bias was still persistent in preclinical studies [2]. In 2014, NIH issued additional guidelines to ensure the inclusion of both sexes in preclinical research [3], yet the success of these policies is mostly unknown, except for a few fields [4].

A recent study found that less than 50% of biomechanical studies had balanced sex distribution in their samples [5], while another identified sex bias in orthopaedic research [6]. We opted to investigate a more specific field in our current study: finite element analysis in hip arthroplasty. Hip fracture is nearly twice as common in women compared to men in the US [7], as are total hip arthroplasty (THA) surgeries. Yet, surprisingly, sex-dependent characteristics are not always considered in design, modeling, and analyses of THA viability. A common method for comparing the viability of THA implants is finite element (FE) modeling because of the accessibility and low-cost operation of computation approaches compared to benchtop experiments. FE modeling is also useful for estimating and analyzing the biomechanical behavior of implanted prostheses. This tool can offer subject-specific insights when modeled accordingly.

In the current study, we first asked if and how FE modeling has been systematically used for comparing sex differences in FE modeling of THA implants. As FE modeling lays the groundwork for clinical research, it is important to understand sex-based differences in models. We performed a systematic review of the literature in 5-year increments to determine if sex bias exists in FE modeling and if and how demographic reporting in FE modeling of hip implants has changed over time.

METHODS

The study design is shown in Figure 1. In brief, PubMed database was systematically searched for eight different years from 1984 to 2019 at discrete 5-year intervals (1984, 1989, 1994, 1999, 2004, 2009, 2014, and 2019). The search keyword was 'Hip and Finite Element'. A total of 432 records appeared in the search; from these, reviews and non-English articles were removed. The remaining records were requested through the University of Michigan Library to obtain the full text. Some articles requested via inter-library loan were excluded due to loan delay of greater than 7 days. 410 full-text articles were acquired and read in total. Articles were excluded from this study if they: (1) were on animal models; (2) did not include FE modeling; (3) were not on hip implants; (4) did not have bony geometry; and (5) were studied in non-physiological conditions. This approach reduced the included articles to n = 122. Demographic data (sex, race, and age) of the following data were noted from the included articles: (1) geometry; (2) Young's moduli; (3) Poisson's ratio; (4) bone density; (5) loading; and (6) model validation. Data were analyzed in Prism v9.0 (GraphPad, LaJolla, CA). The number of studies that used male, female, or other bony geometric models was compared between discrete publication years. If a study used the geometry, Young's moduli, and bone density of the same subject, we identified it as 'subject-specific model,' and their percentage at respective years was plotted. The percentage of studies using experimental model validation was also calculated.

RESULTS

The number of studies that passed the eligibility criteria each year gradually increased and reached steady-state around 2009, ranging from 3 to 32 per year. We found that, generally, researchers model male geometries more frequently than females in the FE analysis of hip

implants (Figure 2). Most articles did not state the sex of the geometry they used (referred to as 'unknown', 25%-100% in earlier years), though this number reduced over time. In more recent years (e.g., 2009 onward), the use of female geometry increased; nonetheless, it was still less common compared with males. Up to 25% of studies annually were based on geometry obtained from surrogate or composite bones (e.g., Sawbone). Some studies did not describe their model; however, that number is relatively low (3 out of 122, not shown in Figure 2). Of all the articles included in this review, fewer than 10% reported geometries from both sexes.

As expected, the percentage of articles that used subject-specific FE modeling increased over time (Figure 3a). In general, the number of studies with male subject-specific models or models of unknown sex were higher than that of female. Surrogates were sometimes used to develop a 'subject-specific' model (e.g., < 5% in 2014 and 2019).

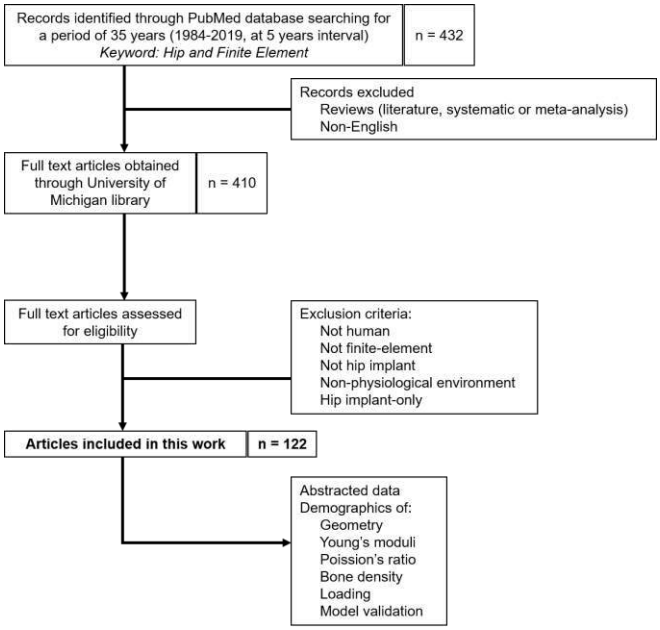

Figure 1: Study flow diagram.

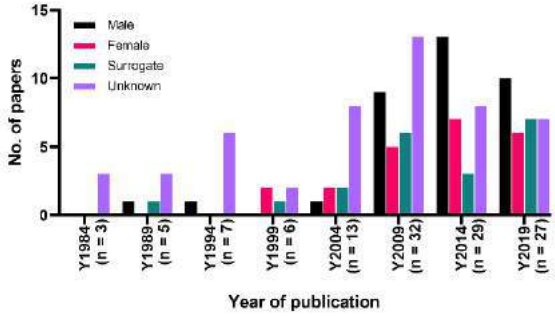

Figure 2: Sex distribution of geometric models in FE analysis of hip implant studies. Most analyses reviewed in this study relied on male geometries. n denotes the total number of articles each year.

The FE model validation rate was less than 50% in all eight years that have been studied (Figure 3b). Besides cadavers, surrogates were also a common option to validate the FE model experimentally, and an upward trend is observed. In recent years (2014 and 2019), almost 50% of the validation studies were completed with surrogates.

Of the demographics included in the studies reviewed systematically, race was the least reported. Fewer than 10% of the articles included in this study stated the race of the subject's geometry.

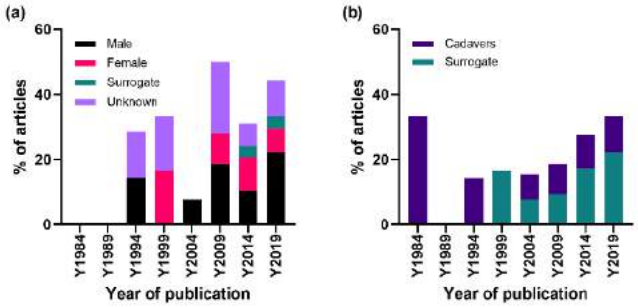

Figure 3: Percentage of articles that included (a) subject-specific models and (b) experimental model validation. Both show an upward trend for increased prevalence over time.

DISCUSSION

We reviewed 122 articles published over 35 years and found convincing evidence that sex bias exists in FE studies of hip implants. We found that male subjects or characteristics are modeled more often than females. Though the number of studies including female geometries has increased recently, we have not yet reached sex equity in FE modeling of hip implants, especially given the increased rate of women undergoing THA compared to men [8].

Bony pelvic geometries are significantly different between men and women. The mature female hip has a greater width to height ratio, anterior pelvic tilt, femoral anteversion, quadriceps angle, acetabular socket depth, and femoral head width compared with the male [9-10]. Such geometric dissimilarities are also observed across different races [11]. Thus, hip joint loading vectors may not be the same between sexes or among races. Moreover, even in the same age group, bone density is different in men and women and can also vary between race [12]. As bone density and strength are directly correlated [13], it is important to consider sex and race while defining the model in FE analysis.

The use of bone surrogates has increased in recent years. Surrogates generally have properties similar to human bones but do not possess inter-specimen variability. However, when it comes to subject-specific FE modeling, surrogates cannot be considered an alternative to the patient-specific bones. As surrogates are designed around a particular age group, these bone analogs may fail to represent aged bone properties.

Subject-specific FE models provide precise information about individuals and help make more informed decisions about patients. However, studies based on only one subject provides information specific to only that subject. We recommend inclusion of multisubject patient-specific models which correspond to different ages, sexes, and/or races so that the results can be applied to a wide range of demographics.

INTRODUCTION

Majority of nontraumatic subarachnoid hemorrhage, which is a devastating condition that carries high rates of mortality, morbidity, and disability, is caused by intracranial aneurysms (IAs) rupture (or called cerebral aneurysms). IAs have an estimated prevalence of 2% - 3%, but most of them stay unruptured [1][2][3][4]. Although medical image technology facilitates detection of unruptured IAs, distinguishing high rupture risk aneurysms remains challenging since the rupture mechanism is not well understood. Mechanically, the wall stress plays a key role in aneurysm rupturing. To accurately obtain local stress results, the thickness of the wall must be known. However, it is impossible to obtain the wall thickness *in vivo* with current medical image technology. Recently, aneurysm wall thickness distribution based on color translucence of intraoperative images are studied [5,6]. The study suggested that the relative wall thickness can be estimated from the pixel intensity. The relative thickness, in conjunction with an inverse method of stress analysis which can effectively determine the wall tension, may open a way to estimate the relative stress level in IAs, and thus locate the high stress region.

To explore the idea, we conduct a pilot study. A patient specific aneurysm 3D model is segmented from computed tomography angiography image, and inverse stress analysis is performed to predict the tension distribution in the wall. The aneurysm is further sub-divided into dome, neck and bleb regions based on their geometric locations; and average tensions in these regions are computed. Later, color intensities of the three regions are computed. Based on Beer-Lambert Law, the relative color intensity level is considered to be a relative thickness level. The relative stress is then computed.

METHODS

The lumen of aneurysm is segmented from CTA medical images and then the 3D geometry is reconstructed using Insight Toolkit (ITK). The wall thickness was set to 0.3 mm uniformly in both parent artery and aneurysm region. The inlet and outlet of the models were fixed. The inner surface of the model was loaded with a uniform pressure 85 mmHg. The inverse finite element method developed by Lu's group was applied on 3D aneurysm models. The method takes the imaged geometry as the current configuration and solves the wall stress by means of finding the reference configuration. For thin walled, sack-like structures, the method enables to determine the stress using hypothetical material models. In the analysis, we used a 5-parameter Mooney-Rivlin type strain energy density function as in [7], which writes as:

$$W = C_{10}(\bar{I}_1 - 3) + C_{01}(\bar{I}_2 - 3) + C_{20}(\bar{I}_1 - 3)^2 + C_{11}(\bar{I}_1 - 3)(\bar{I}_2 - 3) + C_{02}(\bar{I}_2 - 3)^2$$

where $\bar{I}_1$ and $\bar{I}_2$ are the first and second invariants of a normalized deformation gradient $\mathbf{F}$. The material coefficients C_{ij} were obtained from published experimental data [8]. Specifically, C_{10}, C_{01}, C_{02}, C_{20}, and C_{11} are set to 0.42, -0.12, 0.56, 0.58 and 0.585 MPa respectively for all cases computation in this paper. Note that since the uniform wall thickness is assumed, the 'stress' so obtained is in fact the wall tension scaled by the assumed thickness.

To obtain relative thickness information, Beer-Lambert law is employed. The law writes in:

$$A = \varepsilon l c$$

where A is the absorbance, ε is the absorptivity of the attenuating species, l is the optical path length and c is the concentration of the attenuating species. In this study, we assume ε and c are constant for the aneurysm tissue. Absorbance A can be computed by $\log(\frac{I_{out}}{I_{in}})$, where I_{in} and I_{out} are color intensities of incident and transmitted lights respectively. According to Anderson et al., to linearize the intensity, intensity I can be computed with:

$$I = 0.2126\,R + 0.7152\,G + 0.0722B$$

where R, G, B are red, green, blue color value within a pixel [9]. Noted that the image was taken in a surgery room illuminated by white light, $I_{in} \approx 1$. Therefore, color intensity ratio between two locations can be estimated by

$$\frac{Log(I_1)}{Log(I_2)} \approx \frac{I_1}{I_2} \quad (1)$$

RESULTS

As shown in Figure 1, an aneurysm sac is sub-divided into three different regions: bleb, which is a rounded outgrowth on the sac; neck is a annular band connected the sac and its parent artery, and dome is the region between the bleb and neck area. Average tension in bleb, dome and neck regions are 0.13, 0.18 and 0.27 MPa·m respectively. Tension ratio values between dome and neck, bleb and neck are 0.67 and 0.48.

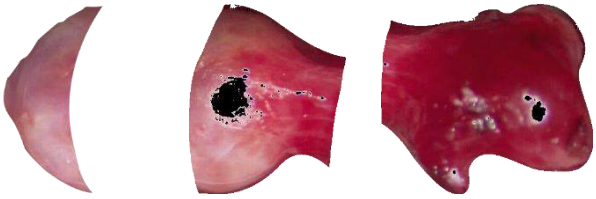
(a) Bleb (b) Dome (c) Neck

Figure 1: Sub-divided regions demonstration.

Rupture site of the aneurysm is carefully observed by doctors during traumatic surgery and scrupulously marked out in the 3D models as shown in Figure 2.

(a) Rupture site (b) Intraoperative image

Figure 2: Rupture site identification and intraoperative image.



(a) Neck (b) Dome (c) Bleb

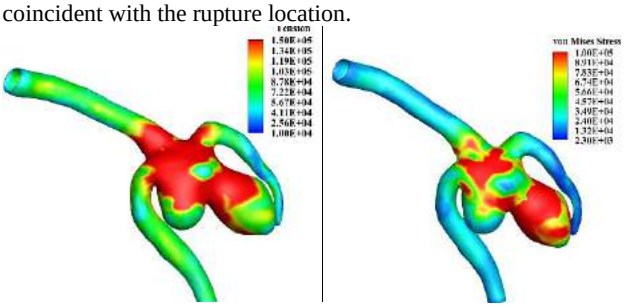
Figure 3: Image sub-divided regions demonstration.

The intraoperative image is sub-divided into three regions correspondingly as presented in Figure 3. Glary spots on the image are excluded in intensity calculation. Average intensity in bleb, dome, and neck regions are 0.15, 0.43 and 0.49 respectively. Thickness ratio between dome and neck is 0.88, bleb and neck is 0.31. By definition, stress is equal to tension divided by thickness. Consequently, stress ratio between dome and neck is 0.76, between bleb and neck is 1.55. Stress level of bleb region is the highest in the three. Ratio calculations are summarized in Table 1.

Table 1: Relative ratios of tension, thickness and stress

Ratio	Bleb/Neck	Dome/Neck	Neck/Neck
Tension	0.48	0.67	1.00
Thickness	0.31	0.88	1.00
Stress	1.55	0.76	1.00

With the thickness ratio, regional stress level distribution is calculated. Since thickness information of the parent artery is missing, we assume it is the same as the thickness of neck. To compare, tension and stress distribution are plot side by side in Figure 4. As can be seen in Figure 4 (b), most of the high stresses concentrate at the bleb region. Based on the rupture site identified on 3D model (Figure 2 (a)), the region is coincident with the rupture location.



(a) Tension (b) Stress level

Figure 4: Tension and stress results

DISCUSSION

The current medical technology is not able to measure the thickness *in vivo* and this hinders the prediction of wall stress. Under this condition, estimating relative thickness, and thus to estimate the relative stress level, merits investigation. In this abstract, a new method that integrates *in vivo* tension analysis and relative thickness estimation from intraoperative image is explored. Relative thickness ratio between dome and bleb (also rupture location) regions is found to be about 2.87. MacDonald et al., used polarized light microscopy to estimate the thickness and found a ruptured wall-thickness ranges between 16 – 212 μm [10]. By taking average value 114 um and considering the aneurysm dome thickness is about 300 μm [11], dome over bleb ratio is about 2.63 which is close to our findings. Also, thickness of dome and neck regions are roughly the same which agrees with the conclusion by Sherif et al. [12]. In conclusion, our case study shows that relative thickness level of an aneurysm sac can be reasonably estimated, and the results indicate that the rupture site may have the highest relative stress level.

INTRODUCTION

The lamina cribrosa (LC) is a connective tissue that forms part of the eye wall in the optic nerve head (ONH). The human LC is formed from cribriform plates composed of elastin, collagen types I and III, and various proteoglycans [1]. When viewed *en face*, the plates resemble a beam and pore network. The LC functions to support the capillaries, cells, and axonal structures of the optic nerve head from the various loading conditions imposed by the intraocular pressure (IOP), intracranial pressure, and extraocular muscles [2]. RGC axon injury has been shown to occur at the LC in human glaucoma and in animal models of glaucoma with increasing IOP [3]. The severity of axon damage in glaucoma is strongly associated with IOP, and higher IOP is associated with increased prevalence [4-5]. The LC has been shown to remodel with glaucoma. The plate-like structure thins and becomes more curved with progressive axonal damage [6]. The collagen, elastin, and proteoglycan composition also change, and the pores may become smaller [1,7-8]. Therefore, the structure, curvature, and biomechanics of the LC are important aspects of glaucoma that may differ between diagnosed glaucoma eyes and normal eyes.

Previous work by Ling et al. [9] examined the LC network microstructure of eyes with no known history of glaucoma and found that lower pressure-induced LC strains were associated with structural features that indicated greater collagen density and beam connectivity. Midgett et al. [10] compared the strain response of normal eyes to glaucoma eyes and found that the stiffness of the LC pressure-strain response was greater in diagnosed glaucoma eyes. The objective of this study is to measure the curvature and features of the collagen beam-network structure of the LC of post-mortem human glaucoma eyes and analyze for differences between diagnosed glaucoma and age-matched normal eyes.

METHODS

We received 10 normal human eyes and 16 diagnosed glaucoma eyes with an age range of 76-93 years and average ages of 83.8 ± 6.1 years and 87.3 ± 5.4 years, respectively [10]. The optic nerves of the enucleated eyes were cut flush to the sclera to remove the post-LC myelinated optic nerve and to reveal the trabecular structure of the LC. The posterior scleral cups were subjected to inflation testing at 5 and 45 mmHg. At each pressure, the LC was imaged using laser scanning second harmonic generation (SHG) imaging as described in Midgett et al. [11]. SHG image volumes were analyzed using digital volume correlation (DVC) to calculate the strain field caused by inflation from 5-45 mmHg [11].

The maximum intensity Z projection of the SHG image Z stack was enhanced using Frangi filter and masked before being analyzed by a custom algorithm developed by Ling et al. [9] for ten structural features including pore area fraction, beam aspect ratio (length/width), and tortuosity (contour length/straight-line distance) of the LC beams (Fig 1) [9]. Average pore size was calculated with a modified version of this method where each image of the SHG image Z stack, instead of the maximum Z projection, was enhanced and masked. Each layer was processed by the algorithm and pore size from each z-slice was averaged to obtain the overall average pore size for the LC.

Curvature was calculated by creating a point cloud of the anterior surface of the DVC-correlated LC volume and fitting a 5th order polynomial to the point cloud using Matlab curve fitting toolbox. Curvature of the surface was determined using the Matlab *surfature* function [12].

To investigate the regional variation of the strain response in the inflation test and structural features, the LC was divided into eight regions centered about the central retinal artery and vein (CRAV), resulting in 80 total regions across the 10 normal eyes and 128 total

regions across the 16 glaucoma eyes. The structural and strain outcomes were averaged over all the LCs and regionally. Preliminary analysis comparing normal eyes to glaucoma eyes are reported using linear regression and unpaired t-tests.

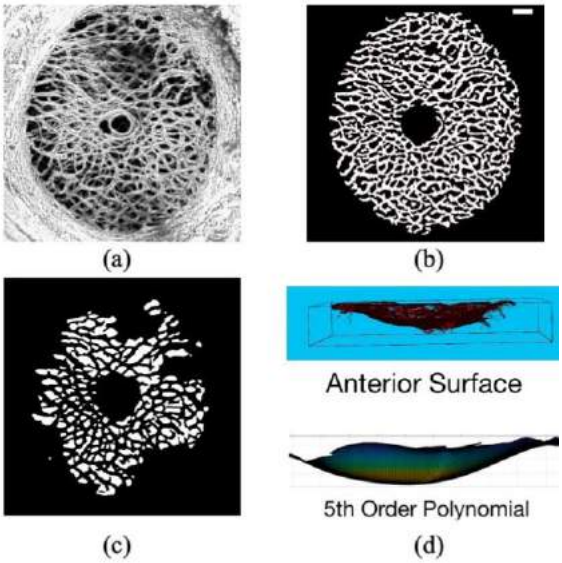

Figure 1: Morphological analysis of the SHG imaged volume of a human LC showing: (a) the maximum projection of the SHG volume, (b) a binary mask of the LC collagen network (scale bar = 200 µm) (c) pores in one slice of the SHG volume, (d) anterior-most points of the SHG volume, and a 5th order polynomial surface fit.

RESULTS

Preliminary results showed the specimen averaged mean curvature (p=0.023) and Gaussian curvature (p=0.015) were significantly greater in the 16 diagnosed glaucoma LCs compared to 10 age-matched normal eyes (Fig 2a). The beam tortuosity was significantly greater in diagnosed glaucoma eyes than age-matched normal eyes (p=0.002) (Fig 2b), while the averaged pore size (p=0.016) and beam aspect ratio (length/width) (p=0.04) were significantly smaller in 16 glaucoma eyes than 10 normal eyes (Fig 2c & d).

Comparisons of the regionally averaged outcomes (n=80 for normal and n=128 for glaucoma eyes) showed that the mean curvature (p<0.001), gaussian curvature (p<0.001), maximum curvature (p=0.004), and tortuosity (p<0.001) were significantly greater in glaucoma eyes than normal eyes, which were consistent with the analysis for the specimen-averaged outcomes. The beam length was significantly shorter (p=0.006), and the beam width was significantly wider (p=0.013) in glaucoma eyes than normal eyes, which were consistent with the finding of a smaller specimen-averaged beam aspect ratio in glaucoma eyes.

Linear regression analysis for the regionally averaged strains in glaucoma eyes showed that the regionally averaged principal strain increased with an increase in principal curvature (n=120, p=0.04). Additionally, principal strain increased with increasing pore area fraction (n=120, p=0.001). The regionally averaged shear strain increased with an increase in pore area fraction for glaucoma eyes (n=120, p≤0.001) and normal eyes (n=74, p=0.03). However, glaucoma eye shear strain increased at a higher rate than normal eye shear strain.

DISCUSSION

The results described glaucoma eye LC microstructure as having

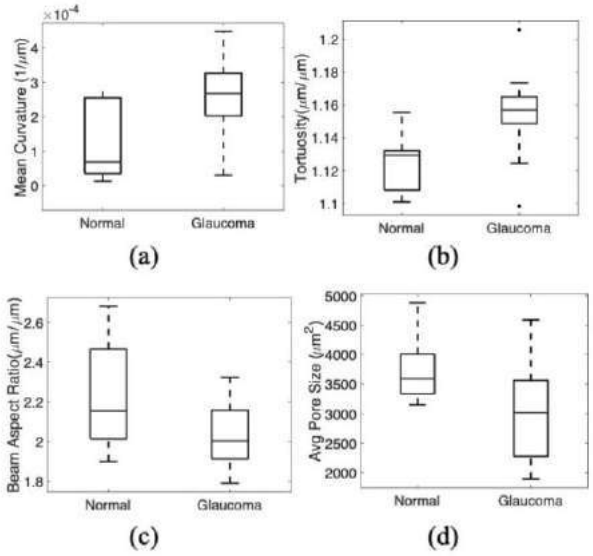

Figure 2: Comparing the specimen averaged (a) mean curvature, (b) tortuosity, (c) beam aspect ratio, and (d) average pore size of the LC of normal (n=10) and glaucoma eyes (n=16) using unpaired t-tests. The mean curvature and tortuosity were higher in glaucoma eyes than normal eyes (p≤0.04), while beam aspect ratio and average pore size were lower in glaucoma eyes than in normal eyes (p≤0.04).

curvier, shorter, and wider beams with smaller pores and higher LC curvature than normal eyes. Some of these features, such as the smaller average pore size and beam aspect ratio in glaucoma eyes may contribute to a stiffer pressure-induced strain response of the LC found in early glaucoma eyes. In contrast, the greater curvature and beam tortuosity should produce a more compliant strain response. Results will be verified using generalized estimating equation models and linear mixed models.

The work demonstrated the need for computational modeling to estimate the effects of the curvature and LC network structure on the strain response.

INTRODUCTION

Males and females have been found to respond differently to cardiovascular disease (CVD)[1]. Prior studies[2-3] have investigated cardiovascular sex differences in healthy subjects to better understand sex differences in CVD. 4D Flow MRI is an increasingly used tool to study cardiac function by non-invasively measuring time-resolved velocity fields in the heart and large vessels[4], and previous studies using 4D Flow MRI have shown kinetic energy (KE) and vortexes to be altered in a variety of CVDs[5-6].

The 4D Flow MRI literature has neglected that cardiovascular function is a combination of both the heart and vasculature's status. The first conceptual framework of the cardiac and vascular interactions was formulated as ventricular vascular coupling (VVC)[7]. The purpose of this study was to apply the concept of VVC to define a novel metric 4D Flow MRI VVC based on the hypothesis that elevated kinetic energy in the left ventricle (LV) is not necessarily inefficient if LV KE is successfully transferred to aortic KE.

METHODS

In this IRB-approved and HIPPA-compliant study, 20 subjects with no history of heart disease (10 male and 10 female) were recruited. MRI was performed on a 3.0T imaging system using bSSFP sequence and the 4D Flow MRI sequence PC-VIPR[8]. Ventricular volumes were segmented and quantified calculated from bSSFP images, and the LV and aorta were segmented from time-averaged 4D Flow MRI, using the Mimics (Materialise, Leuven, Belgium).

Kinetic energy at peak systole and peak diastole for the LV and peak systole for aorta, along with vorticity (ω), and viscous energy loss (EL) for both the LV and aorta were calculated from equations 1, 2, & 3,

$$KE(t) = \int_V \frac{\rho}{2} u_i(t)^2 dV \quad (1)$$

$$\omega = \frac{1}{V\,T_{HB}} \int_{T_{HB}} \int_V \boldsymbol{\nabla} \times u_i dV\, dt \quad (2)$$

$$EL = \int_{T_{HB}} \int_V \mu \mathbf{S_{ij}^2} dV\, dt \quad (3)$$

where ρ is density (1060 kg/m3), ui is the velocity vector, V is the segmented LV or aortic volume, ∇× is the curl operator, THB is the heartbeat duration, and Sij is the strain rate tensor. The results were normalized by stroke volume and normalized by mask volume, in dimensionless form for the LV and aorta, respectively. VVC for both KE and vorticity was calculated by calculating the LV-to-aorta value ratio. Aorta wall shear stress (WSS) was calculated from triangulated surface meshes by taking the cross product of the velocity vector and the surface normal vector and then averaged over the aorta surface, as shown in equation 4.

$$\tau_w = \frac{1}{A} \int_A \mu \frac{\partial u_i}{\partial n_i} dA \quad (4)$$

where μ is viscosity (4 centipoise), and ni is the surface normal vector. WSS was reported as a raw measurement and in dimensionless form. The Male and female groups were compared using the non-parametric Mann-Whitney U test. Figure 1 displays the velocity across the LV and aorta, and the WSS of the aorta.

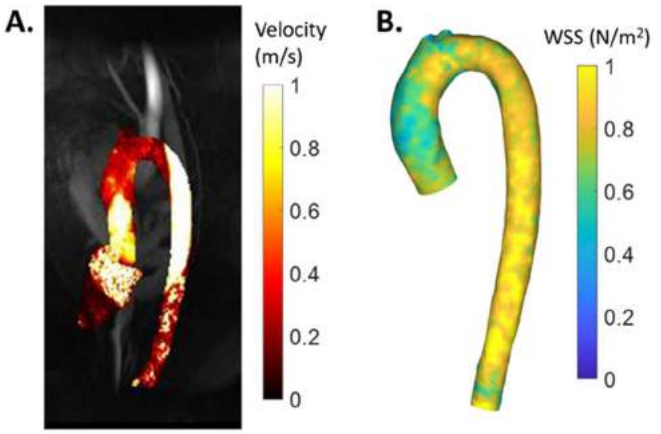

Figure1: A. LV and aorta velocity overlaid on the complex difference angiogram, B. contours of aorta wall shear stress.

RESULTS

Systolic LV KE normalized by stroke volume was significantly larger in male participants (p=0.04), and diastolic LV KE normalized by stroke volume trended towards being greater in male participants (p=0.07). When LV KE was normalized by EDV, it was similar for both groups. Average LV vorticity when normalized SV and EDV was significantly larger in females (p=0.02 and p=0.04). LV EL trended towards being greater in female participants when normalized by EDV (p=0.13). Dimensionless LV flow parameters were similar between male and female participants (systolic p=0.81, diastolic p=0.42). For aortic (Ao) flow, when normalized by either SV or Ao volume, Ao KE, EL, and WSS were all similar between both groups, while vorticity trended towards being smaller in males (p=0.08 & p=0.12 respectively).

Differences in KE VVC and vorticity VVC were not found between male and female participants. KE and vorticity were consistently greater in the aorta giving KE VVC values less than 0.25 and vorticity VVC values less than 1.0 (Figure2).

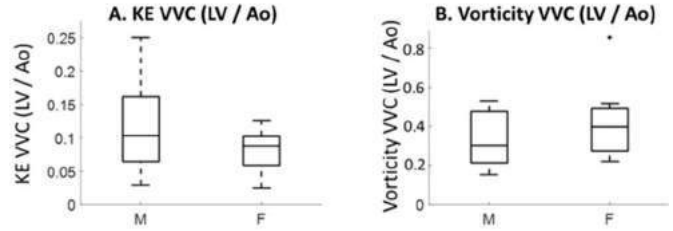

Figure2: A. Kinetic energy ventricular vascular coupling (VVC), B. Vorticity ventricular vascular coupling.

DISCUSSION

By applying the concept of VVC to 4D Flow MRI, it was found that males have greater kinetic energy and females have greater vorticity in the left ventricle; aortic flow was similar between the two groups. No differences in VVC were found between male and female participants suggesting that both flow patterns equally transfer transported flow variables from LV flow to aortic flow. This dimensional analysis suggests that previously identified sex differences in LV flow[9] were largely due to men having greater cardiac output and ventricular volumes than women.

In our results, dimensional analysis accounted for differences in cardiac output and ventricular volume explaining the differences found in LV flow showing the utility of dimensional to accounts for the anatomic differences between healthy men and women when comparing healthy and diseased populations. The advantages of presenting results in dimensionless form, as shown in this study, including that the impacts of SV, EDV, and HR are accounted for in addition to being the proper way to normalize variables from a fluid dynamics perspective.

Our concept of 4D Flow MRI-based VVC is not attempting to non-invasively calculate the traditional VVC like other approaches based on ventricular volumes[10]. Instead, we applied a similar conceptual framework to develop a novel metric of the coupling of aorta flow and LV flow. The analysis methods and results of this study may be of further use in understanding ventricular vascular coupling of transported flow variables in healthy sex differences, healthy aging, and various CV conditions.

SUSTAINED IL-10 DELIVERY ENHANCES RECOVERY FROM VOLUMETRIC MUSCLE LOSS INJURY THROUGH IMMUNOREGULATORY FACTORS

INTRODUCTION

Volumetric muscle loss (VML) overwhelms skeletal muscle's regenerative machinery and dysregulates skeletal muscle regeneration. Tissue healing following VML is characterized by a prolonged pro-inflammatory response that is thought to contribute to the substantial fibrosis that occurs at the site of injury [1]. Pre-clinical research suggests that autologous minced muscle (MM) is a promising VML treatment strategy that has been shown to promote functional recovery, but the results do not yet warrant progression to the clinic [2]. What we believe has been overlooked is the importance of reestablishing a pro-myogenic immune environment as part of the regenerative repair strategy. Evidence from our preliminary efforts as well as published evidence from others suggest that VML injury decreases endogenous IL-10 which is a critical cytokine produced by immune cells driving tissue repair and regeneration as well as promoting the transition from the pro-inflammatory / proliferative to the anti-inflammatory / regenerative stage of muscle healing [3, 4]. The objective of this study was to determine if treatment using combined minced muscle and delayed sustained IL-10 injection (immunotherapy) can improve functional muscle recovery following VML injury.

METHODS

Sprague Dawley rats were subjected to ablation of the middle third of the left tibialis anterior followed by repair with autologous minced muscle. To create the VML defect, an 8mm biopsy punch was inserted to a depth of 3mm to create a circular defect in the tibialis anterior muscle (TA). The resulting muscle plug was removed and weighed (defect mass =20% of total TA mass). The MM was prepared by hand-mincing the muscle plug with scalpel and scissors. All of the collected MM was implanted back into the defect site. The contralateral limb remained untreated to serve as an uninjured control. Animals were assigned to receive either IL-10 (2000 ng/ml) or PBS injection (IM at site of repair) beginning 7 days after injury + repair and continuing until day 14 (100ul every other day = 4 injections total) (**Fig 1a-b**). At 14 and 56 days post injury + repair (DPI), muscle contractile torque (N mm/ kg body weight) was measured and TA muscles (treated and contralateral) were collected (n=8/group/ (timepoint). TA tissues samples analyzed using RNA-Seq, multiplexed ELISA, and semi-quantitative histology with a focus on early cellular and genetic responses at 14 DPI and longer term structural muscle recovery at 56 DPI (**Fig 1a**).

RESULTS

At 14 days DPI, mean muscle torque values remained significantly below uninjured values for both PBS controls and IL-10 delivery groups (35%). However, at 56 days DPI, IL-10 delivery torque values had recovered to 68% of uninjured, yet PBS injection controls showed little recovery (**Fig 1c**). The statistically significant increase in contractile torque with IL-10 delivery was accompanied by a significant increase (22% compared to PBS) in normalized TA mass (**Fig 1d**). Whole transcriptome analysis of tissues collected at 14 days revealed activation of several key wound healing signaling pathways in response to IL-10 delivery, most notably IL-10 and muscle hypertrophy signaling (**Fig 2a**). In additional to pathway activation, IL-10 delivery resulted in pro-regenerative changes to several critical genes related to immune cell dynamics, matrix remodeling, and inflammation, but surprisingly little effect on genes associated with satellite cell dynamics / myogenesis were observed (**Fig 2b**).

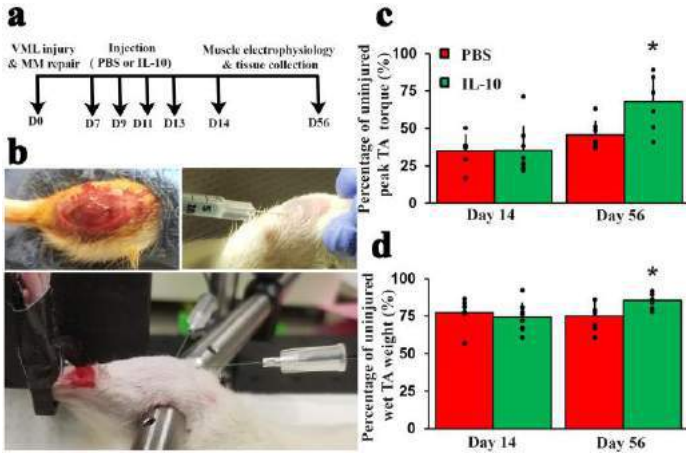

Figure 1. (a) VML injury, repair, and IL-10 delivery experimental timeline. (b) VML injuries (TA muscle) were created and repaired using minced muscle implants. Starting seven days following repair, IL-10 (or PBS control) was administered every other day at the repair site (injection) for a duration of one week. (c) The percentage of normalized peak contractile torque (%) and (d) of muscle wet weight (%) comparing to uninjured internal control were assessed in both IL-10 treated and PBS controls at 14 and 56 DPI. Group means + SD are presented; n=8/group. * denotes statistically significant ($p<0.05$) differences between groups.

Overall, the histological findings were consistent with the RNA-Seq data and detected little effect of IL-10 delivery on myogenesis, but revealed a marked increase in the presence of T-cells and improvements to repair site muscle structure in response to sustained IL-10 delivery. At 14 days DPI VML repair site immunoreactivity to

embryonic myosin heavy chain (eMHC is a protein present in de novo myofibers) (**Fig 3a and e**) was similar in both IL-10 treated and PBS controls, suggesting a similar myogenic response for both groups. However, CD3e (a pan-T cell marker) immunoreactivity (**Fig 3b and f**) was markedly increased within IL-10 treated repair sties (128% compared to PBS) suggesting an IL-10 mediated increase in T cell infiltration during the early of muscle healing.

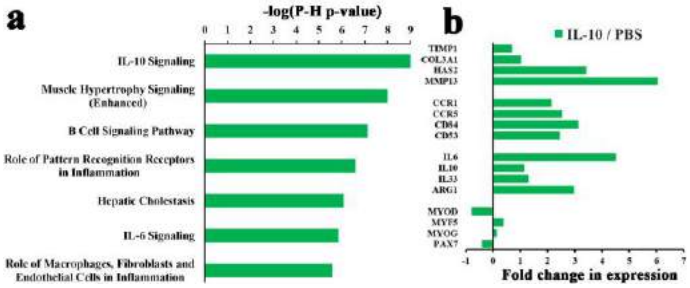

Figure 2: IL-10 delivery repair site RNA-Seq data showing (a) top enriched pathways associated with IL-10 delivery and (b) log fold expression changes for key matrix remodeling, immune cell marker, immune signaling molecules, and myogenesis genes (normalized to PBS controls)

At 56 days DPI some notable structural changes at the site of VML repair were observed. Specifically, while IL-10 did not improve/decrease repair site muscle tissue fibrosis (Col I+ tissue area), both IL-10 treated and PBS controls were marked by extensive Col I immuno-reactivity at the site of repair (**Fig 3c and g),** the sustained delivery of Il-10 did nearly double the size (97%) of repair site muscle fibers measured at the site of repair (**Fig 3d and h**). A finding that is consistent with increase in contractile force that was observed with IL-10 delivery.

Multiplexed analysis of protein concentration at the VML repair site revealed significant increases to key wound healing cytokines in response to IL-10 delivery. When compared to PBS controls, the sustained delivery of IL-10 increased tissue levels of the anti-inflammatory cytokine IL-4 (+207%), the myokine IL-6 (+52%), and the pro-angiogenic growth factor VEGF (+34%). All increases were statistically significant.

DISCUSSION

These *in-vivo* findings suggest that properly timed and sustained IL-10 delivery can have a positive effect on skeletal muscle recovery following VML injury, improving both muscle function (torque) and structure (fiber size). Previous studies investigating the effect of exogenous IL-10 in muscle showed that early delivery (during the first few days following injury) has a negative effect on muscle regeneration [5]. However, a more holistic appreciation of endogenous IL-10 production would suggest that early post injury delivery was unlikely to produce much benefit. It is well accepted that the increase in endogenous IL-10 production during tissue healing is delayed and timed to trigger the transition from the early proliferative to the later differentiation and growth stage, and as such elevated IL-10 levels may be detrimental when delivered too early. Our data is the first to confirm that the timing of IL-10 delivery is critical and specifically indicates that a delayed IL-10 delivery window timed to the biology of muscle healing is necessary to enhance muscle recovery.

Lastly, the early transcriptome, histology, and cytokine data suggests that IL-10 may improve muscle recovery from VML injury through its anti-inflammatory effect on both immune system cell dynamics, most notably T cells, rather than through direct enhancement of early satellite cell dynamics. The important role of T-cells, and more specifically T regulatory cells during the later stages of muscle healing, is known. However, this data appears to be the first to find that the T-cell population at the VML repair site can be enhanced to improve muscle recovery from VML injury. More broadly these finding suggest that immuno-regulation of the muscle wound healing environment can be employed to enhance muscle recovery.

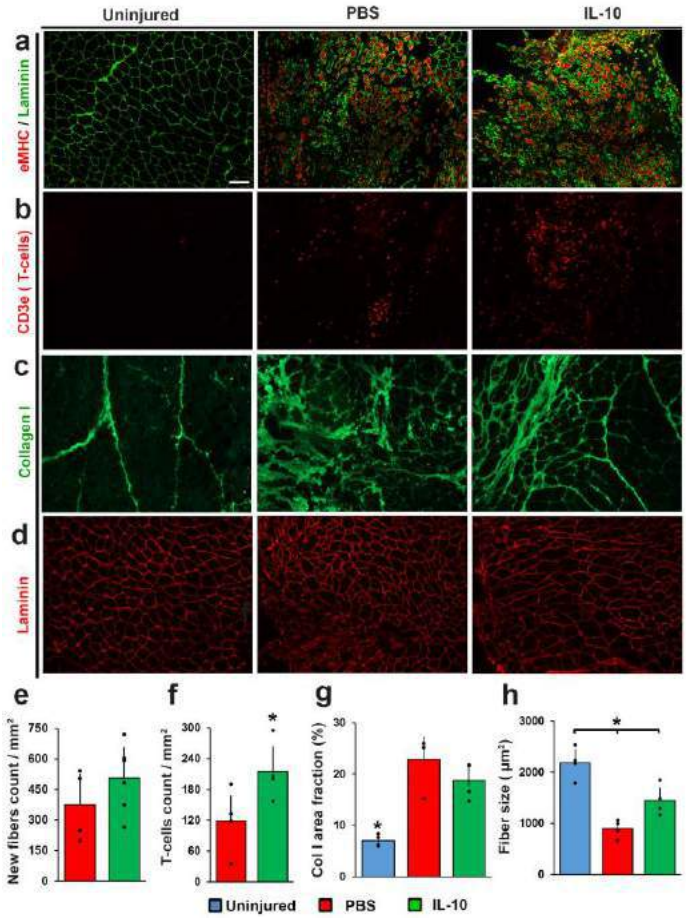

Figure 3: TA muscle cross-sections were stained using immuno-markers targeted against (a) eMHC (red) co-stain with laminin (green) (b) and CD3e (red) at 14 days DPI, as well as (c) collagen I (green), (d) laminin (red) at 56 days DPI. Scale bar = 100µm. Sections were imaged and analyzed to quantify (e) new fiber formation, (f) T-cell infiltration (g) fibrosis / non-contractile tissue area, and (h) muscle fiber cross-sectional area. Group means + SD are presented; n=4-6/group. * denotes statistically significant ($p<0.05$) differences between groups.

INTRODUCTION

Aortic aneurysm could claim lives without any premonitory symptoms or signs [1]. Ascending aortic aneurysms (AsAA) often include the dilatation of sinotubular junction (STJ) and extend into the root part of the aortas, which could lead to aortic insufficiency [2]. The pathologies of the root, valve and ascending aorta can be eradicated by traditional surgeries such as full aortic root replacement. However, this kind of surgery may represent excessive surgical intervention for infirm or elderly patients. The novel surgery [3] of the V-shape resection of the noncoronary sinus has been shown to be a simpler procedure, comparing with the traditional surgeries. The V-shape surgery could reduce the diameter and cross-sectional area of the aortic root aneurysm [3]. However, its detailed effect on the stress field and rupture risk of the aorta has not been fully investigated. Moreover, it is also essential to estimate the growth and dilation of the root post-surgery for evaluation of the outcomes of the surgery. In this study, we performed patient-specific finite element (FE) simulation of the aorta pre- and post-surgery of patients who underwent the V-shape surgery. We obtained the aortic wall stress and investigated the influence of the V-shape surgery on the stress field and rupture risk of the aortic root, ascending aortic aneurysm and aortic arch. Moreover, we also studied the growth and dilation of the aortic root post-surgery by estimating the temporal evolution of the enclosed volume of the aortic root.

METHODS

Patient Data: Deidentified cardiac CT images were obtained for a total of 14 patients (P1-P14) who underwent the surgery of V-shape noncoronary sinus resection at Yale-New Haven Hospital. For 10 patients (P1-P10) among the total 14 patients, the CT images of the thoracic and abdominal aorta pre- and post-surgery were obtained. We used these 10 patients to investigate the effect of the V-shape surgery on the stress of the aorta. For 6 patients (P1, P8, and P11-P14) among the total 14 patients, the CT images of the aortic root at two follow-up time points post-surgery (Post1 and Post2) were obtained. We used these 6 patients to study the growth and dilation of the root post-surgery.

Finite Element Analysis: For each patient of P1-P10, the three dimensional (3D) surface geometry of the aorta was reconstructed from the CT images using 3D Slicer (www.slicer.org). The aortic root, ascending aorta, aortic arch together with the three branches around it, and the descending aorta were obtained. The surface geometry was exported from 3D Slicer and imported into Altair HyperMesh 2017 (Altair Engineering) to generate the finite element model for the aorta. We performed finite element (FE) simulation of the aorta by the Abaqus/Standard 2019 (SIMULIA, Providence, RI) based on the static determinacy approach [4]. The analysis of mesh size independence was performed. The stress field of the aorta pre- and post-surgery was extracted and analyzed.

Dilation of the Aortic Root Post-Surgery: For the 6 patients of P1, P8, and P11-P14, 3D geometries of the aortic root post-surgery at Post1 and Post2 were reconstructed from the CT images by the same method as that in last subsection. Figure 1 shows the 3D geometries of the inner surface of the aortic root (from STJ to aortic annulus) of a representative patient (P13), with Post1 (blue) at the time point about 4 months after the surgery and Post2 (red) at the time point about 20 months from Post1. The geometries in Fig. 1 indicate that the aortic root grew and dilated after the surgery.

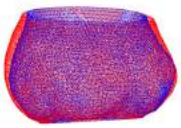

Fig 1. 3D geometries of the aortic root of a representative patient (P13) post-surgery at Post 1 (blue) and Post2 (red).

We calculated the enclosed volumes of the aortic root of Post1 and Post2 for the 6 patients to quantitatively estimate the root dilation post-surgery. We also performed finite element (FE) simulation of aortic root only of Post1 and Post2 for the 6 patients based on the static determinacy approach and obtained the stress of the aortic root.

RESULTS

Wall Stress of the Aorta Pre- and Post-Surgery: The wall stress of the aorta of the 10 patients (P1-P10) pre- and post-surgery was obtained from the FE simulation. Figure 2 shows the max-principal (MP) stress field of the aorta of a representative patient (P1) pre- and post-surgery. We extracted the MP stress field of four ring-bands of the aorta of each patient, with band-1 at the operated aortic root (from STJ to sinus), band-2 at the ascending aneurysm position with the maximum diameter pre-surgery, band-3 at the ascending aneurysm position with diameter affected little by the surgery and band-4 at the position right distal to the aortic arch. The width of the four ring bands is approximately the same for pre- and post-surgery.

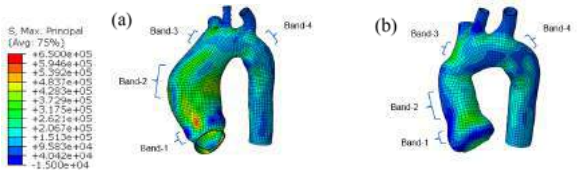

Fig 2. Max-principal stress field of the aorta of a representative patient (P1): (a) pre- and (b) post-surgery.

Figure 3 shows a statistic analysis based on the two-sample T-test of the MP stress between pre- and post-surgery for the 10 patients. The label "mean" on the horizontal axis denotes the mean value of the MP stress within one band of one single patient, while the bar chart represents the mean+standard error (SE) of the 10 patients. For example, the first bar chart in Fig. 3a represents the mean+SE of the 10 patients for mean MP stress within band-1 of each patient pre-surgery. The two "mean" should not be mixed.

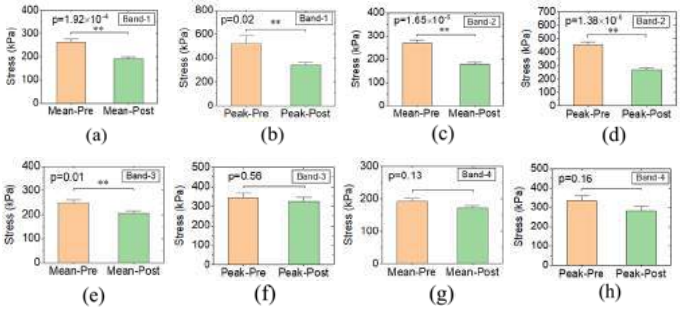

Fig 3. The mean+standard error (SE) for the 10 patients of the mean and peak MP stress of the band1-4. **: p value less than or equal to 0.02.

Dilation of the Aortic Root Post-Surgery: Table 1 presents he enclosed volume of the aortic root of Post1 and Post2 for the 6 patients (P1, P8, and P11-P14), which shows that the enclosed volume of the aortic root increased after the surgery, with a minimum increase of 6.35% for P12 and a maximum increase of 13.69% for P14. Figure 4 shows the relation between the volume change from Post1 to Post2 and the mean MP stress of the aortic root (from around STJ to aortic annulus) of Post1 and Post2.

Table 1. Enclosed volume of Post1 and Post2. Chg: volume change from Post1 to Post2; Chg (%): percentage change of the volume; ΔT: time interval of Post1 and Post2 in month (Mon).

	P1	P8	P11	P12	P13	P14
Post1/cm³	11.58	32.71	34.50	28.18	20.88	36.37

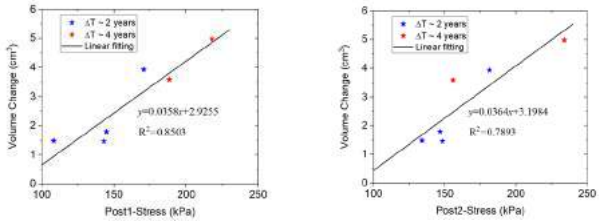

Fig 4. Relation between the mean MP stress and volume change of the aortic root of Post1 and Post2 for patients in Table 1.

DISCUSSION

The V-shape surgery significantly reduces the mean and peak wall stress of the root (Fig. 3a,b). The reason could be that it reduces the diameter of the root [3]. If the rupture strength of the wall is assumed to be unchanged post-surgery, the rupture risk will decrease with the decreasing wall stress. The major portion of the ascending aneurysm (band-2 in Fig. 2a) was replaced by an ascending aortic graft (band-2 in Fig. 2b). The diameter of the graft is much smaller than that of the ascending aneurysm pre-surgery and thus the stress of band-2 (Fig. 3c,d) also reduces significantly. Although the tough graft post-surgery has no rupture issue, the reduction of the diameter of band-2 may contribute to the stress reduction (Fig. 3e) of the adjacent band-3 (live aortic tissue).

The 6 patients in Table 1 are classified into two groups with the first group (P1, P8, P12 and P13, blue stars in Fig. 4) having about 2 years interval between Post1 and Post2, and the second group (P11 and P14, red stars in Fig. 4) having about 4 years interval between Post1 and Post2. Figure 4 indicates that the dilation of the root post-surgery may be induced by the root stress, since larger root stress results in larger volume increase within both groups. The patient-specific dilation rate could be also affected by other factors including sex, age, weight, height, hypertension, diabetes, complications, etc. In the future study, we will identify the critical factors that influence the dilation rate of the aortic root post-surgery and further stratify the patients who may or may not benefit from the V-shape surgery per long-term outcomes, with follow-up CT images for more patients and longer time period being obtained.

INTRODUCTION

Osteoarthritis (OA) is a progressive, multi-tissue joint disease with degenerative changes in articular cartilage and subchondral bone [1]. It is characterized by an asymptomatic early stage and a debilitating late stage progression. At present, there are no early treatment modalities that provide conclusive relief, whereas late-stage treatment options mostly involve major surgical interventions. Although the nature of OA is complex, the degradation of extracellular matrix (ECM) of cartilage is one of the key parameters for disease progression [2,3]. In particular, crosslinks (CxLs) stabilize the collagen (COL) fibril network, and their disruption results in the loss of tensile strength and structural integrity [3,4]. Therefore, introducing CxLs to OA-afflicted cartilage offers the potential to stabilize the degrading ECM network and impede progression of OA. Similarly, induction of COL CxLs to increase the mechanical strength of structurally compromised corneas has been established as a module to treat keratoconus. Crosslinking of corneal stroma with 365 nm ultraviolet-A (UVA) lamp irradiation, while using riboflavin as photosensitizer has been widely studied and recently approved for treating keratoconus in the U.S. [5-6]. However, the same approach has not translated to cartilage, due to its significant linear absorption of 365 nm light and greater opacity compared to cornea [7].

Our previous work has demonstrated that, in both cartilage [8] and cornea [9], a femtosecond laser can be used to ionize interstitial water and induce a photochemical reaction, which results in CxL formation, and thus increased stiffness and wear resistance [8]. CxLs were induced in the absence of a photosensitizer, providing promise that the proposed treatment modality could be clinically relevant. In this study, we hypothesize that application of a photosensitizer may result in a more efficacious CxL process, which can be more readily imaged to reveal the spatial distribution of imparted CxLs and the penetration depth of the laser treatment. Further, we examine if riboflavin may be activated in cartilage using an infrared (IR) femtosecond laser as an excitation source [10], effectively relying on the second harmonic generation (SHG) effect to actuate it. The study presented here provides valuable insight into the laser treatment characteristics and, in the future, comparison between crosslinking mechanisms.

METHODS

Sample Preparation. Cartilage tissue was harvested from the knees of immature bovine calves (2-3 months old, Green Village Packing Co., New Jersey, USA). Explants (∅3 mm × 2 mm) were biopsy-punched from the femoral condyle and cut to a final thickness of 2.0±0.2 mm. Samples were stored frozen and thawed before treatment.

Crosslinking Treatment. Before laser irradiation, cartilage plugs were soaked overnight in 0.2% Riboflavin 5'-monophosphate (Sigma-Aldrich Inc., USA) with 20% Dextran (Sigma-Aldrich Inc., USA). Wavelength tunable (680-1080 nm) Ti: Sapphire laser Chameleon Ultra II (Coherent Inc., Santa Clara, USA) with out-of-cavity beam waist of 1.2 mm was used to produce 760 nm laser irradiation with 120 fs temporal pulse length at 80 MHz repetition rate. The average power of the light source was adjustable. The laser beam was focused using a ZEISS LD plan-Neofluar 40x/0.6 Corr objective with Numerical Aperture of 0.1463. The focal plane position at the surface of the superficial zone of cartilage was found by identifying a spark on the bottom of a 0.15 mm coverslip pressed against the sample. Lasing was rasterized into the specimen with a hexapod (H-840.D2A-AXIS_X, Physik Instrumente, USA), moving at 1.2 mm/s. Four groups of samples (Groups A, B, C and D) were tested. Groups A, B and C

were subjected to average laser power of 165 mW. Group A had a zigzag grid pattern in the XY-plane, with a spacing of 50 μm between parallel laser paths; the treatment was repeated for 5 layers, 50 μm apart in the Z-direction. Group B had the same treatment pattern in the XY-plane, with 11 layers along Z, 20 μm apart; Group C had a denser zigzag grid with 25um spacing in the XY-plane, and 5 layers along Z, 50 μm apart. Demonstrative Group D had the same in-plane zigzag treatment pattern as Group A, with 3 layers along Z, 50 μm apart, each having a different average laser power: 165 mW, 330 mW, and 495 mW at the 1st, 2nd and 3rd layer, respectively. For Group A, B and C, 5 samples were treated and paired with untreated control samples under similar experimental conditions but not irradiated by the laser.

Multiphoton Confocal Microscopy. Multiphoton confocal imaging is known to reveal the presence of CxLs in collagenous tissues and gels [11,12]. Imaging was performed with a Nikon Ti Eclipse inverted microscope using a Ti: Sapphire laser Chameleon Ultra II at 860 nm as the light source and a Nikon Apo LWD 25x gel immersion objective for focusing. The emission filter was set at FITC channel for autofluorescence signal collection. The XY scanning area was 516 μm by 516 μm, and Z scanning was 250 μm deep with 5 μm increments.

RESULTS

For Group A (Figure 1a1 and 1a2), the XY zigzag pattern and increments along Z are clearly distinguishable compared to the background signal. For Group B (Figure 1b1 and 1b2), the 20 μm increments along Z produce connected sheets across the 11 treatment layers. For Group C (Figure 1c1 and 1c2), the narrower 25 μm XY distance is evident. With a uniform average power of 165 mW for all Z depths, as the laser focal plane delves deeper into the superficial zone, the fluorescence signal intensity of all samples clearly decreases. The autofluorescence signal in Group D is shown in Figure 1d1 in the XZ plane and 1d2 in 3D. With 2-fold power at the 2nd plane and 3-fold power at the 3rd plane, autofluorescence signal intensity increases down to a depth of 200 μm, whereas the signal in groups A, B, C generally decreases to the background level at approximately 150 μm.

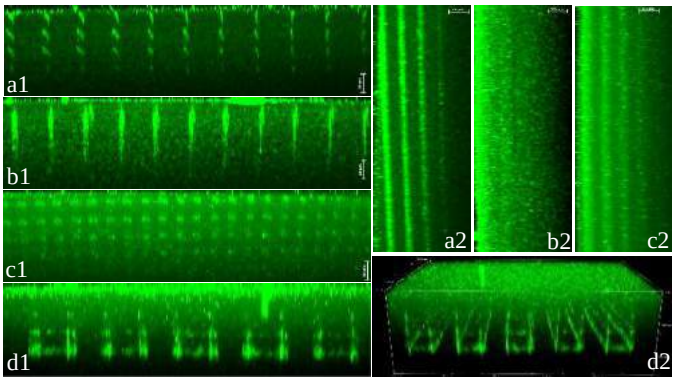

Figure 1. Autofluorescence signal of the treated superficial zone of cartilage. XZ views for Group A, B, C, D shown in a1, b1, c1, d1. YZ views for Group A, B, C shown in a2, b2, c2. Volumetric 3D view for Group D shown in d2. All scale bars are 50μm. XYZ size is 516×516×250 μm. Intensity and size are adjusted for clarity.

The size of the crosslinked regions mostly agreed with the focal volume (FV) estimated from the laser treatment path lines, approximated as a cylinder with radius $W_{xy} = 0.32\lambda/\sqrt{2NA}$, where λ =laser wavelength, and NA =objective numerical aperture [13], and height $2Z_R$, where $Z_R = 2\pi n W_{xy}^2/\lambda$ is the Rayleigh range, n =tissue refractive index [14]. We calculated W_{xy} =1.18 μm and Z_R =7.98 μm.

DISCUSSION

Tightly focused ultrafast laser pulses at 760 nm excite riboflavin via a non-linear, two-photon process [10] and enable CxLs to form in the cartilage. Compared to the single photon process using a UVA light source at 365 nm, it is assumed that the multiphoton laser-photochemical reaction only occurs within the focal volume region where the light intensity is at its highest. This feature provides spatial precision of the crosslinking treatment with a relatively low average power. However, the tissue's depth-dependent light absorption (A) still plays a role and may be governed by the Beer-Lambert Law, $A(\lambda) = \varepsilon(\lambda)c\ell$, where c is concentration, ε absorptivity, and ℓ optical path length. As light penetrates deeper into the tissue, assuming negligible changes in c and ε of attenuating species, absorption increases [15], thus decreasing the efficacy of the crosslinking process. Simultaneously, due to the non-uniform spatial distribution of the native components of the superficial zone of articular cartilage, heterogeneity of the optical refractive index causes a mixture of Rayleigh and Mie elastic scattering of light [16]. While scattering effect decreases with wavelength, absorption is the lowest at near-IR ranges in biological tissues [17]. The superficial zone also introduces optical aberrations as an extension of the focusing lens, including spherical aberration due to its inherent curvature, and chromatic aberration due to group velocity dispersion. The resulting temporal and spatial anomalies of the pulse shape are proportional to the optical path length inside the medium and cannot be neglected for femtosecond pulses [18]. Optical aberrations, together with the absorption and scattering of light, induces loss of crosslinking efficacy in deeper zones of the tissue. This loss can be corrected by raising the focal plane irradiation intensity by adjusting the average power in the deeper treatment plane, as shown here.

In this study, we investigated CxL of COL in articular cartilage. To the best of our knowledge, this was the first time that riboflavin was activated in cartilage with an ultrafast laser through a non-linear excitation process. The process is spatially resolved and allows for precise control of the induction of CxLs. The density of imparted CxLs is a function of focusing and lasing parameters. While the crosslinking mechanism presented in this study is different from the laser-based treatment in the absence of photosensitizers reported in our earlier studies [8, 9], it is likely that the conclusions related to the CxL spatial distribution and laser attenuation can be translated to it.

BENT BUCKLING OF ARTERIES WITH NON-CIRCULAR CROSS SECTION

Yasamin Seddighi (1), Hai-Chao Han (1)

(1) Department of Mechanical Engineering
The University of Texas at San Antonio
San Antonio, TX 78249, USA

INTRODUCTION

Mechanical stability of arteries is important for normal arterial functioning. Artery buckling may impede blood flow and result in ischemic attack to the distal organ and other pathologic changes [1]. Axial tension and lumen pressure provide mechanical stability for blood vessels which prevent curling, bending and collapse of the artery [1].

Many arteries do not have ideal uniform circular cross section, but instead having noncircular, such as oval shape or eccentric cross sections [2]. It is unclear how these noncircular cross section shapes will affect the stability of arteries.

Therefore, the objective of this study was to investigate the effect of oval shape cross section on the critical buckling pressure of the arteries.

METHODS

Arteries are modeled as cylindrical tubes with an elliptical cross section. The major lumen diameter, length and uniform thickness are 3.27, 52, and 1.86 mm, respectively [3]. A lumen aspect ratio (AR), defined as the minor to major diameter ratio, of 0.8-1.0 (with corresponding outer wall aspect ratio of 0.91-1.00) were analyzed. The arterial wall is assumed to be a homogeneous, anisotropic, incompressible material with Fung strain energy function [4] in the form of

$$\mathrm{w} = \frac{C}{2} e^{Q} \tag{1}$$

with

$$\mathrm{Q} = b_1 E_\theta^2 + b_2 E_z^2 + b_3 E_r^2 + 2 b_4 E_\theta E_z + 2 b_5 E_z E_r + 2 b_6 E_\theta E_r \tag{2}$$

Where b_1, b_2, b_3, b_4, b_5, b_6 and C are material constants obtained from experimental measurements and are provided in Table 1. E_r, E_θ and E_z are components of Green strain tensor and subscripts r, θ and z represent radial, circumferential and axial direction, respectively.

Table 1: Convex material constants of porcine carotid artery used in Fung strain energy function [5]

b_1	b_2	b_3	b_4	b_5	b_6	C(kPa)
0.679	0.751	0.228	0.0519	0.033	0.051	20.42

Commercial FEA package ABAQUS® was used to simulate bent buckling behavior of arteries. Arteries of elliptic cross sections of different aspect ratio were created and meshed using 8-node linear hybrid hexahedral element with constant pressure (C3D8H). A mesh size of 0.2 mm was used after pilot convergence study. A 1-degree initial curvature along the longitudinal axis was included in the models to facilitate vessel buckling. Arteries were first stretched axially to the length of 67.6 mm (1.3 times of initial length) to mimic the in vivo axial stretch in the arteries [5]. Then, a uniform static pressure (up to 50 kPa) was applied to the vessel lumen. Both ends of the artery were restrained from rotations or axial move but allowed for radial displacement (i.e., had only one degree of freedom).

The displacement of the four points located on the minor and major diameters of the outer wall in the middle section of the artery were monitored to determine the changes in aspect ratio and central axis. The onset of buckling is the time when the central axis starts deflection.

RESULTS

Change of lumen shape under axial stretch and lumen pressure

Changes in the aspect ratio of the middle cross section of the arteries were observed due to the applied axial stretch (time=0-1s) and pressurized inflation (time=1-2s) (Fig.1). The cross-sectional shape of

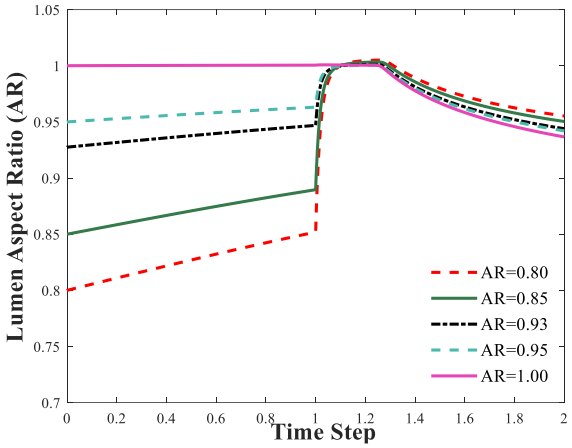

Figure 1. Change of lumen aspect ratio (AR) of the middle cross section of the vessel under axial stretch (time steps 0 - 1) and lumen pressure (time steps 1-2). The vessel buckles in the direction of the minor diameter. Buckling occurred at time step around 1.2 where the aspect ratio starts to decrease.

the elliptic arteries tend to deform into circular shape under increasing lumen pressure and then become elliptic after buckling.

On the other hand, arteries of initially circular lumen but with eccentricity tends to become elliptic at low pressure but then become circular at high pressures.

Effect of aspect ratio on the critical pressure

All arteries buckled when the lumen pressure reached a critical pressure. The maximum deflections (at the middle point of the axial length) for arteries with different lumen aspect ratios are plotted with lumen pressure as shown in Fig.2.

The initial lumen aspect ratio has a small effect on mechanical stability of the arteries. For arteries with lumen aspect ratio in the range of 0.8-1.0, the critical pressure, which is defined by the pressure at which the maximum deflection of the central axis at the middle of the vessel length reaches 0.1mm, decreases with decreasing aspect ratio (Fig.3). The mean critical pressure is 9.32 ± 0.16 kPa for these arteries with lumen aspect ratio in the range of 0.8-1.0.

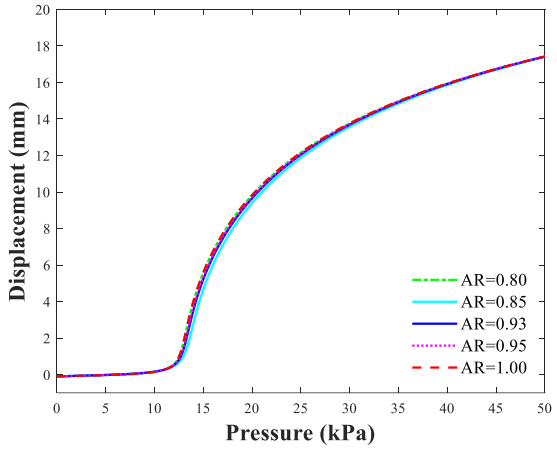

Figure 2. Deflection at the middle section of the vessel plotted as function of lumen pressure.

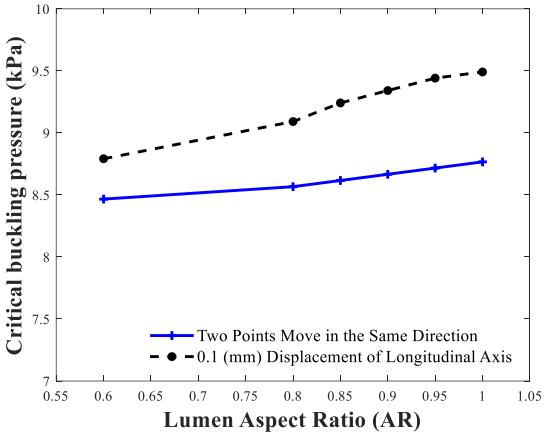

Figure 3. Critical buckling pressure of the artery plotted with the initial lumen aspect ratio

DISCUSSION

Critical pressure of arteries with oval shape cross section has been investigated and compared with the results of the artery with circular cross section which was validated by experimental results of [5].

Our results demonstrated that arteries with elliptical cross section buckle in the direction of minor axis. While increasing lumen pressure initially deforms the elliptic vessel towards circular shape, the vessel lumen become elliptical post buckling. The aspect ratio of the initial lumen has little effect on the critical pressure of the vessels. A possible reason is that all these vessels of different initial AR become very close to circular at high pressure right before buckling occurs.

There are a few limitations in this study. First, static pressure was applied to the lumen and pulsatile pressure was not considered. Secondly, a homogenous material was used for the three-layered arterial wall. Further studies are needed to fully consider the combination of eccentricity and ellipticity of the vessels. Despite of these limitations, current study increases our understanding of the stability of arteries with elliptical cross section.

INTRODUCTION

Wound healing is a key process that restores mechanical function after injury [1]. Though there is a general understanding of this process that has resulted in existing theoretical and computational models [2], current mathematical descriptions of wound healing ignore the complex mechanical response of the extracellular matrix (ECM) and its coupling with cell mechanobiology. Here, we explicitly model the adhesion of cells to the underlying ECM with a modified version of the well-established model by Bell [3] in order to account for nonlinear mechanics of the ECM. This updated model of cell-ECM interaction is then coupled through an integration point subroutine to a tissue-scale finite element model. Thus, our work addresses existing gaps in wound healing models by explicitly coupling microscale mechanobiology to the macroscale mechanical behavior of tissues.

In previous work, we proposed a computational model of wound healing at the tissue level coupled with a systems-based approach for mechanobiology [2]. However, this model used a phenomenological equation to relate cell density to active tissue contraction. Here, we include Bell's adhesion model [3] to describe the interaction between fibroblasts and the ECM. A key modification of [3] we propose here is to consider nonlinear ECM mechanics. This extension of Bell's model naturally captures cell mechanosensing; as the ECM deforms, changes in the tangent stiffness lead to changes in cell adhesion and traction.

To complete the representation of cell-ECM coupling, an accurate strain energy for the passive material response of the ECM is needed. In previous work, we used the model by Gasser et al. (GHO) [4]; however, after further consideration of the literature [5,6] and our own data, we propose here a new constitutive equation that better describes the mechanical response of collagen and fibrin fibers. We analyze existing fibrin and collagen single fiber data, as well that from fibrin and collagen gels, to describe mechanics at the cell and tissue scales.

METHODS

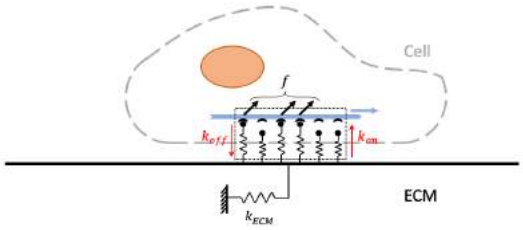

Figure 1: Adhesion model schematic.

Adhesion model. The adhesion process of fibroblasts to the ECM is illustrated in Figure 1. The mathematical form can be written by

$$\dot{\phi}_b = k_{on}(1-\phi_b) - k_{off}\phi_b \quad (1)$$

where ϕ_b denotes the density of integrin-ligand bonds, and k_{on} and k_{off} characterize the association and dissociation rate of integrin - ligand pairs. The association process is spontaneous, so we choose this intrinsic parameter, k_{on}, as a constant. The dissociation rate, k_{off}, is proportional to the energy stored in the adhesion according to [3],

$$k_{off} = \hat{k}_{off}\, e^{\frac{\Delta E}{k_B T}} \quad (2)$$

where $\hat{k}_{off}$ is a constant, k_B is the Boltzmann constant, T is the temperature in Kelvin, and ΔE is the stored energy of adhesion. For a purely elastic adhesion model, $\Delta E = f^2/(2k_{ECM})$, where f denotes the intra-cellular contractile force and k_{ECM} is the stiffness of the ECM. In [3] and most derived work, k_{ECM} is a constant. By considering the nonlinear mechanics of the ECM, the energy in the adhesion becomes a

function of the stretch in the ECM fibers,

$$\Delta E = \frac{f^2}{2k_{ECM}(\lambda)}. \quad (3)$$

From Eq. (1), we solve the ODE and obtain ϕ_b at the equilibrium state to get the relationship between the equilibrium density of bonds and the stretch of the ECM. We also adopt a Monte-Carlo simulation to verify the results.

Mechanical equilibrium at the tissue level. At every point of the tissue domain, we require the vanishing of the stress divergence

$$\nabla_{\mathbf{x}} \cdot \boldsymbol{\sigma} = \mathbf{0}. \quad (4)$$

We split the total stress into three parts, which include a pressure term, the passive isochoric contribution, and the active contribution. The mathematical form of the total stress can be written as

$$\boldsymbol{\sigma} = \mathrm{p}\mathbf{I} + \boldsymbol{\sigma}^{\mathrm{pas}} + \boldsymbol{\sigma}^{act} \quad (5)$$

where p denotes the pressure Lagrange multiplier, $\boldsymbol{I}$ is the identity matrix, and $\boldsymbol{\sigma}^{pas}$ and $\boldsymbol{\sigma}^{act}$ are the passive and active contributions. For the passive contribution of the stress, we assume hyperelastic behavior and we propose the strain energy

$$\psi = k_0\big(I_1 - 3\big) + \phi\,\psi^f \quad (6)$$

$$\psi^f = \frac{k_1}{2k_2}\Big(\mathrm{e}^{k_2\,(\boldsymbol{A_0}:\boldsymbol{C}-1)} - k_2(\boldsymbol{A_0}:\boldsymbol{C}-1) - 1\Big) \quad (7)$$

where k_0, k_1, k_2 are parameters, ϕ is the volume fraction of fibers, I_1 is the first invariant of the deformation, $\boldsymbol{C}$ is the right Cauchy-Green tensor, $\boldsymbol{A_0} = \kappa\boldsymbol{I} + (1-2\kappa)\boldsymbol{a_0}\otimes\boldsymbol{a_0}$ is the structural tensor with $\boldsymbol{a_0}$ the fiber direction and κ the fiber dispersion in the reference configuration. We fit experimental data of single collagen and fibrin fibers [5,6] to obtain two sets of k_1 and k_2. The volume fraction is estimated by comparing experimental data of gels and single fibers as well as computed the approximate value from fiber densities of collagen and fibrin. The pressure p is computed using a plane-stress assumption. The active contribution in current configuration is written as

$$\boldsymbol{\sigma}^{\mathrm{act}} = \phi\, t_\rho \frac{\boldsymbol{A}}{tr(\boldsymbol{A})} \quad (8)$$

$$t_\rho = f \cdot \rho_i \cdot \phi_b(\lambda) \quad (9)$$

where f, ρ_i are contractile force per adhesion and density of integrins on a fibroblast, and $\boldsymbol{A}$ is the structural tensor pushed to the current configuration. The coupled mechanics-mechanobiology problem is solved using a custom finite element implementation.

RESULTS

We simulated uniaxial and biaxial tests for both collagen and fibrin fibers and gels using the strain energy function proposed here. The results of the stress, σ_{xx}, of both fiber types with different dispersions were simulated (Figure 2). When there is no dispersion ($\kappa = 0$), the stress shows large nonlinearity in the case of collagen, while fibrin mechanics are less nonlinear. Increasing dispersion (larger κ) results in lower stress under uniaxial loading for the same fiber density, which reflects that not all the fibers are under tension, only the ones in the direction of loading.

Next, we computed the active contribution of cells to the total stress when interacting with collagen or fibrin fibers. In the absence of deformation ($\lambda = 1$), the difference in cell active stress between collagen and fibrin substrates is entirely defined by the different initial stiffness of these two substrates. Stretching the substrate increases the active cell stress due to the coupling in Eq. (3) (Figure 3). Higher dispersion results in a decrease of the active stress, but it will not influence the maximum value of σ^{act}. Finally, we constructed a wound

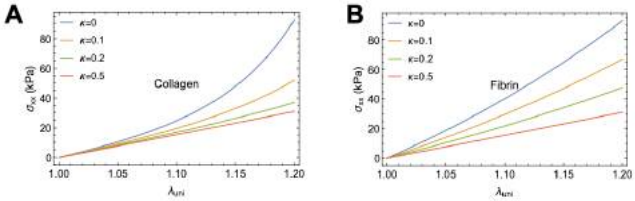

Figure 1: Uniaxial tests of (a) collagen and (b) fibrin fibers. Four different dispersions were tested. The stress components in the x direction, σ_{xx}, is plotted as a function of fiber stretch, λ_{uni}.

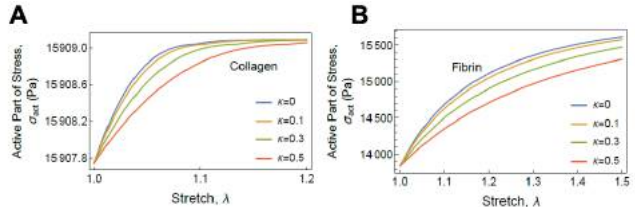

Figure 2: Influence of stretch, λ, on the active contribution, σ^{act} on (a) collagen and (b) fibrin substrates for various dispersions κ.

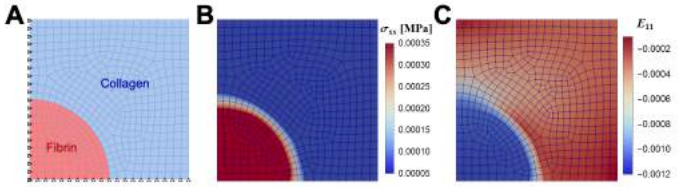

Figure 4: Simulation of a sample wound. (a) x- and y-symmetry boundary conditions were applied on the left and bottom; no tractions were applied. (b) Stress and (c) Green-Lagrange strain contours in response to the active stress produced by a uniform cell density field.

domain to simulate the contraction process [1] (Figure 4). The total stress vanished due to equilibrium; passive stress balances active stress. The strains are not uniform due to the heterogeneity of the material properties, which leads to heterogeneous contraction predicted by Eq. (3) even in the absence of any external forces.

DISCUSSION

To address existing gaps in understanding how tissue-level mechanics influence cell mechanobiology, we coupled a cell adhesion model to a finite element model of tissue. Incorporating the nonlinear behavior of the ECM with Bell's model of adhesion [3], we show that increasing ECM stretch increases cell adhesion, which in turn feeds back to the mechanical equilibrium by affecting the cell active stress. Other works [7] also considered active stress; however, they ignored the underlying mechanism of cell-ECM interaction. Limitations of our model include lack of viscoelastic behavior as well as growth and remodeling, which are being incorporating in our ongoing work.

INTRODUCTION

A tracheostomy tube is used for almost 90% of patients who need long-duration (2-3 weeks) of the ventilator. Since it is also known that there is a correlation between high survival rates and short-duration of the ventilator [1], precise oxygen supply with a tracheostomy tube (Fig. 1(a)) is necessary for postoperative patients with tracheostomy to early removal of the ventilator. Although there is a common sense that a positive end-expiratory pressure (PEEP) should be preserved to prevent the pulmonary collapse [2], much is still unknown about inflow rates of oxygenated air to achieve the PEEP in the patients supported by tracheostomy tube. Numerical approach is useful to investigate mechanical parameters for PEEP considering the flow field of the tracheostomy tube. Therefore, the objective of this study is to develop a computational platform to evaluate PEEP based on the flow filed in 3-dimensional (3D) space of tracheostomy tube. Calculated tracheal pressure, which is the outlet pressure in the tube, will be compared with animal experiments. In this abstract, we report a computational framework, where computational fluid dynamics in 3D, is coupled with a 0-dimensional (0D) lung model. Using developed model, we evaluated the tracheal pressure as a function of inflow rates of the air.

METHODS

To evaluate PEEP, 3D fluid dynamics of the airflow in the tube is coupled with 0D lung model. Each model explanation and coupling method are described follows.

Flow model. The air is modeled as an incompressible, Newtonian fluid, and is governed by the continuum and Navier-Stokes equations. A realizable k-ε turbulence model [3] is also applied. For each boundary shown in Fig. 1(b), constant velocity U_{in} and pressure P_{out} (= 0) are given in the inlet and outlet, respectively, where U_{in} is determined based on the flow rate Q_{in} (= $A_{in}U_{in}$ = 10, 30 and 50 L/min). The velocity on the boundary attached to the trachea U_{tr} is given by 0D lung model, which is described below. A no-slip condition is applied to all walls. The fluid mesh size is set at 1.0 mm (a polyhedral mesh), and an adaptive meshing (prismatic layers) is considered to be lining the walls. CFD is performed by STAR-CCM++ (Version 15.04.010; SIEMENS, Germany). More detail computational descriptions are referred to [4].

0D lung model. Alveoli pressure P_{al} is balanced with pleural pressure P_{pl} driven by respiratory muscle change and elastic stress σ acting on the lung tissue, i.e.,

$$P_{al} = P_{pl} + \sigma. \tag{1}$$

Here, P_{pl} is given as a sinusoidal function such that $P_{pl} = -P_0 \sin(\pi t/T) - P_{base}$, where T = 5 [s], P_0 = 250 [Pa] and P_{base} = 750 [Pa]. The lung tissue is modeled as an isotropic and hyperelastic material. The strain energy function W per unit volume of the lung tissue is given as [5]:

$$W = C_1\left(\widehat{I_c} - 3\right)^2 + C_2\left(\widehat{I_c} - 3\right)^3 + C_3(-2\ln J + J^2 - 1) \tag{2}$$

where C_i (i = 1-3) is the model parameter, $\widehat{I_c}$ is the modified first invariant of right Cauchy-Green deformation tensor $\mathbf{C}$, and J is the volumetric Jacobian defined as the determinant of the determinant of the deformation gradient tensor $\mathbf{F}$ (i.e., J = det($\mathbf{F}$)). Assuming isotropic deformation, the Cauchy stress tensor $\boldsymbol{\sigma}$ can be described as:

$$\boldsymbol{\sigma} = \frac{1}{\det(\mathbf{F})}\mathbf{F}\cdot\mathbf{S}\cdot\mathbf{F}^{\mathrm{T}} = 2C_3\left(J - \frac{1}{J}\right)\mathbf{I} \tag{3}$$

where $\mathbf{S}$ (= $2\partial W/\partial \mathbf{C}$) is the second Piola-kirchhoff stress tensor and $\mathbf{I}$ is the unit tensor. Tracheal velocity U_{tr}, which is a boundary condition in flow model, can be obtained with a linear equation of the flow resistance R and with the assumption of isotropic deformation, i.e.,

$$P_{tr} - P_{al} = \mathrm{R}\dot{V}_{lung}, \tag{4}$$

$$\dot{V}_{lung} = \mathrm{U}_{tr}\pi r^2, \tag{5}$$

where P_{al} is the alveoli pressure, which is given by Eq. (1), and r is the radius of the boundary attached to the trachea (Fig.1(a)). C_3 is determined based on physiological relevant lung deformation such that dV_{lung} = 500 cm^3 and dP_{pl} = 500 Pa [6].

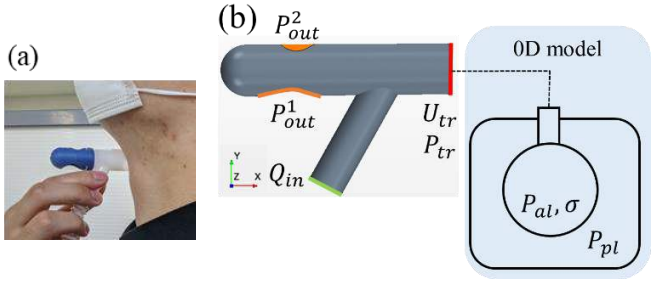

Fig. 1. (a) Tracheostomy tube (Fisher&Paykel Healthcare, New Zealand) . (b) Tube model for 3D CFD and schematics of 0D lung model. For the tube model, each boundary condition set at an inlet velocity U_{in} (green), outlet pressure P_{out} (orange), and tracheal velocity U_{tr} (red) obtained with 0D lung model.

RESULTS AND DISCUSSION

Response of 0D model. Fig. 2(a) shows time histories of calculated alveoli pressure P_{al}, tracheal velocity U_{tr}, and given pleural pressure P_{pl}. The result is obtained with $Q_{in} = 30$[L/min]. The amplitudes of P_{al} and U_{tr} were approximately 100 Pa and 1.7 m/s, respectively. Fig. 2(b) shows the time average of mean P_{al} during a cycle for different $Q_{in}(= 10, 30, 50$ [L/min]), where P_{al} and Q_{in} are normalized by $2A_{pl}$ (here, A_{pl} is the amplitude of P_{pl}) and Q_{in} = 10 L/min (Q_{in_10}), respectively. The time average of maximal and minimal P_{al} are also displayed in Fig.2(b). Since the lung volume increases with Q_{in} resulting in large stress to assist the exhalation, P_{al} increases while its amplitude decreases with Q_{in}. Hence, our developed 0D model qualitatively represents a characteristic response of the lung driven by the lung tissue elasticity [6].

3-dimensional (3D) fluid simulation. Considering outlet velocity U_{tr} obtained with 0D lung model, the airflow in 3D space of tracheostomy tube was simulated. Figs. 3(a) and 3(b) show the pressure and velocity field at Q_{in} = 30 L/min, respectively. Fig. 3(c) shows the time average of mean, maximal and minimal P_{tr} normalized by $2A_{pl}$ as a function of $Q_{in}/Q_{in,10}$. The results of P_{tr} increases with Q_{in} as well as its amplitude. Although model validation has not been fully completed, we are planning to compare calculated P_{oral} with those in animal experiments. Based on these results, we will discuss whether PEEP can be evaluated based on P_{tr}. Our developed model may be useful to estimate minimal Q_{in} to achieve PEEP for individual postoperative patients with tracheostomy.

SUMMARY

We developed a computational platform to evaluate PEEP in the postoperative patients with tracheostomy. The tracheal pressure, which is outlet pressure of the tracheostomy tube, was calculated by 3D CFD analysis coupled with 0D lung model. In the future study, calculated tracheal pressure will be compared with those in animal experiments. We hope that developed model will be applied to evaluate PEEP and minimal inflow rates for individual patients.

INTRODUCTION

An important predictor of mortality of all forms of pulmonary hypertension (PH) is right ventricular (RV) function, which in turn depends on RV afterload. RV afterload has two components: a steady (mean) component described by pulmonary vascular resistance (PVR) and an unsteady component dependent on proximal artery compliance and distal arteriolar distensibility (α). Distensibility reflects the ability of the smallest pulmonary arteries to dilate in response to an increase in blood pressure [1]. This increase in diameter, which is ~2% per mmHg in healthy subjects [Reeves], helps to maintain a low PVR during exercise [2]. However, in the settings of chronic hypoxia [3] and PH [4] α decreases significantly, which can impair exercise capacity and contribute to increased RV afterload.

Typically, α is determined using multipoint pressure-flow data [1], which can be collected from an invasive exercise test. Single-point methods have also been used [4]. However, patients with PH may not be able or willing to exercise. A passive leg raise is a simple, easy-to-perform maneuver that works to shift blood from the venous system back towards the heart to increase cardiac preload and has been reported to increase pulmonary artery wedge pressure (PAWP) [5]. Here we sought to determine whether α calculated with a passive leg raise (PLR) maneuver was similar to α calculated with exercise in three different phenotypes of PH: pre-capillary PH (PAH), isolated post-capillary PH (Ipc-PH), and mixed pre-/post-capillary PH (Cpc-PH).

METHODS

Invasive cardiopulmonary exercise testing (CPET), consisting of a right heart catheterization (RHC) and simultaneous expired gas analysis during graded exercise, was performed in patients with suspected PH (n = 46). Hemodynamic evaluation was performed under three conditions: rest (supine), PLR (semi-recumbent) and peak exercise (semi-recumbent). In the semi-recumbent position, the subject's upper body was supported with a wedge-shaped pillow at a 45-degree angle. The PLR maneuver was performed with the subject's feet resting in the pedals of the exercise bike for five minutes. Exercise was performed on a semi-recumbent cycle ergometer at 60 rpm. The workload was increased in increments of 10-20 Watts/min until exhaustion. The study was approved by the UW-Madison institutional review board (2019-0535).

Hemodynamic evaluation consisted of PAWP, cardiac output (CO) by direct Fick method, and pulmonary artery (PA) pressure. These data were recorded at the conclusion of each condition using a balloon-tipped, double-lumen, fluid-filled 7 Fr PA catheter via an internal jugular vein approach. PVR was calculated as:

$$PVR = \frac{mPAP - PAWP}{CO} \tag{1}$$

where mPAP is the mean PA pressure.

Subjects were classified into one of four groups (PAH, n = 10; Ipc-PH, n = 19; Cpc-PH, n = 12; or No PH, n = 5) based on mPAP, PAWP and PVR per 2019 ESC/ERS guidelines [6]. Subjects with No PH had mPAP/CO slope<3.0 and rest mPAP<20 mmHg.

Assuming that the pulmonary arteries are fully recruited, dilated and homogeneously distensible, α can be determined using the governing equation [1]:

$$mPAP = \frac{[(1 + \alpha PAWP)^5 + 5\alpha R_o CO]^{\frac{1}{5}} - 1}{\alpha} \tag{2}$$

where R_0 is the total pulmonary vascular resistance at rest, calculated as:

$$R_0 = \frac{mPAP}{CO} \quad (3)$$

Using the method of successive iterations [1], α was fit to two conditions: rest and peak exercise or rest and PLR.

Results were analyzed with a 2-way ANOVA for condition (peak exercise vs. PLR) and group (PH phenotype or No PH). Two-way interaction effects were evaluated between PH-phenotype and condition but were not found to be significant. Tukey's honestly significant difference test was used as a post hoc test of significance. $p<0.05$ was considered significant and results are presented as mean ± standard deviation.

RESULTS

Table 1 shows the hemodynamic parameters measured at rest, PLR and peak exercise in each subject group.

Table 1: Hemodynamic evaluation of subjects from RHC

PH-Phenotype	No PH	Ipc-PH	Cpc-PH	PAH
mPAP, mmHg				
Rest	19±2	28±7	39±8	38±10
PLR	22±2	34±9	47±8	44±12
Exercise	27±8	44±11	56±8	55±10
CO, L/min				
Rest	6.2±1.1	5.3±1.3	4.7±1.4	4.1±1.0
PLR	6.2±1.2	5.0±1.4	4.2±1.3	4.0±1.3
Exercise	14.1±5.1	8.5±2.9	7.1±2.5	6.4±1.7
PAWP, mmHg				
Rest	13±2	18±4	18±4	13±2
PLR	15±2	24±6	26±6	17±4
Exercise	18±3	31±7	32±6	21±2
PVR, Wood Units				
Rest	0.8±0.6	2.0±0.7	4.9±2.2	6.0±2.1
PLR	1.1±0.5	2.3±1.1	5.1±1.8	6.7±2.1
Exercise	0.8±0.8	1.7±1.0	3.7±1.0	5.8±2.6

There was no significant difference ($p = 0.513$) in α between the two conditions: peak exercise (1.02 ± 0.94% per mmHg) and PLR (0.95 ± 0.71% per mmHg) (Figure 1). The PLR-based measure of α was significantly lower in the Ipc-PH (1.17 ± 0.60% per mmHg), Cpc-PH (0.51 ± 0.22% per mmHg) and PAH (0.44 ± 0.29% per mmHg) groups compared to the No PH group (2.18 ± 0.69% per mmHg) (Figure 2). In addition, α was significantly lower in the groups characterized by a significant pre-capillary PH component (Cpc-PH and PAH) compared to the Ipc-PH group (Figure 2).

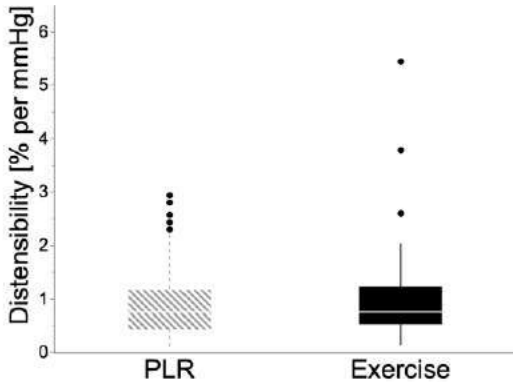

Figure 1: Pulmonary vascular distensibility comparison between the two conditions: PLR and peak exercise (n = 46). P=0.513.

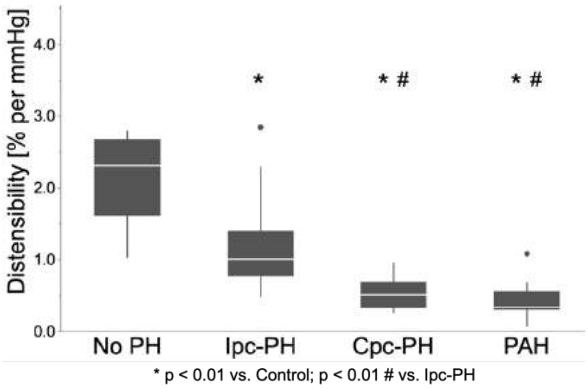

Figure 2: PLR-based measure of pulmonary vascular distensibility for the four groups: No PH (n = 5), Ipc-PH (n = 19), Cpc-PH (n = 12) and PAH (n = 10).

DISCUSSION

RV function depends on RV afterload. The pulmonary arteries dilate to protect the afterload-sensitive RV from excessive increases in pressure. Thus, α acts to help limit the afterload that the RV confronts in conditions of increased pressure (e.g., disease and exercise). Here we show that in subjects with and without PH, pulmonary vascular α can be measured via PLR, which is clinically important for subjects with contraindications to exercise and subjects with severe PH whose exercise capacity is essentially nil.

The present calculations of α for the No PH group agree with prior studies in which a value of 2% per mmHg was observed [3, 8, 9]. Distensibility was significantly decreased in all PH phenotypes, with the lowest values obtained in the groups with a significant pre-capillary component. Reduced α was also observed in a study with PAH [4] and heart failure subjects compared to control [9]. An important limitation to this study is that data were not disaggregated or analyzed for sex or age differences in α, both of which have been reported [10]. In addition, the No PH group cannot be considered healthy as they had dyspnea and suspicion of PH.

In conclusion, we present a clinically simple and robust alternative to exercise for measuring pulmonary vascular distensibility. Broader use of this metric of pulmonary vascular function may shed light on the origins of exercise intolerance in a range of pulmonary vascular diseases and the hemodynamic mechanisms by which PH causes RV failure.

INTRODUCTION

Monoclonal and multi-specific antibody-based immunotherapies constitute an expanding therapeutic armamentarium against various diseases, including cancer and viral infection. Due to the complex mechanism of therapeutic antibodies, and often times, their lack of cross-reactivity to murine counterparts of their intended targets, drug testing using animal models or conventional 2D human cell cultures are not sufficient to predict patient drug efficacy. Moreover, in vivo quantification of immune cell infiltration in real-time is challenging. Many previous in vitro models do not recapitulate immune cell extravasation and migration at the same time. New 3D organotypic models that employ 3D cell culture of human cells within a microfluidic device allow detailed characterization of critical biological interactions (1,2). In particular, microfluidic chips that have the capability to create a perfusable microvascular network can deliver signaling molecules and immune cells using microfluidic flow (1–3). Compared to 2D cell culture, spheroids and organoids are better representations of the structure of an organ where each cell is in contact with other cells and the extracellular matrix. Integrating 3D structures such as spheroids and organoids into microfluidic systems not only recapitulate the physiological state of the cells within a body but also allow interactions between cells in a tissue and peripheral cells or circulating immune cells. In this project, we describe a new 3D cell culture model consisting of an in-vitro human perfusable vascularized tissue with cylindrical wells for the insertion of tumor spheroids. We use this system to characterize the effect of interstitial flows and macrophage polarization on monocyte recruitment and establish a model for therapeutic antibody testing. Using the new microfluidic model, we demonstrate the efficacy of UniTI102, a therapeutic multi-specific antibody targeting CSF-R, CCR2 and TGFb, in blocking monocyte recruitment by a tumor spheroid.

METHODS

Microfluidic device fabrication, and cell culture methods for normal human lung fibroblasts (NHLFs), and human umbilical vein endothelial cells (HUVECs) have been previously reported (4,5). Briefly, vascular networks are created by seeding NHLFs (1 M/ml NHLFs) and HUVECs (11 M/ml) in thrombin (2 U/mL) and fibrinogen (6mg/ml) gel solution. Gel holes are created by pushing a bubble into the gel solution or removing spacers from the gel chamber before the gel solution polymerizes. Open channels on both sides of the gel chamber are then filled with media. 3 days later, HUVEC suspension (1M/ml) is added into the two media channels. Primary monocytes (CD14+CD16-) are isolated from human's whole blood from healthy donors. M0 macrophages are differentiated from CD14+CD16- monocytes by culturing with M-CSF (100ng/ml) using 6 well or 12 well plates (1M cells/1.5ml). M2 macrophages are obtained by culturing M0 macrophages in RPMI media supplemented with 10% FBS, IL4 (20 ng/ml) and IL10 (10 ng/ml) overnight. Tumor spheroid composition is 40,000 NHLFs, 13,000 tumor cells (MDA-MB-468), with the presence or absence of 13,000 macrophages per spheroid. Cells are mixed and cultured in low adhesion round-bottom 96-well plates in 5%CO2 at 37C with RPMI media. 6 d after the vascular network is seeded, a tumor spheroid is inserted into the cylindrical well and embedded in rat tail collagen (final concentration is 2mg/ml when the gel solution is mixed). Monocytes are freshly isolated from blood or thawed from frozen vials and are stained with far red cell tracker (3µM, 30 min) at 37°C 5% CO2. 160,000 monocytes are suspended in 100 µl Vasculife (VEGF supplement kit without Heparin sulfate and VEGF, 10% FBS) and perfused into the vascular networks. By generating a pressure difference between two media channels, monocytes are perfused into the vasculatures. 3mmx3mm ROI of the tumor spheroid and the surrounding microvasculature are acquired using FV1000 Laser Scanning Confocal Microscope (Olympus, PA, USA). A Fiji plugin is used to count the number of monocytes in the device. By quantifying the number of immune cells that are inside the central hole and the total number of cells in the ROI, we can characterize the percentage of the cells that are recruited by the tumor spheroid, i.e. both extravasate from the vasculature and migrate through the gel. UniTI102 drug is provided by Elstar Therapeutics (MA, USA). Unpaired Student's t-tests were applied between two groups (significance indicated as $p<0.05$). The analysis was performed by Prism 7 (GraphPad, San Diego, CA).

RESULTS

A polydimethylsiloxane device with several vertical holes on top of the gel channel is used to create the host microvascular endothelial (HOME) network (Fig. 1A). A fibrin gel solution that has HUVECs and NHLFs in suspension is injected into the device. Later, these form a blood-vessel-like network that is also perfusable (Fig. 1B). Tumor spheroids are formed by coculturing MDA-MB-468 tumor cells (T), NHLFs (F), and macrophages with different polarizations: either non-polarized (M0) or polarized toward M2, denoted by TFM0 and TFM2 respectively (Fig. 1C). One day after inserting a tumor spheroid into the HOME networks through the hole together with collagen, freshly-isolated monocytes are perfused into the networks by luminal flow. We observe that after 2 d, majority of the monocytes remain either within the vasculature or extravasate but stay inside the fibrin gel outside of the hole containing the tumor spheroid (Fig. 1Di). On day 2, interstitial flows from the tumor spheroid toward the vasculature are generated by the application of a hydrostatic pressure from a column of media contained in a pipette tip placed on top of the hole containing a spheroid (see Fig. 1C).

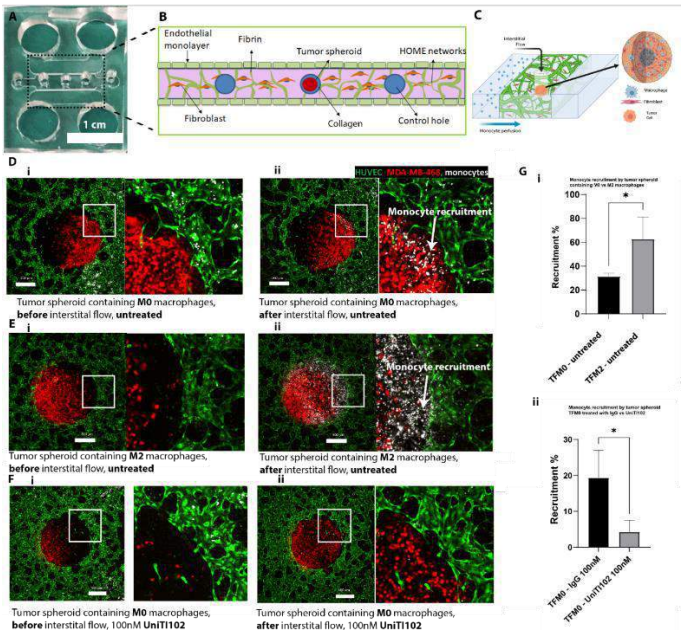

Figure 1: Design and use of the microfluidic chip containing chambers for studying tumor vascularization and immunotherapy. A) Microfluidic chip (transparent) without cells. Gel channel is flanked by two media channels. **B)** Schematic of microfluidic chip in (A) after a few days in culture. A tumor spheroid is placed in holes surrounded by endothelial networks. **C)** Generation of interstitial flow and immune cell recruitment assay. Fluid flow is applied from the opening of the device, passing through the extracellular matrix surrounding the spheroid and directed toward the vascular network. Right: schematic presentation of a tumor spheroid. **D-E)** Effect of interstitial flows and macrophage phenotype on monocyte recruitment. Panels display the top view of a region of a device that has one well containing a tumor spheroid with MDA-MB-468 tumor cells (red), fibroblasts, and macrophages (either M0 or M2 phenotype, in Fig. D and E respectively) surrounded by vascular networks that contain monocytes, before (i) and after (ii) interstitial flows are applied. **Di)** Monocytes (white) still stay inside vascular networks 2 d after perfusing them into the device that has a tumor spheroid containing tumor cells, fibroblast and M0 macrophages (denote TFM0). **Dii)** After applying interstitial flows from the top of the well through the tumor spheroid and toward the vasculature, monocytes within the vascular networks leave the vasculature more readily and migrate toward the spheroid inside the well. **Ei)** Device with a spheroid containing M2 macrophages (TFM2). Before interstitial flow, monocytes also do not migrate into the well. **Eii)** Monocytes in the TFM2 device migrate into the tumor spheroid after an overnight application of interstitial flow. **F)** Device containing TFM0 treated with 100nM UniTI102 for 2 days display less monocyte migration both before (Fi) and after (Fii) applying interstitial flows. Due to the drug that blocks monocyte migration, far fewer monocytes are recruited by the tumor spheroid in (Fig. Fii) compared to (Fig. Dii). In D-F, tumor cells express RFP (red); HUVECs express GFP (green). Scale bars: 500µm. **Gi.** Quantification of monocytes recruited by TFM0 (N=4) versus TFM2 (N=4). **Gii.** Quantification of recruited monocytes in TFM0 devices treated with 100nM IgG (N=4) or with 100nM UniTI102 (N=4).

The device is then imaged on the next day, and we observe that monocytes migrate from the vascular networks and the gel outside of the vascular networks into the hole containing the tumor spheroid (Fig. 1Dii). When a TFM2 spheroid is inserted into the HOME networks, it recruits more monocytes than the TFM0 spheroid (Fig. Ei and Eii), under the same interstitial pressure applied 2 d after perfusing monocytes. Recruited monocytes are the population that leaves the blood vessel and migrate into the hole. The pooled experimental results from 2 different batches showing monocytes are recruited better by the TFM2 spheroid than the TFM0 spheroid (Fig. 1Gi). These data demonstrate that interstitial flow from the tumor spheroid to the vascular networks is essential for monocyte recruitment. In addition, they highlight the importance of macrophage polarization in monocyte recruitment.

UniTI102 is a bispecific antibody targeting CCR2, and CSF-1R, and contains a TGFβ trap (Elstar Therapeutics, MA, USA). It is designed to selectively binds to CCR2+ and CSF-1R+ myeloid cells and is capable of functionally inhibit both CSF-1/CSF-1R and CCL2/CCR2 signaling pathways. Thus, we characterize the ability of UniTI102 to suppress monocyte recruitment. We compared devices having a TFM0 spheroid that are untreated (Fig. 1D) or treated with UniTI102 (Fig. 1F) and observed fewer monocytes migrating into the hole in the presence of 100nM UniTI102. Quantitative data showed that fewer monocytes are recruited when devices are treated with 100nM UniTI102 than 100nM IgG (Fig. 1Gii).

DISCUSSION

We describe here a newly engineered tumor model that has functional perfusable vasculature to study immune cell recruitment and use the platform to screen a new therapeutic antibody. This system is unique in terms of the method used to create an empty space surrounded by a perfusable vascular network. Immune cell trafficking across blood vessels and migrating toward the tumor are characterized in real-time and high resolution using confocal microscopy. Compared with the methodology used for other *in vitro* cell culture systems (2), this technique could better reproduce the complexity of a tumor by incorporating a perfusable vasculature. Furthermore, we employ the open-top hole to generate interstitial flows from the tumor spheroid toward the vasculature, mimicking the physiological interstitial flow emanating from a tumor, and show that interstitial flows help support immune cell recruitment. Moreover, we show that when tumor spheroids have mature M2 macrophages, they recruit more monocytes. Using this new platform, we demonstrate the effect of a therapeutic multi-functional antibody candidate in preventing monocyte recruitment to the tumor spheroid. We believe that immune-competent physiological models, such as the work described here, will play a central role in immunotherapy drug screening in the future.

INTRODUCTION

Each year ~1.4 million patients require arterial grafts in the US. Synthetic vascular grafts are required in ~10-20% of patients when autografts are unavailable; however, synthetic vascular grafts in small diameter applications (ID < 6 mm) have high failure rates. Synthetic grafts are associated with a 40-50% reduction in patency after 2 years and a 40% failure rate at 5 years [2]. This loss of patency due to intimal hyperplasia has been attributed, in part, to poor compliance-matching with native arterial tissue [1]. Data demonstrate that the high compliance of native vessels (e.g., coronary artery, 10-15 %/mmHg*10^{-2}) permits expansion and contraction during the cardiac cycle, whereas commercially available synthetic grafts have limited deformation at these pressure loads (e.g., ePTFE, 1-2 %/mmHg*10^{-2}). Notwithstanding the role of altered hemodynamics at the graft-tissue interface leading to neointimal hyperplasia, improved compliance matching between the graft and arterial tissue has been identified as a key determinant of long-term patency and graft success.

Advances in material chemistry and microfabrication strategies have allowed the manufacturing of polyurethane-based small diameter vascular graft with improved compliance matching [3]. Indeed, these grafts have been shown to reduce cellular markers for intimal hyperplasia, however, the increased compliance resulted in grafts that were prone to kinking, occlusion, and failure. To improve kink-resistance, a polymeric coil was added, but the addition negatively impacted compliance [4]. Due to the nearly infinite combinations of coil geometric properties, optimization strategies can be integrated to balance offsetting graft properties (e.g., kink resistance vs. compliance) and aid fabrication. Herein, we highlight the development and experimental validation of a computationally-informed design process to tune the mechanical properties of synthetic vascular grafts and aid compliance matching with vascular tissue.

METHODS

Vascular Graft Fabrication and Experimental Testing: A 24% Bionate® segmented polyurethane (DSM Biomedical) in dimethylacetamide solution was utilized for electrospinning. A 5 mm mandrel was coated in a polyethylene glycol (Mn = 35 kDa) sacrificial layer (5% in dichloromethane). An initial electrospun layer was deposited via a flow rate of 0.5 ml/hr and charges of +15-16.5 kV and -5 kV were applied to the 20G needle and mandrel, respectively, with a working distance of 50 cm. An 18 wt% solution of Bionate®55D in hexafluoroisopropanol was subsequently deposited on the initial layer forming a kink-resistant coil [outer diameter (d_o) = 0.38 mm]. Finally, a second electrospun layer was deposited on top of the coil forming the final tri-layer kink-resistant graft (Fig. 1A).

Graft compliance was calculated by measuring the change in inner diameter (d_i) of the vascular grafts, as measured via a laser micrometer, from lumen pressures of 80 mmHg to 120 mmHg via the following equation,

$$C = \frac{d_{i,120\ mmHg} - d_{i,80\ mmHg}}{d_{i,80\ mmHg} * 40\ mmHg} \quad (1)$$

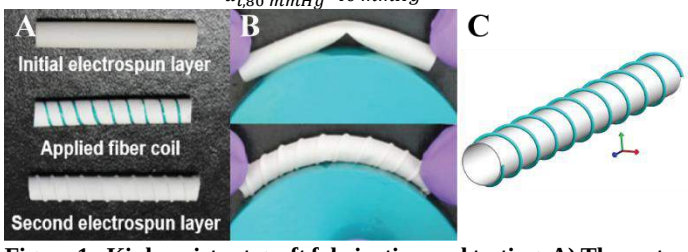

Figure 1: Kink resistant graft fabrication and testing. A) Three step fabrication process. B) Measurement of kink radius of control (no coil) and reinforced graft. C) CAD model of reinforced graft.

The radius of curvature that initiates graft kinking (i.e., kink radius) was examined by bending the graft around a tapered mandrel until a kink was visually observed (~50% reduction in diameter, Fig. 1B). Compliance and kink radius were determined in a control (no coil) and coil reinforced graft. Data are reported as mean±SD.

Computational Modeling: The tri-layer graft was modeled as an axisymmetric cylinder ($l = 40$ mm, $d_i = 4.74$ mm, $d_o = 4.94$ mm) with a reinforced coil wrapped around the other surface (pitch = 0.4 mm, Fig. 1C). Two fiber coil diameters were evaluated ($d_o = 0.19$ and 0.38 mm).

The graft and spiral coil were discretized with hexahedral and tetrahedral elements, respectively. Both the mesh and fiber coil were described as a nearly incompressible neo-Hookean solid with material properties derived from mechanical testing of the fabricated graft (μ =1.315 MPa) and spiral coil (μ =8.13 MPa) constituents. Two computational simulations were performed on a control (no coil) and each coil reinforced geometry to quantify compliance and kink resistance. To quantify compliance (Eq. 1), a lumen pressure from 0 to 120 mmHg to predict changes in diameter. To quantify kink-resistance, a 1° bend was applied to the central axis of the graft and the lumen was pressurized to 120 mmHg, as previously established to evaluate artery buckling [5]. Bending displacement was quantified as the deviation of the central graft axis in the central region under pressurization. For all models, symmetry boundary conditions were enforced on the graft to restrict rigid body motions in the circumferential and axial directions. A tied-elastic contact formulation was implemented between the outer graft surface and the spiral coil. Finite element analysis was performed using open-source finite element software package FEBio [6].

RESULTS

Experiments demonstrated that the presence of the fiber coil ($d_o =$ 0.38 mm) reduced graft compliance and bending displacement when compared to the control graft (no coil). For example, addition of the reinforcing coil resulted in a reduction in compliance from 8.0 ± 0.9 %/mmHg*10^{-2} to 1.5 ± 0.4 %/mmHg*10^{-2} (Fig. 2A). Kink radius measurements indicated an improvement in the kink resistance of the coil (a reduction in kink radius indicates improved kink resistance), as the value decreased from 99 ± 5 mm (control) to 63 ± 3 mm (Fig. 2B). Comparison of the computational and experimental data revealed strong agreement between measures of compliance and kink resistance. Modelling data showed that the addition of the coil decreased compliance from 8.0 %/mmHg*10^{-2} (control) to 1.5 %/mmHg*10^{-2} (Fig. 2A,D) in good agreement with the experimental compliance measurements. Furthermore, the model-predicted bending displacement decreased from 0.15 mm to 0.12 mm for the control and coil reinforced grafts, respectively, correlated with the improved kink-resistance (a reduction in bending displacement indicates improved kink resistance, Fig. 2C,E).

To demonstrate the utility of computational modeling to inform graft fabrication, we examined the impact of changes in coil geometry on predicted graft properties. Modeling data demonstrated that reducing the coil diameter from 0.38 to 0.19 mm resulted in an increase in compliance from 1.5 %/mmHg*10^{-2} to 4.1 %/mmHg*10^{-2}; however, kink resistance was maintained, as a minimal decrease in bending displacement was observed (0.12 to 0.11 mm). These graft fabrication parameters will be used in the next iterative of graft testing.

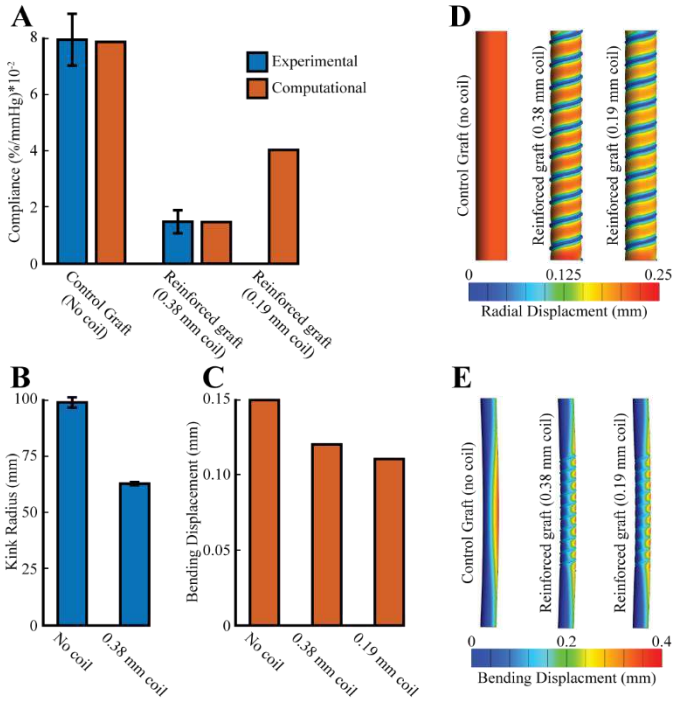

Figure 2: Compliance and kinking resistance data for fabricated and modeled grafts. A) Reduction of compliance with reinforcing coil. B) Reduction of kink radius with reinforcing coil. C) Model-predicted reduction in bending displacement with reinforcing coil. D) Model-predicted radial displacement and E) bending displacement at 120 mmHg.

DISCUSSION

Our investigation demonstrates the potential of computational modeling to inform synthetic vascular graft design, particularly when mechanical properties run counter to each other (e.g., high compliance, kink-resistance). We report that initial computational results agree well with experimental data evaluating the compliance and kink-resistance in a novel graft with a reinforcing polymeric coil. Data show that addition of the coil improves kink-resistance of the graft, but reduces compliance. As a proof-of-concept, we highlight how the computational modeling framework can identify a modified coil geometry (reduced coil diameter) that maintained kink-resistance while improving compliance. Such efforts illustrate the capability of computational modelling to optimize graft design and accelerate testing. We anticipate that the combination of precise material fabrication and model-directed design is expected to provide a kink-resistant graft with high compliance for small diameter vascular graft applications. Ultimately, these unique grafts have potential to improve clinical outcomes by addressing failures of current synthetic grafts.

COLLAGEN DAMAGE IN ARTERIES – CHOICE OF ANALYSIS TECHNIQUE MATTERS IN IDENTIFYING RATE DEPENDENCE

INTRODUCTION

Since the 1970s, researchers have sought to define tissue damage and failure. Damage occurs across the entire hierarchy of tissue structure but is, to date, poorly understood. The recent use of collagen hybridizing peptide (CHP) to identify damage in mechanically overloaded cerebral arteries [1] and tendon [2] confirmed the delamination theory of tropocollagen damage. We previously reported that CHP does not significantly bind to tissue failed at high strain rates [3]; however, our work was limited to a layer-specific analysis using confocal microscopy. Recent research shows that an alternative digestion-based microplate assay improves the quantification of damage in the highly aligned fibers of tendon [4]. It is less clear if such global quantification of tropocollagen damage is preferred in arteries, where collagen fiber directions vary dramatically through different layers, and baseline collagen remodeling activity is likely higher [1]. To address this knowledge gap, we stretched arteries axially to failure, both quasi-statically and at high strain rate, and compared CHP quantification using confocal analysis of the adventitial layer (where collagen fibers are largely aligned with the axial direction) with quantification using a global microplate assay. We find that the microplate assay does not identify any rate dependence in collagen delamination, while the confocal analysis shows a statistical difference between the two experimental groups. This shows that the choice of CHP analysis technique is critical in identifying damage phenomena in the multi-layer environment of arteries.

METHODS

Brains were removed from Göttingen minipigs, and the middle cerebral arteries (MCAs) were removed and placed in calcium-free phosphate-buffered saline (PBS). The pia-arachnoid complex was removed from the tissue, branches were ligated, and the vessels were stored at 4°C until mechanical testing. All mechanical testing was done within 48 hrs of death. Vessels were mounted onto a previously described tester [5] and preconditioned via pressure cycles at increasing axial stretch levels [1]. The MCAs were then pulled to failure either quasi-statically (0.01 s^{-1}) or at a high strain rate (>150 s^{-1}) as described in [3]. Seven vessels were selected for analysis from the quasi-static group and five from the high-rate group.

Following mechanical failure, the selected arteries were removed from the tester and stained with 20 µm F-CHP (fluorophore tagged CHP; 3Helix #FLU300, Salt Lake City) for at least 12 hours, and rinsed three times in PBS. Samples were then cut longitudinally and laid flat on a glass slide, using Fluormount (Fluoromount G; Southern Biotech) as the mounting medium. Image stacks were acquired with a confocal microscope (Fluoview FV1000, Olympus) at 2 µm slice increments. Following imaging, the image slice having the greatest brightness in axially oriented fibers was selected to represent the adventitial layer of the artery. The selected adventitia image was then normalized by undamaged control samples from the same animal to eliminate contributions from auto-fluorescence and remodeling. CHP attachment was calculated as the percent of pixels having a brightness greater than a threshold of four times the average control brightness.

The use of enzymatic digestion to evaluate CHP attachment largely followed previously established protocols [4]. After confocal imaging, each vessel was removed from its slide and rinsed in deionized water. It was assumed that the total quantity of collagen in the vessels was directly proportional to the dry weight. To evaluate dry weight, vessels were briefly dehydrated and weighed on a microbalance (UMX2 ultra-

microbalance, Mettler Toledo), after which the average of three measurements was recorded. Following weighing, vessels were rehydrated in deionized water and placed in a 100 µL solution of 1 mg/mL proteinase K (in deionized water) for 24 hours at 60° C. Each sample volume was then split into 50 µL segments and placed in an opaque microplate. Fluorescence was evaluated using a microplate reader (SpectraMax Gemini XPS, Molecular Devices, Sunnyvale, CA) with an excitation wavelength of 485 nm and an emission wavelength of 525 nm. The signals from the duplicates were averaged and divided by the dry weight previously obtained to normalize results. CHP attachment was reported as a multiple of control brightness.

Student's *t*-test was used to compare quasi-static and high-rate results for both methods. Significance was concluded for $p<0.05$.

RESULTS

As previously shown [3], vessels tested at quasi-static rates displayed notably higher levels of microstructural damage than those tested at high strain rates (Figure 1; p=0.015). However, this difference in observed damage levels with strain rate disappeared when the same vessels were evaluated using the microplate assay (Figure 2; p=0.35).

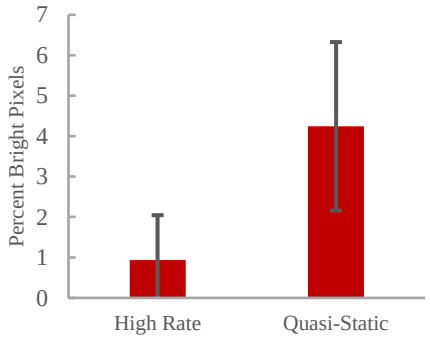

Figure 1: Local CHP quantification using the confocal microscopy technique shows a dramatic reduction in collagen delamination in vessels stretched dynamically compared to those stretched quasi-statically (p=0.015). Mean ± std dev.

DISCUSSION

Our results indicate that the selection of CHP damage quantification technique in the reported experiments has a dramatic effect on conclusions that can be drawn regarding the influence of strain rate on collagen delamination. This provides an interesting case study on the broad significance of method selection in science.

In comparing the two methods, it is clear that tropocollagen delamination differences with strain rate are significant at the local level but are not detectable at the global scale. One factor that seems to be important in this discrepancy is the complexity of the tissue. When used in fiber-aligned rat tail fascicle, the proteinase K assay is clearly accurate in indicating levels of collagen damage [4]. However, when used in cerebral arteries, sensitivity to layer-specific fiber orientation [1] is largely lost. It is interesting, though, that overall indication of damage to the tropocollagen structure is maintained in the microplate assay. While this is under investigation, it seems most likely that there is lower-intensity damage (that is not rate dependent) in layers other than the one chosen for analysis for its greatest fiber brightness, and that the sum of the fluorescence of these other layers overwhelms the specificity of the brightest adventitial damage signal.

Several limitations are inherent to the confocal imaging approach, perhaps the most impactful being the heavy dependence on the operator's ability to interpret collagen fiber orientation and positioning within the vessel wall. Additionally, researcher bias may be introduced while masking out artificial artifacts such as debris or suture. These limitations, together with the time investment required to image each vessel in entirety, demands a relatively large time commitment. Furthermore, the quantification algorithm is complicated and sensitive to the chosen steps. The confocal image analysis and quantification is an ongoing area of advancement but will remain challenging as the complexity level of the examined tissue increases.

The proteinase K assay is limited in its usefulness by its destructive nature. After tissue decomposition, it is impossible to extract fiber direction or other histological landmarks that may increase understanding of damage development. Drawbacks also exist for normalizing the proteinase K assay. Here, the dry weight was obtained using a highly precise microbalance (readability 0.1 µg) where the weight of each vessel ranged from approximately 10 to 50 µg. An alternative is proposed by Lin [4] in which a trypsin-hydroxyproline assay is used to estimate total collagen content. This process, while applicable to a wide range of tissues, is time consuming and carries its own risks of data loss during assay processing.

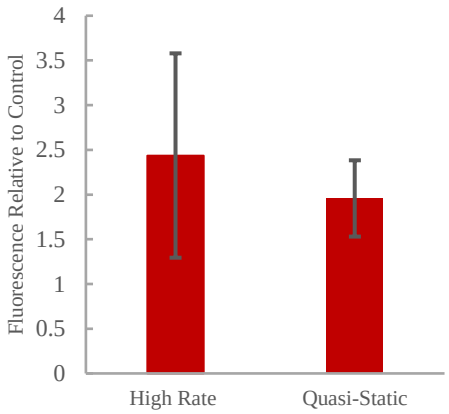

Figure 2: Global CHP quantification using the proteinase K microplate assay technique suggests no difference in extent of collagen delamination with strain rate. Mean ± std dev.

In conclusion, we find a disparity in rate dependent damage shown by CHP attachment when quantified using confocal microscopy compared with a microplate assay. This indicates that the rate-dependent CHP signal, while locally significant, is likely overwhelmed by global CHP attachment elsewhere in the vessel. Future work will further examine this phenomenon, but we expect that proteinase K will continue to be useful for general examination of vessel damage, while a microscopy approach will be required for microstructure-focused examination.

STUDY ON HEATING CAPABILITY OF NEW RADIOFREQUENCY ANGIOPLASTY BALLOON

Hongying Wang, Shiqing Zhao, Jincheng Zou and Aili Zhang

Department of Biomedical Engineering
Shanghai Jiao Tong University
Shanghai, China

INTRODUCTION

Percutaneous transluminal angioplasty (PTA) based on balloon and stents is widely used to dilate the artery narrowed by atherosclerotic plaque and restore blood flow[1]. However, restenosis often occurred after six months[2]. The main factor of restenosis is endothelial injury brought by the mechanical force in the PTA, which triggered a serial of inflammation process and caused vascular smooth muscle cell (VSMCs) proliferation and migration into the endothelial layer[3]. To inhibit the proliferation of VSMCs while protecting the endothelium may obtain a better therapeutic outcome.

Recently, Zhao et al proposed a novel treatment for atherosclerosis, in which the electrodes on the outer surface of balloon heat the plaque while the cooling water circulating in the balloon to lower the temperature of endothelium [4]. The numerical and phantom heating experiment results demonstrated that the novel treatment could heat the deep region and maintain the lower temperature in the endothelium. However, the conformal heating in the depth direction was not realized, in other words, the depth of heating cannot be adjusted based on the morphology of plaque, which varies with each other[5]. Herein， in order to realize the conformal heating in the depth direction, an experimental system, in which the temperature and velocity of cooling water could be adjusted, was established. Besides, the negative feedback regulation of output voltage on the electrodes was implemented via a temperature control algorithm, in which the setting temperature and voltage was the input and output variable. To investigate the effect of three parameters (the temperature, the velocity of water, the setting temperature) on the heating capability, several phantom heating experiments were conduct and computational model were established.

METHODS

Experiment setup: The experiment setup was similar with the previous study[6]. The cooling water flowed through a polyimide tube as a substitute for the balloon, which was connected with an adjusted water pump and a temperature adjustable thermostat bath. The electrodes were adhered on the outer surface and controlled by the radiofrequency system. The tube with electrodes was inserted into the tissue-mimicking phantom (see Fig.1A). In order to monitor the temperature evolution, three small thermocouples were unilaterally inserted into the phantom (see Fig.1A). Besides, one thermocouple as a control point was located between the two electrodes and the temperature was the input in the control algorithm (see Fig.1B and C, the red point). The intervals between the thermocouples (TC0, TC1, TC2, TC3) were 0.854, 1.61, 1.62mm, respectively. Phantom heating experiment was conducted with different parameters (the temperature and velocity of cooling water, the setting temperature) and duplicated three times. The cooling water pump was switch on 45s before the heating. The heating was lasted for 2 minutes. The temperature of the phantom and water, the voltages were recorded for further analysis.

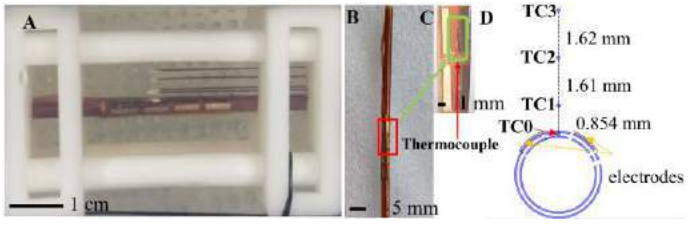

Figure 1: (A) picture of the phantom, electrodes and inserted with five thermocouples, (B) The polyimide tube pasted with microelectrodes and thermocouples, (C) Sectional view of polyimide tube with thermocouple and electrodes.

Temperature control algorithm: A temperature-controlled algorithm, PID control algorithm of integral limit (see Eq.1 ~ 3), was implemented by C# language. The voltage on the electrode and the temperature measured by TC0 were output and input variables. The coefficients in algorithm were determined manually.

$$RFVoltage(\mathrm{k}) = \begin{cases} 35\ (V);\ e(k) > 4\ ;\ e(k) < 4, PID(k) > 200 \\ 0.187 * PID(k) - 2.25\ (V); e(k) < 4, 100 < PID(k) < 200 \\ 16.5\ (V);\ PID(k) < 100 \end{cases} \quad (1)$$

$$e(k) = Tset(k) - T(k) \quad (2)$$

$$PID(k) = Kp * e(k) + Ki * \sum_{j=0}^{k} e(j) + Kd * \big(e(k) - e(k-1)\big) \quad (3)$$

Numerical modeling: In order to obtain the 3D temperature distribution, a finite element model (FEM) with the realistic experimental parameters was established in COMSOL Multiphysics (COMSOL, Inc., Burlington, MA, USA) to quantitatively assess the relationship between ablation zone and the parameters. The model setting details were same with the study[6].

RESULTS

With the fast response of the hardware circuit and the high sampling frequency of the data acquisition card, the temperature of control point reached the setting temperature (40℃) within 10s and the fluctuation was only ±0.5℃. The final temperature of point 0.845 mm away from the electrodes was about 60℃ and far higher than the inner surface temperature.

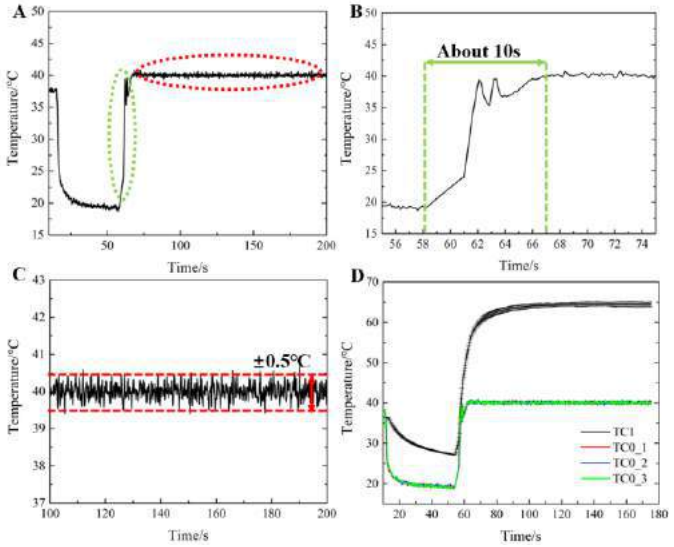

Figure 2: (A) The evolution of control point temperature (TC0), (B~C) The magnified view of the temperature increasing stage and equilibrium stage, (D) TC0 and TC1 temperature evolution (n=3).

The temperature in the phantom (TC1~TC3) increased dramatically as the setting temperature increased and showed a linear relationship, and TC1~TC3 temperature increased by 2.11℃, 1.06℃, and 0.49℃ respectively for every 1℃ increment of TC0. On the contrary, TC1~TC3 temperature decreased as the cooling water temperature increased and the decreasing trend gradually slowed down. The temperature in the phantom stayed almost the same as the velocity increase, especially when the velocity exceeded 3.5m/s.

The ablation area and depth on the middle plane of electrode (see Fig.4A) were calculated in the computational model. Here, we take 50℃ as the threshold of ablation temperature for the tissue[7]. The area and depth linearly increase by 1.001mm² and 0.092mm as the setting temperature increase 1℃ (see Fig.4B), and decreased with the temperature of cooling water. Moreover, the decreasing rate decreased as the cooling water temperature increased. The area and depth drop approximately linearly when the cooling water temperature is lower 20℃, and almost undiminished when the cooling water temperature was higher 25℃ (see Fig.4C). The average ablation area and depth are about 15mm² and 2.5mm, which is close to the size of cardiovascular plaque[8].

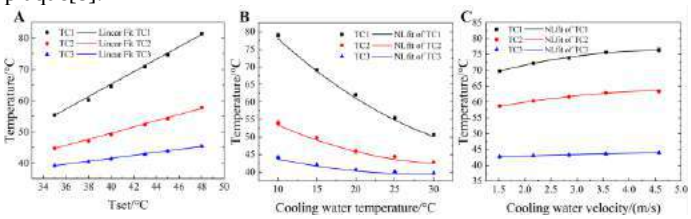

Figure 3: The final temperature in the phantom (TC1~TC3) varied with different parameters: (A) the setting temperature, (B) The cooling water temperature, (C) The cooling water velocity.

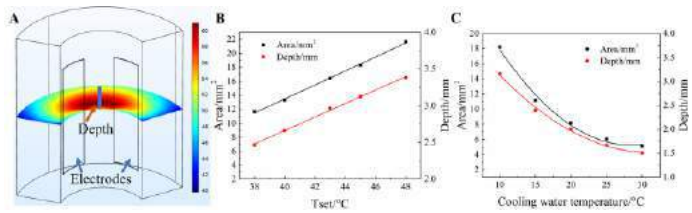

Figure 4: (A) The cross section and the definition of depth, (B~C) The ablation area and depth change as the control point temperature and the cooling water temperature increased.

DISCUSSION

The experimental results demonstrated the temperature control algorithm had a good precision and fast response time. With the algorithm, higher temperature focus on the areas about 0.4mm from the electrode surface and maintain lower temperature on the inner surface of lumen, which may ablate the plaque, inhibit the smooth muscle cell proliferation and protect the endothelium.

Moreover, the setting temperature in the PID algorithm and cooling water temperature had a significant impact on the temperature in the phantom. The effect of water velocity on the temperature was limited. The relationship between the parameters and the heating depth and area would be used to establish a conformal heating algorithm in future. With the help of intravascular imaging, a precise morphology of plaque could be obtained before treatment. Through tuning the setting temperature and the temperature of cooling water, a conformal heating in the depth direction may be realized.

WAVY FIBER STRUCTURE IMPROVES CONTRACTILE PHENOTYPE OF VASCULAR SMOOTH MUSCLE CELLS

Chun-Yu Lin and Pen-hsiu Grace Chao

INTRODUCTION

Elastic lamellae of arterial media forms three-dimensional network with circumferential wavy microstructure that contributes to mechanical functionality of the vessel (Figure 1A, [1]). With aging, the lamellar structure fragments and flattens due to mechanical damage and proteolytic activity [2]. At the same time, the resident vascular smooth muscle cells (VSMCs) change from a more quiescent and contractile phenotype to proliferate and synthesize matrices, resulting in arterial stiffening, a significant risk factor for cardiovascular health. Although regulation of VSMC phenotype by biochemical factors has been widely investigated [3], the effects of age-associated architectural changes remain unknown. Using electrospun straight and wavy fibrous scaffolds, we examine the topographical regulation of primary VSMC phenotype.

METHODS

Material Fabrication Poly-L-lactide solution (PLLA, 6% w/v in hexafluoropropylene) and polyethylene oxide solution (PEO,13.5%w/v in 80% ethanol) were electrospun based on previously reported parameters [4]. After PEO removal, the remaining PLLA fibers were heated at 85℃ for 15 minutes to induce crimp formation [5]. Fiber morphology was confirmed with SEM. Scaffolds were sterilized and treated with dopamine hydrochloride to facilitate collagen I coating (100 μg/ml). Fiber crimpness was assessed from the SEM images and was defined as the normalized difference of fiber path length and end-to-end distance.

VSMC Culture Primary VSMCs were isolated from explant cultures of thoracic aortae from 8 to 10-week-old mice. Isolated VSMCs were cultured in DMEM/F-12 supplemented with 10% FBS and GlutaMax. Cells from passages 2 and 5 were seeded at 600 cells/cm^2 on glass coverslips for one week for immunofluorescence assessment. Cells from passages 3 and 6 were seeded at 15000 cells per scaffold (1x2 cm^2) for 3 weeks for proliferation and immunofluorescence assays.

Proliferation Assay Alamar Blue dye was used to access cell activity during culture according to the manufacturer's protocol (Thermo Fischer Scientific). Briefly, VSMCs on the fibrous scaffolds were cultured in 10% Alamar Blue dye for three hours and the medium was read at 590 nm.

Immunofluorescence Assessment Samples were fixed in formalin, permeablized, and blocked in 1% BSA. Primary antibodies included anti-alpha smooth muscle actin (αSMA, Sigma), anti-transgelin (SM22, Abcam), and anti-calponin-1 (Abcam). Secondary antibodies (Alexa Flour-conjugated), DAPI, and phalloidin were used to fluorescently label the respective primary antibody, DNA, and f-actin targets. Images were acquired using a Nikon Ti-E2 wide field microscope (2D cultures) or a Leica SP-8 confocal microscope (3D scaffolds).

Data Analysis Statistical tests (student's t test, ANOVA with Tukey's HSD post hoc tests, or Fisher's exact test with Bonferroni corrections) and data figures were generated using R.

RESULTS

To investigate the topographical regulation of VSMC phenotype, scaffolds recapitulating wavy microstructure of native arterial wall were fabricated as previously described (Figure 1B, [4]). Compared to the control group (straight scaffolds), crimp fibers had significantly higher crimpness (Figure 1B). Primary VSMCs cultured on the fibrous scaffolds had elongated morphology with linear actin filaments through the length of the cell, while cells in crimp scaffold had discontinuous and wavy stress fibers at the cell periphery (Figure 1C). To confirm VSMC identity, they were immune-characterized with contractile phenotypic markers. Approximately 80% of cultured cells at passage 2 expressed α-SMA and SM22 (Figure 2A and B). Both markers

decreased significantly with passage, where less than 5% of the cells express SM22 at passage 5. Together with the concomitant decrease in population doubling time (Figure 2C), these results indicated that VSMCs switched from the differentiated contractile phenotype to the synthetic phenotype with subcultures. When the late passage VSMCs (P6) were cultured on fibrous scaffolds, the 3D structure improved expression of the contractile markers, which is further enhanced on the crimp scaffolds (Figure 3A). The crimp fibers also suppressed cell proliferation compared with the straight scaffold (Figure 3B, $p<10^{-4}$), indicating fiber morphology regulates VSMC phenotypic switch.

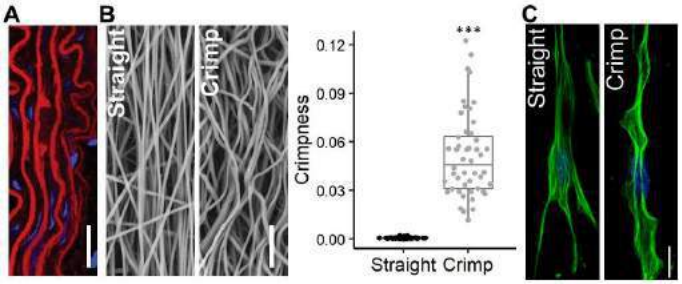

Figure 1 (A) Cross-section of mouse aorta (red-elastin, blue-nuclei, bar: 20μm [6]) (B) SEM images of scaffolds and quantification of fiber structure (bar = 20μm, ***$p<10^{-5}$) (C) Representative VSMC morphology on fibrous scaffolds (blue-nuclei, green-αSMA, bar = 20μm)

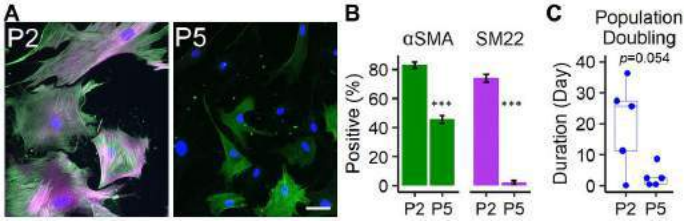

Figure 2 (A) VSMCs at passages 2 and 5 on tissue culture plastic (green-α-SMA, magenta-SM22, blue-nuclei, bar = 50μm) (B) Effects of passaging on the proportion of VSMCs expressing α-SMA or SM22, and (C) population doubling time (***$p<10^{-5}$).

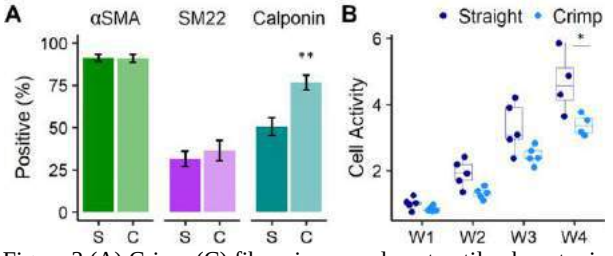

Figure 3 (A) Crimp (C) fibers improved contractile phenotypic expression of late passage VSMCs, compared with straight (S) fibers (**$p<0.001$) (B) Crimp fibers suppressed normalized VSMC activity in culture (W-week, *$p<0.05$).

DISCUSSION

Environmental factors play critical roles in modulating VSMC. Previous studies have found linear topographies control VSMC contact guidance and phenotype [7, 8]. We have also reported that wavy microgrooves regulate nuclear structure and DNA synthesis in VSMC cell lines [9]. In this study, we establish primary VSMC cultures and examine VSMC phenotype in three-dimensional biomimetic crimp fibers. Despite the loss of contractile markers with subculture (Figure 2), 3D scaffolds recover the differentiated phenotype, characterized by decreased proliferation and enhanced calponin-1 expression. In addition to mechanical functionalities [10, 11], our results point to an instructive role of vascular ECM structure on VSMC phenotype. Future studies will investigate the transcriptomic effects of scaffold structure, as well as the interactions of fiber structure and mechanical stimulation on VSMC regulation. As the crimp structure is lost with aging and disease, our findings provide new insights in the maintenance and pathology of vascular homeostasis and health.

EFFECT OF ECM HETEROGENEITY ON CELL MECHANOSENSING

Maria Proestaki (1), Jacob Notbohm (1)

University of Wisconsin-Madison
Madison, Wisconsin, USA

INTRODUCTION

Cells sense mechanical signals within the extracellular matrix, the most familiar being stiffness, but matrix stiffness cannot be simply described by a single value. Randomness in matrix structure can cause stiffness at the scale of a cell to vary by a factor of 3 or greater. Additionally, the extracellular matrix contains stiff and compliant features such as ducts, glands and vessels. Diseased tissues may also contain features of abnormally high stiffness, such as fibrotic scars, stiff arterial walls and tumors. As these various stiff and compliant features alter the matrix stiffness, they could potentially affect the stiffness sensed by a cell. How the features of different stiffness and matrix heterogeneity together affect cell sensing remains unclear. Here we use a combination of experiments and modeling to establish a method to quantify the critical distance over which a cell can sense a locally stiff feature. This method is then used to sort out the effect of matrix heterogeneity on this critical distance.

METHODS

To identify the critical distance over which cells can sense a stiff feature, we conducted experiments using the migratory human breast cancer cell line MDA-MBA-231. Using a 3D Petri dish micro-mold (MicroTissues, Inc.) we formed cell spheroids with an average diameter of 500 μm. A thick layer of rat tail collagen I (Corning) with final concentration 3 mg/mL was polymerized at the bottom of a glass bottom dish, and then a second 3 mg/mL collagen layer was polymerized on top of the first with one cell spheroid and a stiff inclusion embedded into it, as shown in Fig. 1a. Stiff inclusions were introduced by embedding PMMA spheres of 3.5 mm diameter at a distance in the range of 0.5-3 mm from the centroid of each cell spheroid. After 96 hours, images of the cell spheroids were captured, and the area of cell migration toward and away from the stiff inclusion was computed (Fig. 1b). A ratio equal to 1 indicates no preference of cells migrating towards or away from the stiff inclusion, whereas a ratio larger than 1 indicates that cells preferentially migrated towards the stiff inclusion.

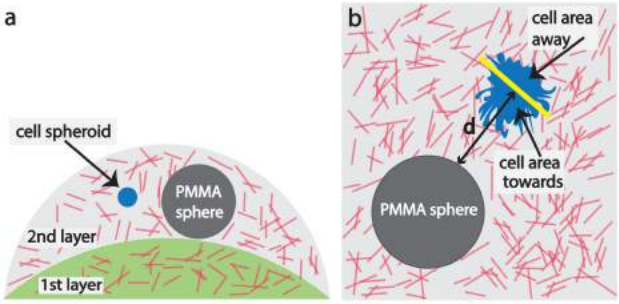

Figure 1: Cell spheroids and stiff inclusions embedded in collagen gels. (a) Schematic of a cell spheroid and a stiff inclusion (PMMA sphere) embedded in a 2-layered collagen gel. (b) Schematic of a collagen matrix with a PMMA sphere located at a distance d from a cell spheroid. Areas of cell migration toward and away from the PMMA sphere are shown.

Additionally, we created a 2D finite element model of a fibrous matrix, that mimics the structure and properties of collagen networks[1]. Each fiber is modeled as a Timoshenko beam that can stretch, bend and buckle and has a stretching, bending and shear stiffness. The important ratio $\kappa = EI/EAL^2$ defines the dimensionless ratio of bending to stretching stiffness, where E is the fiber's Young's modulus, I is the fiber's moment of inertia, A is the fiber's cross sectional area and L is fiber length. For fibrous materials κ is around 10^{-3}, indicating a low resistance to bending compared to stretching[2]. Under compression,

buckling occurs, resulting from bending instability. To match the experiments, a contracting inclusion of radius r and a stiff inclusion located at a distance d from contracting inclusion's centroid were embedded in the fiber network. We quantified the potential for sensing the stiff inclusion by finding the apparent stiffness sensed by the contracting inclusion by applying a nonlinear continuum model for fibrous materials[3]. Because fibers buckle under compression, the stiffness in compression is far smaller than in extension, a phenomenon referred to as compression weakening. The continuum model accounts for compression weakening by introducing a compression weakening factor ρ, which represents the ratio of stiffness in compression to tension, with $0 \le \rho \le 1$. To represent the apparent stiffness sensed by the inclusion, we followed the method of our previous paper[4] to derive an expression for the Young's modulus of the fiber network in the local region surrounding the inclusion, E^n,

$$E^n = \frac{E^i}{g(\nu,\rho)}\left(\frac{\varepsilon^T}{\varepsilon} - 1\right) \qquad (1)$$

where E^i is the Young's modulus of the contracting inclusion, $g(\nu,\rho)$ is a function of Poisson's ratio ν and compression weakening factor ρ, ε^T is the contracting inclusion's strain if it were not in the fiber network and ε is the contracting inclusion's strain in the fiber network. In the results, we express the apparent stiffness as the product of Young's modulus E and function $g(\nu,\rho)$. To determine how the mechanical properties of the fiber network such as fiber density and fiber length can affect the potential for sensing the stiff inclusion, we tested various fiber networks of different density and fiber length.

RESULTS

Results from experiments using cell spheroids and PMMA inclusions showed that the median ratio of the cell migration areas toward the inclusion to away from the inclusion was statistically different than 1 for the cell spheroids located at a distance less than 1.1 mm from the inclusions. Specifically, for the ratios of the spheroids located at a distance less than 1.1 mm from PMMA (Fig. 2 red dots), the sign test rejected the null hypothesis that the median of the data equaled to 1, giving a p-value of 0.02. However, for the ratios of the spheroids located greater than 1.1 mm from PMMA (Fig. 2 black dots), the sign test failed to reject the null hypothesis, with a p-value of 1. The dimensionless ratio of distance d = 1.1 mm to spheroid radius r = 250 μm is 4.4.

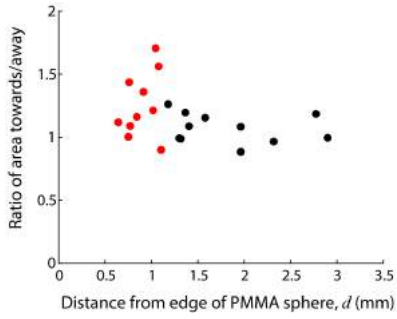

Figure 2: Ratio of cell migration areas towards and away from the PMMA sphere. Each dot represents one cell spheroid. The initial radius r of cell spheroids was approximately 250 μm. Spheroids at distance < 1.1 from the inclusion (red dots) had area ratios significantly greater than 1 (p = 0.02, sign test), whereas spheroids at distance > 1.1 (black dots) had area ratios not significantly greater than 1 (p = 1, sign test).

Results from the fiber network simulations are shown in Fig. 3 for various fiber networks of different fiber density and fiber length. Heterogeneity in stiffness in networks with high density and short fiber length is less than in networks with low fiber density and long fiber length.

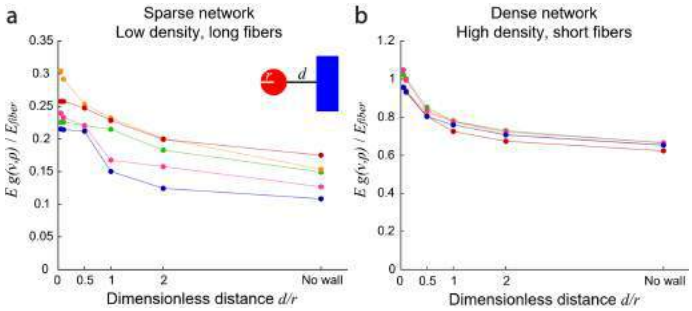

Figure 3: Stiffness expressed as the product of Young's modulus E and function $g(\nu,\rho)$ sensed by the contracting inclusion in different fiber networks in the presence of a rigid wall located at different distances. (a) Product of Young's modulus E and function $g(\nu,\rho)$ for 5 different fiber networks of low fiber density and long fiber length for 15% strain. Young's modulus E is made dimensionless by dividing with the Young's modulus of individual fibers, E_{fiber}. Each line represents a different fiber network. The horizontal axis gives the dimensionless distance d/r, where d is the distance from the contracting inclusion to the stiff inclusion and r is the radius of the contracting inclusion, as shown in the schematic in panel a. The last point in the horizontal axis gives the case of absence of a rigid wall. (b) Product of Young's modulus E and function $g(\nu,\rho)$ for 5 different fiber networks of high fiber density and short fiber length for 15% strain.

DISCUSSION

Our results from simulations showed a large degree of heterogeneity in fiber networks of low fiber density and long fiber length, in which the ratio of inclusion size to fiber length is small. This randomness due to different fiber networks (or, equivalently, different positions in the same fiber network) has a greater effect on local modulus than the presence of a wall. Hence, a cell in a network with low fiber density and long fibers has no chance of sensing the stiff region. In the fiber networks of high density and short fiber length, in which the ratio of inclusion size to fiber length is greater, there is a lower degree of heterogeneity. Thus, in such fiber networks the critical distance increases and a cell may potentially sense the stiff region.

In the experiments, the ratio of cell spheroid size to fiber length is big. Hence the experiments are conducted in fiber networks having short fiber length. Consistent with the theory, the cells sense and respond to the presence of the rigid boundary for small and moderate distances between spheroid and boundary.

FORCE TRANSMISSION WITHIN THE MIGRATING ENDOTHELIUM REGULATES SHUNT FORMATION DURING ANGIOGENIC REMODELLING

Lowell T. Edgar **Miguel O. Bernabeu**

Usher Institute
College of Medicine and Veterinary Medicine
University of Edinburgh
Edinburgh, United Kingdom

INTRODUCTION

Developmental angiogenesis occurs in distinct phases: an initial spouting phase followed by a later remodelling phase in which endothelial cells (ECs) composing blood vessels rearrange in response to shear stress signals from blood flow [1]. Some time ago, Pries et. al. proposed "The Shunt Problem" in which they demonstrated that remodelling driven by shear stress signals alone results in the dominance of short proximal pathways at the expense of longer distal pathways, thereby "shunting" blood flow away from downstream regions of the vascular tree [2]. In their hallmark work they proposed that additional "upstream" signalling is required to maintain both proximal and distal paths. We have since demonstrated that these signals may originate from collective migration of ECs during remodelling, possibly in the form of force transmission between cells at adherens junctions [3].

The cellular mechanisms of vascular shunting remain poorly understood despite being highly relevant in the context of arteriovenous malformations (AVMs), a leading cause of stroke and neurodegeneration [4]. To elucidate and demonstrate the role of force transmission during collective migration in shunt formation, we have designed an agent-based model of flow-mediated migration and angiogenic remodelling. We represent individual cells as discrete entities which interact with one another via transmitting force. With this model we can vary the parameters that control the levels of force transmission and will attempt to identify which factors push the system towards shunt formation.

METHODS

We simulated EC migration within an idealised capillary plexus consisting of vessels arranged in a "honeycomb" configuration. Vessels were discretised into cylindrical segments representing the lumen. We prescribed pressure at the inlet and outlet and use the Poiseuille approximation to solve for blood flow. EC agents, confined to the surfaces of the luminal segments, consisted of a pair of nested ellipses. The inner ellipse (semi-major A, semi-minor B) represents the undeformed "stress-free" configuration of the cell, while the outer ellipse (semi-major ΓA, semi-minor ΓB) represents the "yield surface" of junction connections. ECs experiencing tension at their junctions will deform up to a stretch ratio of Γ, after which they will release the junctional connection and attempt to return to the stress-free configuration. Agents also polarise along their major axis against the direction of flow.

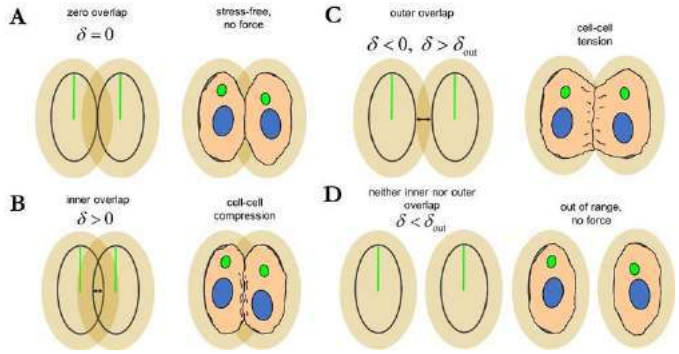

Figure 1: ECs represented as nested ellipses. Overlap between the ellipses produces various modes of cellular mechanics: (A) adjacent inner ellipses with no overlap represents the stress-free configuration with no force transmission. (B) overlap of the inner ellipses produces an extrusive force and represents compression. (C) overlap of the outer ellipses produces a cohesive force and represents tension. (D) cells with no overlap are out of range and transmit no force between one another.

ECs transmit force to one another depending on the overlap, δ, of adjacent ellipses (Figure 1). When considered two agents, i and j with

distance vector $\boldsymbol{r}_{ij}$ between them, the overlap between the agents is defined as

$$\delta_{ij} = \frac{\lambda_i + \lambda_j - \|\boldsymbol{r}_{ij}\|}{2A}, \quad (1)$$

where λ_i and λ_j are the radius of intersection for each agent. The outer boundary of overlap is similarly defined as

$$\delta_{\text{out}} = \frac{(1-\Gamma)(\lambda_i + \lambda_j)}{2A}. \quad (2)$$

The force transmitted between the two agents is then calculated as

$$\boldsymbol{f}_{ij} = \begin{cases} -k_{\text{ext}}\delta_{ij}^2 \hat{\boldsymbol{r}}_{ij}, & \text{if } \delta_{ij} \geq 0 \\ k_{\text{coh}}\delta_{ij}^2 \hat{\boldsymbol{r}}_{ij}, & \text{if } \delta_{\text{out}} \leq \delta_{ij} < 0. \\ \boldsymbol{0}, & \text{if } \delta_{ij} < \delta_{\text{out}} \end{cases} \quad (3)$$

If the inner ellipses of the agents overlap ($\delta_{ij} \geq 0$) the agents transmit an *extrusive force* (scaled by k_{ext}) to push the agents back to the stress-free configuration. If the outer ellipses of the agents overlap ($\delta_{\text{out}} \leq \delta_{ij} < 0$) the agents transmit a *cohesive force* (scaled by k_{coh}) to pull the agents back to the stress-free configuration. The agents are out of range from each other if $\delta_{ij} < \delta_{\text{out}}$ and thus transmit no force. Additionally, each agent produces a migratory force along their polarity vector $\hat{\boldsymbol{p}}_i$ scaled by the parameter k_{mig} which causes them to migrate against the direction of flow. The force transmission parameters can be expressed as two energetic parameters: the work to push cells together and the work to pull cells apart,

$$W^*_{\text{push}} = \frac{k_{\text{ext}}}{k_{\text{mig}}}, \quad (4)$$

$$W^*_{\text{pull}} = \frac{k_{\text{coh}}|1-\Gamma|^3}{k_{\text{mig}}}. \quad (5)$$

Lastly, we implement an overdamped dynamic model (assuming quasi-static equilibrium) to calculate the migration speed $\boldsymbol{v}_i$ of each agent via the summation of all transmitted forces and the migratory force,

$$\eta \boldsymbol{v}_i = \sum_j \boldsymbol{f}_{ij} + k_{\text{mig}}\hat{\boldsymbol{p}}_i, \quad (6)$$

and use Euler's method to update the position of each agent across each step in time. ECs migrate upstream until the encounter a vessel bifurcation: at flow-divergent bifurcations, ECs simple combine at the parent vessel. At flow-convergent bifurcations, ECs are evenly split amongst the two child branches. Additionally, periodic cell boundary conditions were prescribed such that cells exiting via the inlet re-enter at the outlet.

To interrogate the role of force transmission during remodelling, we ran the model with 50 different random seeds (randomising initial cell position each time) at various values of W^*_{push} (0, 1, 3, 5) and W^*_{pull} (0, 1/9, 2/9, 3/9) and collected various network-level features associated with shunt formation for which to perform our analysis.

RESULTS

We found that we could push our system from stable perfusion to shunt formation via control of a single parameter, the amount of cohesion within the system W^*_{pull} (Figure 2). Simulations with little to no cohesion resulted in cells evenly distributed across the plexus and perfusion maintained throughout. However, simulations with high levels of cohesion resulted in aggregations of cells along a minority of the flow pathways, depleting cells and flow from other regions of the plexus.

Increased extrusion within the system allowed the cells to intercalate and reduce stress within the endothelium whilst increased cohesion inhibited this intercalation and created tension. Increased cohesion also produced more prolonged flow reversals and the time vessels spent with reversed flow increased (Figure 3 A). Flow reversals exert a critical behaviour change within the system as they switch the direction of cell migration and flow convergence/divergence at bifurcations. Lastly, the aggregation of cells disrupted perfusion within the plexus, and the time-integrated percentage of flow pathways which lost flow increased with cohesion (Figure 3 B).

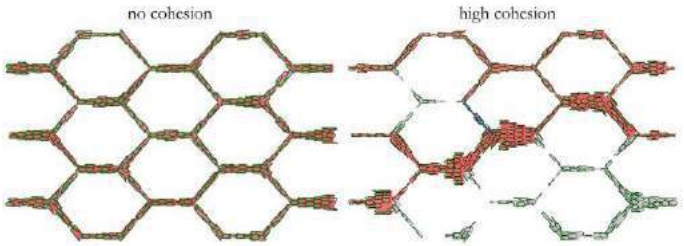

Figure 2: Excessive cohesion produced shunt formation. (Left) Simulations with littler to no cohesion resulted in a stable plexus during remodelling, with cells well distributed and flow uninterrupted. (Right) High levels of cohesion resulted in cells aggregating along a small percentage of flow paths, robbing the remainder of the plexus of cells and perfusion. Vessels with forward flow are coloured in red, reversed flow in blue, and flow loss in grey.

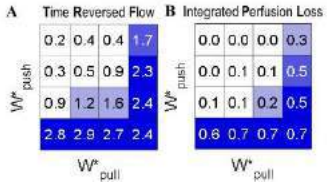

Figure 3: Excess cohesion disrupts flow and perfusion whilst extrusion stabilizes. (A) Time vessel spent with reversed flow decreased with extrusion and increased with cohesion. (B) Perfusion loss similarly increased as cohesion increased.

DISCUSSION

With our model we have demonstrated how excess cohesion between migrating ECs can promote shunt formation by creating large cell aggregates, diverting cells and perfusion away from other regions of the plexus. We believe the primary mechanism of these shunt formations comes in the form of prolonged flow reversals that occur in simulations with high cohesion. In simulations without cohesion, flow reversals that develop are quickly resolved as the cells intercalate to reduce stress and smooth out any aggregates that begin to form. High levels of cohesion disrupt this intercalation and allow flow reversals to persist. Flow reversals lead to a critical switch in EC migration behaviour at vessel bifurcations, switching flow-divergent bifurcations where ECs once split apart to flow-convergent bifurcations where cells now combine (Figure 4). Prolonged switching of bifurcation behaviour causes cells to aggregate along a small percentage of flow paths, creating vascular shunts. These results provide valuable insight into the mechanisms of shunt formation in vivo, implicating cohesion and flow reversals as critical mechanisms and may provide additional targets for vascular normalization strategies in the future.

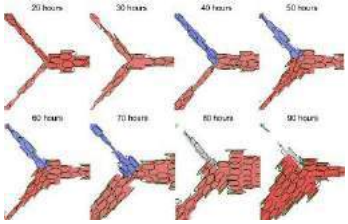

Figure 4: Flow reversals switch flow-divergent bifurcations to flow-convergent bifurcations, and prolonged flow disruptions have a dramatic impact on cell distribution and producing cell aggregates which lead to shunt formation.

INTRODUCTION

While cage-free housing of egg-laying enhances hen natural behavior it leads to increased incidence of fractures to the keel bone. Figure 1 depicts an image of keel bone with a visible fractures and healed fractures. Observed by dissection, one observes a line on the underside of the keel bone (inside the body cavity) and rarely sees any indication of a fracture on the outside where the breast muscle is attached.

Figure 1: Tip of a keel bone with fracture and healed fractures.

The biomechanics of keel bone fracture is poorly understood. This lack of foundational biomechanics knowledge limits efforts to reduce fracture incidence and leaves interventions through housing changes, nutrition, lighting etc. to mostly trial and error. There are very limited publications on the assessment of the biomechanics of the keel bone [1-5] and none have considered detailed computational models of the keel bone and keel bone fracture initiation and propagation during the egg-laying processes. Advances in the understanding of the biomechanics of keel bone fractures are of significance The US egg industry is moving toward cage-free egg production. Currently, 23.3% of the egg industry is in cage-free housing but to meet commitments by retailers, food service and fast-food businesses 71% would need to be cage-free by January 1, 2026 [6]. Bone fracture simulations can be conducted as shown in [7] by the use of the extended finite element method. Here, this approach is applied to investigate keel bone fracture.

METHODS

We obtain a CT-scan of an egg-laying hen without visible fracture. The CT scan data were reconstructed and converted into a finite element mesh using the code Synopsys' Simpleware™ software. The keel is segmented into bone and cartilage components. The finite element discretization was constructed and employed 10-node tetrahedra elements. The total number of finite elements is defined 26,884 in the specific keel bone model considered here. The keel bone was endowed with elastic properties for bone (E_{bone}= 1.96 GPa, ν_{bone}=0.37) and cartilage (E_{cart}=1.0 GPa, ν_{cart}=0.37). Furthermore, a maximum principal stress failure criterion is considered for the onset of fracture formation. The strength of bone is s_{bone}=3.92 MPa for bone and that of cartilage s_{cart}=1.0 MPa. Past the initiation of failure, the material separation to a full loss of load transfer across the propagating fracture process zone is given as 0.1 mm for both bone and cartilage. Bone and cartilage are considered as fully bonded to each other and no interface failure is considered to occur. The keel bone is fixed in space at its fulcrum-near

termination and is free at the opposite end, mimicking anatomical boundary conditions. A rigid body is ascribed a displacement in order to mimic the path an egg would take. The computational model is solved using a finite element code (ABAQUS) with the extended finite element method for material failure. Figure 2 depicts the model with boundary condition and a representation of the loading process.

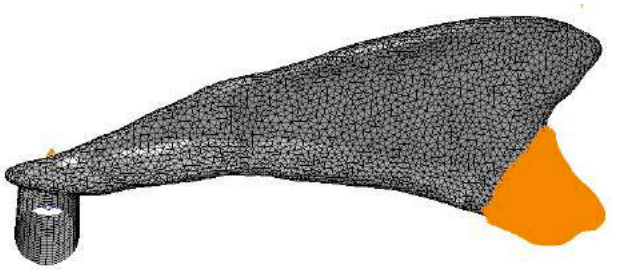

Figure 2: FE model of a keel bone as loaded simulating an egg-laying process.

RESULTS

The finite element simulation of the egg-laying processes predicts a crack initiation site close the tip of the keep bone with the crack initiating from the broad size of the keel bone. Figure 2 depicts the deformed keel bone under the simulated egg-laying load with the as-computed crack visualized. The comparison of Figures 1 and 3 indicates a validation of the simulation model regarding the approximate fracture location. From a biomechanics perspective, the keel bone is found to be a T-shaped cantilevered beam with a graded cross section geometry and a graded effective material property. The stiffness of the keel bone/cartilage combination declines towards the keel tip. As such the location of the fracture is determined by a combination of all such factors in combination. Aging and calcification, i.e. replacement of cartilage by bone, will result in a relocation of the fracture and to potentially increased fracture risk. An increase in egg-size increases the applied displacement on the keel bone and will as well have the potential to increase fracture risk.

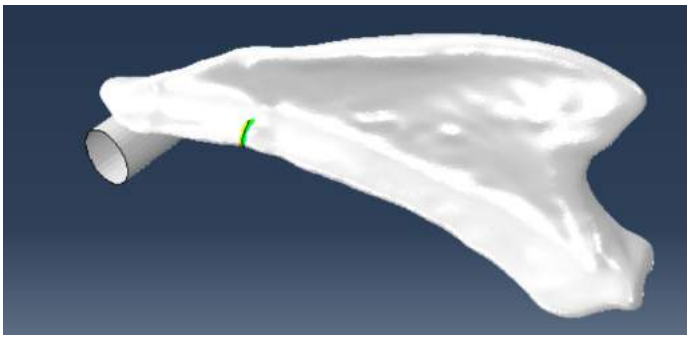

Figure 3: FE model with computed crack following a loading process simulating the egg-laying processes.

DISCUSSION

Keel bone fracture is considered as problem of significance to the poultry industry. If such fractures can be avoided, benefits to both animal welfare and egg production would be realized. Computational simulations of the keel bone fracture by use of an extended finite element approach are demonstrated to allow for the analysis of the interaction effects of geometry, tissue biomechanical properties and egg-laying processes related biomechanical loading scenarios. The present model only considers the keel bone and none of the muscle and additional bones. Models under the consideration of these components, Figure 4, will improve the predictive capability of the computational analysis.

INTRODUCTION

Collagens are found in nearly every tissue in the human body. Close to 30 different types of collagens have been identified in vivo, and type I collagen (COL1) is one of the primary structural components found in the extracellular matrix (ECM). Fibrous COL1 plays a vital role in providing mechanical and structural support to bones, tendons, muscles, and other tissues. Over the past several decades, in vitro models have been established to systematically study the relationship between COL1 properties and cell responses. For example, in the tumor microenvironment, bulk matrix stiffness, density, and fiber alignment have been found to influence cell motility and have provided unique approaches to study guidance cues that can direct tumor cells through the ECM. The COL1 microarchitecture is rapidly remodeled in response to both traction forces and biochemical stimuli, resulting in spatial variations (gradients) in matrix properties. More recently, techniques to engineering gradients of matrix properties have emerged. These "taxis" cues include continuous gradients in stiffness (durotaxis) [1], local cues (ratchetaxis) [2], and tethered biomolecules (haptotaxis) [3] have all been shown to influence cell motility.

The reorganization of COL1 fibers can have clinical significance, where the presence of anisotropic (aligned) fiber domains orthogonal to a tumor boundary can predict poor prognosis in breast cancer patients [4]. *In vitro* models to study tumor cell motility on anisotropic fiber domains have been established by several groups [5,6] but exploring the effects of gradients in collagen anisotropy have not been demonstrated within 3D gel environments. To explore cell motility on aligned fiber gradients (gradient alignotaxis), we introduce a microfluidic system that can create controlled gradients in COL1 fiber anisotropy using controlled extensional strain rates (i.e., the velocity gradient along the direction of flow). Leveraging our experience relating extensional strain rate and fiber anisotropy, we create gradients in fiber anisotropy by flowing neutralized collagen solutions through non-uniform channel networks. Under a constant flow rate Q, changes in the cross-sectional area (A) introduces a change in average velocity (V) according to the relationship ($V = QA^{-1}$). Thus, a rapid increase in A produces a drop in velocity along the flow direction and result in a rapid drop off in extensional strain rate and translates to defined gradients in fiber anisotropy.

METHODS

Microfluidic channels: Channels were fabricated via standard soft lithography techniques using a mold with 60 µm tall features. After replica molding, the PDMS channels were cut out, and access ports were cored with a 1mm diameter biopsy punch. Devices were then sequentially cleaned in ethanol followed by water. They were dried and plasma bonded to a glass coverslip. As shown in Figure 1A, the geometry consisted of an inlet region with two access ports (ports 1 and 2), a well region with one access port (port 3). The two regions were connected with a constriction.

Collagen injection: Bovine type I atelocollagen (Advanced Biomatrix) was neutralized using 1M NaOH and diluted down to 2.5 mg/ml using ultrapure water and 10X PBS. The channel was prefilled using 2.5 mg/ml collagen with all access ports open. Then, access port 2 was blocked and 2.5 mg/ml collagen was injected along the path 1-3 at Q = 0.5 ml/min using a syringe pump. (Figure 1B). After injection, the remaining access ports were blocked to prevent evaporation and the microfluidic chip was then incubated to promote COL1 gelation.

Particle Image Velocimetry (PIV) and COMSOL: 5 µm fluorescent beads were added to the collagen solution to measure the velocity field using PIV. PIV data is presented as a mean of 3 individual replicates.

The COMSOL simulation was then validated using the PIV results, and the values matched to within 10%.

Imaging and processing: Collagen fibers were imaged under confocal reflectance microscopy (CRM) using a 40x objective water immersion lens. 2 µm stacks (0.13µm/slice) were obtained 30µm above the coverslip. LOCI CT-FIRE was used to obtain the angle of individual fibers. The coefficient of alignment (CoA) is calculated as the number of fibers within 15˚ of mode of fiber angle to total number of fibers.

RESULTS

As shown in Figure 1, we use microfluidic channels with varying cross-sectional areas to control change in strain rate. COL1 was injected at a flow rate of 0.5 ml/min in a prefilled microchannel as shown in figure 1B, following a path from port 1 to port 3. The velocity of the COL1 solution increased as it passed through the constriction to a maximum of 1.6 m/s and dropped to 0.6 m/s within 200µm of exiting the constriction, as measured using COMSOL and verified by PIV.

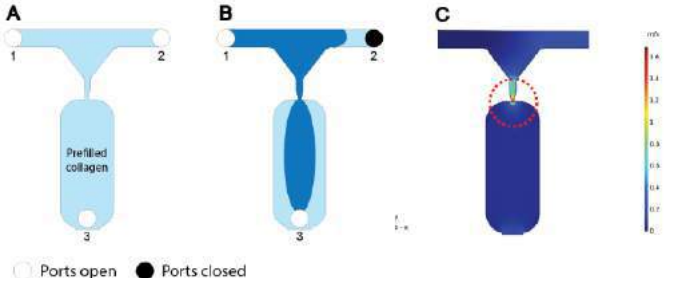

Figure 1: A) Shows the schematic of chip prefilled with collagen with three ports. B) Schematic of second collagen injection with port 2 closed. C) Shows the velocity contour plot of collagen injection at 0.5 ml/min

In figure 2A we show a micrograph of collagen fibers with varying degree of CoA in the ROI (red circle shown in figure 1C). The CoA was plotted for four regions as shown in 2A. The change in CoA was plotted as a function of distance from the constriction as shown in figure 2B. CoA falls from 0.9 to 0. 57 across 200 µm. A polynomial curve was best fitted to the data set with an R^2 of 0.903.

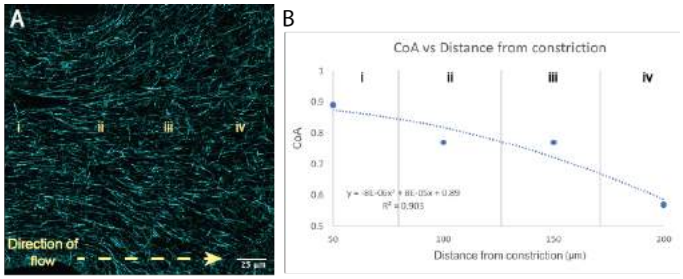

Figure 2: A) Shows the micrograph of collagen fibers in ROI. B) Shows the graph of CoA as a function of strain rate

DISCUSSION

Our results demonstrate the ability to generate gradients in collagen fiber anisotropy, over cellular length scales (100s of micrometers). We created a microfluidic channel network with varying cross section to impose controlled extensional strain on the COL1 solution. With our current design, we can generate a rapid drop in fluid velocity over hundreds of micrometers. Using this system, we leveraged the rapid change in velocity to yield rapid changes in extensional strain rate, which created gradients in fiber anisotropy.

This work builds upon our previous work [7] where we have demonstrated the use of extensional strain rate for controlling fiber direction and anisotropy. Furthermore, we allow access to micro engineered collagen gel by reversibly bonding PDMS to glass coverslips using surface functionalization. Thus, this platform allows to combine the ability to create defined cell length scale anisotropic fiber gradients while providing unrestricted access to engineered microgels. Future development of this technique will establish design rules to create defined gradients in CoA to investigate the effects of gradient alignotaxis on cell motility within a 3D micro engineered gel.

INTRODUCTION

Tendinopathies are a progressive pathology associated with a chronic degenerative tissue state. Current surgical, material, and cell-based strategies for tendon repair are limited and re-injury is frequent resulting in loss of mobility and quality of life[1]. Chronic tendinopathies result in altered tensile loading of tendon cell populations[1]. Tensile cues are central to the homeostatic function of tendon fibroblasts and loss of these cues induces aberrant cell behavior[2]. Both normal and aberrant phenotypes in tendon fibroblasts are defined by their current transcriptional activity, which in turn is controlled by accessibility of genomic loci. How tension regulates tendon fibroblast transcriptional and chromatin profiles, the transcriptional pathways involved, and how these play a role in degenerative tendinopathies has yet to be explored. Understanding these mechanisms could lead to therapeutic treatments for tendinopathies.

METHODS

Isolation and culture of tendon fibroblasts: All animals and procedures were approved by the UPenn IACUC. CD1 mice (4-6 weeks old) were sacrificed and tail tendons were extracted. Tendons were digested in an enzymatic cocktail of Liberase and DNase I for 1 hour at 37 ºC. Cells were filtered through a 70 μm strainer and plated in DMEM supplemented with 10% FBS and antibiotics. Blebbistatin (10 μM), a myosin contractile inhibitor, was administered for 6 hours in low-serum (0.1% FBS) DMEM. All cells were used between passage 2 and 3. *ATACseq*: 50,000 cells were subjected to Assay for Transposase Accessible sequencing (ATACseq) following the published protocol[3]. DNA fragment size was analyzed using a Fragment Analyzer. Libraries were sequenced to 50 base pairs from both ends using an Illumina NovaSeq. Raw reads were aligned to the mm10 genome using Bowtie2. Picard and Samtools were used to generate bam files and to filter out duplicates and mitochondrial reads. Peaks were called using MACS2 using the following options: ““--keep-dup all -q 0.01 -no model”. Diffbind was used to identify differentially accessible chromatin loci between groups (n=3 biological replicates/group). Motif analysis was completed using the findMotifsGenome.pl command within Homer. *RNA isolation and sequencing:* RNA was isolated using the Qiagen RNeasy Plus Mini kit following the manufacturer's protocol. RNA quality was evaluated using a BioAnalyzer. RNA libraries were prepared using the Ilumina truSeq stranded poly-A library prep kit and single-end reads were sequenced to 100 base pairs using an Illumina NovaSeq. Reads were aligned to the mm10 genome using Hisat2. Picard was used to generate bam files and sort by chromosomal coordinates. FeatureCounts was used to generate count files. Deseq2 was used for differential expression analysis between groups (n=3 biological replicates/group). Gene ontology analysis was completed using Panther. *siRNA*: siRNA for mouse Yap1 and Wwtr1 (Taz) were administered to primary mouse tendon fibroblasts. Scramble siRNA was used as a control. After 3 days, RNA was isolated as described above. cDNA was synthesized using SuperScript IV Vilo according to manufacturer's protocol. qRT-PCR was performed using Fast SYBR on a QuantStudio6 machine. Statistical evaluation was performed using unpaired t-test.

RESULTS

To investigate the role of tensile cues in regulating chromatin accessibility, we cultured primary mouse tendon fibroblasts in the presence of blebbistatin for 6 hours and performed ATACseq, a fast and efficient next-generation sequencing method to identify active DNA regulatory elements (enhancers and promoters) across the genome. Using an FDR ≤ 0.05 and a log2 fold-change of +/- 1, we observed that blebbistatin treatment reduced accessibility of 954 chromatin loci and increased accessibility at only 17 chromatin loci (**Fig. 1a**). These findings suggest that cytoskeletal tension positively regulates chromatin accessibility. In addition, these accessibility changes were in close

genomic proximity to established mechano-responsive genes (e.g. *Acta2*, *Cyr61*) (**Fig. 1b**). Given that chromatin accessibility is a proxy for transcription factor occupancy, we next performed *de novo* DNA motif enrichment analysis on the 971 differentially regulated accessibility loci to identify putative transcriptional regulators facilitating these accessibility changes. Ranked by ascending P-value, the top predicted transcriptional regulator was Tead (**Fig. 1c**), the transcriptional co-activator for Yap and Taz, major mechano-responsive transcription regulators of the cell[4]. Taken together, these observations demonstrate cytoskeletal tension positively regulates chromatin accessibility potentially through Yap and Taz.

To better understand how these tension-regulated chromatin alterations relate to transcriptional changes, we performed RNA sequencing of mouse primary tendon fibroblasts following blebbistatin treatment for 6 hours. Using an FDR ≤ 0.05 and a log2 fold-change of +/- 1, we identified that inhibition of cytoskeletal tension downregulated the expression of 462 genes while also upregulating expression of 570 genes (**Fig. 2a**). We next performed gene ontology analysis on the gene sets that were downregulated and upregulated by blebbistatin treatment to identify pathways which are activated and repressed, respectively, by cytoskeletal tension in an unbiased fashion. Interestingly, we identified collagen catabolism as being repressed by cytoskeletal tension (**Fig. 2b**). Within this gene set we noted a number of matrix metalloproteinases (MMPs), enzymes involved in matrix degradation, which significantly increase expression following blebbistatin treatment (**Fig. 2c**). Together, these results suggest active tensile cues and cell contractility repress matrix degradation pathways in tendon fibroblasts.

To test whether Yap/Taz facilitate the repression of the same genes which were regulated under blebbistatin treatment, we performed siRNA-mediated knockdown of Yap and Taz in mouse primary tendon fibroblasts. Knockdown of Yap and Taz resulted in upregulation of these same genes (**Fig. 3**), demonstrating Yap and Taz play an active role in repression of matrix degradation pathways.

DISCUSSION

Matrix degradation is an early event in progressive degenerative tendinopathies. MMP expression is also elevated in de-tensioned three-dimensional tendon explant models[5]. However, the mechanistic basis defining what pathways regulate this pathogenic activity in tendon fibroblasts is not known. Here, we demonstrate a cytoskeleton/Yap/Taz axis which is central to the transcriptional regulation of these matrix degradation pathways. Ongoing work is exploring the functional effect of Yap/Taz in matrix degradation models *in vitro* and *in vivo*. Together, this work supports a potential therapeutic avenue of targeting Yap/Taz to thwart the onset of progressive degenerative tendinopathies.

EXPLORING THE LINK BETWEEN WALL SHEAR STRESS TOPOLOGICAL SKELETON AND NEAR-WALL MASS TRANSPORT IN CARDIOVASCULAR FLOWS USING A EULERIAN-BASED METHOD

INTRODUCTION

Mass transport plays a key role in vascular disease. Several studies have suggested that, e.g., high plasma levels of low-density lipoproteins (LDL) are involved in the atherosclerosis process [1]. In this context, in the last decade, computational fluid dynamics (CFD) has been adopted to elucidate the links (if any) among disturbed shear, atherogenesis and mass transport in human arteries [2][3]. However, modelling mass transfer in cardiovascular flows requires the detailed, computationally expensive solution of the advection-diffusion equations [4]. To overcome this limitation, a marked interest has recently emerged on the Lagrangian-based features of the WSS topological skeleton, which have demonstrated to provide a reliable template for near-wall transport [5]. Briefly, the WSS topological skeleton is composed by fixed points, points where WSS vanishes, and stable/unstable connection lines (manifolds), identifying WSS expansion/contraction regions. Moving from the proven effectiveness of WSS Lagrangian Coherent Structures as a template of near-wall mass transport in cardiovascular flows, here a Eulerian-based method [6] recently proposed to analyze the WSS topological skeleton, whose features recently emerged as clear indicator of wall degradation in aortic aneurysm [7] and carotid restenosis risk [8], is applied. The final aim is to test its capability to provide a reliable template of the near-wall mass transport in patient-specific computational hemodynamic models of three distinct arterial district, i.e. the aorta, the carotid bifurcation and the right coronary artery.

METHODS

A scheme of the methods applied in this study is provided in Fig. 1. The 3D geometries of a human thoracic aorta, a carotid bifurcation, and a right coronary artery were reconstructed from medical images as extensively described elsewhere [4,9,10].

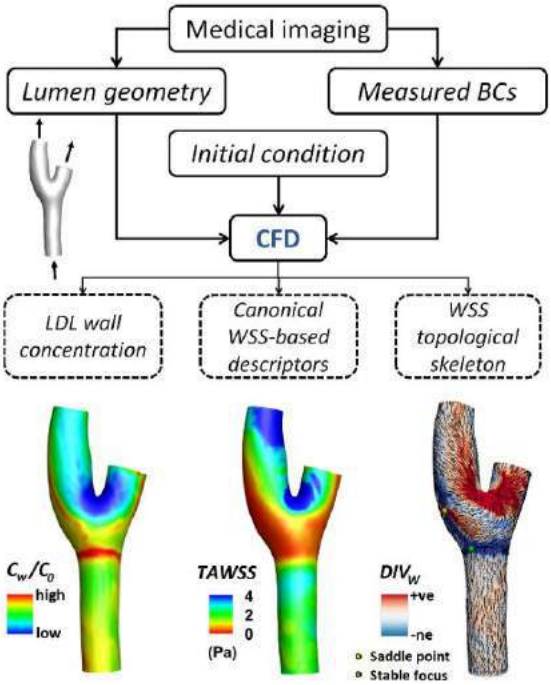

Figure 1: Overview of the proposed approach.

Computational hemodynamics. To model the transport of low-density lipoprotein (LDL), the finite volume method was applied to solve the coupled Navier-Stokes (NS) and advection-diffusion (AD) equations in their discretized form, using Fluent (ANSYS Inc., USA) on computational mesh-grids with 30 boundary layers of high-quality

prismatic cells near the wall [4]. Subject-specific boundary conditions (BCs) were prescribed to solve the NS equations [4,9,10]. A constant LDL concentration C_0 (equal to the average LDL concentration in whole blood) was applied at the inflow section, and the stress-free condition at the outflow sections, to solve AD equation [4]. The LDL blood-to-wall transfer was modelled as follows:

$$C_W v_W - D_{LDL} \frac{\partial C}{\partial n}\Big|_W = 0 \quad (1)$$

where C_W is the LDL concentration at the vessel wall, v_W the water filtration velocity through the wall, D_{LDL} is the diffusivity of LDL in blood, $\frac{\partial C}{\partial n}$ is the concentration gradient normal to the wall. Details on the applied numerical schemes are extensively provided elsewhere [4,9,10].

WSS topological skeleton. A recently proposed Eulerian method to analyze the WSS topological skeleton [6] was here considered. Briefly, based on Volume Contraction theory, it was demonstrated that the divergence of the WSS unit vector field $\boldsymbol{\tau}_u$, defined as:

$$DIV_W = \nabla \cdot \left(\frac{\tau}{\|\tau\|_2}\right) = \nabla \cdot \boldsymbol{\tau}_u \quad (2)$$

represents a template of the WSS vector field manifolds, identifying the WSS expansion/contraction regions on the arterial luminal surface. To complete the WSS topological skeleton analysis, the Poincarè index and the Jacobian analysis were carried out to identify and classify fixed points, according to the scheme proposed in [6]. Here, the Eulerian-based WSS topological skeleton analysis was applied to the cycle-average WSS vector field.

To complement the analysis, the luminal distribution of three well-established descriptors of flow disturbances, i.e., the time-average WSS (*TAWSS*), the oscillatory shear index (*OSI*), and the relative residence time (*RRT*), were also evaluated.

Co-localization analysis. The analysis of the co-localization between WSS manifolds as identified by DIV_W, and local LDL uptake, was carried out according to schemes proposed elsewhere [4]. Briefly, (1) the surface area (SA) exposed to normalized LDL concentration values (C_W/C_0) higher than the 90th percentile was quantified and denoted as LDL90, and (2) the SA exposed to DIV_W values lower than 10th percentile was identified and denoted as DIV10. Similarly, luminal SAs exposed to altered hemodynamics were identified by the lower 10th percentile for *TAWSS* (TAWSS10), and upper 90th for *OSI* and *RRT* (OSI90 and RRT90, respectively), and their co-localization with LDL90 was investigated.

RESULTS

The luminal surface distributions of DIV_W and normalized LDL are provided in Fig. 2 for the three analyzed vascular districts (panel A and B, respectively). WSS contraction regions are coloured in blue (negative DIV_W), while WSS expansion regions are presented in red colour (positive DIV_W, Fig. 2-A). It clearly emerges by visual inspection that contraction regions of the WSS vector field co-localize with LDL concentration polarization on the vessels wall. The observed co-localization is evident: (1) at the inner wall of the aortic arch and in the descending aorta for the thoracic aorta; (2) in the proximal carotid sinus where the bulb expansion starts to occur, and at the outer wall of the internal and external carotid artery; (3) along the inner curvature of the right coronary artery. A direct co-localization analysis between LDL concentration polarization and WSS contraction regions is provided in Fig. 2-C, where LDL90 and DIV10 (black contour lines) luminal SAs are displayed. A marked spatial overlap between LDL90 and DIV10 emerges, with the contour lines of DIV10 mostly encasing luminal regions with high LDL luminal concentration. The co-localization of LDL polarization concentration with WSS contraction regions is less pronounced only locally in the proximal part of the right coronary artery. From a quantitative analysis, it emerged that WSS contraction regions co-localize with high LDL concentration regions at least the 40% more than canonical WSS-based descriptors, with an increase from 20% to 35% (the 75% more) in the right coronary artery (Table 1).

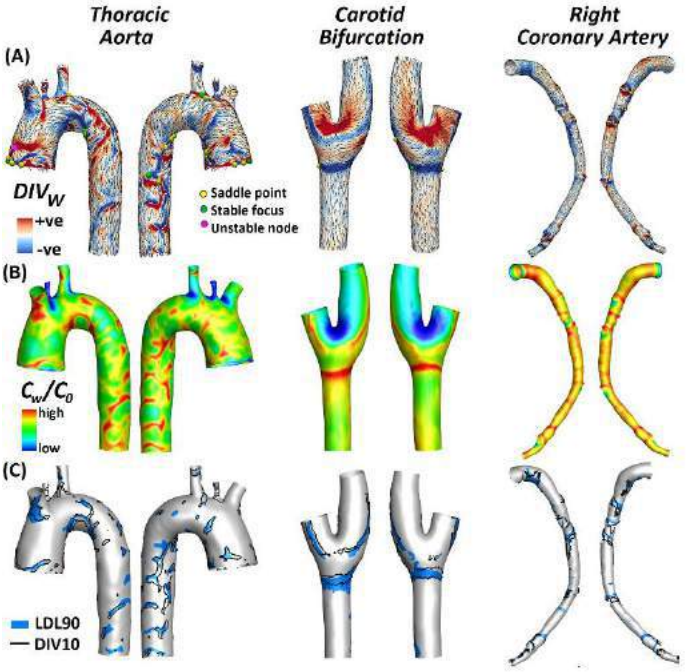

Figure 2: (A) Cycle-average WSS topological skeleton. (B) LDL wall concentration. (C) Distributions of LDL90 an DIV10.

Table 1: Percentage overlap with LDL90

	TAWSS10	OSI90	RRT90	DIV10
Thoracic Aorta	33%	27%	34%	46%
Carotid Bifurcation	30%	28%	29%	48%
Right Coronary Artery	21%	19%	20%	35%

DISCUSSION

The findings of this study: (1) confirm that WSS manifolds can be used as reliable templates of near-wall mass transport in cardiovascular flows [5]; (2) demonstrate that the recently proposed Eulerian-based method for analysing the WSS topological skeleton [6] efficiently provides a template of the LDL blood-to-wall transfer. The methodology, requiring less computational efforts with respect to a fully 3D simulation of mass transport in cardiovascular flows, candidates as an effective tool enriching the analysis of cardiovascular flows, avoiding solving AD equation to identify near-wall regions where mass transport is more pronounced [4]. Moreover, the co-localization of the LDL luminal polarization distribution with the WSS vector field contraction regions is higher than canonical WSS-based descriptors of flow disturbances.

INTRODUCTION

A considerable amount of historical research was performed using nonhuman primates (NHP) to investigate brain injuries [1]–[4]. Recent advancements in computational processing and power, finite element methods, and neuroimaging methods enable the development of advanced, high-fidelity computational models of the brain. These data provide a valuable resource to investigate the regional response of the brain to different severities and vectors of exposure. Research has shown that the regions brain are susceptible to loading with varied localized response [5]–[7]. While it is known that the regional brain-strain response is affected by exposure; little research has been performed to develop injury risk functions using regional strain response metrics as input criteria [5], [7]. Few finite element (FE) models of non-human primate (NHP) brains exist in the literature. Two recent studies have described the development and use of NHP FE brain models and efforts to investigate scaling relationships from NHP to human models [8], [9]. This objective of this study is to describe the development of a generalized, anatomically accurate, NHP brain model and demonstrate its feasibility with initial results.

METHODS

The NHP model was developed using a structural and anatomical atlas of the Rhesus Macaque [10]. The structural atlas includes basic identification of the cerebral spinal fluid (CSF), grey matter, and white matter. Additional granularity in anatomical structures is provided by an anatomical atlas (NeuroMaps Rhesus Macaque) that includes the cortical and sub-cortical anatomy of the brain (grey and white matter, thalamus, basal ganglia, corpus callosum, and other components) [10], [11].

The first step for creating the model was to generate the anatomical regions of interest using the NHP brain atlas and anatomical labels. The atlas and associated anatomical label information were imported into 3DSlicer and STL files were created for each structure (Figure 1). Subsequent review of the anatomical structures by a practicing clinical neurosurgeon aided with the grouping of multiple anatomical components from the atlas into larger regions of interest (Figure 2). For comparisons with current and developmental human brain models, the anatomical regions of interest for the NHP model included the grey and white matter for the cerebrum, cerebellum, thalamus, pallidum, midbrain, hippocampus, corpus callosum, basal ganglia, brain stem, and third, fourth and lateral ventricles. Comparable regions of interest are included in the latest version of the Global Human Body Model (GHBMC) head/brain model. Similar regions exist in a human model currently being developed and validated by the authors.

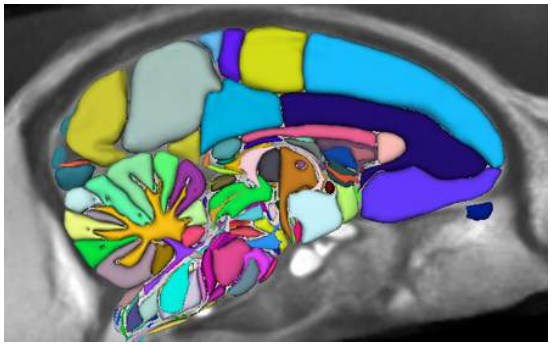

Figure 1: MRI-based brain atlas and regions of interest definition

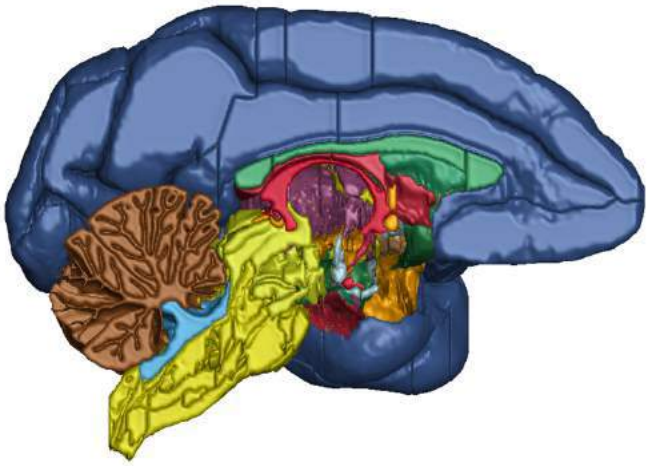

Figure 2: Combined regions of interest based on clinical input

Second, a mask of the cerebral spinal fluid identified in the atlas was created in 3DSlicer and then exported as an STL file. The cerebral spinal fluid surface STL (representing the exterior surface of the brain) was then imported into ANSA and was used to develop a global mesh using the multi-blocking method and hexahedral elements (Figure 3). The ANSA-generated brain mesh was imported in HyperMesh to check element quality (aspect ratio, warpage, Jacobian, etc.).

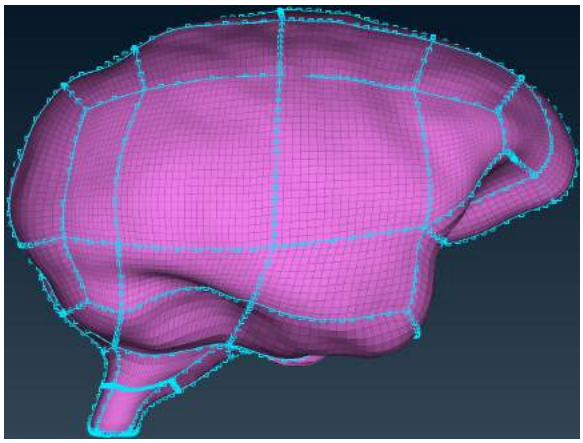

Figure 3: Initial mesh box pattern

RESULTS

There were a total of 378 separate anatomical structures identified in the NeuroMaps labels, 321 were used to generate the 13 brain regions of interest. The 67 anatomical structures left out of the regions of interest consisted of structures that were either very small (e.g., less than the size of 2 elements in the mesh), spanned multiple regions of interest as defined, or defined recesses within the brain that were not feasible for inclusion in a computational model.

For the global mesh, total of 52 hex boxes, including 203 box edges, 177 box faces, and 1340 control points, were created during the multi-blocking process to capture the brain's left hemisphere (brain is symmetrical about the midsagittal plane). The thresholds used to evaluate hexahedral mesh quality were an aspect ratio below 8, warpage below 50, and Jacobian below 0.3. Less than one percent of elements failed the element quality check.

DISCUSSION

Methods for the development an anatomically accurate NHP model were identified, and a multidisciplinary team approach was used for the finite element model. Additionally, element quality checks for the surface mesh were completed. The model has a high-quality mesh with less than 1% of elements failing the quality check.

The development of an anatomically accurate, high-quality NHP model has applications in the automotive, sports, aviation, and military environments, as traumatic brain injuries continue to be a burden on the individual and society, albeit with different mitigation strategies and safety standards. Previous efforts have focused on developing and evaluating scaling relationships between NHP and human for the prediction of injury. An additional application is to analyze historical datasets to develop new metrics for the prediction of injury that can be scaled. With recent advancements in computational power, finite element methods, and imaging capabilities, there may be significant gaps that can be answered using the wealth of historical experimental data collected. For example, recent injury risk curves developed for different accelerative loading vectors from NHP experiments could be updated to provide component-based and overall/global brain response metrics for the prediction of injury using head kinematic data [1]. These updated metrics and injury risk curves can then be scaled to human models to predict human injury from match pair human brain finite elements models that have paralleling component definitions.

ACKNOWLEDGEMENTS

INTRODUCTION

Benefits of intra-articular (IA) drug delivery are hindered by rapid drug clearance from the synovial joint space [1]. The synovium is a thin, multi-layered tissue separating the avascular IA space from vascularized tissues surrounding the joint [2]. IA pressure and a solute's concentration gradient drive drug transport through the synovium, whose draining lymphatic and blood vessels limit drug residence time. Although drug clearance has been studied in pre-clinical models and human subjects, comparing quantitative parameters such as half-life ($t_{1/2}$) and diffusivity remains challenging due to unknown boundary conditions and geometries [3,4]. We and others have studied drug transport in synovial explants, but presented parameters such as diffusivity may vary in dimensions and magnitudes across studies [5,6].

Previously, we developed a computational model of synovium as a porous, multi-phasic tissue and used an inverse method to determine urea's effective diffusivity (D_{eff}) through devitalized human and porcine explants [7]. This experimental-computational approach was used in the current study to determine the D_{eff} for uncharged solutes of varying MW in synovial explants as well as to estimate their $t_{1/2}$ that could be compared with *in vivo* transport properties.

METHODS

Synovial explants were harvested from healthy pig or human knees after sacrifice. Tissues were harvested from the medial, lateral, and posterior regions of pig joints. Human donor tissues were similarly obtained via an agreement with the Mid-America Transplant Foundation. All samples were cryoprotected in 15% and 30% sucrose solutions for 24 hours. To ensure devitalization, explants were snap frozen in liquid nitrogen and stored at −80 °C for at least 48 hours. Explants were then trimmed to under 1 mm thickness on a sledge microtome (Leica SM2400, Allendale NJ) and hydrated in phosphate buffer solution (PBS) overnight.

Explant thickness was estimated with a laser-scanning profilometer (Keyence LJ-V7080, Itasca IL) prior to unsteady diffusion experiments. Each explant was placed in a custom-built diffusion chamber between two baths: an upstream "donor" bath containing a finite amount of model solute, and a downstream "sink" bath that was continuously drained with PBS to mimic the draining lymphatics. At time $t = 0$, a model solute (urea, mannitol, or 3 kDa, 10 kDa, or 70 kDa fluorophore-conjugated dextran) of known concentration (C_0) was added to the donor bath; 5 µL aliquots were collected from the donor bath to measure solute concentration over 72 hours using colorimetric assays (urea and mannitol) or fluorescent emission (dextrans).

Following diffusion experiments, desorption of select solutes (3 kDa and 10 kDa dextrans) was assessed in a subset of tissues ($n = 7$). These explants were suspended in a volume of PBS 3x the sample's volume and placed atop a nutating shaker at 37 °C. At 24, 48, and 72 hours, the PBS was removed and replaced with fresh PBS. After 72 hours, solute concentration in the overlying media taken at all three time points was measured as described.

Finite element modeling (FEM) was used to construct a specimen-specific mesh of thickness L in contact with a well-mixed donor bath containing uncharged solute at $t = 0$ [$C_{bath}(x=0, t=0) = C_0$]. At the subintimal face, boundary conditions were set to zero [$C(x=L, t) = 0$] (Fig. 1). Explants were modeled as multi-phasic tissues of fixed permeability, porosity, and material properties (Table 1). A built-in optimization module in the software suite FEBio (University of Utah, Salt Lake City UT) was used to predict solute D_{eff} in the synovium [8]. To compare with *in vivo* data, $t_{1/2}$ was determined by fitting a single exponential decay in C/C_0 against time for each experiment. Differences in D_{eff} and $t_{1/2}$ were evaluated across solutes via one-factor ANOVA

with Tukey's post-hoc test in GraphPad Prism 8.0 (GraphPad Software, La Jolla, CA).

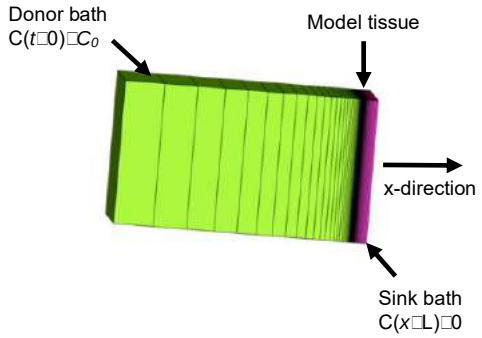

Figure 1. Explant-specific FEM mesh used to model solute diffusivity through synovium.

Table 1. Material properties used in synovium FEM optimization: solid volume fraction (ϕ_s), elastic modulus (E), Poisson's ratio (ν), and hydraulic permeability (k).

ϕ_s	E	ν	k
0.19	100 kPa	0.4	10^{-9} mm^4/μN s

RESULTS

Molecular transport through n = 51 porcine and n = 31 human synovial explants was described well by first-order exponential fitting ($R^2 \geq 0.897$), with the exception of 10 kDa ($R^2 = 0.749$) and 70 kDa ($R^2 = 0.519$) dextrans in human tissue; larger solutes cleared from the donor bath more slowly than smaller solutes. Clearance of 3 kDa and 10 kDa dextrans from n = 7 synovial explants was confirmed by the end of desorption experiments, where concentrations in overlying media were less than 12% of those measured at the final time point of diffusion experiments in all cases.

FEBio predictions of solute clearance showed good agreement with concentration data from unsteady diffusion experiments as evaluated by nonlinear regression fit statistics (RSS < 0.06) normalized by C_0. Solute D_{eff} trended downward as MW increased (Fig. 2), and significant differences were found between solutes below and above 3 kDa MW ($p < 0.05$).

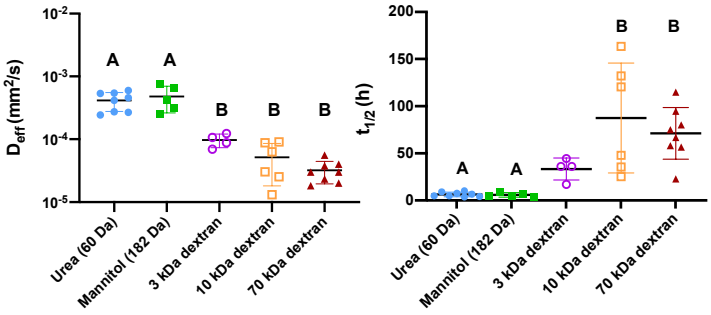

Figure 2. Mean D_{eff} and $t_{1/2}$ for 5 solutes in human synovial explants. Statistical differences are indicated between groups of different letters ($p < 0.01$).

Data for time-varying concentration in the donor bath was also well-described by a single exponential term used to determine solute $t_{1/2}$. Solute $t_{1/2}$ in the donor bath generally increased with MW, as urea and mannitol's values were lower when compared to larger solutes ($p <$ 0.0001). The $t_{1/2}$ for these solutes were compared to those previously measured *in vivo* using radiolabeled probes (Table 2). While *in vitro* half-lives were larger than *in vivo*, that solute $t_{1/2}$ in the joint space increases with MW was nevertheless consistent in both cases.

Table 2. Comparisons of $t_{1/2}$ in synovial explants to *in vivo* IA clearances reported in pre-clinical and human studies, organized by MW. Shaded, italicized rows represent data acquired in the current study in porcine explants.

DISCUSSION

Contrary to previous works that have documented solute clearance but not reported intrinsic diffusivity parameters, we determined D_{eff} through porcine and human synovium using a multi-phasic modeling approach supported by FEBio. Experimental and computational results agreed well, together confirming that MW governs transport of uncharged solutes across synovial explants of known surface area and thickness. Importantly, this work complements *in vivo* drug clearance studies, which also find that solute $t_{1/2}$ increases with MW. For similar MW, however, the $t_{1/2}$ *in vivo* tended to be less than half of $t_{1/2}$ quantified here. This discrepancy can be attributed to active transport rejecting solute retention in vivo, as well as poorer sensitivity when detecting drug within the fluid cavity (e.g. synovial fluid or serum) in living subjects. Nevertheless, general agreement suggests that *in vitro* studies in synovial tissue could predict some aspects of drug transport *in vivo*. The current model is prerequisite to incorporating more complex features, such as charged solute-matrix interactions and pathological contributions such as increased IA pressure.

INTRODUCTION

Millions of people worldwide are blind or have reduced vision due to damage to the retinal ganglion cell axons that carry visual information from the retina to the brain (Figure 1). [1] In many pathologies, including glaucoma, axonal damage starts within the optic nerve head, specifically within the lamina cribrosa (LC). Although the mechanisms of axonal damage vary between pathologies, it has long been thought that a primary contributor is an insufficient oxygen supply within the LC due to compromised blood perfusion. [2, 3] Measuring LC oxygen experimentally is not yet possible and thus it is usually studied using numerical models. LC oxygen models have been highly simplified and generic, [3] or eye-specific but 2D. [4] Our goal was to leverage novel 3D eye-specific models of the LC microvessel network to identify the factors with the largest influence on the LC oxygen. Specifically, we focused on the minimum (10^{th} percentile) oxygen concentration as potentially indicative of hypoxic conditions.

METHODS

3D reconstruction of the microvessel network. Serial histological sections (thickness: 16 µm) were obtained from a normal monkey optic nerve head, in which the blood vessels had been labeled with a fluorescent dye. The sections were imaged with fluorescence microscopy at a resolution of 0.73 µm per pixel and registered to one another to create a 3D stack. The vessels were identified using a semi-automated algorithm based on a Hessian filter. The result was then skeletonized and converted into a graph, and any isolated branches were removed to ensure that all vessels were connected except at the model periphery (Figure 1). The region modeled was larger than the LC. Microvessels in the LC region were identified based on the LC collagenous beams. The skeleton was converted into a mesh of vasculature for solving flow numerically.

Modeling blood flow and oxygen concentration. Blood was considered as an incompressible Newtonian fluid, and its flow behavior was described by the Hagen-Poiseuille equation. [5] Arteriole pressure of 50 mmHg was applied at the periphery to simulate blood flow from the circle of Zinn-Haller. [3] Venous outlet pressure of 15 mmHg was applied at the center to simulate blood drainage through the central retinal vein. [6] Pressures of 20 mmHg and 16 mmHg were applied at the pre and retrolaminar boundaries, respectively, to simulate the effects of intraocular and cerebrospinal fluid pressures. [7] The oxygen consumption rate of neural tissues was assumed as 5e-4 $cm^3/cm^3/s$. [8] A Green's function method was employed to estimate LC neural tissue oxygen concentration. [9]

Statistical analysis. Using a Monte Carlo approach, 500 models were generated with varying (baseline ± 20%) microvessel diameter, pressures (arteriole, venule, prelaminar, and retrolaminar), inflow hematocrit, and oxygen consumption rate (Table 1). ANOVA was used to determine factor influences on the minimum LC oxygen.

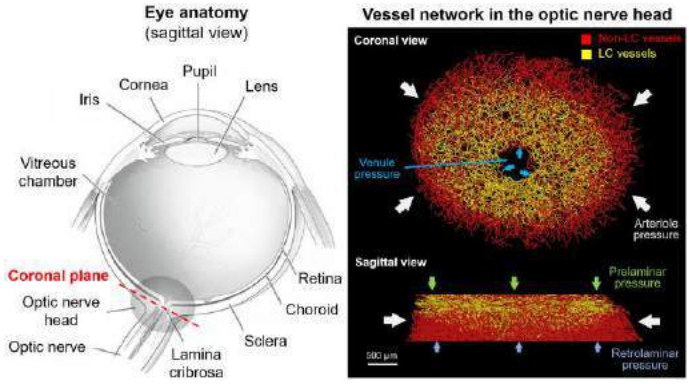

Figure 1: (Left) Anatomy of the eye in sagittal cross-section. Adapted from a diagram by the NEI. (Right) Hemodynamics boundary conditions for the microvessel network in the optic nerve head. We applied boundary conditions at the model edges (periphery for inflow, center for outflow, and pressure-based at the prelaminar and retrolaminar boundaries).

Table 1: Factor baseline values and ranges in sensitivity analysis.

Input parameters	Units	Baseline	Low	High
Microvessel diameter	μm	8	6.4	9.6
Arteriole pressure	mmHg	50	40	60
Venule pressure	mmHg	15	12	18
Prelaminar pressure	mmHg	20	16	24
Retrolaminar pressure	mmHg	16	12.8	19.2
Inflow hematocrit	/	0.45	0.36	0.54
O_2 consumption rate	$cm^3/cm^3/s$	5e-4	4e-4	6e-4

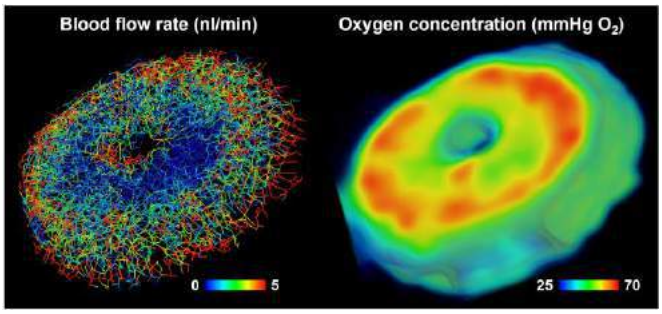

Figure 2: Example microvessel network colored by blood flow rate (left) and contour plots of oxygen concentration in the neural tissues (right), for a model with baseline values of all input parameters. Notice that there are similarities in the regional distribution of high/low blood flow rate and oxygen concentration, but there are also regions of disagreement.

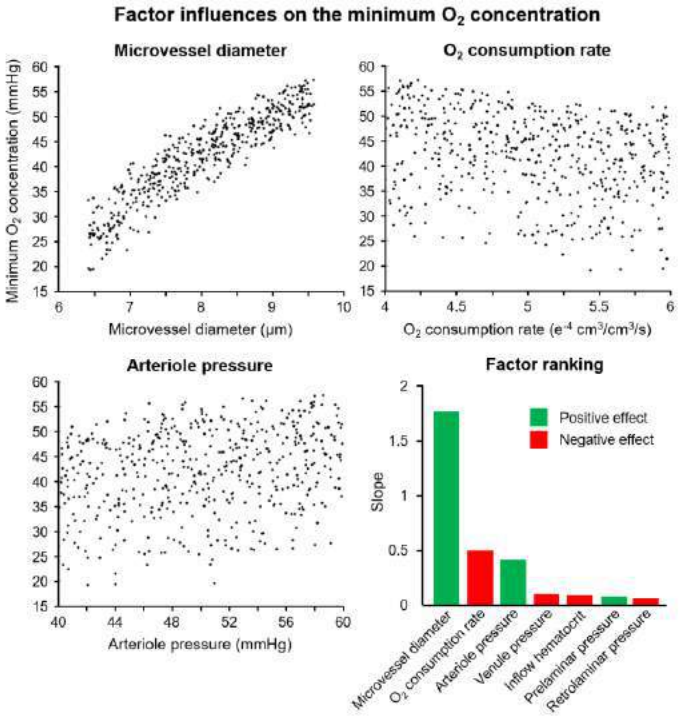

Figure 3: Minimum LC oxygen concentration as a function of the three most influential factors: microvessel diameter, oxygen consumption rate, and arteriole pressure. Each dot is one model. Bar chart of factor influences (ANOVA).

RESULTS

The 3D LC microvessel architecture and its blood flow were quite complex, and the oxygen concentration was heterogeneous (Figure 2). The factors influencing the minimum oxygen concentration the most were: the microvessel diameter ($p<0.001$), oxygen consumption rate ($p<0.001$), and arteriole pressure ($p<0.001$); and to a less extent: the venule pressure ($p<0.001$), inflow hematocrit ($p<0.001$), and prelaminar ($p<0.001$) and retrolaminar ($p<0.003$) pressures (Figure 3).

DISCUSSION

Our goal was to leverage novel 3D eye-specific models of the LC vessel network to identify the factors with the largest influence on the LC oxygen. Our models predicted that the microvessel diameter, oxygen consumption rate, and arteriole pressure have the largest influence on the oxygen concentration in the LC. Below we discuss each of the influential factors in detail.

Microvessel diameter. The minimum oxygen concentration in the LC was positively associated with the microvessel diameter. This is because an increase in microvessel diameter decreased the flow resistance, increasing the blood flow rate, resulting in more efficient oxygen transport and higher oxygen concentrations in the LC.

Oxygen consumption rate. The minimum oxygen concentration in the LC was negatively associated with the oxygen consumption rate of the neural tissues. Note that we assumed the neural tissue consumption rate to be constant and uniform. Early glaucomatous neural tissue degeneration is often localized to specific regions of the optic nerve head [10, 11]. Future studies could consider region-dependent or pressure-dependent oxygen consumption rates.

Arteriole pressure. The minimum oxygen concentration in the LC was positively associated with the arteriole pressure. Arteriole pressure is related to systemic blood pressure. Low systemic blood pressure has been associated with a higher risk of glaucoma, [12] which is consistent with our findings.

The complexity of LC microvessel architecture makes this a difficult region to understand blood flow and oxygenation. However, if as reported herein, relatively few factors account for the oxygenation state of the LC, this may allow for better prediction of LC hemodynamics. With advances in imaging techniques, particularly in optical coherence tomography angiography and super-resolution ultrasound, accurate in vivo measurement of oxygen concentration and blood flow in the LC will be possible in the future.

INTRODUCTION

Cerebrospinal fluid (CSF) is the fluid in the brain ventricular space and subarachnoid space (SAC) covering the central nervous system (CNS). Abnormal CSF circulation closely associates with CNS diseases such as normal pressure hydrocephalus (NPH), and thus underlying mechanism of the intracranial CSF circulation has been much attracted [1]. In previous experiments, pulsatile flow of the CSF driven by the motions of the SAC and brain ventricles was observed in a phase contrast magnetic resonance imaging (PC-MRI). However, much is still unknown especially about the effect of the boundary movements on the pulsatile flow of the CSF in a whole intracranial space, consisting of complex and narrow pathways [2].

To address this issue, computational fluid dynamics (CFD) simulation is a promising approach. Previous numerical studies proposed various computational modeling of the CSF with considering elastic deformation of the brain parenchyma [3, 4], or with flux exchanges between the CSF and interstitial fluid [5]. Although these novel studies have gained insights into some of underlying mechanism of the CSF circulation in whole brain system, it is still uncertain whether characteristic pulsatile flow of the CSF can be formulated in the same context independently of subjects.

The objective of this study, therefore, we develop a computational framework to investigate patient-specific CSF flow. Using a patient-specific geometry of the CSF domain and pulsatile flux measured based on the PC-MRI data, we conduct a CFD simulation of the intracranial CSF with prescribed moving-wall boundary conditions.

METHODS

MRI image acquisition

Brain MRI images of the normal subject was acquired in Shiga University of Medical Science hospital. Computational domain was set in the brain ventricles and SAC domain geometry, which were reconstructed from MRI images (Fig. 1 (a)). Since the intracranial, the SAC space is geometrically separated by Liliequist's membrane [6], we did not consider the top of intracranial SAC space in the computational domain.

Based on the CSF velocity measured in PC-MRI, we calculated the flux in the cerebral aqueduct (CA), which is a pathway between third and fourth ventricles, and in the foramen magnum (FM) during a cardiac cycle (see Fig. 2). In the PC-MRI images, image resolution is $0.5\times0.781\times0.781$ mm^3 and the velocity encoding of PC-MRI is 10 cm/s.

CFD simulation

The computational domain was discretized as a set of first order tetrahedral elements using Netgen (https://ngsolve.org). The number of nodes and elements of the constructed computational grid is 52,115 and 228,491, respectively. The CSF flow was modeled as Newtonian fluid, and driven by moving-wall boundaries was expressed by the equation of continuity and incompressible Navier-Stokes equations in Arbitrary Lagrangian-Eulerian (ALE) form, given by

$$\nabla \cdot \mathbf{u} = 0, \tag{1}$$

$$\rho\left(\frac{\partial \mathbf{u}}{\partial t} + \tilde{\mathbf{u}} \cdot \nabla \mathbf{u}\right) = -\nabla p + \mu \nabla^2 \mathbf{u}, \tag{2}$$

where ρ is density, μ is viscosity, p is pressure, $\mathbf{u}$ is velocity vector, $\tilde{\mathbf{u}}$ is advection velocity in the ALE coordinates. Eqs. (1) and (2) were spatially discretized by streamline-upwind Galerkin method (c.f., [7]) and updated by the fractional step method iteratively. The displacement field of the computational nodes by the moving-wall boundary condition was expressed by solving the Laplace equation for the entire computational domain at each time step.

Boundary condition and physical properties

We gave the displacements in the upper wall of the lateral ventricles (MW1) and the medial wall of the subarachnoid space (MW2) based on [4] (Fig. 1(b)). We assumed that the volume change of the lateral ventricles was equivalent to the in/out flux in the CA, and also that the volume change in whole computational domain except the lateral ventricle was equivalent to the in/out-flux in the FM subtracted by the flux in the CA. Prescribed displacements were assigned on each node on the moving-wall boundaries and its direction was set to unit surface normal. Magnitudes of these displacements were assumed to be uniform, for simplicity.

Pressure boundary condition of 0 Pa was set at the FM, and no-slip wall boundary condition was imposed. Physical properties of the CSF were set to be equivalent with water (density of $\rho = 998.2$ kg/m^3 and viscosity of $\mu = 1.0 \times 10^{-3}$ Pa · s). Time increment in computation was set to 1.0×10^{-3} s and computed totally four cardiac cycles.

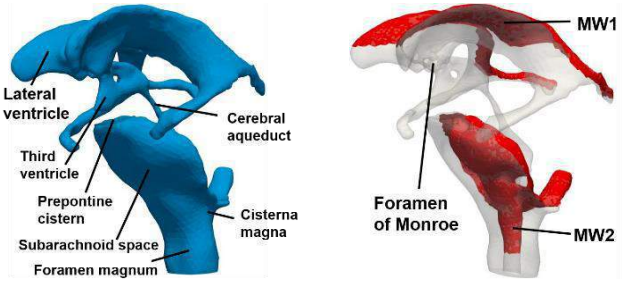

Fig. 1 (a) Computational domain consisting of ventricular constructed based on MRI images. (b) Moving boundaries are represented in red (upper wall of lateral ventricle, inner wall of subarachnoid space).

RESULTS & DISCUSSION

Figure 3 shows representative snapshots of the CSF velocity distribution in the third ventricle at t = 0 s and 0.5 s, respectively. Our numerical results successfully demonstrated characteristic pulsatile flow of the CSF, which was observed in previous experimental observations [8]. Although the effect of the displacement of LV on CSF flow was investigated in [4] considering with fluid-structure interaction problem, the magnitude of the displacement remains to be arbitrary. In our numerical analysis, on the other hands, we gave the displacement of the LV based on the PC-MRI data, and the order of the magnitude of the peak velocity O(vmax)$\cong 10^1$ mm/s agree with the experimental observations [8]. Furthermore, the simulations clearly exhibited the CSF velocity distribution in narrow pathways in the foramen of Luschka and Magendie as shown in Fig. 4. According to Fig.4, the influx (or efflux) in the foramen of Luschka was approximately 85% against total influx (or efflux). Since the CSF flow in such narrow pathways cannot be always detected by PC-MRI measurement due to resolution, our numerical model can be useful not only to investigate the spatiotemporal flux of the CSF but also to quantify the effect of the moving-walls and pulsatile flow of the CSF.

SUMMARY & FUTURE STUDIES

We developed a computational framework to investigate a patient-specific CSF flow. The patient-specific geometry of CSF was constructed based on the MRI data, and the displacement of moving-wall boundaries were determined based on the flux in the CA and FM during a cardiac cycle, which was measured by PC-MRI techniques. Although this study is a first step to clarify the CSF circulation in whole brain, there are several physiological conditions to be considered. For instance, the non-uniform displacements on the brain tissue may be considered to represent more physiologically reasonable ventricle wall movements. It is also necessarily to strictly compare between the CSF flow velocity obtained with simulation and that obtained with PC-MRI data. In the future study, we will gain insights into CSF circulation in whole brain system, and also into mechanics background of NPH.

INTRODUCTION

Atherosclerosis is the leading cause of morbidity and mortality in the Western world, and it is the number one cause of death in the US. Vessel wall thickening and formation of plaques associated with atherosclerosis can be detected using noninvasive imaging techniques such as MRI, CT, and PET. Hemodynamics, and specifically, low and oscillatory wall shear in the carotids have been implicated in localization and development of atherosclerotic lesions [1].

Computational Fluid Dynamics (CFD) technique has been used for decades to simulate the blood flow hemodynamics and determine wall shear stress in arteries [2]. CFD uses computational processing to perform numerical analysis on fluid flow inside a 3D models of vessels. The 3D models can come from the reconstruction of the vessel segmentation from images acquired with magnetic resonance angiography (MRA). Three issues which hamper the use of MRA for creating CFD geometries are: 1) the inadequate spatial resolution to create a realistic geometry, 2) flow artifacts that reduce contrast in areas of very high or very low velocity, and 3) respiratory and cardiac motion which cause blurring in the images [3].

Free-running 5D MRA uses signals inherent in the acquisition data to resolve cardiac and respiratory phases on the 3D MRI. Reconstruction uses compressed sensing to reconstruct up to 60 sparsely sampled 3D data sets at different respiratory and cardiac positions. This technique is capable of visualizing arteries high-resolution at multiple cardiac phases without respiratory motion correction [4]. The technique requires an iron-based contrast agent (Fereheme, AMG pharmaceuticals) to shorter the blood T1 values so adequate signal between the blood and static tissue is present.

In this study, we examined a pig model that had undergone a balloon catheter injury on one of the carotid arteries, causing the artery wall thickening and formation of stenosis. *The aim of this study* was to use CFD simulations to calculate velocity distribution and WSS in the diseased and healthy carotid using image data acquired from the free-running 5D MRA to determine the vessel wall geometry. *We hypothesized* that WSS would the equivalent in the healthy artery and the non-diseased section of the injured artery, and that WSS would be elevated in the area of the stenosis.

METHODS

Pig Model: Data were acquired in three hypercholesterolemic Wisconsin mini-pigs who underwent a catheter-based balloon injury on one of the carotid arteries. Institutional Animal Care and Use Committee approval was obtained for the study.

MRI acquisition: The pigs were placed in a 3T scanner (MAGNETOM Prismafit, Siemens Healthcare) in a head-first and supine position. A 20-channel body coil was placed over the heart. Data was acquired with a continuous, ungated, golden-angle spoiled GRE sequence over a 192 x 192 x 192 mm^3 field-of-view (FOV) with 192 samples per readout, giving an isotropic spatial resolution of 1 mm^3. Following acquisition, the raw data were exported offline for reconstruction [5]. To provide velocity boundary conditions, a phase-contrast magnetic resonance (PCMR) scan was performed in the proximal and/or distal carotid. The PCMR scan had a velocity encoding (VENC) value of 80 cm/s and 25 timeframes were acquired over the cardiac cycle. The velocity information was extracted by converting the voxel values into velocity using the defined VENC value. The velocity information extraction is done through the software Segment (http://segment.heiberg.se)

Image Processing: The vessel segmentation is done through Mimics (Materialise NV, Leuven, Belgium). To segment the carotid geometry, vessel segmentation started at the acquisition slice as the PCMR was taken. 3D reconstructions were generated in the software,

manually smoothing was performed, and mesh generation was done in 3-Matic (Materialise NV, Leuven, Belgium). To reduce the computational complicity, the adaptive mesh was used when meshing the 3D models. The maximum mesh size is 2mm and the minimum mesh size is 0.7mm. Extensions on both inlets and outlets was added to the mesh for fully developed flow and numerical stability, respectively.

CFD simulation: For all simulations, Fluent 2019R1 (Ansys, Inc., Canonsburg, PA, USA) was used. All the inlets and outlets enforced mass flow rates. If two outlets were present, their flow weights were calculated based on the ratio of their areas. The fluid was modeled as blood with a density of 1060 kg/m^3 and viscosity of 0.0034 kg/m^{-1}s. Steady flow simulation used the time-averaged flow rate derived from PCMR and transient simulation adopted the time-varying flow waveform from PCMR with a time step size of 0.001s. The duration of a cardiac cycle was 0.49s. The convergence criteria was residual decrease to 10^{-3}.

RESULTS

The segmentation and simulation was successful in both the healthy and injured carotid in two pigs. In one pig, the PCMR was not successful so a subject-specific simulation could not be performed. We generated 3D models of steady and time-dependent velocity and WSS, figure 1, 2. We examined the cross-sectional mean velocity and velocity profile of each carotid at five different locations: near the inlet, proximal to the stenosis, at the narrowest portion of the stenosis, distal to the stenosis, and near the outlet.

In figure 1 and 2, we can see that the two carotids have a similar velocity at the inlets. Velocity differences become more significant at the center of the stenosis, peak velocity is approximately three times larger in the stenosis carotid.

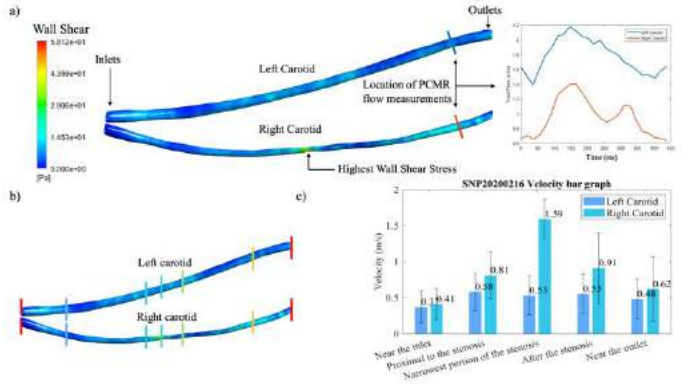

Figure 1 SNP20200216 WSS and Velocity Profile

In the transient flow simulation. From figure 3, normal carotid has similar time mean WSS across the all locations in one of the pigs. WSS increases at the stenosis.

DISCUSSION

Our investigation showed that wall shear stress is the similar at the inlets and outlets in both the injured and health carotids despite the changes in vessel size and flow rate. As expected, CFD simulation results show that WSS and velocity are higher at stenosis. Our hypothesis was that the WSS would be equivalent upstream and downstream of the stenosis, and be similar in both carotids. Furthermore, WSS would be elevated near the stenosis. The data supports this hypothesis, but the number of animals was insufficient to provide statistical significance. WSS has been shown to regulate vessel diameter and wall thickness [6] and this model and these measurements support that mechanism.

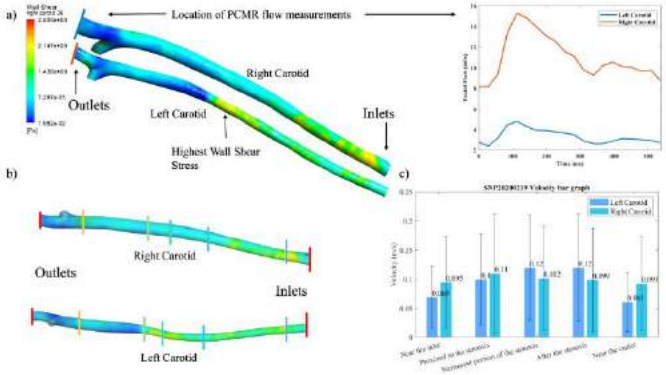

Figure 2 SNP20200219 WSS and Velocity Profile

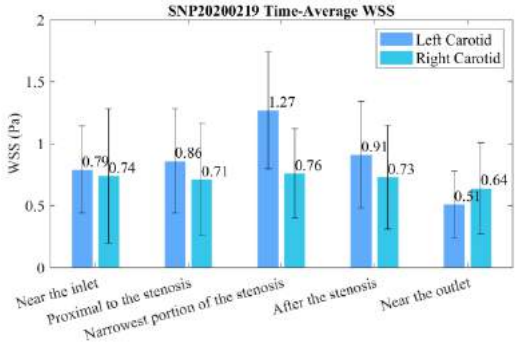

Figure 3. Time-average WSS

The image quality of the 5D free-running MRA sequence with the Fereheme contrast agent was excellent. The high contrast between the blood pool and the static tissue allowed for simplified segmentation of the vessels geometry.

A limitation in this project is that we only have 3 pig models. Our future goals include doing more pig scans and CFD simulation and comparing our simulation data with the histology results.

DIFFERENTIAL PROPENSITY OF DISSECTION ALONG THE AORTA

Ehsan Ban (1), Cristina Cavinato (1), Jay D. Humphrey (1)

(1) Department of Biomedical Engineering
Yale University
New Haven, CT, USA

INTRODUCTION

Aortic dissections are typically characterized by intramural tears of the aorta that communicate with the true lumen and allow the entry and accumulation of blood within the vessel wall. Such dissections may be life-threatening events, especially if occurring in the ascending aorta. Margot Roach and colleagues presented experimental studies that addressed the greater propensity of aortic dissection in the thoracic than in the abdominal region [1]. They inserted a needle into the wall of excised porcine aortas and injected pressurized India ink to measure the possible delamination of the wall. They reported drastically different behaviors in the thoracic and abdominal regions. A sudden mode of tearing was observed in the thoracic region, where the wall tore at about 70 kPa, followed by a monotonic decrease of pressure (Fig. 1). In the abdominal region, the aorta started tearing at a smaller pressure. The pressure, however, increased in a stepwise fashion at increasing volumes of injection, which requires more energy. In this work, we utilized computational modeling and microscopy to study the characteristics of tearing in the abdominal and thoracic aortic samples by the intramural injection of fluid.

METHODS

We used a finite element phase-field model of fracture combined with a Fung-type four-fiber family model of wall deformation and a hydrostatic model of the pressurized intramural fluid. Increments of the volume of the intramurally injected fluid were prescribed by a global Lagrange multiplier, similar to the pressure-like field employed to enforce the incompressible deformation of tissue. A homogeneous model was used for the tearing of the thoracic aorta, whereas a microstructural model was used for the abdominal aorta. The microstructural model was motivated by multiphoton microscopy of the structure of the arterial wall.

Microscopy was performed using aortas harvested from three adult female C57BL/6J mice using protocols approved by the Institutional Animal Care and Use Committee of Yale University. The three-dimensional microstructure of elastin within the aortic wall was captured in a stable in vivo-equivalent mechanical configuration through the entire thickness.

RESULTS

In the thoracic region, as the volume of injection increased, pressure increasing accompanied by the rising of the portion of the wall above the injection. The wall subsequently tore, with the tear extending horizontally in the opening mode. Parametric computations demonstrated that the square of the critical pressure of tearing followed the relation

$$P_{\text{tear}}^2 \propto G_c K_t / \sqrt{A_{\text{torn}}}, \tag{1}$$

where G_c and K_t are the characteristic energy of tearing and tissue tangent stiffness. A_{torn} is the torn area of the tissue in the plane of propagation. The change of pressure with increasing injection volume agreed with the experiments in the thoracic region (Fig. 1C).

Multiphoton microscopy demonstrated the higher frequency of radially oriented elastin struts in the abdominal aorta compared with the thoracic aorta (Fig. 2). Informed by multiphoton microscopy, a model with multiple elastic lamellae and radial struts was tested (Fig. 1A). The sequential tearing of the interlamellar medium and radial struts resulted in the stepwise increase of pressure as injection progressed,

qualitatively similar to the experiments of abdominal aortic tissue (Fig. 1B). The struts stiffened the tissue by holding the adjacent lamellae together and increased the tissue characteristic energy of tearing by forming obstacles to the propagation of the pressurized fluid.

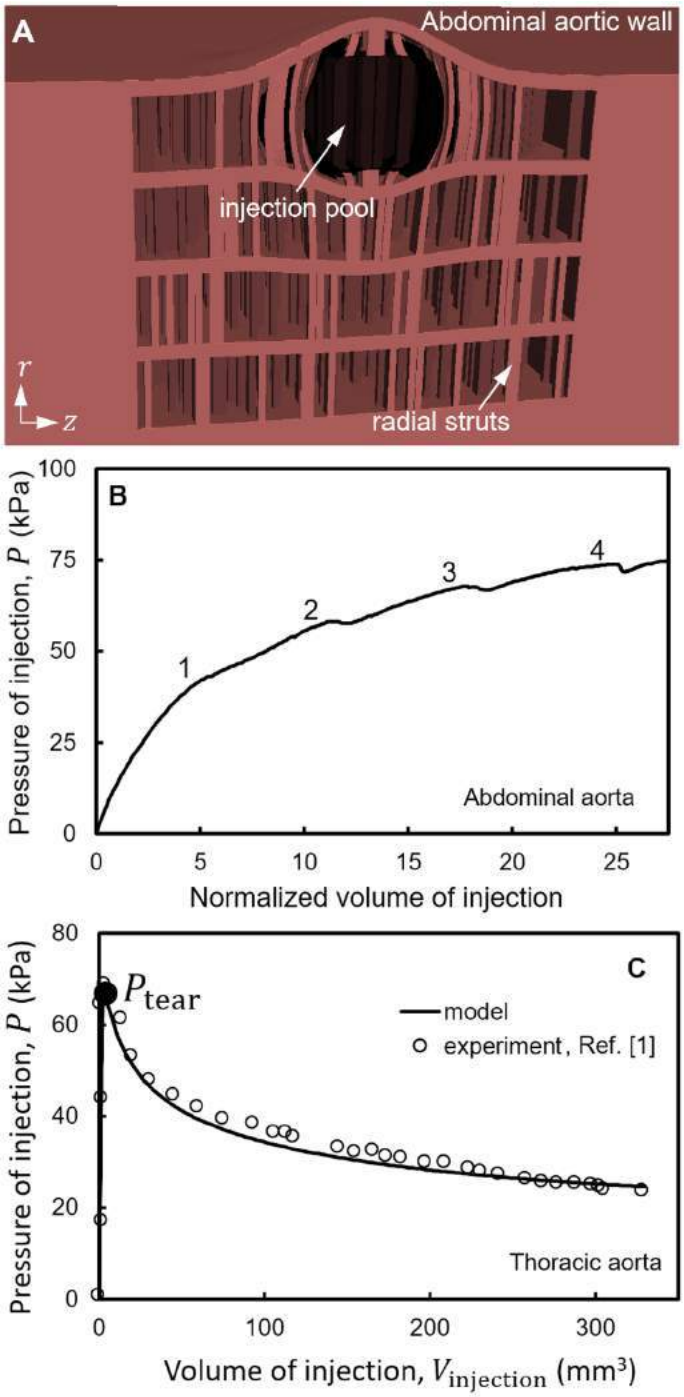

Figure 1: (A) Model of fluid injection into the abdominal aortic wall. The pressure of the injected fluid as a function of volume in (B) the stepwise tearing, observed in abdominal samples, and (C) sudden tearing observed in the thoracic samples that can manifest in other regions. In panel C, 1 refers to the pressure, where the matrix starts tearing; 2, 3, and 4 each correspond to the snapping of a radial strut.

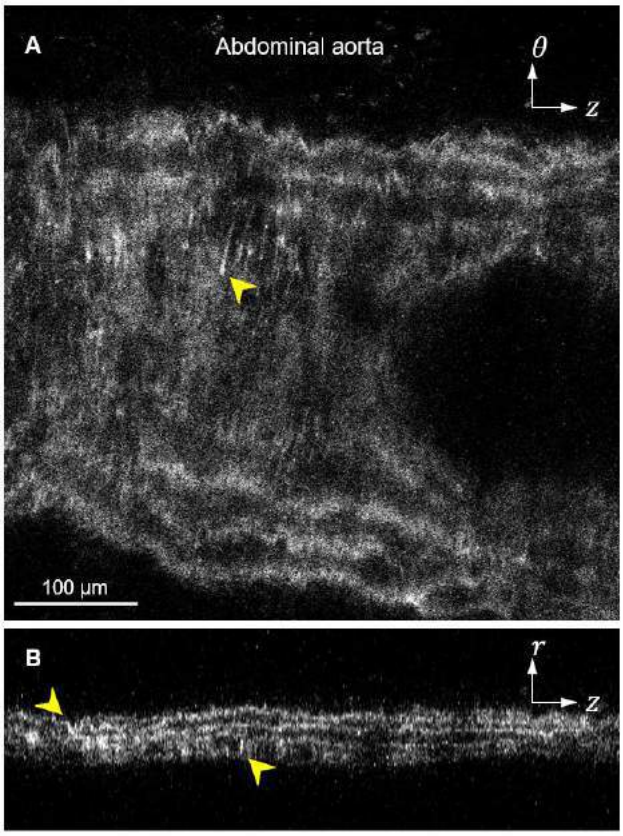

Figure 2: Representative two-photon fluorescence microscopy images of elastin within the aortic wall in the suprarenal abdominal aorta. The yellow arrows point to interlamellar struts.

DISCUSSION

The present work provides computational support for the seminal observations of Roach and colleagues that sites of intramural swelling can lead to propagating delaminations within the aortic wall. Furthermore, the inverse relationship reported between the square of the pressure of tearing and the square root of the torn area of the tissue implies that given a large enough initial tear, the normal pressure of blood can propagate dissections even in healthy aortas. Finally, this work confirms the importance of the radially oriented structural constituents within the wall in allowing or arresting dissection (cf. Ref. [2]).

INTRODUCTION

Historically, pathologies such as tumors or lesions have been identified by physicians by manually palpating soft tissue to compare mechanical properties of healthy tissue to potentially malignant tissues. However, for organs such as the brain, this technique is not feasible, although the mechanical properties of the brain can elucidate significant information about its health and development, such as cell density, myelination, and inflammation [1]. This information can be used to diagnose injuries and diseases, such as Alzheimer's disease, Frontotemporal dementia, or Parkinson's disease [2,3]. Magnetic resonance elastography (MRE) is a technique for determining the mechanical response of tissue using applied harmonic deformation of the tissue and motion sensitive magnetic resonance imaging (MRI) [4]. Currently, studies investigating the mechanical properties of the human brain using MRE are performed at conventional clinical MRI scanner with magnetic field strengths of 3 Tesla (3T) and 1.5T.

More recently, there have been a few attempts at performing MRE on the human brain at the ultra-high field strength at 7T [5]. This ultra-high field strength allows for higher resolution images and higher signal-to-noise ratio (SNR), potentially allowing for the determination of the properties of smaller brain-substructures that have been suggested at 3T MRE [6, 7]. In order to perform MRE at 7T, however, a novel actuator that is ultra-high field compatible and approved needs to be developed and validated due to the size, material, and T2 relaxation constraints imposed by moving to 7T.

In MRE, mechanical waves generated by the actuator, usually transmitted in a burst of specified duration, must be synchronized with the MR signal excitation [8]. The vibration frequency, dependent on the application, is generally in the range of 40-120 Hz [8]. Additionally, since this actuator must be used in an ultra-high MR setting, the tissue-contacting portion of the actuator must contain only ultra-high MR-safe materials. Common electromagnetic and piezoelectric actuators are inherently made of metals and may not be ultra-high field MR-safe. Specifically, electromagnetic actuators can cause electromagnetic interference during MR signal acquisition, while 7T-safe versions of piezoelectric actuators are cost-prohibitive and can cause distortions due to eddy currents. With a pneumatic design, the active metallic components can be stored in the equipment room, while all of the tissue-contacting components used in the scanner room can therefore be made entirely of plastics. However, both acoustic wave attenuation and synchronization with the scanner can present an issue with this type of design due to the time delay of the acoustic waveform moving from the active pneumatic driver to the end-effector.

Therefore, the purpose of this investigation is to develop a 7T MR-compatible actuator for MRE data acquisition, quantify the frequency response using laser doppler vibrometry, and perform a 3T validation scan on a phantom of known mechanical properties.

METHODS

The proposed pneumatic actuator design consists of a modified dual 12" cone subwoofer (MTX 1200 W max, 2 Ω impedance) as an active driver to provide harmonic vibration in the form of pressure waves through flexible PVC tubing (1" ID, 1-1/4" OD) to a pillow-like passive driver as the tissue-contacting end effector. Both cones have acrylic sheets mounted to the front with custom hose attachments to direct the acoustic waves into the tubing and to the passive driver. The passive driver is constructed from heat-sealed polyurethane and compressible foam. The modified subwoofer is driven by a function generator (RIGOL DG-1022) through an audio amplifier (300 W), which provides a harmonic signal to the active driver and a TTL signal synchronized with that signal to the MRI control PC to trigger the MRE acquisition sequence. The schematic of the design is shown in Figure 1.

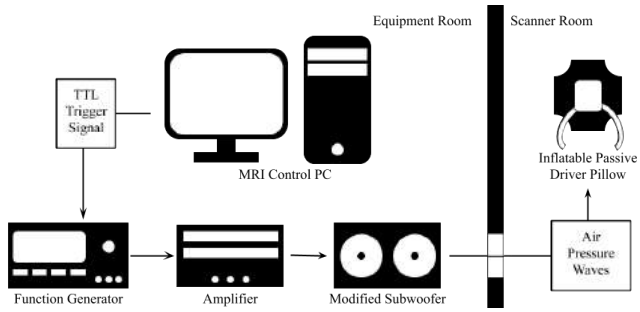

Figure 1: MRE hardware and sequence triggering setup.

To address the time delay from the active driver to the passive driver and the frequency response of the actuator, a laser doppler vibrometer (LDV) was used to capture the harmonic motion of the passive driver. A small square of reflective material was attached to the center of the passive driver, and the laser was aligned with the square. Both the output of the LDV and the signal generator driving the modified subwoofer were visualized in an oscilloscope, and both the amplitude of vibration of the pillow and the time delay (ms) between peaks was measured for driving frequencies 50-100 Hz (5 Hz increments). These data were then phase-unwrapped, and a linear regression was developed to quantify the time delay as a function of driving frequency to be used in that driving frequency range.

To validate that the actuator functions as intended, a custom silicone MRE phantom (CIRS 049) of dimensions 21.0×15.0×10.7 cm was acquired with a background Young's modulus of 5±1 kPa and spherical inclusions of 3, 8, 12, and 20 kPa, ±1 kPa. The passive driver was attached to the surface of the phantom using compression bandages, and while performing MRE imaging, the MRE sequence provided TTL triggering to drive the modified subwoofer in sync with the motion encoding gradients. MRE data was acquired for 24 slices with 3D motion encoding gradients using an echo planar spin echo 2D pulse sequence [9] with vibration frequency 60 Hz, 8 phase offsets, 90-degree flip angle, FOV 300x300mm, resolution of 3.125×3.125 mm, and slice thickness of 2.5 mm. This was performed inside of a 3T Siemens Skyra scanner with a 16-channel head coil (Siemens Healthineers).

Acquiring special mapping of displacement patterns under the external harmonic loading [4], curl filtering was used to capture wave propagation fields (Fig. 3), and an algebraic inversion algorithm without phase wrapping [10, 11] and Romano filtering was utilized to acquire shear stiffness maps of the phantom's cross section.

RESULTS

The linear regression developed from the LDV testing (Fig. 2) to calculate time delay from trigger signal to pillow movement, where f is the driving frequency and n is any positive integer, is shown as equation 1. The R^2 value of this linear regression was 0.9986.

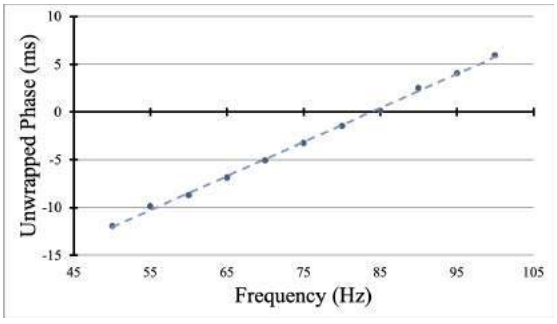

Figure 2: LDV testing time delay linear regression.

$$timedelay = \frac{0.3565f - 29.882}{2\pi f} - \frac{n}{f} \quad (1)$$

The peak-to-peak amplitude of the pillow ranged from 0.6 mm to 0.3 mm, dependent on the frequency of actuation.

Shear wave propagation (from the top of the phantom down) due to the actuator are shown in Figure 3 in units of mm/mm. This algorithm was able to distinguish shear wave propagation in homogeneous slices (Fig. 3a) and those with a spherical inclusion (Fig. 3b). The shear stiffness estimates of the background ranged generally from 1.4-1.6 kPa, which, assuming a Poisson's ratio of 0.5, is equivalent to a Young's modulus of 4.2-4.8 kPa. The shear stiffness estimates for the inclusion ranged from 0.7-0.9 kPa, or a Young's modulus of 2.1-2.7 kPa.

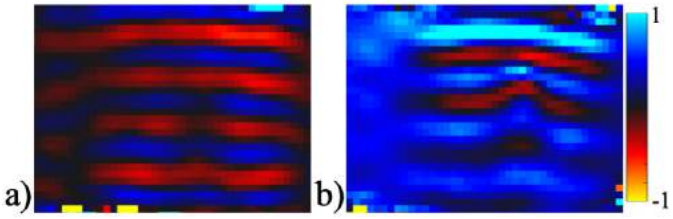

Figure 3: Shear wave propagation in MRE phantom, without an inclusion (a) and with a spherical inclusion (b).

DISCUSSION

While wavefield images and stiffness maps were successfully obtained, there is attenuation as the shear waves propagate farther from the actuator attached to the top surface of the phantom, therefore, the shear stiffness estimate is not as homogenous as we assume the custom phantom is. These estimates are, however, within the ranges of the custom phantom's specifications, indicating that the actuator and inversion algorithm result in accurate stiffness estimates.

In order to generate a more accurate and homogenous stiffness estimate, a more powerful amplifier can be used in the actuator setup to generate higher amplitude acoustic waves, and stiffer and shorter tubing can be used to decrease wave attenuation. Additionally, in the future, this actuator will be tested using a 7T human MRI scanner as well as with human subjects in order to estimate the shear stiffness of the human brain. For this future work at 7T, ultra-high-resolution MRE data of 1.1 mm isotropic resolution will be acquired using a custom (under development) single-shot spin-echo EPI (echo planar imaging) sequence with three orthogonal trapezoidal flow-compensated motion-encoding gradients.

ACKNOWLEDGEMENTS

We acknowledge support from NSF funding 1953323 and NIH funding R21AG071179. We would also like to thank Dr. Curtis Johnson (University of Delaware) for providing the MRE sequence.

DEVELOPMENT OF A METHOD TO QUANTIFY ELASTIN CONTENT IN LARGE DATASETS OF BLADDER TISSUE HISTOLOGY WITH MACHINE LEARNING ALGORITHM

Eli Broemer (1), Sara Roccabianca (1)

(1) Mechanical Engineering
Michigan State University
East Lansing, MI, USA

INTRODUCTION

Extracellular matrix remodeling in which the structure and/or distribution of collagen and elastin fibers in the urinary bladder wall are modified has been associated with dysfunction [1]. Histological images are useful in studying microstructural changes, however, quantifying elastin content in these images is challenging. Specifically, the Verhoeff-van Gieson's (VVG) stain is known to effectively differentiate elastin fibers with sharp intense contrast, although it also stains cell nuclei and other connective tissue [2]. Despite having limitations, the stain is relatively easy, and elastin has high affinity to the dye, making VVG one of the most common elastic tissue stains [3].

Analyzing amounts of elastin in bladder tissue with VVG histologies has long been done qualitatively [4, 5]. Yet, quantitative attempts with VVG micrographs are less common, and may include visually scoring fiber density [6, 7], or estimating area fraction in a region of interest by thresholding the dark fibers from the light background [8, 9]. The primary limitation with the simple thresholding scheme is that cell nuclei and other noise are not removed by the cutoff value, or more strict cutoffs significantly erode the elastin fibers. To solve this issue, prior studies relied on substantial manual postprocessing and homogenization of connective tissue [8, 10]. Alternatively, computationally intense methods have been proposed, however limitations of these are that they either use proprietary software [10] or unsupervised image transforms to segment fibers [11]. Our goal is to improve on the latter approach by simplifying the segmentation procedure and by adding a machine learning postprocessing step to reduce the manual processing of large data sets.

Random forest [12] is a type of machine learning algorithm, and is regarded one of the best overall for prediction problems [13]. In short, the model fits an output dataset by building a decision tree used to interpret the input parameters [14]. Then, bootstrapping the data produces a forest of decision trees, and its final prediction is typically the average or most frequent result from the forest. This makes the algorithm robust to outliers, missing data, and irrelevant parameters. Random forest is easy to implement, fast to train, and has been applied to histology problems before [15]. Yet, its application to identify elastin in bladder tissue is novel and presents unique challenges.

The current work was initiated with a proof-of-concept by training a random forest algorithm on a pseudo dataset representative of VVG stained bladder tissue after simple thresholding to ensure feasibility. Then, we developed a software for processing true histology specimens. The software is used to, first, segment histology images and, second, to label the segments as elastin fibers or not. A segmenting protocol as simple as thresholding was enhanced by preprocessing more powerful image transforms. Then, the labelling process allows for multiple researchers to easily train a new elastin classification algorithm. When the random forest is sufficiently trained by showing reliable accuracy, it can automatize the quantification of elastin area fractions in large data sets, which will significantly improve the time needed for analysis.

METHODS

A set of 35 VVG stained rat bladder wall microscopy images was contributed from a separate study for use. Image preprocessing starts when images are uploaded to the custom-made software. Each image is treated with a combination of transformations that were found to be generally successful at isolating the specific components of interest and masking the background noise. For every image, a set of 50 masks with varying levels of strictness is obtained by tweaking the combination of image transforms. Then, segmentation is done by a researcher choosing the strictness of the final mask with a slider to best capture elastin and remove noise, as shown in **Figure 1**. Combining varying image transforms (i.e., thresholding, contrast normalization, dilation, noise

reduction) and then sorting the resulting image masks by the number of pixels masked allows the researcher to leverage these powerful techniques. This protocol was implemented into a web application using the python Bottle library. The software is hosted locally in the research lab, and lab members can login to easily segment images with this enhanced thresholding method, or label objects extracted from images.

Once an image is segmented, each object isolated by the mask is extracted, and on a different screen, shown in **Figure 2**, a researcher can label the objects based on their expertise. Furthermore, objects may carry labels from multiple researchers, and this is in fact encouraged as some objects are ambiguous and multiple opinions will reduce bias.

RESULTS

The segmentation screen (**Figure 1**) allows quick masking of cells and elastin by utilizing preprocessed image transformations that are more powerful than simple thresholding. The mentally taxing process of tweaking the image transformations is supplanted with simply selecting more/less masking from the set of preprocessed transforms. Segmentation is faster and requires less image analysis intuition.

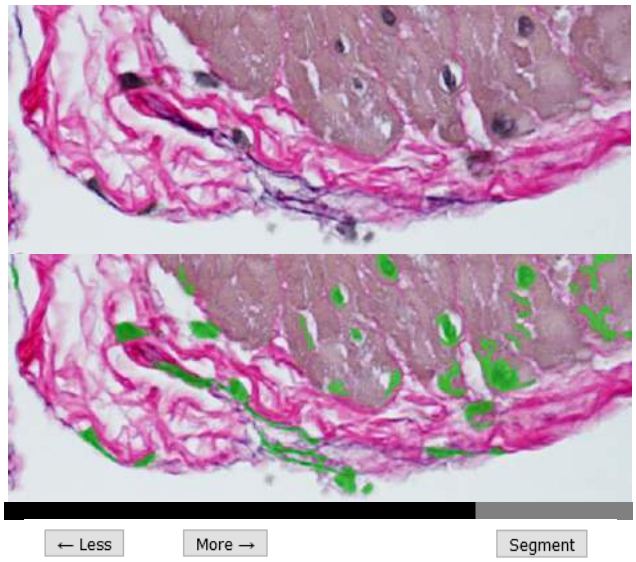

Figure 1: Segmentation screen utilizing enhanced thresholding method. Black/gray slider at the bottom has been adjusted so that cells and elastin are masked (green highlights) as best possible.

The labelling screen (**Figure 2**) presents individual microstructure for the researcher to identify. A given histology image may have between 50 – 200 objects isolated after segmentation, and it can take a time near 5 – 10 minutes to fully label an image. Since the software is hosted locally, loading and saving times are often near instant. This approach is faster and easier than the proof-of-concept method in which image files of isolated objects were labelled correspondingly in a spreadsheet. Data labels are used to train random forest predictions.

DISCUSSION

This histological elastin extraction software shows promise for estimating area fraction of elastic fibers in VVG stained tissues. Other means of quantifying elastin in tissues include commercial assays or Western blots. However, these procedures consume the sample and so the tissue morphology cannot be assessed from the same sample. Scanning electron and confocal microscopy are also used to capture images of elastin, although these technologies are more cost prohibitive.

Figure 2: Labelling screen prompts user to identify if an object is elastin. Extracted object is shown with context (left) and also magnified with outline (right) for clarity.

Current limitations of this study are microstructure components that are not fully separated during segmentation. For example, an elastin fiber intersecting a cell are both joined as one object and cannot be labelled accurately. Next steps include solving this limitation by developing a secondary segmentation option when a researcher encounters this scenario during labelling.

As the development dataset is small, more histology images from bladder tissue are to be added. Then, a new random forest algorithm will be trained and tested on the data using this software. Fully labelled data is to be split 80/20 for tuning algorithm hyperparameters. That is, 80% of the data is used to train and 20% is used to test the algorithm. Random forest parameters including number of trees and branch splitting criteria will be optimized with 5-fold cross validation to assess accuracy. The model will also be tested on new data to further validate.

Later steps include implementing and comparing the accuracy of other machine learning schemes such as Support Vector Machine and Naïve Bayes classifiers.

ACKNOWLEDGEMENTS

We thank fellow lab member Tyler Tuttle for the histology images, and the MSU Investigative Histopathology Lab for staining tissues. This research was inspired by Miguel Contreras' work at SB3C 2020 [16].

INTRODUCTION

Vertebral compression fracture (VCF) is a major clinical concern in treatment of cancer patients with metastatic disease to the spine. These sudden fractures often lead to persistent back pain in patients, who may not be able to perform normal daily activities, and some of them develop into kyphosis, seriously affecting their quality of life. Vertebroplasty is a common treatment modality used to help stabilize VCF in patients[1]. This procedure is usually associated with injection of a polymeric material (e.g. PMMA bone cement) to reinforce the vertebral structure. However, injection of PMMA imposes risks such as intra-spinal cement leakage[2] and development of new fractures. These complications pose a significant challenge to clinicians in the medical treatment of high-risk patients. Therefore, prospective data on the optimal use of Vertebroplasty is vital for the management of high-risk VCF patients.

While biomechanical loads are believed to play a major role in the initiation of VCF injury mechanisms, very little is known on the progression of microstructural damage in the bone. It remains unclear how the underlying relationship between spinal loads and the morphological changes to the vertebral bodies (because of disease and treatment) may contribute towards the initiation of microstructural damage and consequent fracture. Computational methods (e.g., finite element) and machine learning algorithms provide a viable non-invasive scheme to elucidate mechanisms that lead to vertebral instability, failure and eventual fracture. Further, leveraging Computational Fluid Dynamics (CFD) tools in the simulation of vertebroplasty enables surgeons to virtually control and evaluate various parameters such as the needle position and injection flow rate virtually. Here, we will present an AI-assisted computational framework that involves constructing a *digital-twin*[3] of the patient's vertebra, to assess the risk of VCF in cancer patients with spinal metastasis. The concept of digital twin is borrowed from engineering principles, where *in-silico* representations of a complex system (e.g., vertebral body) are used as virtual models to analyze current condition and predict future performance with real-time connection between the physical system and the model

METHODS

In this effort, micro-Quantitative Computer Tomography (micro-QCT) imaging datasets will be utilized to train a Deep Learning (DL) network for creating patient's vertebral digital twins. These surrogate models will then be transformed into an in-house high-fidelity FE mesh for biomechanical analysis. A level-set method is then utilized within a CFD framework to track the displacement of the interface between injected cement and bone marrow. Next, a nonlinear damage model is utilized to simulate the initiation and progression of damage in the vertebra under various loading conditions.

RESULTS

In this section, we have provided a feasibility study to understand failure mechanism of the vertebra subjected to various loading conditions. Morphology of vertebra and tumor lesion is extracted from CT and MR images of a 51 years-old female patient with lung cancer admitted to the Ohio state university comprehensive cancer center (OSUCCC). To conduct high-fidelity FE simulations, the reconstructed vertebral models are first transformed into FE meshes with BMD-dependent elastic properties using an in-house FE modeling framework. The failure behavior of each model is quantified as the force-displacement curves resulted from the FE solver. Such measurement provides us with a good estimate of the vertebral fracture strength as the peak force in the aforementioned curve. Furthermore, the crack propagation is tracked

through visualization of damage initiation and progression patterns projected on the deformed geometry of the vertebra.

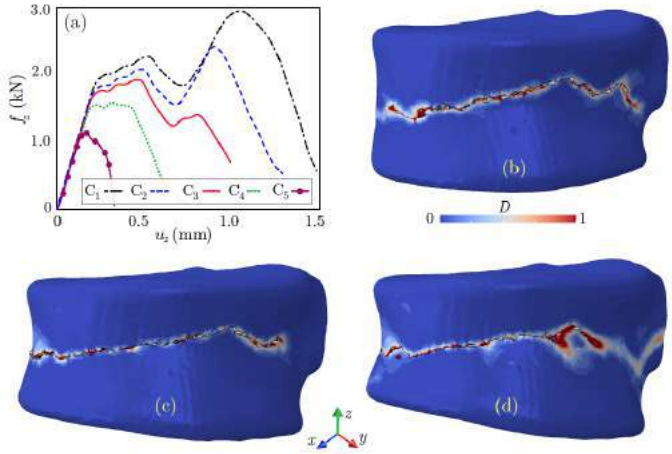

Figure 1: (a) Force-displacement curves. Note that C1-C5 corresponds to loading case scenarios with 0.0, 0.1, 0.2, 0.4, 0.5 °/sec applied rotations. (b-d) Failure pattern after the failure point for the studied vertebra subject to multi-axial loading with compression and (b) 0.0, (c) 0.2, and (d) 0.4 °/sec flexion angle.

In order to investigate the effect of flexion on the failure response, force-displacement curves are quantified for the studied lytic vertebra subjected to multi-axial loading with compression (0.05 mm/sec) and bending (0.0, 0.1, 0.2, 0.4, 0.5 °/sec). Figure 1a illustrates that deformation begins with an elastic region followed by strain hardening, which is associated with trabecular yielding. However, as the flexion angle increases, strain hardening modulus decreases. Under smaller flexion angles i.e. 0.1, 0.2 °/sec, trabecular yield accompanied by initiation and propagation of multiple micro-cracks in regions of trabeculae with higher stress concentrations. Such localized failure mechanism is generally observed as a softening response within the force-displacement curve. As the internal micro-cracks propagate and coalesce to find the path of least resistance, the cortical bone starts to provide mechanical support for the vertebral body. This observation can be explained by stress redistribution after trabecular failure, which activates cortical damage under higher displacements. Such failure mechanism is not observed for the vertebra under higher flexion angles i.e. 0.4, 0.5 °/sec. Therefore, under these loading cases, the catastrophic vertebral failure happens at lower displacements, which explains the importance of anterior height calculations in the clinical assessment of VCF[4]. Note that fracture behavior under flexion, is strongly influenced by the strength of vertebra at the periphery i.e., farthest regions from neutral axis of vertebral body. Therefore, the trabecular microstructure is expected to have lower involvement in load bearing capacity and energy absorption under higher flexion angles. This leads to more brittle failure (limited nonlinearity) with lower vertebral strength as flexion angle increases. These observations justify the prevalence of wedge-shaped fractures in osteoporotic patients, particularly in the thoracic spine, which are subjected to high flexions.

These fractured vertebrae can easily be augmented by virtually embedding the injected cement geometry within the microstructure to re-estimate the risk of fracture after performing vertebroplasty. However, since determination of cement distributions pre-operatively is not feasible, a computational tool allowing surgeons to predict the cement morphology based on injection pressure, location and local tissue micro-architecture could significantly reduce the risk of cement leakage or re-fractures. For this reason, a two-phase level-set method is utilized within a CFD framework to track the displacement of interface between injected cement and bone marrow during the vertebroplasty. Figure 2 shows the vertebroplasty results for three scenarios: (1) cement injection within an intact vertebra with no lesion (injection rate=0.5 mL/sec) (2) cement injection within a lytic vertebra (injection rate=0.1 mL/sec) (3) cement injection within a lytic vertebra (injection rate=0.5 mL/sec). For the intact vertebra a uniform cement distribution is observed, which qualitatively matches clinical observations of vertebroplasty in patients with osteoporosis. However, for the vertebral model with lytic metastasis, risk of cement leakage increases as the injection flow rate increases, which matches with observations from literature[5]. This phenomenon can be explained by the higher viscosity of cement under lower injection flow rates. Finally, a biomechanical damage analysis could be performed to re-evaluate risk of fracture in the vertebral body.

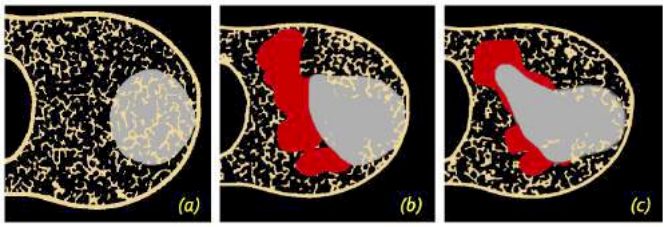

Figure 2: cement morphology (gray color) for (a) intact vertebra (b) lytic vertebra with injection rate of 0.1 mL/sec, and (c) lytic vertebra with injection rate of 0.5 mL/sec. tumor lesion is demonstrated with red color.

DISCUSSION

The computational framework proposed in this is the promising step towards providing a quantitative metric for predicting VCF thresholds in vertebral bodies. Although, achieving its full potential would require further developments beyond the scope of this manuscript, the digital twin concept could potentially translate to innovative clinical applications such as personalized treatment patients with bone diseases (e.g., osteoporosis and cancer metastasis). Note that an accurate prediction of VCF requires a real-time estimate of external stimuli i.e. the spinal loadings applied on the vertebral body during daily life activities. Therefore, the next step is to incorporate the proposed computational framework within our personalized musculoskeletal model.

The parameters used in the biomechanical damage model and estimation of the bone elastic modulus based on BMD are adopted from literature. However, adopting generic parameters from literature for the real subjects without carefully assessing the FE model could undermine the fidelity of predictions. Therefore, a direct and effective comparison with in-vitro (e.g., cadaveric mechanical testing) and in-vivo (e.g., MR Elastography) measurements is of great importance.

THE EFFECTS OF FETAL HEAD SIZE ON MATERNAL COCCYX ROTATION DURING A VAGINAL DELIVERY

INTRODUCTION

Childbirth is a complex mechanical process that puts both the mother and the infant under a risk of injury. The coccyx, despite its small size, serves a big role during the childbirth process. It provides crucial support to the structural integrity of pelvic floor muscles during childbirth. Its mobility also helps the fetus negotiate through the maternal pelvis. Therefore, the coccyx is a key factor in understanding both maternal and fetal injuries.

The goal of this study is to develop a computational model of vaginal delivery that includes the maternal bony pelvis, a complete maternal pelvic floor, and most importantly, a coccyx that can rotate around the sacrococcygeal joint. This model allows the effects of fetal head size on coccyx rotation during a vaginal delivery to be quantified.

METHODS

A series of three-dimensional (3D) computational models of vaginal delivery were developed including both the mother and the fetus. Three spherical fetal head models with diameters of 74 mm, 80mm, and 86 mm, representing the 3rd, 50th, and 97th percentile head circumferences of newborns [1], were constructed, after considering a 20% reduction in circumferences due to molding. The mechanical properties of the fetal head were set to be nearly rigid. The maternal geometric model was based on the *in vivo* MRI images of a 21-year-old nulliparous woman at the gestational stage of 35 weeks and 6 days. The 3D maternal geometric model includes the bony pelvis (i.e., hip bones, sacrum, pubic symphysis, and coccyx), and soft tissues (i.e., levator ani, coccygeus, and the superficial perineal muscles and perineal membrane). A finite element mesh of the maternal model was constructed in Hypermesh (version 2020, Altair). The maternal bony pelvis was meshed using first-order triangular shell elements, with an average element size of 5 mm and a thickness of 1 mm. The pubic symphysis was added to the maternal pelvis during the meshing process, using the same shell elements. All maternal soft tissues were meshed using first order tetrahedral elements, with an average size of 4 mm. The finite element mesh model was composed of 28379 first order tetrahedral elements, 15077 first order triangular elements, and 14130 nodes, as shown in Figure 1.

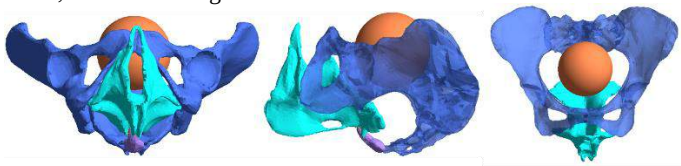

Figure 1: Overview of the childbirth finite element model, from (a) caudal to cranial direction, (b) left to right direction, and (c) ventral to dorsal direction. The fetal head with the 50th percentile circumference is presented in the picture.

The material properties of the maternal bony pelvis were described as rigid. The material properties of the maternal soft tissues were described using a Mooney-Rivlin material, the strain energy density function of which is written as

$$W = C_1(\bar{I}_1 - 3) + C_2(\bar{I}_2 - 3) \quad (1)$$

where $C_1 = 26kPa$, $C_2 = 14\ kPa$ [2]. The density of the pelvic floor soft tissues was $1060\,\frac{kg}{m^3}$ [3]. Rayleigh damping ($\alpha = 0.1$) and material damping ($d = 0.5$) were added to filter out low frequency and high frequency vibration of the soft tissues, respectively.

The maternal pelvis was positioned with a 45° angle between the pubic symphysis and the ground. All degrees of freedom of the following locations were fixed: (1) levator ani's insertion points at the pubic bone; (2) levator ani's insertion points at the ischial spines; (3) the

ends of the ischiocavernosus that join the bulbocavernosus near the pubic symphysis; and (4) the ends of the ischiocavernosus that join the superficial transverse perineal muscle near the ischial tuberosities. Displacement of the following locations were fixed in certain directions: (1) nodes around the anus were restricted from moving in the left - right direction; (2) nodes on the anococcygeal raphe were restricted from moving in the left–right and the cranial–caudal direction; and (3) nodes on the ischiocavernosus along the inferior pubic rami were restricted from moving in the ventral–dorsal and the cranial–caudal direction. The pelvic floor was connected to the coccyx using 11 belt elements that had nearly rigid tensional strength but zero compressive strength.

The descent trajectory of the fetal head followed the Curve of Carus. It consisted of six points described as follows: Point 1- the middle point of the pelvic inlet; Point 2 - the middle point of the mid pelvic cavity; Point 3 - the middle point of pelvic outlet; Point 4 - the projection of the pubic symphysis' lower end on the ground surface at the level of Point 3; Point 5 - the lower one quarter point of the vaginal hiatus; and Point 6 - a point on the extended line of Point 4 and Point 5 that is at a distance of 60 mm from Point 5.

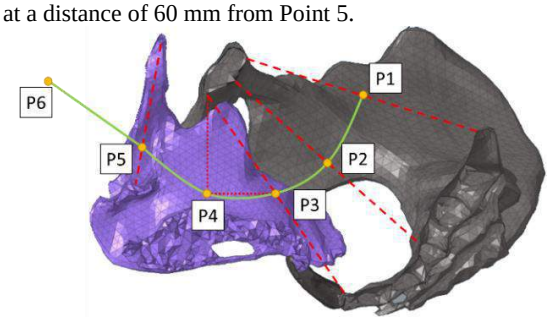

Figure 2: Landmark points and the descent trajectory of the fetal head during the second stage of labor. Points 1 – 6 are marked using yellow dots and labeled as P 1 – 6 in the picture.

The descent trajectory was represented by a spline interpolation going through the five landmark points, fitted by XMADgic (version 7.7, Siemens) using a series of 5th degree polynomials. The delivery time was set to be 1 hour, which is the median time duration of the second stage of labor for nulliparous women without epidural. During the delivery, the fetal head moved along the trajectory in constant speed This dynamic model system was solved in MADYMO (version 7.7, Siemens).

RESULTS

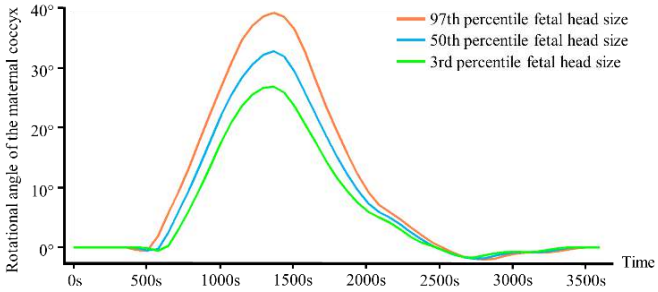

Figure 3: Rotational angle of the coccyx corresponding the delivery of the 3rd, 50th, and 97th percentile fetal head during the second stage of labor.

The rotational angles of the maternal coccyx were recorded at 50 evenly distributed time points. The coccyx rotated around the sacrococcygeal joint and moved in the dorsal, caudal direction as the fetal head went through the pelvis. As shown in Figure 3, different fetal head sizes contributed to different peak angles, but the peak time and the general trend were the same: the maximum angles were all reached at 1368s, when the center of the fetal head is between Point 3 and Point 4. After the peak angle, the coccyx rotation decreased and overshot slightly in the ventral, cranial direction before it returned to its original position from the beginning of the second stage of labor. The peak angles are 39.1°, 32.8°, and 26.8° for the 97th, 50th, and 3rd percentile fetal head size, respectively.

DISCUSSION

This study simulated the second stage of labor using a computational model that included the complete pelvic floor soft tissues and a coccyx with the sacrococcygeal joint. The increased coccyx rotational angle due to a larger fetal head was as expected. Since the descent trajectory was prescribed, the rotation of the coccyx is the only way that fetal head can negotiate through the pelvis. This also explains why certain obstetrical maneuvers are effective at resolving difficult labors. For example, by hyperflexing the mother's legs during a McRoberts' maneuver, the pelvis will be tilted, which leaves room for the coccyx to rotate.

Although the childbirth process has been extensively studied computationally, the rotation of the coccyx has not gained the attention it deserves. Researchers have long acknowledged the rotation of coccyx during the second stage of labor. However, very limited quantitative data can be found in the literature. Bø and colleagues [4] measured the rotational angle of the coccyx during contraction and straining of the pelvic floor in an upright sitting position using dynamic MRI. They reported a ventral, cranial rotation of $15° \pm 10.2°$, and a dorsal, caudal rotational degree of $12.9° \pm 10.9°$. Their angles are much lower that what is reported in the current study because these data were achieved merely through participants' voluntary efforts without passage of a fetus through the pelvic floor. In a computational model for the second stage of labor from Jing and colleges, a rotating coccyx was included, but no rotational angles were reported [5]. In another study that addressed the importance of the coccyx during labor, the coccyx provided extra supporting boundary condition for the pelvic floor but was not allowed to rotate [6]. In a recent study, Borges and colleagues reported a 15.7° rotation of the coccyx in their childbirth computational model [7]. The main factor contributing to the rotational angle difference between their study and the current one is likely to be the different initial position of the coccyx. In Borges's study, the coccyx was positioned along the curvature of sacrum, while in the current study the coccyx was positioned pointing anteriorly based on *in vivo* MRI images.

By addressing the mobility of the coccyx at the sacrococcygeal joint, the current study provides a valuable platform through which more accurate childbirth processes may be simulated. By including more detailed muscle and internal organ representation, along with articulated fetal models, a better understanding of childbirth mechanisms and fetal and maternal injuries can be achieved.

INTRODUCTION

The brain development is among the most complex biological phenomena, including dynamical changes of biochemical and mechanical cues. Myelination is an important process taking place during the brain development, which has shown to be related to the brain tissue stiffening [1]. Even though numerous non-invasive elastographic techniques are able to precisely predict the response of brain tissue to specific strain rates *in vivo* [2, 3], there is still limited understanding between biochemical cues and mechanical response during myelination. Therefore, an *in vitro* dorsal root ganglia (DRG) neuron-oligodendrocytes (OL) co-culture system was designed to mimic the neuron myelination process in developing brain, with controlling different neuronal alignments which represents different anisotropic levels observed in grey and white matters. Despite the fact that *in vitro* culture is not capable of fully mimicking the dynamic environment of the brain, the system provides a simplified and controlled environment, allowing us to investigate the variation of mechanics and biochemical behaviors in cellular level during the myelin development. We hypothesized that the stiffening effect starts occurring at cellular scale after myelin sheath wrapping around axons, which may further serve as mechanical cues to trigger downstream biochemical behaviors.

METHODS

DRG neurons were isolated following a well-established protocol [4] and either dissociated or directly plated as explants on matrigel coated glass substrates. Neurons were allowed to extend axons for 2-3 weeks in either anisotropic (highly aligned axons in DRG explants) or isotropic (non-aligned axons in dissociated DRG neurons) patterns prior to their use in myelinating co-culture experiments. Primary oligodendrocyte progenitor cells (OPC) were purified from mixed glial cultures of postnatal day 1 rat cerebral cortices using immunopanning [4, 5]. Freshly purified OPC (Ran2-, A2B5+) were seeded directly onto DRG neurons for co-cultures (50,000-100,000 cells). OPC alone cultures were maintained in Sato media with 10 ng/ml PDGF and 10 ng/ml bFGF for proliferation, or induced to differentiate into mature oligodendrocytes (OL) in Sato containing T3 (30 ng/ml) for 1-3 days. All animal work was with IACUC regulations and under approved animal protocols.

Myelination was induced by changing DRG-OL co-cultures to MEM media containing 10% FBS, 2 mM L- glutamine, and 4 mg/mL glucose. Cultures were fixed at different time points (3, 7, 14 and 21 days) and confocal microscopy was used to check for the extent of myelination using antibodies to myelin basic protein (MBP), in combination with Olig2 (oligodendrocyte) and NF (neurofilament).

For mechanical characterization, atomic force microscopy (AFM, Bruker BioScan Resolve coupled with an Olympus fluorescent microscope) Peakforce measurement was performed on different tissue cultures at the microscale, coupled with live cell imaging using SiR-Tubulin, Sir-Actin (Cytoskeleton) and FluromyelinTM (Invitrogen) to enable visualization of the cellular structures and myelination level. Bruker PFQNM-LC-CAL pre-calibrated probe was used with spring constant k~0.08 N/m and tip radius R~70 nm in order to reveal microstructure of neurons. Axons moduli were measured at different time points (3, 7, 14 and 21 days) to investigate its variation during the myelination process. Furthermore, we probed into the differences of microstructure and cellular components, performing Peakforce scanning along the axon with and without myelination. Finally, we aimed to build a relationship between axonal myelination, mechanics and fiber orientation, where fiber alignment and myelination level were quantified by ImageJ.

RESULTS

The DRG-OL co-culture system showing the myelination progression with time, as shown in Figure 1. OL started to extend

myelin sheath and wrapped around axons at day 3, and clear myelinated axons were observed by day 7. Local variation of myelination stages originated from the same OL of making myelin in several axons were observed on day 3: non-myelinated axon (white arrow), thin myelin (yellow), and thin MBP+ projections with granulated-like structure (magenta). The amount of myelination, represented by MBP expression, increased significantly from week 1 up to week 3.

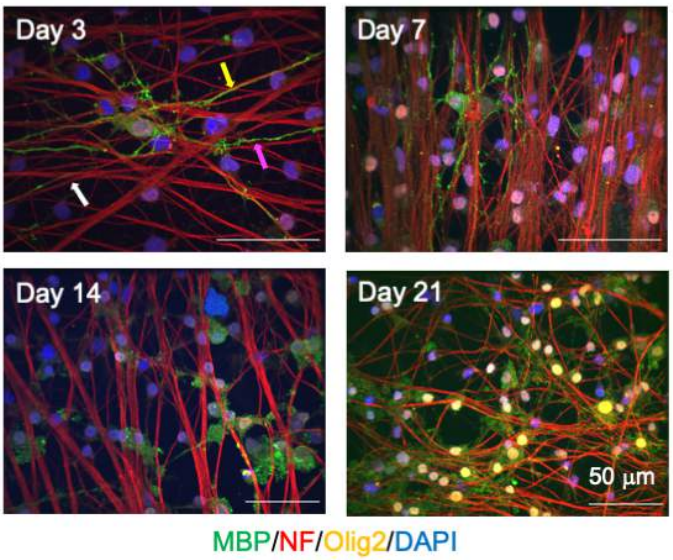

Figure 1: Confocal images of DRG-OL explants co-culture at different time points. Representative images showing increasing MBP expression over time, indicating myelin formation. (Green: myelin basic protein (MBP). Red: neurofilament (NF). Yellow: Olig2. Blue: DAPI)

In order to investigate whether DRG neurons were stiffened during the myelin development, AFM Peakforce measurements were mapping on individual axons to obtain force curves at nanoscale. 3 selected axons were measured at day 14 and 21, respectively, as shown in Figure 2. Increasing modulus were observed from day 14 (mean = 3.4±1.8 kPa, $p<0.0001$) to day 21 (mean = 6.8±2.8 kPa), indicating the axonal stiffening correlates with myelin progression over time.

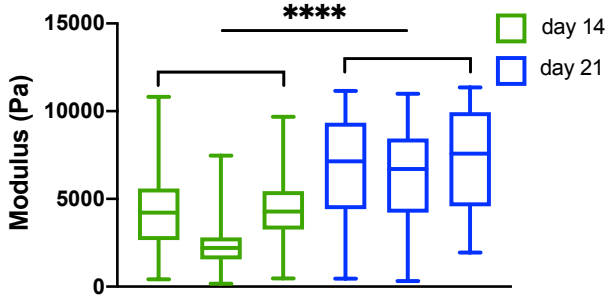

Figure 2: AFM Peakforce mapping on 3 selected axons in DRG-OL explants co-culture at day 14 and 21, respectively. After determination of the contact point, an Ogden fit was applied to the force curve to obtain Young's modulus E. 500 force curves from each axon mapping were used for analysis.

However, myelination was not homogeneous throughout the whole culture up to day 21. Therefore, we probed into a single axon, comparing the modulus on myelinated and un-myelinated segments, respectively, as shown in Figure 3. We found that at an early, pre-myelinating stage (day 3 in culture), when fine MBP+ OL processes begin to align and extend along axons, local heterogeneity of the modulus was already observed between pre-myelinated and un-myelinated axon segments. The pre-myelinated area showing significantly higher modulus (1.83±0.87 kPa, $p<0.01$) compared to the area without myelin sheath wrapped (MBP-, 1.64±0.60 kPa).

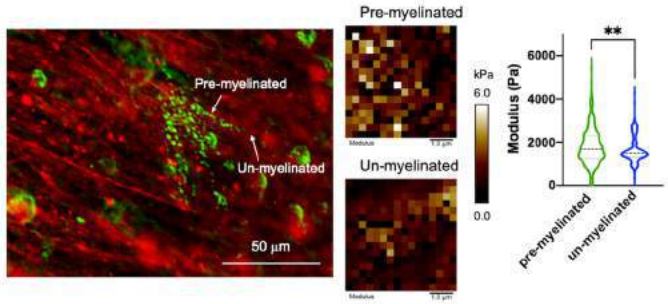

Figure 3: AFM Peakforce mapping on pre-myelinated and un-myelinated axons, respectively, in DRG-OL explants co-culture at day 3. Higher modulus was observed on pre-myelinated area along the axon. 250 force curves from each mapping area were used for analysis. (Green: MBP. Red: NF. Yellow: Olig2.)

DISCUSSION

In this work, an *in vitro* DRG-OL co-culture system was developed to study myelin progression, mimicking the pediatric brain development. Different culturing methods – explants or dissociated DRG, providing various axonal anisotropy models, which represents the variations observed in grey and white matters. We hypothesized that the microstructure of tissue will cause mechanical differences in elasticity and viscoelastic relaxation, and also affect myelin progression. Therefore, quantifications of myelination and fiber alignment will be analyzed, along with mechanical measurements, where we hope further experiments would demonstrate a relationship between these three properties.

AFM results of axonal modulus in the explant co-culture, along with confocal images showing increasing myelination over time, confirming our hypothesis that DRG neuron tissue stiffened during the myelination process existed at cellular level. The increasing moduli of axons were observed over time, however, local heterogeneity of myelination and moduli along axons persisted during myelin development. We find the stiffening effect correlated with myelination at cellular scale which showed heterogeneity along the axon, even though day 3 might be at early pre-myelinating stage. The spatial and temporal mechanical variation during myelination existed in cellular scale which could be revealed by an *in vitro* co-culture model. Furthermore, due to the mechanosensitivity of neurons and oligodendrocytes [6, 7], local stiffening of axons causing from myelination may trigger certain biochemical behaviors, which could be explored in further studies.

INTRODUCTION

Musculoskeletal soft tissues in joints, including ligament, tendon, and meniscus, are frequently torn, leading to pain, joint instability, and increased risk of osteoarthritis. Tissue tears are most commonly associated with single high-magnitude loading events, known as static failures; but tears may also develop from repeated exposure to low-magnitude loads, known as fatigue failures [1]. The risk of fatigue failures in conventional materials (e.g. polymers, composites) has been greatly reduced by the development of failure models that accurately predict fatigue damage, yet comparable fatigue models currently do not exist for soft fibrous tissues.

Fatigue damage can be mathematically described and predicted through constitutive models. Constitutive frameworks that have had success in simulating the damage processes of soft biological tissue include continuum damage mechanics (CDM) [2,3], pseudoelasticity [4], and elasto-viscoplasticity [5] where most of these models have been validated with experiments that use displacement control loading. A loading condition that is more physiological to fatigue injury is repeated application of a targeted stress (force-control), which results in three characteristic stages of cyclic creep (stages I, II, III). However, to our knowledge, no study has modeled force-control fatigue data in any soft tissue. Moreover, no study has used the same constitutive model to simulate both fatigue and static failures in soft tissues.

A novel and elegant solution for modeling cyclic creep behavior in soft tissue may be possible using discontinuous CDM with viscoelasticity. Previous work has determined that discontinuous CDM with strain energy-based failure criteria can model static failure in soft tissue [6] but has intrinsic limitations in modeling steady state creep since damage evolution is restricted under a constant load. Conversely, viscoelastic models can represent steady state creep [7], but not damage propagation to rupture. We hypothesize that by pairing a discontinuous CDM model with a viscoelastic model, damage will evolve in response to viscoelastic creep during fatigue loading.

The objective of this study is to determine the feasibility of using a viscodamage model to simulate high-cycle tensile loading in human meniscus. A validation study was performed to determine if the viscodamage model is also predictive of static failure.

METHODS

This study combined experimental and computational methods.

Fatigue experiment: Prior to fatigue testing, quasi-static uniaxial tensile tests to failure were performed on 8 dumbbell shaped meniscus specimens from 5 human knees to generate a correlation between tangent modulus and ultimate tensile strength (UTS). This allowed for the non-destructive prediction of UTS from modulus data. Tensile fatigue tests were then performed on eight dumbbell shaped specimens from the same set of human menisci used for UTS tests. Force-control loading was applied at 30% (n=3), 50% (n=3), and 70% (n=2) of UTS using the tangent modulus from the last cycle of a 20-cycle triangular waveform to 8% strain. A 4 Hz tensile-tensile sinusoidal waveform was applied to the targeted stress [8] until failure or one-million cycles was reached. All specimens were tested in a 0.9% saline tank at 37 C, and no failures occurred at or near the grips.

Constitutive Model Comparison: Three constitutive models were investigated: viscodamage, visco-only, and damage-only. The cyclic creep curves from the fatigue experiments were used to calibrate the material parameters for each model and NRMSE calculations were used to determine the efficacy of each model.

Viscodamage Model: The viscodamage model used a convolution integral and discontinuous, CDM formulation, where 2nd PK stress **S** was modulated by a damage variable *D* that ranged from zero to one, with one representing complete rupture (Eq. 1). A viscoelastic

relaxation function G was comprised of six material parameters that regulated material relaxation at time t, accounting for all prior times s [9]. An energy-based Weibull cumulative distribution function (CDF) was used for the damage evolution model where damage D is a function of the Simo damage criteria and the Neo-Hookean strain energy density.

$$\mathbf{S}(t) = \int_0^t G(t-s)(1-D(t))\frac{\mathrm{d}\mathbf{S}^e}{\mathrm{d}s}\mathrm{d}s \qquad (1)$$

Visco-only Model: A viscoelastic model, with no damage, was created by setting the CDF parameters in Eq. 1 to high values, effectively making damage 0 for all stretches used in this study.

Damage-only Model: A damage model, with no viscoelasticity, was created by setting all six viscoelastic parameters of the relaxation function in Eq. 1 to 0, effectively eliminating the viscoelastic response.

Curve Fitting Using a Single Element Model: To overcome the inherit limitations of FE solvers when modeling force-controlled damage, a three-dimensional single element material model was developed in MATLAB (Fig. 1A). This custom optimization program consisted of two nested loops. The inner loop used the Levenberg-

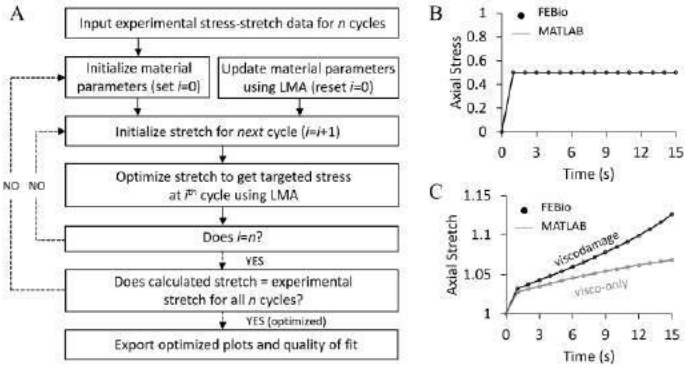

Fig. 1: Force-control single element simulation. A) The MATLAB logic was verified by comparing A) input and B) output to FEBio.

Marquardt algorithm (LMA) to calculate axial and lateral stretches at each time point for a targeted loading profile (force-control) while the outer loop applied LMA to the entire stretch-time profile to optimize the fit of specimen specific material parameters.

Verification and Validation: For verification, axial stretches calculated with our MATLAB program and the finite element (FE) solver FEBio [9] where compared using the same viscodamage model and parameter values (Fig. 1B-C). For validation, the viscodamage material parameters that were curvefit to the fatigue data were used to produce quasi-static pull to failure curves, which were compared to the mean quasi-static tensile results from the same set of five knees.

RESULTS

In general, the viscodamage model resulted in excellent fits for all three stages of fatigue for all experiments (Fig. 2). In comparison, the damage-only model was unable to simulate steady-state creep behavior (stage II), and the visco-only model was unable to simulate failure propagation (stage III). On average, the resulting NRMSE values for stretch at all fatigue stages were 0.22%, 0.45%, and 2.03% for the viscodamage, visco-only, and damage-only models, respectively. The NRMSE values for all creep stages were significantly less for both the viscodamage and visco-only models than the damage-only model ($p=0.004$, $p=0.009$), respectively. When examining each stage of fatigue separately, compared to the visco-only model, the viscodamage model had less than half the NRMSE in stage II and III, but this difference was not significant ($p=0.09$, $p=0.25$, respectively).

The predicted pull to failure results using a viscodamage model resulted in characteristic stress-strain curves when using parameters fit to fatigue tests run at 50% and 70% of UTS (Fig. 3; red and blue lines). For these five tests, the average predicted UTS was 13.6±9.2 MPa, compared to the 14.9±9.9 MPa experimental results; and the average predicted failure stretch was 1.31±0.06, compared to the 1.19±0.04 experimental results. Material parameters used to fit fatigue tests run to 30% were poor predictors of pull to failure experiments (Fig. 3; black lines).

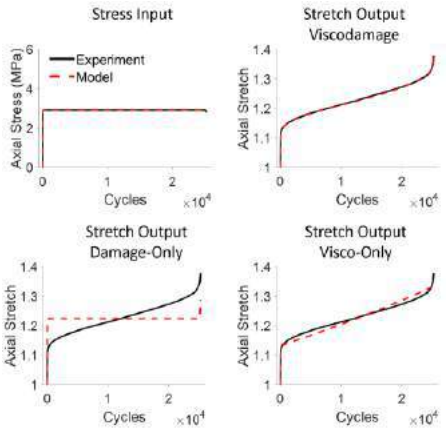

Fig. 2: Model fits to a fatigue experiment. The viscodamage model had the best fit.

DISCUSSION

This study demonstrates for the first time the feasibility of using a viscodamage model to simulate the cyclic creep of soft fibrous tissue during force-control fatigue loading. These results support our hypothesis and highlight the importance of pairing both viscoelasticity and damage formulations when modeling fatigue behavior. This suggests that fatigue injuries in meniscus, ligament and tendon are linked to the intrinsic viscoelasticity of these tissues.

The viscodamage model also reasonably predicted modulus and UTS values from quasi-static pull to failure experiments using parameters fit to fatigue tests, except when using parameters fit to fatigue tests with low stress input (Fig. 3; 30%). To our knowledge, this is the first study to have success simulating both fatigue and static failure with the same model, which could have major implication in future computational studies of musculoskeletal injury mechanisms.

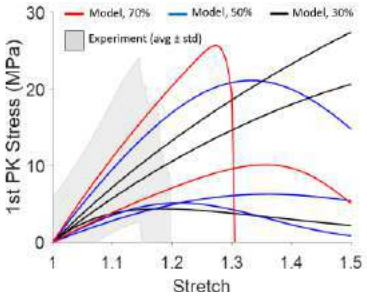

Fig. 3: Prediction of static failure using viscodamage model with parameters fit to fatigue tests.

For this study, a custom MATLAB code was developed to overcome limitations of FE solvers related to parameter optimization in force-control. This code logic (Fig. 1A) could be implemented with a FE solver to examine problems with more complex geometries.

INTRODUCTION

Three of the rotator cuff muscles, the supraspinatus, infraspinatus, and teres minor insert on the greater tuberosity of the humerus. Specifically, the greater tuberosity is morphologically comprised of three distinct flat surfaces termed the superior, middle, and inferior facets[1,2] (Figure 1). The supraspinatus inserts on the superior facet and superior half of the middle facet, the infraspinatus on the entire middle facet, and the teres minor on the entire inferior facet[1]. It has been shown that each facet can be easily identified in cadavers that did not exhibit any glenohumeral joint pathology[3]. However, it is unclear if there are boney morphologic changes of the facets in subjects with symptomatic isolated supraspinatus tendon tears.

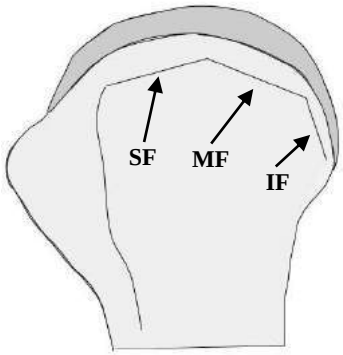

Figure 1: Normal anatomy of the greater tuberosity facets (SF, Superior Facet; MF, Middle Facet; IF, Inferior Facet). Adapted from White E.A. et al., *Emergency Radiology*, 2018.

In the presence of a tear, force is no longer being applied at the insertion cite through the tendon where the tear is located, and in the case of impingement, there may be bone on bone contact. Both mechanisms may lead to boney morphological changes due to resorption or mechanical impact. If the boney morphology of the facets has changed, it may be difficult for surgeons to properly anchor the repaired tendon in the correct location due to the altered anatomy. Therefore, the objectives of the study were: 1) To determine if the superior, middle, and inferior facets are present in-vivo in subjects with symptomatic isolated supraspinatus tendon tears, 2) Determine the association between tear location and presence of the superior, middle, and inferior facet.

METHODS

Forty subjects (mean age 61.1 ± 9.0 years, mean BMI 27.1 ± 4.5, 18 males and 22 females) with a symptomatic rotator cuff tear isolated to the supraspinatus tendon were recruited for the study and provided IRB-approved written informed consent prior to all research procedures. Main exclusion criteria included asymptomatic tears, previous shoulder injury, or presence of severe capsule tightness. Each subject underwent computed tomography (CT, slice thickness of 0.625mm) of the affected shoulder and the images were segmented to create a 3-dimensional (3D) subject specific surface model of the humerus using Mimics 20 software package. The humeri models were then imported into MATLAB, and vertices comprising each facet were identified using the naming convention of a previous study[2]. If a single vertex comprising the facet was missing, the facet was considered unidentifiable.

Ultrasound was used to quantify tear location within the supraspinatus tendon. Assessments utilized a 6-15 MHz linear array transducer and was measured by a musculoskeletal radiologist. Subjects were seated with the glenohumeral joint in extension, and the involved

side hand on the iliac wing to expose the supraspinatus tendon. The transducer was positioned transversely to the supraspinatus tendon, and a short-axis image was acquired. Tear location was quantified as the distance from the posterior edge of the long head of the biceps tendon to the most anterior edge of the tear.

Percentages were calculated for the number of subjects in which each facet could be identified. Furthermore, a Point-Biserial Correlation was used to determine the association between tear location and presence of the superior, middle, and inferior facets. Significance was set at $p < 0.05$.

RESULTS

All variables were successfully collected in 37 subjects (three subjects ultrasound images were not measurable). There were no associations between tear location and presence of the superior, middle, or inferior facet ($p > 0.05$, Table 1). Overall, the superior, middle, and inferior facet were identifiable in 22.5%, 30.0%, and 50% of subjects, respectively. Seventy percent of subjects had tear locations immediately posterior to the biceps tendon and tear location ranged from 0.0mm to 19.0mm.

Qualitatively, rounding of the greater tuberosity was observed in 59.5% of subjects (Figure 2). Five subjects showed rounding of the entire tuberosity and nine subjects showed rounding of the transition between the superior and middle facets. The remaining observations occurred at individual facets (3 superior, 2 middle, 3 inferior).

Table 1: Associations between tear location and presence of the superior, middle, and inferior facets.

Facet	Tear Location	
	r	p
Superior	-0.06	> 0.05
Middle	-0.09	> 0.05
Inferior	-0.14	> 0.05

Figure 2: Lateral view of a subject specific humerus with a "rounded" greater tuberosity. The highlighted region demonstrates the inability to directly identify the distinct facets compared to a "healthy" example shown in Figure 1.

DISCUSSION

Our data demonstrates that symptomatic isolated supraspinatus tendon tears significantly impact the boney morphology of the superior, middle, and inferior facets of the greater tuberosity without respect to the tear location. The inability to identify each facet in the majority of subjects is indicative of changes in boney morphology that are likely due to reductions in force applied to the bone due to the tear. Furthermore, this study demonstrates that even in the presence of relatively small rotator cuff tears, there are also alterations in the middle and inferior facets as well. Inability to identify the superior facet in 77.5% of subjects is important information for orthopaedic surgeons as it may influence the effectiveness of surgical repair of the torn tendon. Changes in the boney morphology of the facet may result in incorrect placement of the bone screw used to reattach the torn tendon since they are not observing the normal anatomy.

A previous study investigating the orientation and inclination of the rotator cuff footprint was able to identify the superior, middle, and inferior facets in all 28 "healthy" cadaveric humeri studied[3]. Average age of the cadavers was 78.0 ± 12.9 years. Therefore, even though subjects in the present study were younger, the presence of a relatively small rotator cuff tear results in significant boney morphological changes. Additionally, a study in cadavers has shown that there is overlap between the tendinous junctions of the supraspinatus and infraspinatus on the middle facet[1]. This overlap is likely why changes were observed throughout the facets due to the rotator cuffs inherent mechanical interactions.

The majority of subjects had tear locations immediately posterior to the biceps tendon and reflects what is most commonly seen clinically, resulting in translational conclusions to the clinic. Therefore, we were able to show that small rotator cuff tears isolated to the supraspinatus tendon result in significant changes to the greater tuberosity's boney morphology. This information is useful for orthopaedic surgeons as it may impact decision making when placing anchors during arthroscopic rotator cuff repair due to altered anatomy.

PROTEIN SPREADING PATTERNS IN ALZHEIMER'S DISEASE: EXPLORING THE DIFFERENCE BETWEEN A CONNECTIVITY-BASED AND PROXIMITY-BASED CONNECTOME MODEL

Shima Jalalian (1), Johannes Weickenmeier (1)

INTRODUCTION

Alzheimer's disease (AD) is the most prevalent form of dementia and is a significant health burden on our aging society. There are two primary proteins associated with disease progression in AD: amyloid-beta (Aß) and tau [1]. It has been hypothesized that these two proteins spread in a prion-like manner where toxic, misfolded proteins recruit proximal healthy proteins to turn toxic as well [2].

There is growing evidence from postmortem and PET imaging studies that neurotoxic Aß-plaques and tau tangles spread through the brain in a characteristic progression pattern [2]. Strikingly, there seem to be two competing mechanisms, however, by which plaques and tangles spread: PET [3] and in vivo mouse studies [4] have shown that neurofibrillary tangles spread along axonal pathways, i.e., intracellular transport, while Aß-plaques appear to spread by proximity, i.e., diffusion through surrounding tissue [5]. Several computational progression models have been proposed thus far. Typically, protein spread is modeled as a (reaction-)diffusion equation that is solved on either an anatomically accurate brain finite element model [6] or a graph theory-based discrete connectome model [7].

In the present work, we use the connectome data provided by the Budapest Reference Connectome (BRC) [8] to construct two models, a connectivity model, and a proximity model, in order to systematically study the effect on protein spreading behavior.

METHODS

We pose that the prion-like protein spread of Aß-plaques and tau tangles is best described by the Fisher-Kolmogorov reaction-diffusion equation, where toxic protein concentration, or also referred to as biomarker concentration, c, is governed by the following equation:

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} + \alpha c[1-c]. \qquad (1)$$

Parameter D controls diffusivity of the biomarker, and parameter α characterizes the growth rate, i.e., the conversion rate of healthy into toxic protein. We discretize equation (1) on two graphs G^{con} and G^{dist}. Introducing nodal biomarker levels c_I, we obtain protein spread as:

$$\frac{dc_I}{dt} = \mathrm{k}\sum_{J=1}^{N} L_{IJ}c_J + \alpha c_I[1-c_I], \qquad (2)$$

where k controls the diffusion between two nodes. Using connectome data from 100 BRC subjects, we construct two different weighted Laplacians, L_{IJ}^{con} and L_{IJ}^{dist}. The Laplacian is the difference between the degree matrix, D_{IJ}, and the adjacency matrix, A_{IJ}, as follows:

$$L_{IJ} = D_{IJ} - A_{IJ} \text{ with } D_{IJ} = \mathrm{diag}\sum_{J=1,I\neq J}^{N} A_{IJ}. \qquad (3)$$

The connectivity graph is based on the adjacency matrix A_{IJ}^{con} that incorporates the number of fibers, n_{IJ}, and mean fiber length between two nodes, l_{IJ}. The proximity graph is based on the adjacency matrix A_{IJ}^{dist} that is constructed from the inverse Euclidian distance between two neighboring nodes. That is:

$$A_{IJ}^{con} = \frac{n_{IJ}}{l_{IJ}} \; and \; A_{IJ}^{dist} = \frac{1}{\sqrt{(x_I - x_J)^2 + (y_I - y_J)^2 + (z_I - z_J)^2}}, \qquad (4)$$

where $\{x_I, y_I, z_I\}$ are the coordinates of node I.

RESULTS

Figure 1 shows the normalized adjacency matrix for the proximity and connectivity graph, respectively. It can be seen that there are more connections in the connectivity-based connectome than in the proximity connectome, indicative of a more complex structural network.

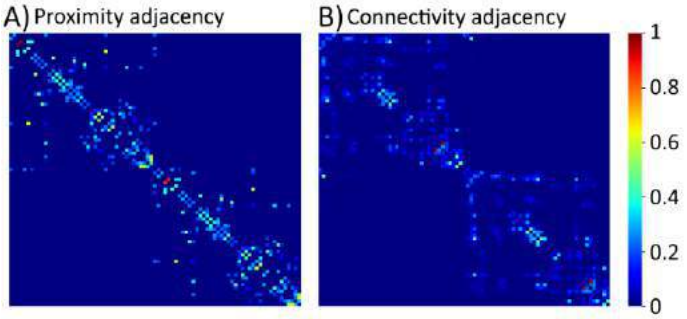

Figure 1 Normalized adjacency matrix for the A) proximity-based and B) connectivity-based graphs

Figure 2 shows the spatial distribution of biomarker concentration for six time points determined via the connectivity and proximity graphs. In both models, proteins originate from the seeding location in the entorhinal cortex and spread throughout the brain. On the one hand, the connectivity-based simulation shows that biomarker concentration appears in dispersed locations in the parietal and frontal lobe as AD progresses; the proximity-based simulation, on the other hand, demonstrates a characteristic diffusive pattern where the biomarker gradually spreads through the brain, reaching the occipital lobe first, then the parietal lobe, and ultimately reaching the frontal lobe.

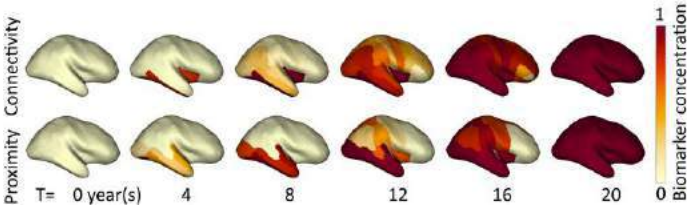

Figure 2: Spatial distribution of the biomarker concentration based on connectivity and proximity at multiple time points.

Figure 3 shows the temporal evolution of biomarker concentration in five specific nodes, i.e., brain regions, that are linked to hallmark symptoms in AD. Based on our model, hippocampus and amygdala, both associated with short term memory loss, are affected first, followed by the posterior cingulate and pars triangularis, which are linked to behavioral changes and speech impediments [9], respectively, and lastly, the frontal pole which contributes to emotional regulations [10].

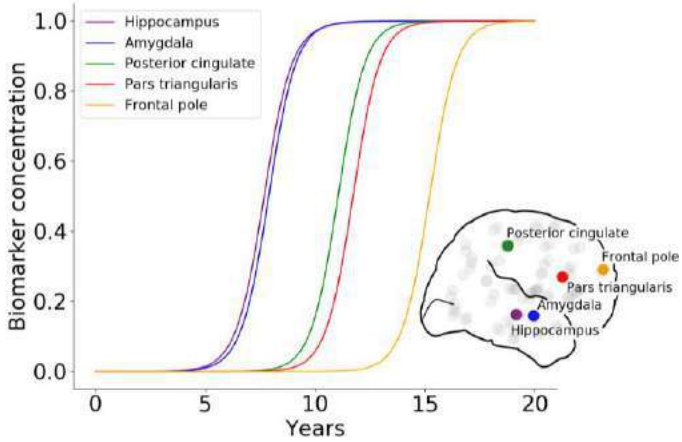

Figure 3: Biomarker concentrations in five nodes associated with hallmark symptoms of AD. The temporal pattern is consistent with the onset of symptoms such as memory loss, behavioral changes, and ultimately loss of speech and motor control.

DISCUSSION

In this work, we built a physics-driven diffusion model to observe protein progression patterns in AD. We specifically aim at exploring the difference between proximity-based and connectivity-based spreading along the brain's connectome network.

Figure 4 shows the dependence biomarker concentration on model parameters D, α, and initial seeding concentration c_0. Higher diffusivity leads to faster spreading; higher growth factor causes more rapid production of toxic proteins and higher initial concentration, c_0, accelerates infection time across the network. These parameters may be treated as patient-specific indicators for disease severity, and the variation in AD progression observed in clinical practice.

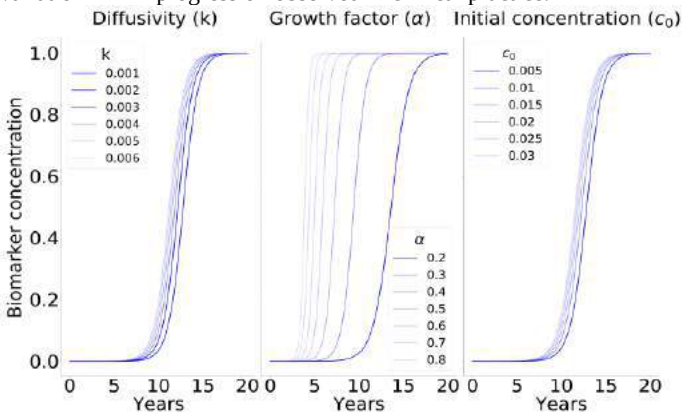

Figure 4: Biomarker concentration in the amygdala as a function of critical model parameters in Equation (2).

The well-established Braak stages of AD indicate that toxic tau is first found in the entorhinal cortex and then appears in the hippocampus and amygdala. From there, it spreads out into the structurally connected inferior regions of the temporal and occipital lobe and the pre- and post-central gyrus. Our connection-based tau model, derived from structural connectome data, replicates this pattern very well, as shown in Figure 2. The results from our proximity graph demonstrate remarkable agreement with the spreading patterns observed for Aß-plaques that are characterized by a homogeneous increase in Aß-concentration across the entire brain [2]. As a next step, we will investigate spatiotemporal correlations with structural brain shape changes associated with AD, including cerebral atrophy and cortical thinning.

In summary, our work supports the notion that Aß and tau follow distinctly different progression patterns. Although it has been shown that tau is a strong biomarker for AD severity, we lack a proper understanding of the coupling between Aß and tau to rationalize the variation in clinically observed AD progression patterns.

INTRODUCTION

A significant challenge faced by 3D bioprinting technology is to develop a way to supply cells with nutrients and drain their waste products simultaneously [1]. It requires vascularization of bio-printed tissue constructs embedded with blood vessels [2]. Until now, most methods didn't involve any regulated exchange of metabolites - instead, they relied on the simple diffusion process that occurs spontaneously in a cell culture medium. 3D bio-printer based bioreactor acts as a robotic device, which can print any tissue, organs, and blood vessels layer by layer according to the respective CAD model [3]. After printing, the entire bio-printed structure is cultured within a bioreactor. However, this approach of regeneration of organ/tissue is not similar to the natural process for the same phenomena under in vivo conditions [4]. The purpose of the proposed model is to match in vivo and in vitro conditions of blood vessel formation and provide precise control on all the parameters during printing, such as the thickness of blood vessels, media transportation, shear stress, etc. The model development involves the following steps:

❑ Designing of a functional bioprinter for replicating the actual micro-environment for human tissue and organs.

❑ Identification of certain cell-types and extracellular matrix (ECM) components for 3D bio-printing.

❑ Designing of artificial blood vessels by 3D bio-printer.

METHODS

The system uses an extrusion-based co-axial 3D bio-printer, and the printed layer is cultured by a modified rotatory bioreactor (Figure 1). A co-axial nozzle is used to make printing on the printing bed, and it will be located inside a closed chamber housing. The temperature of housing is maintained at 36°C to 40°C. Cellular media (media + CO_2 + O_2) will be fed to the reservoir for cell culture of the printed layer. Regulatory control of each component like media pressure, temperature, valve, pH and CO_2 and N_2 delivery, etc., are managed by a Programmable Logic Controller (PLC). Simulation of the electronic circuit is conducted by LabView Software. A decision-based logic circuit is used to improve the utilization factor of media. $CaCl_2$ is used as a chemical cross-linker during printing using GelMA as a bioink. The corresponding CFD analysis of flow segments of media within the system drainage section is evaluated using ANSYS. Induction of media to the housing is made using a pulsatile pump. It creates pulsatile hydrostatic pressure to the printed bioink. The flow of media is controlled by passing it through the rotating tube, which consists of an array of pores on the lateral wall of the inner concentric cylinder of the housing. The drained-out media from the housing is checked for conductivity. Based on the result of conductivity of the outlet media, PLC operates the valve to direct the flow into a waste reservoir or media reservoir. Some parts of the internal fluid of the printed layer are collected within a microfluidic chamber for real-time analysis of biochemical properties of the media. A pressure sensor, temperature sensor, flow sensor, pH sensor, and dissolved oxygen measurement sensor will be used to sense and regulate all respective variable values using PLC.

RESULTS

The simulation result performed using PLC and LabVIEW indicates that all the logic and circuits are working properly. A signal conditional circuit is used for pH control, waste product, rotational speed control, media stem rod, co-axial nozzle temperature, and pressure. The results show that the proposed algorithm/logic maintains the variable values at the desired range. In our model, shear stress near the wall of the cylindrical hollow housing where bioprinting materials are getting stacked up is altered by three variables - pressure, velocity (v), and strain rate (y). The influence of pressure on shear stress is evaluated by altering one variable while other variables are kept constant. Figure 2

represents the relationship between shear stress and pressure at different points. First, shear stress is calculated for different values of pressure under constant velocity while varying strain rates. It can be concluded that the shear stress is constant for the entire range of applied pressure.

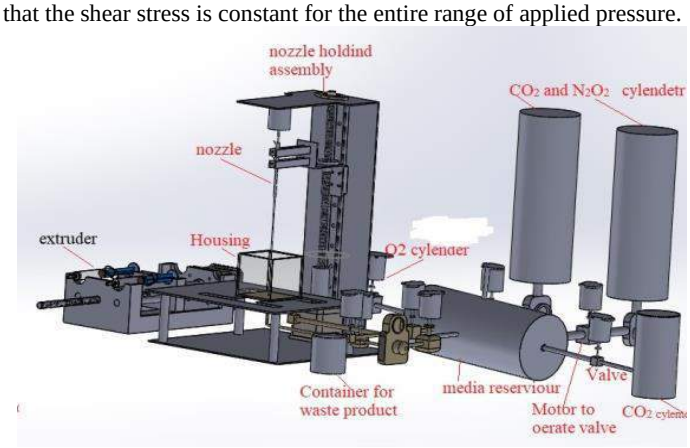

Figure 1: Implemented 3D model of integrated system.

The strain rate variation produces a small change in shear stress for different pressures. Thereafter, shear stress is calculated for different values of pressure under constant strain rate but varying velocity. A linear relationship between the shear stress and pressure for different velocity is observed.

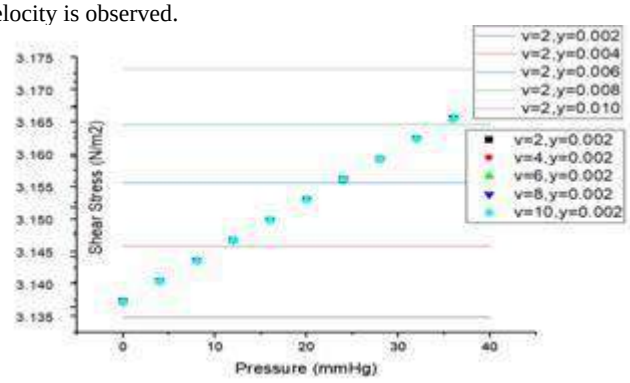

Figure 2: Relationship between shear stress and pressure under constant velocity (all horizontal lines) and constant strain rate (dotted line).

Effective implementation of simulator programming code in hardware has been confirmed by uncertainty analysis. Uncertainty analysis of shear stress and pores height has been performed. The uncertainty of pore height is 7.60 x 10-4 m (minimum). Similarly, the uncertainty of stress was found to be 179.36501 N/m^2. Real-time shear stress generated on the printed structure is also derived. CFD analysis has been performed on the proposed model having three segments: (1) mixing of media, O_2, and CO_2 inside a reservoir; (2) transportation of media from the reservoir to housing; and (3) microfluidic chamber. The velocity profile of module 3 (containing the drained fluid on a microfluidic platform for conductivity evaluation) is shown in Figure 3. Flow path lines inside the micro-channel of the chip represent the velocity vector, as determined by ANSYS. It is observed that the region of the mixture provides better homogeneity of the velocity field.

Figure 4 shows the CAD model and printed geometry of a network of channels simulating blood vessels embedded in GelMA ECM. The channel walls are embedded with Human Umbilical Vein Endothelial cells (HUVECs). Live-Dead Assay will be performed over 14 days to ascertain the cell viability maintained in the bioreactor.

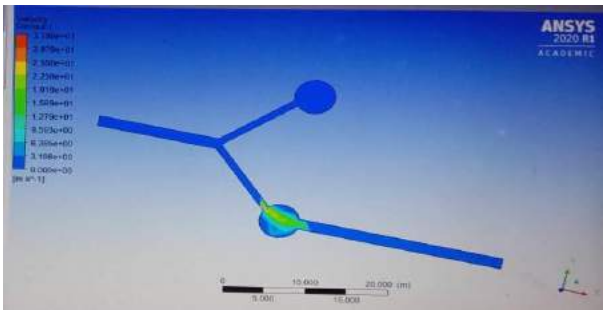

Figure 3: Velocity profile inside the micro channel of microfluidic chip

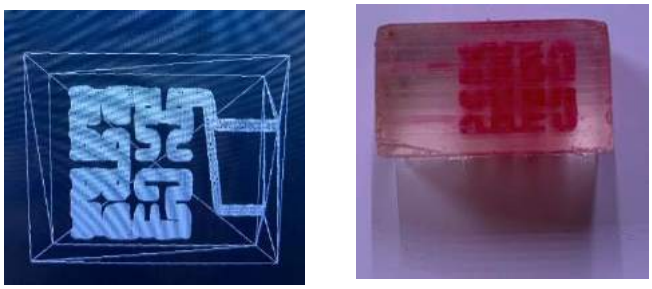

Figure 4: Sample bioprinted tissue construct using GelMA constructs and embedded channels seeded with HUVECs.

DISCUSSION

A unique 3D bio-printing system using a rotary forming device has been developed to fabricate vessel-like structures that will provide precise control over-proliferation of cells within the tubular scaffold. In vivo environmental conditions are mimicked to follow blood vessel generation. The novel concept of conductivity circuit used in our model enhances the utilization of the media. This advanced version of the rotatory bioreactor overcomes the limitations of scaffold size. This model provides a better environment for extrusion based coaxial nozzle printed structure along with rotatory bioreactor for maintaining vascularization in bioprinted constructs.

INTRODUCTION

Soft tissue degeneration such as osteoarthritis (OA) is a severe medical and socioeconomic burden afflicting more than 10% of adults over 60 worldwide [1]. The pathogenesis of cartilage degeneration is largely unknown, as is the impact of daily activities such as walking. Currently, OA can only be detected in the late stage using techniques like radiography. To probe early OA pathogenesis, MR-based imaging methods have been advanced to investigate the structure-function relationship of soft joint tissues such as cartilage. We previously used displacement encoding with stimulated echoes (DENSE) MRI to calculate heterogenous cartilage displacement and strain during cyclic compressive load [2]. In an effort to accelerate image acquisitions suitable for human imaging *in vivo*, we explore the use of spiral acquisitions on DENSE MRI [3] and collect images with a 40 ms temporal resolution on a bovine joint. We also adapt compressed sensing (CS) on low signal-to-noise ratio (SNR) images. We find spiral *k*-space trajectory allows high temporal resolution images and CS reduces imaging time to approximately 2 minutes while having similar magnitude and phase data with high SNR images which takes 7 minutes to acquire.

METHODS

Specimen Preparation: For a proof-of-concept demonstration, a single bovine joint (1-month-old) was obtained from an abattoir. The joint was prepared and mounted by securing both the tibia and femur to a sample holder using bone cement. The sample was placed in a pneumatic loading device (Figure 1A) ready for imaging within a clinical MRI system (3T; Siemens Prisma^{fit}).

Spiral DENSE MRI with Exogenous Cyclic Loading: To mimic gait, the joint underwent cyclic loading (400 N for 1 second, within a 2 second cycle) along the superior-inferior axis. Two spiral interleaves were timed to loading using triggering to allow for cine image acquisition [3], with a total of 22 images (frames) collected within the loading time frame. Each image frame was equivalent to 40 ms. Echo time (TE) and relaxation time (TR) were 2.5 and 20 ms, respectively. The spiral sequence completed when all 22 images had total ten interleaves each. Images were averaged one, four, and eight times to control the SNR. Image acquisition parameters were: field of view = 125×125 mm^2, matrix = 350×350 pixels^2, slice thickness = 1.7 mm, displacement encoding gradient = 1.28 cycles/mm. Prior to spiral DENSE MRI acquisition, the loading cycle was applied for 15 minutes to achieve a quasi-steady state response, and high SNR double echo steady state (DESS) images were collected for segmentation and to confirm that joint tissues were responding to load.

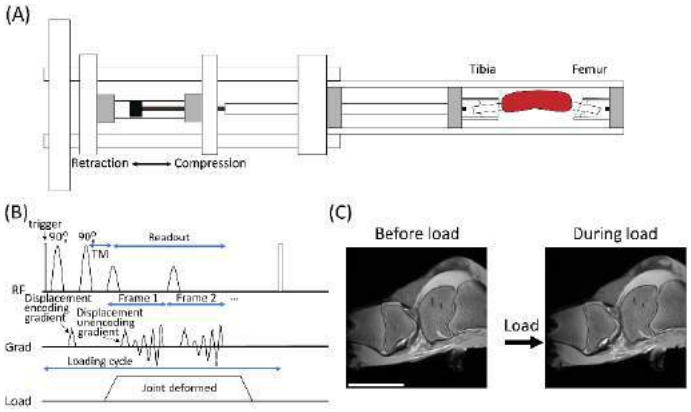

Figure 1: MRI compatible knee loading device for measuring tissue deformation. (A) Pneumatic cyclic loading device with bovine joint placed at the isocenter of a 3T MRI system. (B) Spiral DENSE MRI pulse sequence diagram. DENSE encoding and unencoding gradients are applied before sinusoidal gradients for readout. Three-point phase cycling (θ = 0, 2/3π, 4/3 π) is used to reduce artefacts. (C) Magnitude images of bovine joints obtained of the sagittal plane before and during loading (400 N). Scale bar = 50 mm.

Displacement and strain calculation: Articular cartilage regions of interest (ROIs) were manually segmented using custom software (MATLAB) and binary masks were created to represent the tibial and femoral articular cartilage regions. Displacements for each pixel within the ROIs were determined from phase data as previously described [4]. Displacements were manually phase unwrapped followed by smoothing with a locally weighted scatterplot smoothing (LOWESS) filter and then

the smoothed displacements were used to calculate in-plane Green-Lagrange strains and principal strains.

Compressed Sensing: We used Berkeley Advanced Reconstruction Toolbox [5] PICS command to reconstruct the images where the inputs were the spiral trajectory, channel sensitivity map, and acquired *k*-space data along the interleaves. The regulation parameter was 0.01 and all processes go through five iterations.

RESULTS

Displacement and strain maps were acquired on 22 time-lapse images during loading (Figure 2). A higher number of averages resulted in higher SNR with the cost of longer acquisition time. The acquisition time was two, seven, and fourteen minutes for one averaged (SNR = 1.39), four averaged (SNR = 2.57), and eight averaged (SNR = 4.16) DENSE images, respectively. DENSE images showed heterogeneous patterns of the displacement and strain across cartilage. The 0 to 280 ms time period showed the maximum change of displacement and strain. As seen in previous work, the predominant displacements of the tibial and femoral cartilage regions indicated both compression and shear occurred between the tibia and the femur [2]. Average displacements along the direction compressive load in the femoral cartilage were 0.256 mm. As compressive load is applied, the knee joint bends and moves towards the left which is reflected on the displacement values.

CS enhances the SNR and reduces the number of discontinuous pixels on the displacement map before manual phase unwrapping (Figure 3). Also, the root mean square error (RMSE) of the displacement maps before phase unwrapping with respect to the average 8 images drops substantially after applying CS.

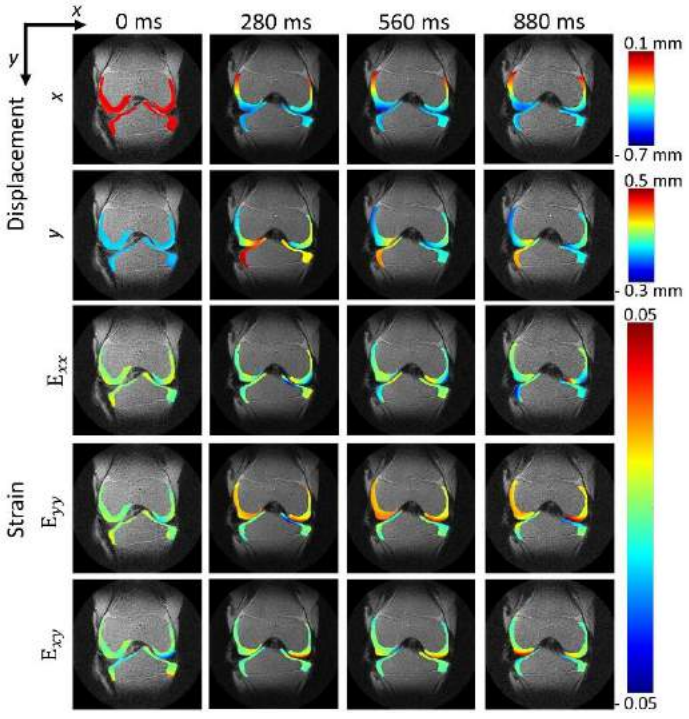

Figure 2: Displacements and strain in tibiofemoral joint cartilage acquired at defined time points within a cyclic loading cycle by displacement-encoded MRI. Spiral acquisition of *k*-space enables rapid and cine collection of image data.

DISCUSSION

Understanding intratissue tissue mechanics under physiologically relevant motion is crucial for OA early detection. In this study we were able to collect DENSE MR images during compressive loading with a temporal resolution of 40 ms by taking advantage of accelerated spiral acquisition and 0.5 Hz cyclic loading of the knee joint. Spiral scanning was able to improve the temporal resolution since high-density *k*-space data are collected in the center of the frequency space, allowing for acquisition of critical displacement-sensitive information. We also verified that CS significantly improves the SNR, while reducing the number of discontinuous displacement pixels and minimizing artefacts. Thus, CS shortens the total acquisition and data processing time without sacrificing data quality. Total acquisition time in this study is significantly shorter than our previous study [2] using single-shot fast spin echo which takes over 30 minutes. Our acquisition scheme is not exclusive, and can additionally be combined with other useful analyses (e.g. relaxometry).

INTRODUCTION

Aortic aneurysm is the most common cause of death amongst conditions requiring emergency surgery in high-income countries [1]. Many patients suffering from ascending thoracic aortic aneurysm (ATAA) remain asymptomatic until sudden acute rupture or dissection, which carry a mortality rate of 50% within the first 48 hours. There is an unmet clinical need in the management of ATAA due to a lack of understanding of the mechanisms leading to growth and dissection. Currently, risk stratification relies on size criteria. Intervention is recommended in patients who have a maximal aortic diameter ≥55mm, with lower thresholds for those with bicuspid aortic valves or connective tissue disease. This is clearly inadequate as the incidence of dissection in ATAA below the size threshold is being increasingly reported, with up to 60% occurring below 55mm [2].

The degradation of extracellular matrix (ECM) structures in ATAA is well reported and several studies have linked abnormal wall shear stress (WSS) to disruption of the aortic wall microarchitecture [3], but detailed flow-to-tissue patient-specific mapping that incorporates the whole aneurysm is lacking.

In this work, we integrated imaging, computational fluid dynamics (CFD) and computational pathology to study ATAA in a patient-specific fashion. Our study aims to understand the underlying pathogenic factors associated with aortic medial degeneration in order to develop better risk prediction criteria.

METHODS

10 patients undergoing proximal aortic surgery to treat ATAA were recruited as part of this study. The main exclusion criteria were connective tissue disease, bicuspid aortic valve and redo-aortic surgery. Pre-operative magnetic resonance imaging (MRI) and 4D flow data were collected. Central aortic pressure was measured prior to the scan.

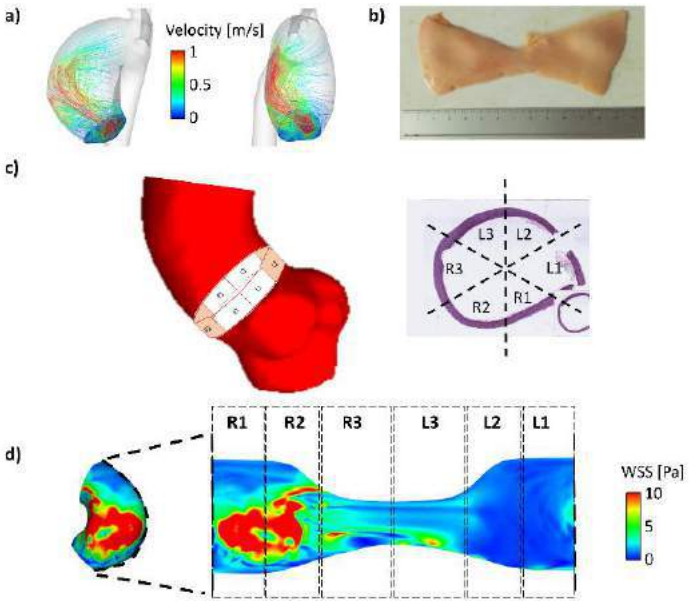

Figure 1: Study methodology: a) Patient-specific CFD analysis of ATAA were conducted for each patient; b) Patients' aortic tissue sample were collected at the time of surgery; c) Each sample was processed for computational histology and subdivided into 6 equal circumferential regions - R1, R2, R3, L1, L2, L3; d) Computational results post-processing: the aneurysmal region was unwrapped from the outer wall (dashed line) and was segmented to obtain 6 circumferential regions (dashed squares) matching the regions used for histological analysis.

MRI data were used to reconstruct patients' aortic geometry. 4D flow images and pressure measurements were used to extract patient-specific boundary conditions for computational fluid dynamic (CFD) analysis, as previously described [4, 5, 6] (Fig. 1a). 3D patient-specific time-varying velocity profiles were imposed at the model inlet, which was located in the aortic root, upstream of the ATAA region. 3-element Windkessel models were used at the aortic outlets, located at the supra aortic branches and thoracic descending aorta. CFD simulations were performed using Ansys CFX.

Aortic specimens (Fig. 1b) were collected immediately after surgical excision. 5mm circumferential portions of the tissue were removed and used for computational histology. Whole slide imaging of full circumferential rings of ATAA samples were obtained using a high-resolution digital optical system (Hamamatsu TM) and uploaded onto a digital processing software (QuPath) for further analysis in ImageJ. Images of each ATAA were divided into six equal circumferential regions (Fig. 1c). Microstructural density calculation of smooth muscle cells (SMCs) and elastin (from slides stained with Elastin Van Gieson) and collagen (slides stained with picrosirius red) was conducted.

Computational results were processed in Ansys EnSight. The aneurysmal region was unwrapped from the outer wall and each patient aorta was segmented to obtain six circumferential regions matching the regions used for histological analysis (Fig. 1d). For each region time-averaged WSS (TAWSS) was calculated.

RESULTS

Maximal WSS levels were significantly higher on the outer curvature of the aorta (24.98 ± 7.79 Pa) compared to the inner curvature (10.18 ± 4.14 Pa). TAWSS values were also considerably higher on the outer curvature (4.85 ± 2.07 Pa) compared to the inner curvature (2.67 ± 0.81 Pa). Asymmetric medial degeneration was observed, with the outer curvature more affected than the inner curvature.

To assess the influence of WSS, linear regression models (Fig. 2) were constructed, finding a statistically significant (p=0.035) negative effect of the maximum value of TAWSS ($TAWSS_{max}$) on elastin abundance. Higher levels of WSS were also associated with higher levels of collagen in the aortic media. However, results of linear regression analysis were non-significant.

The influence of $TAWSS_{max}$ on SMC count was also found to be significant (p=0.021), with higher levels of $TAWSS_{max}$ linked to lower counts of SMCs. A multilevel mixed effects model was used to assess the effect of WSS parameters on elastin and SMC count while also accounting for patient differences. WSS was found to have a persistently negative influence on SMC count (p=0.03).

DISCUSSION

Through segmental analyses using a robust ATAA flow-to-tissue patient-specific mapping approach, we found a co-localization of areas of elevated WSS with regions of the aortic wall presenting enhanced medial degeneration, the hallmark of ATAA disease. This suggests a negative remodeling process of the aortic wall in response to chronic exposure to high shear forces exerted on the wall by the blood.

Higher TAWSS levels were found to be associated with a reduction in both elastin abundance and smooth muscle cell count. Also, albeit not statistically significant, collagen abundance was higher in areas of higher TAWSS. The observed reduction in SMC count suggests a process of mechanodysregulation in response to elevated WSS. Dysfunctional mechanosensing can lead to cellular apoptosis and/or an atrophic remodeling [7], thus disturbing the structural integrity of the aortic wall.

Our findings agree with several previous computational studies assessing flow in TAA, which found asymmetric WSS distribution, highest on the outer curvature [3]. This loss of elastin integrity and relative increase in collagen match the reduced compliance and increased stiffness of the aorta observed in older subjects. Enhanced collagen deposition has also been previously reported in ATAA and linked to compensatory fibrotic changes resulting from the disease process [8]. Elastin fiber thinning in the aortic wall has also been previously linked to increased WSS in BAV patients [3], thus supporting a flow mediated pathogenesis in ATAA, increasing the likelihood of acute dissection.

Aortic samples have also been mechanically tested to evaluate key mechanical parameters (e.g. maximum tangential stiffness, tensile strength, dissection energy). Further statistical analyses assessing the link between WSS and wall mechanical properties are currently ongoing.

Larger sample sizes and the incorporation of patient-specific finite element modelling will form the basis of future work.

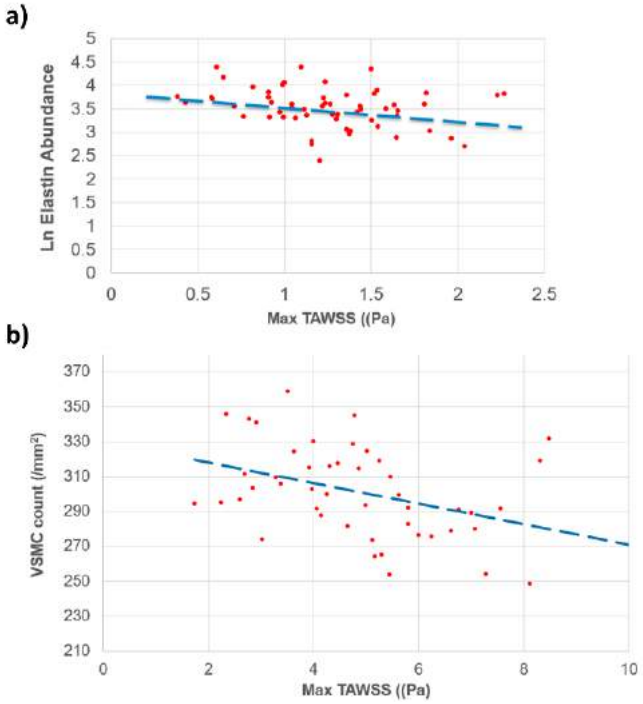

Figure 2: Linear regression analysis results for a) Elastin abundance and b) Smooth muscle cells (VSMC) vs $TAWSS_{max}$. Each data point (N=60) corresponds to a single aortic segment arising from the 10 analyzed patients (6 segments for each patient).

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) has evolved into a routine clinical practice to treat patients with aortic valve stenosis. There have been numerous computational and experimental studies on the design, implantation, and post-procedural complications since the advent of TAVs [1-6]. These studies have provided valuable information on the effect of valve shape, deployment configuration, and balloon inflation volume on paravalvular leakage (PVL) and thrombogenic events [1, 2]. Also, the impact of TAVR on mitral valve regurgitation [3], pressure recovery in balloon and self-expandable valves [4], as well as the role of TAVR and BASCLICA on the sinus and non-sinus hemodynamics [5, 6] have been investigated. There are a few computational studies that have considered valve positionings [1, 2, 7, 8], and there is still lack of data on all possible valve configurations and their potential post-procedural effects.

The objective of this study is to develop a computational framework to assess effect of the TAV orientation on the aortic root stresses that may ultimately allow us to predict post-TAVR complications including root rupture, coronary obstruction as well as the PVL. Findings from this study may be ultimately used for surgical planning to notify clinicians on the optimal deployment configuration for a specific patient. Moreover, the methods employed, when applied on a larger cohort, will provide training data for future predictive modeling using machine learning algorithms.

METHODS

MODEL CREATION AND MATERIAL ASSIGNMENT

Pre-procedural computed tomography (CT) images of a 55-year-old male patient with aortic stenosis who received a SAPIEN 3 TAV at Piedmont Atlanta Hospital were obtained after Institutional Review Broad approval. Aortic wall and leaflets of the patient were segmented from pre-TAVR CT images and meshed using Materialize MIS (Leuven, Belgium). We did not include the calcium nodules as it was out of the scope of the current study. The 3D geometry of the aortic wall and leaflets were discretized using explicit 4-node linear tetrahedron elements. Neo-Hookean hyper-elastic constitutive equation was used to represent the aortic material properties with shear modulus, μ=1 MPa, bulk modulus, κ=10 MPa, and density, ρ=1000 kg/m^3 [9]. Stent model employed was SAPIEN 3 29mm which meshed into modified quadratic tetrahedral elements. The SAPIEN material, used an elasto-plastic model with Young's modulus, E=193 GPa, σ_Y (0.2%) =340 MPa, σ_U (48%) =670 MPa, Poisson's ratio, ν =0.29 and, density, ρ =7760 kg/m^3 [10]. The balloon was modeled with quadrilateral shell elements as a linear elastic material with E=600 MPa, ν =0.45 and ρ=1100 kg/m^3 [10].

TAV POSITIONING AND DEPLOYMENT

The balloon and stent models of the TAV were crimped using a cylindrical crimper in ABAQUS (Dassault Systèmes, Johnston, RI, US). The crimped balloon and stent were positioned coaxially inside the aortic root (Z-axis). Rotation boundary conditions (around the X-axis) were applied to the balloon-stent assembly with three degrees of rotation, i.e., 4°, 8° and 12° (Figure 1). Output data for each configuration was used as an initial condition for the deployment step. Fluid-cavity based approach was employed to inflate the balloon and deploy the stent [1]. The aortic side of the aortic root was constrained in its translational and rotational degrees of freedom. Scaled penalty contact was employed for the stent-balloon and stent-AV interactions. Rotation simulations were completed approximately 1.5h and deployment simulations were solved in about 3h on 22 processors. Results were visualized and analyzed in ABAQUS output database.

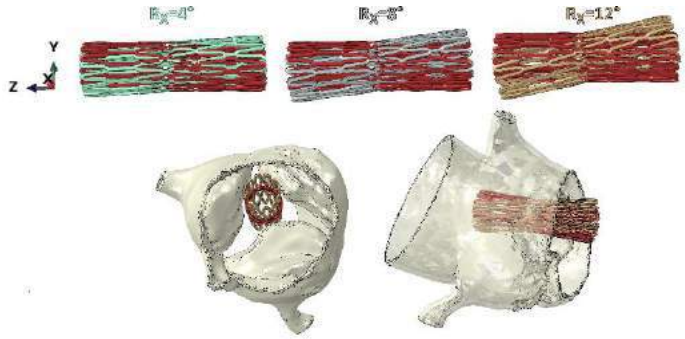

Figure 1. Stent rotation pre-deployment. Top: stent orientation in the aligned (red) and three misaligned states rotated around the X axis by 4°, 8° and 12°. Bottom: stent configuration of the aligned and 12° misaligned states in the aortic root.

RESULTS

Contour plots of stress within the aortic leaflets and wall are indicated in Figure 2 for the aligned state of the stent and for rotation of the stent around the X axis by 4°, 8° and 12° respectively. Top row shows stress distribution on the right and non-coronary AV leaflets of the aortic root and bottom row shows the distribution on the left and right AV leaflets. There is a decrease in stress with increasing in stent rotation on the aortic wall above the leaflets.

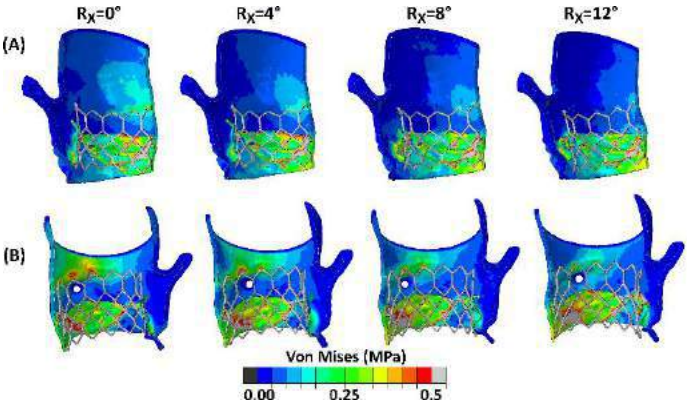

Figure 2. Stress distribution on the aortic root including (A) right and non-coronary sinuses (B) left and right coronary sinuses

Contact pressure distribution on the aortic root is depicted in Figure 3. Higher contact pressure is more concentrated on the non-coronary leaflet. There are some local differences observed on the leaflets with an increasing trend in contact pressure with increase in stent rotation on the left coronary leaflet.

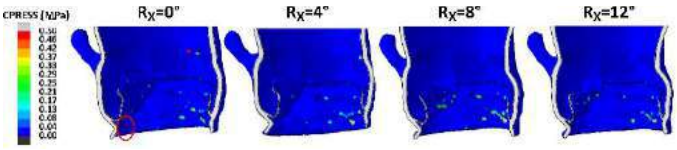

Figure 3. Contact pressure distribution on the aortic root. Red ellipse indicates approximate location of the membranous septum.

DISCUSSION

In this study, effect of the TAV orientation was investigated in a patient specific geometry through computational finite element analysis. The accuracy of the deployment method has been successfully verified previously through comparison of the final configuration obtained from simulation with post-procedural CT imaging of the patient.

As it can be appreciated from Figure 2, during deployment of the stent, there is a strong dependency of valve orientation with respect to the stresses on the root above the leaflets which can be attributed to the contact between the balloon and aortic wall. There is also a trend noticeable for this region: as the angle of rotation increases, the stress values decrease. This shows that the higher 12° orientation is most beneficial for this specific root and the risk of root rupture might be higher for lower angles of rotation. In a study by [7], the stent orientation was determined based on the angle between the native leaflets and prosthetic leaflets (0°-105°). They reported a trend for stress alterations with respect to the angle of orientation and showed that at 0° and 60°, the leaflets experienced lowest and highest stress. In another study by [2], two orientation states were defined similar to [7] and it was shown that when the prosthetic and native valve leaflets are aligned, the PVL is less. The findings from these studies emphasize the impact of the device orientation on structural and hemodynamic parameters.

Contours of the contact pressure in Figure 3 indicated an overall similar distribution within the leaflets. However, there were still some local differences observed which were more defined on the left coronary sinuses. Contact pressure on the membranous septum is negligible showing no abnormality of the atrioventricular conduction system. Our data were consistent with [8] where they showed that the contact pressure did not change for three stent orientations.

Some of the modeling considerations and limitations of the current study are described as the following: (1) We did not include the TAV prosthetic leaflets as it has been shown it has a minimal effect on deformed configurations of the stent [11], (2) Material properties of the aortic valve tissue are not patient-specific. The paucity of data on material properties of the healthy and pathologic aortic valves is a common limitation of the valve studies. Nonetheless, the literature derived material properties used in the current study still meet the objective of the work, (3) Calcific plaques were not included in the modeling. The influence of calcific nodules in combination with degree of rotation of the stent on the deployment results and stress of aortic root will be analyzed to further improve our understanding of the TAV performance and deterioration under these deployment scenarios.

In conclusion, the findings of this study indicate that: (1) the orientation of the stent should be considered when there is a concern for root rupture and (2) optimal TAV configuration can be characterized in a patient-specific manner. Furthermore, similar studies on a larger patient population that include other possible TAV deployment orientations and depths will provide a database for use in predictive algorithms which allow for an improved and more rapid decision making.

DECOUPLING HYDROSTATIC AND DEVIATORIC STRAIN ENERGY DENSITY IN BIOMATERIALS WITH POISSON'S RATIO LARGER THAN 0.5

Amevi M. Semodji, Katherine A. Hollar, Gunes Uzer, Ph.D., Trevor J. Lujan, Ph.D.

INTRODUCTION

Strain energy density is a scalar measure of deformation in nonbiological and biological materials. It represents the energy stored in the material during deformation and can be decomposed into two components: hydrostatic energy, responsible for volume change, and deviatoric energy, responsible for shape change (distortion). Decoupling strain energy density is a common engineering practice as each component guides different responses in the material. For example, hydrostatic energy is predictive of cortical bone remodeling [1], while deviatoric energy theory is an excellent predictor of failure in ductile materials [2]. Deviatoric energy may also be a key predictor of damage, growth, and remodeling in soft fibrous tissues (e.g. ligament), but large Poisson's ratios in soft tissue have made this analysis difficult.

The Poisson's ratio is a fundamental metric that defines a material's resistance to distortion or volume change. Several biological materials exhibit a large Poisson's ratio under uniaxial tension (3.0 for tendon [3], 1.7 for collagen constructs [4]), indicating volume loss. Previous studies have investigated the structural origins for these large Poisson's ratios [5,6], but little interest has been given to their strain energy. Finite element (FE) solvers can output strain energy values for deformed materials; yet several solvers, including ABAQUS, lack the energy decoupling feature. FEBio [7] is one of the rare FE solvers that can decouple strain energy, but only for uncoupled materials with Poisson's ratios less than 0.5. A need thus exists to develop a technique to decouple strain energy in materials with a large Poisson's ratio.

The objective of this work is to present a numerical approach to decoupling strain energy density in materials with a large Poisson's ratio. The method will be validated using a FE solver for a material with small Poisson's ratio and will be used to decouple strain energy in type-I collagen constructs, known to have large Poisson's ratios, under simple and complex loading.

METHODS

Strain energy density can be described as the area under the characteristic stress-strain curve of a material (Fig. 1). The integral form of this relationship is defined by equation (1), where $\boldsymbol{\sigma}(\boldsymbol{\varepsilon})$ denotes the engineering stress tensor, and $\boldsymbol{\varepsilon}$ represents the engineering strain tensor.

$$W = \int \boldsymbol{\sigma}(\boldsymbol{\varepsilon}) : \boldsymbol{d\varepsilon} \tag{1}$$

The integral can be numerically computed using a technique similar to the trapezoidal numerical integration. The total area can be subdivided into small intervals, and for each interval, the stress and strain tensors can be formed. For each interval, the stress tensor $\boldsymbol{\sigma}$ can be decomposed into its hydrostatic and deviatoric components $\boldsymbol{\sigma^{HYD}}$ and $\tilde{\boldsymbol{\sigma}}$ respectively (Eq. 2). $\boldsymbol{I}$ denotes the identity tensor, and tr is the tensor trace operator.

$$\boldsymbol{\sigma^{HYD}} = \frac{1}{3} tr(\boldsymbol{\sigma})\boldsymbol{I} \quad \text{and} \quad \tilde{\boldsymbol{\sigma}} = \boldsymbol{\sigma} - \boldsymbol{\sigma^{HYD}} \tag{2}$$

Similarly, the strain tensor can be decoupled. The energy components can be computed by approximating each one with a pair of triangular and rectangular areas (Fig. 1).

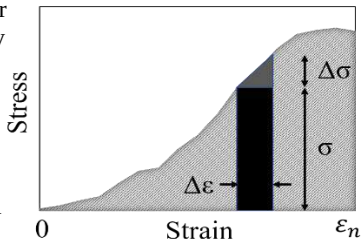

Figure 1: Decomposition into rectangular and triangular

The total hydrostatic energy, W^{HYD} and the total deviatoric energy, $\widetilde{W}$ are found by summing all the area pairs over the entire strain interval (Eq. 3&4).

$$W^{HYD} = \sum \left(\frac{1}{2} \Delta\boldsymbol{\sigma}^{HYD} : \Delta\boldsymbol{\varepsilon}^{HYD} + \boldsymbol{\sigma}^{HYD} : \Delta\boldsymbol{\varepsilon}^{HYD} \right) \tag{3}$$

$$\widetilde{W} = \sum \left(\frac{1}{2} \Delta\tilde{\boldsymbol{\sigma}} : \Delta\tilde{\boldsymbol{\varepsilon}} + \tilde{\boldsymbol{\sigma}} : \Delta\tilde{\boldsymbol{\varepsilon}} \right) \tag{4}$$

The total strain energy density W is computed as the sum of the hydrostatic and the deviatoric energies. A custom MATLAB function was developed to implement this numerical method.

Method validation. To verify our numerical approach: three test cases (based on experimental results using collagen constructs) were set up in FEBio: uniaxial tension (T), uniaxial compression (C), and biaxial tension-compression in equal magnitudes (CT). A single element cube model was designed to represent the material, and displacement was prescribed through a rigid body. A sliding-elastic contact was defined between the cube and the rigid body. The cube was assigned a Mooney-Rivlin material in the T and C loading conditions, and an orthotropic elastic material in the CT loading condition.

The stress and strain values obtained from FEBio were imported into the custom MATLAB function to compute the hydrostatic and deviatoric energies as well as the total energy. The total energy results were compared to the results outputted by FEBio. Additionally, the deviatoric energies were compared to the FEBio results for the C loading condition, which was the only condition that displayed a Poisson's ratio less than 0.5 in our test cases.

Application to uniaxial and biaxial loading. The developed method was used to decouple energy in 3D collagen constructs subjected to different loading configurations. Experiments applied simple and complex loads at a single targeted total energy on collagen specimens (N=5) in a biaxial bioreactor. Type-I collagen sponges were speckled with water insoluble black ink, cut into dog-bone shapes, and hydrated in water overnight. The dog-bone shaped specimen was then placed in the culture chamber of the bioreactor (Fig. 2A). A camera was placed underneath the culture chamber to track displacements in a region of interest (ROI) of the specimen. Each specimen was subjected to the same three tests described in the previous section. Images obtained from the camera were processed via digital image correlation (DIC) to obtain a strain distribution over the 2D surface of the specimen (Fig. 2B).

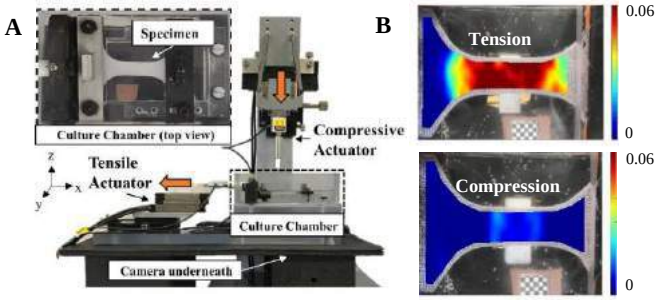

Figure 2: A) Biaxial bioreactor. B) Strain maps for (T) and (C)

A custom LABVIEW program attached to the bioreactor was used to extract load and displacement data, which, added to the strain distribution obtained via DIC, were used to compute the stress and strain tensors in the ROI. The custom MATLAB function was used to compute the hydrostatic, deviatoric, and total strain energy density values. A one-way ANOVA and Tukey-HSD post-hoc was performed to detect differences in energies between the three loading configurations.

RESULTS

FEBio validation. The custom MATLAB function accurately predicted the total energies in all three loading conditions with a percent difference less than 0.03% (Table 1). It also predicted the decoupling of the strain energy density in the uniaxial compression FEBio model with 0.4% difference in deviatoric energy (Table 1).

Table 1: Total (W) and deviatoric ($\widetilde{W}$) strain energy density comparison between MATLAB and FEBio

	W (J/m^3)			$\widetilde{W}$ (J/m^3)		
	FEBio	MATLAB	% Diff	FEBio	MATLAB	% Diff
T	*277.17*	*277.17*	*0.00*	-	*333.98*	-
C	*230.74*	*230.72*	*0.00*	*142.25*	*141.68*	*0.40*
CT	*248.54*	*248.48*	*0.02*	-	*482.84*	-

Uniaxial and biaxial experiments. The experiments hit the target total energy in all three loading conditions (Fig. 3). Additionally, the MATLAB function revealed a significant difference in hydrostatic and deviatoric energies between loading conditions (Fig. 3).

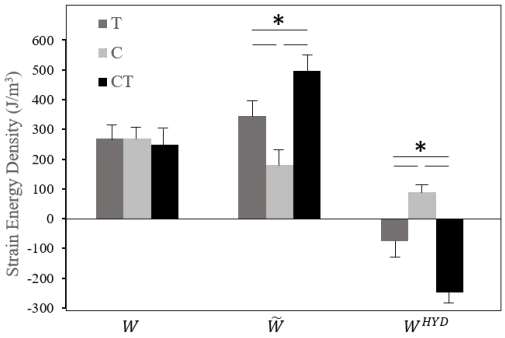

Figure 3: Total (W), hydrostatic (W^{HYD}), and deviatoric ($\widetilde{W}$) strain energy density per loading condition (* p<0.05)

DISCUSSION

This work presented a numerical approach to decoupling hydrostatic and deviatoric strain energy density in materials with large Poisson's ratio. The decoupling computation was validated using FEBio, which could only decouple energy in our C loading condition where Poisson's ratio was less than 0.5 (Table 1). Our method successfully decoupled strain energy density in type-I collagen gels, that experienced similar total strain energy densities but significantly different hydrostatic and deviatoric energies (Fig. 3).

Interestingly, a negative hydrostatic energy was revealed in the T and CT loading conditions (large Poisson's ratios, Fig. 3). To our knowledge, this is the first time a negative hydrostatic energy has been explicitly reported for a biomaterial. Mathematically, a negative hydrostatic energy can be explained as a sign contradiction between the change in hydrostatic strain and the applied hydrostatic stress. Physically, a negative hydrostatic energy occurs from a volume loss due to exudation of fluid from the material [5,6]. One can describe the negative energy as energy loss in the material via the leaving fluid. It's worth noting that fluid exudation leads to significantly greater deviatoric energies, as observed in the CT loading condition (Fig. 3).

This numerical method will finally allow us and others to investigate whether specific energies drive the mechanobiology of soft tissue and, more specifically, whether deviatoric energy can predict damage, growth, and remodeling in native and surrogate soft tissue.

INTRODUCTION

In healthy muscle fibers, myofibrils are arranged uniformly in parallel. In many muscle diseases myofibril disarray is present and studies show a correlation between this disorganization and impaired function. This study utilizes a Huxley-based cross-bridge distribution model of half-sarcomeres embedded in an implicit finite-element (FE) model of contractile tissue to investigate the effect of myofibril disarray in a muscle fiber. Specifically, this multiscale model is used to simulate isometric twitches and loaded shortening conditions. It is shown that in twitch simulations, peak stress and time to half-relaxation decrease as disarray increases. Furthermore, loaded shortening simulations show that efficiency is also decreased.

METHODS

Cell Contraction Half-sarcomeres were simulated using MyoSim [1]. The kinetics scheme used to describe the states of binding sites on the thin filament and myosin heads on the thick filament is shown in Figure 1. Transitions between these states have been previously described [2]. Briefly, binding sites can be described as OFF or ON and are activated in the presence of intracellular calcium and include a cooperative effect from the binding/unbinding of myosin heads. Myosin heads can exist in one of three states: super relaxed (M_SRX), disordered relaxed (M_DRX) or force-generating (M_FG(x)). The force-generating state is discretized over the working range of a cross-bridge (-10 to 10 nm) and thus has a spatial dependence. The transition from M_SRX to M_DRX is force-dependent and the transition from M_FG to M_DRX includes strain-sensitive detachment of cross-bridges. This yields a system of ODEs whose solution is the relative populations in each state. Active stress for a half-sarcomere T is calculated from the population in M_FG as

$$T = k_{cb} \sum_{i=1}^{n} M_{FG}(x_i) * (x_i + x_{ps}) \quad (1)$$

where k_{cb} is the spring stiffness of a cross-bridge and x_{ps} is the power-stroke distance.

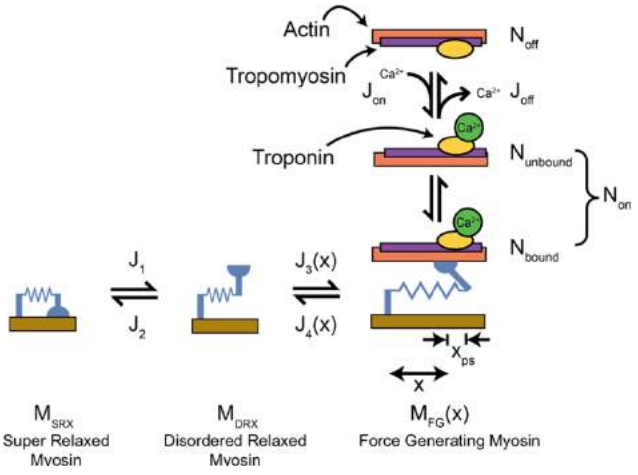

Figure 1: Cell contraction kinetic scheme

Constitutive Equations The contractile tissue is considered a hyperelastic, incompressible material. A local orthogonal coordinate system $\{\mathbf{f}_0, \mathbf{s}_0, \mathbf{n}_0\}$ is defined using the prevailing fiber, sheet, and sheet-normal directions respectively. An element of contractile tissue has a stress state that is additively decomposed into an active contraction stress tensor ($\mathbf{S_a}$) and passive response stress tensor ($\mathbf{S_p}$):

$$\boldsymbol{S}_a = T(\boldsymbol{f_0} \otimes \boldsymbol{f_0}) \quad (2)$$

$$\boldsymbol{S}_p = \frac{\partial W_{bulk}}{\partial \boldsymbol{E}} + \frac{\partial W_{myofibril}}{\partial \boldsymbol{E}} \quad (3)$$

$\mathbf{S}_p$ is further decomposed into contributions from the myofibril and the remaining bulk tissue. The strain energy functions for bulk [3] and myofibrils [4] are

$$W_{bulk} = \frac{C}{2}\left(e^{\left(b_f E_{ff}^2 + b_t\left(E_{ss}^2 + E_{nn}^2 + E_{sn}^2 + E_{ns}^2\right) + b_{fs}\left(E_{fs}^2 + E_{sf}^2 + E_{fn}^2 + E_{nf}^2\right) - 1\right)}\right) \quad (4)$$

$$W_{myofibril} = \begin{cases} C_2\left[e^{C_3(\alpha-1)^2} - 1\right] & \alpha > 1 \\ 0 & \alpha \leq 1 \end{cases} \quad (5)$$

where E_{ab} represent the components of the Green-Lagrange strain tensor with respect to the local fiber coordinate system and α represents the stretch of the myofibril.

Simulation Protocols A series of simulations were performed to simulate an isometric twitch response and a loaded shortening response of the muscle fiber at various degrees of disarray. Disarray was introduced by selecting the cartesian components of the f0 vector at each integration point from a gaussian distribution of varying widths (w) and normalizing the resulting vector. For the isometric twitch simulations, the fiber was stretched 10% to elicit an initial passive stress response and an approximation of a twitch calcium transient [5] was used to drive contraction. The elements within 10% of the ends of the fiber were set as non-contracting tissue to allow the contractile elements to shorten against compliance. Parameters for the contraction model were chosen to mimic a force twitch response [6] and the passive material parameters chosen to obtain an average myofibril shortening of ~8%. For loaded shortening simulations, the twitch protocol was used except for a traction boundary of 30 kPa being applied to the right end once the resultant forced was high enough to satisfy this condition. This allowed the fiber to shorten and subsequently re-lengthen as active force generation declined. Efficiency was calculated using the work done by the fiber during shortening and the energy consumption of the fiber:

$$Total\ Energy = \frac{\pi\rho\left(L_{fiber}\right) * \Delta G' * \sum_{N_G} \sum_{i=1}^{21} J_4(x_i)}{L_0 N_A N_G} \quad (7)$$

where ρ is the density of half-sarcomeres in contractile tissue, $\Delta G'$is the free energy produced by ATP hydrolysis, L_{fiber} is the length of the fiber, L_0 is the reference half-sarcomere length, N_A is Avogadro's number, N_G is the number of integration points, and the summation is the sum of fluxes out of M_FG(x) over N_G.

RESULTS

The muscle stress, peak stress, and time to half-relaxation for twitch simulations were calculated for varying amounts of disarray. Both quantities decrease as disarray increases (Figure 2).

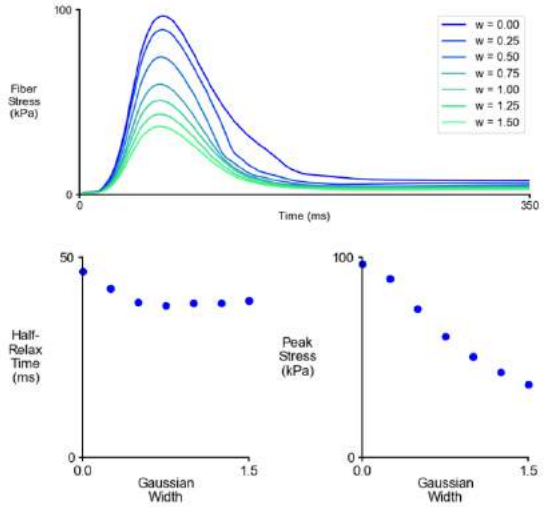

Figure 2: Twitch Simulation Data

The loaded shortening relative length profiles show the magnitude of shortening and also how the duration of shortening is affected. As disarray increases, fiber efficiency decreases (Figure 3).

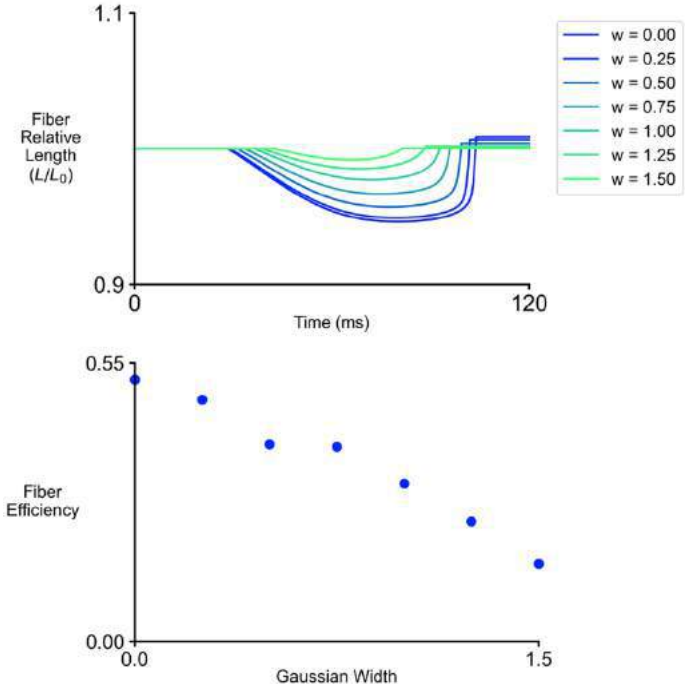

Figure 3: Loaded Shortening Simulation Data

DISCUSSION

This study uses a multiscale finite element framework driven by a physiologically motivated cell contraction model to simulate physiologically relevant experiments. The embedded cell contraction model also allows for the calculation of ATPase, showing that form influences function. Specifically, this study shows that disorganization in myofibrils results in muscle fibers that produce less force and require more energy to do the same amount of work as an organized cell. This example of testing hypotheses linking form to function and energetics will be carried forward in future work regarding growth and remodeling.

INTRODUCTION

Nearly half (%40) of the patients with symptomatic peripheral arterial disease have aortoiliac occlusive disease (AOID) [1]. Currently guidelines favor open surgical of AOID [2,3]. No consensus is achieved on the management of multilevel occlusive disease, except to treat the inflow (i.e., aortoiliac lesion) first. There is controversial data about Aorta femoral graft (AFB) patency in the presence of Superficial femoral artery (SFA) occlusion [4,5]. The standard procedure is to take inflow from aorta to common femoral artery above the bifurcation of profunda femoral artery and SFA. In this case, while performing endarterectomy to the femoral bifurcation in a patient with total occluded iliac arteries and SFA, the common femoral artery severely got damaged and we had to anastomose the graft to the profunda femoral artery in an end-to-end anastomosis technique. We ligated the common femoral artery, and the ostium of SFA. This way of anastomosis might provide a more stable flow into the main target vessel -profunda femoral artery. Thus, we think it requires to be investigated by engineering methods [6-8].

METHODS

In the present work, aorta femoral by-pass graft operation has been assessed from the haemodynamic point of view [9]. A 55-year-old male patient was selected with an occluded iliac artery on the right leg and the iliac artery and superficial femoral artery was occluded on the left leg. The patient had diabetes mellitus type 2 and dislipidemia comorbidities. There was flow in profunda lumens on both sides. Aortic bypass operation was performed on the right side of the aorta and femoral bypass on the left side to the femoral junction. Pre-operative and post-operative computed tomography angiography (CTA) images were obtained with Toshiba Aquilion Helical CT (Asteion; Toshiba Medical Systems, Tokyo, Japan). The three-dimensional (3D) models for region of interests are obtained from multi-sliced DICOM images with image processing and segmentation tools by Mimics Innovation Suite 19.0 (Materialise, Leuven, Belgium) Figure 1.

The models were optimized with computer–aided design tools (Geomagic Studio (Geomagic Software, 3D Systems, Rockhill, SC, USA).

Approved software ANSYS was used to simulate the blood flow in both models with the computational fluid dynamics (CFD) method (ANSYS Inc, Somerset, PA, USA). The simulation model was governed by Navier-Stokes equations under the assumptions of laminar flow or turbulent flow:

$$\boldsymbol{\nabla} \cdot \boldsymbol{u} = 0 \tag{1}$$

$$\rho \boldsymbol{u} \cdot \boldsymbol{\nabla} \boldsymbol{u} = -\boldsymbol{\nabla} p + \boldsymbol{\nabla} \cdot [\mu(\boldsymbol{\nabla} \boldsymbol{u} + (\boldsymbol{\nabla} \boldsymbol{u})^T)] \tag{2}$$

where $\boldsymbol{u}$ is the velocity vector, p the pressure, t the time, ρ and μ the density and the dynamic viscosity of the blood, respectively. Besides NS equations, the SST k – ω model was included to simulate the turbulence.

The inlet boundary condition has been assigned a plug velocity profile and the outlet boundaries has been assigned a pressure outlet. Results were considered as guiding parameters in the comparison.

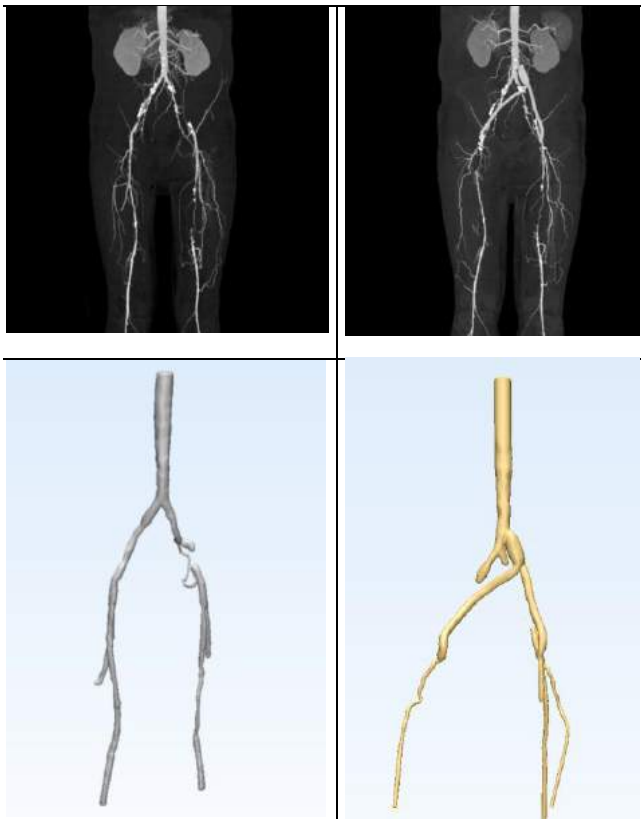

Figure 1: Top: Pre-op (left) and post-op CTA images, Below: Pre-op (left) and post-op three-dimensional virtual models.

RESULTS

The preliminary results are presented in this section for pre- and post-op stages of the surgery. The pressure distribution of both stages is presented in Figure 2. The decrease of pressure from the inlet to the outlets are observed as expected for steady state blood flow. The narrowing regions (obstructions) decrease the pressure substantially for especially the post-op stage.

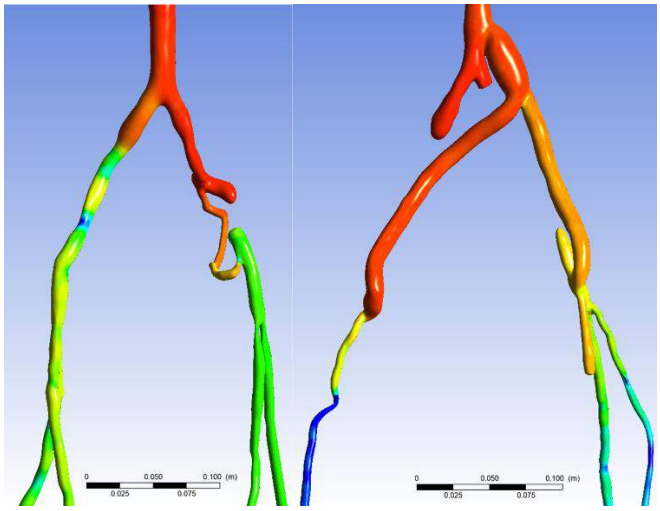

Figure 2: Pressure distribution at pre-op (left) and post-op (right) stages.

Figure 3 shows the wall shear stress (WSS) for both stages. WSS is calculated since it is correlated with re-stenosis and plaque formation. The stenosis or sharp lumen diameter changes cause severe WSS value increases due to high velocity and shear rates. This is valid for both pre- and post-op stages. The larger inlet zones have relatively low WSS due to undisturbed flow profile and low velocity. Also, the pre-op stage has non-symmetric distribution due to flow differences at the branches.

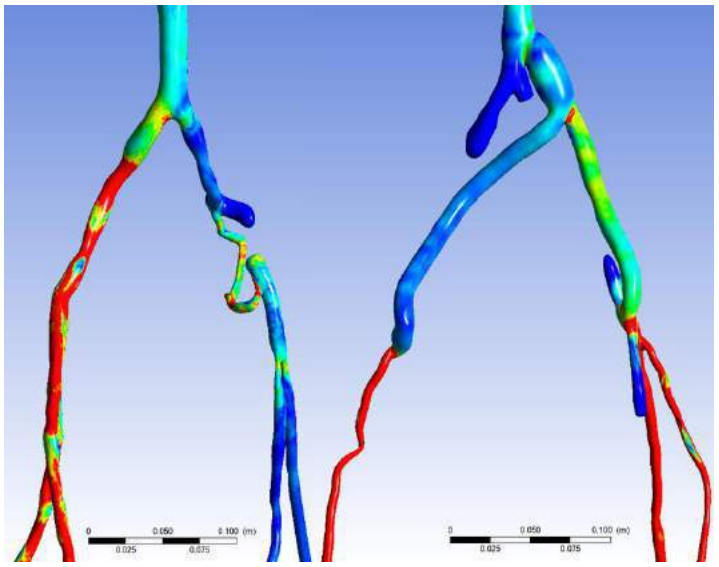

Figure 3: WSS distribution at pre-op (left) and post-op (right) stages.

DISCUSSION

Here, we have presented the first results of our study on pre surgical planning of profunda bypass operation. Early results show the insight of hemodynamics which would otherwise would not be possible by routine clinical investigations. The results show that the location of anastomosis and its configuration are critical as well as the diverging location of the bypass graft. Since we have pre-op and post-op images of the same patient, the analysis of the simulation data are comparable to each other without using any assumptions. The boundary conditions do not belong to the patient since they were not available at the time of the simulation. Also, the walls of the arteries are assumed to be rigid. We are now collecting patient specific boundary conditions for future work. The proposed framework is promising regarding the optimization of the aorta femoral bypass graft placement.

INCORPORATING ENGINEERING STANDARDS INTO A BIOMECHANICS LABORATORY COURSE

Kristen L. Billiar

Department of Biomedical Engineering
Worcester Polytechnic Institute
Worcester, Massachusetts, USA

INTRODUCTION

Engineering standards are critical in the design process for efficiency of the process, uniformity in validation, product safety, and market acceptance.[1] Although ABET has dropped the explicit requirement of "incorporating appropriate engineering standards" in the Criterion 4: Professional Component section, the need for safe and effective medical devices is clear. Further, the FDA requires testing according to published standards, thus the importance for biomedical engineering students to understand how to find and adhere to engineering standards remains.

But where do engineering students learn about engineering standards? Requiring senior capstone design students to list the standards their product would have to adhere to if produced neither aids in their learning nor assesses their understanding. Yet an entire course on engineering standards is difficult to fit within an already packed curriculum. Further, discussion of standards outside of their theoretical underpinnings loses the opportunity to demonstrate the application of engineering theories in real world context. There is a continuing need to implement engineering standards within technical courses in curricula.

The goal of this work is to describe the implementation of engineering standards for mechanical testing of medical implants into a junior-level biomechanics laboratory course. Students were presented lectures on why standards are needed, who develops standards, and the (long) process for such development. They then utilize the standards for characterizing specific aspects of the mechanical performance of various medical devices and report out the required metrics. This work is a work in progress: no statistical analyses of student learning were performed, and the student outcomes were not compared to a control group.

METHODS

Engineering standards were incorporated into a junior-level biomechanics laboratory course focused on characterization of the mechanical behavior of biological tissues and biomaterials. Characterization of metal fracture fixation plates and screws was added to align with accessible ASTM test standards in the fall semesters of 2019 and 2020, with enrollments of 45 and 36 students, respectively.

General lecture materials highlighted the benefits of standards in the design and manufacture of medical implants. These include demonstrating safety and integrity of devices, uniformity of test methods, consistency of data reporting across the industry for valid comparisons, avoiding development and validation of methods by individual companies, and market acceptance. Who develops standards and the standards setting process were also discussed so that the aspiring engineers could understand that they can change and create standards in the future. Additional lectures covered the specific metrics in a few engineering standards including: burst strength and suture pull-out for blood vessel grafts;[2] proof load, bending stiffness, and flexural rigidity of metallic fracture fixation plates;[3] and screw pull-out strength of metallic medical bone screws.[4]

After two preliminary projects involving uniaxial testing of leather and flexure testing of wood and bone through which they students gained the skills to safely perform mechanical testing using an Instron 5544 and to analyze the data using Matlab, the student teams were then challenged to characterize the mechanical performance of metallic plates and screws following ASTM standards (e.g., refs [3] and [4]). As standards often do not specify specific values for test parameters (e.g., sample or fixture dimensions, rate of test, temperature), the students were also asked to assess the effects of one test parameter on each metric and perform statistical analysis (t-test on the slope of the regression line).

RESULTS

From the point of view of the instructor, the standards are helpful in that they provide for the students clear diagrams of the test configurations with dimensions indicated, e.g., Figure 1 for 4-point bending of a metallic plate showing the center span distance, a, and the loading span distance, h. They also provide unequivocal definitions for test variables and equations for calculating the device properties (with units), e.g., bending stiffness (K, N/mm) and bending structural stiffness (EI, N-m^2, Equation 1).

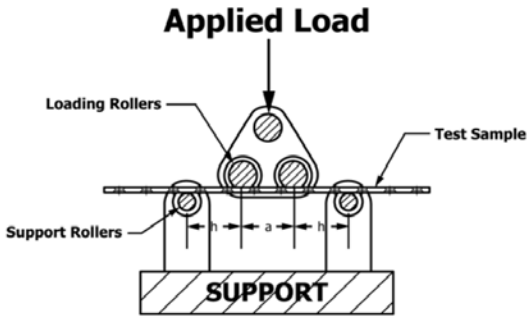

Figure 1: 4-point bending test configuration from [3].

$$EI_e = \frac{(2h+3a)Kh^2}{12} \quad (1)$$

The students were at first confused by the difference in nomenclature between their stress analysis textbook and the standards; however, upon watching the lectures which provided the derivation of the equations from basic stress analysis, they were able to clearly see the connection. In their lab reports, they were also able to demonstrate an understanding of the limitations of their analyses, e.g., often not being able to have a sufficient support span/sample thickness ratio to neglect shear stress.

Through their parametric tests, many groups demonstrated that certain test parameters have little effect on the results, e.g., intrinsic properties such as material modulus or rate of test on the bending stiffness of a fixation plate since it is metal (Figure 2), whereas other test parameters must be controlled carefully, e.g., the span ratio (center/support) for functional properties such as the bending stiffness and for the depth of insertion of a bone screw into a Sawbones polyurethane foam test block (Figure 3).

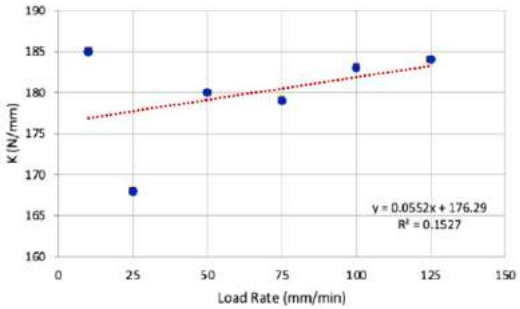

Figure 2: Plot of bending stiffness, K, as a function of load rate with regression showing lack of significant effect of rate (p= 0.44 for t-test on slope); data and plot from team e4.

One group commented in their report: "…this result signifies the importance of a universal standard. This is the reason for the ASTM bone screw standards. The ASTM standard for bone screw pullout testing states the screws should be a depth of 20mm, or 60% of the screw length for smaller screws [4]. Changing just [insertion depth] yields dramatically different maximum loads, proving that the standards are necessary to make data uniform and analyzable."

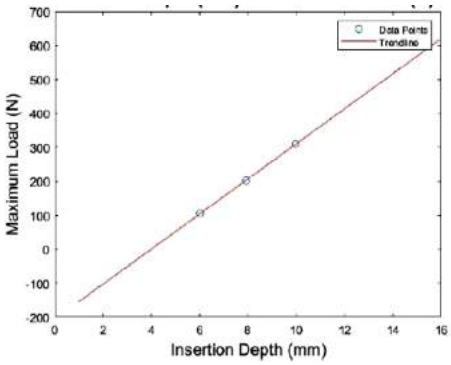

Figure 3: Plot of maximum load from screw pull-out test as a function showing strong linear correlation (p=0.008 for t-test on slope); data and plot from team 1f.

The overall grades on the final project in which they used standards to guide their mechanical characterization were 91% ±7% in 2019 and 86%±11% in 2020, indicating good overall following of the standards for their methods, analysis, and data reporting.

DISCUSSION

Overall, based on lab report content, instructor observations, and student feedback, use of engineering test standards helped students learn how to perform high quality mechanical tests and analyze and report the resulting data in a uniform manner.

The parametric studies demonstrated to the students the need to control critical parameters very tightly, and why standards allow variation in other parameters (e.g., due to vastly different sizes of fixation plates for different applications). This exercise also helped them understand how an engineer goes about choosing value of certain parameters e.g., rate of testing.

Use of standards helped the students draw connections between academic lab exercises and actual industry practice. Standards also showed them first-hand how their coursework (e.g., stress analysis) applies to the mechanical characterization tests completed in industry and required by the FDA.

INTRODUCTION

Concussions continue to be a prevalent safety concern in contact sports due to their potential short-term and long-term neurodegenerative effects. Studies suggest that repetitive, non-concussive head impact exposure may lead to similar pathologies as those caused by concussion.[1,2] With approximately 3.5 million youth athletes (age 6-13) participating in football each year, it is essential to minimize head impact exposure to prevent future brain injury.[3-6] There is limited information on how individual-level determinants (i.e., characteristics internal to the individual) affect an athlete's head impact exposure.[7,8] Therefore, the objective of this study was to examine the effect of confidence in sports, perceived coach support, and competitive aggressiveness and anger in relation to head impact exposure in football.

METHODS

Thirteen (n=13) middle school level (ages 12-14) and 21 high school level (ages 14 -18) football players were enrolled in this study. Using the Head Impact Telemetry (HIT) System, head impact exposure data was collected from the participating athletes over the span of one season. Each athlete completed the Trait-Robustness of Self-Confidence Inventory (TROSCI)[9], the Sports Climate Questionnaire (SCQ)[10], and the Competitive Aggressiveness and Anger Scale (CAAS)[11] during the season. Head impact exposure was quantified in terms of total number of impacts as well as the median and 95th percentile linear and rotational acceleration. Risk Weighted Exposure (RWE), a cumulative exposure metric encompassing frequency and magnitude of impacts was calculated. Each metric was evaluated for the entire season and separately by exposure attributed to practices and games.

Data analysis was completed using SAS statistical software. The survey results (e.g., TROSCI, SCQ, CAAS) were compared against the biomechanical parameters using linear regression analysis to determine whether survey scores influenced the biomechanical data. Cook's distance was computed to remove outliers from each regression. Data were grouped for the entire sample (youth + high school) and stratified by level of play.

RESULTS

Combined Sample

The means and standard deviations for each survey score for the combined and individual teams are provided in Table 1, below. The TROSCI and SCQ scores for the entire sample were not significantly associated with any biomechanical parameter. The CAAS score for the entire sample was significantly positively associated with the number of impacts overall ($p=0.014$, $R^2=0.236$), number of impacts at practice ($p=0.015$, $R^2=0.198$), RWE overall ($p=0.035$, $R^2=0.145$), and RWE at practice ($p=0.026$, $R^2=0.183$). The CAAS score for the entire sample was negatively associated with the 95th percentile rotational acceleration at practice ($p=0.015$, $R^2=0.232$).

Table 1: Mean and standard deviation values for the teams.

Parameter	Team	Mean	Std. Dev.
TROSCI	Combined	43.09	10.20
	Middle School	42.31	12.05
	High School	43.57	9.150
SCQ	Combined	86.74	17.87
	Middle School	87.46	17.00
	High School	86.29	18.79
CAAS	Combined	29.88	10.86
	Middle School	26.69	9.437
	High School	31.86	11.42

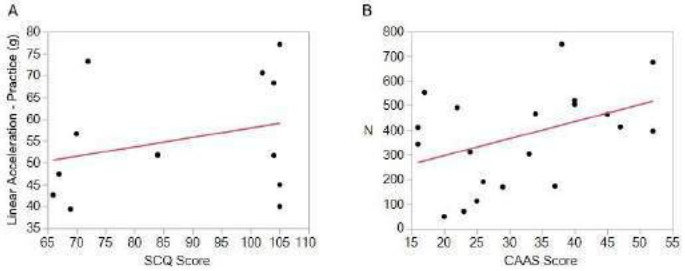
Middle School Sample

The TROSCI score for the middle school team was significantly negatively associated with number of impacts during competition ($p=0.027$, $R^2=0.508$) and significantly positively associated with the linear acceleration during practices ($p=0.009$, $R^2=0.783$). The SCQ score for the middle school team was also significantly positively associated with the linear acceleration during practice ($p=0.008$, $R^2=0.800$); however, the SCQ score for the middle school team was significantly negatively associated with the number of impacts overall ($p=0.008$, $R^2=0.656$) and during practice ($p=0.042$, $R^2=0.542$), and RWE during practice ($p=0.037$, $R^2=0.553$). The CAAS score for the middle school team was significantly positively associated with the number of impacts overall ($p=0.006$, $R^2=0.687$) and RWE at practices ($p=0.021$, $R^2=0.572$).

High School Sample

The TROSCI and SCQ scores for the high school sample were not significantly associated with any biomechanical parameter. The CAAS score for the high-school-level team was significantly positively associated with the number of impacts overall ($p=0.036$, $R^2=0.574$) and significantly negatively associated with the 95th percentile rotational acceleration at practice ($p=0.023$, $R^2=0.284$).

Figure 1: Strong correlations observed for each team. (A) Linear acceleration at practice versus SCQ at the middle school level. (B) Number of impacts overall versus CAAS at the high school level.



Differences Between the Samples

In evaluating the differences between the separate high school and middle school teams, the only significant parameters were the 95th percentile linear acceleration during practice ($p = 0.020$) and the 95th percentile rotational acceleration during competition ($p=0.005$). The middle school athletes had significantly higher linear acceleration at practice than their high school counterparts. The high school athletes had significantly higher rotational acceleration at competition than the middle school athletes.

DISCUSSION

This study examined the effect of confidence in sports, perceived coach support, and competitive aggressiveness and anger in relation to head impact exposure metrics for youth football. Trends were seen among all survey measures and many biomechanical metrics.

The CAAS score was positively correlated and the number of impacts (overall, practice) and RWE (overall, practice) for the entire sample. Among the high school sample, a significant positive association between CAAS score and the overall number of impacts was observed. Among the middle school athletes, overall number of impacts and RWE in practices were significantly positively correlated to the CAAS score. These results support that players with more aggressive tendencies may not only be more willing to engage in contact more frequently, but also involve themselves in riskier collisions, in general. The negative relationships between the CAAS score and rotational acceleration at practice was not expected. This implies that more aggressive and angry players might have less rotational acceleration at practice.

The positive relationship between TROSCI score and linear acceleration at practice, for the middle school team, may imply that athletes in this age range were more likely to quickly accelerate and engage in contact with greater force if they were more confident. The negative association between TROSCI score and number of impacts at competition could result from confident players engaging in less hits, possibly by outrunning or dodging opponents.

Linear acceleration at practice was found to be positively associated with SCQ score. Middle-school-level athletes have a lot of interaction with their coaches during practice; therefore, greater perceived coach support may indicate trust among the athletes and their coach. If harder hits are celebrated by the coaching staff, this may further encourage risky behavior to impress their coaches; however, the contrary may be true of athletes striving for more coach support. SCQ score was negatively associated with number of impacts, overall and during practice, and RWE during practice. Athletes who feel unsupported by their coaches might try to engage in more collisions in an attempt to earn support. In the same way, players with little perceived support might attempt to hit harder and subsequently experience more cumulative exposure over the season.

The significant difference between the rotational acceleration at competitions in high school and middle school samples is congruent with what was expected. High school athletes likely hit with more force and have more advanced skills which allow for them to better anticipate other players' moves and tackle from side positions. The significant difference between the linear acceleration at practices in high school and middle school samples could be explained by practice structure. High school practices might involve more advanced technical drills and focus less on head-on impacts, therefore causing those athletes to have less linear acceleration at practice. Both of the aforementioned differences could also be explained by player position. In high school, athletes have a dedicated position that they practice and compete in. This could lead to a specialization in tackling or dodging that increases the rotational acceleration as compared to middle school athletes. In middle school, athletes rotate through positions. They might have less position-specialized practice which would allow for players to experience the same high linear acceleration drills.

DEVELOPMENT AND MULTI-LEVEL VALIDATION OF A HUMAN AORTA MODEL FOR TRAUMATIC INJURY

W. Zeng, A. Caudillo, S. Mukherjee, M. Panzer

Center for Applied Biomechanics, University of Virginia, Charlottesville, VA, USA

INTRODUCTION

As one of the leading causes of fatalities in blunt impact, traumatic aortic injury (TAI) is only less prevalent than brain trauma [1]. However, there is no consensus on the injury mechanism of TAI in traffic accidents, mainly due to the complexity of occurrence scenarios, limited field data, and difficulty of reproducing testing conditions for TAI.

About 10 to 14% of traumatic aortic rupture (TAR) occurred at the ascending aorta according to a study on autopsy of victims [1]. Nevertheless, the most frequent site of fatal blunt TAR in traffic accidents, accounting for more than 50% deaths, was found to be at the aortic arch and peri-isthmic region, which is located on the junction between the aortic arch and the descending aorta [2]. Several hypotheses have been proposed to anatomically and/or mechanically explain the mechanisms underlying this injury during nonpenetrating thoracic trauma, e.g., the tethering by ligamentum arteriosum [3], deceleration of the thoracic aorta [4], "shoveling effect" theory [5], "water hammer" effect [6]. Based on testing using nine human cadaver thoraces, Forman et al. (2008) found that the posteriorly directed acceleration alone was not sufficient to generate TAR [7]. Otte et al. (2017) analyzed occurrence, frequencies and mechanisms of TAR in Germany during a 40 years' period (1973-2014), and found that the aortic rupture in most cases was caused by high compression force directly on the thorax [8]. In this work, a computational model of the aorta with nonlinear mechanical characteristics and accurate morphology was developed and integrated within a thorax finite element (FE) model that included all major anatomical structures. To maximize the model's capability for predicting TAI, a multi-level process was presented to validate the model comprehensively.

METHODS

The baseline model of the thorax used in this study was the GHBMC detailed mid-sized male occupant model (M50-O v4.5, by LS-DYNA), which included all major components that form the ribcage and internal organs. Fig. 1 displayed the FE model of the aorta and associated regions. The aortic wall model was created to include nonlinear behavior with a single mean thickness of t=2 mm [9]. The mechanical properties of the aortic wall in published studies exhibited a very large discrepancy [10–14]. Most of these investigations showed that the anisotropy of aorta tissue along longitudinal and circumferential directions was not significant [12,14], or even showed as isotropic without directional dependence [11,13]. As such, in this study we adopted *MAT_Simplified_Rubber (*MAT_181) constitutive model to characterize nonlinear aorta tissue behavior, and the input material response was defined by the mean stress-strain curve averaged from dynamic responses reported in Ref. [10] using fresh aorta tissues.

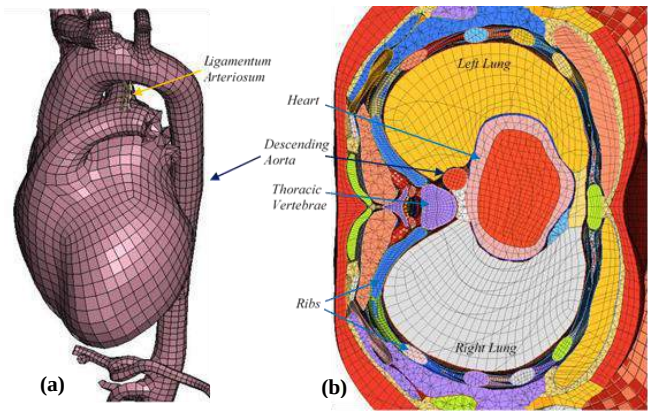

Figure 1: FE model of aorta and thorax: (a) aorta, ligamentum arteriosum and associated heart, and (b) cross-sectional view of the thorax model at T7 level.

Three different sets of experimental data were utilized to validate the developed aorta model. At component level, the *in vitro* aortic pressurization testing was simulated to mimic the aortic burst pressure before rupture [15]. Then, a sled test of a truncated cadaver was modeled

to evaluate aorta response under posterior acceleration [7]. The frontal chest pendulum impact was utilized to validate the performance of the aorta within full body model under direct chest compression [16]. A parametric study was implemented to determine a proper injury tolerance for the aorta under these different loading conditions.

RESULTS

For aortic pressurization, the simulated peak pressure before aorta rupture was 79.5 kPa (the failure threshold was set as MPS=55%), which was within the range of the experimental results [15]. For sled tests under posterior acceleration, the chest deflection and aorta pressure were examined and compared with the experimental data [7]. Fig. 2 compared the cross-sectional aorta pressure between simulation and experimental results. Following the validation by sled test, a validation case involving a chest pendulum impact was simulated. The overall thoracic model performance was evaluated by the force-deflection response under frontal chest pendulum impact. The simulated force vs. deflection response agreed well with the experimental corridor [16].

Our parametric study of aorta failure thresholds showed that when the MPS=50% was adopted as failure strain, several elements exceeded this failure threshold and were deleted on the aortic arch under both sled test and chest pendulum impact. However, the strains (MPS) of these elements were all less than 55%, so a failure threshold of MPS=55% ensured no injury on the thoracic aorta, which matched the results that no aortic injury was observed in the cadavers tested [7,16].

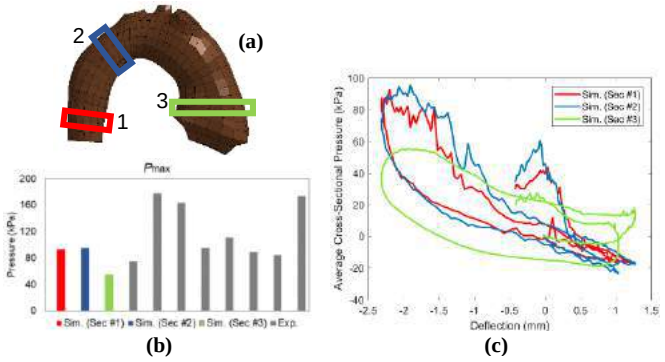

Figure 2: Cross-sectional aorta pressure: (a) three cross-sections selected for pressure measurement, (b) comparison of peak value of the averaged cross-sectional pressure between simulation and experimental data, (c) the cross-sectional pressure-deflection relationship.

DISCUSSION

The mechanism of traumatic aortic injuries remains controversial. Mechanically, major potential mechanisms of TAR associated with loading include excessive intra-aortic pressure, high thoracic acceleration, large stretching and tearing due to chest compression, etc. The primary goal of this study was to develop a computational model of the aorta for blunt traumatic injury prediction, focusing on accurate material and structural representation. To the authors' knowledge, the model developed in this work represents the first effort to provide a multi-level validated computational model capable of predicting traumatic aortic injury. At thorax level, the overall chest deflection was validated against sled testing subjected to posterior acceleration, and the force vs. deflection response of the model subjected to pendulum impact was validated against associated experimental corridor. At the component level of aorta, the peak intraluminal pressure before aortic rupture was validated by the burst pressure obtained from *in vitro* aortic pressurization data, and the cross-sectional pressure of thoracic aorta was validated against the measured pressure due to posterior acceleration. At aortic tissue level, the injury tolerance of aortic wall tissue was determined by the parametric study of tissue failure under all three different experimental testing conditions. Nevertheless, similar to developing other human body models, there are some limitations of this study which can be enhanced in future research. For example, the aorta rupture was not validated by impact loading along the lateral direction due to a lack of experimental data or details, as well as the difficulty to duplicate boundary and loading conditions from the tests [17]. It is expected that this work will encourage additional modeling, validation and biomechanical studies of aortic injuries. The developed aorta model integrated with the thorax FE model will serve as a valuable tool for safety researchers and automobile designers to predict, prevent, and mitigate aortic injuries due to vehicle crashes. In a larger scope, this study provides a framework to improve and validate the biofidelity of future computational human body models for injury prediction and prevention.

INTRODUCTION

Pediatric hydrocephalus (PHC) has a significant human and economic cost making it a national and international public health problem. Complications such as permanent neurological deficits, worsening of neurocognitive outcomes and even death can occur with or without treatment [1]. Post-hemorrhagic hydrocephalus (PHH), with its long-term repercussions, is one of the most serious complications associated with prematurity. 8-38% of low birth weight infants who developed germinal matrix-intraventricular hemorrhage (IVH) during their NICU stay (approximately 20% [2]) will develop hydrocephalus requiring surgical intervention [3]. A combination of clinical and radiographic measures is currently used to diagnose hydrocephalus. In infants, clinical signs include cardiopulmonary instability, rapid head growth, a bulging fontanelle, splaying calvarial sutures and, sometimes, lethargy or vomiting in the most severe cases. Hydrocephalus is diagnosed in association with brain imaging demonstrating enlarged ventricles. Current standard of care for the management of PHC is cerebrospinal fluid (CSF) diversion in the form of ventriculoperitoneal shunt (VPS) placement. Recent studies have analyzed the biochemical profiles of CSF in hydrocephalus, to better understand the pathophysiology of the disease and identify candidate biomarkers of diagnostic and therapeutic value [4]. Despite advances in the field, for example concerning soluble amyloid precursors proteins [5] or markers of extracellular matrix upregulation [6], there is a need for additional tools and strategies for the management of neonatal PHC patients. Since intrinsic brain motion, driven by cardiac pulsatility, is directly coupled with the CSF dynamics, it appears as a potential candidate biomarker for PHC. It has been well established in prior studies that brain dynamics and movement patterns are altered in brain pathologies such as Chiari Malformation type 1 (CM1) [7] and cerebral aneurysms [8]. However, the periodic deformation and movement of the brain associated with hydrodynamic pulsatility are subtle, making them difficult to visualize and quantify on traditional cine MRI images such as phase-contrast cine MRI [9] or DENSE MRI [10]. Recently, we have applied the amplified MRI (aMRI) processing method [11], [12] to Chiari malformation Type I. Using this technique, sub-voxel motion of the brain can be quantified through video amplification and denoising [13]. Considering the pathophysiological variations in CSF dynamics in neonatal hydrocephalus patients, changes in intracranial pressure and CSF flow during the development of hydrocephalus are likely to change brain motion. In this study, we analyzed aMRI scans of a neonate hydrocephalus patient before and after surgery, thereby demonstrating the perturbations in brain motion induced by the pathophysiologic state of pediatric hydrocephalus. By comparing pre-surgery and post-surgery brain motion, we will identify potential markers that could aid in the initial diagnosis of pediatric hydrocephalus.

METHODS

Neonatal patient: The patient is an infant born at 31 weeks gestation by planned Caesarian section for progressive fetal ventriculomegaly. He underwent brain MRI on day of life 1 and was diagnosed with congenital aqueductal stenosis (AS). He was monitored in the neonatal intensive care unit (NICU). His ventriculomegaly progressed and he experienced increasing bulging of his fontanelle with apneic and bradycardic events, prompting surgical treatment with endoscopic third ventriculostomy with choroid plexus cauterization (ETV-CPC) on day of life 22. After surgery he underwent repeat MRI on day of life 30 to demonstrate patent ETV and reduced ventriculomegaly. His post-operative course was uncomplicated.

Imaging protocol: With IRB approval and informed consent, scans were performed on the hydrocephalus patient using a 3T MR imaging system (Skyra, Siemens Healthcare AG, Germany) with a 16-channel

head coil at Icahn School of Medicine at Mount Sinai. 3D cine MRI were acquired using the following imaging parameters: acquisition matrix = 256 x 246, flip angle = 25-26◦, FOV = 180×180 mm^2, TR/TE=17.52/1.82 ms, pixel bandwidth = ±700 kHz, 17-19 cardiac phases, and 14 slices with 2 mm thickness.

3D aMRI algorithm and motion tracking: The aMRI method first applies a spatial decomposition through a complex steerable pyramid [14] to retrospective cardiac-gated cine MRI data. This is followed by temporal filtering and amplification of the MRI cardiac-gated frames with a specific amplification factor ($\alpha = 20$) before synthesizing a motion-amplified cine data set. As a result, aMRI enables subtle motion of the brain to be visualized. To perform the motion tracking of amplified displacement, we used a non-parametric diffeomorphic image registration based on the Demons algorithm. The original Demons algorithm could be considered as an optimization procedure over the whole displacement field space. This optimization procedure was adapted to a diffeomorphic transformation space, to achieve transformations smoother and closer to reality. The final output of this function is a volumetric displacement field which gives a 3D direction and magnitude for each voxel.

RESULTS

After amplification, pre-surgery and post-surgery displacement fields were acquired with Demons registration algorithm (Fig. 1). Ventricles were masked and excluded from the registration algorithm, since these regions showed flickering due to high CSF flow, creating artifacts that interfered with the measurement of displacement. In post-surgery brain volume, a cavity in the forehead was also excluded (Fig. 1b).

In pre-surgery data, a maximum displacement of 0.56 pixels was observed in the top of the brain, between frontal and parietal lobes. The distribution of displacement in the rest of the brain was inhomogeneous, with a mean displacement around 0.30 pixels and localized regions of higher displacement. The density of these higher displacement spots was lower in the occipital lobe region. In post-surgery data, a maximum displacement of 0.98 pixels was observed in the pons region. High displacement spots were located in the pons and cerebellum area. Displacement is the rest of the brain was low and homogeneous, with an average displacement of 0.10 pixel, except for a high displacement spot located in the occipital lobe where the displacement reaches 0.62 pixels.

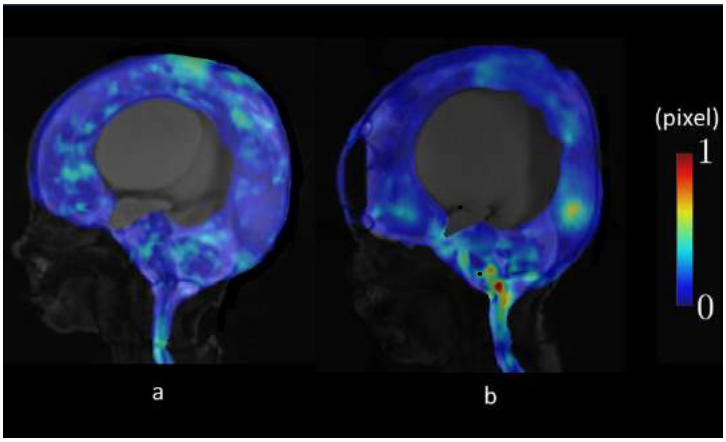

Figure 1: Comparison between pre-surgery (a) and post-surgery (b) amplified displacement fields.

DISCUSSION

In this work, 3D aMRI method was used to compare pre-surgery and post-surgery brain motion in pediatric hydrocephalus patient. Qualitatively, we observed that the brain motion pattern was considerably modified by the surgery. After surgery, high displacement spots were located in pons and cerebellum, when they were located at the top parietal lobe before. Maximum displacement value was also noticeably increased post-surgery, while the displacement field in the rest of the brain is more homogeneous with a lower average value. We hypothesized that changes in intracranial pressure and CSF flow during the development of hydrocephalus were likely to change brain motion. We observed with this case that before surgery, abnormal CSF flow led to unusual high displacement in the parietal lobe and low motion in pons, cerebellum and other hindbrain structures. Then, the surgery has restored normal CSF circulation. This resulted in a motion pattern similar to that observed in healthy subjects [15], with higher displacement located in pons and cerebellum. These results confirmed our hypothesis by showing that, for this case, the abnormal CSF circulation resulted in a measurable change in the brain motion. Absence of high displacement in pons and cerebellum could then be identified as a potential marker for the diagnosis of pediatric hydrocephalus.

Our results showed 3D aMRI's capability as a potential diagnostic tool for pediatric hydrocephalus. With this tool, we demonstrated the differences in brain motion pattern of a pediatric hydrocephalus patient, before and after surgery. This first case seems to confirm that the analysis of brain movements with 3D aMRI is a valid tool to help for the diagnosis, but also to evaluate the success of a surgery and to give proper indications on the prognosis. As a future work, we would recruit more neonatal hydrocephalus patients to assess if the marker identified in this study is generalizable and to confirm that motion analysis with 3D aMRI is feasible and useful in a clinical context.

INTRODUCTION

Tissue engineering aims to create viable and functional engineered tissues via biodegradable scaffolds and autologous cells. Scaffolds play an essential part in organizing the architecture of developing tissues and aid in the proper function of implants acutely by serving as mechanical support and long-term by degrading and undergoing absorption as *de novo* tissue is produced. Typically, isolated autologous cells are seeded onto the polymer scaffold to begin forming viable three-dimensional tissues *in vitro*. These 3-D tissue structures are then deployed *in vivo* where they trigger biological mechanisms for repair, remodeling, and growth to continue developing over time. Biodegradable polymers are preferred as they are easy to manipulate in terms of mechanical strength, degradation rate, and permeability and the porous scaffolds will degrade as new tissue forms resulting in a fully functioning replacement [1]. However, some cases require the seeding of cells onto irregular constructs, which can prove challenging.

Engineered tissue vascular grafts (ETVGs) requires cell seeding onto small diameter tubular scaffolds. The tubular geometry makes it difficult to efficiently deliver cells onto the scaffold surface evenly. Many existing techniques are hampered by the length of time required and complexity of the procedure; however, continued investigation and improvement of methods is essential. Optimizing seeding efficiency relieves current research constraints related to cell availability, prolonged culture protocols, and mechanical and physiological performance. Here, we compare a bioreactor mediated perfusion-seeding method against traditional drip seeding in seeding efficiency. We aim to establish perfusion-seeding as a reliable method for creating engineered tissue vascular grafts for further experiments.

METHODS

A solution of polycaprolactone (PCL; Mn = 80,000) at 14 wt% (w/w) in 1/1 DMF/THF was used for electrospinning of tubular scaffolds suitable for small diameter ETVGs. Resulting scaffolds where approximately 40 mm long, 2 mm in diameter, and 200 µm thick. SV40LT-SMC cells were cultured and expanded in DMEM containing 10% FBS and 200 mcg/mL G418. Between passages 4-6 cells were lifted, isolated and seeded onto scaffolds at a density of approximately 15,000 cells/mm^2 with three distinct methods (Figure 1).

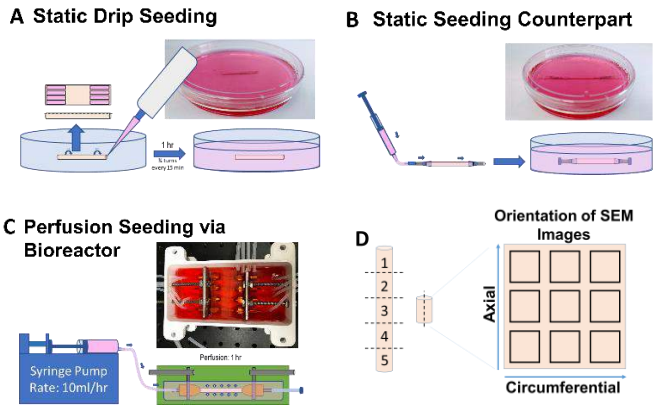

Figure 1: A) Drip seeding method. B) Static counterpart method. C) Perfusion seeding method. D) diagram of scaffold sample orientation for SEM analysis.

A. Static Drip Seeding: using standard seeding procedures, a concentrated cell suspension is carefully pipetted directly onto the lumen of each scaffold. Seeded scaffolds were placed in separate wells, incubated for 1 hour at 37°C, and rotated every 15 minutes. Then the ETVGs were submerged in media with 15% FBS and left in the incubator overnight.

B. Static Seeding Counterpart: Scaffolds were mounted onto shortened cannulas and filled with cell suspension. Scaffolds were then submerged in cell media and left overnight.

C. Perfusion-Seeding: Scaffolds were mounted into our custom bioreactor and seeded via transmural perfusion for 1 hour. After initial seeding the pressure is released and cells are allowed to rest overnight.

After the incubation period (24 hr) is complete, ETVGs are collected and split into 5 sections to be evaluated individually with the goal of characterizing the seeding efficiency of each method across the full length of the scaffold (Figure 1D). We use SEM imaging to evaluate surface coverage over the entire length of the scaffold. We verify cell viability via alamarblue assays. Transmural penetration of cells into the scaffold and phenotype after seeding is evaluated via histology and immunofluorescence. We assessed gross morphology with H&E; collagen with picrosirius red and collagen I and III antibodies; VSMC viability, density, shape, orientation (DAPI), and phenotype with α-SMA and SM-MHC.

RESULTS

Our custom-made bioreactor houses 4 scaffolds for perfusion-seeding and subsequent culture. To test its performance as a perfusion-seeding method, we first mounted scaffolds and perfused dyed fluid through them while taking transluminal pressure readings. Throughout the experiment, dye perfused evenly along the length of the scaffold, and transmural pressure differential never reached over 1 psi through the course of the 1-hour perfusion seeding period at a rate of 10ml/hr. We have verified with SEM imaging that perfusion seeding caused no damage to the microstructure of the luminal surface of the PCL scaffold.

We compared perfusion-seeding against more traditional methods and analyzed seeding efficiency with qualitative and quantitative imaging methods. For SEM imaging, each section was imaged in a 3x3 grid to give an approximate view of the total cell coverage of the luminal surface of the entire scaffold (Figure 1D). SEM only provides a topographical view of the scaffold surface, so individual cells are difficult to pick out, and thick layers of cell aggregates appear as "sheets" covering the scaffold surface (Figure 2). Static seeding methods lead to a concentration of cells along the "bottom" of the scaffold due to gravitational forces. Static seeding methods resulted in a "sheet" of cells forming along the surface of the scaffold, while perfusion methods showed cells penetrating the first luminal layer of scaffold fibers. Drip seeding showed the least amount of cell coverage, mostly restricted to the bottom and both ends of the scaffolds. Histology and immunofluorescence results have corroborated with the those obtained via SEM. Results of viability assays with alamarblue to verify that our perfusion seeding does not impair cell function and they remain viable are currently in progress.

DISCUSSION

The challenges of developing any engineered tissue construct include: (1) determining the appropriate/necessary functional requirements; (2) finding how to engineer an implant meeting them; and (3) predicting its performance after implantation. For ETVGs, a robust cell layer in luminal surface could be beneficial for the continued remodeling of *de novo* tissue after implantation, and relieve problems associated with the development of impenetrable interstitial thrombus [2]. The favored

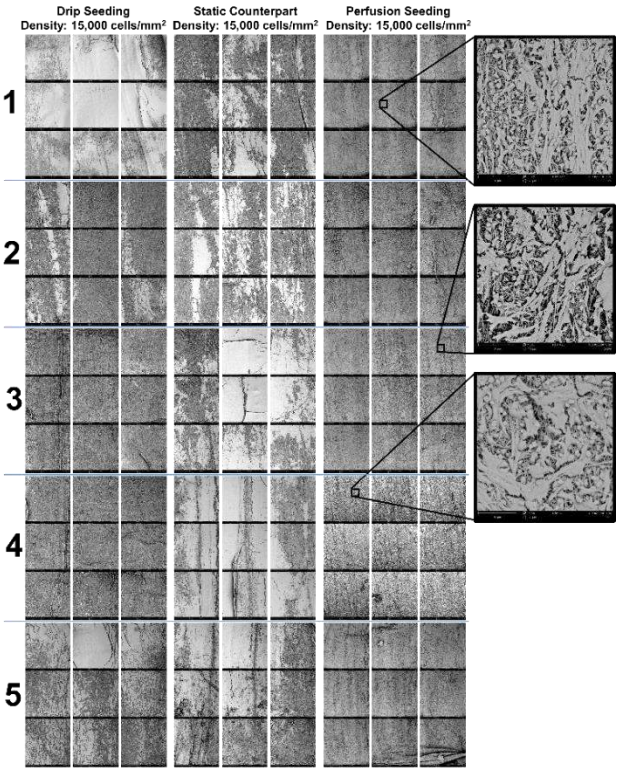

Figure 2: The luminal surface of each scaffold captured with SEM imaging.

methodology to obtain ETVGs is functionalized acellular scaffolds with morphogenic cues to stimulate the regeneration of vascular tissue *in situ* [3]. While this method conceptually shows great promise, the lack of transanastomotic outgrowth of endothelial cells in humans compared to animals and resultant lack of cells in the medial section of ETVGs *in vivo* still poses a serious issue [2].

Our method, like many others, involves bioreactor-mediated *in vitro* culture of ETVGs. However, perfusion-seeding methods are used sparingly, and even fewer attempt to seed ETVG scaffolds on their luminal surface. We believe that creating luminal VSMC layers may serve as a precursor for a basement membrane and help shield the blood-contacting surface from possible inflammatory response initiated by the foreign body response to the implant. We also hypothesize that a confluent VSMC layer will aid in the retention and proliferation of endothelial cells and regulate gene and protein expression essential for native vascular function. The next steps of our research would include extended *in vitro* culture studies, characterization of the mechanical properties of the ETVGs after full term *in vitro* incubation, and pilot studies with small animal models to investigate the host *in vivo* response.

INTRODUCTION

As prosthetic technology evolves, advanced devices for individuals with lower extremity amputation strive to offer more biomimetic features and benefits to users. The Empower (Ottobock, Germany) is one of the most advanced ankle-foot devices currently on the market offering powered push-off at terminal stance. As this technology becomes more widely available, it is important to understand how these devices affect critical gait parameters, such as ankle-foot roll-over shape characteristics. The objective of this preliminary analysis was to determine the effects of using an Empower ankle-foot device (PWR), as well as a device-specific PT intervention, on dynamic function (effective foot length ratio (EFLR), instantaneous radius of curvature (IROC), and radius of curvature (ROC)) for individuals with transfemoral amputation (TFA) compared to traditional energy storing and returning (ESR) prosthetic feet.

Ankle-foot roll-over shape characteristics may be critical in advancing our understanding of the most effective prosthetic designs, which can aid in evidence-based clinical practice and prosthesis prescription guidelines. We hypothesized that the PWR foot would generate roll-over shape characteristics that would suggest improved dynamic functionality compared to ESR feet. We also hypothesized that the PT group would generate improved roll-over shape characteristics at 4 and 8 weeks compared to the non-PT group.

METHODS

Motion capture and kinetic data were captured for 5 people with unilateral TFA during overground walking at the Veterans Affairs New York Harbor Healthcare System (VA NYHHS). Participants were biomechanically assessed at baseline on their current ESR foot and then fit with the Empower device. Participants were then randomized to two different groups during the initial 4 weeks of acclimation to the PWR foot. One group received the standard of care (non-PT group), which included training on the proper use and care of the foot by the study prosthetist and physical therapist (2 participants). The second group also received standard of care, but additionally underwent twice weekly, device-specific PT sessions with the study physical therapist (3 participants) (PT group). The PT program specifically targeted strengthening muscle groups to potentially improve the effectiveness of the PWR foot. Each patient completed a baseline data collection using their ESR foot as well as data collections after acclimating to the PWR foot for 4 and 8 weeks. Center of pressure (COP) data were transformed into the shank coordinate system during single limb stance. EFLR, a measure of the percentage of the foot that is effectively used during a step, was calculated as the distance from the prosthetic heel to the most anterior point of the COP progression divided by the overall length of the foot. Circular arcs of best fit were also applied to the COP data to determine roll-over shape characteristics, such as height-normalized ROC [1]. The IROC was calculated by evaluating the first derivative of COP forward travel with respect to shank angle. The peak IROC is representative of the fastest COP forward travel.

RESULTS

Figure 1 shows that EFLR of the ESR foot at baseline had a value of 0.67±0.04. The PWR foot at 4- and 8-weeks had EFLR values of -0.61±0.04 and 0.60±0.05, respectively for all subjects (n=5). A one-way between subjects Analysis of Variance (ANOVA) suggested a trend toward lower EFLR values of the PWR foot at 4- and 8- weeks compared to the ESR foot ($p=0.07$). Furthermore, the PWR foot at 4- and 8- weeks had peak IROC values of 25.8±7.9 cm and 23.8±4.0 cm, respectively, while the ESR foot at baseline had an average peak IROC value of 31.5±10.7 cm, although differences were not significantly different ($p=0.37$ and $p=0.17$ for 4- and 8- weeks respectively). The

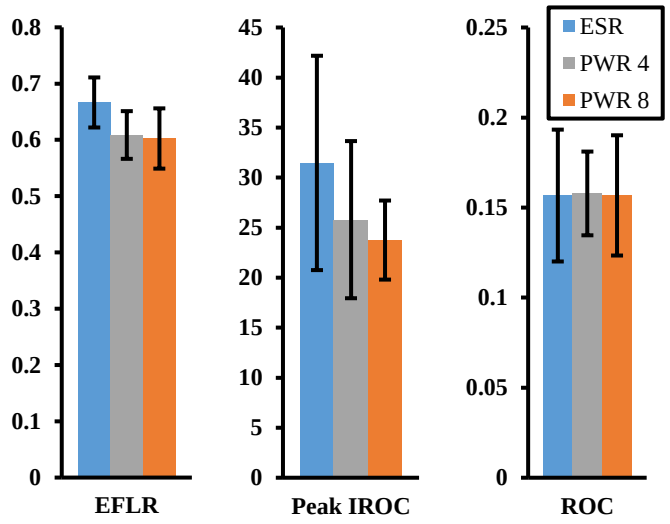

Figure 1: Average EFLR, Peak IROC (cm), and height-normalized ROC for ESR, PWR 4, and PWR 8.

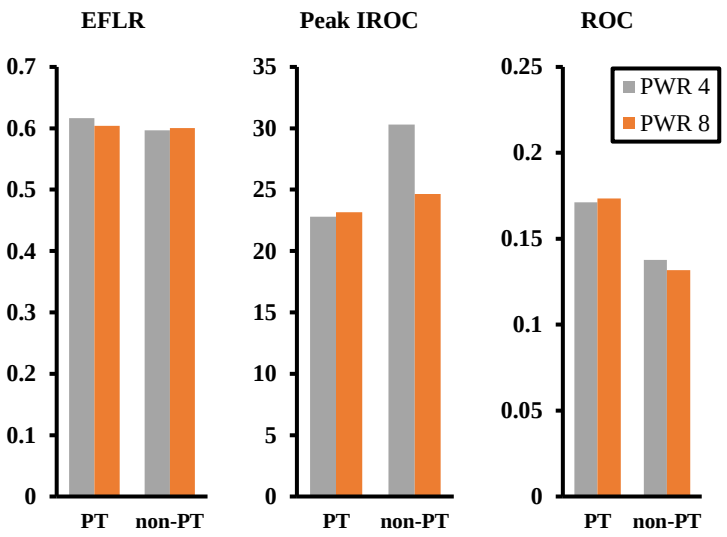

Figure 2: Comparison of PT and non-PT groups average EFLR, Peak IROC (cm), and height-normalized ROC.

height-normalized ROC of the ESR and PWR feet at 4- and 8- weeks were nearly identical (0.16±0.04 ESR; 0.16±0.02 PWR 4; 0.16±0.03 PWR 8).

Figure 2 represents a comparison of ankle-foot rollover shape characteristics between the PT and non-PT PWR groups, though statistical analysis between these groups was not conducted due to the small sample size. Figure 2 shows that the EFLR for the PT group after 4 weeks had a value of 0.62±0.05, while the non-PT group after 4 weeks had an EFLR value of 0.60±0.05. The EFLR of the PT and non-PT groups was similar at 8 weeks (0.60±0.07 and 0.60±0.06, respectively). After 4 weeks, the PT group averaged peak IROC values of 22.8±4.4 cm compared to the non-PT group 30.3±11.9 cm, however peak IROC results may be skewed by an outlier. Finally, the height-normalized ROC for the PT group at 4- and 8- weeks were both 0.17±0.01. The non-PT group had height-normalized ROC values of 0.14±0.03 at 4 weeks and 0.13±0.05 at 8 weeks.

DISCUSSION

The ELFR of the PWR foot at both 4- and 8-weeks showed a trend of being reduced in comparison to the ESR foot. This indicates that the COP did not progress as far anteriorly during single leg stance, which may correlate to a reduced ankle lever arm in late stance, decreasing walking efficiency. Reduced EFLR effectively shrinks the lever arm, potentially limiting the transmission of joint power that the PWR foot is designed to produce. This could highlight an area of improvement for the PWR foot as ESR foot designs may emulate more efficient passive mechanical properties. Although currently only 3 subjects, the PT intervention may slightly improve EFLR after the 4-week PT intervention compared to the non-PT group. This may indicate that a device-specific PT intervention can improve anterior progression of the COP during single-leg stance, improving the walking efficiency of the PWR foot. However, the acute effects were not sustained beyond the PT intervention as shown by the lower EFLR at 8-weeks in Figure 2. This suggests the need for a more-focused home exercise program to help sustain the long-term EFLR improvements. As more participants complete the protocol, EFLR may become a key parameter that shows improvement from a PT intervention.

The PWR foot also demonstrated decreased forward travel, as indicated by lower peak IROC compared to ESR feet, which suggests reduced stability [2]. Figure 2 shows that the non-PT group showed slightly higher peak IROC compared to the PT group however, the non-PT group saw a reduction in peak IROC from 4 to 8 weeks. PT training focused on initiating pelvis movement may have promoted a smoother transition from heel to toe rocker.

This preliminary data set showed no overall differences in ROC between the ESR and PWR feet. Potential differences in ROC can be seen between the PT and non-PT groups, though ROC values did not change from 4 to 8 weeks for either group. The non-PT group showed reduced ROC compared to the PT group. This result could suggest improved stability for the PT group during single leg stance because the foot is rotating about a larger rocker which may be resultant from focused muscle strengthening over the 4-week intensive PT program.

Although large changes in roll-over shape parameters have been shown to affect aspects of gait, it is unclear if the changes seen in this study are clinically relevant. Of note, the PWR foot is specifically designed to provide powered plantarflexion at terminal stance and is therefore not active during the single limb stance phase in which this analysis was conducted. This preliminary analysis of ankle rollover shape characteristics suggests that overall, the PWR foot may exhibit less efficient passive mechanical properties than the ESR feet. The PT group is showing trends of improvement in some parameters and may generate benefits over the standard of care. These results can inform clinicians of the benefits of prescribing the PWR foot along with a device-specific treatment. Additionally, manufacturers can design new componentry and devices to improve the current design with more attention to the passive components.

THE EFFECT OF HEMATOCRIT ON THE VISCOELASTIC BEHAVIOR OF EMBOLUS ANALOGS

Bryan C. Good (1)

(1) Mechanical, Aerospace, and Biomedical Engineering
University of Tennessee
Knoxville, TN, USA

INTRODUCTION

An estimated 700,000 acute ischemic strokes (AIS) occur each year in the Unites States, as a result of embolic occlusion of a cerebral artery. In spite of the improved recanalization rates of cerebral arteries, by means of novel stent retriever devices, 15% of patients' arteries still cannot be recanalized. In addition, 17% of patients with successful arterial recanalization die within 90 days [1]. Currently there is little understanding as to why some thromboemboli are successfully removed, and others are not. In order to improve our understanding of thromboemboli adhesion and removal in AIS, we must first be able to characterize their mechanical properties and accurately model their behavior. Therefore, we are developing embolus analogs (EAs) from bovine whole blood to mimic the properties of human thromboemboli in AIS patients and experimentally measuring their complex viscoelastic properties.

METHODS

EAs were created from bovine blood collected in CPDA-1 anti-coagulated bags (LAMPRE Biological Laboratories, Pipersville, PA). The whole blood was then separated into its components using a centrifugation protocol and reconstituted to maintain consistent concentrations of red blood cells (RBCs) and platelet-rich plasma (PRP). Coagulation of the reconstituted blood was initiated with the introduction of $CaCl_2$ at a concentration of 20 mMol in blood and allowed to clot for four hours in one of two methods: 1) statically in 50 ml falcon tubes or 2) dynamically on an orbital shaker in 6-well plates. The cylindrical falcon tube clots were cut with a scalpel into disk shapes that were less than half as thick as they were wide to avoid buckling during compressive loading (approximately 20 mm diameter and 10 mm thickness). The well plate clots were removed from their individual wells and tested as is (approximately 30 mm diameter and 12 mm thickness). The exact thickness and diameter of each individual sample was measured prior to testing using digital calipers.

Figure 1: Cyclic compression testing of dynamically formed EAs to measure their viscoelastic behavior.

To investigate the effect of hematocrit on EA mechanical properties, the separated RBCs and PRP were recombined at varying ratios from 0% to 60% hematocrit in 10% increments to represent the range of clot compositions seen clinically. Two different cyclic compression testing protocols were used with a Single Column Materials Testing System and a 50N load cell (Instron, Norwood, MA). All samples were pre-loaded to 0.01 N and then cyclically compressed for four cycles to allow for preconditioning [1]. The first protocol, applied to the static EAs, consisted of compressing the clots to 50% of their original thickness at a rate of 0.1 Hz, while the second protocol was conducted at 1 Hz. These protocols were chosen to investigate any differences in loading frequency and with the 1 Hz frequency to closely mimic the expected loading conditions of lodged thromboemboli in cerebral arteries under 60bpm pulsatile blood flow. A total of eight samples were tested and averaged for each composition and loading condition, with blood coming from two separate donor animals (n = 4 for each).

RESULTS

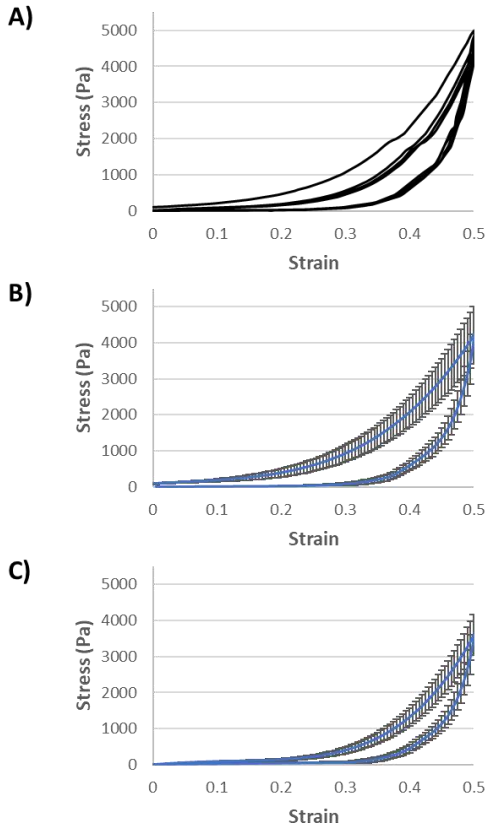

Figure 2: A) An example stress-strain cyclic loading curve for a single 50% hematocrit EA loaded at 0.1 Hz. Averaged data of the B) first cycle and C) fourth converged loading cycles for eight 50% hematocrit EAs.

As observed in **Fig. 2**, the bovine EAs exhibited hyperelasticity, hysteresis (an indication of viscoelasticity [2-4]), and cyclic softening. Example stress versus strain data for a single EA is shown in **Fig. 2A**. Cyclic softening is also clearly observed over the initial loading cycles, but an approximately cyclic steady state was achieved by the third cycle. The averaged stress-strain response from both the first and final (converged) loading cycles for the 50% hematocrit EAs loaded at 0.1 Hz are shown in **Figs. 2B** and **2C**, respectively. Peak stresses at 50% compression were measured to be 6302 ± 1203 Pa during the first loading cycle and 5395 ± 828 Pa in the final converged loading cycle. Under monotonic compressive loading, the EAs behaved linearly up to a strain of approximately 10% with an elastic modulus of 979 ± 157 Pa.

In **Fig. 3**, stress-strain data is shown for EAs of varying hematocrit under 1 Hz compressive loading conditions during the fourth converged loading cycle. As hematocrit increased, from 0-60%, there was a drop in maximum applied stress (19,500 Pa to 11,700 Pa, respectively). Additionally, large differences were observed in the results from **Fig. 2** to **Fig. 3**, with the higher loading frequency (1 vs. 0.1 Hz) leading to larger applied stresses.

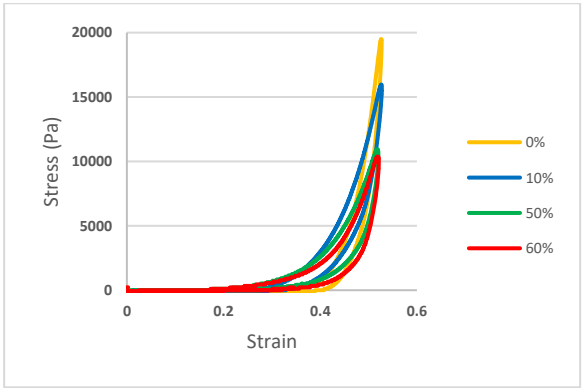

Figure 3: Stress-strain cyclic loading curves for 0, 10, 50 and 60% hematocrit EAs loaded at 1 Hz.

DISCUSSION

These results clearly display a viscoelastic behavior of EAs that is highly dependent on both the amount of RBCs and plasma in their composition as well as the cyclic loading conditions used for mechanical testing. Both higher frequency loading and decreased levels of RBCs both led to larger peak stresses.

Future work will further elucidate the effects of cyclic frequency to determine how clots could behave differently *in vivo* depending on how they are loaded during mechanical thrombectomy procedures. Additionally, EA compositions will be further investigated histologically to determine if the distribution of RBCs, platelets, and fibrin within the EA structure has an influence over their mechanical behaviors.

DEVELOPING COMMUNITY TO SUPPORT FIRST GENERATION FRESHMAN IN AN ENGINEERING PROGRAMMING COURSE

Sara E Wilson (1,2), Molly A McVey (1), Nolan M Norton (2)

(1) Mechanical Engineering
University of Kansas
Lawrence, Kansas, USA

(2) Bioengineering
University of Kansas
Lawrence, Kansas, USA

INTRODUCTION

First generation students, typically defined as students for whom neither parent received a 4-year college degree, face unique challenges in college. It is estimated that 15 to 40% of college students in the US are first generation students (1-3). First generation students have been found to have an achievement gap when measured by degree completion and time to degree (2). In Mechanical Engineering at the University of Kansas, we observed in a sophomore course that first generation students, who made up 6.5% of the course population, had an average grade substantially lower than the overall classroom population (2.20 versus 2.83). By the subsequent junior level course, first generation students only made up 4.5% of the population.

First generation students are, on average, from lower income households (2,4). These students are also disproportionally from underrepresented racial and ethnic groups (2,5). But more importantly, these students as a whole may lack the "cultural capital" or inside knowledge of how to succeed in college that many of their continuing generation peers may have (2-3). These students may suffer from many of the challenges that other underrepresented groups face such as stereotype threat and imposter syndrome. These challenges have been exacerbated by the COVID pandemic and the move to online and hybrid courses.

In Galina's work, a number of methods are proposed to tackle the challenges first generation students face (2). These include 1. increasing transparency of expectations, 2. teaching study skills that may be missing due to the limited inside knowledge of these students, 3. organizing study groups to build social network, 4. using rubrics to communicate expectation, and 5. developing personal relationships with students to improve dialog.

In this abstract, we will examine one course, a freshman programming course for engineers, and the use of several proposed mechanisms to support first-generation students in hybrid/online learning.

METHODS

ME 208 is an introductory programming course in Mechanical Engineering at the University of Kansas. This course is typically taken in the freshman year. The course was transitioned to a hybrid/online course in Fall of 2020 in response to the COVID pandemic. Students have the option to attend entirely online or in a hybrid mode with online instruction and in person laboratories. One hundred students took the course. The course covers Arduino (C++) programming for the first half of the course and Matlab programming for the second half of the course. The Arduino component required students to program, wire, and instrument microcontroller boards. For this portion of the course, students purchased a Sparkfun Inventor's Kit which included a Arduino-compatible board (Redboard), a breadboard, jumper wire, sensors, LEDs, and motors (https://www.sparkfun.com/products/15267, Sparkfun, Niwon, CO).

The course had 4 major elements each week:
1. Weekly prerecorded tutorial videos on concepts for the week with a comprehension quiz
2. A Monday, 45 minute, live, online class in which students were oriented towards the tasks of the week
3. A 15 minute project online group meeting with the instructor and/or graduate teaching assistants in which groups worked on two course projects (one in Arduino and one in Matlab) and
4. A 45 minute in person or online laboratory with a follow on homework assignment.

The course also had 4 exams, two on Arduino topics and two on Matlab topics.

To tackle the issues of social isolation and help all students (including first generation students) develop networks, project groups were created with 6-7 students in each group. The teams were given a channel within Microsoft Teams to facilitate communication, share files, and organize group meetings. These project groups met with an instructor each week to work on two projects over the course of the semester. For the first project (Arduino), the groups needed to come up with a device that used at least one sensor and one motor. The group was expected to write the code together, but each student was expected to build a prototype from their own kit. Examples of projects created for this first project include an automated toilet flusher and a temperature sensitive fan. The second project in Matlab was to design a STEM related game for second grade children. The game needed to include a variety of programming elements including a graphical display, functions, loops, and if/else conditions.

With approval of the University of Kansas human subjects committee, students were invited to participate in an anonymous survey at the end of the semester. This survey included questions about obstacles faced and questions about the usefulness and importance of different elements of the course in learning.

RESULTS

Thirty-one students completed the survey (31% response rate), but one did not answer the question about being a first-generation student, so only thirty responses were analyzed for this data. Six of the thirty (20%) self-identified as first-generation college students. Consistent with previous studies, first generation students reported finding work and family responsibilities more of an obstacle to learning (Figure 1). These students also were more likely to identify a lack of in person coursework as an obstacle to learning.

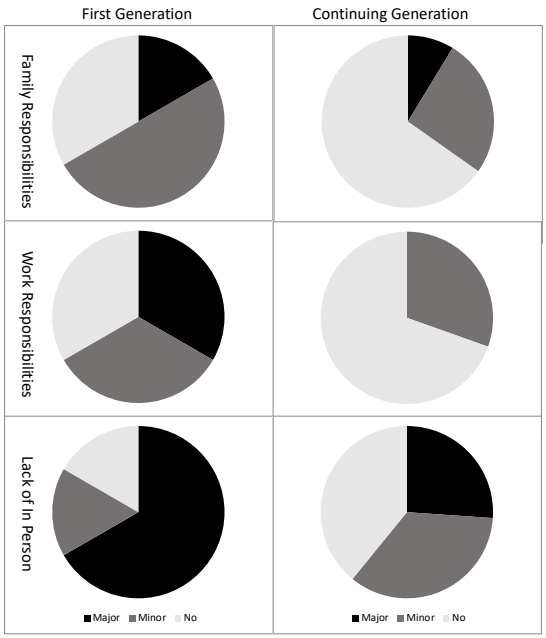

Figure 1. These charts illustrate the obstacles to learning. First generations students were more likely to say family and work responsibilities were a major or minor obstacle to learning.

The project groups were designed to encourage students to connect with each other and facilitate learning teams. The vast majority of students found their project group members to be slightly or very important sources of assistance outside the classroom (Figure 2). However, first generation students were more likely to rely on faculty or teaching assistant office hours and less on other students and outside materials (such as from the Mathworks and Arduino websites) for assistance. First generation students also rated provided materials and exercises (weekly videos, labs, homework, and exams) as more useful to their learning.

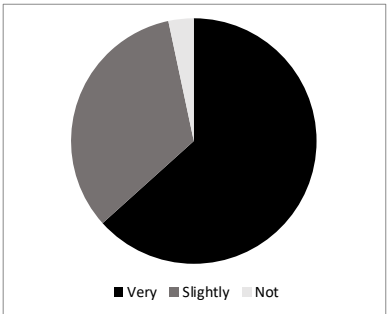

Figure 2. Students found project team members to be an important source of support outside the classroom.

DISCUSSION

The results from this first semester have indicated that having project work that brings students together but also requires individual contributions is effective in developing networks for students to succeed, particularly during the hybrid and online course models of a pandemic. For first generation students, this may be particularly important. However, it was found they did not utilize these networks as much as continuing generation students. In the Spring 2021, the course will be again run as a hybrid/online course. Some modifications will be made to increase the effectiveness of the teams. In particular, group active learning exercises with the teams will be added to the Monday online orientation session to further develop the group. The survey will be repeated with this cohort to examine change in how students utilize resources.

INTRODUCTION

As cycling increases in popularity both as a sport and as a rehabilitation activity, its effects on overall joint health have become an area of interest. The relationship between knee joint forces, moments, and range of motion (ROM) can influence hip and knee joint health (i.e., osteoarthritis, patellofemoral disorder, ligament damage, etc.). Reducing hip and knee joint forces has been seen to result in reduced lower limb injury risk [1]. Hip and knee joint compressive forces and ROM may differ based on varying crank lengths (CL) on a bicycle. Increases in crank length has been shown to have increased peak hip extension and flexion joint powers [2]. Currently, no studies have analyzed the effects of crank length on resultant forces in cycling. The purpose of this study was to examine the effects of four different CL (155, 165, 175, and 185mm) on ROM and resultant compressive forces on the hip and knee.

METHODS

Participants. Twenty-six non-cyclists (12M, 14F, aged 18-55) participated in a single blind randomized cross-over experiment with four CL. Participant characteristics are shown in Table 1. Seven of the participants were excluded from the kinetic data analysis due to error, but all were used for kinematic data for corresponding ROM.

Table 1. Participant Characteristics, Mean ± SD shown.

Participants	N = 26
Age (years)	29.2 ± 11.4
Height (cm)	174.0 ± 8.2
Weight (kg)	69.9 ± 13.0
BMI (kg/m^2)	23.0 ± 3.3
Weekly Training (hrs/week)	6.9 ± 4.3

Equipment. A 12-camera 3D motion analysis system with Cortex software (Motion Analysis Corp., CA, USA) was used to capture kinematic data. Kinetic data was collected using a stationary bike (SRM IndoorTrainer, Germany) retrofitted with custom pedals containing 6-axis load cells (AMTI, MA, USA).

Protocol. An Enhanced Helen Hayes marker protocol was used to place 32 retroreflective markers on anatomical landmarks to track kinematic data (Figure 1). A 3-minute warm-up for each CL was performed at 1.5 W/kg and 70 rpm. 4x1 minute trials were conducted at 2 W/kg. The first two trials were at a constant cadence of 70 rpm and the second two trials were at a constant pedal speed (PS) of 1.47 m/s (RPM = 90, 85, 80, 76 rpm respectively). This value was determined by Equation (1). There were 10 seconds of rest between trials and 5 minutes of recovery between each condition. Saddle and handlebar height was adjusted for each condition to maintain the same height for corresponding crank length.

Data Analysis. Kinematic data was processed using Cortex software and filtered (4th order Butterworth, cutoff 6 Hz) (Figure 2). Kinetic data was filtered using MATLab (MathWorks, MA, USA). All data was averaged from 30 seconds of each trial. A repeated measure ANOVA was performed with Tukey post hoc comparisons.

Equations

$$RPM = (1.47 \text{ m/s} \times 60)\,(2\pi \times CL)^{-1} \quad (1)$$

Figure 1. Experimental Setup

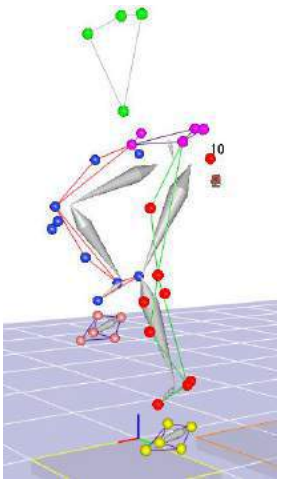

Figure 2. Cortex Processing

RESULTS

During submaximal cycling, the 155 and 165mm CL had a significantly smaller hip ROM compared to the 185mm CL (42.20 & 44.22 degrees vs. 48.34 degrees, p= 0.000 & 0.028 respectively) (Figure 3). ROM at the knee was also significantly smaller between the 155mm CL and the 185mm CL (72.67 degrees vs. 79.52 degrees, p= 0.008) (Figure 4).

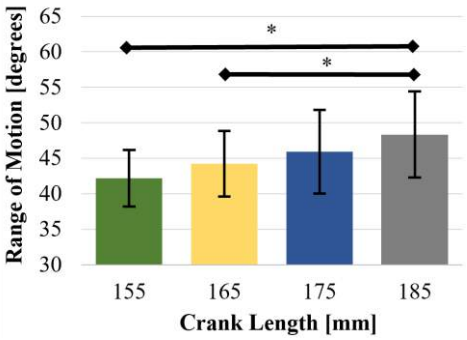

Figure 3. Hip ROM Across the CL. Mean ± SD shown.
*** = significant difference (p<0.05)**

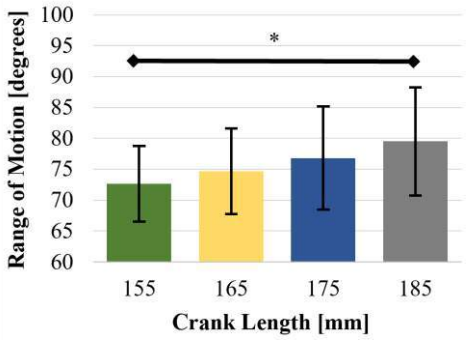

Figure 4. Knee ROM Across the CL. Mean ± SD shown.
*** = significant difference (p<0.05)**

The maximum compressive forces on the knee and the hip at 70 RPM and at a constant pedal speed of 1.47m/s showed no significant difference between CL (p>0.05). Maximum compressive force values for each CL are shown below for the hip (Table 2) and knee (Table 3). The constant pedal speed trials produced lower peak knee and hip compressive forces across all CL (Table 2 & 3) compared to the 70 RPM trials.

Table 2. Maximum Compressive Forces on the Hip, Mean ± SD

CL (mm)	70 RPM (N/kg)	1.47 m/s (N/kg)
155	1.35 ± 0.37	0.82 ± 0.33
165	1.26 ± 0.41	0.84 ± 0.33
175	1.15 ± 0.39	0.84 ± 0.31
185	1.03 ± 0.34	0.85 ± 0.31

Table 3. Maximum Compressive Forces on the Knee, Mean ± SD

CL (mm)	70 RPM (N/kg)	1.47 m/s (N/kg)
155	2.88 ± 0.38	2.50 ± 0.33
165	2.82 ± 0.42	2.57 ± 0.32
175	2.74 ± 0.40	2.57 ± 0.30
185	2.66 ± 0.37	2.54 ± 0.32

DISCUSSION

Hip and knee ROM were significantly greater with a longer CL. Cycling is a useful tool to help restore range of motion during rehabilitation without increasing strain when a person is recovering from an injury to their hip or knee. Using a shorter crank arm would allow for a reduced ROM to assist in rehab efforts.

The constant pedal speed trials at 1.47 m/s produced lower peak knee and hip compressive forces across all crank lengths compared to the 70 RPM trials. If your goal is to lower peak compressive forces, at any CL, picking a higher cadence may be ideal. However, further statistical analysis needs to be conducted.

There were no significant differences in either knee or hip compressive forces across the various CL. The lack of a significant difference reveals that a change in crank length would reduce concerns about any adverse effects it may have on the hip or knee joints. 25% of the population will experience anterior knee pain sometime during their life and for cyclists, the knee joint is one of the most affected by overuse injuries [1]. Whether you are changing crank length for fit, comfort, advantage, etc., you should be able to do so without developing concerns regarding any adverse effects. This finding is beneficial to the countless people who are prescribed cycling has a rehabilitation activity after injury.

These findings add to previous research that found that CL on a bicycle may affect knee and hip joint compressive forces and ROM [2]. Barrett concluded that increases in CL will increase peak hip extension and flexion joint powers. Our findings took these results one step further to show that different CL effect ROM, but do not significantly affect compression forces. No other studies had yet analyzed the effects of crank length on resultant forces in cycling.

Some limitations faced during this study included excessive sweating and loose clothing that may have altered placement of the retro-active markers, software complications that limited the data pool for analysis (some data had to be excluded), and that our pedal configuration did not allow for the foot to be locked in place, therefore possibly altering our results.

During future analysis of our study, trials will be processed through OpenSim along with EMG data to better analyze direct bone to bone contact forces of knee joints.

INVESTIGATION OF ELASTIC MODULI OF MINERALIZED COLLAGEN FIBRIL AND EXTRAFIBRILLAR MATRIX IN BOVINE CORTICAL BONE USING PEAKFORCE TAPPING ATOMIC FORCE MICROSCOPY

Y. Zhou (1), J. Du (1)

(1) Department of Mechanical Engineering
Pennsylvania State University
State College, PA, USA

INTRODUCTION

An important function of bone is its load-bearing capacity. Bone is a bio-composite that consists of organic and inorganic components. The strength and toughness of bone arises from assembly of these components at multiple scales. Understanding the elastic properties of bone at micro- and nano- scales is important because it can help understand the strengthening and toughening mechanisms of bone; generate inputs for the computational models at micro- and nano- scales; and inspire the design of manmade materials.

The elastic properties of the mineralized collagen fibril (MCF) and the extrafibrillar matrix (EFM) have not been thoroughly characterized. Atomic force microscopy (AFM) has been used in AFM-based tension test of single collagen fibrils[1,2] and AFM-based nanoindentation of bone and cartilage[3,4].

In this work, PeakForce Tapping AFM was used to scan the surface of cut and polished surfaces of bovine cortical bone, when they were submerged in water. The elastic modulus maps were obtained for scans in micro-meter scales. The elastic moduli of mineralized collagen fibrils and the surrounding matrix were extracted and calculated, respectively. The structural and compositional variations that may underly the variations in the measure elastic moduli were discussed.

METHODS

The fresh bovine femur of a 20-month-old cow was obtained from Pennsylvania State University Meat lab. The soft tissues and bone marrow were removed mechanically. Several strips in the mid-diaphysis portion at the posterior side was cut. They were dominated by the haversian bone. They were sectioned into thin slices with its surfaces perpendicular to the longitudinal axis of the femur by a precision saw with diamond blade (Isomet 1000 Precision Cutter, Buehler, Lake Bluff, IL). The size of each specimen was about 10 mm × 10 mm × 1.5 mm.

The specimens were polished by a grinder polisher (EcoMet 30, Buehler, Lake Bluff, IL) using silicon carbide grinding papers with progressively finer grit of 800 and 1200 and then using diamond suspension with grades of 6, 3, 1, 0.5 and 0.1 μm on silk polishing cloths (South Bay Technologies, San Clemente, CA and SMS Labs, Sturbridge, MA). After each round of polishing, they were cleaned in an ultrasonic cleaner (Branson Ultrasonics, Danbury, CT) in deionized (DI) water for 2 minutes. The polished and cleaned specimens were glued onto petri dish using epoxy resin, and was kept moisturized in modified Hanks' Balanced Salt Solution (HBSS) (Sigma Aldrich, St. Louis, MO) until testing.

The elastic modulus map of the polished surfaces on the bone specimens were measured using an AFM (BioScope Resolve, Bruker, Billerica, MA) under PeakForce Tapping mode. Etched silicon AFM probe (RTESPA-525, Bruker, Billerica, MA) was used to scan the polished surface of the bone specimens submerged in DI water. The deflection sensitivity of the probe was calibrated on a sapphire sample (SAPPHIRE-12M, Bruker, Billerica, MA). The setpoint was 400 nN; the peak force frequency was 1kHz; the scan rate was 0.5 Hz. Several scans with size small than 10-μm were obtained at different locations of the specimens. The number of points being tapped in each scan was 256×256.

At each tapping point, cantilever deflection and the vertical position of the AFM tip were recorded. The load-separation relationship was given by the Derjaguin-Muller-Toporov (DMT) model, which has a Hertzian contact profile. The AFM probe was calibrated on a highly oriented pyrolytic graphite sample (HOPG-12M, Bruker, Billerica, MA) with a known nominal elastic modulus of 18 GPa. The elastic modulus of the specimens at each tapping point was be obtained by fitting the load-deformation curves during tip retraction in NanoScope analysis software (Bruker, Billerica, MA).

The elastic moduli measured from the mineralized collagen fibril and the extrafibrillar matrix regions were extracted and compared using t-test using Minitab software (Minitab, LLC, State College, PA). The histograms of the elastic moduli of MCF and EFM were modeled the sum of general normal distributions, respectively, using OriginLab software (OriginLab Corporation, Northampton, MA).

RESULTS

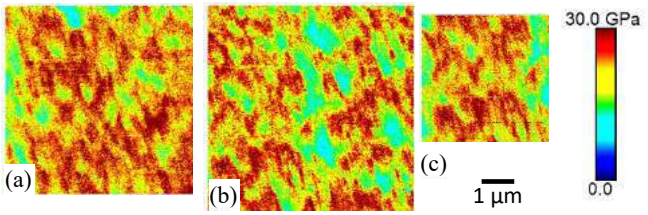

Figure 1: Elastic modulus map of bovine cortical bone showing the mineralized collagen fibril bundles and surrounding matrix (scan size: 6, 6.6 and 4 µm, respectively)

Structures of softer fibril bundles surrounded by harder matrix were observed in both the osteons and the interstitial bone in the scans. Representative scans at three different locations are presented in Fig. 1. The elliptical shape cross sections of the MCF bundles had 0.58 – 1.25 µm major axis and 0.22 – 0.49 µm minor axis. In spite of variations in major and minor axes, the aspect ratio is relatively consistent between different bundles, ranging from 2.34 to 2.72. The elastic moduli for the MCF bundles and EFM, were measured to be 12.94 ± 2.71GPa (n = 4,200) and 28.39 ± 5.75 GPa (n = 7,564), respectively. The difference was statistically significant ($p < 0.05$).

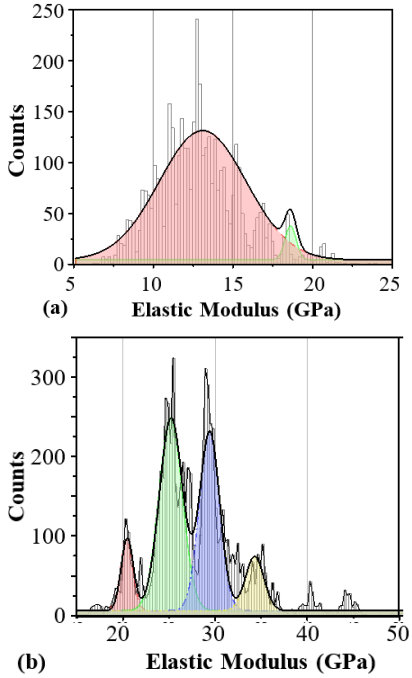

Figure 2: Histograms of elastic moduli for (a) mineralized collagen fibril bundles and (b) extrafibrillar matrix.

Fig. 2 present the histograms of elastic moduli measured in the MCF bundles and the matrix, respectively. The histograms for MCF bundles were modeled by summations of 2 general normal distribution functions with the mean values of 12.48 GPa and 16.90 GPa. The histograms for the matrix were modeled by summations of 4 general normal distribution functions with the mean values of 20.52 GPa, 25.27 GPa, 29.46 GPa and 34.33 GPa. The coefficients of determination, R2, of the curve fittings were 0.8 and 0.87, respectively.

DISCUSSION

In prior works, the elastic modulus of collagen fibrils and MCFs was calculated to be 1.3 - 6.23 GPa by molecular dynamics [5,6]; the elastic modulus of collagen fibrils in air-dried bovine Achilles tendon and MCFs in deer antler was measured to be 2-7 GPa by AFM-based tensile test of single fibrils[1,2]. These are lower than the elastic modulus of MCF measured in this work. The higher values measured in the current work may be attributed to the testing condition in which the specimen was fully submerged in water or to the different species and anatomic locations of the specimens. Harley et al. reported that collagen fibres in NaCl solution have a higher elastic modulus than the elastic moduli of air-dried and dry collagen fibres[7].

Moreover, in this study, the elastic modulus of MCF bundles were measured to lower than that of the matrix. It indicates that the MCF bundles have less mineral content than the matrix.

The histogram for the elastic modulus of MCF bundles (Fig. 2a) was dominated by one general normal distribution. It indicates one dominating angle between the fibrils long-axis and the AFM tapping direction, which is also the long axis of bone. It is consistent with the rope-like twisting fibril structures inside the bundles[8], in which the angle between each single fibril and the long axis of the MCF bundle is the same. In contrast, the 4 general normal distributions in the histogram for EFM (Fig. 2b) can be attributed to the random orientations of fibrils, substantial ground substance, and sub-micron voids[9].

INTRODUCTION

Microfluidic encapsulation of cells/tissues in hydrogel microcapsules has attracted tremendous attention in the field of cell-based medicine [1,2]. However, when encapsulating rare cells and tissues (e.g., pancreatic islets and ovarian follicles), the majority of the resultant hydrogel microcapsules are empty[3,4]. Empty capsules should be excluded from the sample because it makes downstream processing difficult and is undesirable for cell/tissue transplantation because *in vivo* space is limited[5]. Furthermore, the cell-laden hydrogel microcapsules are usually suspended in an oil phase after microfluidic generation, while the microencapsulated cells require an aqueous phase for culture/ transplantation and long-term suspension in oil could compromise the tissues[6]. Therefore, an effective method for selective extraction of cell-laden microcapsules from oil into an isotonic aqueous phase timely on-chip can be very important to maintain the cell quality for use in clinical settings. Contemporary extraction methods either require labeling of cells for their identification which can be detrimental for downstream processing and expensive detection systems or have a low extraction purity (< ~30%)[7-9]. Here, we utilize a deep learning neural network system to detect cell aggregates present in microcapsules and sort them on-chip into cell-laden and empty microcapsules and report high efficiency of detection (~100%) and extraction (~97%), high purity of extraction (~90%), and high cell viability (>95%).

METHODS

Experimental Setup. As illustrated in Figure 1a, the system consists of a microfluidic device for microcapsule generation, a cell phone camera for imaging the on-chip detection area, a deep learning model for detection via analyzing the video frames from the camera in real-time, and a microcontroller that receives the output from the deep learning model and controls the switch to activate/deactivate the DEP-based extraction. The workflow of our approach is illustrated in Figure 1b. In the microfluidic device, an aqueous solution of sodium alginate containing cell aggregates is connected to inlet 1 (I1), the oil emulsion containing $CaCl_2$ for gelling the sodium alginate solution into calcium alginate hydrogel is connected to I2, and the isotonic aqueous extraction solution is connected to I3. The microcapsules further flow into the detection region (ii) where images are taken by a cell phone camera via the objective of a bright-field light microscope. An iPhone 7 cell phone is attached to the microscope eyepiece, streaming video to the computer. The deep learning model on the computer analyzes the input images in

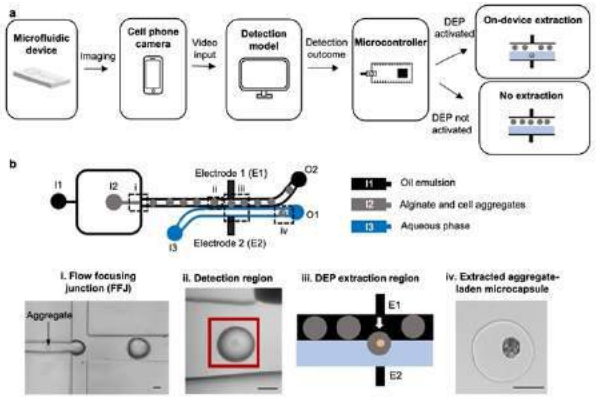

Figure 1. Overview of the deep learning-based detection and extraction system. (a) Flow chart of the overall system design and order of operations. (b) A diagram of the microfluidic device showing its use for generating microcapsules and the deep learning-based label-free on-chip selective extraction of the cell aggregate-laden microcapsules. Scale bar: 100 µm.

real-time to determine if the microcapsule currently in the detection region contains a cell aggregate or is empty. A microcontroller controls a switch that turns on when the model determines there is a microcapsule containing a cell aggregate in the detection region. When the switch is turned on, an electric field is applied across the microchannel via the two electrodes (E1 and E2) to generate DEP force for selectively extracting the cell aggregate- laden microcapsule from the oil emulsion into the isotonic aqueous extraction solution (iii). The extracted microcapsules then flow to outlet 1 (O1, iv) and non-extracted capsuled are collected at outlet 2 (O2).

Deep Learning Model. A deep learning model is utilized to enable label-free detection of cell aggregate-laden microcapsules in real time in this study. This is achieved through training the deep learning neural network model using pre-labeled (i.e., with or without a cell-laden microcapsule) images of the detection region. The detection model is based on the single shot multibox detector (SSD), a current state-of-the-art model for object detection[10]. Three backend models that are first pre-trained on the COCO dataset, an open source dataset of labeled images used for model training, are compared[11].

Purity and Efficiency. To determine the detection efficiency, videos of the detection region are analyzed, and the number of cell aggregates is counted. The detection efficiency is defined as the percent of cell aggregate-laden microcapsules that the deep learning program detects out of all the cell aggregate-laden microcapsules passing through the detection region. To determine the selective extraction efficiency and purity as well as cell viability, microcapsules are collected from both the aqueous outlet O1 and oil outlet O2 (Figure 1b). Extraction efficiency is defined as the percent of cell aggregate-laden microcapsules that were collected containing aggregates out of all aggregates collected from both channels. Extraction purity is the percent of cell-aggregate laden capsules out of the capsules collected from O1.

RESULTS

Based on the speed needed for real-time detection and the imaging rate of the iPhone 7 camera, an acquisition speed of 30 frames per second (fps) is chosen. MobileNet was chosen as the backend structure based on the need for real-time application at 30 ms determined after running a model time comparison[12]. A video frame breakdown of the deep learning-based detection and selective extraction is shown in Figure 2a. The detection region is indicated by a green box (Figure 2a.1) that turns red when the model detects a cell aggregate-laden. If a cell aggregate-laden microcapsule appears in the detection region (Figure 2a.2-3), the computer program sends a corresponding signal to the microcontroller which activates DEP to extract the cell aggregate-laden microcapsule from oil emulsion into the aqueous phase (Figure 2a.4-6). If no cell aggregate-laden microcapsule is detected, DEP stays off and the microcapsule continues to flow down the oil channel (Figure 2a.7-9). It is determined that the deep learning-based label-free method can detect cell aggregates (50-250 µm in diameter) with an ~100% detection efficiency (Figure 2b). The extraction efficiency and purity of the cell aggregate-laden microcapsules in the selectively extracted sample are ~97% (Figure 2b) and ~90 % (Figure 2c), respectively. The purity of the selectively extracted micro-capsules is significantly much higher than that (~2%) without selective extraction. Typical images of the samples without and with selective extraction showing the difference in their purity are given in Figure 2d. Quantitative analysis of live/dead aggregate staining shows more than 95% of cells in the selectively extracted microcapsules (n=3) are viable (Figure 2e), which is not significantly different from that of fresh cells (control) in the cell aggregates without micro-encapsulation or extraction.

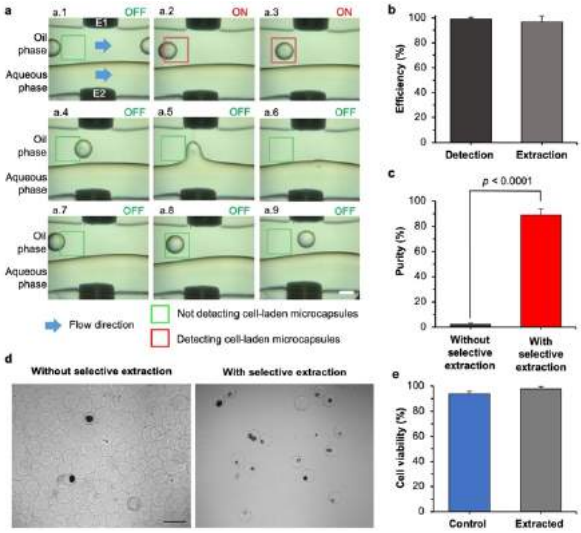

Figure 2. Characterization of the deep learning-enabled detection and selective extraction of cell aggregate-laden microcapsules. (c) Extraction purity. (d) Microcapsules collected with and without selective extraction. Scale bar: 500 µm. (e) Aggregate viability.

DISCUSSION

The deep learning-based label-free method can detect cell aggregates of 50-250 µm in diameter with an ~100% detection efficiency, which enables selective extraction of the cell aggregate-laden microcapsules via DEP force with a ~97% extraction efficiency. This is much better than a previously reported optical sensor-based approach that is unable to detect or extract any cell aggregates less than 82 µm[9]. This is important for biomedical applications, for instance for islet microencapsulation, because islets can be as small as 50 µm[13]. The purity (~90%) of the deep learning-based extraction is also much higher than that (~30%) achieved with an optical sensor-based detection method for DEP-based extraction[9]. However, the purity is lower than the extraction efficiency. The oil-water interface in the extraction area is destabilized slightly during extraction of a cell-laden microcapsule, which may cause an upstream neighboring microcapsule (either empty or cell-laden) to be extracted. This issue may be overcome by using an extraction method faster than DEP. Similarly, a more precise extraction method could further improve the extraction efficiency to ~100%, since the efficiency for the deep learning-based detection is ~100%. This technology may find many potential applications including microencapsulating pancreatic islets, ovarian follicles, and stem cell aggregates for the treatment of diabetes and infertility and stem cell-based therapy of many diseases.

INTRODUCTION

Back pain, one of the most common reasons for doctor visits and the leading cause of disability, has been associated with degeneration of the intervertebral discs (IVD) [1–3]. The IVD, the connective tissue between vertebral bodies, is a complex load-bearing composite tissue populated by a relatively low density of mechanosensitive cells (Fig. 1a) [4]. In advanced painful disc degeneration, the current treatment paradigm includes spinal fusion or total disc replacements [5,6]. In both approaches, the native disc tissue is removed and replaced with either a metal cage containing bone grafts to promote fusion or with a motion-preserving artificial disc implant. Despite the vast differences in how these surgical treatments work, both are associated with complications in the surrounding tissues, namely adjacent segment disease, due to disruption of the mechanics of the spine [6,7]. To address this limitation, we have begun to optimize a 3D printing approach of flexible and biocompatible polymer, FPLA, to create a replacement disc insert that has mechanical properties that mimic native IVD properties.

In a previous study, we optimized the mechanical properties of 3D-printed FPLA mesh scaffolds to mimic equilibrium and dynamic moduli of IVD motion segments in tension and compression (Fig. 1b) [8]. These mesh scaffolds, which were optimized by varying the fiber spacing, are also scalable for mimicking idealized geometry of a large animal or human IVD. However, evaluating these scaffolds in a small animal model proved to be more complex, as scaling down the fiber spacing of 3D printed mesh scaffold to suit the geometry of a rodent IVD was limited. Based on literature studies, the rat IVD height is around 1 mm, has a lateral width of 3-6 mm and a total area of 9-20 mm^2, limiting the scaling down of 3D printed FPLA mesh scaffold to this dimension [11].

To overcome the limitation of printing FPLA mesh scaffolds for rat anatomy, this study evaluated two different 3D printed FPLA replacement disc inserts for their biomechanical properties, specifically comparing hollow (0% infill density) shells versus solid (100% infill density) FPLA samples (Fig 1c). To determine an idealized geometry for printing, rat caudal motion segments were also analyzed using µCT, and resulting dimensions were used in generating rat caudal IVD replacement inserts.

Figure 1: a) Schematic of IVD loading, b) 3D printed FPLA meshes, c) 3D printed FPLA IVD disks for rat and 2X scaled up dimensions.

METHODS

Caudal motion segments were dissected from three mature, male Sprague-Dawley rats ranging from 300-500g after freezing. Full bone-disc-bone segments were isolated by cutting through the adjacent disc on either side with a scalpel blade. Motion segments were placed in a tube and packed with PBS soaked KimWipes to retain hydration and prevent motion during the scan. Scans were performed on a SkyScan 1272 (Bruker) with a pixel size of 12.8 µm, power of 70 kV, image size of 1344 x 2016, and a Al 0.5mm filter. Frames were averaged 2 times to remove any background. Reconstructions were performed using SkyScan NRecon.

To measure the segments and make 3D models, the reconstructed scans were imported into DataViewer and converted into coronal image slices. CTAn software was used to select an ROI, despeckle, fill holes to create a solid shape (Fig. 2 center) and binarize the images. CTAn software was used to export the image files to an STL file and CTVox

software was used to visualize the implant. To generate dimensional estimates of the IVD, 2D images from the center of the coronal plane were used to measure width, inner, and outer height based on boney anatomy (Fig. 2). 3D idealized cylinder disks were designed based on these measurements.

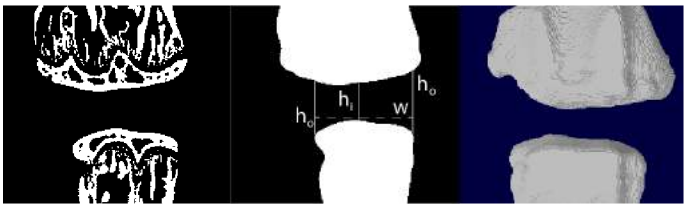

Figure 2: (left) binarized µCT scan (center) outer height, inner height, and width measurements (right) 3D model

Cylinders were printed from FlexiFil PLA (FPLA), a thermoplastic co-polyester elastomer/polymer blend (FormFutura) using a Makerbot Replicator plus 3D printer (Makerbot) and a Makerbot Experimental Extruder with 0.4 mm print nozzle. Tape was used to adhere the scaffold to the bed of the printer during printing to avoid warping of the structure. Printing parameters included extrusion speed of 90 mm/s, extruder temperature of 245 °C, and 0.2 mm layer height. Hollow structures (0% infill) were printed with one shell and solid structures were printed with two shells, and 100% circular pattern infill. Two sizes were printed, rat caudal (1.5 mm height and 4 mm diameter) dimension and 2x the rat caudal dimensions, for characterization of a potential oversized implant as a press fit approach (Fig. 1c).

Unconfined compression tests were performed on a TA Electroforce DMA 3200 Mechanical Tester with a 100lb load cell. Samples were loaded between two stainless steel platens and the top platen was brought into contact with the sample before initiating a displacement ramp of 0.2 mm/min until failure was observed. Elastic modulus was measured from the linear segment of calculated stress-strain curves using Matlab.

RESULTS

The average width of the rat caudal disc was measured to be 4.3 ± 0.9 mm (n=3). The inner IVD height was measured at the narrowest point between the two caudal bones to be 1.04 ± 0.34 mm (n=3) and the outer height was measured on both sides of the outer edge of the caudal bones to be 1.78 ± 0.11 mm (n=3, 2 measurements per sample). An overview of measurement locations is shown in Figure 2.

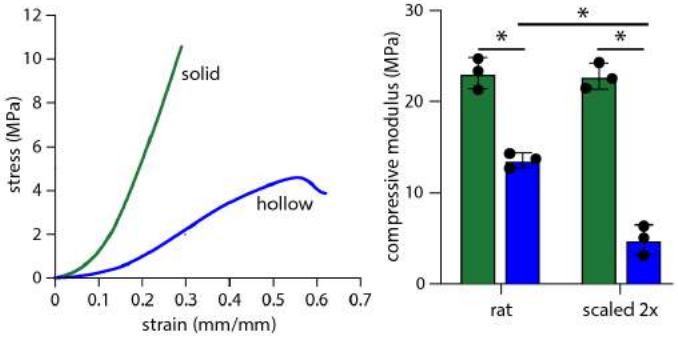

Figure 3: (left) stress-strain curve of hollow and solid 2x printed replacements (right) equilibrium modulus of printed replacements.

Compression testing showed that the solid disks had a significantly larger modulus than the hollow replacements ($p < 0.001$) (Fig. 3). The compressive modulus of rat sized disks was 4.84 ± 1.64 MPa (hollow) and 22.78 ± 1.42 MPa (solid). The scaled up (2x) disks had a compressive modulus of 13.59 ± 0.83 MPa (hollow) and 23.14 ± 1.70 MPa (solid). The solid elastic moduli were similar in the rat sized and scaled up dimensions, indicating no geometric scaling factor ($p = 0.8$), while the hollow elastic moduli were significantly different ($p = 0.0012$) between sizes, indicating that the mechanics of the hollow structures scale with size.

DISCUSSION

Mechanical characterization of 3D printed solid FPLA samples yielded compressive moduli that ranged from 5-23MPa. The hollow (0% infill) structures exhibited a compressive modulus that was within the benchmarks for IVD motion segments in compression (3-10 MPa) [10]. Not surprising, the moduli of the hollow disks changed with width dimension, while solid disks did not have a dependence on dimensions. While the solid printed replacements were significantly stiffer than the hollow, the ~20 MPa is much closer to the native benchmark mechanics than the metals that are currently used in surgical treatment. These results also demonstrate that µCT scans can be used to determine the geometry of individual rat discs as well as create idealized 3D models of specific rat IVD. Our geometric measurements were consistent with literature values [11], confirming the method, while variations can be attributed to the size and age of animals or spinal level.

Future studies will use the µCT reconstructions to perform a 3D volumetric analysis, and to create a customized IVD implant for *in vivo* evaluation in the rat. These disks will be used to drive *in vivo* studies in Sprague Dawley rats, beginning first with subcutaneous implantation to determine the *in vivo* compatibility of the FPLA material and then with implantation in the caudal disc of a rat to observe integration and behavior of the adjacent segments to implantation.

EVOLVING STRUCTURE-FUNCTION RELATIONS IN AORTIC MATURATION AND AGING

INTRODUCTION

Microstructural and mechanical changes that promote homeostasis during aortic maturation and aging are crucial in age-specific adaptations and disease evolution. To ensure sufficient mechanical strength under hemodynamic loads, the aorta consists of a multi-layered composite wall, with collagen and elastic lamellae dominating the passive mechanical behavior and strength. Aortic microstructure, mechanical properties and structural integrity are regulated by arterial cells, in large part via mechanosensing of extracellular matrix, with smooth muscle cells (SMCs) and fibroblasts responsible for its continued mechanoregulation to promote mechanical homeostasis [1]. Notwithstanding the importance of traditional analyses of the global properties of the wall, each aortic region exhibits different local characteristics [2]. Two-photon imaging is a nondestructive method suitable for *ex vivo* 3D assessment of regional microstructural properties of aortic wall components in loaded conditions, and this applies especially for small model organisms such as mice that allow representative observations through the entire aortic thickness. However, there are few studies comparing multiple wall constituents properties across maturation and aging at age-specific loading conditions despite the important role age plays in medicine [3]. Mice are intensively studied for their marked age-related similarity with humans in the patterns of many vascular diseases, but an essential aspect is that the age relationship between mice and humans changes drastically at different stages of their lives. Recent analyses oriented to the age-specific arterial tissue mechanics are insightful [4,5] but there is still a significant need for consistent microstructural and mechanical information across a sufficient number of age stages. In this work, we combined *ex vivo* multiphoton microscopy and computer-controlled biaxial testing to analyze aortic microstructural and mechanical properties in mice as a function of normal postnatal maturation and aging, at 5 age stages from weaning up to one year. For this purpose, a methodology was developed to quantify multiple microstructural parameters of the primary extracellular components – fibrillar collagen and elastic lamellae – and three fundamental cell types – endothelial cells (ECs), SMCs, adventitial cells – locally, in 3D, and as a function of biaxial loading.

METHODS

Samples. Segments of descending thoracic aorta (DTA) were collected from female C57BL/6J mice at postnatal ages of 21 days (P21, n = 4), 42 days (P42, n = 4), 98 days (P98, n = 4) 230 days (P230, n = 4) and 1 year (P365, n = 4).

Biomechanical characterization. Following preconditioning, passive distension-extension protocols consisted of: (i) 3 cycles of pressure-diameter testing cycled between 10 mmHg and age-specific maximum pressure at three different fixed values of axial stretch (*in vivo* value ±5%); (ii) 4 axial force-length cycles with axial force varied from 0 to the maximum load reached at the maximum pressure and *in vivo* +5% axial stretch at a fixed age specific luminal pressure measured *in vivo*. The nonlinear passive mechanical behavior was described by mean axial and circumferential (circ) stress, axial and circumferential material stiffness, elastic stored energy (best fit for an independently validated four fiber family model) and distensibility [6].

Microstructural characterization. Following biomechanical testing, multiphoton microscopy delineated simultaneously multiple components of the aortic wall: collagen fibers, elastic lamellae, and cell nuclei subdivided in EC, SMC, and adventitia cell nuclei. Acquisitions were made at systole, diastole, and half diastole *ex vivo* equivalent blood pressures and sample-specific in vivo axial stretch ± 5%. Dorsal and ventral regions were analyzed consistently. Due to the near cylindrical shape of the samples, analysis of separate wall layers was allowed by

transformation from Cartesian to polar coordinates. A systematic analysis was developed to quantify the following microstructural parameters from 3D images at all different configurations and regions: layer specific thickness and volume fractions, collagen fiber straightness, alignment and bundle width, cell densities and cell alignment, elastic lamella number and inter-lamellar distance.

RESULTS

Several microstructural changes were quantified (Figure 1a) during late stages of maturation (P21-P98) and aging in adulthood (P98-P365). The media was characterized by a progressive decrease in smooth muscle cell density and alignment though with inter-lamellar widening from intermediate to older ages, suggesting cell hypertrophy, matrix accumulation, or both. The endothelium showed progressive reductions in cell density and altered cellular orientation. Despite not changing in tissue thickness, the aging adventitia exhibited a marked thickening and straightening of collagen fiber bundles and reduction in cell density, suggestive of age-related remodeling not growth. Multiple microstructural changes correlated with age-related increases in diameter and material stiffness, among other mechanical metrics (Figure 1b).

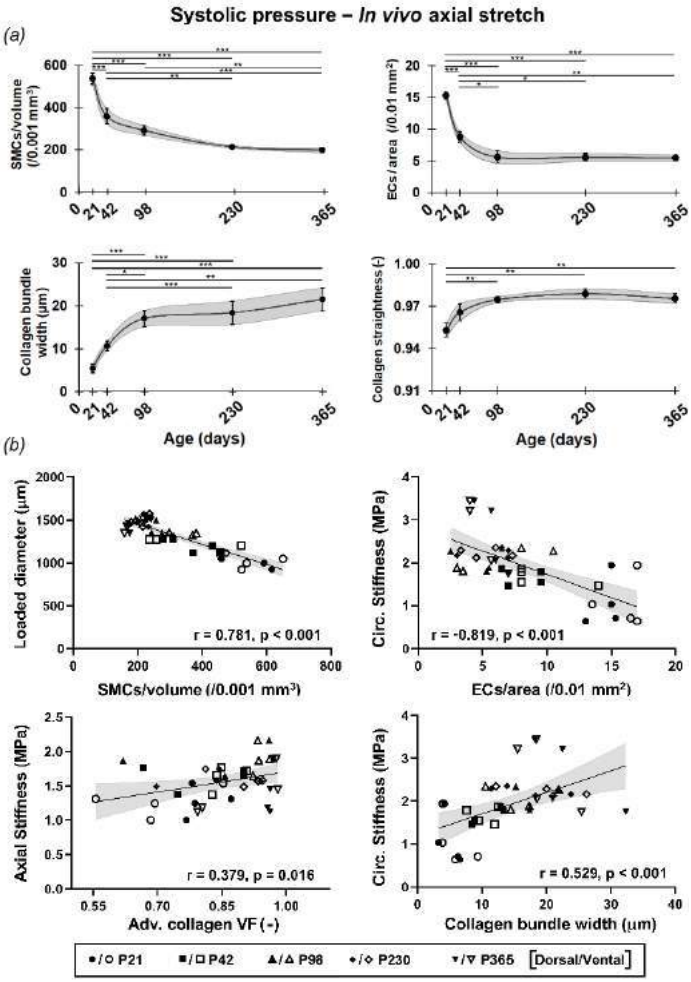

Figure 1: (a) Evolution of selected microstructural parameters (Mean ± SEM) reveal distinct time courses of maturation and aging. * p<0.05, ** p<0.01, *** p<0.001. (b) Sample-specific microstructural and mechanical parameters in statistical correlation for pooled age groups.

These significant correlations indicated the fundamental role of cells and deposited extracellular proteins, including reductions in endothelial and smooth muscle cell densities as well as increases in straightness and thickness of collagen bundles in relation to the increase in circumferential stiffness of the aortic wall.

DISCUSSION

Introducing a continuity between postnatal maturation and aging, our study complemented but extended prior studies via consistent analysis of sample-specific structure-function. Importantly, in maturation and aging, circumferential stiffness associated with collagen morphology as well as SMC density and morphology, supporting the discussions about interactions between SMCs and ECM and ECM-driven SMC modulation which leads to pathologies in aged arteries [7]; axial material stiffness seemed to be governed by the fibrillar collagen fraction. Interestingly, while EC density appeared to be correlated to circumferential stiffness throughout aging, flow-mediated shear stress, seems to have a large influence on EC orientation.

In conclusion, some correlations of fundamental importance highlight relationships between the microstructural organization of collagen and intramural cells and the passive biomechanical metrics in both circumferential and axial directions. The present data show how recent advances of imaging can help to better understand microstructure and mechanics of the aging aorta, providing critical comparators for future studies of diverse diseases that may have different ages of onset.

INTRODUCTION

Elevated intraocular pressure (IOP) is a primary factor for the development and progression of glaucoma [1]. However, the mechanism(s) by which the elevated IOP leads to the biological effect of neural tissue damage remains not well understood and controversial [2]. A leading hypothesis is that the elevated IOP causes deformations of the lamina cribrosa (LC), such as stretch, compression, and shear, and that these deformations act as mechanical insult on the astrocytes and retinal ganglion cell axons at the LC, triggering or contributing to axon damage and death, and thus loss of vision [3, 4]. Glaucoma, however, is a chronic disease. Glaucomatous neural tissue damage does not occur after a few seconds or even minutes of elevated IOP [5]. Glaucoma results from chronically elevated IOP. As a living biological structure, an eye under chronically elevated IOP has the opportunity to remodel, ostensibly to adapt to increased mechanical load. [6]. If this were the case, the effects of an acute increase in IOP would be smaller after an eye has been subjected to chronically elevated IOP. Nevertheless, studies analyzing overall morphometric features of the optic nerve head suggest that in the early stages of glaucoma it is the opposite effect, namely that acutely elevated IOP has a larger effect in an eye that has been under chronically elevated IOP [7]. This intriguing effect is still not well characterized or understood, in part because it has not been measured precisely in vivo.

Our goal was to measure the in vivo LC deformations caused by acutely elevated IOP in an eye when healthy, and after experimentally induced chronically elevated IOP.

METHODS

The optic nerve head (Figure 1) of four eyes of four rhesus macaque monkeys were imaged using optical coherence tomography (OCT, Spectralis) in several imaging sessions. Herein, we analyze three sessions, two before (baselines 1 and 2) and one at the onset of laser-

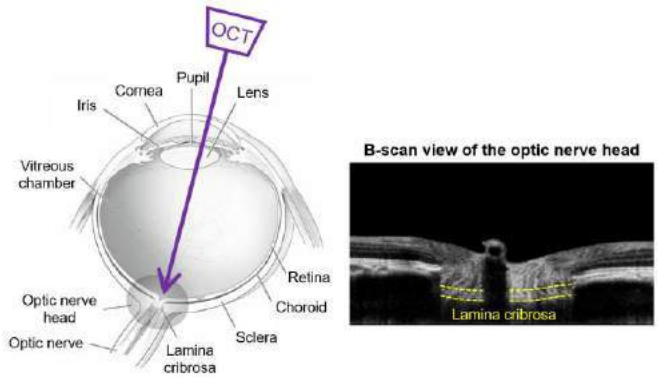

Figure 1. (Left) Anatomy of the eye in longitudinal cross-section. Adapted from a diagram by the NEI. (Right) Example OCT B-scan with manual marks indicating the lamina cribrosa (yellow dashed line) spanning across the scleral canal.

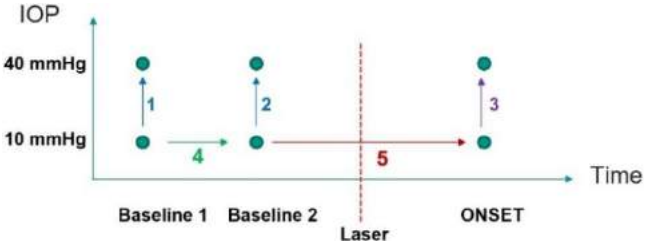

Figure 2: Experiment design with 5 steps comparisons: 1 acute at baseline; 2 acute at baseline repeated; 3 acute at onset; 4 chronic baseline-to-baseline; 5 chronic baseline-to-onset.

induced early glaucoma (EG). Onset was defined as confirmed peripapillary RNFL loss detected using OCT. In each session, the optic nerve heads were scanned after IOP was set for 10 minutes to 10 mmHg and then to 40 mmHg.

Digital volume correlation (DVC) analysis was then used to determine the LC changes between scans. LC changes represent either acute (between IOP levels) or chronic deformations (between sessions at same IOP, Figure 2).

RESULTS

LC deformations between baseline 1 and baseline 2 at low IOP (10 mmHg) were the smallest changes (compression 2-3%) in all four eyes, indicating good repeatability (Figure 3, Step 4). When the eyes were normal, comparing baselines at different IOPs, acute IOP-induced LC deformations were substantially larger (8-12%) and consistent in all four eyes at both tests (Figure 2, Steps 1 and 2), indicating a stable LC compliance in a given eye. Compliance varied between eyes.

Compared with the acute IOP effects at baseline, the acute IOP effects at EG onset (Figure 3, Step 3) were larger in three monkeys (up to 17%) and smaller in one monkey (5%). This indicates that chronically elevated IOP led three eyes to soften and one eye to stiffen.

Interestingly, at onset of EG, the LC changes induced by chronically elevated IOP were larger than the acute IOP-induced LC deformations at baseline (Figure 3, Step 5, 8-15%).

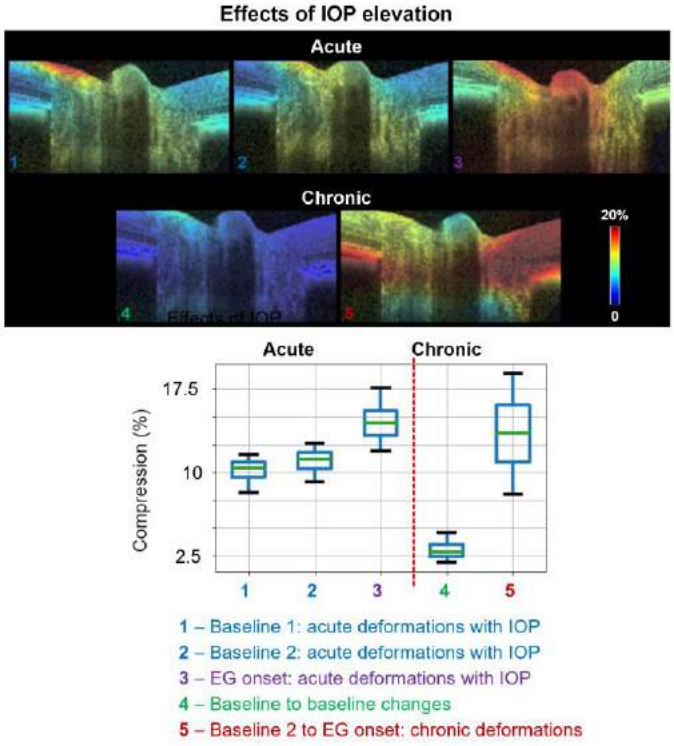

Figure 3: (Top) Example central optic nerve head B scans colored according to the compression magnitude. (Bottom) Distribution of LC compression measurements of a monkey eye using standard box plots (green line: median, box: quartiles, whiskers, 95th percentiles). The differences between any two steps were significant ($p<0.001$).

DISCUSSION

Our goal was to measure LC deformations induced by acutely and chronically elevated IOP when healthy and at onset of experimental glaucoma. Our results first demonstrate that our experimental and computational pipeline allows direct, repeatable measurement of these deformations in vivo in a non-human primate model. At EG onset, three of four monkeys exhibited substantial changes in the LC and increased LC compliance, suggesting that the damage and remodeling processes are already advanced. The fourth monkey exhibited smaller in the LC and slightly decreased compliance.

It is important to note that what is being measured by DVC between time points (steps 4 and 5) are not displacements or strains per se, but instead chronic changes through the development and progression of glaucoma. These could include, among others, neural tissue loss and remodeling of the LC.

Our results support and extend previous results obtained using gross optic nerve head morphology [7]. This demonstrates the great value of the carefully controlled model of chronically elevated IOP possible with the non-human primate. The tools developed in this project enable us to interpret the data and to understand the pathophysiology of glaucoma. Studies using similar OCT/DVC techniques [8] did not find a significant difference in the optic nerve head deformations caused by an acutely elevated IOP between healthy humans and patients with glaucoma. A potential explanation could be that we focused here in the LC region at EG onset. The loss of soft neural tissues and abundant “scars” suggest that in more advanced glaucoma the tissues are likely less compliant [9].

INTRODUCTION

Total ankle arthroplasty (TAA) is developing as an effective treatment to restore function in patients with end-stage ankle arthritis [1,2]. However, due to inferior performance in comparison to hip and knee replacements, a need exists to improve the design of patient specific instrumentation for more accurate placement. Biomechanically, a contemporary TAA implant has been shown to nearly restore functional kinematics of the ankle and adjacent joints during simulations of healthy stance in level walking [3]. Despite this, patients with end-stage arthritis could develop compensatory gait abnormalities that persist after surgery. Patients who adopt abnormal walking patterns may be implanted with devices designed to restore normative walking patterns, potentially exacerbating further gait abnormalities [4]. Therefore, our objective in this study is to isolate the individual and combined effects of TAA implantation and gait adaption from ankle arthritis on foot and ankle kinematics during simulated level walking. We hypothesized that foot and ankle kinematics would primarily be altered through adaptations in gait resulting from ankle arthritis and that the combined effect of the implantation and adaption would further deviate kinematics from normative values

METHODS

An adaptive robotic gait trajectory was formulated through collection of *in vivo* level walking data from 10 post-surgical TAA subjects (Age 62-76; 7M, 3 F; Follow up time 26-77 months) who had incurred ankle arthritis prior to surgery. All subjects were implanted with the Salto Talaris TAA (Salto; Integra LifeSciences; Plainsboro Township, NJ). Three-dimensional gait analysis was performed using a 12-camera motion capture system which tracked retroreflective markers attached to the tibia and foot. Subjects completed three level walking trials over an embedded force plate (Bertec Corp.; Columbus, OH) while tibial kinematics, electromyography of the gastrocnemius and tibialis anterior muscles, and ground reaction forces were collected. The data was then converted into force plate trajectory and muscle inputs to be used for gait simulation.

Twelve mid-tibia cadaveric specimens (5L, 7R; 9M, 3F; Age at time of death: 28-80) were used in this study with Institutional Review Board approval. A validated six-degree of freedom robotic gait simulator was used to simulate stance phase (Baxter, 2016). The simulator recreates kinematics and loading incurred through gait through rotating a force plate around a stationary tibia while muscle forces are applied by eight linear actuators. For each specimen a fuzzy logic controller is used to iteratively converge the *in vivo* ground reaction force profile from the human subject data collection. Reflective markers attached to intracortical bone pins were attached to the tibia, talus, navicular, calcaneus, and first metatarsal. Motion was then tracked by an 8-camera motion capture system during simulations.

In testing, the specimen was first placed on the simulator in the intact condition, where it was simulated in both healthy and adaptive gait simulations. The specimen was then implanted with a Salto Talaris TAA (Integra LifeSciences) by a surgically trained orthopaedic fellow and then loaded back onto the simulator, where adaptive and healthy gait trials were again conducted in the implanted condition. In total, four conditions were collected on each specimen: intact with a healthy walking trajectory (intact-healthy), intact with an adaptive walking trajectory (intact-adaptive), implanted with TAA with a healthy walking trajectory (TAA-healthy), and implanted with TAA with an adaptive gait trajectory (TAA-adaptive).

Ankle, subtalar, and talonavicular joint kinematics in each condition were compared to intact-healthy to isolate the effects of implantation and adaptive gait on kinematics. Although all kinematics were recorded and processed, the results reported in this abstract correspond with joint rotations in the primary anatomic plane for each joint: ankle sagittal rotation, subtalar coronal rotation, and talonavicular transverse rotation. Bias-corrected 95% confidence intervals were calculated of the repeated-measures difference between each condition and intact-healthy. Significant differences were noted in instances in which the confidence intervals did not cross zero.

RESULTS

In the comparison of foot and ankle kinematics between the intact-healthy and intact-adaptive conditions, significant differences were noted in the ankle, subtalar and talonavicular joint (Figure 1). In isolating adaptive gait, ankle dorsiflexion significantly increased in

mid-to-late stance. In the subalar joint, adaptive gait significantly increased in eversion at toe-off, near the end of the stance phase. In the talonavicular joint, adaptive gait significantly increased in abduction for a short period of time in early and late stance.

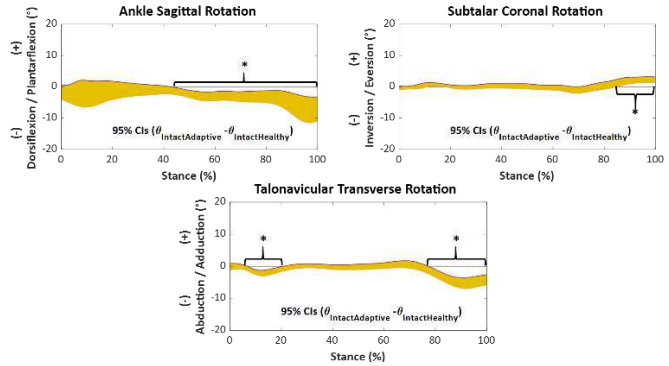

Figure 1: Bootstrapped 95% confidence intervals for the difference between joint kinematics of the intact-healthy condition and the intact-adaptive condition during simulations of level walking. {*} denotes periods of stance which significantly deviates from normative values

In the comparison of foot and ankle kinematics between the intact-healthy and TAA-healthy conditions, significant differences were noted in the ankle, subtalar and talonavicular joint which occurred at different instances of gait than the differences found in isolating gait adaptation (Figure 2). In isolating ankle implantation, the specimens demonstrated increased ankle plantarflexion, increased subtalar eversion, and increased talonavicular abduction compared to intact-healthy stance in mid-stance.

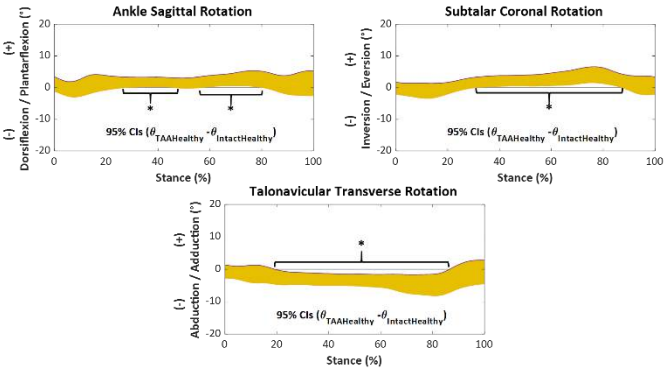

Figure 2: Bootstrapped 95% confidence intervals for the difference between joint kinematics of the intact-healthy condition and the TAA-healthy condition during simulations of level walking. {*} denotes periods of stance which significantly deviates from normative values

In the comparison of foot and ankle kinematics between the intact-healthy and TAA-adaptive conditions, in looking at the combined effects of gait adaptation and implantation, significant differences were amplified in the subtalar and talonavicular joints (Figure 3). In the ankle joint, plantarflexion increased in early stance and dorsiflexion increased in late stance compared to the intact-healthy condition. In the subtalar joint, significant increases in dorsiflexion occurred throughout much of the stance phase with adaptive gait and implantation. In the talonavicular joint, abduction also significantly increased throughout most of the stance phase.

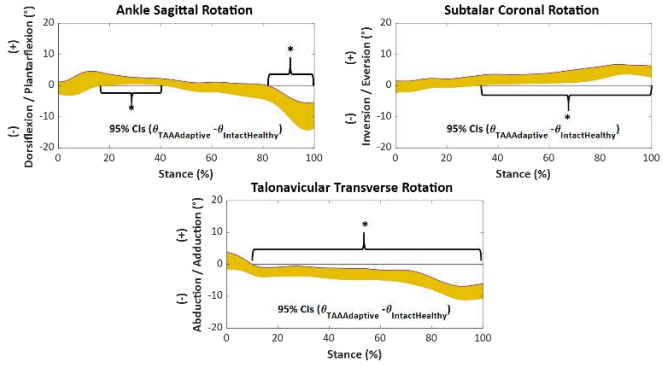

Figure 3: Bootstrapped 95% confidence intervals for the difference between joint kinematics of the intact-healthy condition and the TAA-adaptive condition during simulations of level walking. {*} denotes periods of stance which significantly deviates from normative values

DISCUSSION

Our results suggest that gait adaptation and implant constraint both contributed to changes in ankle and adjacent joint kinematics. The two factors also appear to influence two different regions of the stance phase. For the most part, isolation of gait adaptation demonstrated significant changes to joint kinematics in late stance. Isolation of the effects due to implantation revealed significant differences primarily within mid-stance. The combined influence of gait adaptation and implantation appears to amplify or negate deviations from normal kinematics at times throughout stance. For instance, adaptive gait increased subtalar eversion and talonavicular abduction in late stance and implantation increased them in midstance, which resulted in an amplification of these changes when looking at their combined influence. In contrast, adaptive gait increased dorsiflexion in mid-to-late stance but implantation increased plantarflexion in mid-stance, which resulted in less changes in ankle sagittal rotation from intact with healthy gait in mid-stance when considering both gait adaptation and implantation. Our findings have important implications for the future of development in total ankle arthroplasty. Oftentimes, ankle implants are evaluated or designed based on information derived from healthy kinematics and loading [1,6], which is the ideal scenario but may not be the best case to consider during development. Instead, a more realistic scenario is that patients maintain gait adaptations long after implantation [7]. Therefore, kinematic and loading differences from gait adaptations that remain after implantation may need to be considered in the development process of future devices along with implant constraints.

ESTIMATION OF CLINICAL SIZE OF BREAST TUMOUR LESIONS USING CONTRAST ENHANCED MAGNETIC RESONANCE IMAGING: DELINEATION OF TUMOUR BOUNDARIES

Manpreet Singh (1), Manjesh Dalal (2), Gurasis Singh Sodhi (2)

INTRODUCTION

Breast Imaging-Reporting and Data System (BI-RADS) classifies breasts into four categories in the order of radiographic breast density composition namely extremely dense (ED)-10% (type-D), heterogeneously dense (HD)-40% (type-C), scattered fibroglandular (SF)-40% (type-B) and predominantly fatty (PF) is reported in about 10% of women (type-A) [1]. Under such classification BI-RADS defines tumour into namely six assessment categories[2]. TNM (Tumour-Node-Metastasis) tool is widely used to describe the stage of tumour. T refers to size of the tumour, N relates to primary inspection whether cancerous cells spread to lymphatic nodes and M explains whether it invades to other organs of the patient. Clinically, the staging of the tumour in the breast may be defined as T1 (size≤20 mm): T1mi (≤ 1 mm), T1a (1 mm < size ≤ 5 mm), T1b (5 mm < size ≤ 10 mm), T1c (10 mm < size ≤ 20 mm); T2 (20 mm < size ≤ 50 mm); T3 (≥ 50 mm); T4a (tumour has grown into chest wall), T4b (tumour has grown into skin), T4c (grown into chest wall and skin), T4d (inflammatory).

The delineation of tumour is defined using three fundamental axioms i.e. tumour volumes[3] namely gross tumour volume (GTV), clinical target volume (CTV), planning target volume (PTV) is critical to design an effective radiotherapy planning or thermal ablation treatment therapy (Radiofrequency Ablation) etc. Hence, the accurate tumour boundaries needs clear demarcation in order to ensure the safety of organs at risk (ORs) considering that the organs must not receive higher-than-safe-dose. Therefore, clinical size of tumour holds a great significance for the tumours such as glioblastoma multiforme (GBM), CWR (Chest Wall Recurrence) etc. where damage to healthy anatomical structures such as spinal cord, chest wall etc., produces a severe clinical manifestation[4].

METHODS

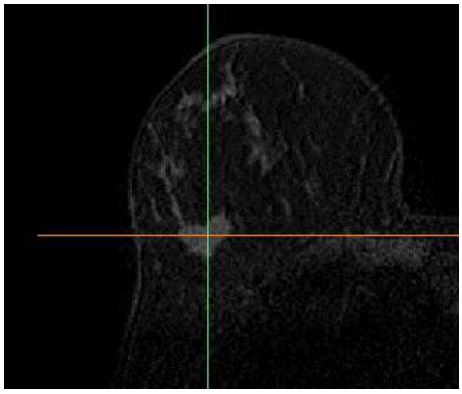
Clinical breast MRI examination was performed at Government Medical College and Hospital, Chandigarh, India in the department of Radiodiagnosis & Imaging with Phillips at magnetic field of 1.5T using a standard and consistent contrast enhanced injections following a clinical breast MRI protocol. MRI uses magnetic fields instead of x-rays to produce very detailed and refined cross-sectional images of the cancerous lesion of breast organ. Six Woman were imaged in the prone position using a dedicated multichannel surface array breast coil. After the native scan was obtained, Contrast Enhanced sequences (CE) were acquired in axial plane employing 3D T1-weighed fast gradient echo-based DCE series with one pre and three post-gadolinium contrast-enhanced sequences. MRI exams for breast imaging use a contrast material (usually gadolinium-DTPA) that was injected into a vein in the arm before or during the exam to improve the ability to capture detailed images of breast tissue. The DICOM format information about both breasts including other organs was captured. The nearest neighbor of tumour (subpart node T) node corresponds to the node *i* in the breast (object) mesh having the minimum Euclidean distance (ED) to the tumour node via eq. 1 as:

$$ED = \sqrt{(x_{nodeT} - x_i)^2 + (y_{nodeT} - y_i)^2 + (z_{nodeT} - z_i)^2} \quad (1)$$

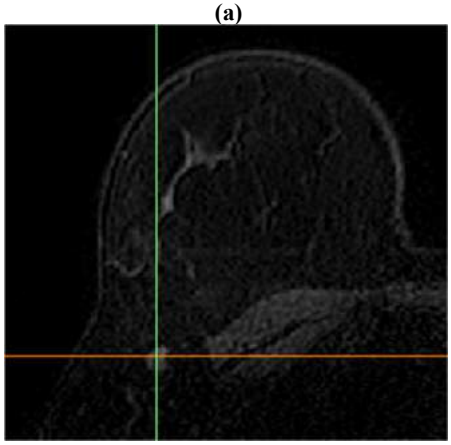
where, *x, y, z* represents the nodal coordinates. It is ensured that tumour offers a higher level of refinement compared with the mesh for the breast anatomy as a single unit.

RESULTS

Fig. 1 illustrates one slice from a set of 1051 images of DCE-MRI acquisition. In the first case scenario, the breast composition is found to resemble a case of type-A predominantly or entirely fatty breast anatomy. A relatively well defined irregular mass lesion with spiculated



(a)



(b)

Figure 1: Case Scenario-1: a) DCE-MRI slice of type-A breast cancerous lesion in axial plane, b) spicule is approaching chest wall.

margins measuring 19 ×17×14 mm in size and appearing isointense to glandular tissue on T2W images and hyperintense on STIR images is noted in the upper outer quadrant of the right breast. The cancerous lesion is reported at a distance of 1.5 cm from the skin at the lateral border of the breast and 1.8 cm from the chest wall. It can be followed from fig. 1b that one of the spicule appears mildly bulky and pulled up and is seen reaching upto the pectoralis muscle. A lymph node measuring 10 × 6.3 mm is also noted in the axillia along the chest wall. Hence, first case is assessed as BI-RADS V (malignant case). Referring to fig. 2, the second case scenario, the breast composition is a case of type-B scattered fibroglandular breast anatomy. STIR hyperintense diffuse subcutaneous thickening thickening measuring 1.3 cm with corresponding mild linear non-mass enhancement curves. It can be coined as a case of BI-RADS IVa. Fig. 3 shows a well circumscribed homogeneously enhancing STIR hyperintense mass lesion measuring 1.4 × 0.8 cm and appearing isointense to glandular tissue on T2W images is noted in retro areolar location in midline with type II enhancement and is a case of BI-RADS IV C. The distance from the skin at anterior surface of the breast is 2.1 cm. Homogeneous internal enhancement is found on post contrast images.

DISCUSSION

This study covers an extended spectrum of clinical cases (1) to analyze the accurate tumour size, (2) to demarcate accurate tumour boundaries in order to plan an effective target volumes for radiotherapy, thermal ablation including radiofrequency ablation and nanoparticles induced thermal ablation. Once the clinical size of the tumour is established, realistic three-dimensional volume of the tumour can be calculated with its realistic shape and irregular nodal features with the available computational imaging platforms such as MIMICS, 3-matic, Simplewa-

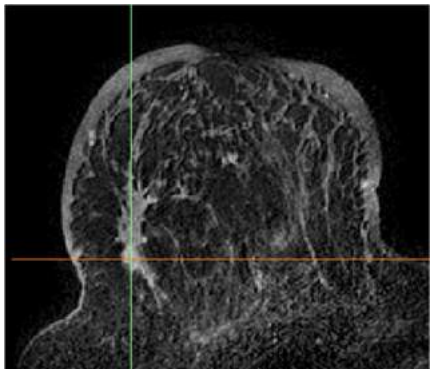


Figure 2: Case Scenario-2: Illustration of DCE-MRI slice of type-B breast carcinoma in axial plane.

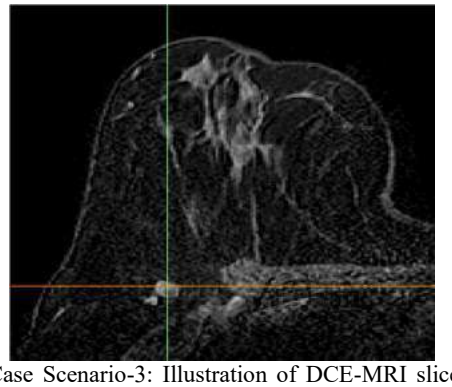

Figure 3: Case Scenario-3: Illustration of DCE-MRI slice of type-B breast carcinoma in axial plane.

-re etc. Such domains can be successfully imported into ABAQUS, Comsol-Multiphysics, ANSYS etc. as mesh files to do heat transfer analysis or run Monte-carlo simulations for effective radiation planning. Accurate margins (0.5 cm-1 cm) can only be sacrificed if true tumour boundaries with irregular spread can be retrieved. Hence, this study helps in enhancing the treatment efficacy of cancer treatments and thereby designing protocols for radiation, thermal ablation and hyperthermia therapies. As used in first case scenario, the high resolution data with slice thickness equivalent to 0.5 mm or lesser must be used in order to capture the detailed anatomical features and pathology of tumour. The future effort in this direction would be to capture the blood supplying vessels to the tumour using MRI-Angiogram although not commonly used in imaging.

INVESTIGATING THE EFFECT OF SPORTS HELMETS ON THE FREQUENCY RESPONSE OF THE HUMAN BRAIN

Fargol Rezayaraghi (R. Araghi) (1), Javid Abderezaei (1), Efe Ozkaya (1), Colleen E Shea (1), Mehmet Kurt (1,2)

INTRODUCTION

Sport-related mild traumatic brain injury (mTBI) is one of the causes of mortality and morbidity in athletes, which can be prevented or reduced in severity by wearing protective headgears such as helmets. These protective helmets are often designed to mitigate the head kinematics during an impact [1, 2] and their efficacy is evaluated by analyzing their effect on linear and rotational kinematics of the head [1, 3]. While recent studies have shown that brain substructure dynamics plays an important role in concussion mechanism, these dynamic characteristics are currently not considered in helmet designs. Investigation of the brain substructure biomechanics during impacts has revealed crucial frequency dependent and localized phenomena that have been associated with the injury outcome [4, 5]. Characterizing the dynamics of the brain during impacts has shown the existence of localized modes and multi-modal behavior in the brain [4]. Also, by using modal analysis and Finite Element (FE) simulations a strain concentration in deep regions of the white matter, and distinct modal frequency in corpus callosum have been reported [4, 5]. Specifically, the brain has been shown to be sensitive to displacement frequencies around 30Hz, which exacerbated the observed deformation [4, 5]. Despite the importance of brain substructures in mTBI mechanism, most of the helmet designs have only focused on mitigating the head kinematics. Helmet performance still needs to be improved by including the effect of the dynamics of the brain substructures, along with the mitigation of head kinematics. Here, in this work, our aim was to evaluate the effect of different helmets on dynamic frequency response of the brain substructures during impacts. We performed impact pendulum experiments and then conducted brain FE simulations. Finally, we investigated the dynamic frequency response of different brain substructures by a modal analysis technique.

METHODS

Impact Pendulum Tests: We used an impact pendulum test setup to apply impacts to a Hybrid III anthropomorphic head-neck system (Figure 1(a)). Impact pendulum was released at a 60° angle for each test, with approximate impact velocity of 4.3 m/s. Three different commercially available helmets including a hockey helmet (Figure 1(b)), a football helmet (Figure 1(c)) and a ski helmet (Figure 1(d)) were tested three times to compare their effectiveness on mitigating the head kinematics, and the resultant dynamic response of the brain. Head kinematics were measured using a 6DOF sensor package (DTS, Seal Beach, CA), consisting of one tri-axial accelerometer (ACC3 PRO) and three angular rate sensors (ARS PRO-8K 2000 Hz), which were located at the center of gravity (CoG) of the dummy headform. We applied side impacts to induce coronal rotation, since it has been reported that rotations in the coronal direction can cause large strains in certain vulnerable regions such as corpus callosum [6,7].

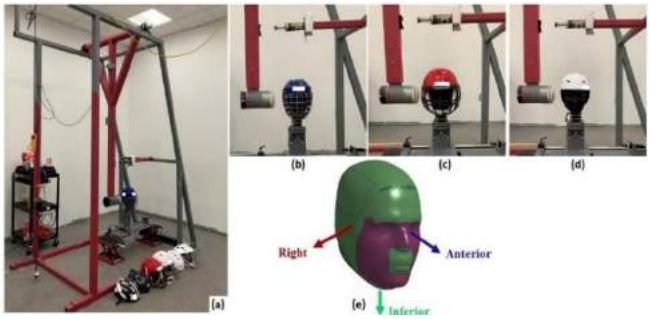

Figure 1. Helmet tests through an impact pendulum: (a) Impact pendulum test setup. (b) Hockey helmet. (c) Football helmet. (d) Ski helmet. (e) Coordinate system in FE model.

Finite Element Analysis: The Global Human Body Models Consortium (GHBMC) skull-brain model was used in this study (Figure 1(e)) to simulate head impacts in the LS-Dyna environment [8]. The purpose of these simulations was to observe the effects of different helmets on the dynamic response of the brain substructures. To this end, we extracted nodal coordinates from brain substructures to calculate their relative displacement to the skull.

Dynamic Mode Decomposition: Dynamic Mode Decomposition (DMD), is a multivariate method that we used for extracting the modal behavior of the brain tissue. It allows analyzing the spatiotemporal differences within the brain substructures as a function of modal frequency [4].

RESULTS

Extracted kinematics datasets from the impact pendulum tests were used as inputs to the finite element model to observe the deformation of each brain region during an impact. Figure 2 (a-c) shows the rotational velocity in three directions for the mentioned helmets. The average maximum rotational velocity was 32.3 rad/s for the hockey helmet, 31.2 rad/s for the ski helmet and 30.9 rad/s for the football helmet.

In the next step, our aim was to study the dynamic response of the brain substructures. Nodal displacements of the corpus callosum, brainstem and cerebellum were extracted to calculate relative displacement of the brain-skull system. We performed DMD analysis on these data to find temporal modes of the corpus callosum, cerebellum and the brainstem (Figure 2 (d-f)). In the corpus callosum, the first frequency was around 10 Hz for all helmets (Figure 2 (d)). At this frequency, the ski helmet had a lower modal amplitude compared to other helmets. The second harmonic appeared at a frequency regime around 40 Hz for the football and ski helmets. For the hockey helmet, the second harmonic was at a frequency of 30 Hz with a higher modal amplitude compared to other helmets. In the brainstem, the main frequency of motion was around 6-10 Hz and the second one was around 35-40 Hz for all helmets (Figure 2 (e)). At the second harmonic, higher amplitude was observed in hockey helmet, which was two times higher than the modal amplitudes of the ski and football helmets. In the cerebellum, while the main frequency of motion for the ski and football helmets was observed around 10 Hz, the first harmonic for the hockey helmet occurred at the frequency of 50 Hz, in which the second harmonic of the ski and football helmets was observed (Figure 2 (f)).

DISCUSSION

Protective helmets are usually designed to mitigate the kinematics of the head during an impact [1]. To improve the performance of the helmets, it is crucial to also investigate the dynamic characteristics of the brain as well as the kinematics of the head. Here, we studied the effect of different helmets on head kinematics and the dynamic response of the brain substructures. When only analyzing the head kinematics, we observed that the football helmet performed better compared to the other helmets. Looking into dynamic frequency response of the brain, our results showed that in the corpus callosum and the brainstem, which have been reported as vulnerable regions in injury, the modal amplitude around the frequency regime of 20-30 Hz was higher in hockey helmet compared to ski and football helmets. This range of frequency was important to us, since in previous studies, it was reported that the brain is more susceptible to injury for vibrations within the frequency regime of 20–40 Hz [4]. Our results suggested that the tested hockey helmet cannot dissipate frequency components of the brain around 35-45 Hz compared to football and ski helmets which is troubling, since it has been shown that the brain is sensitive to these frequency regimes, and such harmonics might lead to strain concentration in corpus callosum [9]. In the future, we will focus on testing these helmets in other impact loading conditions to provide a holistic view between helmet properties and frequency-dependent brain substructure response.

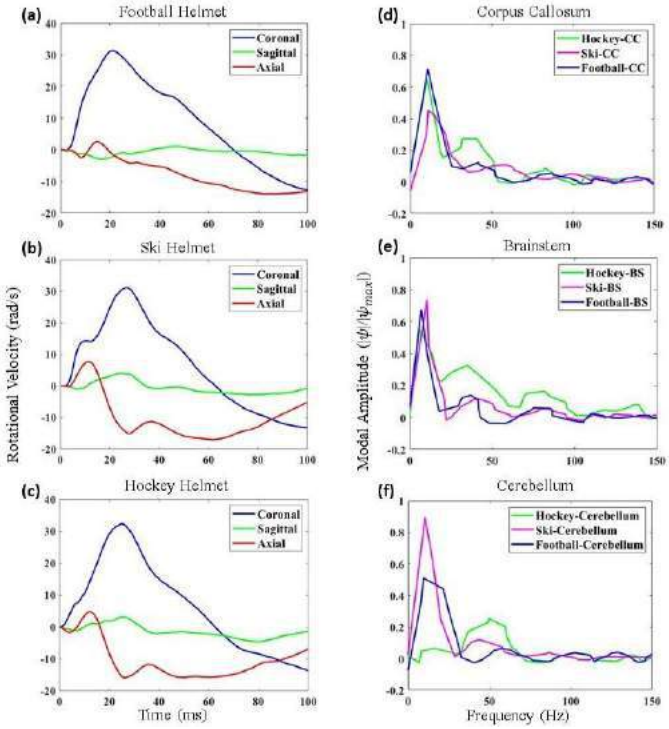

Figure 2. The effect of different helmets on rotational kinematics and modal amplitudes: The rotational velocity of the head for (a) Football helmet, (b) Ski helmet and (c) Hockey helmet. Modal amplitudes of (d) Corpus callosum, (e) Brainstem and (f) Cerebellum for different helmets.

INTRODUCTION

The meniscus plays an integral role in the mechanical functioning of the knee joint, offering load support and congruency while also providing lubrication [1]. The presence of a healthy meniscus is essential for protecting the underlying articular cartilage against osteoarthritis, a serious condition affecting millions of people each year. To perform its function, the meniscus has a highly organized extracellular matrix composed of parallel collagen fiber bundles that run along the circumferential direction, imparting the tissue with the strength to withstand complex loading [1]. Understanding the structure-function relations for mechanical properties of the meniscus can provide important insight into the tissue physiology and pathology. Such quantitative information is valuable for developing new strategies for treating meniscus defects and/or degeneration, either by way of tissue engineered substitutes or via computational modeling. Atomic force microscopy (AFM) is a state-of-the-art method that can be employed to measure the Young's (elastic) modulus of soft tissues such as the meniscus. The AFM technique allows for measurement of distinct tissue regions, making it suitable for investigating mechanical inhomogeneities in the meniscus.

The objective of this study was to determine the effect of region and direction/orientation on the micromechanical properties of porcine meniscus. We hypothesized that both anisotropic and inhomogeneous properties would be determined, based on our knowledge of the structure of the meniscus. Thus, we used AFM to measure the Young's modulus of porcine meniscus in medial and lateral meniscus from the inner and outer regions and in the axial and circumferential directions.

METHODS

Specimen Preparation: Fresh porcine knees were obtained from a local abattoir. Menisci were harvested, wrapped in saline soaked gauze, and stored in plastic bags at -20ºC. On the day of the experiment, two slabs of tissue were isolated from the central region of a meniscus: one in the circumferential direction and one in the axial direction, see Figure 1. Samples were cut to 1.5mm thickness using a Compresstome® (VF-200-0Z, Precisionary, Natick, MA). The samples were then divided into the outer one-third and the inner two-thirds for 4 total samples per meniscus: axial inner (AI), axial outer (AO), circumferential inner (CI), and circumferential outer (CO), see Figure 1. Samples were also divided into medial and lateral groups, for a total of 8 sample sets. Prior to AFM measurements, each sample was secured to its own petri dish using super glue and then immersed in phosphate buffered saline (PBS) solution supplemented with Protease Inhibitor (Roche) to prevent degradation of the tissue during experimentation.

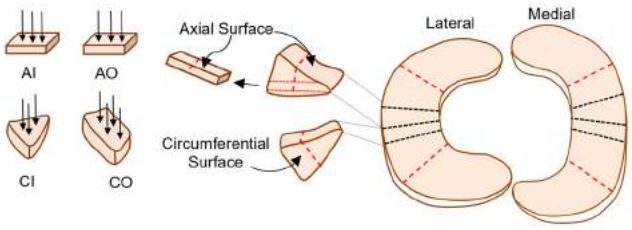

Figure 1: Schematic of locations and orientations of test specimens

AFM Measurements: A custom AFM fitted with a silicon nitride cantilever (k=5.4 N/m) with a 5µm diameter borosilicate glass particle tip (Novascan, Ames, IA) was used to perform indentation tests on the meniscus samples [2]. All tests were performed at room temperature (~22ºC) on fully hydrated tissues. Measurements were repeated 10 times at 3 different locations on each sample to account for normal variations in measurements. Force-indentation data was curve-fit to the

Hertz model using a custom MATLAB code, yielding measurements for the Young's (elastic) modulus of the specimens [2]. The goodness of fit for each was visually assessed to ensure accurate model fitting.

Statistical Analysis: All measurements from each sample set were pooled together. Outliers (more that 2 standard deviations from the mean) were excluded from statistical analysis, resulting in a different total number of measurements in each group. ANOVA analysis of variance followed by Tukey post-hoc testing was used to determine statistically differences between groups; significance was set at α=0.05.

RESULTS

The results for Young's modulus of elasticity for the 8 groups investigated are shown in Figure 2. For each group, n=5. ANOVA showed a significant effect of all factors on the tissue elastic modulus. For outer medial menisci, elasticity was higher in the circumferential direction then the axial direction (i.e., MCO>MAO, p=0.001), but no significant difference was found for corresponding lateral samples. Also in medial menisci, the modulus in circumferential specimens was higher in the outer region than in the inner region (i.e., MCO>MCI, p=0.001). The opposite trend was found for lateral samples (LCO<LCI), although the difference was not significant (p=0.082).

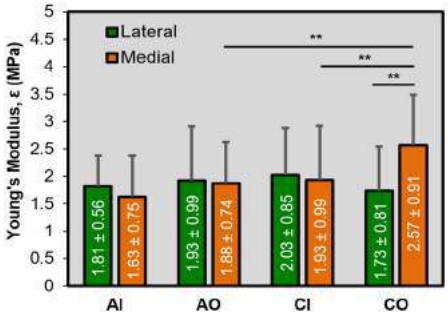

Figure 2: Results (mean ± standard deviation) for modulus of elasticity measurements for all 8 groups. n=5 for each. **: p<0.01

For the circumferentially oriented specimens in the outer region of the tissue, the elastic modulus of medial samples was significantly higher than that of lateral samples (i.e., MCO>LCO, p=0.001). There were no other significant differences between medial and lateral for corresponding specimen groups tested. Therefore, to further investigate correlations with a larger sample size, we pooled medial and lateral specimens into the 4 groups noted (AO, AI, CO, CI), for a total of n=10 for each group, and completed a second ANOVA with Tukey post-hoc testing. The results are shown in Figure 3. There was a significant effect of direction on the Young's modulus. For both inner and outer regions, the modulus in the circumferential direction was higher than in the axial direction (AI<CI, p=0.004; AO<CO, p=0.02). There was no significant difference comparing inner and outer specimens with the same orientation, although for both axial and circumferential groups, the elasticity was higher in the outer region compared to the inner region (p=0.086 for axial and p=0.24 for circumferential).

DISCUSSION

In this study, we investigated the effect of region and orientation on the micromechanical properties of porcine meniscus tissues. Our results, which averaged 1.93 ± 0.88 MPa across all specimens, are within the range of nanoindentation and AFM studies in the literature for meniscus tissues [3-9]. It should be noted that our results are higher than those determined in some other AFM studies; however, these discrepancies are likely the result of important differences in specimen

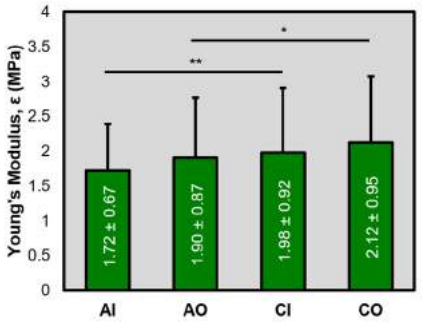

Figure 3: Results (mean ± standard deviation) for modulus of elasticity when pooling medial and lateral groups. n=10 for each. *: p<0.05; **: p<0.01

preparation techniques. That is, our samples were thicker and were fully hydrated during testing. Differences may also be due to species types.

The anisotropic trend for elastic modulus was expected based on the collagen fiber arrangement in the tissue, which includes parallel bundles organized in the circumferential direction of the tissue, allowing the meniscus to withstand hoop stresses upon loading [1]. Previous studies have shown a similar trend as that shown in Figure 3, with elasticity being higher in the circumferential direction [4].

Results also indicated that the region of the tissue (inner vs. outer) affected the mechanical properties, particularly for circumferentially oriented specimens. Region-dependent elasticity in the meniscus has been found previously [4-7]. This is again likely the result of the structural organization of the tissue: an earlier imaging study showed that the fiber bundles become less organized moving from outer to inner regions [10]. This relates with the function of the different tissue regions, with the outer zone bearing tensile forces and the inner zone bearing more compressive forces [1].

Only limited significant differences between medial and lateral meniscus biomechanical properties were found here. While some studies have found that mechanical properties differ between these two tissue types [8-9], others have failed to find differences [3]. The lack of significance here may be due to a small sample size (n=5); more extensive studies are warranted to better understand this effect.

Taken together, the results of this study provide important insight into the inhomogeneous and anisotropic micromechanical properties of the meniscus. This information can be employed to develop site specific tissue scaffolds for tissue repair, which have properties that appropriately mimic the native tissue. Future studies will address study limitations, including small sample size and use of porcine, rather than human tissues, in order to more fully understand tissue micromechanics and related function and pathology.

INTRODUCTION

Four-dimensional flow cardiovascular magnetic resonance imaging (4D flow cMRI) provides a non-invasive, non-ionizing radiation-based technique to evaluate the *in vivo* blood flow environment [1]. The ability of 4D flow cMRI to capture multidimensional flow fields provides a more comprehensive evaluation of the hemodynamic environment over 2D-based techniques (e.g., ultrasound). In addition to continued developments to improve image quality, recent advances in 4D flow cMRI pulse sequences now afford flexibility in the acquisition gating strategy. With prospective gating, MR data acquisition begins after detection of a physiologic "trigger" (e.g., an R-wave), and data are acquired across a finite time window that is set far lower than the cardiac cycle period (Fig. 1). As a result, a gap in acquisition at the end of the cardiac cycle occurs to avoid a missed trigger. With retrospective gating, data are acquired continuously across the complete cardiac cycle and later grouped based on a physiologic measure (e.g., EKG) collected simultaneously with the MR data. Notably, retrospective gating can lead to changes in image quality due to potential temporal smoothing. Thus, the selection of gating techniques is a compromise that ultimately depends on the clinical application of 4D flow and data of interest.

Hemodynamics in the carotid bifurcation are of considerable clinical interest due to the association of complex flow patterns in the carotid bulb and atherosclerosis [2]. In this anatomic region, low fluid velocity and flow reversal occur in late systole and throughout diastole in the carotid bulb, and suggests that retrospective gated 4D flow acquisitions may offer increased prognostic value in the clinical management of stroke. Thus, the aim of this investigation was to quantitatively compare the 4D flow cMRI-derived hemodynamic environment in the carotid bifurcation between prospective and retrospective gated acquisitions.

METHODS

Image data were independently acquired in the left and right carotid bifurcation from two healthy volunteers using a 3T MRI scanner (PRISMA, Siemens, Erlangen, Germany) and bi-lateral carotid coil (Fig. 1). Prospective and retrospective EKG gating techniques were utilized to acquire data at each anatomic location with identical volume coverage. Data were collected across a field of view of 200×163×160 mm with 12 slices, resulting in a voxel size of approximately 1.5×1.5×1.8 mm^3. A velocity encoding (VENC) value of 70 cm/s was used in all spatial directions. Temporal resolution was approximately 49 and 35 ms for prospective and retrospective scans, respectively, and temporal coverage was approximately 85% and 100%, respectively, of the cardiac cycle. To allow evaluation of intra-scan variability, two prospective and retrospective gating acquisitions were performed in one volunteer during the same imaging session.

Acquired image data were segmented with semi-automatic techniques (Seg3D, SCI Institute, Univ. of Utah) to define the fluid (blood) volume (Fig. 1). Raw voxel values were converted to velocities using the defined VENC, and volumetric data were processed to provide interactive visualization of the flow fields and focal quantification of kinematic quantities. For flow visualization, image data were imported into ParaView, which included the OSPRay ray tracing framework plugin for high-quality renderings [3]. The velocity values were used to create streamlines which were encoded with velocity magnitude values for visualization. For quantitative analysis, velocity data were extracted in cross-sections perpendicular to the vessel centerline at locations ~3.5 mm from the carotid bifurcation in the common carotid, internal carotid (i.e., carotid bulb), and external carotid arteries (Fig. 1).

To evaluate the inter-scan (prospective vs. retrospective) and intra-scan variability in acquired data, through-plane velocity values (i.e., v_z) in corresponding anatomic planes (Fig. 1) and time points in the cardiac

cycle were examined. Data were compared at peak systole, as well as temporal average values across the complete (cycle time-average) or diastolic portion (diastolic time-average) of the cardiac cycle. Agreement was evaluated by calculating the concordance correlation coefficient (CCC) and with Bland-Altman analysis. Data are presented as mean±SD.

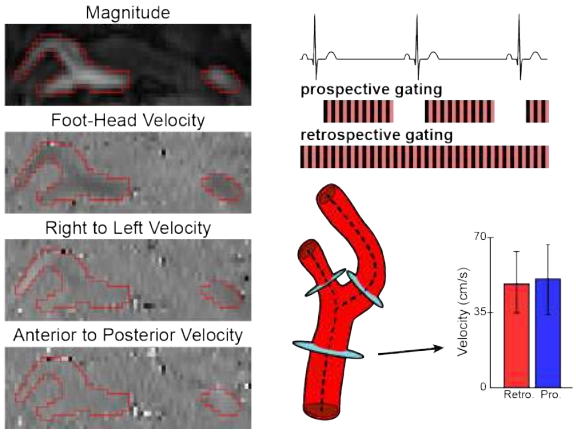

Figure 1: Schematic of image acquisition and quantitative analysis, including MR images (left), gating techniques (top right), and quantification of velocity data (bottom right).

RESULTS

Evaluation of the hemodynamic data revealed similarities between visualizations of flow streamlines encoded with velocity magnitude whether the data were collected with prospective or retrospective gating. For example, streamlines encoded with velocity at peak systole in the right carotid bifurcation of volunteer 1 demonstrated flow pattern similarities, including parabolic flow profile in the common carotid artery and multidirectional flow in the carotid bulb, and high velocities in the distal internal carotid artery (Fig. 2). Similar observations were also observed in the left carotid bifurcation of volunteer 2.

Quantitative examination of velocity data complemented the observed similarities in flow streamline data between the prospective and retrospective gated acquisitions. For example, strong agreement was observed between prospective and retrospective gated scans when comparing velocity values across both volunteers, all anatomic locations, and evaluated time points evaluated (CCC = 0.96; Fig. 3). In addition, Bland-Altman analysis revealed minimal bias (1.42 cm/s) in

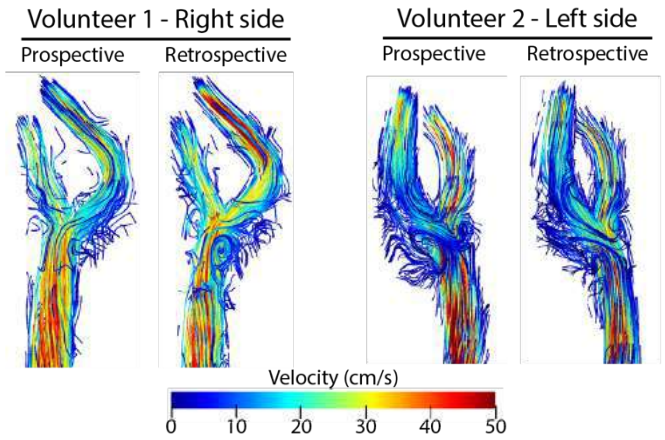

Figure 2: Flow streamlines in carotid bifurcations at peak systole from prospective and retrospective gated acquisitions.

velocity values between the prospective and retrospective gated acquisitions. A voxel-by-voxel comparison across gating techniques demonstrated an average difference of 0.33±4.41, 0.67±8.67, and 0.14±3.66 cm/s from cycle time-averaged, peak systole, and diastolic time-averaged velocity values, respectively. Finally, ~75% of the voxels had a difference of < 5 cm/s.

Evaluation of intra-scan variability (i.e., repeatability) demonstrated similar agreement and bias when compared to inter-scan variability (Fig. 3). For example, strong agreement (CCC = 0.93) and minimal bias (1.15 cm/s) was observed when comparing prospectively gated data independently acquired across two acquisitions. Similar values were seen when examining intra-scan variability with retrospectively gated techniques (CCC = 0.99; bias = 0.87 cm/s).

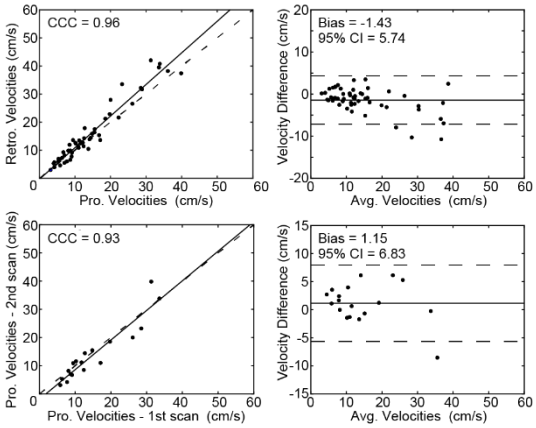

Figure 3: Linear regression (left) and Bland-Altman (right) analysis demonstrating strong agreement between the prospective and retrospective gated acquired velocities (top row) that is comparable to intra-scan agreement with prospective (bottom row) and retrospective (data not shown) gated acquisitions.

DISCUSSION

Our investigation demonstrates strong agreement in fluid velocities acquired with either prospective or retrospective gated 4D flow cMRI in the carotid bifurcation of healthy volunteers. We report qualitative similarities in flow patterns extracted from image data acquired with the two gating techniques with supporting quantitative data highlighting strong agreement and minimal bias in fluid velocities between the gating techniques. Furthermore, the inter-scan variability in velocity values was within the range of differences observed across intra-scan variability for each gating technique. Importantly, there is a clear advantage with the retrospective gated sequence as it covers 100% of the cardiac cycle, whereas the prospective gated sequence only covered 84%. Future studies that utilize 4D flow cMRI with retrospective gating may provide increase prognostic value in the clinical management of patients with stroke.

RAPID FORMATION OF 3D TUMOR MODEL WITH TUMOR-STROMA INTERFACE AT EXTREMELY HIGH CELL DENSITY

Cih Cheng, George T.-C. Chiu, and Bumsoo Han

Mechanical Engineering
Purdue University
West Lafayette, IN, USA

INTRODUCTION

Three-dimensional (3D) cell culture systems are becoming increasingly popular due to their ability to more closely mimic the in vivo microenvironment than the traditional 2D cultures. These 3D cultures present both structural and chemical ECM environment and recapitulate various aspects of the interactions between cell-cell and cell-matrix. Recent advances in cell biology, microfabrication, and tissue engineering enable a wide variety of 3D cell culture techniques. These include multicellular spheroids, organoids, hydrogel scaffolds, organs-on-chips, and 3D bioprinting [1]. These models have been developed and adopted for drug discovery, cancer cell biology, stem cell study, engineered functional tissues for implantation, and other cell-based analysis [2]. Among these applications, 3D cell culture models were mostly developed for oncology research. Numerous 3D tumor models have been reported [3], such as multicellular layers on porous membranes, scaffold-embedded cultures, multicellular spheroids, and tumor organoids. These 3D in vitro tumor models simulate the in vivo physiological microenvironment and may be useful platforms for preclinical studies [4].

Recent advances in biomaterials and microfabrication (e.g., microfluidics and microprinting) offered great opportunities to recreate 3D models in a controlled manner. Several groups have attempted to utilize hydrogels as biomimetic matrices [5]. These hydrogels have been tailored into different compositions with flexible properties to support 3D culture. Despite these contributions, challenges remain. The ability to construct functional organs/tissue for therapeutic use remains a challenge, which requires millions of cells to be organized into functional units. However, the typical seeding density of cells on the 3D engineered models is around 10^6 to 10^7 cells/ ml, and it would take several weeks to achieve the cell density of $\sim 10^8$ for the highest cell density to mimic the native tissues. Therefore, two most critical challenges are low cell density and time-consuming fabrication.

In the study, we report a novel method to generate tumor-stroma 3D cultures rapidly. The 3D structures could be formed within one day with a high cell density of $\sim 10^8$ cells/ml.

METHODS

The rapid fabrication of tumor-stroma 3D cultures was developed by inkjet printing of cell-laden hydrogels. The collagen-based hydrogel ink is prepared by mixing 3 mg ml/L rat tail collagen type-I (Corning Inc., NY) solution with 1% w/v poly(N-isopropyl acrylamide-co-methyl methacrylate) (P(NIPAM-AM), PolySciTech, IN) solution. Human pancreatic cancer cells (Panc10.05) with red fluorescence protein and pancreatic cancer-associated fibroblast (CAF19) with green fluorescence protein were used in this study. The cell-laden inks were prepared by mixing the collagen-based hydrogel solution with harvested cells, which are Panc10.05 and CAF19.

The process is illustrated in Figure 1. Firstly, Panc10.05-laden ink drops were deposited on a glass well-plate by a Pipejet system to form a line array. Then, the well-plate was placed in an incubator for 3 minutes for the gelation of the polymer matrix. Next, CAF19-laden ink drops were deposited on the glass well-plate to form a line array adjacent to the first line. Again, the well-plate was placed in the incubator to gelate the polymer matrix. After printing and curing, we added the medium into the well and put the well-plate in an incubation stage for time-lapse imaging. The behavior of the cell-containing matrix was recorded. Due to the cells' contraction force, the matrix will start to shrink and finally form a tumor-stroma 3D aggregate within one day.

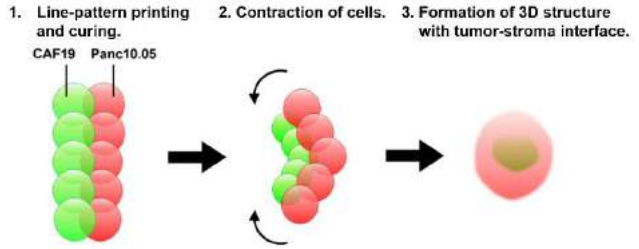

Figure 1. Illustration of the process of the rapid formation for 3D tumor-stroma culture.

RESULTS

The rapid formation of a 3D tumor-stroma culture after printing and curing is illustrated in Figure 2. The fluorescent time-lapse images showing the formation process are displayed in Figure 2(A). The volumetric strain of the matrix, the cell density, and the collagen concentration during the formation process are shown in Figure 2(B).

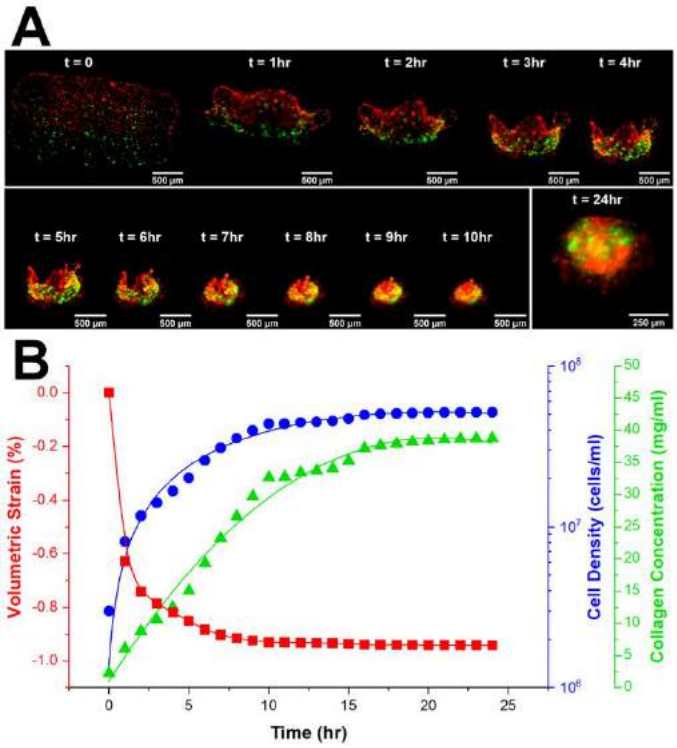

Figure 2. The rapid formation of 3D tumor-stroma culture. (A) Fluorescent time-lapsed images at different time points during the formation (B) the matrix's volumetric strain, the cell density, and the collagen concentration during the formation.

After being printed and cured, the cell-laden hydrogel matrix would detach from the glass surface and float in the culture medium when adding the medium. The matrix will then experience shrinkage due to the cells' contraction force and eventually form a 3D cellular aggregate. It is noted that the 3D aggregate could be quickly formed in 10 hr, which can be seen in Figure 2(A) that the size changed fast initially while it slowed down after ~10hr. In Figure 2(B), the volumetric strain also shows that the size reduced rapidly in the first 10 hr. The formed 3D culture possessed a structure that the CAF19s (green) assemble at the central region, surrounded by the Panc10.05s (red), as shown in Figure 2(A) at t = 24hr. This is because of the contractility difference between CAF19 and Panc10.05 (CAF19 has a strong contraction force while Panc10.05 is less contractile). The change of cell density and the collagen concentration during the formation are quantified. As seen in Figure 2(B), the initial seeding density is $\sim 10^6$ cells/ml. During the formation, the cell density would increase with the decrease in size. The formed structure's final cell density can reach near 10^8 cells/ml. However, the cell density is underestimated since we neglect the cell growth in the first-day culture. It means that the final cell density could be higher, close to cell densities in human tissues. Similarly, the collagen concentration would increase as the size decreases. The collagen concentration is also a conservative estimation since the collagen would degrade and be synthesized by the fibroblast, which is not considered. Nevertheless, Figure 2(B) demonstrates a high cell density and high collagen concentration in the formed structure, comparable to human tissues.

The 3D tumor-stroma aggregates prepared by the proposed method could be further co-cultured to speed up the culturing process and lead to a larger structure. As shown in Figure 3, six tumor-stroma aggregates are co-cultured in a U-bottom shape well-plate. After co-culturing for two days, a 3D model with a size of ~1mm can be obtained.

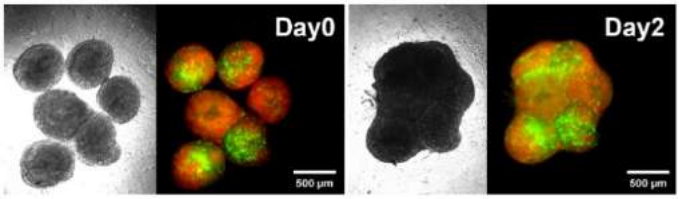

Figure 3. Bright-field and fluorescent images of six 3D tumor-stroma structures at Day0 and Day2 after co-culturing.

DISCUSSION

3D cell culture systems have shown great potential to replicate physiologically relevant cell and tumor models. These 3D constructs can be used as 3D models for human cancers and support diverse cancer research applications. However, current fabrication technologies are limited by the time-consuming and high-cost production, low cell density, and lack of a standardized protocol for any given cell type.

This study reports a rapid formation method to create a 3D structure with the tumor-stroma interface by inkjet-printing of cell-laden hydrogels. The printed collagen-based hydrogel shrinks and self-assembles to a 3D system within one day due to the cells' contraction force. The formed 3D structures could be cultured for more than two weeks. The results demonstrate that the proposed method is a fast and versatile way to create 3D tumor models with high cell density, similar to native human tissues. Moreover, it is applicable to multiple cell lines.

The underlying mechanism of the formation is the force balance between the cell's contraction force and the matrix stiffness. Therefore, the shape of the formed structures can be further controlled by manipulating the cell type, matrix stiffness, and cell density. In the future, when combined with immune cells and fibroblasts, this could be a 3D tumor model for immune-oncology applications.

INTRODUCTION

The vagina provides support to the pelvic organs and is critical for facilitating normal physiological activities such as menstruation, intercourse, and childbirth. The vagina is comprised of various glycosaminoglycans (GAGs) which are negatively charged molecules that sequester water, and vaginal GAG and water content increase during pregnancy.[1,2] GAGs play a significant role in tissue repair due to damage or injury, therefore, GAG may also play a role in the vagina with vaginal birth injuries and in the development of pelvic floor disorders.[3,4] Osmotic loading experiments demonstrate that GAG and water content correlate to viscoelastic function in other soft tissues.[5] However, it is unknown how GAGs contribute to the viscoelastic response of the vagina, which is critical to maintain pelvic support. Therefore, the objective of this study was to quantify the effect of hypo- and hyper-osmotic loading on vaginal creep. It is hypothesized that hypo-osmotic loading induces swelling, increasing vaginal wall thickness and subsequently increasing creep. Further, we posit that hyper-osmotic loading decreases both vaginal thickness and creep.

METHODS

Female nulliparous wildtype C57BL6 x 129SvEv mice 3-6 months of age at estrus (n=9) were used in this IACUC approved study. Carbon dioxide inhalation euthanized all mice. The vaginas were explanted, snap-frozen with liquid nitrogen, and stored at -80ºC until mechanical testing. Sutures secured each vagina onto 3.75-mm cannulas within a biaxial extension-inflation system (Biodynamic 5170 System, TA Instruments Electroforce, New Castle, DE; Fig 1A) in room temperature Hanks Balanced Salt Solution (HBSS).[6] A laser micrometer (Mitutoyo 6200 Laser Scan Micrometer, 2 µm resolution; Mitutoyo Corporation, Kanagawa, Japan) optically tracked the outer diameter and a load cell (1000 g; 0.03 g resolution) measured axial load. The experimental physiologic length was determined wherein axial load remained constant over a physiologic range of increasing pressures.[7] Cyclic pressurization preconditioned the vaginal tissue (10 cycles from 0 to 15 mmHg at 1.5 mmHg/s), followed by 10 minutes of equilibration. At the physiologic length, a constant *in vivo* vaginal pressure was applied (7 mmHg; 1.5mmHg/s) for 100 seconds and the laser micrometer recorded the dynamic outer diameter (Fig. 1A).[8-10] Pressure was then removed for 1000 seconds of recovery.[10] At the physiologic length and 7 mmHg pressure, short-axis B-mode ultrasound (40MHz transducer) imaged the vagina (Fig. 1B).[9] ImageJ was used to measure vaginal thickness to calculate volume.[9]

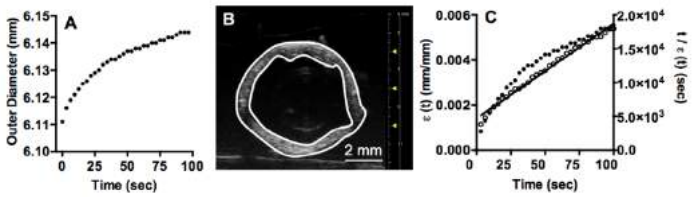

Figure 1: Representative outer diameter over 100 seconds creep curve (A). Representative B-mode ultrasound image of the vagina (B). Peleg's equation linearly (open circle right axis) transformed the strain (filled circle left axis) versus time curve (C). A linear regression determined the slope and intercept of the linear line (black line).

The vagina was randomly placed in either normo-osmotic (134 mM sodium chloride; n=3), hypo-osmotic (46 mM sodium chloride; n=3), or hyper-osmotic (300 mM sodium chloride; n=3) HBSS for 1-hour.[11,10] After osmotic loading, ultrasound imaging was repeated,

followed by preconditioning and equilibration. At the physiologic length, a constant 7 mmHg pressure was applied for 100 seconds.

To analyze the creep data, the outer diameter was normalized by calculating strain with reference to the original outer diameter (i.e. at 0 seconds; Fig 1C). Peleg's equation linearized the nonlinear creep data (equation 1; Fig 1C).[13] A linear regression determined Peleg's constants k_1 (intercept) and k_2 (slope).[13] Peleg's constants were used to calculate the rate of creep (equation 2).

$$t/\varepsilon(t) = k_1 + k_2 t \quad (1)$$

$$b = k_2/k_1 \quad (2)$$

The thickness, volume, Peleg's constants, creep rate, and creep strain at 100 seconds were calculated pre- and post- osmotic loading for all conditions (normo-, hyper, and hypo). To compare the hyper- and hypo-osmotic response to the normo-osmotic control the post-osmotic value for thickness, volume, Peleg's constants, creep rate, and creep strain at 100 seconds were normalized to the pre-osmotic value.[11] A normalized value of 1 indicated no change between the pre- and post-osmotic response. A value greater than 1 indicated an increase, and a value less than 1 a decrease. Multiple unpaired t-tests with Bonferroni correction ($p<0.05/2=0.025$) evaluated the normalized normo-osmotic thickness, volume, Peleg's constants, creep rate, and creep strain to the normalized hyper- and hypo-osmotic values.

RESULTS

Hypo- and hyper- osmotic loading did not significantly affect normalized thickness (Fig. 2A) and volume (Fig. 2B) when compared to the normo-osmotic control. The vagina displayed a similar creep response pre- and post- normo- (Fig. 3A), hyper- (Fig. 3C), and hypo- (Fig. 3E) osmotic loading. Hyper- and hypo- osmotic loading did not significantly affect normalized Peleg's constants (Fig. 3B), creep rate (Fig. 3D), and creep strain at 100 seconds (Fig. 3F) when compared to the normo-osmotic control.

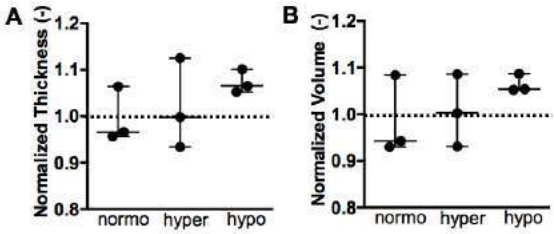

Figure 2: Normalized thickness for normo-, hyper-, and hypo-osmotic loading (A). Normalized volume for normo-, hyper-, and hypo-osmotic loading (B).

DISCUSSION

This study evaluated the effect of osmotic loading on the murine vaginal viscoelastic behavior. Hypo- and hyper-osmotic loading did not significantly affect vaginal wall thickness and volume compared to the normo-osmotic control. This is consistent with previous findings in the murine vagina where hypo-osmotic loading did not significantly affect thickness or volume.[12] The lack of geometrical differences with hyper- and hypo- osmotic loading may be a result of treatment time. In the intervertebral disc, the cross-sectional area and water content significantly decreased after 12 hours of hyper-osmotic loading.[14] Thus, within this study 1 hour may be insufficient time to observe significant changes. Contrastingly, the lack of significance may be due to the vagina lacking a significant number of GAGs to sequester water in the non-pregnant state, as vaginal GAGs, water content, and creep significantly increase during pregnancy.[2] Similarly, this may contribute to lack of significant differences observed in this study.

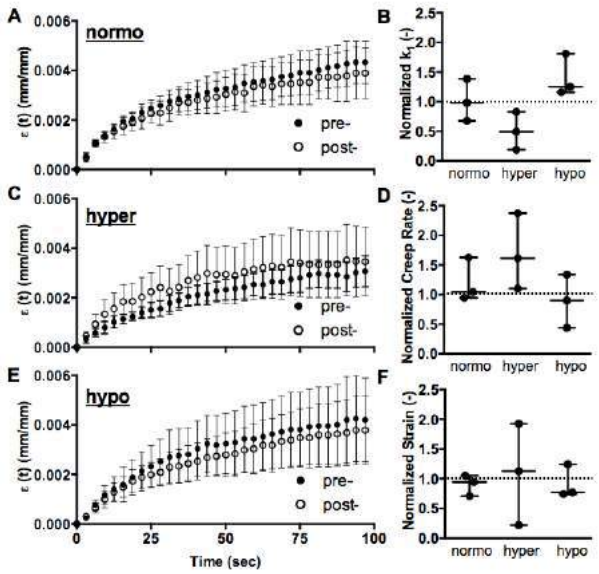

Figure 3: Creep strain verse time pre- (filled) and post- (open) normo- (A), hyper- (C), and hypo- (E) osmotic loading. Data reported as mean and standard error of mean. Normalized Peleg's constant k_1 (B), creep rate (D), and strain at 100 seconds (F) of normo-, hyper-, and hypo- osmotic loading.

Likewise, osmotic loading did not significantly affect creep in the colon.[15] Activation of the colonic smooth muscle cells, however, significantly increased creep suggesting they may significantly contribute to the viscoelastic response.[15] Additionally, previous studies in the knee medial collateral ligament suggest that collagen fiber recruitment dominates the creep phenomenon.[16,17] Future work evaluating changes in GAGs, water, smooth muscle content, and collagen fiber architecture, throughout pregnancy, may improve our understanding of how these components contribute to vaginal creep and subsequently pelvic organ support. Elucidating the key microstructural processes that dictate vaginal creep behavior is critical to understand how and why failures in pelvic organ support may occur during or following pregnancy, as well as changes that may occur following the onset of menopause.

INTRODUCTION

Metastasis is the leading cause of cancer-related death, yet the metastatic process is poorly understood due to its complexity and tumor heterogeneity [1]. In the initial steps of metastasis, tumor cells acquire the ability to migrate out of the primary tumor into adjacent tissue due to alterations in signaling pathways or changes in the extracellular matrix (ECM) [2,3]. The physical cues provided by the tumor ECM influence the behavior and migration of cells [4]. Contact guidance is the process through which cells sense and respond to substrate anisotropies, ultimately altering cell adhesion formation, directionality, and migration [5,6]. However, the structural features that dictate invasive cell migration and the mechanisms by which cancer cells sense topographic features remain unclear.

While *in vivo* models are extremely useful for studying tumor development and growth, the sheer complexity of the tumor microenvironment makes it impossible to use them to dissect the mechanisms that regulate cell-ECM interactions during invasive migration. Therefore, many *in vitro* approaches have been used to deconstruct the complex ECM and understand the mechanisms by which cells sense the fibrous architectures of the ECM [7-9]. To understand the role of fibrous structures during invasive cell migration, here we used synthetic, electrospun fibrous extracellular matrices and live cell imaging to characterize the collective cell migration pattern of the highly invasive MDA-MB-231 breast cancer cell line.

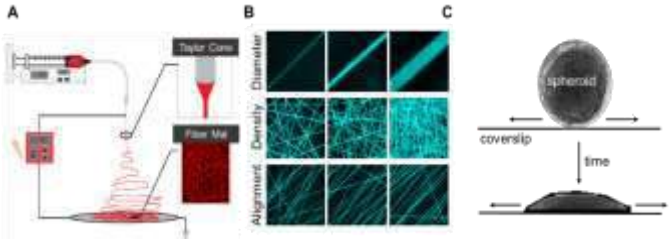

Figure 1: (A) Electrospinning is a voltage-driven process where a synthetic polymer is drawn to a coverslip creating fiber networks. (B) Representative images of synthetic fibrous networks designed to mimic *in vivo* structures. (C) Cancer cell spheroids adhere to the fiber-coated coverslip, and over time cells collectively migrate onto the fibers. (electrospinning figure adapted from Zagho, M.M. et al. *Electrospinning-Material, Techniques, and Biomedical Applications*. 2016).

METHODS

Fabrication of fibrous matrices: To create DexVS, dextran was reacted with divinyl sulfone in a previously described procedure [10]. Electrospinning solution was created by dissolving lyophilized DexVS in a 1:1 solution of water and dimethylformamide with 0.6% (w/v) LAP photoinitiator. DexVS solution was then electrospun onto 25 mm diameter coverslips and rhodamine-labeled fibers were crosslinked with UV light and LAP photoinitiator (**Fig 1A&B**). Cell Culture: MDA-MB-231 cells were cultured in DMEM supplemented with 10% FBS. Spheroids were formed by depositing cells into a 1.2% poly-HEMA coated v-bottomed 96 well plate. 96 well plates were spun on day 0 at 300G for 10 minutes and incubated for 6 days. Cell Migration Assay: Spheroids were plated onto DexVS fiber mats coated with 100ug/mL

type I bovine collagen. Spheroids were allowed to adhere to fibers for 2 hours before imaging. Spheroids and fiber mats were imaged every 10 minutes for 22 hours by fluorescent cell microscopy using a Zeiss Observer 2.1 microscope with an automated stage and incubation chamber (**Fig 1C**). The fibers were functionalized with rhodamine to enable visualization, and the cells are labeled with the nuclear dye, Hoechst 33342 (**Fig. 2**). The migration patterns of the cells were analyzed by automated FIJI tracking plugin, TrackMate, and a custom MATLAB script which extracts cell migration parameters such as cell speed, directionality, persistence, and the prevalence of single cell dissemination [12]. The approximate geometry of the fiber mats is determined using a fluorescent image of the fibers and a MATLAB code which utilizes the Fourier transform (designed by the Barocas Lab at University of Minnesota) [13].

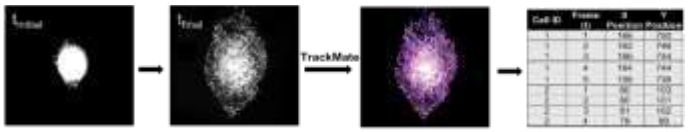

Figure 2: Workflow for tracking cell migration over time where cells are labeled with a nuclear dye. TrackMate identifies nuclei in each frame based on nuclear diameter. Each nucleus/cell is given a unique ID and its corresponding location for each frame.

RESULTS

In our previous studies, we employed nanoscale surfaces with aligned ridges or asymmetric sawteeth to mimic ECM fibers [7]. We discovered that breast cancer cell lines exhibit the ability to sense and respond to physical asymmetric guidance cues in a cell type-dependent manner. Using scanning electron microscopy and fluorescence live cell imaging, we discovered that two breast cancer cell lines with opposite migration behaviors on nanosawteeth exhibit distinct cell cortical plasticity and focal adhesion patterns.

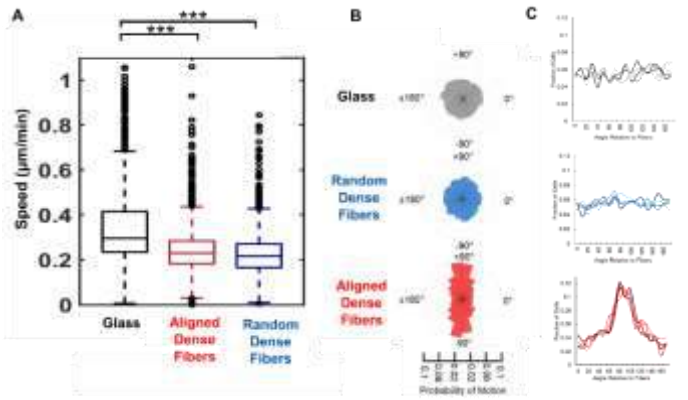

Figure 2: MDA-MB-231 cell migration metrics. (A) Mean cell speed distribution. (B) Probability distribution of cell motion direction. (C) Level of biased cell migration correlated with cell speed where darker colored lines indicate faster binned cells. * = p<0.05 ** = p<0.01 ***= p<0.001

To determine if fibrous architectures also bias collective cell migration, we assessed the group migration phenotype for the MDA-MB-231 invasive breast epithelial cell line. We found that the MDA-MB-231 breast cancer cell line can sense and respond to aligned fiber mats, displaying evidence of contact guidance. In addition, the MDA-MB-231 cells show a decreased mean cell speed when migrating on dense fiber mats, compared to glass surfaces (**Fig. 3A**). Our data indicate that the MDA-MB-231 cell line shows a strong contact guidance response on aligned dense fiber mats (**Fig. 3B**). In addition, we found that the contact guidance response was not dependent on cell speed (**Fig. 3C**).

DISCUSSION

Based on our preliminary findings, we anticipate that invasive breast cancer cell lines will migrate more directionally on aligned fibrous surfaces compared to less invasive breast cancer cell lines, suggesting that invasive breast carcinoma cell lines have more developed contact guidance capabilities. We are currently working on identifying the signaling mechanisms that regulate the distinct migration phenotypes observed. We envision that the spatiotemporal recruitment of Rho GTPases and subsequent focal adhesion distribution are responsible for the distinct migration phenotypes of breast cancer cell lines on similar fibrous surfaces. In conclusion, since cells migrating *in vivo* encounter fibers ubiquitously, our studies will lead to a better understanding of the mechanisms regulating cancer cell invasion.

INTRODUCTION

While breast cancer has high rates of early stage detection (ranging from 47% at ages 15-39 to 68% at ages 65+), metastasis of the primary tumor can reduce the patient's 5-year survival rate by 73% (1). Even regional invasion of the cancer can reduce 5-year survival rates by 14%; recurrence rates are even worse for other solid tumors (1). Thus, it is essential to determine tumor aggressiveness when disease is local or regional in order to effectively predict the likelihood of recurrence. However, it is difficult to determine tumor outcomes due to a lack of universal molecular prognostic markers (2, 3).

Prior evidence strongly supports weak cellular adhesion strength to the ECM as a biophysical marker of aggressive and/or metastatic cells, due to an increase in focal adhesion turnover and contractility that stems from intrinsic transcriptomic differences in proteins involved in the microtubule cytoskeleton and vesicular transport (4,5). This transcriptomic profile, when present in triple negative breast cancer patients, correlated with shorter disease-free intervals (5). Despite the strong evidence, the assays were performed in vitro and thus cannot truly mimic the tumor microenvironment. Therefore, it is essential to demonstrate the link between decreased adhesion strength and increased invasive and metastatic behavior in vivo. Using a murine mammary tumor model, we have observed that cells that have locally invaded into the stroma have a decreased adhesion strength in comparison to cells that have remained in the tumor bolus.

METHODS

Isolation of MDA-MB 231 Cells by Adhesion Strength

1×10^6 MDA-MB 231 cells, expressing GFP and Luciferase, were suspended in 40 μL of Matrigel-PBS (1:1) mixture and were injected bilaterally into the inguinal mammary fat pads of 11-week-old female NOD/SCIDγ mice. Tumor growth was monitored at 2-week intervals and the mice were sacrificed at 6 weeks post-injection. Mice were dissected and the fat pads were surgically removed. Using an inverted fluorescent microscope, the stiffened tumor bolus was manually separated from the surrounding stroma. GFP-positive cells in tumor and stroma sections were sorted via FACS.

Sorting and Injection of MDA-MB 231 Cells for Lung Metastases Study

GFP+ Luc+ MDA-MB 231 cells were seeded (~5000 cells/cm^2) overnight onto fibronectin-coated glass slides. Using the parallel-plate flow chamber, the slides were exposed to 25 dynes/cm^2 shear stress for 2 minutes to collect the weakly adherent cells, then exposed to 90 dyn/cm^2 shear stress for 2 minutes. Any cells that remained on the slide were removed via 0.25% trypsin and collected as the strongly adherent cells. The weakly adherent and strongly adherent cell fractions were cultured separately for 48 hours, as well as a perfused but unsorted control population. 1×10^6 GFP+ LUC+ MDA-MB 231 cells from the strongly adherent fraction, weakly adherent fraction, or the unsorted control were suspended in 40 μL of Matrigel-PBS (1:1) mixture and were injected into the inguinal mammary fat pad of 11-week-old female NOD/SCIDγ mice. Tumor growth was monitored at 2-week intervals and the mice were sacrificed at 6 weeks post-injection. At time of sacrifice, the lungs and primary tumors were harvested, frozen in optimal cutting temperature compound, and stored at -80° C.

RESULTS

Invaded Cells Have Decreased Adhesion Strength Compared to Cells in the Tumor Bolus

Our previous findings have shown that within metastatic cell lines, weakly adherent cells isolated using a microfluidic shear assay were

more migratory, more contractile, and had more labile focal adhesions than strongly adherent cells (5). Since decreased adhesion correlated with an increase in behaviors associated with more aggressive cancer cells, we wanted to investigate if these findings could be recapitulated *in vivo*. We injected GFP+ Luc+ MDA-MB231 cells into the mammary fat pads of 11-week-old NOD/SCIDγ mice and resected the tumor 6 weeks post injection. GFP+ cells were isolated from the tumor bolus and surrounding stroma, separated manually, and sorted using FACS (Fig. 1A). The percentage of stroma GFP+ cells was less than those present in the tumor (Fig. 1B). Using a spinning disk shear assay, we observed that the invading GFP+ cells in tumor-adjacent stroma had significantly decreased adhesion strength compared to cells that remained in the tumor (Fig. 1C); when assessing paired samples, we found that tumor adhesion strength was 60% higher than for GFP+ cells isolated from the stromal region (Fig. 1D). These data are consistent with *in vitro* findings that link decreased adhesion to increased metastatic potential.

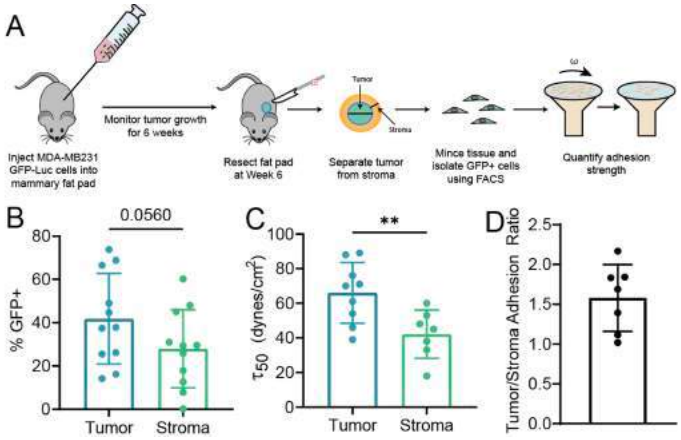

Figure 1: Invaded cells exhibit decreased cell adhesion strength. (A) Timeline of tumor resection study. (B) There are fewer GFP-positive cells present in the stroma versus the tumor. (C,D) Invaded MDA-MB231 cells have decreased adhesion strength compared to MDA-MB231 cells that remain in the tumor. (B,C) Statistical analysis via unpaired t-test. ** represents p<0.01.

Mice Injected with Strongly Adherent Cells Exhibit Fewer Lung Metastases

We next hypothesized that mice injected with pre-sorted weakly or strongly adherent cells would have more or fewer incidences of lung metastases, respectively; thus, weakly or strongly adherent cells should be more or less able to migrate out of the primary tumor microenvironment and enter distant locations in the body, respectively. To test this hypothesis, we injected 11-week-old NOD/SCIDγ mice with unsorted, weakly adherent, or strongly adherent GFP+ Luc+ MDA-MB231 cells into the mammary fat pad, monitored their tumor growth biweekly for 6 weeks using IVIS imaging, then sacrificed the mice and quantified primary tumor size and the number of lung metastases (Fig. 2A,B). While there was no difference in the primary tumor weight among three groups of mice (Fig. 2C), there were notable differences in the number of lung metastases, with the strongly adherent mice having the least number of lung metastases, and the weakly adherent mice having the greatest number of lung metastases (Fig. 2B,D,E). These results are consistent with invading or migratory cancer cells having decreased adhesion strength, exhibiting this weakly adherent phenotype.

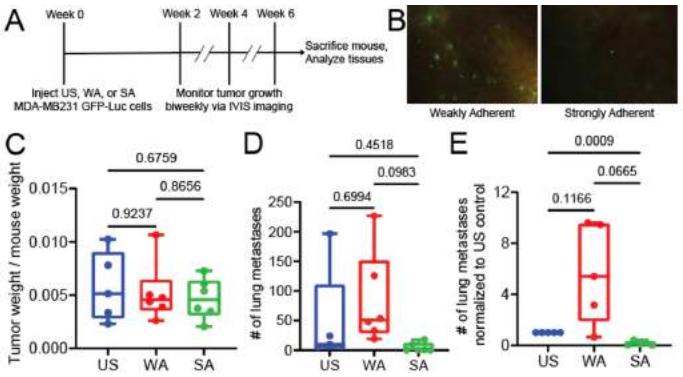

Figure 2: Mice injected with weakly adherent cells have few lung metastases. (A) Timeline of metastasis study. (B) Representative images of GFP+ lung metastases. (C) There is no difference in the tumor size among groups. (D,E) Weakly adherent mice have the most lung metastases and strongly adherent mice have the fewest. (C-D) Statistical analysis via unpaired t-test.

DISCUSSION

Despite a rise in early-stage detection of certain cancers, particularly breast cancer, local or regional invasion can reduce the 5-year survival rate of patients (1). Due to heterogeneity within the tumor and across tumors from different patients, there are no universal biological markers that can predict disease outcome. Adhesion strength has emerged as potential biophysical marker, but its links to cancer cell aggression and metastatic potential have only been demonstrated in vitro (5). It is essential to show that weak cellular adhesion correlates with more aggressive cells vivo to demonstrate the clinical relevance of adhesion strength as a prognostic marker. As such, we sought to correlate in vitro findings of aggressiveness of weakly adherent cells to increased invasion and metastatic tumor formation in vivo.

We observed, in a murine mammary tumor model, that invaded cells within the mammary stroma have lower cellular adhesion strength than cells that remain in the stiff tumor, observation consistent with in vitro findings. Further, we found that mice that were injected with strongly adherent cells exhibited fewer metastases than mice injected with either weakly adherent cells or an unsorted control population. Moreover, these mice injected with strongly adherent cells consistently showed the development of minimal metastatic tumors, which is in stark contrast to the broad range and greater of metastatic lung tumors in mice that received unsorted or weakly adherent cells. These results suggest that strongly adherent cells lack the ability to migrate out of the primary tumor microenvironment, therefore, tumors that are composed of only strongly adherent cells lack the ability to form metastatic tumors. Broadly, these data suggest that adhesion strength can serve as a marker of metastatic potential and can be utilized in a prognostic fashion to screen patient samples.

AN *IN SILICO* MODEL OF HUMAN CORNEA SUBJECTED TO PHYSIOLOGICAL AND NON-PHYSIOLOGICAL LOADING: INVESTIGATION OF THE MECHANICAL ENVIRONMENT OF CORNEAL KERATOCYTES

A. Pant (1), E. Paul (1), A. Vahdati (1)

(1) Department of Engineering
East Carolina University
Greenville, NC, USA

INTRODUCTION

Multiscale computer models of the cell-tissue-organ units offer the potential to improve our understanding of various disease pathogenesis. Experimental studies have shown that keratocytes, the predominant corneal cells, although normally quiescent, respond to injury by transitioning into repair phenotypes [1]. Therefore, developing a multiscale computer model of the cornea incorporating the keratocytes may allow us to better understand the cellular causes and responses to injury, which in turn may offer avenues in understanding and preventing the corneal pathologies in the early stages. Therefore, in this study, we developed a computational model of the cornea comprising of the underlying ground matrix and the keratocytes. We then utilized a computational approach to simulate the effect of different loading conditions in the immediate vicinity of the cells located throughout the thickness of the cornea, under physiological intraocular pressure (IOP) loading, and under non-physiological conditions such as IOP spike and eye-poking [2].

METHODS

A finite element model of the cornea, including the limbus, was constructed based on the geometry described by Grytz et al. [3]. We fixed the limbus edge and applied a pressure load to the posterior surface of the cornea and the limbus. To obtain the stress-free geometry of the cornea, we implemented an iterative approach, as proposed by Pandolfi et al. [4].

To study the mechanical response of the cells and to develop the multiscale model of the keratocytes, Ansys software (Ansys Inc, Canonsburg, PA, USA) was used. The solution from the macroscale model of the cornea-limbus was applied as the boundary condition for our microscale cell model. Since keratocytes are flat-shaped cells, we constructed the geometry of the keratocytes to be a nearly flat ellipsoid with dimensions 2 μm for the shorter semi-axis and 7.5 μm for the longer semi-axis. We then ran the simulations for three different cases, with the location of keratocytes changed along the thickness of the cornea (Figure 3). The keratocytes were placed:

i. Near the anterior surface of the stroma
ii. In the middle of the stroma, and
iii. Near the posterior surface of the stroma

We applied two different cases of non-physiological loading conditions in the simulation. For the first case, we considered the effect of elevated IOP. Additionally, eye-rubbing is one of the risk factors for keratoconus, hence, for the second type of loading condition, we simulated the poking effect caused by eye-rubbing by pushing the anterior surface of the cornea to a defined displacement using an idealized indenter representing the second base knuckle bone.

RESULTS

Figure 1 shows the total deformation distribution in the cornea when the cornea is subjected to three different loading conditions respectively: physiological IOP, a moderate IOP spike of 5 mmHg and an indentation (poking) of -0.3 mm. Under the load of 15 mm Hg IOP, IOP spike of 5 mm Hg, and 10 mm Hg, the averaged magnitude of the maximum principal stress in the immediate vicinity of the cell was largest in the cell located near the anterior surface of the stroma and lowest in the cell located near the posterior surface of the stroma.

The magnitude of the maximum principal stress increased as the IOP increased from a physiological loading to an IOP spike of 5 mm Hg to an IOP spike of 10 mm Hg for all the cells located at different locations. For the cell located in the middle of the stroma, the direction of the averaged minimum principal stress changed from a tensile one to

a compressive one as the IOP increased. For the cell located near the posterior surface of the stroma, the averaged minimal principal stress was compressive for all different cases of IOP (Figure 2).

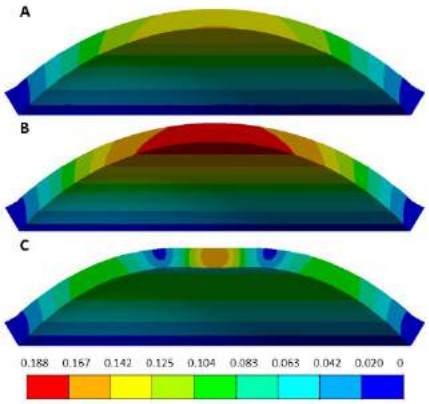

Figure 1: Magnitude of the total deformation (mm) in the cornea (compared to the undeformed configuration) when the cornea is subjected to (A) physiological IOP, (B) IOP spike of 5 mm Hg, and (C) eye-poking loading condition using 0.3 mm downward displacement [2]**.**

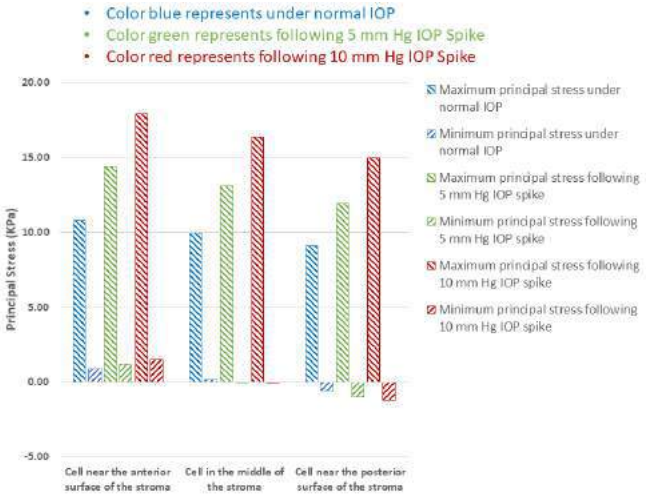

Figure 2: Averaged values of maximum and minimum principal stress developed in the cell's immediate vicinity in different locations following normal (physiological) IOP loading, IOP spike of 5 mm Hg, and IOP spike of 10 mm Hg [2].

Interestingly, under normal IOP, the averaged maximum and the minimum principal strain in the immediate vicinity of the cell did not change significantly irrespective of the location of the cells in the corneal stroma. Similar observations were made under IOP spikes of 5 mm Hg and 10 mm Hg. Results obtained from the progressive eye-poking loading conditions are distinct from the results obtained from IOP loading patterns. The pattern of stress and strain distribution in the immediate vicinity of the cell changed with different displacements used for simulating the poking effect. For all different indentation levels, the cell located near the anterior surface of the stroma experienced on average a large compressive stress state, whereas the cell located near the posterior surface experienced on average tensile stress states (Figure 3).

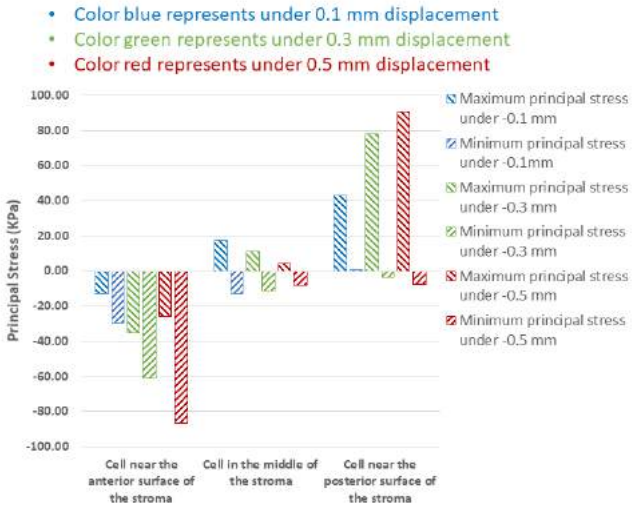

Figure 3: Averaged values of maximum and minimum principal stress developed in the cell's immediate vicinity in different locations following different levels of eye-poking [2].

DISCUSSION

Our study showed that the differences in location of the cell in stroma and the loading condition applied to the cornea can noticeably affect the stress and strain distribution in the surrounding extracellular matrix of the keratocytes. Furthermore, our results demonstrated that while increased IOP can cause large changes in strain and stress magnitude sensed by the cells in a depth-dependent manner, changing the loading mode from IOP to simulated eye-poking can dramatically alter both the direction and magnitude of the stress and strain in corneal keratocytes. From a mechanobiological point of view, it is expected that such large changes in the stresses and strains magnitude and distribution under different loading conditions could have implications for the keratocytes fate and may disrupt the normal corneal homeostasis. While changes in the stress and strain could be induced by either eye-poking or increased IOP, the severity of alterations in loading patterns of keratocytes was more pronounced in the case of simulated eye-poking.

Simulated eye-poking caused inwards bending of the cornea in our simulations, which not only altered the stress and strain magnitudes at different depths but also produced significant changes in the direction of stress and strain and their overall distribution pattern. Our *in silico* findings indicate that the cells near the anterior and posterior surface of the cornea may experience larger strains when compared to the cells present in the middle of the stroma under severe eye-poking.

MEASURING PROSTHETIC FOOT USE BY ACTIVITY LEVEL WITH STEP ACTIVITY MONITORING

John M. Chomack (1), Alexis N. Sidiropoulos (1), Michael N. Poppo (1), Jason T. Maikos (1)

(1) Veteran Affairs New York Harbor
Healthcare System
New York, NY, USA

INTRODUCTION

As prosthetic foot technology advances and becomes more readily available, patients will have increased opportunities to access a range of energy storing, articulating, and powered devices. Therefore, it is critical to use objective measures for prosthetic prescription to meet the biomechanical and functional needs of each patient outside of the clinic. Capturing a patient's prosthetic performance while navigating his/her everyday environment is a key piece of information that has yet to be effectively utilized in the prescription process [1].

Step activity monitoring for individuals with lower extremity amputation has been previously studied to determine compliance and reporting of community ambulation activity in the prosthetic population. Activity monitoring devices, such as the Modus™, StepWatch 3™ used in this study, have been utilized in over 360 peer reviewed publications. The StepWatch 3™ device boasts a 99.7% accuracy for those walking at low speeds and a 92% accuracy for those ambulating with a prosthesis [2]. This study sought to capture the community ambulation activity levels for individuals with transtibial amputation (TTA) while using three different types of prosthetic feet over four weeks. The purpose of the investigation was to determine if a specific foot type promoted higher activity levels as determined through cadence; and if the activity per level correlated with the outcome measures used in this study.

METHODS:

Fifty-one individuals living with TTA age 56.1±12.8 years, height 1.79±0.08 m, and weight 94.7±18.4 kg with at least 1 year of experience with their prosthesis have completed the study protocol to date. These participants were recruited from the Veteran Affairs (VA) New York Harbor Healthcare System (NYHHS), the James A. Haley VA Medical Center, VA Puget Sound Healthcare System, and Walter Reed National Military Medical Center. All procedures were approved by their respective Institutional Review Boards. Participants within this study were randomized to use 3 types of prosthetic feet: energy storing and return foot (ESR), an ESR with articulation (ART), and a powered articulating foot (PWR). Each study device was attached with duplicated, well-fitting below knee sockets.

Study participants wore each foot for a 1-week acclimation period and then completed a series of functional outcomes (FO), questionnaires, and a biomechanical assessment. Participants repeated this process for each subsequent foot type. After wearing each foot for 1 week, participants were instructed to take all study feet home for 4 weeks and to wear the feet as desired. Modus™, StepWatch 3™ step activity monitors (SAMs) were fixed to each prosthesis to track daily steps and activity levels. At the conclusion of the 4-week at home portion, the study devices were returned, and a close-out survey of the participant's device preference was conducted.

Of the 51 participants to complete the study, 38 used 2 or more feet during the at-home portion. Only these 38 participants were included in this analysis. The SAMs were programmed to record the number of steps taken at each minute for 30 consecutive days. Cadence was calculated for each minute, which was then categorized into activity levels: low (1-15 steps/min), moderate (16-40 steps/min), and high (>40 steps/min). Percent of steps taken while active at each activity level was then calculated. At each activity level, we determined the frequencies of the feet with the greatest percent of steps, and, if these feet corresponded to the subject's foot preference. A one-way between subjects Analysis of Variance (ANOVA) was conducted to compare the effects of prosthetic device type to percent steps taken in low, moderate, and high activity levels. Additionally, a simple linear regression was calculated to predict percent steps based on the following FOs: Orthotics Prosthetics User Survey Functional Status, Prosthesis Evaluation Questionnaire Ambulation section, Timed Up-And-Go, 6-

Minute Walk Test, Amputee Mobility Predictor, Stair Assessment Index, and Hill Assessment Index.

RESULTS

Figure 1 represents the frequency of greatest percentage of steps taken at low, moderate, and high activity levels for each foot type as determined through cadence. Results of the ANOVA indicated that there were no significant effects of prosthetic device type on percent steps taken in any of the 3 activity levels ($p>0.05$ in all cases). However, a trend towards significance was observed for the PWR foot at the high activity level ($p=0.06$), with a frequency of 18 of 37 subjects utilizing the PWR for the greatest percent of steps at the high activity level.

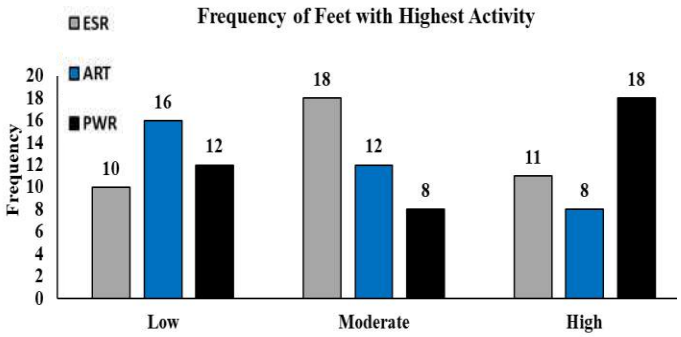

Figure 1:Frequncy of greatest percentage of steps at low, moderate and high activity levels by foot type. (Low, Moderate: N=38)(High: N=37)

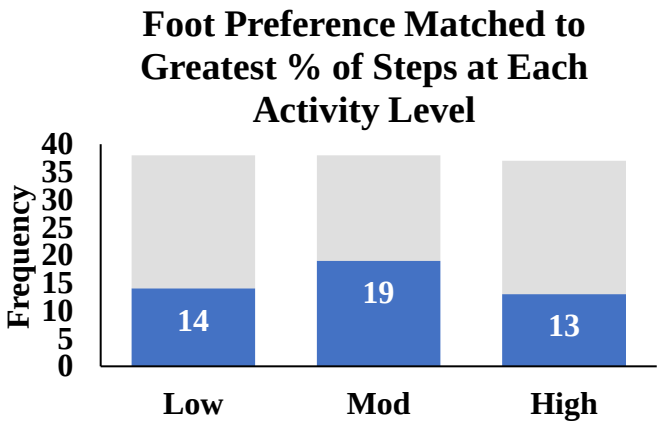

Figure 2: Frequency of subjective foot preference when matched to greatest percentage of steps at low, moderate, and high activity.

Figure 2 represents the frequency of subjective foot preference that matched to the greatest percent of steps taken at each activity level (preference determined by the close-out survey). At high activity 13 of 37 participant (35%) chose the foot that accounted for the greatest percentage of steps. Of the 18 occurrences that the PWR foot provided the greatest percent of steps at high activity, only 6 participants preferred the PWR foot (33%). We observed at low and moderate activity, 37% and 50% of subjects preferred the device that provided the greatest percent of steps. Regression analysis indicated that none of the functional outcome measures were able to predict the percent steps at any of the activity levels ($p>0.05$ in all cases).

DISCUSSION

Step activity monitoring can be a valuable tool to use as part of the prosthetic prescription process since it can help evaluate community ambulation activities. Currently, this key information has been underutilized for this process [1]. This investigation sought to determine if a foot type (ESR, ART, PWR) promoted higher activity levels, and if those associated values correlated to objective metrics. SAM data was recorded for participants using 3 different types of prosthetic feet within their home and community environments over a 4-week period. Percent of steps performed at low-, moderate-, and high-activity were determined and frequencies of prosthetic devices that resulted in the greatest activity at each level were reported.

This preliminary analysis of activity levels for 38 participants showed no significant differences between prosthetic device and percent steps taken at the 3 activity levels. The regression analysis between the objective testing criteria and high activity percent steps taken yielded weak correlative values, suggesting the FO may not be indicative of a subject's activity outside the clinic. However, a trend towards significance was observed for the PWR foot at the high activity level. This trend may be attributed to the powered plantarflexion at terminal stance, which aims to replicate the function of the gastroc-soleus complex. This may allow the user to walk at a consistently higher cadence (>40 steps/min), reducing overall energy expenditure.

Of note, only 35% of users preferred the prosthetic device that promoted the greatest percent of steps taken at high activity (regardless of foot type). Furthermore, of the 18 occurrences in which the PWR foot showed the greatest percent of steps at high activity, only 33% of subjects (n=6) preferred the PWR foot. Participants may not have consistently preferred the PWR foot due to inherent drawbacks of the device, such as heavier weight, increased noise, and the need for daily battery charging. There was an increased percentage of participants who preferred the foot that provided the greatest percent of steps at moderate (50%) activity levels. Because the majority of daily steps were taken at moderate activity levels, these findings suggests that participants may prefer to walk at moderate cadences and select/prefer the prosthetic device that matches the greatest percent of steps at these activity levels.

As more participants complete the protocol, they will be added to this analysis to determine if significance levels can be achieved. Factors such as the number of days of use or accounts of a foot being used specifically for high level activities will need further investigation.

INTRODUCTION

Weakening of the pelvic floor supporting structures could likely lead to the descent of pelvic organs (uterus, rectum, bladder) into the vaginal canal; a condition known as pelvic organ prolapse (POP). Ten percent of women in the United States undergo surgical intervention related to POP [1], and 4 out of 10 women experience reoccurrence of prolapse symptoms 2 years after surgery [2]. There is a huge economic burden associated with this condition, with over $1 billion incurred annually for POP associated interventions in the United States alone [3]. The underlying mechanisms of POP are not understood, but some risk factors include obesity, vaginal delivery, age, race, and mechanical injury [2,4].

The vagina provides pelvic organ support [5,6,7]. It is primarily composed of collagen fibers, smooth muscle, and elastin [8,9]. Biaxial properties which are assessed from two axes simultaneously, provide a more physiologically-relevant biomechanical properties than the widely used uniaxial approach, which only provide a limited information in a single direction. Despite this importance of biaxial properties, including obtaining vital biomechanical properties like anisotropy, no study has reported the biaxial properties of human vaginal samples from women affected by POP. Therefore, the aim of the study was to quantify and compare the biaxial biomechanical properties of vaginal samples from post-menopausal women with or without POP.

METHODS

Vaginal samples were obtained (Ochsner Clinical School IRB approved: 2017.016A) from post-menopausal women with either non-POP (n=9, 62.7±1.7 years old, 32.3±1.6 kg/m^2 BMI), POP I/II (n=6, 60.8±2.5 years old, 29.9±2.9 kg/m^2 BMI) or POP III/IV (n=7, 67.2±2.6 years old, 31.8±3.1 kg/m^2 BMI) condition following transvaginal hysterectomy surgeries (Figure 1). Samples were snap-frozen following surgery and stored at -80°C until the day of biomechanical assessment. Most samples were from Europeans/White women. Five samples were from African-Americans/Black women (non-POP controls only) and two were from Middle-Eastern women (1 non-POP control and 1 POP I/II group). POP III/IV group comprised samples from only Europeans/White women. **Biaxial testing**. Samples were thawed at room temperature, cut into squares, and then speckle coated with alcohol ink for strain tracking (Figure 1) [10]. Using a non-contacting laser micrometer, tissue thickness was measured across multiple locations and averaged. Four fishhooks were used to mount each sample side into a custom planar biaxial test device equipped with load cells (22 N) in both axes, and a camera (Figure 1) [2,11]. The samples were fully submerged in Hank's balance saline solution throughout the experiment. A tare load of 0.1N was applied in the circumferential and longitudinal loading directions, followed by 10 equibiaxial preconditioning cycles to 0.1MPa, after which the samples were allowed to equilibrate for 10 minutes. Next, samples were loaded in the circumferential and longitudinal loading directions to different circumferential:longitudinal loading ratios [12, 13] of 1:0.5, 1:0.75, 1:1, 0.75:1 and 0.5:1 at 0.2%/sec. For each of the loading ratios, 5 preconditioning cycles were applied. **Statistical Analysis.** All data are presented as Mean±SD. Independent samples t-tests were used to assess differences in age, body mass index (BMI), parity, and gravidity between non-POP and POP groups. Statistical significance was set to $p<0.05$. All statistical analyses were performed using SPSS software.

RESULTS

The measured unloaded thicknesses were 1.9±0.2 mm, 2.8±0.4 mm and 2.5±0.2 mm for the non-POP, POP I/II and POP III/IV specimens, respectively. No statistically significant differences were identified with respect to age (p=0.17), BMI (p=0.20), parity (p=0.38), and gravidity (p=0.46), between the non-POP, POP I/II and POP III/IV groups. All vaginal samples exhibited a nonlinear behavior in both the circumferential and longitudinal loading directions (Figure 2), and tissues demonstrated anisotropic behavior. Vaginal samples from POP III/IV groups were most extensible, as compared to samples from the non-POP and POP I/II groups, particularly in the circumferential loading direction (Figure 2A). There were no differences in the

extensibilities between the non-POP and POP I/II in both the circumferential and longitudinal loading directions (Figure 2A,2B).

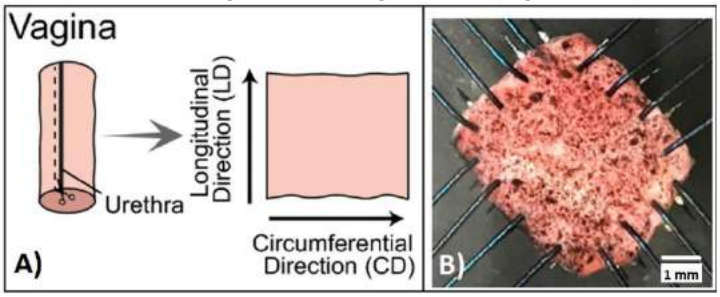

Figure 1: (A) Figure of the vaginal sample showing before and after cutting into a square shape for the biomechanical testing [9]. (B) Samples were speckle-coated and mounted in a planar device via fishhooks for biomechanical testing.

DISCUSSION

Direction-dependent biomechanical properties and nonlinear stress-strain relationships were observed for the vaginal samples. Similar nonlinear behavior has been determined earlier for uniaxial properties of POP vaginal samples [14,15]. The increased extensibility observed in the POP III/IV group may suggest changes in the circumference of the vaginal wall with the progression of POP because of a decreased ability to withstand loads in that direction. This information is useful for reconstructive surgical planning and development of new graft materials for POP repair [2]. A previous human study [16] showed that vaginal biomechanical properties were significantly lower with POP compared to controls. Hence, degeneration of the biomechanical properties in pelvic support may lead to POP development. Further, the POP III/IV uterosacral ligament exhibited the largest extensibility for the main in *vivo* loading direction in a prior study [10], similar to the vaginal response in the circumferential direction herein. Additionally, the perpendicular loading direction did not exhibit differences between the different POP groups in the previous study (uterosacral ligament) and this study (vaginal samples). Perhaps similar biomechanical/structural changes occur with the progression of POP for these two pelvic organs. However, it is important to note that the study herein and the prior study in uterosacral ligament [10] tested samples obtained from the same patient population. Contrary to these results, prior studies leveraging uniaxial tests in the longitudinal direction reported that POP vaginal tissues are significantly stiffer compared to non-POP [17]. Future work is needed to determine if the discrepancies in results are due to differences in biomechanical testing protocols, or whether the POP group was separated into different stages as performed in this study.

Changes in the biomechanical properties exhibited in this study may be caused by changes in the underlying vaginal microstructural composition with respect to the different POP groups. In future, histological analyses will be conducted to determine the composition of the main load-bearing constituents (e.g., collagen fibers, smooth muscle, and elastin) of vaginal samples in each group. The obtained information will subsequently be correlated to the biomechanical properties obtained herein. Prior work, however, reports contradictions in vaginal tissue compositional changes with POP. Some studies report increased [18] levels of collagen III as POP progresses, while others [19] report decreases. Collagen III is the predominant collagen throughout the vaginal wall. Also, some studies report decreased amount of smooth muscle in vaginal tissue with POP, however, the contractile properties of vaginal smooth muscle were not examined in the current study [20,21,22,23,24].

One limitation of the study is the lack of racial diversity in the patient population. Current patient recruitment seeks to improve diversity. Noting, however, that the rate of POP in the African Americans/Blacks population is much lower than other racioethnic groups [19].

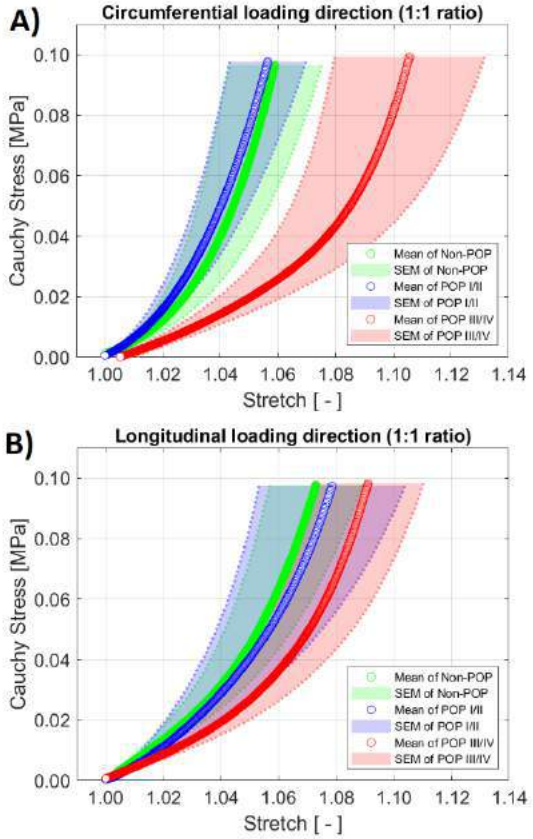

Figure 2: Mean (SEM) of Cauchy stress-stretch plots of vaginal samples loaded at 1:1 ratio for non-POP and various POP stages (I-IV), in the circumferential (A) and longitudinal (B) loading directions.

INTRODUCTION

The effective transfer of muscle forces across the tendon-to-bone attachment ("enthesis"), is critical for joint stability and mobility. Recent advancements in high-resolution imaging revealed that the fibrous architecture of the tendon enthesis may be key to enabling the attachment to withstand multimodal and multidirectional loadings [1]. Nevertheless, many painful and physically debilitating conditions occur at or near this interface when this architecture is compromised [2].

Tendons present different fibrous architecture depending upon their function within joints. Positional tendons, such as flexor tendons of a hand, function primarily to move joints with precision [3], while energy storing tendon, such as the Achilles and patellar tendons, enable efficient locomotion by stretching and recoiling to store and release energy during joint movement [3]. The excursion and deformation of these tendon groups differ significantly, and range of motion (ROM) varies greatly from joint to joint. For the supraspinatus tendon in the shoulder, loading angles range from 0° to 120°; for the Achilles tendon in the ankle, these range from –40° to 20° [4]. Technologies to repair these tendons and their entheses are very similar, but it is unknown what aspects of these govern and enable their unique function, and what aspects of the entheses provide toughness to protect the tendon-bone interface from injury.

Therefore, our aim was to determine the roles of architectural and positional factors on enthesis toughness in a previously validated positional-recruitment model [5]. We hypothesized that energy storing tendons prioritize toughness over strength relative to positional tendons, regardless of loading direction. Furthermore, we hypothesized that the bony anatomy of each enthesis dictates the toughness profile with changing loading direction.

METHODS

Samples: All animal procedures were approved by the Columbia University IACUC. Supraspinatus, patellar, and Achilles tendon-to-bone attachment units were harvested from healthy adult (>12 weeks) C57BL6/J mice (n=15).

Imaging: Samples were submerged in a 5% mercury chloride ($HgCl_2$, Sigma-Aldrich) for 24 hours fixed at appropriate positions (flexion, straight, and extension; n=3-4 per position). $HgCl_2$ solution was used as a contrast agent to enhance enthesis visualization using high resolution x-ray computed tomography (microCT, Bruker Skyscan 1272, 60kVp, 166uA, 5µm resolution).

Positional-recruitment model: We consider N linear elastic fibers of thickness t, each spaced a distance s apart, beginning with a fiber that is immediately to the left of an elliptical bone ridge with a long axis A and the short axis B. We take the initial (unloaded) length of the inner most fiber (a fiber that is immediately to the left of a bone ridge) to be the shortest; fiber length increases with the distance from the bone ridge of fiber n, $A_o^n = R + 0.5t + (n-1)s$. During loading, fibers engage and contact their neighbors or the bone ridge (**Fig. 1**) at a point:

$$\vec{r}_1^n = -A^n \cos\phi_1^n \,\hat{\imath} + B^n \sin\phi_1^n \,\hat{\jmath} \qquad (1)$$

where the long axis and short axis of the centerline of the wrapped fiber (when the curvature takes an effect) is $A^n = A + (n-0.5)t$; $B^n = B + (n-0.5)t$ and the contact angle is $\cos\phi_1^n = R^n/x_0^n$. A rigid grip at the distal end holds all fibers. When the grip is turned at an angle θ to represent postural change, fibers are stretched in a direction $\hat{e}$. The angle ϕ_2^n at which contact is lost is determined by the innermost fiber, which always stays in tension. Contact is lost at the point $\vec{r}_2^n(t)$ at which the unit vector between $\vec{r}_2^n(t)$ and the connection point on the grip for the strand, $\vec{r}_3^n(t)$, is tangent to the ellipsoid formed by the midline of fiber n. Using this we can determine the maximum length of a fiber when it is engaged and contacts the bone ridge:

$$L_{en}^{n}(t) = \|\vec{r}_1^{\,n} - \vec{r}_0^{\,n}\| + Arc_{L_{en}}^{n}\Big|_{\phi_1^n}^{\phi_2^n(t)} + \|\vec{r}_3^{\,n}(t) - \vec{r}_2^{\,n}(t)\| \quad (2)$$

The $Arc_{L_{en}}^{n}$ is the arc length of an ellipse from ϕ_1^n to $\phi_2^n(t)$ with the long axis A^n and the short axis B^n, computed using the Ramanujan formula.

$$L_{en}^{n}(t) = \|\vec{r}_3^{\,n}(t) - \vec{r}_0^{\,n}\| \quad (3)$$

Load-displacement curves were generated from this position-dependent fiber kinematic model by assuming elastic, brittle fibers.

Initial conditions: To model positional tendons, initial lengths of each enthesis fiber were kept constant for all pull directions simulated. To model energy storing tendons, gauge lengths for all pull directions simulated were kept constant, making initial length of each enthesis fiber change with pull directions simulated. To evaluate effect of bone ridge flattening, energy-storing tendons were simulated with constant long axis (A=1) and changes to the short axis (B=0.2 to 1).

RESULTS

The positional-recruitment simulation, run with 20 fibers, revealed that strength, stiffness, and toughness depended on loading directions and were significantly different between positional tendons (i.e., supraspinatus model) and energy storing tendons (i.e., Achilles model) (**Fig. 2**). The strength of energy storing tendons peaked when the tendon enthesis was pulled straight (i.e., at 90°), decreased rapidly at higher loading angles, and decreased gradually at lower loading angles. In contrast, the strength of positional tendons was highest at -30° and decreased monotonically with increasing loading angles. The stiffness profile for energy storing tendons followed its strength profile. In contrast, the stiffness of positional tendons was relatively constant for all loading angles. When examining toughness, energy storing tendons absorbed more energy before failure at all angles compared to positional tendons, with gradual decreases in toughness with increasing loading angles.

Contrast enhanced images of rotator cuff, ankle, and knee joints at flexion, straight, and extension positions showed that the bone ridge anatomy where tendon attaches to bone (circular, B=1; flat, B=0.2) significantly affected the orientation and engagement of tendon enthesis fibers (**Fig. 3**). The effect of bone ridge flattening on the position-dependent load-sharing of the tendon enthesis was evaluated using the initial conditions for energy storing tendons. The simulation revealed that strength and stiffness increased with bone ridge flattening (**Fig. 4**). There were only modest changes in toughness with bone ridge flattening. Notably, toughness was highest for perfectly circular bone ridge (B=1) for all angles simulated.

DISCUSSION

Our novel fiber recruitment model enables simulation of position-dependent mechanical behavior of tendons for joints with varying bone ridge geometries. Simulated mechanical behaviors of positional and energy storing tendons depended strongly upon the initial loading conditions and bony anatomy of enthesis fiber attachment. These factors also affected responses over the physiologic ranges of loading angles. Consistent with our hypothesis, energy storing tendons appeared optimized for toughness: a small tradeoff in strength gave rise to a large gain in toughness throughout all loading angles. The trade-off was particularly apparent at lower loading angles, where, for instance, rotator cuff muscles would be most engaged and enthesis loads would be highest [6], allowing the enthesis fibers to optimize energy absorption (i.e., protect against onset of injury). Interestingly, the stiffness of positional tendons was constant throughout all loading angles. Positional tendons function to move joints with a precision; a constant stiffness likely allows for better muscle control of these precise motions across a wide range of motion.

The simulations provided insights into why thresholds for injury differ with loading angles for each joint. Acute rotator cuff tears often occur at high abduction angles (110°) [6], while Achilles tendon ruptures occur with a sudden plantar flexion of the foot (–30°) [7] and patellar tendon ruptures with the knee flexed (60°) [8]. These positions coincide with the lowest respective strengths in the simulations (**Fig. 2**). Although factors such as post-yield resistance certainly also contribute, the simulation results showed a clear role for bony anatomy and fiber recruitment in tendon enthesis mechanics.

INTRODUCTION

Coarctation of the aorta (COA) is a congenital heart disease characterized by a narrowing in the aortic arch or proximal descending aorta [1]. COA results in altered aortic flow dynamics (elevated pressure gradient, deranged flow) and subsequent complications such as post-stenotic aneurysms or insufficient blood supply to the periphery. Interventional treatment such as surgery, stent placement, and balloon angioplasty are often performed to restore normal aortic hemodynamics [2]. Diagnostic imaging, such as echocardiogram and cardiovascular magnetic resonance (CMR), for aortic hemodynamics is important for intervention planning and assessment of treatment success. Despite advances in CMR such as 4D flow MRI [3] for in-vivo analysis of cardiovascular flow dynamics, current techniques have limitations in phase offset errors, insufficient spatio-temporal resolution, and distortion of images due to stent (metal artifact), and thus unreliable quantification of flow metrics. Methods have been developed to better predict hemodynamic outcomes using patient specific CMR data supplemented by computational models of cardiovascular fluid dynamics. The purpose of this study was to evaluate the feasibility of patient specific MRI-based computational models using a novel method called adaptive mesh refinement (AMR) for improved quantitative flow dynamics analysis in patients with different types of COA repair.

METHODS

In-vivo 4D flow MRI was performed on three pediatric subjects following an IRB-approved protocol. Patient 1, a pediatric patient with COA and an associated mycotic aneurysm, was scanned before and after surgical repair with interposition graft (at ages 6 and 8). Patient 2 presented with COA and severe aortic kinking in the proximal descending aorta and underwent 4D flow MRI before and after repair by stent placement (at ages 13 and 16). The third subject was a healthy control (age 10). For all subjects, 3D segmentation of the aorta was performed (MIMICs) based on contrast enhanced MR angiography (CE-MRA) or CT scans, and a total of 5 models of the aorta (2 patients pre- and post-COA repair, 1 healthy control) were generated for numerical simulations. Flow velocities derived from in-vivo 4D flow MRI studies (EnSight, CEI) were used to define patient specific boundary conditions. Computational fluid dynamics (CFD) simulations were conducted on Converge CFD software using AMR. AMR refines the local computational grid size based on previously calculated discretization errors [4]. Implementing AMR reduces the computational resources required for the CFD simulations while maintaining high accuracy in the numerical results. Figure 1 shows the schematic of this computational method enhancing 4D flow MRI for cardiovascular flow dynamics analysis for patient 2 before stent placement. Velocities from CFD simulations were compared with 4D flow MRI derived in-vivo velocities.

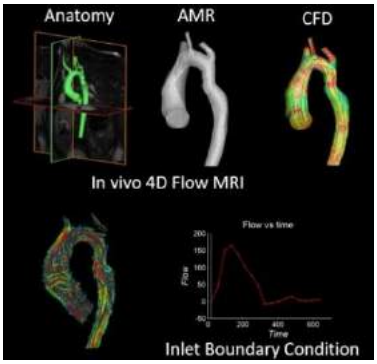

Figure 1: Schematic of computational method enhancing 4D Flow MRI for patient 2 pre-repair. Top (left to right): Patient anatomy

from CE-MRA, autonomously changing computational mesh grid due to AMR, CFD simulation results showing flow information. Bottom (left to right): 4D flow MRI study, flow information extracted from in vivo study used for inlet boundary condition for numerical simulation.

RESULTS

A total of five CFD simulations were successfully executed using patient specific anatomical geometries and flow conditions. For patient 1, the differences in mean velocities (at systole and diastole) between CFD and 4D flow studies were 5.4% and 13.3% in the ascending and descending regions, respectively. For patient 2, differences (at systole and diastole) were 0.3% and 1.8% in the ascending and descending regions, respectively. The locations of vortical flow from CFD simulations matched those from 4D flow MRI data. Figure 2 shows in-vivo 4D flow MRI and CFD results for patient 1 before intervention. CFD simulations revealed flow inside the aneurysm previously not captured by 4D flow MRI due to low flow velocities relative to the velocity encoding (VENC). Figure 3 shows in-vivo 4D flow MRI and CFD results for patient 2 after stent placement. 4D flow MRI results were clearly distorted due to metal artifact of the stent. Notably, numerical simulations could recover flow dynamics inside and distal to the tendered region that could not be resolved by in-vivo 4D flow MRI. The temporal resolution of enhanced CFD method was higher with a timestep size of 10 ms, compared to 38.5 ms for 4D flow MRI. The computationally enhanced technique showed better spatial resolution as well, resulting in visualization of flow in the aneurysm (Figure 2) and stent (Figure 3). The post-intervention cases were compared with the in-vivo 4D flow MRI and CFD results of the healthy control. Qualitative analysis of in-vivo and CFD flow dynamics show that post repair cases had residual complexities in the hemodynamic flow with larger vortices in the ascending region.

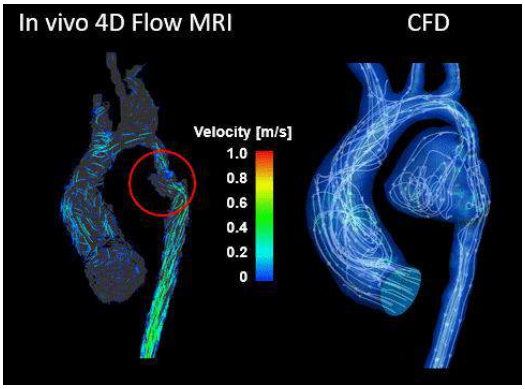

Figure 2: Comparison between in-vivo 4D flow MRI and CFD results for patient 1 pre-repair. Good agreement in velocity magnitudes at acceleration regions and vortical locations can be seen. The VENC used for the acquisition was too high for the low aneurysmal velocities and could not be detected in-vivo (red circle).

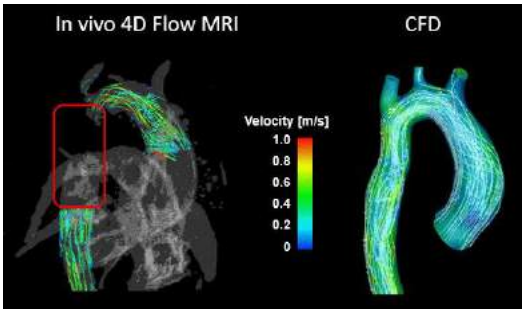

Figure 3: Comparison between in-vivo 4D flow MRI and CFD results for patient 2 post-repair (viewed from the posterior). Good agreement in velocity magnitudes at acceleration regions and vortical locations can be seen. In-vivo results does not show blood flow inside stent (red rectangle) due to distortion of image due to stent (metal artifact).

DISCUSSION

Computationally enhanced 4D flow MRI with AMR improved the spatio-temporal resolution across variable COA anatomy. AMR based CFD successfully restored flow metrics in regions of low velocity in patient 1's aneurysm, likely due to low aneurysmal velocities relative to the VENC. This method also predicted cardiovascular flow inside and surrounding the stent in patient 2 and demonstrated hemodynamic differences between post-operative and normal anatomy. Further, CFD provided flow information with good qualitative agreement with in-vivo results. In addition, mean velocities at ascending and descending aortic regions (at systole and diastole) using this method showed agreement with in-vivo data to within 15% difference.

CONCLUSION

The goal of COA repair is to restore normal hemodynamics. Despite improvements, CFD shows residual complex flow regions post-repair when compared to the healthy case. The novel AMR-augmented 4D flow MRI is feasible to derive quantitative flow metrics. This image-based modeling method can be used as a predictive tool for treatment planning and post-intervention assessment in patient specific clinical applications.

INTRODUCTION

Polymeric surgical valve designs have been attempted since the 1960s with failures due to the demanding valve performance *in vivo* and the necessary fatigue life of the valve, with continuous functioning for up to 25 years inside the patient [1]. Still, polymeric technology offers benefits beyond the current bioprosthetic valves and mechanical valves, with the promise of reduced thrombogenic response due to the selection of hemocompatible materials and the resistance of structural valve degeneration due to the resistance of regrowth of calcific masses from the inflammatory response. The recent surge in popularity of transcatheter aortic valve replacement (TAVR), which is a minimally invasive percutaneous approach to replace a stenotic aortic valve with a stented bioprosthetic valve, offers additional benefits to the polymeric leaflet technologies. Polymeric TAVR devices can be designed to resist the damage and high stresses during the crimping and expansion of the stent as well as be designed to maintain leaflet performance in eccentric or under-deployment scenarios.

A novel polymeric valve, PolyV1 (PolyNova Cardiovascular Inc, Stony Brook, NY), has shown performance comparable to the gold standard surgical valves in idealized geometries and comparable to commercial TAVR devices in extreme patient-specific anatomies [2]. The PolyV1 utilizes a hemocompatible thermoset polymer and is cast with compression molding, in contrast to dipcoating used in other polymeric valves [3], to achieve a variable leaflet thickness profile that is optimized to reduce stresses in the leaflet [4]. The casting process allows the creation of leaflets with optimal geometries and thinner profiles to achieve the needed durability and performance.

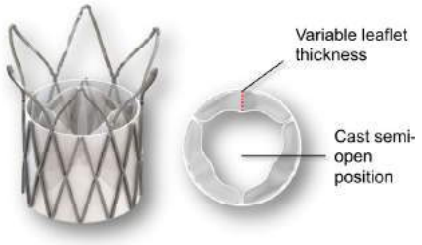

Figure 1 – Rendering of PolyV1 20mm device (left) and top-view of leaflet opening (right).

METHODS

Accelerated wear testing (AWT) was performed with the HiCycle (Vivitro Labs, Victoria, BC, Canada) according to the guidelines outlined in the ISO 5840-3. The (n=4) PolyV1 valves were affixed 3D rigid sleeve and tested with 0.9% saline solution at 37°C. The valves are tested according to the ISO guidelines maintaining a peak differential pressure of 100 mmHg across the closed valve for 95% of the cycles and that 100mmHg is experienced for more than 5% of the cycle. The valves are cycled at 10 Hz and were confirmed to completely open and close at that frequency. The valves were removed from the AWT and the hydrodynamic performance was tested every 50 million cycles. Currently the valves have been tested to 800M cycles (Figure 2) which far exceeds the 200M benchmark (5 year *in vivo* equivalent) defined by the FDA and ISO standard for the minimal valve leaflet durability.

The hydrodynamic performance was evaluated in a Vivitro left heart simulator (LHS) testing for critical valve performance targets of average systolic pressure drop (ΔP), effective orifice area (EOA, Bernoulli derived estimation of opening area), closing flow (backflow during leaflet closure) and leak flows. The valves were tested with a blood analog (50.3/48.8 by weight glycerol/ddH_2O). The valves are tested at various cardiac outputs (2, 3.5, 5, and 7 L/min) at 70 BPM and normotensive of conditions.

Valve imaging: During the hydrodynamic evaluation the valve was imaged with a high-speed camera (1057 FPS HD, Cronos 1.4, Krontech Burnaby, BC, Canada). The valves are imaged perpendicular to the

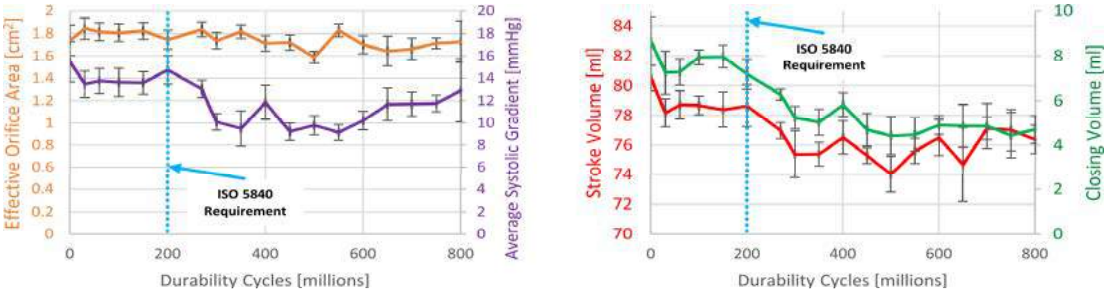

Figure 2 – Progression of EOA (orange), pressure gradient (purple), stroke volume to achieve cardiac output of 5 L/min @ 70 BPM (red), and closing volume (green) over the 800M cycles.

commissural plane with the focus placed upon the commissure attachment. The valves were lit from the aortic side attempting to highlight the leaflet edges. Due to transparent leaflets in the polymeric valve, conventional image processing methods yield poor/noisy segmentation results so a machine learning (ML) approach was adapted. Images were adjusted to increase contrast and then fed into a deep learning-based model that leverages fully convolutional neural networks and Holistically-Nested Edge Detection (HED) algorithm. The model was implemented in Python and was trained using around 200 human-annotated labels to detect the leaflet free edge. Binary images are outputted in which the leaflet edges are predicted and segmented in white. Post-processing in MATLAB is used to close any gaps in the leaflet edges by connecting the endpoints of incomplete segments (Figure 3). The geometric orifice area (GOA, physical opening area) was calculated from the flooded area between the open leaflets and scaled to the commissural diameter.

RESULTS

Initial hydrodynamic results of the valves showed performance meeting or exceeding traditional valves and surgical valves. Over the course of the testing (Figure 2), fatigue characteristics of the valve performance with a drop in the pressure gradient (from 16mmHg to 12mmHg) was seen over the course of the testing and appears to have stabilized. The effective orifice area remained relatively stable (1.7-1.9 cm^2) throughout the entire duration of the testing. Additionally, a drop in the closing volume (9-5 ml/beat) as the semi-open position of the leaflets fatigue into a more closed position. This reduction in closing flow resulted in smaller stroke volumes needed to reach the cardiac output and therefore a stable and higher performance valve is seen over the entire duration of the testing.

The machine learning results were compared to a reference valve (not subject to any fatigue) and shows that the typical leaflet durability behavior is observed, with the reduction in stroke volume, increase in GOA, and shorter period of the leaflet opening. As the leaflets form a more closed morphology, the leaflet opening and closing occurs slower (Figure 3, bottom). Individual analysis of each leaflet shows that a single leaflet can open slower or faster with increasing fatigue cycles, although this does not appear to impact the performance or the fatigue strength of the valve nor is it consistent among the tested valves.

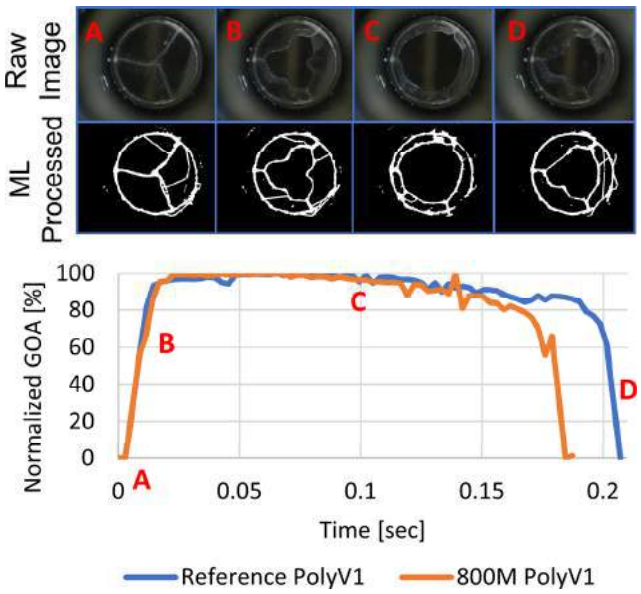

Figure 3 – High speed images of the reference valve (top row) opening and closing (A-D), binary image generated from ML algorithm (middle), and opening profile comparing the opening of one 800M valve to the reference valve (bottom).

DISCUSSION

Increased durability for polymeric valve has been one of the primary pitfalls for adoption of polymeric valve technology and these results are promising. There is no observable wear and tear or catastrophic failure in the four samples tested in the study. The ability to cast a valve in the semi-open position, along with the variable thickness of the leaflet profile to reduce stresses, yields a stable EOA over the expected clinical leaflet fatigue life (5-25 years) as well as the improvement the performance with the reduction of closing flow. With extended leaflet durability testing there are expected changes of the leaflet structure resulting in the changes of the performance as well as the morphology change of a closing leaflet profile.

The generation of a machine learning algorithm will allow further exploration of these fatigue characteristics to the leaflet deformations with minor concern for the changes to the test lighting and exposure over this multi-year study. One limitation of this study is that high-speed imaging the valve was only adopted recently (≥700M cycles) and therefore the machine learning algorithm can only be utilized at the endpoints of the durability study and can only be compared to the reference valve. The machine learning algorithm is also being refined to yield the curvature of the leaflet profile during opening and to track each leaflet individually.

With the initial promise of these results, the cast polymeric technology can be adapted into studying the effects of various semi-open positions of the leaflets as well as more advanced designs such as eccentric valve technologies. The ability to cast a valve with any leaflet profile morphology and design allows the refinement of this durability profile and better success in the clinic and for better patient outcomes.

INTRODUCTION

Mitral annular calcification (MAC) is a degenerative fatal disease which impairs mitral valve function. It is often associated with calcific aortic stenosis (AS) and is present in roughly half of patients with severe AS. [1]. MAC normally occurs in the elderly population thus many patients are deemed high risk of surgical intervention. An alternative is the use of a transcatheter aortic valve replacement (TAVR), specifically the Edwards SAPIEN 3. However, this procedure has low success rate and high 30-day mortality with the most concerning issues being 7% valve embolization rate and 40% rate of left ventricular outflow tract (LVOT) obstruction [2]. This is likely due to the difficulties of anchoring with the complexity of calcium nodule distribution and lack of clinical trials. A recent technique involving laceration of the anterior mitral leaflet to prevent left ventricular outflow tract obstruction (LAMPOON) has shown promise [3]. However, its use in valve in MAC can be difficult with the presence of extensive calcium and has not been thoroughly investigated. Thus clinical guidance optimizing valve sizing and positioning to better device outcome is highly valuable. The goal of this study is to better understand and optimize the valve in MAC procedure through iterative computational techniques.

METHODS

A 60 year old female with severe MAC was analyzed. A cardiac CT scan was obtained under IRB approved protocol. The left atrium, mitral valve, left ventricle, LVOT, and aortic valve were segmented and meshed using Materialize MIS (Leuven, Belgium) (**Figure 1A**).

The SAPIEN 3 29 mm stent was generated in Solidworks (Waltham, MA, USA) based on a microCT performed on the valve. The 23 mm sized valve was also generated through scaling. Both stents were meshed in MIS. Material models were based on those used in previous studies [4-7]. Finite element analysis was then performed in Abaqus

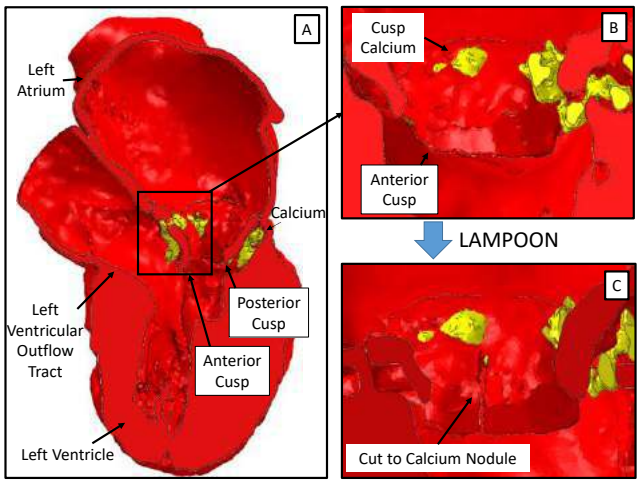

Figure 1: patient segmentation including the mitral anterior and posterior cusps, left ventricle, left atrium, LVOT, and calcium nodules (**A**), anterior cusp and a large calcium nodule at its base (**B**), and LAMPOON procedure cut along the anterior leaflet to the calcium nodule (**C**).

(Johnston, RI, USA). A balloon with the corresponding diameter was generated and computationally deflated for each stent. The stents were then crimped onto their respective balloons. Each stent was positioned in the mitral position and deployed with the bottom of the stent aligned with the annulus after expansion. The LAMPOON procedure was then simulated by making a laceration from the free edge of the anterior cusp to the large calcium nodule embedded at the base of the cusp (**Figure 1B and C**). Both valve procedures were then performed with the LAMPOON geometry. The area of the opening between the mitral

anterior cusp and LVOT wall was measured to analyze LVOT obstruction in each case. Realistically, the SAPIEN valve is designed with an inner skirt covering all cells below the top layer, any of these cells we considered to block flow and subtracted from the opening area calculation. Stent area in contact with the mitral valve surface and calcium nodules was measured to asses stent embolization risk. Contact area was defined as the sum of all element areas where contact force was present.

RESULTS

SAPIEN stent expansion with LAMPOON increased the opening into the LVOT (**Figure 2**).

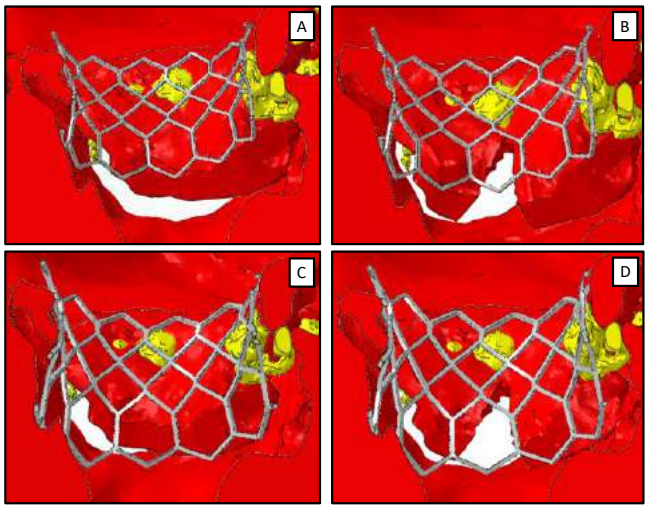

Figure 2: simulation results of the SAPIEN 23 mm without LAMPOON (**A**), with LAMPOON (**B**), SAPIEN 29 mm without LAMPOON (**C**), and with LAMPOON (**D**).

Without LAMPOON the 23 mm stent resulted in a 42% larger opening compared to the 29 mm stent. This was due to the larger diameter causing the stent to push the anterior leaflet closer to the LVOT wall thus limiting the opening area. The LAMPOON procedure increased the opening area by 13% for the 23 mm stent and by 38% for the 29 mm stent. This resulted in only a 16% larger opening after the 23 mm stent deployment compared with the 29 mm stent. The much larger increase in opening for the 29 mm stent deployment was caused by an increased spread of the cut leaflets creating a larger opening specifically where the laceration was located. However, a portion of this opening (13%) was blocked by a closed cell.

The contact area between the stent and tissues is plotted based on balloon expansion percent for each deployment (**Figure 3**).

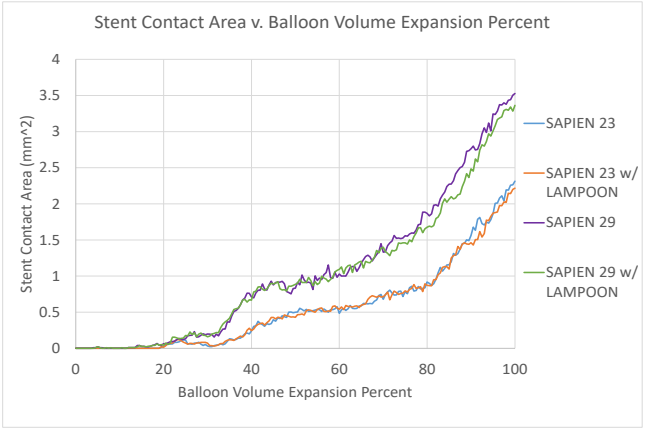

Figure 3: stent contact area plotted against balloon volume expansion percent for each deployment.

The LAMPOON procedure resulted in slightly smaller contact area for both stent sizes. There may have been an increased difference if the calcium nodule was absent thus allowing the cut to be longer. The SAPIEN 23 mm resulted in roughly 50% smaller contact area compared to the SAPIEN 29 mm. This much smaller contact area could be problematic with respect to valve embolization.

DISCUSSION

TAVR implantation in MAC remains to be a complex procedure with high failure rates and limited clinical guidance. This study offers to provide initial patient specific analysis which gives insight into how these procedures may be optimized. When LAMPOON was performed, the larger stent increased the opening of the lacerated leaflet more than the smaller stent. However, when LAMPOON was not performed, the larger stent pushed the anterior leaflet further towards the LVOT wall resulting in a smaller opening compared with the smaller stent. In each case, the large stent had much more contact area which may reduce embolization risk. Lastly, LAMPOON did not significantly lower overall contact area for small or large stents. Further studies should be performed including analyzing additional anatomies, performing computational fluid dynamics to better quantify LVOT obstruction, and deploying more size variations of the SAPIEN stent.

INTRODUCTION

Cancer mortality is the result of the metastatic process where tumor cells migrate from a stiff primary tumor through softer adjacent stroma. While there is limited overlap in biomarkers between cancer types, all solid tumor cells must detach, migrate, and invade the surrounding tissue in order to metastasize. Durotaxis, i.e. migration in the direction of an increasing stiffness, has been observed in the majority of migratory cells [1,2]. However as many tumors progress, the surrounding microenvironment gradually becomes stiffer than the adjacent stroma [3,4], requiring a cancer cell to undergo "reverse durotaxis" in order to metastasize. This suggests there may be a breakdown of the normal processes regulating durotaxis that allows cancer cells to become insensitive to stiffness gradients.

We hypothesize that mechanotypic heterogeneity across and within cell populations might be responsible for differential durotactic behavior in these populations. In recent work, we found that adhesion strength acted as a physical marker that sorted isogenic cells into weakly and strongly adhesive cell groups that were more versus less contractile and migratory [5], respectively. RNA sequencing further showed transcriptional differences characteristic of distinct mechanotypes that sorted patient outcomes in The Cancer Genome Atlas (TCGA); patients with the weakly adhesive gene signatures relapsed at a rate 2-fold higher than the strongly adhesive gene signatures. Such differences could contribute to durotactic differences not previously observed, and here we show that mechanotypic differences are the proximate driver for differential rigidity sensing and adurotactic behavior.

METHODS

Sorting, time-lapse, and traction force microscopy: Weakly and strongly adherent tumorigenic breast (MDA-MB-231), prostate (PC-3), and lung (NCI-H1299) cancer cells were isolated using a microfluidic adhesion-based sorting device. Migration and traction force experiments were conducted with isolated cells seeded on polyacrylamide (PA) gels of elasticity that match both healthy and diseased tissue for each type of cancer. Photopatterned gels containing alternating soft and stiff elasticity profiles were used to observe the durotactic behaviors of WA and SA cells (Fig. 1a). In migration experiments, cell positions were captured every 15 minutes for 24 hours using time-lapse microscopy and then tracked using a custom MATLAB script. Traction forces were captured every minute for 30 minutes on stiff gels containing 0.2 μm fluorescent beads. Traction stresses were then calculated using a custom MATLAB routine and used to determine the strain energy, which was then normalized to cell area.

Model description: In our model, the cell is comprised of a number of focal adhesion (FA) initiation sites that move away or towards the cell's centroid based on actin polymerization or depolymerization. Each site is assumed to contain the adapter proteins necessary to bind a stress fiber (SF). The model loops through the following steps, with each loop completing a single timestep. First, an initiation site will begin to form a FA if an integrin-SF complex binds to an external extracellular matrix (ECM) protein. Bound integrins will have a certain probability of binding or unbinding according to,

$$P_{on} = 1 - e^{-\Delta t k_{on}} \quad (1a)$$

$$P_{off} = 1 - e^{-\Delta t k_{off}} \quad (1b)$$

where Δt is the time step, k_{on} is the integrin binding rate, and k_{off} is the breaking rate based on the catch bond dynamics measured experimentally [6]. Next, the SF applies a force to any bound integrins and associated proteins according to the following equation,

$$F = F_s(1 - e^{-tv_o k_{eff}/F_s}) \quad (2)$$

where F_s is the myosin motor stall force, t is the length of time of the applied force, v_o is the maximal motor velocity, and k_{eff} the effective stiffness of the substrate. If the complex contains a tension sensor protein, which experiences a sufficiently large force, it will expose actin binding sites for recruiting new SFs and integrins, leading to FA growth and maturation. Growth is limited by a finite number of SFs available in the cell. Finally, the forces at all initiation sites are then summed to get the net force on the cell, which is divided by the drag to calculate the velocity and distance the cell will move before the next time step. The positions of the unbound initiation sites are updated and the next iteration begins. We simulate 24 hours of cell migration, and track the cells position relative to the soft/stiff boundary as in the time-lapse microscopy images.

RESULTS

We compared the average speed of cells migrating on stiff or soft regions of the PA gel (Fig. 1a) and found that WA cells migrate faster than SA cells on the same substrate, suggesting that WA cells may have a higher metastatic potential. This is consistent with what has been seen previously [5], and shows that these cells respond differently based on their adherence and local environment. Increased migration speed in WA cells is in part due to greater cell contractility (Fig. 1b), which suggests that migration differences are not solely due to friction from cell-ECM adhesion. Moreover after 24 hours, SA breast and prostate cancer cells preferred to migrate into the stiffer regions whereas the WA cells had no preference (Fig. 1c-d).

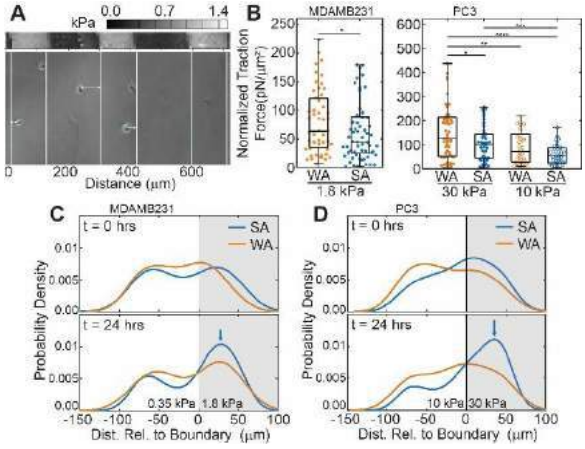

Figure 1: A) Brightfield image of MDA-MB-231 cells (dots) with lines to indicate transitions between soft and stiff substrate regions of step-gradient hydrogels (bottom). Arrows show the distance relative to the closest boundary. Atomic force microscopy (AFM) map is also shown (center) with corresponding color map (top). B) MDA-MB-231 cell speed on step-gradient hydrogels for cells far away from the step-gradient. C-D) At 0 and 24 hours, MDA-MB-231 or PC-3 probability density versus hydrogel position. Blue arrow indicates a peak in the strongly adherent cell distribution at 24 hours. *p<0.05, **p<10^{-2}, ****p<10^{-4}, *****p<10^{-5}.

To test the plausibility of durotaxis occurring due to differing traction forces applied to the substrate through integrin catch bonds, we built a computational model that incorporates cell adhesion, stress fiber (SF) mediated force generation, and catch bond dynamics. Because the load on a catch bond is dependent on the contractility of a cell and the stiffness of the cell's substrate, the bond lifetime can be prolonged under an intermediate load. In our model, cells that were able to exert an intermediate force on stiff substrates exhibited durotaxis, since their adhesions lasted longer than they would on soft substrates. This requires a cell to be optimally contractile, as increasing contractility shifts the load past the catch bond's ideal force. To validate such control in our system, we reduced the number of active myosin motors within a cell, i.e. SF force, finding that it increases the durotactic tendency of cells as predicted by the model between 30 and 45 pN (Fig. 2a). We tested this experimentally by inhibiting the myosin II activity of WA mammary cells with blebbistatin, and found myosin inhibition restored durotactic behavior in these cells (Fig. 2b). Conversely, SA mammary cells also showed a dose dependent response to lysophophatidic acid treatment, wherein the SA phenotype became less durotactic, resembling the adurotactic behavior of WA cells (Fig. 2c).

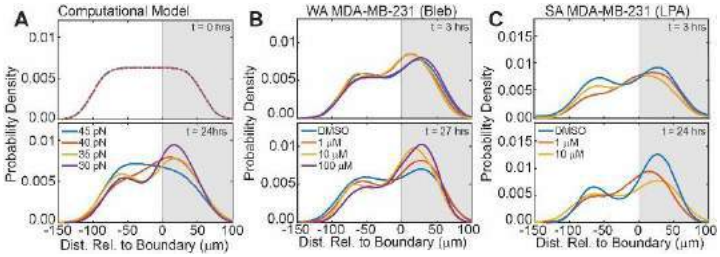

Figure 2: A) Model probability density versus simulated hydrogel position as predicted for 30 (purple), 35 (yellow), 40 (red), and 45 pN (blue) max SF forces at t=0 and t=24 hours. B) Weakly adherent MDA-MB-231 probability density versus hydrogel position for blebbistatin treatment. C) Strongly adherent MDA-MB-231 probability density versus hydrogel position for LPA treatment.

DISCUSSION

The findings of this work help explain how a metastatic cell's distinct mechanotype correlates to the paradoxical migration down a stiffness gradient that occurs during cancer metastasis. Cancer cells isolated by their adhesion strength from a seemingly isogenic population exhibit consistent behavior across different cell lines from vastly different cancer types; moreover, each cancer type exhibits adurotaxis in their tumor-specific niche, which change dramatically for step gradient strength (between 3- and 5-fold) and gradient range (from 0.3 to 30 kPa). Despite these differences, greater contractility in weakly adherent cells is conserved and led to decreased durotactic behavior that is not directly governed by lack of rigidity sensing. From previous work, RNA sequencing shows a distinct underlying phenotype for weakly vs. strongly adherent cells with differences in cytoskeletal protein expression, which relates to decreased progression-free and disease-free intervals when compared to the gene expression signatures of human patients [5]. A weakly adherent cell's ability to migrate against stiffness gradients connects this observation to the material properties of the niche, which contribute to its increased metastatic potential.

INTRODUCTION

Rotator cuff injuries are extremely prevalent and are present in 50% of the population over the age of 80 [1]. Healing of these injuries is poor, with repair failure rates of up to 94% after massive tears [2]. These high failure rates are caused by the body's inability to recreate the multiscale load transfer mechanisms of the healthy tendon-to-bone attachment.

Healthy tendon-to-bone attachments exhibit a number of hierarchical structures that are theorized to decrease stress concentrations. At the millimeter length scale, tendon attaches to bone with a splayed geometry that increases the attachment area, decreasing stress [3]. At the micrometer length scale, an interdigitating interface is seen with gradients in mineral and collagen content, strengthening and toughening the interface [4]. At the nanometer length scale, the mineral crystal size and orientation changes along the attachment[5]. Although we can theorize and model the mechanical roles that these structures play during loading of the tendon-to-bone attachment, there is little to no experimental work measuring their individual contributions.

The small size and complex arrangement of collagen and mineral structures across the attachment have made it difficult to measure their mechanical behavior within the larger attachment tissue during loading. In the current study, we employed *in situ* tissue loading along with high energy synchrotron X-ray diffraction to simultaneously measure whole tissue, collagen fibril, and mineral deformation across the tendon-to-bone attachment. This technique allowed us to identify, for the first time, the mechanisms by which load is transferred across the complex attachment structure.

METHODS

Supraspinatus-humerus complexes were collected from adult canines in accordance with Washington University in St Louis Animal Research Protocols. The complexes were cut along the coronal plane to obtain sections of the supraspinatus-humerus tendon-to-bone attachments measuring ~1 cm in thickness. Samples were wrapped in phosphate buffered saline (PBS) soaked gauze and frozen at -20°C until the time of testing.

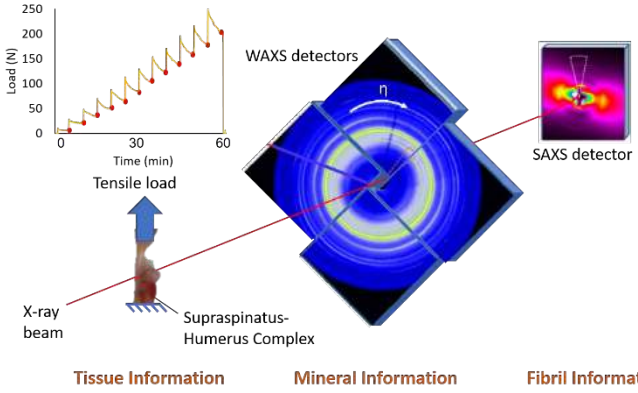

Figure 1: Schematic of experimental set up showing simultaneous collection of tissue, mineral, and fibrillar information.

Samples were brought to hutch 1-ID-E of the Advanced Photon Source (APS) at Argonne National Lab for testing. There, the samples were mounted in liquid nitrogen-cooled freeze clamps in a MTS model 858 hydraulic load frame. Samples (n=2) underwent quasi-static loading up to 250 N in increments of 25 N (**Fig. 1**). Samples were allowed to relax for 5 min after each incremental load after which both Wide and Small angle X-ray scattering (WAXS and SAXS) were recorded. X-ray diffraction patterns were collected simultaneously on 4 GE-41RT detectors in the "hydra" configuration in the case of WAXS and a ScintX DXI-11000R detector in the case of SAXS (**Fig. 1**).

Measurements were made at 10 locations spanning the tendon, enthesis, and bone in intervals of 200 μm with a beam energy of 71.7 keV and a spot size of 30 x 30 μm^2. Whole tissue deformation was measured from the grip displacement.

SAXS and WAXS patterns were analyzed using custom programs in MATLAB as previously described [5, 6]. Mineral d-spacing was calculated from the location of the (002) apatite peak in the WAXS data while fibrillar D-spacing was determined from the location of the 3rd order peak in the SAXS data. Mineral and collagen strain (ε) were calculated according to the equation $\varepsilon=\Delta d/d_o$ where d_o is the d-spacing before loading and Δd is the change is d-spacing with applied load. The mineral and collagen alignment were determined from the FWHM of the intensity peaks as a function η, where a decrease in FWHM represents an increase in alignment. Collagen microstrain (ε_{RMS}) was determined from the width of the 3rd order SAXS peak. Mineral coherent domain size and ε_{RMS} were calculated using the Halder-Wagner method from the width of the (002), (210), and (310) peaks[7].

RESULTS

Tissue scale mechanics exhibited an initial non-linear toe region followed by a linear increase in strain with increasing load.

Fibrillar strain was dependent on both location and applied load (**Fig. 2**). The fibrils in the tendon exhibited very little strain. These fibrils also showed no change in alignment with loading, although there was an increase in fibrillar microstrain. In contrast, the fibrils in the enthesis exhibited very high strains that decreased beyond loads of ~125 N. Despite these high strains, the enthesis fibrils showed no changes in alignment and only small increases in microstrain. Bone fibril strain did not increase until loads >100N and showed no change in alignment or microstrain with loading.

The mineral in both the enthesis and the bone exhibited an increase in strain with increasing applied loads (**Fig. 2**). This increase was immediate in the enthesis, while bone mineral required loads >20N to undergo straining. Neither the size, microstrain, nor alignment of the mineral changed with increasing load.

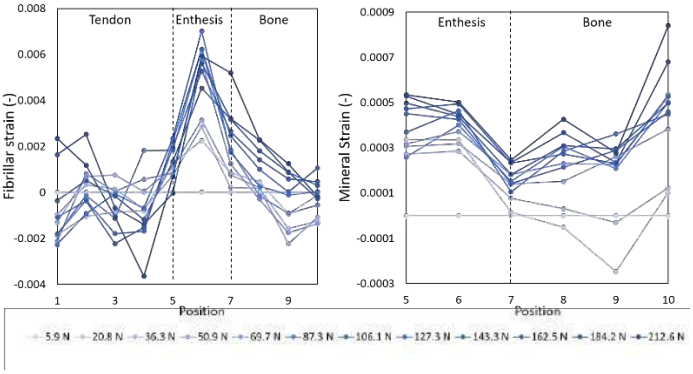

Figure 2: Plots of fibrillar and mineral strain as a function of position and applied load (legend).

DISCUSSION

Tissue-level strain increased linearly with load, indicating that all experiments were performed within the elastic region of supraspinatus-humerus mechanical behavior. This suggests that there was no significant plastic deformation or damage to the tissue during loading.

Strain at the collagen fibril level was far lower than strain at the tissue level during the early portion of loading (i.e., <35 N) (**Fig. 3**). This is indicative of collagen fibril sliding or uncoiling [8, 9]. These changes in the higher order structure of the collagen, likely in the tendon, as indicated by a lack of fibril-level strain at all loads, allows the tissue to deform without stretching the collagen fibrils themselves.

At intermediate levels of loading (i.e., 20-125 N), there was significant accumulation of strain in the fibrils and in the mineral of the enthesis (**Fig. 2**). Unlike the unmineralized tendon, where fiber-fiber sliding dominated, the enthesis exhibited high levels of fibrillar and mineral strain. This is in agreement with other studies that have identified the presence of a compliant zone within the enthesis [10, 11]. The rotation or realignment of collagen and mineral has been suggested as a mechanism for the increased deformation/strain seen in this area [5, 12]. However, the lack of change in mineral and collagen alignment with loading suggests that this is not the cause of the compliant zone. Instead, compositional changes such as the presence of proteoglycans may be responsible for these mechanical behaviors.

At higher levels of load, there was increased strain in the bone mineral and fibrils and a decrease in enthesis fibrillar strain (**Fig. 2**). This suggests that that load sharing was transferred from the enthesis, which may have reached maximum deformation, to the bone. The continued increase in mineral strain with increasing load across the tissues also indicates that collagen is transferring load to the reinforcing mineral.

In conclusion, canine supraspinatus-humerus complexes employed a number of multi-tissue and multi-scale mechanisms to transfer load. At low loads, tissue deformation was mainly dictated by collagen sliding/uncoiling in the tendon. At intermediate loads, there was a transfer of load to the enthesis, which underwent large deformations. Finally, at high loads, the enthesis reached maximum elastic deformation, at which point load was transferred to the bone. These complex mechanisms of load transfer provide the tendon-to-bone attachment with its robust mechanics.

INTRODUCTION

Mechanical forces are necessary for tendon and enthesis (tendon-to-bone attachment) homeostasis and development [1]. Studies in other musculoskeletal tissues have shown that an organelle known as the primary cilium plays a role in sensing and transducing applied mechanical signals [2]. Tenocyte cilia numbers in mice increase following loading deprivation and decrease after treadmill running [3]. In response to *in vitro* cyclical tensile stretching, tenocyte primary cilia disassemble, and the expression of *Ift88* (necessary for cilia assembly) decreases [4]. Furthermore, *in vitro* loading leads to a decrease, and *in vivo* unloading leads to increase, in expression of *Smoothened (Smo),* a component of Hedgehog (Hh) signaling that drives the formation of the tendon enthesis and is regulated by the primary cilium[1,3,5,6]. However, it remains unknown whether the primary cilium is necessary for mechanotransduction in tendon, and whether Hh signaling in tendon and the enthesis is dependent on the function of the primary cilium. Therefore, we investigated the role of primary cilia in the response of tenocytes to mechanical stimulus using an *in vitro* loading model. We hypothesized that tenocyte cilia regulate mechanosensory pathways in tendon and thereby affect Hh signaling.

METHODS

In Vitro Loading Model: Tenocytes were isolated from the tail tendons of adult C57BL/6 mice by collagenase digestion in a shaking incubator. The cells were cultured to passage 3 and then seeded on fibronectin-coated PDMS scaffolds. The next day, cells were serum starved with 1% fetal bovine serum (FBS) media to synchronize cell cycle phase and induce primary cilia formation, or treated with transection reagent in 1% FBS for siRNA knockdown experiments. 24 hours later, PDMS scaffolds were loaded into a custom-built bioreactor and allowed to equilibrate for 1 hr prior to beginning the loading protocol. Control scaffolds underwent a mock protocol of preparation for loading prior to being returned to static culture in the same incubator. All loading groups were subjected to 9% cyclical tensile strain at 1 Hz for 1 hr of loading followed by 1 hr of rest, to best simulate physiological conditions of loading and allow sufficient rest periods for transcriptional changes to occur. The hour on/hour off protocol was repeated for a total of 24 hours to evaluate cellular responses over time. For gene expression analysis, cells were lysed and RNA was isolated immediately after the completion of loading. RT-qPCR was then performed for genes related to primary cilia, Hh signaling, and tenogenesis. For imaging experiments, cells were fixed with 10% formalin for 10 minutes prior to immunostaining with phalloidin (actin cytoskeleton), acetylated alpha tubulin (primary cilia), and DAPI (nuclei). Images were taken at 20x magnification.

Ift88 Knockdown: To investigate the role of the primary cilium in tenocyte mechanotransduction *in vitro,* bioreactor loading experiments were performed on tenocytes with dysfunctional *Ift88*, a ciliary trafficking protein necessary for proper cilia function. To disrupt *Ift88,* tail tenocytes were first isolated from adult C57BL/6 mice and seeded on scaffolds as described above. On passage 3, 24 hours after cells were seeded onto scaffolds, cells were serum starved, and *Ift88* siRNA or scramble RNA (negative control) was added to the low serum media along with Transit-TKO Transfection Reagent (Mirus Bio). After 24 hours, the media was

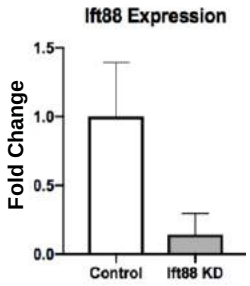

Figure 1: *Ift88* was reduced to 14% of that in scramble siRNA control tenocytes after siRNA knockdown.

replaced with fresh low serum media immediately prior to the initiation of the tensile loading protocol. Changes in the transcriptional and response to loading between tenocytes of *Ift88* knockout and control tenoctyes were compared via RT-qPCR, and qualitative changes in cytoskeletal organization were assessed using immunofluorescence staining.

RESULTS

Primary cilia were mechanoresponsive in tenocytes and disassembled in response to cyclical tensile loading *in vitro* (Fig. 2B and 2C) [10]. Concurrently, the expression of *Ift88* and *Smo* decreased as a result of tensile stretching (Fig. 2A) [4].

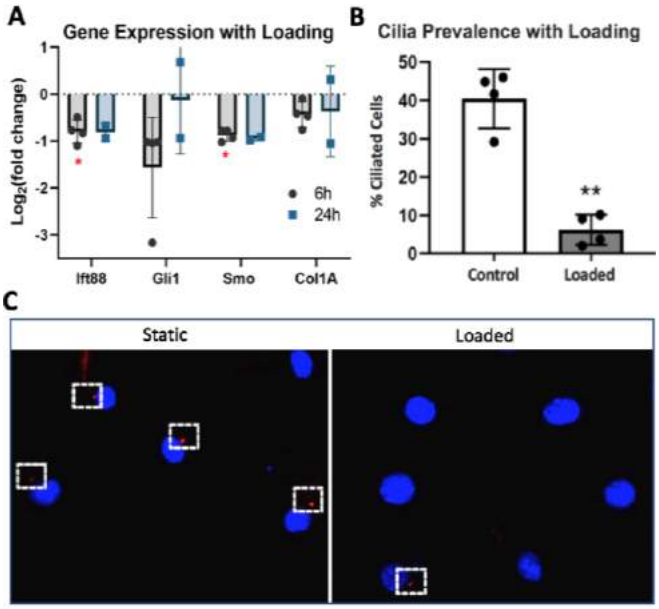

Figure 2: Primary cilia and hedgehog signaling are mechanoresponsive *in vitro*. A) Gene expression related to primary cilia and hedgehog signaling decreased with cyclical tensile loading. B and C) Cilia disassemble after 24 hours of loading (blue: DAPI, red: primary cilia). *indicates p<0.05, **indicates p<0.01.

As a general readout for cell mechanoresponsiveness, the expression of cyclooxygenase-2 (COX-2) was assessed (Fig. 3). COX-2 is upregulated in a variety of cell types in response to loading, and its expression has been tied to primary cilia function in osteocytes [7]. In tendon, it has been shown to play a role in inflammation and in healing [8]. Disruption of cilia function through the knockdown of *Ift88* resulted in a reduction of COX-2 expression in unloaded tenocytes compared to unloaded controls with functional *Ift88 (*Fig. 3). *Ift88* knockdown tenocytes also had lower COX-2 expression after 24 hours of loading compared to loaded controls ($p<0.05$, Tukey's post hoc). Relative abundance was calculated by taking the fold change from COX-2 to GAPDH expression.

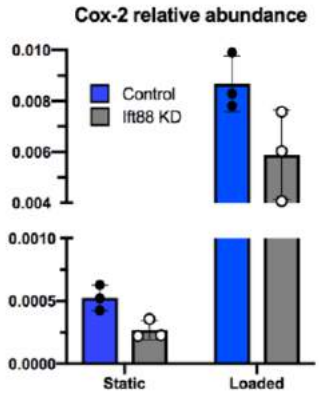

Figure 3: Cox-2 expression was lower in *Ift88* knockdown cells both before and after loading.

To investigate the response of extracellular matrix production and reorganization in the loaded tenocytes, *Col1a1* was also assessed (Fig. 4). *Col1a1* expression was not affected by loading in *Ift88* knockdown and control tenocytes. To investigate the crosstalk between primary cilia and the Hh signaling pathway, the expression levels of *Smo* and *Gli1* (a transcription factor activated by hedgehog signaling) were also assessed [9]. As demonstrated previously and shown in Fig. 2A, *Smo* expression decreased as a result of cyclical tensile loading in control tenocytes. However, in *Ift88* knockdown tenocytes, the expression of *Smo* did not change after 24 hours of loading, demonstrating a loss of mechanoresponsiveness for this gene. Expression of *Gli1* was lower in both static and loaded cells in the absence of *Ift88* compared to control tenocytes.

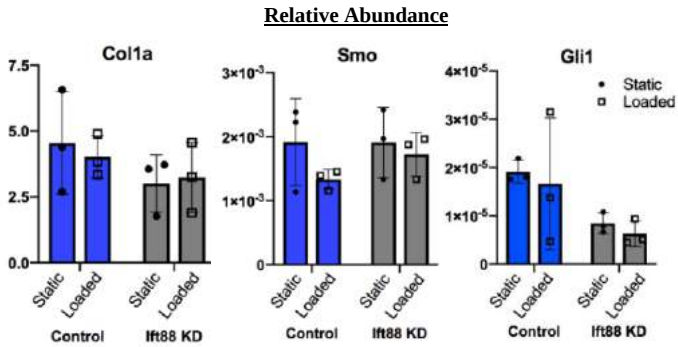

Figure 4: Disruption of primary cilia function via *Ift88* knockdown resulted in changes in the expression of genes related to the hedgehog signaling pathway (*Smo* and *Gli1)*.

DISCUSSION

This study established the involvement of primary cilia in tenocyte mechanosensory pathways *in vitro*. Interestingly, COX-2 expression decreased in tenocytes as a result of the *Ift88* knockdown in static conditions and after 24 hours of cyclical tensile loading. This suggests that primary cilia may play a role in regulating the function of mechanotransduction pathways by regulating the expression of mechanoresponsive genes. Primary cilia also appear to regulate components of the hedgehog signaling pathway, as gene expression levels of *Smo* and *Gli1* were affected by the absence of functional *Ift88* protein in tenocytes. Future studies will explore the effects of primary cilia and Hh agonists on the mechanoresponsiveness of tenocytes. In addition, potential regulation of the inflammatory response to loading through the primary cilium and the Hh pathway will be further investigated.

INTRODUCTION

Cardiac hypertrophy related diseases can occur due to either altered ventricular loading or mutations in sarcomeric protein regulation of cardiomyocytes. Cardiac hypertrophy can be categorized into two groups: 1) Concentric growth, where the ventricular wall mass and wall thickness increase in response to pressure overload condition with small or no change in the ventricular chamber volume. 2) Eccentric growth, in which the ventricular chamber volume dilates due to volume overloading with small change in the wall thickness

Several computational models on cardiac hypertrophy have been developed and provided insight on alterations in mechanics. Although most of these models have yielded stable growth results, many of them did not capture the influence of baroreflex feedback loop and hence they resulted in an alteration in arterial pressure and cardiac output that were not compatible with the published literature.

In this study we extended our previous multiscale model of cardiovascular function via a growth sub-model. The new model was able to capture both types of cardiac hypertrophy in response to any alteration in the ventricular loading (e.g. valvular diseases), while the arterial pressure and cardiac output were maintained with the baroreflex feedback loop. The new model was also able to predict the reverse growth due to partial or proper treatment of valves.

METHODS

The current work extends the multiscale model of cardiovascular function that is presented in Campbell et al. [1] by adding a growth sub-model. The original framework was essentially built on five sub-models that represent different length and time scales, from molecular to organ levels. These sub-models were 1) electrophysiology model of myocardial cell, 2) contraction model of half-sarcomere (MyoSim), 3) hemispherical model of the left ventricle, 4) systemic model of circulation, 5) baroreceptor model of baroreflex feedback loop. The new model is able to capture the evolution of cardiac hypertrophy in response to various changes in ventricular loading.

Both growth laws are stress-driven, in which the active and passive stresses in half-sarcomeres drive the concentric and eccentric cardiac hypertrophies, respectively.

Essentially, a deviation in sarcomeric stresses from their homeostatic levels (set-points) sends a growth signal, g, within the cardiomyocytes. The growth signal g is driven with the following system of ODEs (equation 1) that can be varied between 0 and 1.

$$\frac{dg_i}{dt} = \begin{cases} k_{drive}\dfrac{(S_i - S_{i,set})}{S_{i,set}}(1-g_i) & \text{if} \quad S_i - S_{i,set} \geq 0 \\ k_{drive}\dfrac{(S_i - S_{i,set})}{S_{i,set}}(g_i) & \text{if} \quad S_i - S_{i,set} < 0 \end{cases} \tag{1}$$

where i represents the growth type (i.e. concentric or eccentric). k_{drive} is a constant rate factor. S_i is the driving sarcomeric stress, $S_{i,set}$ is the homeostatic level of driving signal and g_i is the growth signal for growth type i.

When the driving signal (half-sarcomere stress, S_i) is above the set-point, the firing growth signal g_i increases. Whereas, when it drops below the setpoint, the growth signal decreases. The growth signal then transmits into a controller parameter, C_i, via a linear relationship (equation 2). C_i is essentially a proportional gain factor for the output parameter of the growth type i per second.

$$C_i = \begin{cases} m_i(g_i - 0.5) & \text{if} \quad g_i \geq 0.5 \\ -m_i(0.5 - g_i) & \text{if} \quad g_i < 0.5 \end{cases} \tag{2}$$

where, $m_i = 2G_i$ and G_i is the gain factor for growth pattern i. C_i then drives the change in the output parameter θ_i defined as follows. Where

$\theta_{i,n}$ is the output parameter for growth type i at the given time of n and dt is the time step.

$$\theta_{i,n} = \theta_{i,n-1} + \Delta\theta_i$$
$$\Delta\theta_i = \theta_i C_i dt \quad (3)$$

where, θ for concentric and eccentric growth configurations are ventricular wall volume W_{vent} and number of half-sarcomeres in series embedded circumferentially at the basal level of the ventricle n_{hs}, respectively.

RESULTS

The ability of the model in responding to different ventricular loading was assessed by simulating two different cases. First, we tested how the growth law can change the ventricular dimensions in response to a perturbation in the set-point for concentric growth law. Second, we tested a ventricular volume overload case via simulating mitral regurgitation condition and then compared the model predictions with measurements form real patients[2]. Additionally, the ability of the model to predict reverse growth was evaluated by then removing the volume overload condition. All simulations were under continuous regulation of baroreflex feedback loop to maintain the arterial pressure within the range of 110/70 mm Hg.

Perturbed set-point for growth law: Figure 1 shows the model prediction in response to a 50% acute increase of the set-point for active stress. The simulation was initially at steady state for the given set-points for both growth laws, prior to perturbation. The model responded to the perturbed condition by increasing LV chamber volume at end-diastole by 31.2%, LV mass by 2.3%, and stroke volume by 8.4%. The LV wall volume did not change significantly, and hence the maximum wall thickness reduced by 22.5%. Thus, both eccentric and concentric growth of the LV were occurring simultaneously.

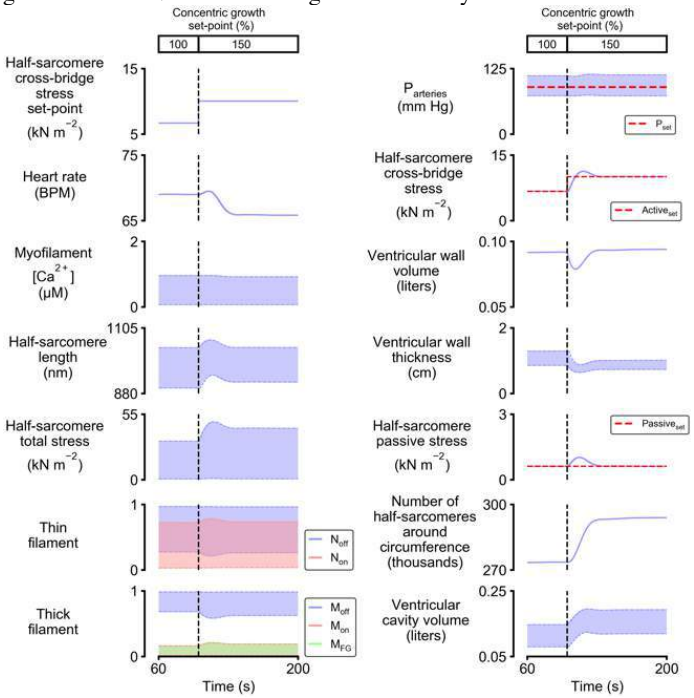

Figure 1: Model prediction in response to perturbed set-point for concentric growth law

Volume overload condition: Mitral valve regurgitation was simulated by allowing a portion of blood volume to flow backward through the mitral valve during systole in the model. The "leakage factor" in the model was tuned to have a consistent regurgitant volume of 40 ml with the measured data from patients in the study by Edward et al. [2]. Figure 2 illustrates the model prediction due to volume overload. The growth module essentially increased the LV chamber volume by 43.9% at end diastole, LV mass volume by 32.5%, and stoke volume by 58.5%. These numbers were quite comparable to those measured data by Edwards et al., where they reported increased LV chamber volume by 41.9% at end diastole, LV mass by 17%, and stroke volume by 31.4%. With respect to the chamber volume, the predicted change in wall thickness was small, representing eccentric growth. When the dilated ventricle was at steady state, the volume overload condition was removed to simulate repair of the mitral valve. The model appropriately predicted the revere growth and changed the ventricular size and shape back to the initial size, before perturbation.

DISCUSSION

For both studied cases, the changes in ventricular size and shape occurred while the arterial pressure was being maintained at the range of 110/70 mm Hg via continuous regulation of chronotropism, Ca^{2+} transient binding to thin filament, myofilament contractility, and vascular tone.

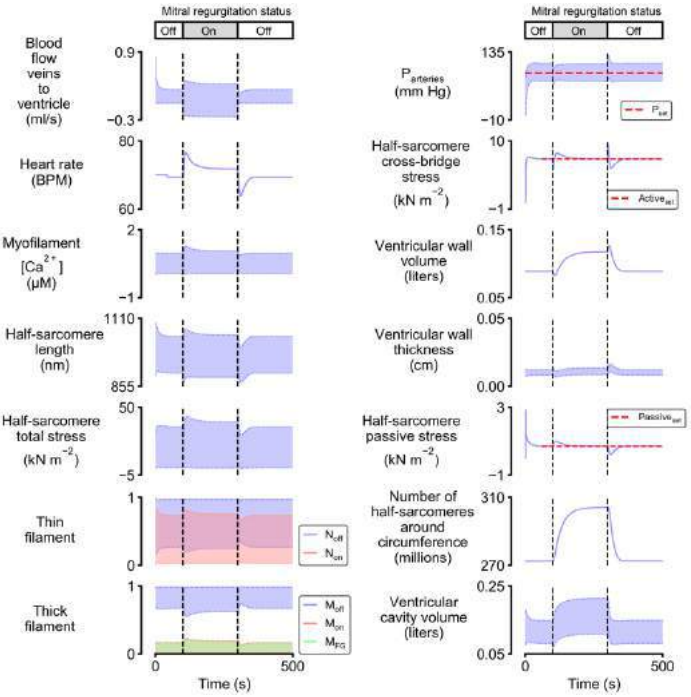

Figure 2: Model prediction in response to volume overload condition and then repair of mitral valve (Mitral Regurgitation)

In conclusion, we introduced a new capability to a multiscale model of cardiovascular function to capture different forms of cardiac hypertrophy simultaneously in response to altered ventricular loading and set-point levels. In addition, the new model is able to predict reverse growth once the perturbations are removed. This framework can be used as an ideal test-bed for exploring different hypotheses before implementing them into more sophisticated models, such as the finite element method.

INTRODUCTION

With over 265 million participants, soccer is the most popular sport in the world.[1] Concussion rates for female soccer players are 1.5-2.4 times higher than males soccer players.[2] Although football tends to garner the most attention when it comes to concussions, women collegiate soccer players have a higher incidence of concussion than American football players.[3,4] Concussions in soccer are often caused by player to player contact;[5] however, most subconcussive head impacts in soccer are headers, a fundamental component of the sport.[6] It has been estimated that soccer players make contact with the ball with their head around 6-16 times per game. [7] Acute heading events are associated with alterations in neurocognition and postural control.[8,9] Exposure to repetitive subconcussive head impacts has been associated with short- and long-term changes to the brain;[10] therefore, understanding the biomechanics of headers is critically important. Specifically, this study aims to evaluate the effect of extrinsic factors related to ball delivery on head kinematics. The results of this study will inform strategies to improve header safety.

METHODS

Eight women's soccer players (ages 18-22) were enrolled in this study approved by the Wake Forest School of Medicine Institutional Review Board. Athletes participated at the collegiate and collegiate club levels of play were instrumented with a custom mouthpiece sensor to measure head kinematics. A KWIK soccer ball launcher was used to simulate four common delivery types observed in live game play: throw-ins, corner kicks, and defensive and offensive goal kicks. Each delivery type was defined by adjusting initial ball launch speed, landing distance, and launch angle.[11] Ball pressure was varied in increments of 3 PSI across the range of 6-15 PSI for throw-ins and 6-12 PSI for corner kicks and goal kicks, according to FIFA ball pressure recommendations.[12] Players performed a total of 13 headers with a Nike size five soccer ball in each session. The order of delivery type was randomized and players had the choice of not performing a header if they felt uncomfortable doing so. After each header, players rated perceived success and comfort on a Likert scale of 1-5, with 5 being most comfortable and successful. Time-synchronized video was collected to allow for pairing of header characteristics observed from video to the associated head impact data. Header characteristics, including incoming and exiting ball speed and incoming ball angle relative to the player's upright position (i.e., vertical), were measured from the video using Kinovea v8.25. The coefficient of restitution, representing the ratio of exiting to incoming velocity of the ball, was also determined.

RESULTS

Kinematic data from 114 headers were collected from eight women's soccer players. Most headers were from throw-ins, followed by corner kicks, offensive goal kicks, and defensive goal kicks (Table 1). Balls delivered from defensive and offensive goal kicks approached the player with the greatest mean incoming velocity and steepest angle, while throw-ins had the greatest coefficient of restitution, on average.

Table 1: Incoming Speed, Angle and Coefficient of Restitution for Ball Delivery Types

Delivery Method	N	Mean Incoming Ball Speed (m/s)	Mean Incoming Ball Angle (degree)	Coefficient of Restitution
Throw-In	46	10.7 ± 1.6	59.5 ± 5.10	0.97 ± 0.20
Corner Kick	32	13.7± 1.7	57.9 ± 6.94	0.68 ± 0.13
Defensive GK	17	14.2 ±1.8	52.5 ± 5.00	0.80 ± 0.20
Offensive GK	19	14.4 ± 1.8	53.5 ± 3.56	0.83 ± 0.10

Kick type, ball pressure, and incoming ball speed each had a significant effect on linear acceleration (all $p<0.05$). Kick type also had a significant effect on rotational acceleration and rotational velocity (both $p<0.05$). Defensive goal kicks resulted in greater mean linear and rotational acceleration than corner kicks ($p=0.0013$, $p=0.0434$, respectively) (Figure 1). Additionally, defensive and offensive goal kicks had greater rotational velocity compared to corner kicks (both $p<0.05$). Offensive goal kicks had greater mean linear acceleration than defensive goal kicks ($p=0.0048$). Throw-ins resulted in lower mean rotational acceleration compared to corner kicks ($p=0.0280$), defensive goal kicks ($p=0.0018$), and offensive goal kicks ($p=0.0089$). Throw-ins also resulted in lower rotational velocity compared to defensive and offensive goal kicks (both $p<0.05$).

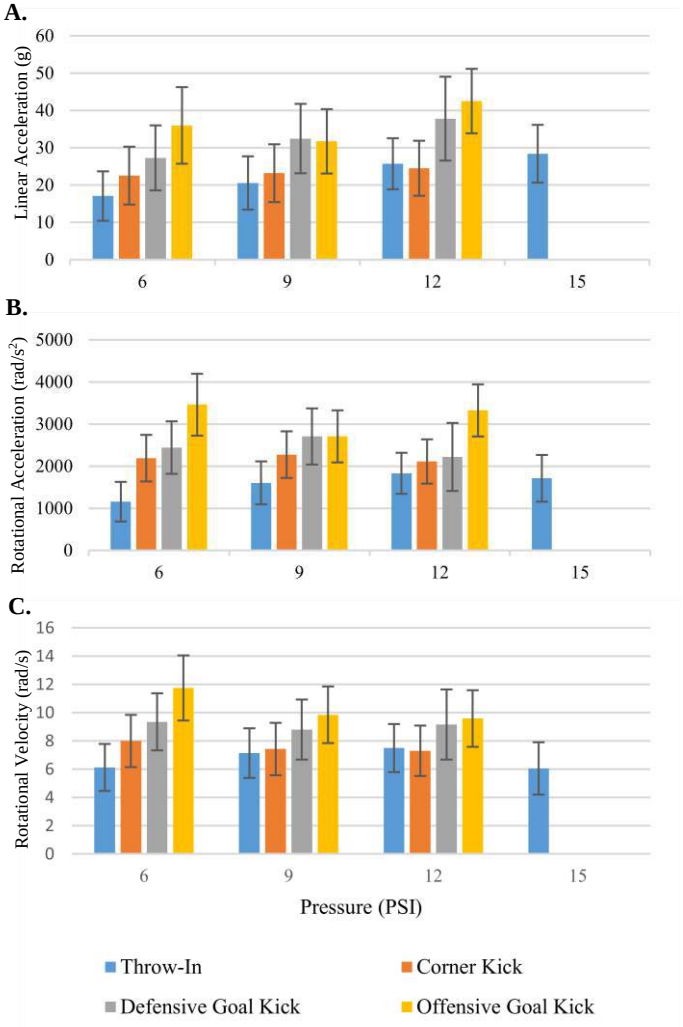

Figure 1: Mean Kinematics and 95th% Confidence Intervals for Varying Ball Pressures and Ball Delivery Types. A. Linear Acceleration and Ball Pressure B. Rotational Acceleration and Ball Pressure C. Rotational Velocity and Ball Pressure

Regarding pressure, headers from balls inflated at 6 PSI and 9 PSI resulted in significantly lower mean linear acceleration than headers from balls inflated at 12 and 15 PSI (6 PSI: both $p<0.005$, 9 PSI: both $p<0.05$). Incoming ball speed was significantly positively associated with all peak kinematics when balls were inflated at 6 PSI and 9 PSI (all $p<0.05$). The strongest correlation between kinematics and incoming ball speed was observed at 6 PSI; rotational acceleration was most strongly correlated ($R^2=0.411$), followed by linear acceleration ($R^2=0.240$), and rotational velocity ($R^2=0.170$).

Kick type had a significant effect on perceived comfort. Throw-ins and corner kicks resulted in higher mean comfort compared to offensive and defensive goal kicks (all $p<0.05$). Overall, headers from throw-ins at 6 PSI were rated most comfortable (4.25 ± 1.14) and offensive goal kicks with balls at 12 PSI were rated lowest comfort (2.5 ± 1.12). No apparent trends were observed among the header characteristics, kinematics, and/or perceived success of the header.

DISCUSSION

This study evaluated head kinematics of headers performed by women's soccer players. This study is novel in identifying the importance of ball delivery characteristics on the magnitude of subconcussive head impacts. Results demonstrate kick type and ball pressure affect head kinematics during headers. Specifically, headers in response to offensive and defensive goal kicks at greater pressures generally resulted in greater peak head kinematics. FIFA law states that ball pressure must be between 8.5 and 15.6 PSI.[12] Results from our study show that balls filled at 6 and 9 PSI have significantly lower linear acceleration compared to balls at 12 and 15 PSI. These trends correlate with findings from similar studies that found reduced accelerations with reduced ball pressures.[13,14] Furthermore, these results provide important insight into future regulatory guidelines related to allowable pressure ranges for soccer balls. One area of study in need of study is use of trainer balls of different material properties to potentially minimize impact magnitude.

Understanding the relationship between peak kinematics and header types can inform future interventions to reduce header magnitude and/or concussion risk. As heading the ball in response to offensive and defensive goal kicks resulted in significantly higher kinematics compared to throw-ins and corner kicks, it may be worthwhile for players to consider chesting the ball in response to these kick types instead. This research is vital to improving player safety and will help to inform efforts to reduce concussion risk and long-term damage from cumulative subconcussive exposure to headers in soccer players.

ACKNOWLEDGEMENTS

We would like to thank the Wake Forest women's soccer players for their participation in this study as well as Virginia Tech-Wake Forest University for providing the resources to conduct this research.

INTRODUCTION

Collagen fibers are the primary load-bearing constituent in the sclera [1], and thus there are many mechanical models of sclera that account for the fibers in some way. However, to the best of our knowledge, current models [2] do not incorporate important aspects of the fiber microarchitecture and mechanics, such as fiber interweaving [3] and fiber-fiber interactions. This is potentially crucial as these characteristics are likely to affect the distribution of stresses and strains at the fiber level, in-turn affecting tissue strength and remodeling.

We have recently developed fiber-based models of the sclera that incorporate fiber interweaving and fiber-fiber interactions [4]. Our goal in this project was to leverage those models to determine the distribution of fiber-level stresses and strains in scleral collagen fibers when the sclera is subjected to a relatively simple equi-biaxial stretch.

METHODS

Fiber structure construction and optimization: The details of the procedure used for constructing and optimizing fiber structure are described elsewhere [4]. Briefly, a rectangular region (484×464 μm) from the coronal section (Figure 1C) was considered for constructing the fiber structure. The fiber orientation distribution obtained from polarized light microscopy (PLM) (Figure 1) was used to assign a direction to the fibers (diameter, $d = 2$ μm). An iterative optimization of fiber architecture was done to introduce interweaving and avoid collisions among the fibers. Later, a pre-stretch equivalent to 2.5% equi-biaxial strain was applied to remove excess fiber undulations introduced during the construction process (Figure 2).

Element type and boundary condition: Fibers were meshed using linear truss elements (T3D2) [4] to avoid any influence of bending stiffness over the results. A displacement boundary condition shown in Figure 2 was implemented to represent equi-biaxial stretch. For the analysis, 2.18% of equi-biaxial strain was applied in agreement with the experimental study [6].

Fiber material properties: The non-linear material behavior of fiber [5] was modelled using a Mooney-Rivlin material model. We then used an inverse-modeling process based on matching the experimental tests of Eilaghi et al [6] to obtain the value of Mooney-Rivlin material constants C_{10} and C_{01}: 5746.9 MPa and -5002.6 MPa, respectively.

Fiber-fiber Interaction: To incorporate the effect of interactions between fibers, a general contact algorithm with no friction was activated in ABAQUS.

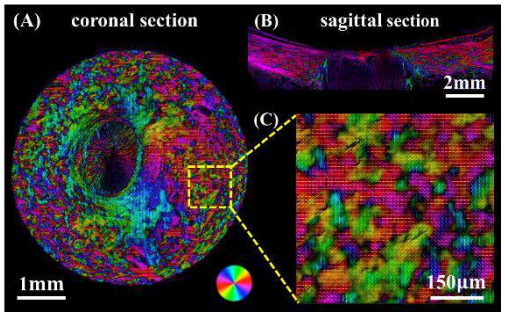

Figure 1. PLM images of (A) Coronal and (B) Sagittal sections of pig and sheep optic nerve head, respectively. Colors represent the local fiber orientation in the section plane. Collagen fiber density was considered directly proportional to the pixel intensity (1 pixel ≈ 1 μm). (C) Close-up of modeled region.

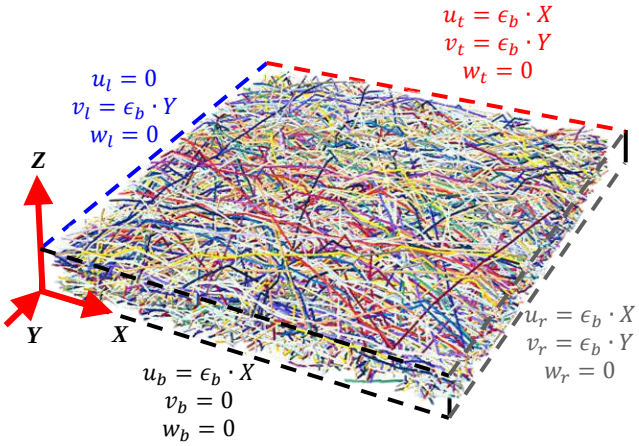

Figure 2. Schematic of displacement boundary condition implemented over fiber structure to imitate equi-biaxial stretch. u, v & w is the displacement in X, Y and Z direction respectively. b, r, t & l represent faces attached to bottom, right, top and left edges of the rectangular domain. ϵ_b is equi-biaxial strain.

RESULTS

The results show a wide range of fiber principal stress and strains (Figure 3). At 2.18% equi-biaxial strain, the value of principal strains varies from 0 to 2.56% and principal stresses vary from 0 to 132.5 MPa at element level (Figure 4). The principal stresses are not directly proportional to the principal strain due to the non-linear material properties. We noticed that fibers with small undulations, the strain could reach levels larger than the applied equi-biaxial strain (Figure 4). Increasing the equi-biaxial strain from 0.55% to 2.18%, approximately 60% of elements transitioned from zero stretch to stretch greater than 0.1% (Figure 5). At 2.18% equi-biaxial strain, approximately 20% of the fiber elements had principal strain lower than 0.1% and the majority of these elements belong to fibers with high undulations (Figure 5B).

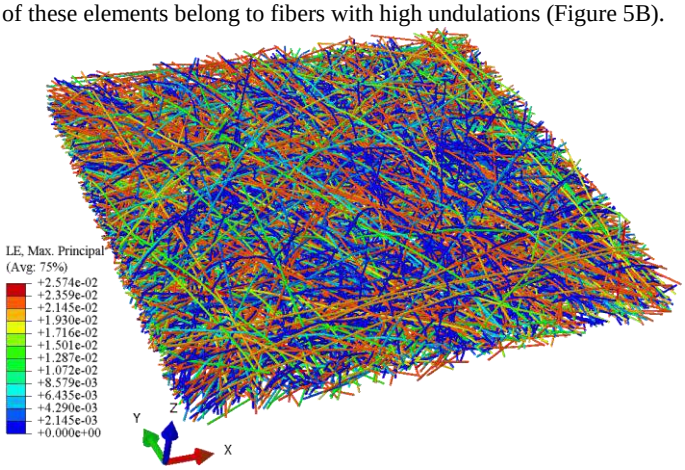

Figure 3. Contour plot illustrating heterogeneous distribution of principal strain in the fiber structure at 2.18% of equi-biaxial strain. The principal strain varied from 0 to 2.56%.

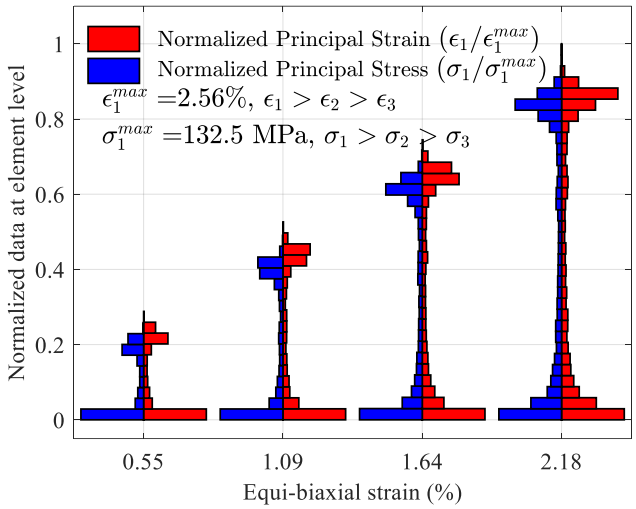

Figure 4. Normalized principal stresses and strains distribution at element level for four different equi-biaxial strains. At 2.18% equi-biaxial strain, the maximum principal stress (σ_1^{max}) and strain (ϵ_1^{max}) among all elements were 132.5 MPa and 2.56% respectively.

DISCUSSION

We simulated a specimen-specific fiber model representing sclera at a micro-scale to determine the heterogeneous distribution of stresses and strains. The results show a wide range of stress and strain due to the presence of fibers with low and high undulations, consistent with the conventional process of fiber recruitment. Fibers with low undulation experienced high stresses and strains. The stresses and strains were low in the fibers with high undulation. The stresses are not directly proportional to strains due to the non-linear material behavior of fiber. The analysis shows the heterogeneous distribution of stresses and strains in the fiber structure. Accounting for this heterogeneity is essential for developing accurate models of structure-function. This type of model provides a much more detailed understanding of the fundamental role of tissue architecture and composition in its biomechanical behavior. The models provide a framework for the study of stress and strain-induced fiber remodeling and failure [7].

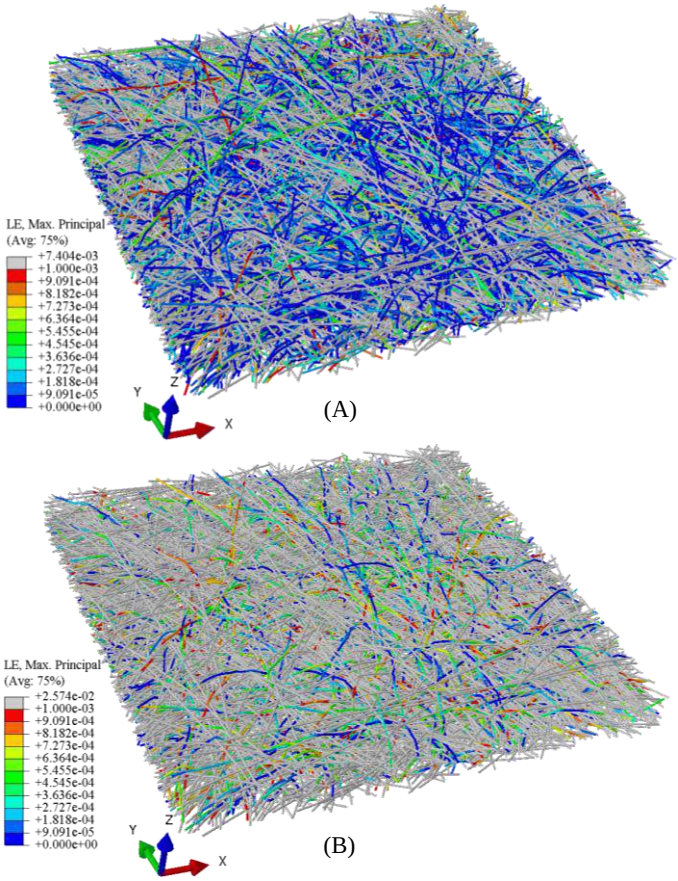

Figure 5. Contour plot showing approximately 60% fiber element transitioned from zero stretch to stretch greater than 0.1% with the increase in equi-biaxial strain from (A) 0.55% to (B) 2.18%. Rainbow color spectrum indicates variation of principal strain (0 to 0.1%) in fiber elements. Grey color indicates principal strain value above 0.1% in fiber elements. Principal strains along the length of fiber were non-uniform.

INTRODUCTION

The development of the lungs happens in three main periods: the embryonic, fetal, and postnatal period. The embryonic stage happens at week 4-7 post conception. This is when the anlage of the right and left lungs presents as two independents outpouchings of the ventral wall of the primitive foregut. Both of these buds will begin to elongate and create a cycle of growth in the mesenchyme and branching. The fetal period is when the formation of the bronchial tree begins and differentiation of the epithelia allow the morphological distinction between conducting and respiratory airways. Lastly, the terminal airways grow in length and in width. This forms clusters of larger airways. As early as 36 weeks gestation, true alveoli start to develop in the postnatal stage. These infant lungs are significantly different from adults because they contain a double capillary bed, whereas, adults only have a singly capillary bed. Lungs continue to grow to adulthood and the tissue expands proportionality to the increase body weight as we age [1]. Various morphological and tissues parameter of lungs will change due to aging. After the age of 30, there is a 1% decline per year in respirator mechanics and lung. Between ages 50 to 80 years of age, lung tissue will become about 7% less compliant[2].

The mechanical properties of the lung demonstrate a tensegrity dynamic that displays a balance of physical forces, stress, and strain which aids in determining the lung function and structure [3]. In addition, the lungs are constantly experiencing large cyclic mechanical stress and deformation with breath as well as cardiac contraction.

Variations of the elastic properties located in the lung linked with aging are crucial in determining lung function [4]. Rheometry can be a tool used to determine the storage and loss moduli of a material. The elastic and viscous components are important in defining the mechanical behavior of a material. The time dependent-properties or viscoelasticity of a material is associated with stiffness [5].

Analyzing the mechanical properties of the lungs over the lifespan is crucial in correlating lung structure, elasticity, and compliance with organ, tissue, and cell-scale behaviors [6]. Current studies looking into the mechanical properties of the intact lung of different species have used: Uniaxial testing [7], atomic force microscopy (AFM) [4,7], and microfluidic system [8]. Rheometry has been shown to be advantageous for its ability to encompass boarder measurement ranges and closely control the testing environment [9].

In this study, our goal was to characterize the mechanical properties of the murine lung. We accomplished the goal by using a TA Instruments DHR-2 Rheometer and testing the lungs from neonatal to old age. The objective of our study was to analyze the effects of age on rheological lung properties.

METHODS

Murine lungs were collected upon euthanization of C57Bl6j mice (neonatal-23 months old). Lungs were then snap frozen immediately and kept at -80◦C until rheological testing. Murine lungs were categorized into four groups: neonatal (0-10days), young adult (3-6 months), mature/middle adult (10-14 months), and old adult (18-24 months). The age samples were broken into two groups: Young Mice (YM) and Middle Age/Old Age Mice (MOM). The YM group included the neonatal and 6-10week. The MOM group included 7-, 10- and 22–24-month-old mice.

Before testing, murine lungs were kept on ice. The testing was then performed using a TA Instruments DHR-2 Rheometer with a 20-mm parallel- plate fixture and a gap of 0.8-1.0mm under frequency sweep conditions. The lower Peltier cell was set to 25 C for sample loading as well as after lowering the measuring system. The system was enclosed within a solvent trap PBS to prevent the lungs from dehydration during testing. The frequency sweeps, had a soak time of 30.0 seconds, 0.5%

strain, and angular frequency 0.1 to 100rad/s. All the sweep were run in triplicate.

RESULTS

Since the lung is both structurally and mechanically heterogeneous tissue, it is difficult to obtain a comprehensive test. To address this, for each age group we tried to get five separate lung samples to test. This gave us a more complete look at the storage and loss modulus of each specific age group.

As the age of the mice increased in the YM group, we saw an increase in the storage and loss modulus. However, the MOM group did not have a strong correlation of increased age with the storage and loss modulus.

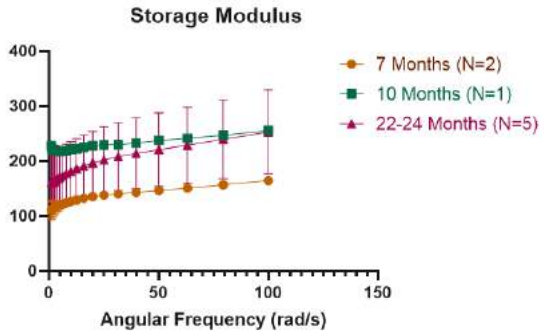

Figure 1: Storage Modulus of MOM group: 7(N=2) ,10(N=1), and 22–24-month-old(N=5) mice.

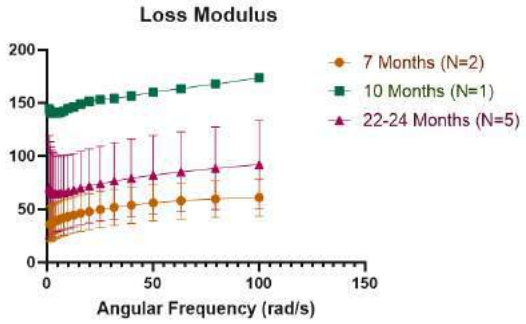

Figure 2: Loss Modulus of MOM group: 7(N=2) ,10(N=1), and 22–24-month-old(N=5) mice.

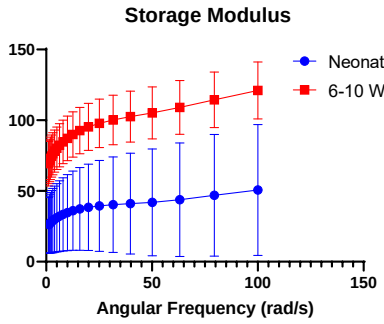

Figure 3: Storage Modulus of YM group: neonatal(N=3) and 6–10-week(N=5) mice.

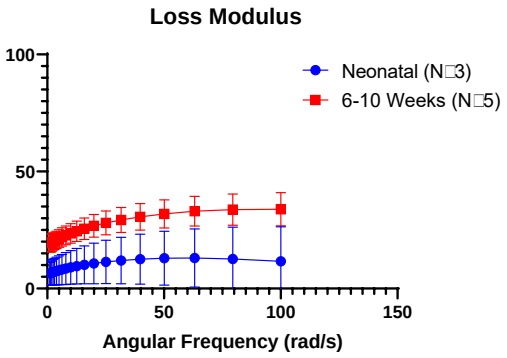

Figure 4: Storage Modulus of YM group: neonatal(N=3) and 6–10-week (N=5) mice.

DISUSSION

Decreased lung function is a common occurrence that happens as we age. This decrease is linked the structural changes that take place on the macro and micro level of the lung. Lung tissue that aid in keeping airways open can lose elasticity as it ages, resulting in smaller and stiffer lung tissue [3]. Using the rheometer, we collected data on the storage and loss moduli of the murine lung. The results displayed that the storage modulus was always greater than the loss modulus, this indicated to us that our lungs were more elastic than viscous. The results also presented an increase in storage modulus which gave the indication that as age increased, the ability for the lungs to deform became more difficult. This indicated that lungs were become stiffer over time.

Our results showed that using rheometer technique can be advantageous in quantifying age impact on the lungs. This study showed similar trend with a previous study done with different human lung compartments which also displayed an increase in Young's modulus as age increased [4]. Some of the limitations we faced during the study is varied number of samples per group. Freezing the sample may have caused some reduction in modulus as shown previously [7].

For future studies, we will gather more samples at different age groups to have a more comprehensive look at the lifespan. These values may be added to develop a more comprehensive computational model of lung mechanics across lifespan. In addition, we plan to decellularize the collected tissue for mass spectrometry to understand the composition of the extracellular matrix at the specific age groups.

INTRODUCTION

Coarctation of the aorta (COA) is one of the most common congenital heart defects (5-8%), presenting as narrowing of the proximal descending aorta. COA can be discrete or more complex and associated with severe complications such as diffuse arch hypoplasia and mycotic aneurysm. Regardless of clinical presentation, the most common therapy is intervention to restore normal aortic blood flow thus, understanding COA-specific hemodynamics is crucial [1-2]. Four-dimensional (4D) flow MRI has shown promise as a tool to assess the hemodynamics of COA in-vivo. However, 4D flow MRI data are acquired with a predefined velocity encoding (V_{enc}), set above the maximum expected velocity to avoid velocity aliasing, and issues can arise when acquiring data in complex flow regions with both high and low flow velocities, e.g. in patients with COA (high velocity flow jets) and mycotic aneurysm (slow vortex flow velocities) distal to the location of the narrowing [3-4]. Pulsatile in-vitro models have proved useful for systematic evaluation of 4D flow performance in complex flow cases by providing a way to produce physiologically realistic geometries and flow conditions that can also be analyzed with higher resolution flow methods, like particle image velocimetry (PIV) [5]. The goal of this study was to: (1) develop a framework for in-vitro modeling of COA hemodynamics using patient-specific aorta COA models and 4D flow MRI and (2) preliminary validation of 4D flow MRI for COA using PIV.

METHODS

The study included a pediatric patient with COA and a mycotic aneurysm who underwent in-vivo 4D flow MRI, following an IRB-approved protocol pre- and post-repair.

Aortic Model Construction: 3D contrast-enhanced magnetic resonance angiography (CE-MRA) was used for segmentation of the aortic anatomy. Following a fabrication process outlined by Ruedinger et. al., two in-vitro, patient-specific silicone models were created representing the pre- and post-repair anatomies [6]. The segmented geometries were 3D-printed in polyvinyl alcohol (PVA), cast in silicone, and then dissolved with water, leaving the aortic cavity in a silicone block. Figure 1 outlines the construction process for the COA models.

4D Flow MRI & PIV Experimentation: The in vitro models were connected to an MRI compatible pulsatile flow circuit and scanned on a 3.0T MRI scanner (Signa Premier, GE, Waukesha, WI) using 4D flow MRI (PC-VIPR technique). Scan parameters were 1.3mm isotropic spatial resolution, 320mm field of view, 150 cm/s velocity encoding and cardiac gaiting. Flow conditions were controlled to match mean aortic flow obtained from in-vivo 4D flow MRI data.

PIV was performed on the pre- and post-repair cases using a solution, seeded with PMMA fluorescent particles (diameter = 10 μm), of 58% glycerol and 42% water (RI = 1.41) to match the index of refraction of the silicone model, minimizing optical distortions. PIV data were acquired using a Flowmaster system (LaVision, Göttingen, Germany), consisting of a dual-pulse 527 nm Nd:YLF laser opposite three high-speed cameras (Vision Research, NJ), oriented at -25, 0, and 25 degrees. The light sheet thickness was 5-mm. Data analysis was performed in Ensight (ANSYS Inc, PA).

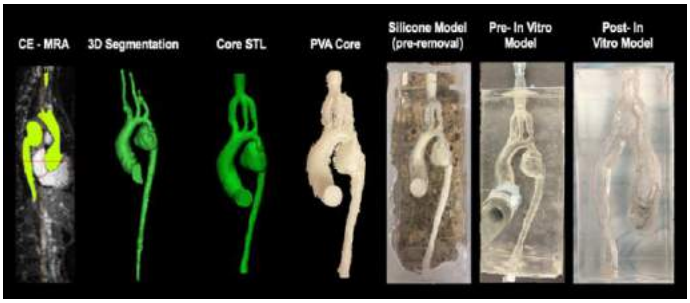

Figure 1: Pipeline for constructing pre- and post- patient-specific, MRI compatible in vitro flow models. Left-to- right: CE-MRA pre-intervention COA dataset. Raw 3D segmentation. STL of post-processed segmentation altered to enhance compatibility with pulsatile flow loop. PVA core cast in silicone block before dissolving step. Fully dissolved core produces patient-specific pre-intervention COA "ow cavity inside the clear silicone block and connectors are placed at the inlet and outlets of the model. Post-intervention in vitro model.

RESULTS

Figure 2 shows the in-vitro 4D flow MRI results pre- and post-repair during the cardiac cycle. Peak pre- and post- repair velocities at the location of the stenosis were recorded as 1.89 and 0.630 m/s, respectively. A high velocity jet was observed for the pre- case upstream of the stenosis and extending to descending aorta. Enhanced flow visualization was achieved in the aneurysm, where vortical flow regions are seen. Post-repair reduction in peak velocity at the location of the coarctation was also observed.

Figure 3 depicts the pre- and post-repair velocity fields at a plane through the center of the in vitro aorta for both 4D flow MRI (left) and PIV (right). For the pre-repair case, the high velocity jet is shown to accelerate in the aortic arch and extend through the aneurysm with PIV showing initialization of the jet earlier in the aortic arch when compared to 4D Flow MRI revealing a displacement artifact. Flow visualization at the stenosis location shows unrealistic disturbances potentially induced by imperfections in the model surface. Post-repair PIV velocity fields are qualitatively consistent with results obtained from 4D flow MRI as both show similar velocity patterns near the inlet and at the COA-repair site, where the velocity jet appears to extend from the arch along the outer wall of the descending aorta and leaving a region of slower, recirculating flow at the inner wall.

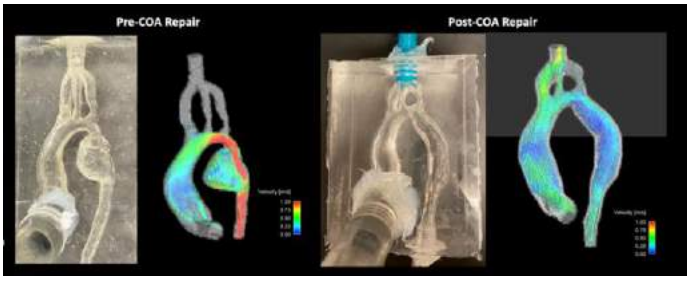

Figure 2: Pre- and post- COA repair in vitro flow models (left) used to generate 4D Flow MRI results (right). 4D Flow MRI derived velocity fields are depicted during peak systole. Clear reduction in pre-operative peak systolic velocities is observed for the post-repair case.

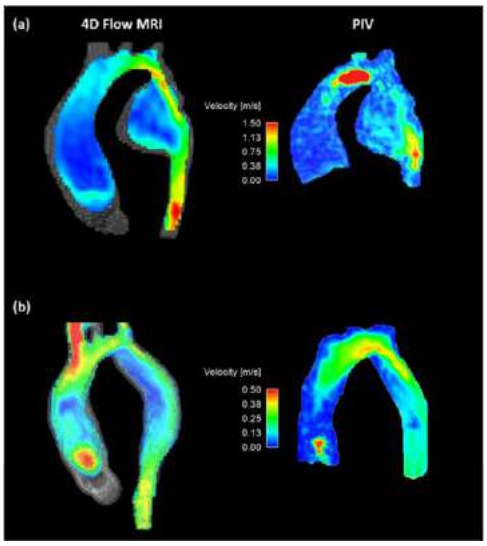

Figure 3: 4D Flow MRI (left) and PIV (right) derived velocity fields for COA in vitro models. (a) Pre-repair case (b) Post-repair case.

DISCUSSION

In this study patient-specific models were fabricated for in-vitro 4D flow MRI experiments to evaluate the blood flow dynamics of COA. The post-repair model showed lower velocities near the stenosis when compared to the pre- case for both 4D flow MRI and PIV. This agrees with clinical expectation, suggesting 4D flow MRI can be employed to characterize COA hemodynamics, however, future comparisons to actual in-vivo datasets must be made. PIV analysis demonstrated feasibility as a validation framework for COA cases. Velocity maps at the center of the aorta show flow features qualitatively consistent with 4D flow measurements, especially for the post-repair case, however, a more robust quantitative analysis is needed. Future direction will concentrate on improving model surface quality and incorporating 3D velocity quantification that can be directly compared to 4D flow MRI results while deriving clinically relevant complex flow metrics such as vorticity and wall shear stress. PIV will also allow for cycle-to-cycle assessment of velocity information, which can account for blood flow dynamics variations not captured with 4D flow MRI [7].

INTRODUCTION

It has long been known that the cortex is thicker in outer folds (gyri) than in inner folds (sulci). The cortical thickness, in particular, serves as an essential biomarker for diagnosing many neurological disorders such as lissencephaly, polymicrogyria, and Autism Spectrum Disorder. Thus, it is imperative to understand the drivers of cortical thickness variations and to be able to account for them in comparisons. Our recent work has suggested that the interactions between mechanics and biology plays a vital role in shaping the thickness variations, as seen in the measurements [5].

However, in the current work, we aim to distinguish between spatial variations that are artifacts of brain folding and those that are due to biological phenomena. As a novel metric of brain morphology, the modified cortical thickness -- or the thickness the cortex would have if it were unfolded and free of the mechanical forces involved in brain folding -- is introduced. Such a metric preserves biologically relevant information that holds great potential for identifying subtle brain morphology changes in heterogeneous disorders such as ASD. The challenge of calculating this new metric from MRI scans is only possible thanks to the rapid advancements of deep learning technology over the past few years, which have revolutionized many sciences and engineering areas. Instead of relying on hundreds of thousands of examples, our investigation is based on our knowledge of the underlying physics of the problem in the form of large deformation mechanics. In particular, we will learn to "undeform" the brain's cortex using a graph neural network, which operates and learns from physics-based simulations of cortical folding.

This work opens the door for precise cortical thickness analysis in neurological disorders, leading to new early diagnosis pathways and effective treatment.

METHODS

In vivo measurements The geometry of N = 564 human brains is measured using software suite Freesurfer [6], which performs automatic reconstruction and segmentation from MRI images (see Figure 1).

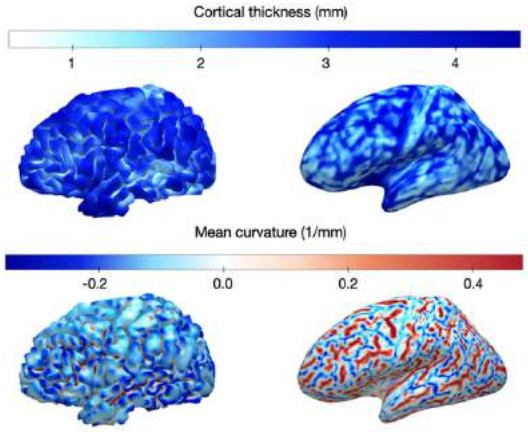

Fig 1. Patterns of cortical thickness and mean curvature in one of N=564 human brains studied. Top: cortical thickness. Bottom: mean curvature. Images to the left represent the anatomical cortical surfaces, while images on the right have been artificially inflated for improved visualization of sulcal values. (Adopted from our recent work [5].)

Constitutive model The cortical folding process undergoes large deformation as well as changes in biological properties. Following Rodriguez et al., 1994 [3], we split the deformation gradient into reversible elastic and irreversible growth counterparts. We model the brain as a bi-layer system consisting of an in-plane growing cortical layer with n_R denoted as its surface out-normal, and an elastic subcortical region underneath. Both tissues are modeled as compressible neo-Hookean material with similar stiffness ($\mu_c/\mu_s = 1$), which is in line with many mechanical testing results [4]. The details of our constitutive model are briefly summarized in Table 1.

We hypothesize that growth is sensitive to mechanical forces, with heterogeneous growth occurring in sulci and gyri after the onset of cortical folding [5]. More specifically, we take the mean curvature κ as a macroscopic evaluation of the local mechanical environment. This is not intended to suggest that cells respond to surface curvature directly, but rather that surface curvature is a convenient proxy for the differing mechanical state between gyri and sulci. Thus, the mean curvature is linked to the cortical growth rate to model preferential growth in either gyri or sulci. The evolution equation of cortical growth parameter ϑ^g is found in Table 1, where G_{ctx} is the homogeneous baseline cortical growth rate constant, $\kappa^* = \kappa t_i$ is the dimensionless mean curvature normalized by the initial cortical thickness t_i, and r^{cur} serves as a curvature sensitivity parameter. As a simplification, we assume that the subcortex does not grow.

Our model is implemented in a commercial non-linear finite element software Abaqus/Explicit [2] by writing user-defined material subroutines. Simulations of cortical folding in 2-D plane-strain and 3-D settings are performed.

Table 1. Summary of our constitutive model

	Gray matter	White matter
Kinematics	$\mathbf{F}^g = \sqrt{\vartheta^g}\mathbf{I} + (1-\sqrt{\vartheta^g})\mathbf{n}_R \otimes \mathbf{n}_R$	$\mathbf{F}^g = \mathbf{I}$
Cauchy stress	$\mathbf{T} = \left[\mu\mathbf{B}^e + (\lambda \ln(J^e) - \mu)\mathbf{I}\right]/J^e$	
Growth evolution	$\dot{\vartheta}^g = G_{ctx}\left[1 - r^{\text{cur}} \tanh(\kappa^*)\right]$	$\dot{\vartheta}^g = 0$

Deep learning Our ultimate goal is to make a meaningful comparison of cortical thickness across human brains from in vivo medical images and investigate the possible correlations between local thickness variations with various neurological disorders. To do that, we seek the *modified cortical thickness,* or the thickness the cortex would have if it were unfolded and free of the mechanical forces involved in brain folding. We assume that the thickness from our finite element simulations is the sum of the uniform normalized thickness and a mechanically driven thickness change, $t_{sim} = t_{norm} + t_{mech}$.

To obtain the modified cortical thickness in neuroimaging data, we use a graph neural network trained on data from the 3-D finite element simulations. It is worth noting that the training data contain the known modified cortical thickness t_{norm} from simulations across all growth modes. In essence, the graph neural network will learn the mapping between the thickness resulting from the combined effects of growth and deformation, and the thickness remaining after elastic forces are released. In the long run, these modified thickness values will then be used at a larger scale to compare typically developing (TD) and Autism Spectrum Disorder (ASD) individuals in an extensive database [7,8].

RESULTS

The measured morphology, including cortical thickness and mean curvature from one of N=564 human brains we studied, is shown in Fig 1. We can quickly tell that the cortical thickness is generally thicker at the gyral peak (negative mean curvature) while thinner at the sulcal fundus (positive mean curvature). Previous literature has shown that the mechanics alone is sufficient to explain such thickness variation [1]. Furthermore, building upon the same foundation, our recent work suggests that a small amount of gyral growth may contribute to the observed thickness difference in addition to the mechanics, suggesting that biological growth and mechanical forces closely interact in the process of cortical folding [5].

Our novel simulations use a randomly assigned initial cortical thickness that varies spatially according to a bivariate normal distribution (Fig. 2). This ensures that the training data for the neural network covers as much thickness variation as possible (the left in Fig. 2).

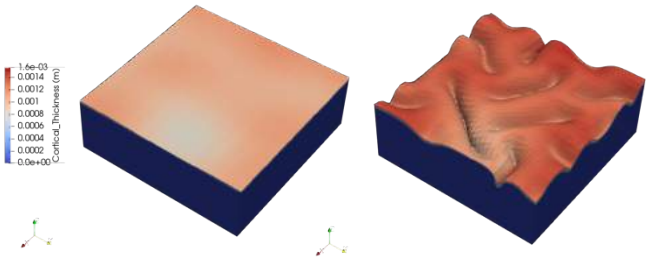

Fig 2. The simulated contour of cortical thickness at the pial surface. Left: the referential state. Right: the deformed state.

DISCUSSION

Cortical thickness serves as an essential biomarker for a wide variety of neurological disorders. Our previous work [1,5] showed the importance of mechanics, biology, and their couplings in predicting the physiological cortical thickness pattern. As an extension, the current work allows a meaningful comparison across human brains via modified cortical thickness. A graph neural network is trained with mechanics-based information to "unfold" the brain and obtain the modified cortical thickness from in vivo medical images.

Looking towards the future, when combined with in vivo medical images at a large scale, our work has the potential to provide a better correlation between cortical thickness variations with various neurological disorders.

INTRODUCTION

A major aim of bioengineering is to develop scaffolds that mimic properties of the extracellular matrix (ECM) to investigate mechanisms of tissue growth and remodeling. While homogeneous scaffolds are commonly used to support tissue constructs, these do not entirely recapitulate the variable characteristics of the ECM that are observed *in vivo* [1], particularly, tissues near interfacial boundaries where ECM composition, organization, and density can differ drastically [2]. For example, ECM heterogeneities between a tumor and the surrounding stroma [2], or a wound surrounded by healthy tissue [3]. Scaffolds that combine various materials have been engineered to achieve mechanical and biological properties that more closely resemble the tumor and wound microenvironments [1,2,3]. Characterizing the non-uniform mechanics of these scaffolds is critical to understanding how variations in material properties influence cellular behavior.

Fibrin is a naturally occurring protein that is polymerized from fibrinogen and thrombin following injury and provides a temporary structure for remodeling during wound healing [4]. It is a common tissue engineering scaffold because fibrin is biocompatible and its structural properties can be controlled by modulating fibrinogen and thrombin concentrations [4]. Here, we propose a method to characterize the non-uniform mechanical behavior of heterogeneous fibrin gels with varying density by leveraging a finite element (FE) model informed by empirical data. This approach can be adapted to predict and characterize the stress-strain distribution of novel engineered scaffolds that are variable in both geometric complexity and material composition.

METHODS

Porous polyethylene (PE) blocks were used as anchor points for fibrin constructs. PE blocks were bonded onto laser cut polyethylene terephthalate frames using Loctite Super Glue. A 3D printed 2.5mm x 6.6mm x 0.75mm (w x l x h) mold was used to control fibrin geometry as it polymerized between two PE blocks (Fig. 1A).

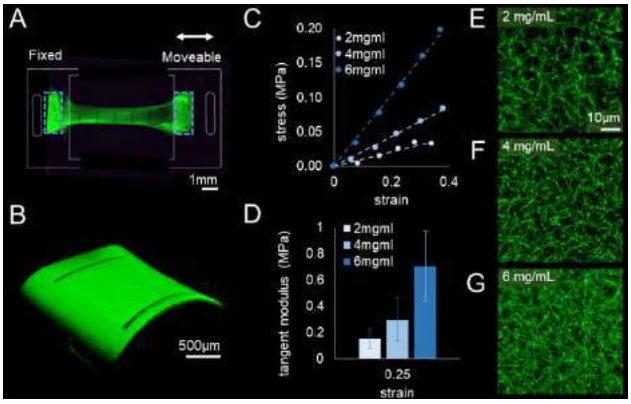

Figure 1: (A) Fibrin on tensile testing frame. PE blocks outlined in blue. (B) 3D rendering of fibrin. (C) Representative stress-strain curves for 2, 4, and 6mg/mL fibrin. (D) Comparison of tangent moduli at ε=0.25 (n=2-4). Error bars=S.D. Microscale structure of 2mg/mL (E), 4mg/mL (F), and 6mg/mL (G) fibrin.

Fibrin concentrations of 2, 4, and 6mg/mL were prepared by combining human fibrinogen and Alexa Fluor (AF) 488 conjugated human fibrinogen at a 1:10 fluorescent to non-fluorescent fibrinogen ratio, 2M $CaCl_2$, and 0.002 U thrombin per mg fibrinogen, in PBS.

Heterogeneous fibrin constructs were made by first pipetting 2mg/mL AF 488-labeled fibrin into a 4mm x 6.6mm x 0.75mm mold, as described above, and then pipetting 4mg/mL AF 546-labeled fibrin into the center of the 2mg/mL fibrin as it polymerized (Fig. 2A).

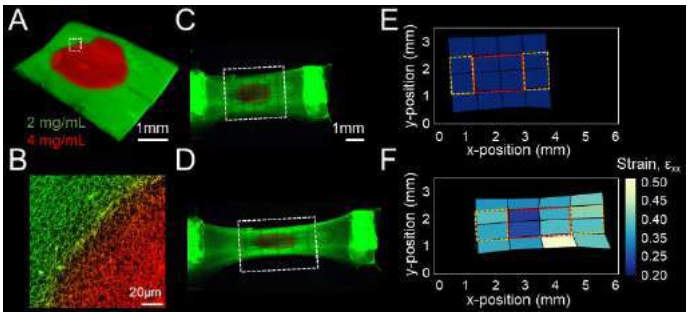

Figure 2: (A) 3D rendering and (B) microscale structure of 2mg/mL fibrin (green) with a 4mg/mL fibrin inclusion (red). Gel before (C) and during (D) tensile testing. Strain field before (E) and during (F) tensile testing. Voxels encompassing and adjacent to the 4mg/mL fibrin outlined in red and yellow, respectively.

Fiducial lines were photobleached onto fibrin in a vertical pattern (Fig. 1A) or a 5x5 grid pattern (Fig. 2C) using a Leica STELLARIS 5 confocal microscope and a 10x objective. Z-stacks were acquired to visualize the macroscale geometry, and FIJI was used to measure cross-sectional areas. The microscale structure of fibrin was imaged using a 63x objective.

A FemtoTools micromanipulator system, microforce sensor probe, custom 3D printed spring, and a Leica microscope camera were used to collect force data and to acquire video of sample deformation, as previously described [5]. Tensile tests were conducted at a strain rate of $0.01s^{-1}$ up to a 6000μm displacement, equivalent to ε=0.91.

For homogeneous fibrin, strain was calculated from the vertical fiducial lines through video analysis using a custom FIJI macro and MATLAB algorithm, as previously described [5]. Stress was calculated by dividing force data by regional cross-sectional area.

For the heterogeneous fibrin gel, FIJI was used to analyze videos and manually track the position of each vertex on the fiducial 5x5 grid. A custom Python code was used to plot the position of the vertices and calculate the strain of each voxel (Fig. 2E, F). A FE model was created in Abaqus to simulate the heterogeneous fibrin gel (Fig. 3).

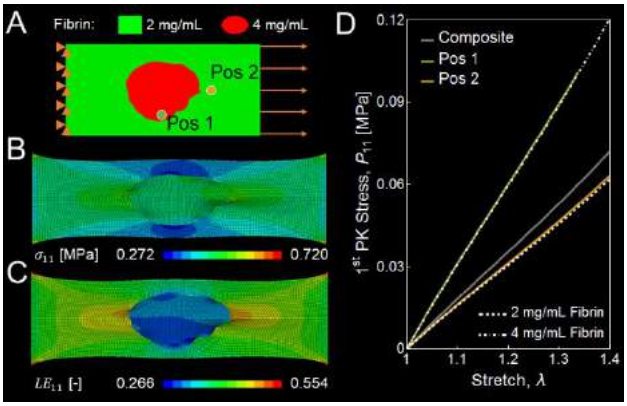

Figure 3: (A) FE model of heterogeneous fibrin gel. Stress (B) and logarithmic strain (C) fields from FE model. (D) Local stress-strain response within (1) and adjacent (2) to 4mg/mL inclusion.

The geometry of the FE model was based on measurements taken from confocal images of the heterogeneous fibrin. Clamped boundary conditions were imposed on the left side of the geometry, and the right side was stretched to 1.5x the original length (Fig. 3A). The model by Gasser et al. [6] was used in Abaqus to simulate the material, with parameters obtained by fitting the bulk material response for 2mg/mL and 4mg/mL fibrin (Fig. 1). Stress-strain data from different locations on the heterogeneous fibrin, encompassing and adjacent to the 4mg/mL fibrin inclusion, were isolated for comparison.

RESULTS

Confocal imaging of homogenous fibrin showed that fibril density increased with higher fibrinogen concentration (Fig. 1E-G). A positive correlation between fibrinogen concentration and stiffness was observed. The average tangent moduli and standard deviations of the 2, 4, and 6mg/mL fibrin at ε=0.25 were 0.15±0.08MPa, 0.30±0.16MPa, and 0.71±0.26MPa, respectively (Fig. 1D).

Confocal imaging of the heterogeneous fibrin gel showed a cohesive interface between the 2mg/mL and 4mg/mL fibrin (Fig. 2B). Different local strains were observed during tensile testing of this gel (Fig. 2C-F). For the displacement shown, voxels encompassing the 4mg/mL fibrin experienced an average strain (±S.D.) of 0.29±0.06. Notably, voxels in the 2mg/mL fibrin region, adjacent to the 4mg/mL fibrin inclusion, experienced a higher average strain of 0.36±0.02.

The FE model showed consistent results with what was observed experimentally. The stress was nearly constant in the 4mg/mL inclusion and the regions adjacent to it on the left and right side (Fig. 3B). However, because the inclusion was made out of a stiffer material, the strain in the inclusion was smaller compared to the adjacent regions (Fig. 3C), as observed experimentally. Position 1, within the 4mg/mL fibrin, had a tangent modulus of 0.29MPa at ε=0.25. Position 2, within the 2mg/mL fibrin had a tangent modulus of 0.15MPa at ε=0.25. The curves of the bulk 2mg/mL and 4mg/mL material are plotted for comparison (Fig. 3D). The homogenized modulus of the heterogeneous fibrin gel was 0.18MPa at ε=0.25.

DISCUSSION

The observed trends of higher fibril density and gel stiffness with increasing fibrinogen concentration matched previously reported findings [4]. For the heterogeneous fibrin gel, strain varied by region upon tensile testing. As expected, regions within higher concentration, 4mg/mL fibrin, experienced a lower strain than regions composed of the lower concentration, 2mg/mL fibrin. This is supported by both the empirical (Fig. 2F) and FE model simulated (Fig. 3C) strain fields.

Creating an FE model based on the mechanical properties of homogenous fibrin allowed us to simulate the stress-strain response of heterogeneous gels that was verified experimentally. The overall stress-strain response of the heterogeneous gel falls in between the bulk response for the 2mg/mL and 4mg/mL fibrin (Fig. 3D). Notably, the strain field for the heterogeneous gel was measured experimentally by imaging the deformation of a fiducial grid (Fig. 2F). These results aligned with the FE model (Fig. 3B, C). This approach can be applied to design and characterize novel biomaterial combinations that seek to recapitulate *in vivo* mechanics to elucidate the mechanisms of tissue formation and to guide regenerative therapies.

INTRODUCTION

Osteoarthritis is a leading cause of severe disability in the United States, characterized by changes to a joint as an organ system. One tissue of the joint that is emerging as a key mediator of degeneration, pain, and stiffness is the soft tissue lining the joint, the synovium[1]. It is hypothesized that fibrotic changes in this tissue not only cause joint stiffness and loss of mobility, but may disrupt cartilage homeostasis by altered lubricant expression, such as lubricin (PRG4)[2]. Loss of lubricin expression may increase cartilage friction, resulting in cell and matrix damage that further the cascade of disease[3]. As such, targeting synovial fibrosis during arthritis progression emerges as a treatment strategy.

In the context of many other tissues (e.g., lung, liver, kidney), fibrosis leads to organ failure. Fibrosis is characterized by excessive matrix deposition by fibroblasts that have differentiated towards a myofibroblastic phenotype. Both biophysical and biochemical cues are potent regulators of this differentiation process through increased matrix stiffness and transforming growth factor-β (TGFβ) signaling, respectively[4]. While TGFβ signaling is essential for many biologic functions, targeting cellular sensing of biophysical cues emerges as a potential therapeutic target to inhibit fibrotic cascades. Here, we connect fibrotic signaling and altered lubricant expression by synovial fibroblasts to mechanosensing. Additionally, we assess a potential small molecule inhibitor to rescue synoviocyte function.

METHODS

Human synovium samples were collected from organ donors (OD) and patients undergoing total knee arthroplasty (TKA). Hematoxylin and Eosin (H&E), alpha smooth muscle actin (αSMA), and lubricin staining were conducted and quantified for each donor (n = 4 OD, 8 TKA). In vitro models were conducted on bovine synoviocytes with altered biophysical (matrix stiffness) and biochemical cues (TGFβ at 10 ng/mL). Cells were assessed via immunofluorescence and RT-qPCR, and conditioned media were assessed for their lubricating ability of cartilage explants via confocal elastography. Two small molecule inhibitors of ROCK (Fasudil) and YAP/TAZ (Verteporfin) were tested

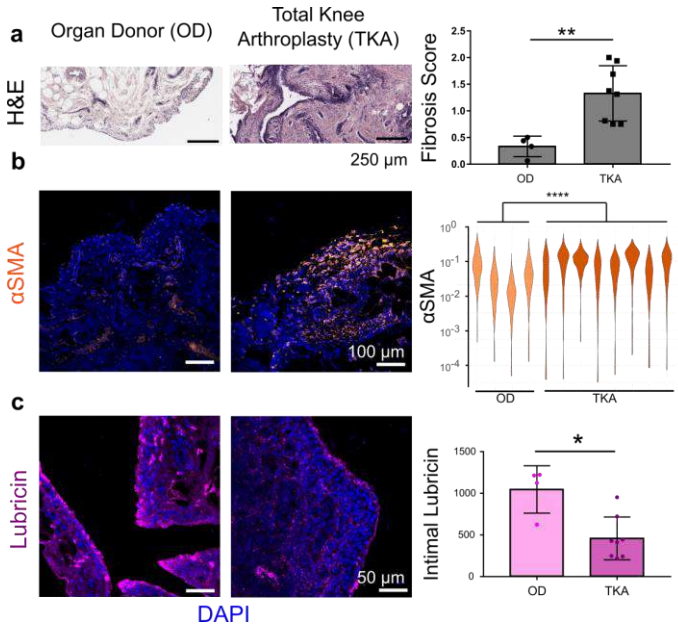

Figure 1. Synovia from TKA patients exhibited (a) higher fibrosis scores, (b) increased αSMA localization, and (c) decreased lubricin at the synovial intima (p < *0.05, **0.01, ****0.0001)

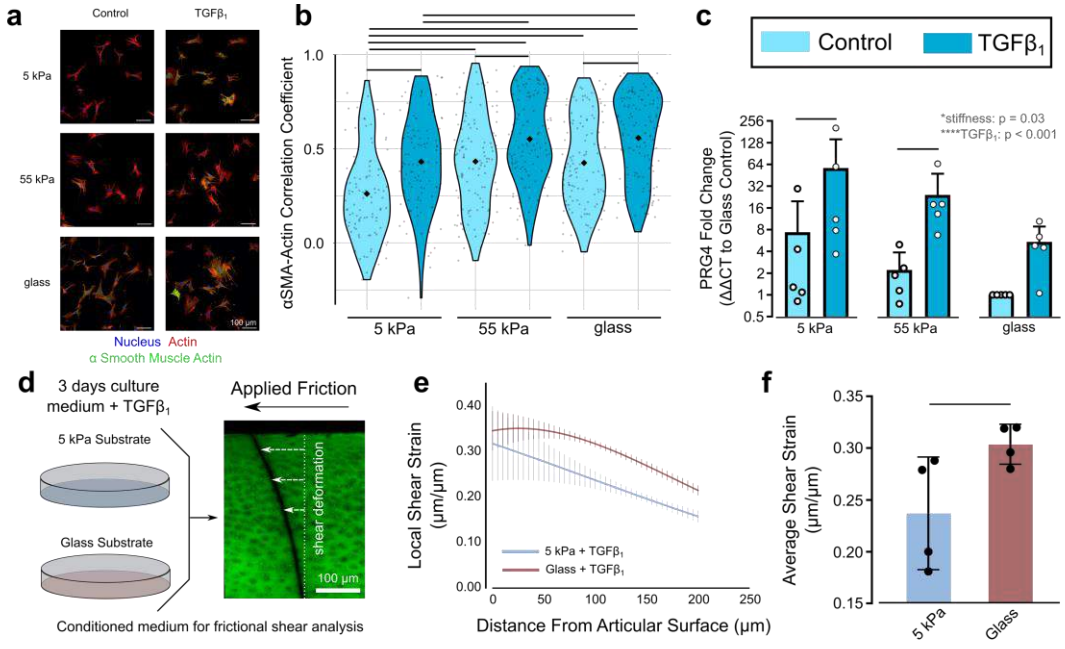

Figure 2. (a) Synoviocytes were seeded on substrates of varying stiffness with or without TGFβ and viewed via confocal microscopy. (b) Both increased stiffness and TGFβ increased αSMA incorporation into stress fibers. (c) Increased stiffness decreased PRG4 (lubricin) expression, while TGFβ increased expression. (d) Conditioned media were assessed for lubricating ability. (e) Confocal microscopy was used to determined depth-dependent deformations due to surface friction. (f) Cells grown on soft substrates secreted biomolecules that reduced cartilage friction deformations. (bars denote p < 0.05)

in cells on glass with TGFβ for their ability to reduce myofibroblast differentiation and restore lubricant expression. Statistical analyses were conducted in R and Prism via one-way or two-way ANOVA with Tukey post hoc, or via t-tests. Sample sizes are denoted by individual dots in plots.

RESULTS

Human synovium samples from TKA patients exhibited consistently increased fibrosis scores compared to organ donors (**Fig 1a**). Additionally, markers of myofibroblast differentiation (αSMA, **Fig 1b**) and increased mechano-signaling (YAP/TAZ, data not shown) were observed in TKA patients. Concomitantly, decreased lubricin localization was observed in TKA patients (**Fig 1c**).

To understand the cues leading to this altered phenotype, both stiffness and TGFβ signaling were assessed in vitro (**Fig 2a**). Both increased stiffness and TGFβ signaling increased myofibroblast differentiation as quantified by αSMA incorporation into stress fibers (via correlation with f-actin fluorescence. **Fig 2b**). In terms of lubricant expression, TGFβ increased PRG4 expression, which is the gene encoding the lubricating molecule, lubricin (**Fig 2c**). To determine change in lubricant function, conditioned media were assessed for their lubricating ability as a function of matrix stiffness via confocal elastography (**Fig 2d**). By quantifying the local shear strains propagating from the articular surface (**Fig 2e**), we observed an enhanced ability of synoviocytes seeded on a soft matrix to secrete lubricating biomolecules (**Fig 2f**). This finding is in agreement with increased lubricin expression in soft environments (**Fig 2c**).

Since substrate stiffness mediates functional lubricant expression, we tested two small molecule inhibitors that target mechanosensing. Fasudil is a ROCK inhibitor that decreases cell contractility and subsequent biophysical cue interpretation, and Verteporfin is a YAP/TAZ inhibitor that inhibits gene expression instigated by stiff substrates. Immunofluorescence imaging revealed decreased cell spreading and decreased αSMA incorporation into stress fibers for both molecules (data not shown). Additionally, RT-qPCR revealed decreased expression of αSMA for both inhibitors (**Fig 3, left**). However, only Fasudil was able to rescue PRG4 (lubricin) expression (**Fig 3, right**).

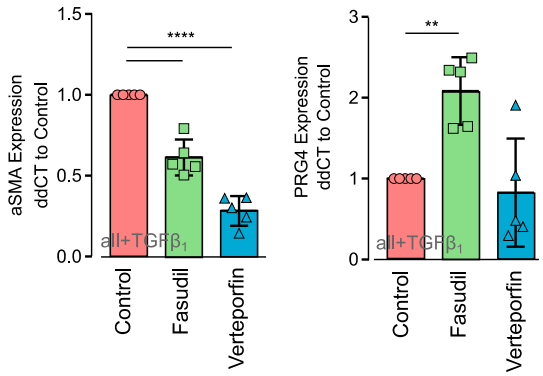

Figure 3. RT-qPCR revealed that both small molecule inhibitors decreased αSMA expression (left), but only Fasudil rescued lubricin (PRG4) expression (p< **0.01, ****0.0001).

DISCUSSION

This study reveals the role that matrix stiffness can play in the emergence or persistence of synovial fibrosis. As such, we revealed the possibility of targeting cellular mechanosensing via ROCK inhibition to alter synoviocyte behavior. Not only does Fasudil decrease myofibroblast differentiation and synoviocyte contractility, but it may rescue lubricant expression to provide chondroprotection.

INTRODUCTION

Women who give birth for the first time over the age of 35 have a 350% greater risk of obstetric injury compared to 25-year-old women[1]. While the etiology of the increased risk for trauma is not defined, remodeling of extracellular matrix (ECM) with age may contribute[2] Disruption of elastic fibers is associated with aging and contributes to pelvic floor disorders such as pelvic organ prolapse[3,4] Elastic fibers provide compliance, constrain collagen undulation, and dictate smooth muscle cell (SMC) phenotypes.[5-7] SMCs provide structural and functional integrity to the vaginal wall.[8] Alterations in ECM may include remodeling of the passive contributions, as well as the active responses in the organization and contractility of SMCs.[9,10] The relationship between vaginal elastic fiber composition, SMC contractility and passive mechanical function, however, are not fully understood. Further, alterations in vaginal elastic fibers and SMC phenotype with increasing maternal age is not known. Biaxial extension-inflation protocols are useful tools to evaluate SMC responses, including the baseline contractile potential in the absence of external stimuli (basal tone).[6,11,] Therefore, the objective of this study is to quantify biaxial relationships and SMC contractility as a function of age. Further, elastase digestion will be used to observe potential interactions between elastic fibers and SMC contractility. We hypothesized that elastase treatment will decrease changes in axial force during maximum contraction and increase material stiffness. Additionally, we hypothesized that material stiffness with increase following removal of SMC tone. Further, we hypothesized that vaginal contractile function decreases with age, but that material stiffness increases.

METHODS

A total of $n = 24$ (2-3-month $n=13$; 4-6-month $n=11$) nulliparous female CD-1 mice at estrus were utilized within this study (IACUC approved). **In Vivo Vaginal Pressure Measurements** ($n = 5$/group) To inform the appropriate loading environment for mechanical testing, intravaginal pressure was measured utilizing balloon catheter at the estrus stage.[11-14] The balloon catheter was inserted into the vaginal canal and the software recorded pressure (PowerLab and LabChart8; AD Instrument). **Specimen preparation** A separate cohort of CD-1 mice at estrus (2-3 months n=8; 4-6 months n=6) were euthanized by guillotine without anesthesia to preserve SMC viability.[11] The vagina was immediately dissected and cannulated within a biaxial inflation-extension device. The unloaded configuration was identified, followed by determining the physiologic length[6,11,14] Vaginal SMCs were preconditioned with isobaric- axially isometric contractions induced by 40 mM potassium chloride (KCl) above and below the measured *in vivo* pressure—8 mmHg and 4 mmHg, respectively.[11] Following SMC preconditioning, the vagina was preconditioned circumferentially with 5 cycles pressurization (P= 0-15 mmHg) as well as axially by extending the tissue from -2% to +2% the physiologic length. **Maximum contraction** Maximum contraction was induced with 40 mM of KCl at the physiologic length and mean *in vivo* measured pressure for a total of 5 mins.[11] Changes in outer diameter and axial force were recorded (Figure 1). **Basal tone** Following equilibration, 5 cycles of pressure-inflation tests were performed at isometric stretches of the physiologic length wherein the pressure was increased cyclically from P =0 mmHg-15 mmHg.[5] **Elastase treatment** Vaginal samples were randomly allocated to either a control (n=4 for 2-3 months; n=3 for 4-6 months) or elastase treatment group (n=4 for 2-3 months; n=3 for 4-6 months). Samples were exposed to 15 U elastase digestion for 45 mins, and then the maximum contraction and basal tone assessments were repeated. [6,11] **Passive treatment** Control and elastase groups were subjected to 2 mM of Egtazic acid for 30 mins to remove SMC contraction potential.[11] The protocols for pressure-inflation and axial-extension cycles were repeated. **Data Analysis** The change in axial force and outer diameter was measured from the force and outer diameter prior to KCl addition to the peak values over the 5-minute time period (Figure 1). For control and elastase groups, vaginal material stiffness was quantified by taking the slope of the stress-stretch curve over the range of measured

physiologic pressures (4 mmHg- 8 mmHg). The net changes in material stiffness were calculated by subtracting the untreated response from the elastase treated (Figure 2). **Statistical analysis** To determine if aging and elastase treatment decreased maximum SMC contractility, a 2-way ANOVA (age, treatment) evaluated the changes in axial force and outer diameter. A 3-way ANOVA (tone, age, treatment) evaluated if SMC tone, age, and elastase treatment increased material stiffness. Data reported herein as mean +/- SEM.

RESULTS

Maximum contractility A 2-way ANOVA identified significant differences in the change in axial force with respect to elastase treatment ($p=0.005$) and a trend among the age groups ($p=0.09$). No significant interactions were identified. Elastase treatment significantly decreased the change in axial force in the 2-3 months age group ($p=0.003$) as well as the 4-6 months age group ($p=0.04$; Figure 1A). A 2-way ANOVA (treatment, age) identified significant differences in the change in outer diameter with respect to elastase treatment ($p=0.005$) and age ($p<0.001$) as well as an interaction between age and treatment ($p=0.03$; Figure 1B). **Material stiffness** A 3-way ANOVA identified significant differences in circumferential material stiffness with respect to elastase treatment ($p<0.001$) and tone ($p<0.001$), however, age was not significant ($p=0.74$). The interaction between tone and treatment was significant ($p=0.009$). The 3-way ANOVA identified significant differences in axial material stiffness with respect to elastase treatment ($p=0.007$) and tone ($p=0.03$), however, age was not significant ($p=0.39$). **Changes in material stiffness following elastase** A 3-way ANOVA (direction, age, tone) for change material stiffness in the axial direction showed significant differences in both treatment ($p=0.007$) and tone ($p=0.001$), however, age was not significant ($p=0.69$) (Figure 2). The interaction between tone and direction was significant ($p=0.03$).

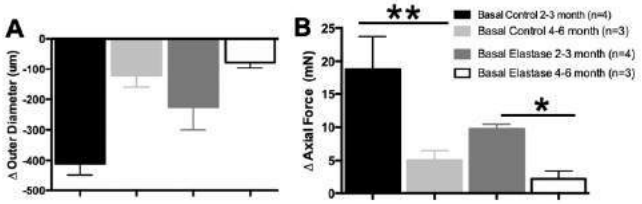

Figure 1: Change in outer diameter (A) and axial force (B) Elastase decreased the force in both age groups (*p<0.05, **p<0.01. Significance was noted in diameter among treatment and tone. Posthoc tests were not performed due to interactions between treatment:tone (p=0.009). Differences among the force were noted in treatment from the basal control 2-3 months (black) to the basal elastase 2-3 months (dark gray) and basal elastase at 2-3 months to basal elastase 4-6 months (white).

DISCUSSION

Maximum contractility Elastase reduced vaginal contractility in both the circumferential and axial directions, as evidenced by the decreased changes in outer diameter and axial force. This decrease is likely due to the disrupted physical interactions between elastic fibers and vaginal SMCs. The diminished contractility has been noted in prior work including the canine trachea and C57BL/6 mouse vagina at 4-6 months of age.[15, 16] However, the previous mouse studies observed significant differences in only the axial direction and was performed in an inbred strain (C57BL/6).[16] Changes in both circumferential and axial directions as a function of ECM composition may suggest SMCs oriented in both directions may be influenced by the ECM structure. Further, performing the experiment in the outbred CD-1 strain provides the benefit of genetic diversity.[18] Maximum contraction of the vagina decreased with age in the circumferential direction and a trend was observed in the axial direction. A statistically significant interaction between age and SMC tone was observed in the circumferential direction. It is possible that the SMC are more prominent or easily influenced by increasing maternal age and elastase disruption compared to the axial direction. This is supported by prior literature finding that the C57BL/6 mouse contains SMC oriented primarily in the circumferential direction.[11] However, the lack of significant changes in the axial direction may be due to the sample size, as a power analysis indicated a required sample size of 14/ group to obtain statistical significance. Future investigations include expanding the age ranges from 6 months to 14 months, which would be comparable to extending the study from 35 human years to 62 years to further elucidate potential changes with maternal age.[17] **Material stiffness** A significant interaction was noted in the circumferential material stiffness between treatment and SMC, however, no significant interactions were noted in the axial direction. This observation further supports the hypothesis that circumferentially oriented SMC may be influenced more by ECM changes. While elastase further increased the material stiffness of the vagina in both basal and passive smooth muscle tone, the difference was exacerbated under passive conditions. This phenomenon is noted in other soft tissues, such as the carotid artery, where the loss of elastic fibers subsequently decreases collagen undulation and alters the stiffness of the tissue.[5] This may be due to smooth muscle tone minimizing the changes in outer diameter following elastase treatment, which would preserve some degree of the native collagen architecture and result in less dramatic changes in material stiffness. Future work to integrate second harmonic generation (SHG) imaging is required to investigate collagen undulation and architecture regarding smooth muscle tone, elastase treatment, and age. Characterizing the mechanical properties of the vagina as a function of increasing age and SMC contractility may provide insight to how structural changes alter the functional integrity of the vagina.

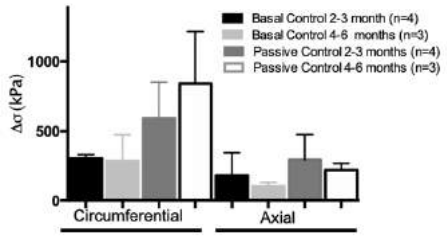

Figure 2: Change in material stiffness along each direction. The 3-way ANOVA showed differences with direction (p=0.007) and tone (p=0.03). The difference was further enhanced by passive induction (2-3 months dark grey, 4-6 months white). Posthoc tests were not performed due to interactions of direction:tone (p=0.03).

INTRODUCTION

The tricuspid valve regulates blood flow between the right atrium and the right ventricle. During ventricular systole, its three leaflets coapt and seal the right atrioventricular orifice to prevent the backflow of blood. In diastole, the leaflets passively allow for ventricular filling. This function, repeated with every heartbeat, relies heavily on the interplay between the tissues of the leaflets, the dynamic tricuspid annulus, and the contracting papillary muscles that prevent leaflet prolapse through chordae tendineae attachment. In a dysfunctional valve, leaflet coaptation is incomplete resulting in retrograde blood leakage through the valve, or tricuspid regurgitation (TR).

Clinically significant TR is an independent predictor of mortality and affects more than 1.6 million Americans [1,2]. Generally, TR is considered secondary or functional, meaning that extrinsic factors result in valvular dysfunction, while the valve tissue itself is intact and healthy [1]. For example, a dilated right ventricle can result in chordal tethering of the leaflets, preventing proper coaptation. However, we have recently challenged this paradigm with evidence of leaflet (mal)adaptation which may suggest a primary contribution to valvular dysfunction. In a tachycardia-induced cardiomyopathy (TIC) ovine model, we found that tricuspid anterior leaflets actively respond to heart disease on all functional scales: protein, cell, matrix, and tissue [3]. This active leaflet response resulted in larger and thicker leaflets, increased and reorganized collagen, and increased leaflet stiffness. While larger leaflets may improve leaflet coaptation (i.e. adaptation), stiffer and thicker leaflets may hinder coaptation (i.e. maladaptation). Thus, leaflet (mal)adaptation may play a diametrical role, both in addressing and contributing to TR.

Our previous study's TIC ovine model developed all salient signs of biventricular heart failure with concomitant TR as it presents clinically. However, due to the rapid development of the model (2-3 weeks) and the exaggerated nature of tachycardic hemodynamics, our results were naturally limited. Firstly, we likely only reported on the early response of the leaflets to disease. Secondly, the TIC model prohibited the ability to isolate the effects of mechanical stimulation (i.e. annular dilation and chordal tethering) from hemodynamic stimulation. In this study, we address these limitations by investigating the tricuspid leaflet (mal)adaptive response in a pulmonary hypertension (PH) ovine model. Our PH ovine model incubates for 8 weeks, extending the time window with a more gradual onset than previously reported on. Additionally, with our PH model we impart hypertensive hemodynamics, while still reliably producing annular and ventricular dilation. As such, we expect this model to better isolate the effects of mechanical stimulation on leaflet (mal)adaptation. The objective of our study is to evaluate and compare the (mal)adaptive response between the TIC and PH ovine models.

METHODS

For this study we utilized TIC and PH ovine models. For our TIC study, in brief, we randomly assigned 50 healthy male Dorset sheep to either control (CTL, n=17) or TIC groups (n=33). We anesthetized and monitored TIC subjects as we implanted a pacemaker. For 2-3 weeks post-surgery, we over-paced at 180-260 bpm until TIC subjects developed all salient signs of ventricular disease including ventricular and annular dilation, and atrioventricular regurgitation. For our PH study, in brief, we randomly assigned 29 healthy male Dorset sheep to either control (CTL, n=12) or PH groups (n=19). We anesthetized and monitored PH subjects as we partially occluded the pulmonary artery through banding. Within 8 weeks post-surgery, PH subjects developed all salient signs of ventricular disease including ventricular and annular dilation, and atrioventricular regurgitation. We euthanized all subjects and harvested the tricuspid valves for evaluation.

Immediately post-harvest, we photographed the tricuspid valves from a floating configuration on a calibrated grid. We digitized the anterior leaflets to determine metrics of leaflet size and shape. We then stored the tissues at -80°C. After thawing the anterior leaflets, we isolated a 7x7mm sample of the leaflet for tensile biaxial testing, aligning the major axis with the circumferential and radial directions. We applied four dots to each sample and photographed the stress-free reference configuration. We then mounted, preconditioned, and tested each sample in force-controlled equibiaxial tension. To analyze these data, we informed deformation gradients via strain tracking, and calculated membrane tensions from raw force and displacement data. To summarize our data, we determined four metrics of each sample curve: calf stiffness (i.e. upper region), toe stiffness (i.e. lower region), transition stretch, and degree of anisotropy.

RESULTS

All TIC and PH animals recovered well from their respective procedures and developed clinically accurate ventricular heart disease.

Morphologically, we observed a 1.2x significant increase in anterior leaflet area for PH subjects when compared to CTL subjects ($p = 0.024$) (Figure 1b). In comparison, we observed a 1.3x significant increase in leaflet area between TIC and CTL subjects ($p = 0.002$) (Figure 1a).

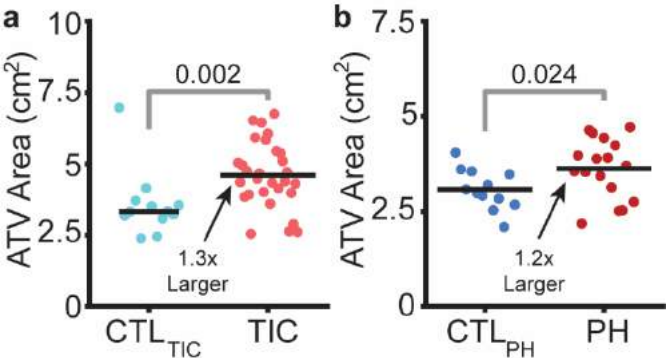

Figure 1: Anterior leaflet areas for (a) tachycardia-induced cardiomyopathy (TIC), and (b) pulmonary hypertension (PH)

From mechanical characterization, we observed a classic J-shaped curve for all samples (Figure 2a,b). Moreover, we found a significant 1.3x increase in circumferential calf region stiffness for PH samples when compared to CTL samples ($p = 0.019$) (Figure 2d). No other metrics for PH resulted in significant findings. Interestingly, in our previous study, we similarly found a significant 1.3x increase in TIC sample calf region stiffness ($p = 0.006$), but instead found this increase in the radial direction (Figure 2c).

DISCUSSION

We set out to compare the (mal)adaptive response of tricuspid valve leaflets between two ovine models: a previously reported TIC model and a newly presented PH model. To this end, we compare the leaflet morphology and the mechanical characterization of each group to healthy control leaflets.

We found that TIC leaflets and PH leaflets each had similar increases in anterior leaflet area. As these measurements were performed under explanted stress-free configurations, we are confident that growth, and not elastic stretch, is responsible for this difference. Interestingly, both TIC and PH leaflets had increased calf region stiffnesses when compared to CTL leaflets, but in opposite directions. The direction of calf region stiffening between animal models may suggest that different stimuli in each model are responsible for the maladaptive stiffening. In TIC we observed radial stiffening, which

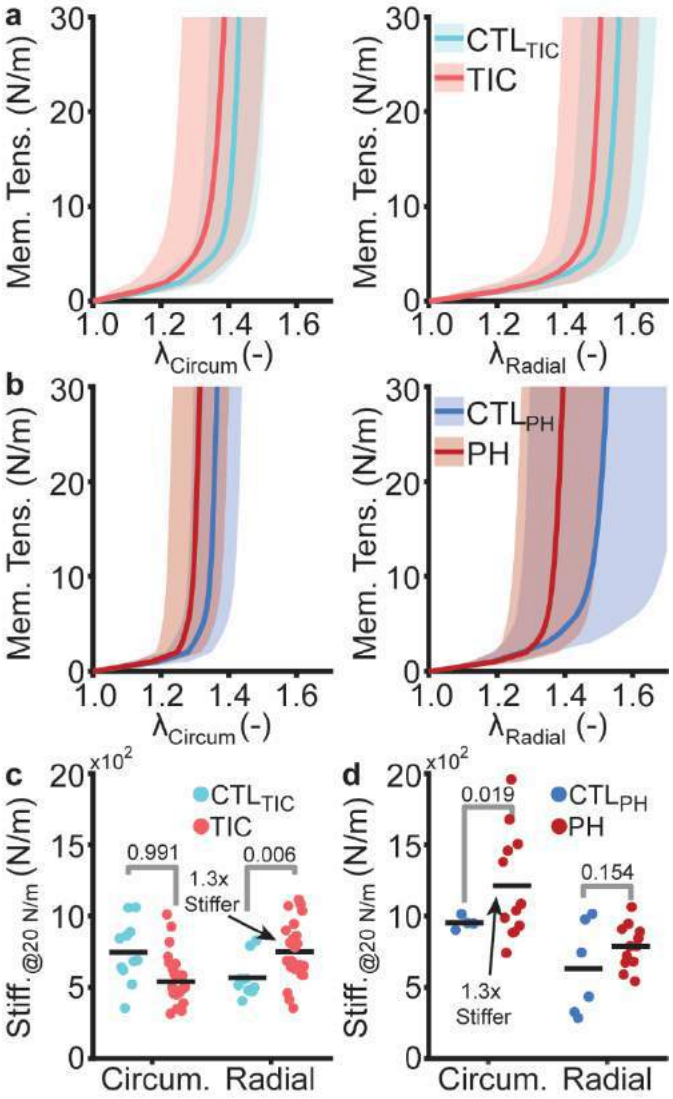

Figure 2: Average equibiaxial curves for (a) tachycardia-induced cardiomyopathy (TIC) and (b) pulmonary hypertension in circumferential and radial directions. (c-d) Calf region stiffness summaries for (c) TIC and (d) PH subjects

may be initiated by either hemodynamic shearing or radial tethering. In PH leaflets, we observed circumferential stiffening, possibly initiated by increased annular dilation stimulation.

In conclusion, the PH ovine model induced (mal)adaptive changes, i.e., growth and stiffening, to the tricuspid valve anterior leaflet, as we observed in our TIC model. As we expand the timeline of TR development, we may continue to understand the underlying mechanisms of maladaptation with promise of future interventions.

INTRODUCTION

Marker-based optical motion capture is the most commonly used method in biomechanics research to examine human movement as it is considered the most accurate, precise, and repeatable approach. Inertial measurement units (IMUs) are a wearable sensor technology that have gained popularity in recent years to analyze human movement as an alternative to motion capture systems. IMUs are portable and cost-effective wearable sensors that gather segment acceleration data to examine human movement. Previous studies have suggested that IMU-derived temporal-spatial parameters, such as step length, are comparable to motion capture data [1]. Further, one case-study on a transfemoral amputee found a 1-3° error between IMU and motion capture knee and ankle joint flexion angles during walking in which greater IMU error was found due to skin and muscle artefact [2]. As skin and muscle artefact increase with tasks requiring greater accelerations [3], it is possible that IMU-derived data during these tasks may be increasingly different from motion capture data. As far as the authors are aware, this has not yet been examined.

IMUs have the potential for clinic and at-home monitoring of daily activities to detect if an individual is at risk for falls. However, it is unclear if IMUs can provide valid data, as compared to motion capture, for tasks that require higher acceleration of a limb, such as recovering from a trip. In particular, the ability of the limb to swing through quickly following a trip event by use of knee and hip flexion [4, 5] is crucial for recovery to avoid a fall to the ground possibly causing subsequent injury.

Therefore, the purpose of this study was to validate IMU-derived knee and hip joint kinematic data on tasks requiring higher acceleration as compared to walking. It was hypothesized that no significant differences would be found between IMU-derived data and motion capture derived data.

METHODS

Five healthy young adults (3 males, 2 females) participated in this study (Age (years): 23.4 ± 2.9, Mass (kg): 69.2 ± 24, Height (cm): 172 ± 11). Kinematic and kinetic data were captured using an 18-camera motion capture system (100 Hz; Motion Analysis Corp., Santa Rosa, CA) synchronized with a dual-belt treadmill (1000 Hz; V-Gait Motekforce Link, Culemburg, Netherlands) and five IMUs (100 Hz; STT Systems, San Sebastián, Spain). Motion capture reflective markers (diameter: 14 mm) were placed bilaterally on the lower-limbs and trunk in accordance with the V-Gait marker set. IMUs were attached bilaterally using a flexible strap on the following body segments: lower-back on the spine, lateral placement on mid-thigh, and anterior placement directly below the knee. These placements are the recommended IMU placements by STT Systems and confirmed through testing of various tibia sensor placements compared to motion capture data.

Participants performed three tasks: treadmill walking, perturbation at small acceleration (2 m/s^2), perturbation at large acceleration (5 m/s^2). Walking data were collected for 30 seconds at the participant preferred habitual walking speed. Perturbations were elicited via treadmill acceleration to occur around toe-off of the right limb as the participant was walking at their preferred speed. A short break (<2 min) was taken between tasks.

IMU-derived joint angle data were calculated within STT Systems proprietary software, iSen. In brief, 3-dimensional vectors from each IMU are transformed into a local reference frame, representative of the bone reference frame, in line with the rotation axis of the joint. Joint angles are calculated as the angle formed by two local vectors (i.e., thigh IMU and tibia IMU generate knee joint angle data). Motion capture data

were exported to visual3D (v6, C-motion, Inc., Germantown, MD, USA) to perform kinematic calculations.

Knee and hip flexion angles were extracted for each task. For walking, data were extracted for twenty gait cycles from heel contact to heel contact. For perturbation tasks, a total of 5 perturbations trials were extracted for each acceleration from the heel contact prior to the elicited perturbation through to the toe-off following the stance after the perturbation. This is representative of the gait cycle in which the perturbation occurred and the stance phase in which recovery from perturbation occurred. Trials were averaged for each participant and time-normalized to 100%.

Statistical Analysis: Paired *t*-tests were performed between IMU and motion capture derived knee and hip flexion angles for each task individually. Statistical parametric mapping, a type of waveform analysis, was utilized to perform the analysis in order to examine the dynamic nature of the waveform. Statistical significance was set at $p<0.05$. Root mean square error (RMSE) was also calculated for each comparison at each data point in the waveform.

RESULTS

No significant differences were found between IMU and motion capture derived knee and hip joint flexion angles (Figure 1) for any task. RMSE values suggest that hip data tended to have greater differences between IMU and motion capture data compared to the knee (Figure 2). Further, RMSE values during stance (~1-60% of time for walking, ~1-50% and 75-100% of time for perturbations) tended to be greater for all tasks than during swing (61-100% of time for walking, and 50-75% of time for perturbations).

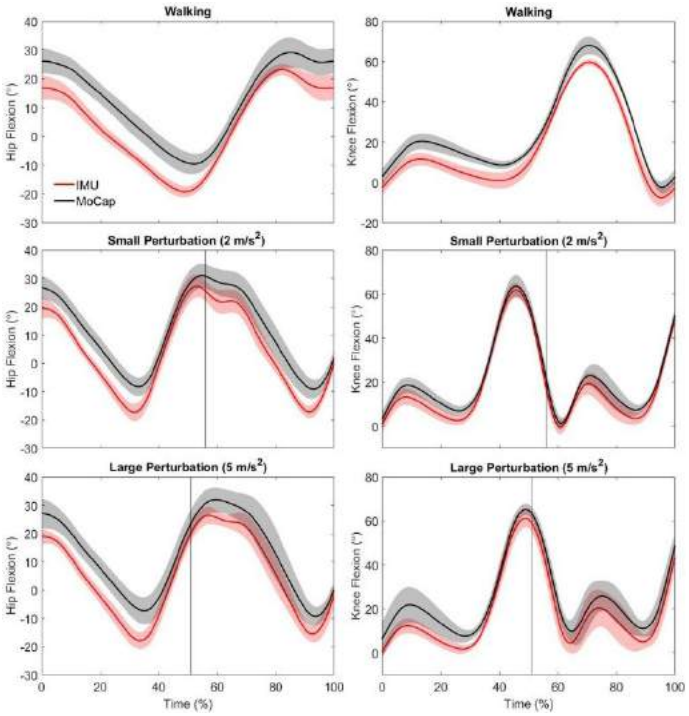

Figure 1: Hip and knee flexion angles from IMU (red) and motion capture (black) data for each task. Vertical solid line represents the average time at which the perturbation occurred.

DISCUSSION

The main finding from this study was that IMU-derived knee and hip joint kinematic data is comparable to that of motion capture data for habitual speeds and higher acceleration tasks. The overall waveform pattern and magnitude was not significantly different between IMU and motion capture joint angles for any task.

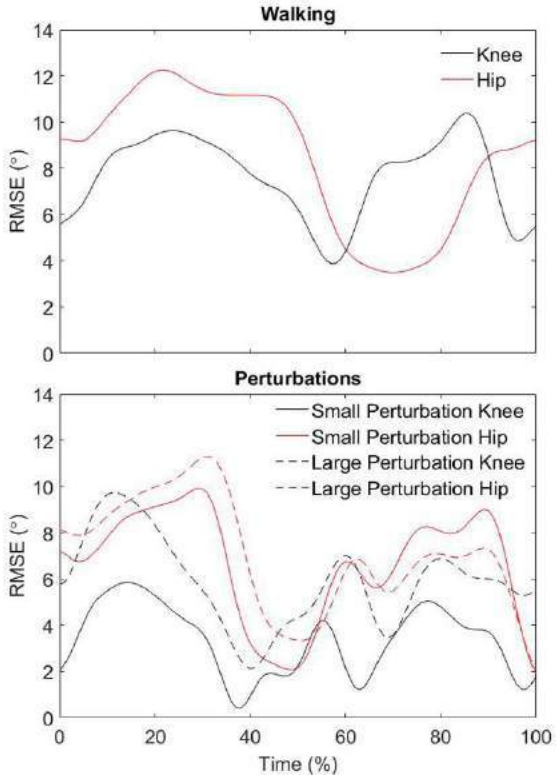

Figure 2: RMSE values between IMU and motion capture knee and hip flexion data for the specified time period of each task

RMSE results found that IMU-derived joint angles were consistently reduced in magnitude (<12° at any given time) compared to motion capture. Further, this magnitude offset was greatest during stance phases of each task (Figure 2). This would suggest clinical significance during phases above 10°, yet, the magnitude offset is most likely a result of the calibration process of the IMUs. Calibration requires the participant to stand in the anatomical standard position at the start of each trial which defines the knee and hip in full extension to 0°. However, if the participant stands with slight flexion at the moment of IMU calibration, this could result in the magnitude offset as presented in Figure 1 at 0% time.

Overall, these data present promising findings for the use of IMUs as a portable and cost-effective alternative to motion capture systems for a variety of task speeds. Further verification is necessary for other tasks and movement features before implementation into clinical settings.

INTRODUCTION

Adipose Tissue (AT) has a unique composition and function. It is composed of 60-80% lipids (mainly triglyceride lipids), 5-30% water, and 2-3% collagen proteins [1]. Compositional variations occur due to different types of AT [2, 3]. The four types of AT are subcutaneous AT (SAT) [2], visceral AT (VAT) [2], white AT (WAT) [2, 3], and brown AT (BAT) [2, 3]. Despite there being various types of AT, they all share similar anatomy [1, 2], as shown in Figure 1. AT's unique anatomical characteristics allow for the storage of energy (in the form of lipids) [1, 2, 4], heat insulation [1, 2, 4], the ability to protect underlying organs by absorbing energy from high impacting forces [1, 2, 4, 5, 6], and the ability for AT to act as an endocrine organ [7, 3].

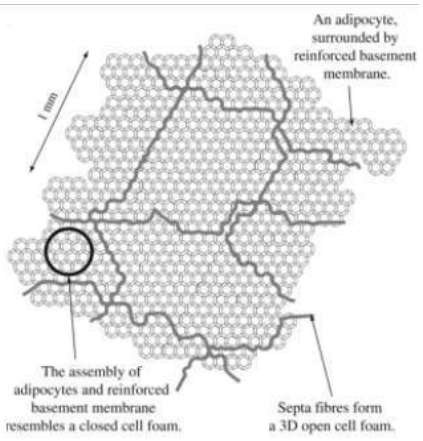

Figure 1: Adipose tissue anatomy

There are very few studies [1, 4, 6, 7, 8] that can be found which seek to analyze the mechanical response of AT. Information on AT's response to mechanical forces can be used for many different purposes. AT's cushion effect [9, 10, 11, 12] could be utilized by car manufacturers to develop safer cars when analyzing injuries obtained in car crashes. During car crashes, AT is known to cushion internal organs in the abdomen by absorbing high impacting forces [9, 10, 11, 12]. Manufacturers of hernia meshes [13, 14] could benefit from a mechanical understanding of AT, especially considering that one-third of patients who receive hernia meshes must undergo revisional surgery [13]. Part of the reason hernia meshes fail is that they do not match the surrounding abdominal tissues' responses to mechanical stimuli [13, 14]. Plastic surgeons could enhance patient outcomes by using a finite element analysis model of AT to stimulate the soft tissue deformation of patients undergoing surgery in preoperative planning [7]. Furthermore, mechanical characterization of AT could also improve the safety profile of high impact sports.

Experimental data on AT's responses to axial compressive loading must be gathered to develop mathematical models of AT [7], simulations of AT responses to various loading conditions [7], and to better tissue-engineer substitutes [13, 14, 15] that respond similarly to native AT under different types of mechanical stresses. In this study, Digital Imaging Correlation (DIC) is used to measure the surface deformation resulting from compressed porcine adipose tissue. The surface deformation is then compared to the engineering strain on the sample and the strain rate.

METHODS

Porcine adipose tissue was sourced from the University of Florida Animal Care Services (ACS). Subcutaneous adipose samples were extracted from the back of each pig. Samples were transported to Williams lab on ice to maintain integrity. They were then hydrated with gauze presoaked in phosphate-buffered saline (PBS). PBS was used to mimic in vivo pH and osmolarity conditions [16]. Samples were cut using a custom-made die tool. The custom die tool was used to slice samples into cylindrical specimens of 9-13 millimeters (mm) in height and 25 mm in diameter. The samples were then sprayed with a random speckling pattern using an airbrush gun (Paasche TG-300R). Compression testing on these samples was performed at 1%/s with the Instron 5942 (Instron, Norwood, MA). True stress and true strain were calculated using equations (1) and (2). Surface deformation was measured using a Digital Image Correlation (DIC) system (Correlated Solutions, Irmo, SC). DIC data was then exported to MATLAB where the strain was compared to surface deformation using equation (3), Poisson's ratio. Figure 2 represents the experimental set-up in the stages before compression (left) and immediately following the application of compressive axial loads (right).

$$\varepsilon = \delta/L \quad (1)$$

$$\sigma = F/A \quad (2)$$

$$\upsilon = -d\varepsilon_{trans/d}\varepsilon_{axial} \quad (3)$$

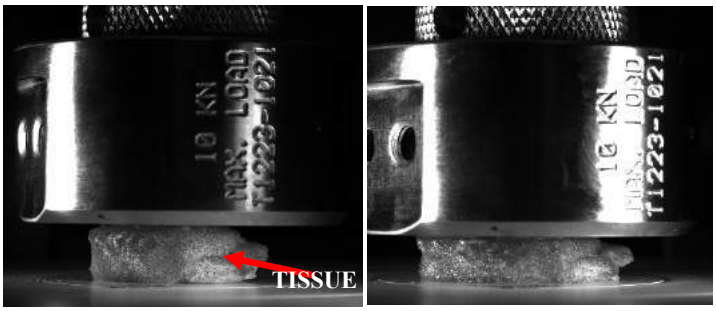

Figure 2: Adipose tissue immediately preceding compression (left), adipose tissue immediately following compression (right)

RESULTS

Early data suggests that the Lagrange number is highest near the center of the specimen and lowers near the top and bottom, as displayed in Figure 3. Table 1 is a presentation of the mechanical properties of four tests. These are calculated using the extension length of the sample and cross-sectional area, respectively. It reveals that compressive strain (as calculated using the extension of the sample) is directly proportional to stress.

Table 1: Stress and strain relationship of porcine AT

	Maximum Load	Compressive extension at Maximum Load [mm]	Modulus (Automatic Young's)	Compressive stress a Maximum Load
1	0.93169	80.95570	0.07633	0.00245
2	20.39441	85.17818	0.35994	0.05365
3	20.39442	85.49871	1.19500	0.05365
4	19.95819	85.80356	1.23527	0.05250

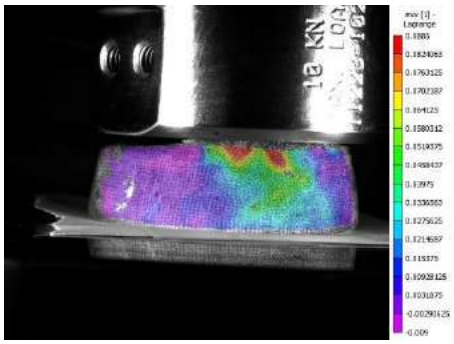

Figure 3: Lagrange distribution of compressed porcine AT

DISCUSSION

Early findings suggest that data obtained during this experiment does align with the suggestions of soft tissue mechanics literature. There is a non-linear stress-strain response and a correlation between stress and strain. Future work on this project will further characterize the mechanics of porcine adipose tissue as it relates to surface deformation and will provide insight into AT's response across low and high strain rates.

ACKNOWLEDGEMENTS

The team would like to thank the University of Florida Animal Care Services for the tissue donation.

INTRODUCTION

End stage kidney disease (ESKD) is a major public health burden that can arise when specialized kidney epithelial cells called podocytes lose their ability to filter blood [1]. Although this is known to be associated with shape changes and eventual effacement of podocyte foot processes, the cytoskeletal structures that regulate podocyte shape have not been fully characterized [2]. A challenge is that these cells should be studied in the natural environment of the kidney's glomerular filtration barrier (GFB), which comprises an intricate epithelial layer of podocytes lying atop the thick glomerular basement membrane (GBM) and the endothelial layer of the glomerular capillary on the opposite side of the GBM [3]. Additionally, the nanoscale features of the slit diaphragms that filter blood are too small to be resolved optically. When injured, podocytes undergo foot process effacement (FPE), a massive change in shape including loss of the intricate foot processes and the replacement of these with a sheet of cell membrane covering the GBM. Although a role of the actin cytoskeleton in these processes is evident from the large list of actin-associated genes whose mutation leads to FPE, the pathways leading to FPE in injury remain unclear, and targets for a cure to ESKD have yet to be identified.

The critical need to identify the mechanobiological structures underlying podocyte shape regulation, structures we hope can one day form the targets for ESKD therapies, motivated us to develop a technique to image these. We hypothesized that the actin cytoskeleton had direct connections to the slit diaphragms, and that these connections and the cytoskeleton itself would be compromised in kidney disease.

METHODS

Overview: We isolated glomeruli from kidneys of healthy mice as well as from three different mouse injury models: *Cd2ap*$^{-/-}$, *laminin beta 2* KO (*Lamb2*$^{-/-}$) and a mouse model of Alport syndrome. We applied a new imaging technique that integrates membrane extraction, focused ion bean scanning electron microscopy (FIB-SEM), and deep learning image segmentation. After actin stabilization and a membrane extraction technique to these glomeruli, they were imaged after sequential layer ablation using FIB-SEM to create a 3D dataset. We applied deep learning segmentation to convert these FIB-SEM datasets into 3D models of the podocyte actin networks.

Image segmentation: To segment the GBM and podocyte actin cytoskeleton from FIB-SEM image stacks of glomeruli of WT control, *Cd2ap*$^{-/-}$, *Lamb2*$^{-/-}$ and Alport syndrome mice, Fiji/ImageJ (version 1.53C) was utilized with the Waikato Environment for Knowledge Analysis (Weka) trainable segmentation plugin (version 3.2.34) [3, 4, 5]. Before training the model, features were selected. For edge detection features, the *Sobel filter*, *Hessian* and *Difference of Gaussian* options were selected. For texture description features, the *Structure* and *Neighbors* options were selected. For noise removal and edges detection features, *Gaussian blur* and *Membrane projections* were utilized [4].

Deep learning: To train deep learning models, we generated independent trained classifier for each dataset: WT control, *Cd2ap*$^{-/-}$, *Lamb2*$^{-/-}$ and Alport syndrome. For each classifier, five elements were classified and assigned to the selected region on the image stack via the graphic user panel. These five elements represented "actin", "GBM", "background", "microtubules" and "gaps", where "gaps" indicated the peripheral fading boundary between the podocyte actin cytoskeleton and the "background" in the image. The development and training of deep learning models for each of the four conditions was based on a region of interest (ROI) within FIB-SEM image stacks. The training ROI was 251 slices at 587 x 218 pixels for WT control, 251 slices at 252 x 676 pixels for *Cd2ap*$^{-/-}$, 201 slices at 378 x 484 pixels for *Lamb2*$^{-/-}$, and 150 slices at 286 x 172 pixels for Alport syndrome. The classifiers were trained based on the ROI and the selected features, one

for each of the image stacks, except for Alport syndrome. The classifiers were then applied to the ROI to generating probability maps.

Image visualization All probability maps were projected into 3D models using Amira software (Thermo Fisher Scientific, Version 2019.4), with each probability map having one channel for each class. The final channels used for 3D visualization were the "GBM" and "actin" channels, resulting in low 3D visualizations of the structures of the GBM and podocyte actin network.

RESULTS

The healthy podocyte cytoskeleton in 3D has direct connections between actin and slit diaphragms: After generating the probability maps of all four types of kidney glomeruli, the segmented regions were projected by using Amira software (Thermo Fisher Scientific, Version 2019.4). For the first time, we were able to view the GBM and the actin assembly in the foot process areas in 3D (Fig. 1). These results supported our hypothesis that the actin cytoskeleton in the foot processes are connected to the slit diaphragms structures.

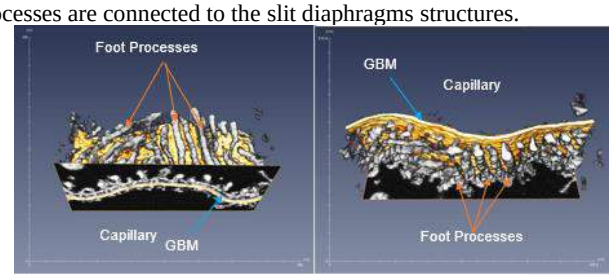

Figure 1: Deep learning segmented model of healthy podocyte FIB-SEM images showing interdigitating foot processes.

The actin-slit diaphragm connections are compromised in injured kidneys: Glomeruli from *Cd2ap*$^{-/-}$ (Fig. 2) *Lamb2*$^{-/-}$ (Fig. 3) and Alport syndrome (Fig. 4) mice showed a disruption in the cytoskeleton integrity and actin condensation, supporting our hypothesis. GBM disruption was evident in the latter two.

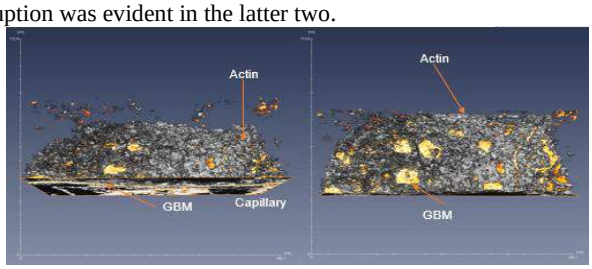

Figure 2: Deep learning segmented model of *Cd2ap*$^{-/-}$ podocyte showing actin condensation in the effaced areas juxtaposing to the GBM.

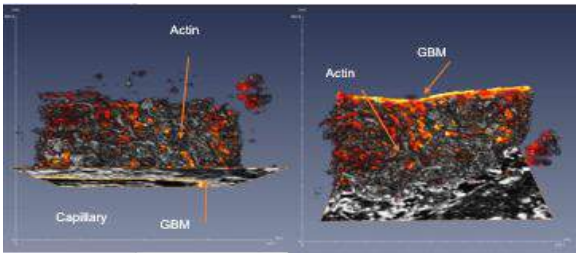

Figure 3: Deep learning segmented model of *Lamb2*$^{-/-}$ podocyte showing occasional GBM splitting and extensive actin condensation in the effaced areas juxtaposing the GBM.

Finally, 3D image segmentation of Alport Syndrome glomeruli showed the irregularly thickened GBM, consistent with the disease features. Our data also the extensive actin condensation similar to the other two injury models (Fig. 4).

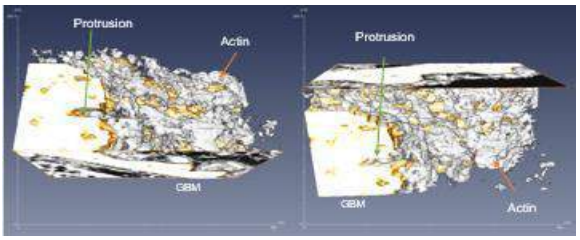

Figure 4: Deep learning segmentation of Alport syndrome podocytes showing irregularly thickened GBM and extensive actin condensation juxtaposing the GBM**.**

DISCUSSION

Results uncovered connections between the actin cytoskeleton and slit diaphragms. This enables construction of a free body diagram showing how filtration and cell contraction combine to provide physiological levels of tension to the cytoskeleton (Fig. 5). The new visualization method enabled us, for the first time, to observe the detailed 3D organization of actin networks in both healthy and injured kidney glomerular podocytes. Data supported the hypothesis of an actin-based underpinning to morphological changes in injury. Similarities between the presentation of actin condensations across all three injury models further suggested common mechanobiological pathways that govern changes to podocyte morphology after injury.

INTRODUCTION

Osteoarthritis (OA) is a multi-tissue disease characterized by degeneration of articular cartilage. Current late-stage clinical treatment methods require invasive surgical intervention and can fail to provide long term pain relief to patients. Despite the pervasive nature of the disease and significant effort dedicated to OA research, there is no existing clinical method that successfully delays the progression of osteoarthritis through repair of diseased cartilage.

The extracellular matrix (ECM) is the primary structural component of cartilage tissue and contains the collagen (COL) fibril network and the proteoglycans (PGs). Tissue integrity depends on the homeostasis between the COL and PGs, as the COL fibril network, maintained with crosslinks (CxLs), counteracts swelling pressure of the PGs. Correspondingly, loss of CxLs results in increased swelling due to the osmotic pressure of PGs, and loss of compressive stiffness in the tissue [1]. Thus, induction of cross-links to restore the COL fibril matrix may impede OA progression and repair damage to the bulk tissue.

The induction of CxLs may be achieved with a non-invasive low-level femtosecond laser. Our preliminary work has demonstrated the efficacy of femtosecond laser treatment for cartilage CxL induction and the corresponding enhancement of tissue mechanical properties [2]. The low-level pulse energy of the laser is below the optical breakdown threshold and thus is able to mimic the effect achieved with higher laser power without damage to surrounding tissue. However, to realize the potential of laser treatment and delineate CxL induction as the source of modulus stiffening, the structural modification of tissue due to thermal effects must be fully understood.

It has been previously shown that thermal exposure of immature bovine articular cartilage to temperatures ranging from 24 to 60 ℃ leads to 8% stiffening to the equilibrium modulus [3] and reduction in relaxation time. However, exposure of human cartilage to 70 °C led to a substantial decrease in its shear modulus [8]. Since articular cartilage is a complex heterogenous structure, the exact effect thermal exposure has on the individual components providing structural integrity to the ECM over a range of temperatures has yet to be elucidated. In this study, we exposed devitalized immature bovine cartilage explants to a range of temperatures from 40 ℃ to 85 ℃, spanning the denaturation temperature of COL (58-65 °C [4]), in an effort to understand structural modification of cartilage due to thermal heating. To distinguish the effect of heating on the COL fibril matrix from PGs, in one sample group we also perform a PG digestion prior to thermal heating. In studying the modification of the cartilage structure during thermal exposure, we aim to better understand changes in cartilage stiffness through modification of the ECM, as well as further identify an envelope of safe treatment parameters for femtosecond laser CxLing.

METHODS

Sample Preparation: Cartilage tissue was harvested from the knees of immature bovine calves (2-3 months old, Green Village Packing Co., New Jersey, USA). Explants (∅3 mm × 2±0.2 mm) were biopsy-punched from the femoral condyle. Samples were stored frozen in phosphate buffered saline containing protease inhibitors (PBSPI) and thawed before treatments.

Intact Thermal Experiment: The equilibrium modulus from unconfined compression was assessed using a custom mechanical testing device under a creep tare load (0.1 N, 600 s) and a subsequent stress-relaxation test to 10% strain (0.5 μm/s ramp, 1800 s). Following the unconfined compression test, the devitalized explants were suspended in PBSPI and heated at a consistent temperature on a hot plate for 12 minutes. Samples were divided into 7 groups for thermal treatments from 40 to 85 °C. The unconfined compression test was repeated after thermal exposure.

PG-Digested Thermal Experiment: The equilibrium compressive modulus of 10 additional explants was assessed using the method described above. Then, 5 explants were sequentially digested of GAG to remove PGs while keeping the COL fibril network intact, following the protocol outlined by Schmidt et al. [5]. The digestion consisted of three sequential 24-hour treatments with chondroitinase ABC, trypsin, and hyaluronidase. Samples were kept at 37 °C under gentle agitation during the 72-hour digestion. The equilibrium compressive modulus of the digested samples was measured directly after digestion. Then, the 10 explants (5 digested samples and 5 control samples) were suspended in PBSPI and heated at 74.0 ± 2.5 °C on a hot plate for 12 minutes. The compressive modulus was reassessed after thermal exposure.

RESULTS

Intact Cartilage Thermal Experiment: Explants exposed to temperatures above 65 °C showed an increase in compressive modulus, whereas samples exposed to temperatures below 65 °C did not show a significant change in modulus (Fig. 1). On average, explants with thermal treatment between 40 and 64 °C (n=24) had a modulus of 662±190 kPa before treatment, and 653±196 kPa after treatment. Samples with thermal treatment between 65 and 85 °C (n=25) had a modulus of 570±247 kPa before treatment, and 733±321 kPa after treatment, representing a significant enhancement of 28.7±17.9% in the compressive modulus due to thermal treatment ($p<0.001$). Statistical analysis using a one-way ANOVA test with Bonferroni correction (NCSS Statistical Software, Kaysville, Utah) confirmed that the change in modulus for samples exposed to temperatures above 65 °C was statistically higher from samples exposed to temperatures below 65 °C ($p<0.05$).

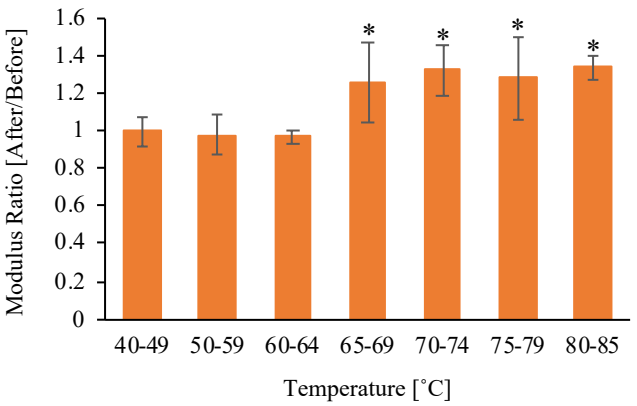

Figure 1: Ratio of bovine sample modulus (After/Before) for different cartilage thermal exposure groups. Thermal exposure produced stiffening in temperature exposure ranges from 65 – 69 °C, 70 – 74 °C, 75 – 79 °C, and 80-85 °C ($p<0.05$*)

PG-Digested Cartilage Thermal Experiment: PG digestion decreased the compressive modulus of articular cartilage samples (n=5) from 665±168 kPa to 27±3 kPa, consistent with results from our prior study [6]. Upon thermal exposure, PG-digested samples stiffened to 303±49 kPa, representing more than a tenfold increase (Figure 2). Statistical analysis using a repeated measures ANOVA test with Tukey-Kramer multiple-comparison (NCSS Statistical Software, Kaysville, Utah) confirmed that the PG-digested samples stiffened significantly after thermal exposure ($p<0.001$). The sample thicknesses averaged 2.03±0.09 mm before digestion, 2.11±0.14 mm after digestion, and 1.95±0.11 mm after thermal treatment. The corresponding undigested control group (n=5) had a modulus of 1070±169 kPa before thermal treatment (thickness 2.18±0.07 mm), and 1289±209 kPa after thermal treatment (thickness 2.24±0.10 mm), representing a significant enhancement of 20.5±5.1% in the compressive modulus ($p<0.002$).

DISCUSSION

Results of the current study showed that heating immature bovine articular cartilage from 40-64 °C to 65-85 °C, spanning the denaturation temperature of COL, caused an increase in its equilibrium compressive modulus by ~20 to 30%. This finding does not contradict prior literature reports of tissue equilibrium modulus stiffening by 8% from 24 to 60 °C [3], as these tests spanned significantly different temperature ranges. The current results indicate an abrupt change in cartilage mechanical properties over a narrow range of temperatures (Fig. 1).

We considered the possibility that PGs could shield COL from the effect of heating. Hypothetically, since the superficial zone (SZ) of articular cartilage is softer than the middle (MZ) and deep (DZ) zones [7], we were concerned that further softening of the SZ due to thermal treatment would manifest itself as an apparent stiffening during compressive testing of the full-thickness cartilage plugs, as the SZ might get compacted under a very low tare load, such that the full-thickness modulus would now reflect the higher modulus of the MZ and DZ. To address this possibility, we digested the PGs and exposed the (mostly-) COL II matrix to heating. Those results demonstrated that thermal treatment considerably enhanced the compressive modulus of the COL II matrix (more than tenfold), in the absence of PGs. Therefore, we can conclude that COL II stiffening with thermal treatment above 65 °C significantly contributed to the increase in compressive equilibrium modulus of intact cartilage explants.

We may also speculate that PGs either provided some measure of protection to COL in explants heated above 65 °C, or thermal effects on PGs led to ECM softening, since the enhancement in tissue modulus was smaller in intact versus PG-digested tissue samples. In fact, Marshall et al. reported that thermal exposure of human articular cartilage to a temperature change from 24 to 70°C reduced its shear modulus significantly [8]. Since articular cartilage shear properties are significantly influenced by PGs [9], we may combine those earlier findings with the results of the current study to hypothesize that thermal exposure of articular cartilage above 65°C has opposite effects on the COL and PG in the ECM, producing a net stiffening of ~20 to 30% in compressive modulus at COL denaturation temperatures (Fig. 1).

In the context of our ongoing investigations of femtosecond laser crosslinking of articular cartilage, we may conclude that our previously reported enhancement in compressive modulus induced by the femtosecond laser treatment [2] was not caused by structural modification of cartilage through thermal heating, since those experiments maintained the temperature of tissue samples below 36 °C. Future studies will investigate the depth-dependent compressive modulus of bovine cartilage explants before and after thermal exposure.

BIOFLUID MECHANICS OF SURFACTANT DELIVERY IN A BIOENGINEERED THREE-DIMENSIONAL LUNG AIRWAY MODEL

Hannah M. Combs (1), Hossein Tavana (1)

Akron, Ohio, USA

INTRODUCTION

Pulmonary surfactant is produced by the type II alveolar cells in the lungs and is responsible for the reduction of surface tension at the air-liquid interface of respiratory airways (1). Dysfunctional or insufficient surfactant can result in high surface tension, leading to blockage and collapse of airways and alveoli. Pre-term infants born prior to 29 weeks are at a greater risk for insufficient surfactant production, due to their immature alveolar cells, and may develop a condition known as Neonatal Respiratory Distress Syndrome (NRDS), where lungs tend to collapse. Re-inflating the lungs requires substantial force beyond the infants' ability. Surfactant replacement therapy (SRT) is a critical treatment for infants suffering from NRDS to facilitate breathing (2). SRT involves intratracheal delivery of a plug of surfactant followed by mechanical ventilation to distribute the instilled surfactant in the lungs. Despite benefits of SRT, there is a large non-response rate of up to ~35% among infants. Considering large variations in the administration methods in terms of positioning of infants with respect to the gravitational field and the ventilation flow, we postulate that optimizing delivery conditions is critical to ensure a uniform distribution of administered surfactant in the lungs and improves the SRT outcomes. Our overarching goal is to approach this problem from a fluid mechanics viewpoint to define specific orientations of the lung airway tree and flow that result in a uniform surfactant distribution. To that end, we have developed a bioengineering approach to construct 3D models of the lung airway tree of infants and study fluid dynamics of the surfactant delivery process in terms of surfactant film deposition, plug splitting at airway bifurcations, and distribution in the airways.

METHODS

The computational lung model was created in Solidworks, beginning with a single tube representing the trachea (generation z=0). The dimensions used for modeling the trachea were a diameter of 3.5 mm and a length of 17.5 mm. Following this, a bifurcation zone was added to the end of the tracheal tube followed by a pair of daughter tubes (z=1 airways) at an angle of $\theta = 80°$, representing the bifurcation angle. The dimensions of these airways and those in subsequent generations (z=1-7) followed the equations below that represent airway dimensions in the lungs of a preterm infant.

$$\text{Diameter, } d_z = d_0 \text{ x } 2^{-\frac{z}{3}} \quad (1)$$

$$\text{Length, } \; l_z \cong 3d_z \quad (2)$$

To account for the rotation of airways in 3D space in the lungs, at the level of z=3 and after, the airways were rotated 90° with respect to their parent generation. At the end of this process, a 3D, eight-generation computational model of the lung airway tree was constructed (Figure 1a). The computational model was used to 3D-print a semi-transparent physical model for studies of intratracheal surfactant delivery (Figure 1b) (1).

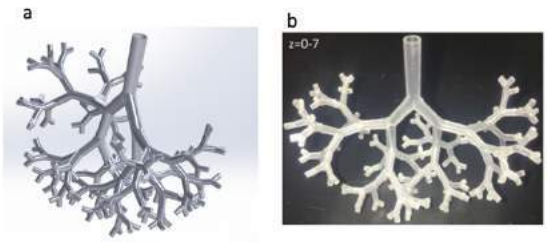

Figure 1: (a) Computational model of z=0-7 airways of preterm infants, (b) 3D printed semi-transparent lung model.

To study fluid mechanics of surfactant delivery, Infasurf (ONY, Inc) surfactant was used at a concentration of 35 mg/ml. Infasurf was heated in a water bath at a temperature of 37℃ and prior to the surfactant plug being inserted, the model was placed in a plasma cleaner (Harrick Plasma) to render it hydrophilic, as in native airways. Once the plug was inserted into the trachea, air pressure from a syringe pump was used to propagate the plug downstream into the airway tree.

RESULTS

We quantified surfactant distribution using a plug split ratio that defines the volume ratio of two daughter plugs formed at a bifurcation. The evaluation of the split ratio was completed by securing the model to a plexiglass platform allowing for adjustment of roll angle (α), which defines relative gravitational orientation of daughter tubes in a bifurcating airway unit. Figure 2 shows a typical result of surfactant plug dynamics. With $\alpha = 0°$, the plug split evenly between the two daughter airways at z=0-1 (Figure 2b) but when α increased to 30°, the plug split asymmetrically, and more solution drained into the gravitationally favored daughter airway (Figure 2c). The daughter plugs propagated into subsequent airways to further split and distribute in downstream airways (e.g., Figure 2d-e for $\alpha = 30°$).

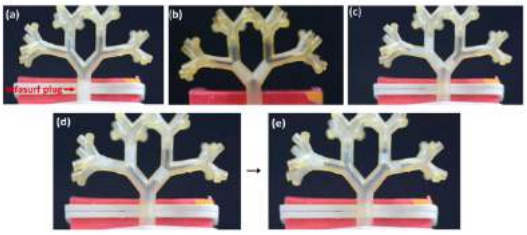

Figure 2: (a) shows an Infasurf plug located in the trachea tube with a roll angle of $\alpha = 0°$, (b) the plug has passed the first bifurcation occupying z=1. (c) the plug passes bifurcation z=1-2 with a roll angle of $\alpha = 30°$ to occupy (d) the left lung, and (e) the right lung (1).

We conducted experiments at $\alpha = 0°, 30°, 60°,$ and $90°$ to determine effects of orientation on the plug splitting. These angles respectively represent an infant receiving SRT laying on their backs or being rolled onto their sides. We also used flow rates to result in a physiologically relevant capillary number of Ca=0.030 at z=0 and Ca=0.024 at z=1. At the z=0-1 bifurcation and an increasing roll angle from $\alpha = 0°$ to $\alpha = 30°$ caused asymmetric splitting with a split ratio of R=0.31 $\pm$ 0.11. As the roll angle was increased to $\alpha = 60°$ and $\alpha = 90°$, there is further reduction in the split ratio from 0.08 $\pm$ 0.04 and 0.07 $\pm$ 0.03 (Figure 3).

Evaluating further into the model, the z=1-2 bifurcation showed a large variation in split ratio from the left and right side of the lung. As the model roll angle was increased from $\alpha = 0°$ to $\alpha = 30°$, there was a 70% greater amount of Infasurf that drained into the lower left daughter tube providing a split ratio of 0.04 $\pm$ 0.07. Following a similar pattern to the z=0-1 bifurcation, there was a decrease in split ratio when the model was increased to $\alpha = 60°$ and $\alpha = 90°$, with the ratio of R=0.24 $\pm$ 0.05 and R=0.18 $\pm$ 0.06 (Figure 3).

The bifurcation (z=1-2) of the right lung once again followed a similar pattern to the previously mentioned split ratios. Increasing the roll angle was from $\alpha = 0°$ to $\alpha = 30°$ resulted in a split ratio of R=0.95$\pm$ 0.11. Further increase in the roll angle to $\alpha = 60°$ and $\alpha = 90°$ gave further reduction in the split ratio to 0.77 $\pm$ 0.08 and 0.83 $\pm$ 0.05 (Figure 3).

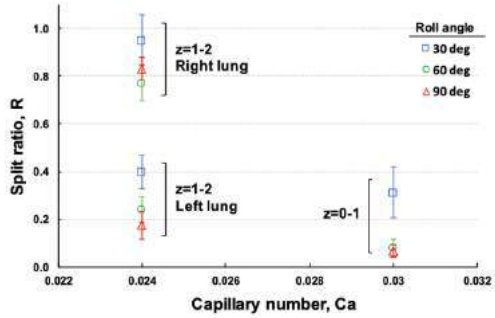

Figure 3: Split ratios using varying roll angles and vs. the Capillary number for bifurcations z=0-1, z=1-2 right lung, and z=1-2 left lung.

At the z=1-2 bifurcation, the upper daughter tube in the left lung was almost horizontal, while the z=0-1 bifurcation is directed farther from the horizontal plane, allowing 75-95% drainage into the lower daughter of z=1-2. The right lung presented less than 30% of plug drainage, due to the roll angle moving z=1 farther from the horizontal plane.

DISCUSSION

We developed a bioengineering approach to computationally design and fabricate biomimetic models of the tracheobronchial tree. This model enabled us to study transport of a surfactant solution in airways and evaluate how orientation of the airway tree in the gravitational field affects distribution of surfactant between left and right lungs. Importantly, results from our empirical approach are consistent with previous computational studies of plug splitting in bifurcations (2). However, unlike previous studies that mainly used 2D numerical models or planar physical models, our study presents the first 3D, multi-generation airway tree model to investigate surfactant transport in airways as in SRT. This ongoing study will help gain a fundamental understanding of fluid mechanics of the SRT and design strategies to uniformly distribute surfactant in airways, either with a single dose or multiple doses at different orientations. This approach may also be used to model and study other respiratory disorders.

INTRODUCTION

The long head of the biceps tendon (LHBT) is the site of numerous pathologies associated with debilitating symptoms. The LHBT originates at the superior glenoid and labrum, extends laterally over the humeral head and through the bicipital groove. Its distal end inserts into the long head of the biceps (Figure 1). Pathologies affecting this tendon include but are not limited to tendon rupture, hypertrophy, and superior labrum anterior and posterior (SLAP) lesions or tears. A previous study on 544 patients who were prescribed shoulder arthroscopy found that 35 patients (6.4%) had Type II or IV SLAP tears, which include damage to the LHBT,[2] with symptoms reported as shoulder pain and a 10-20 degree loss in arm elevation range of motion.[3] An ongoing concern with these injuries is the variety of contributors and thus the varying success rate of injury treatment methods.[4] Therefore, a deeper understanding of the LHBT mechanical environment and underlying mechanisms of its pathologies is of great importance. A finite element (FE) model was developed to investigate the mechanical behavior of the LHBT during arm elevation.

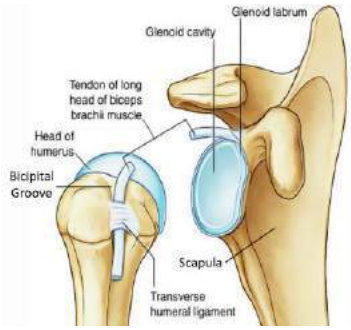

Figure 1: Relevant anatomy of the shoulder.[1]

METHODS

MRI scans of a right shoulder (48-year-old female) were reconstructed using *Mimics* (Materialise, Leuven, Belgium) to create the 3D model of the shoulder joint. An initial 3D mesh was assigned to the 3D models using *HyperMesh* (Altair, Troy, MI) and the humerus, scapula, LHBT, and transverse humeral ligament (THL) were imported into *FEBio*.[5] Four-node tetrahedral elements (TET4) were used for all bony and soft tissue components of the model (Figure 2).

The humerus and scapula were defined as rigid bodies, and the THL and LHBT were given an isotropic, compressible, Neo-Hookean base material with a Young's modulus of 600 and 50 MPa, respectively. The Poisson's ratio for both the THL and LHBT was 0.478.[6] The LHBT was also reinforced with one group of longitudinal power-linear fibers with a Young's modulus of 600 MPa.[7-9] Power-linear fibers are defined by a piecewise function that makes stress increase exponentially while the fibers are crimped and linearly when they are uncrimped. The exponent value for the LHBT fibers was set to 5, and the fibers became uncrimped at 3% strain based on previous experimental data.[7,9] Before implementing motion into the model, these material properties were

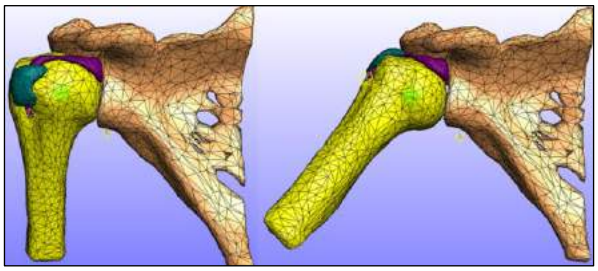

Figure 2: The start and end positions of the shoulder model in the FEBio workspace with meshes applied.

evaluated by performing a uniaxial tensile test simulation on the LHBT and comparing the results to previous experimental data.[9]

Rigid contacts were used to fix the THL and proximal LHBT to the humerus and scapula, respectively. Frictionless sliding contacts were defined between the LHBT and humerus, as well as between the LHBT and THL. In vivo joint kinematics during arm elevation, acquired with bone-fixed sensors through our previous experimental study,[10] were used to drive the simulation. With the scapula fixed to a global reference frame, humeral motion started with an inferior translation to align with the initial neutral position, followed by combined rotations about all three axes to move from the coronal plane with 0° of abduction to the scapular plane with about 45° of abduction (Figure 2). The implemented motion also caused the humerus to undergo external rotation. Forces ranging from 20N to 60N[11] were applied to the distal end of the LHBT during different trials of the simulation to represent the force applied by the biceps muscle during arm elevation. The force pointed toward the distal end of the humerus and was a constant magnitude for the duration of each trial. Since the LHBT is most resistant to tensile loads, the 1st principal stress (i.e., the maximum tensile stress) was exported for comparison across different arm elevation angles and locations in the LHBT.

RESULTS

The initial uniaxial tension study compared favorably with published data on LHBT mechanics, as shown in Figure 3. The stress-strain curves from the model and the literature had similar shapes and stresses. Figure 4 (A) shows the 1st principal stress plotted against arm elevation angle for three different locations in the LHBT. Each location is represented by a single element in the model. Figure 4 (B) shows where each of the three locations are on the LHBT, and it shows a 1st principal stress map on the LHBT.

Qualitatively, the model showed that LHBT geometry and the load on the distal end of the LHBT have a significant impact on LHBT behavior. Only one tendon geometry was used, but observations could be made about how its physical characteristics affected its behavior. The characteristic that had the biggest impact on the LHBT behavior was its thickness. Thick sections of the tendon were less susceptible to deformation and struggled to slide under the THL. The thin section on the distal LHBT slid under the THL with much smaller stresses. Comparing the varying geometries within a single tendon helped form generalized observations on tendon geometry. The loads on the distal LHBT directly impacted its deformation and stresses. Large loads (40-60 N) on the distal LHBT compressed its intra-articular portion to a narrower state as it was pulled against the THL. Narrowing the LHBT with reaction forces from the THL helped the LHBT slide through the bicipital groove, and the entire tendon was primarily under tension. Small loads (20-40 N) on the distal LHBT couldn't cause the intra-articular portion to narrow, which made it difficult for the tendon to slide through the bicipital groove. The result of the LHBT being unable to slide through the bicipital groove was compression and buckling in the proximal LHBT during arm elevation.

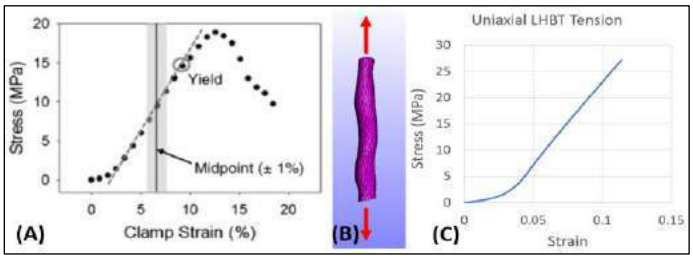

Figure 3: (A) Experimental data by Kolz et al.[9], and (B) and (C) show the FEBio setup and stress-strain data.

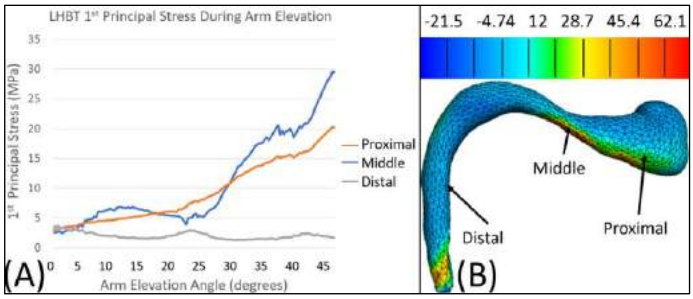

Figure 4: (A) Stresses in the LHBT during arm elevation and (B) the corresponding locations and a 1st principal stress Map (MPa).

DISCUSSION

An important output of the model was how tensile stress varies throughout the tendon. Graphing 1st principal stress shows that the narrow "Middle" section experiences the highest stress, followed by the "Proximal" section and then the "Distal" section (Figure 4). The regional differences suggest either the need for structural differences throughout the tendon, or relative injury susceptibility. The reason for the stress differences could be from varying cross-sectional areas or varying types of loads applied (bending or pure tension). This information along with further enhancement of the model can play a significant role in identifying failure mechanisms of the LHBT. Another important output of the model was the qualitative observation of how the tendon's geometry and biceps loads affect the behavior of the tendon, which can help in identifying patients who are at an increased risk of LHBT injury. Ongoing development of this model will expand upon the quantitative and qualitative findings for improving clinical treatment of LHBT pathologies and more accurately assessing the risk of LHBT injury within overhead athletes and individuals with repetitive overhead shoulder movements.[12]

While the FE model provided promising preliminary results, future work will more meticulously investigate the specific material properties of the THL. Sensitivity analyses will be performed to study the effect of implemented material properties on the stress/strain values and overall behavior of the LHBT. Lastly, more structures and movements will be added to the model to represent native anatomy more realistically.

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a disease associated with an elevated mean pulmonary arterial pressure. Sustained vasoconstriction is one of the hallmarks of PAH. Thus, the treatments of PAH include arterial vasodilators such as PDE5 inhibitors, soluble guanalyte cyclase stimulators, calcium channel blockers along with inhalation of nitrous oxide (NO). To understand the mechanics and degree of effectiveness of these pharmacological treatments, it is necessary to quantitatively estimate the impact of various chemical pathways on modulation of active tone of vascular smooth muscle cells (VSMC). To do so, we aim to develop a biochemo-mechanical model that couples the NO-cGMP-PKG chemical pathway with a hemodynamics model.

The NO-cGMP-PKG chemical pathway has been extensively studied in the last couple of decades. The nitric oxide in the NO-cGMP-PKG pathway is an important cellular signaling system for the regulation of VSMC relaxation. Several mathematical models have been developed to represent the chemical kinetics of this pathway. These models predict the concentrations of different signaling compounds over a time period for a NO-driven signal transduction. [Klinger et al 2007].

Although there have been extensive efforts to model either the hemodynamics or the NO-cGMP-PKG pathway, little attention has been paid to the coupling between the two. There are still many unanswered questions regarding the PAH treatment such as why only some patients respond to inhaled NO treatment, why infants respond differently than adults, etc. To be able to tackle these questions, we need quantitative model and coupling chemical pathway and hemodynamics.

With previous knowledge about change in smooth muscle tone with different concentrations of signaling compounds and quantitative knowledge on the chemical pathway, we aim to develop an integrated model to estimate the mechanical response of vessels in a pulmonary arterial tree. We use our model to study short-term adaptations of pulmonary arteries following pressure fluctuations and NO inhalation. A better understanding of chemical pathways of VSMC and their impact on hemodynamic responses will lead to improved therapies for PAH.

METHODS

A homeostatic optimization framework was used to establish the baseline characteristics of a healthy pulmonary arterial tree [Filonova et al 2020]. In the model, a homeostatic state in the distal arterial tree was determined based on an extension of Murray's law and steady state hemodynamics. Then, each vessel was equipped with a chemical kinetic model of the NO-cGMP-PKG pathway.

Homeostatic Baseline for Pulmonary Vasculature: The homeostatic optimization is a framework to estimate the homeostatic morphometric (e.g, diameters), structural (e.g, thickness), and hemodynamics (e.g., wall shear stress) properties of an arterial tree by minimizing the energy dissipation under the constraint of mechanical equilibrium. In this framework, the mechanics of each vessel are represented using a constrained mixture model, which accounts for the response of individual constituents: elastin, collagen, and VSMCs [Filonova et al 2020]. The homeostatic optimization in the distal arterial tree is determined at steady state hemodynamics and chemical equilibrium of the NO-cGMP-PKG pathway.

Hemodynamics: We consider the pulmonary arterial tree as a 1D bifurcating network, where each vessel is characterized by its radius and length. The steady state hemodynamics in the arterial tree are computed using Poiseuille flow for each vessel, flow conservation and pressure continuity for each bifurcation, and boundary conditions at the tree inlet and outlets.

NO-cGMP-PKG Pathway Model: We extend Yang's model [Yang et al 2005] to quantify blood flow through the pulmonary tree, resulting from a step change of inlet pressure or inhaled NO. This kinetic chemical model is connected to the mechanical model through a linear relation between [NO] concentration and stress in the blood vessels as shown in Figure 1b. In summary, change in [NO] concentration causes a reduction in $[Ca]^{2+}$ concentration in the SMCs, which further induces change in active tone (Figure 1).

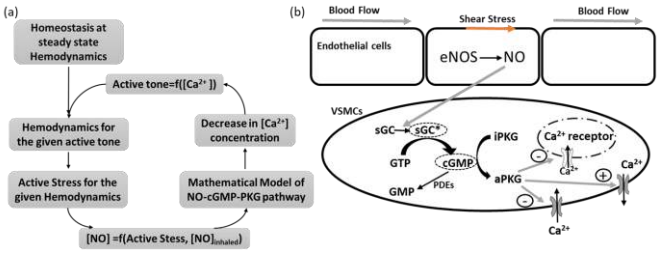

Figure 1. a) Information exchange inside biochemo-mechanical model that account for hemodynamics, tissue homeostasis and NO-CGMP-PKG pathway. b) Series of chemical reactions that occur inside VSMCs to an external stimuli.

The hemodynamics and chemical pathway models are solved iteratively until convergence of chemical and mechanical parameters. The entire system is solved marching forward in time to describe responses to different stimuli.

RESULTS

The results of biochemical part of the model were compared with the Yang's model as shown in Figure 2. The plots in Figure 2 give concentrations of chemical compounds involved in NO-cGMP-PKG pathway changing with time following a step change in the input flux of nitrous oxide at time t=0s. Panel (a) and (b) represents [cGMP] concentration and its rate of production (v_p) and decomposition (v_d). Panel (c) and (d) represents concentration of different sGC forms. The model is in agreement with the previously verified mathematical model.

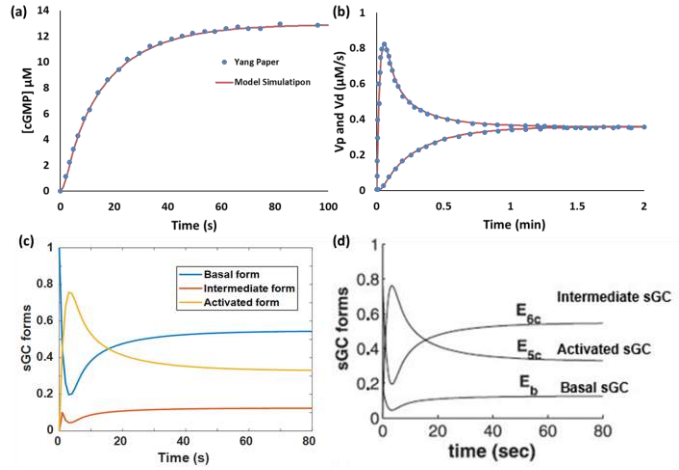

Figure 2. Comparison of Biochemical part of the model with Yang's model [Yang et al 2005] for similar [NO] stimuli. a) Change in concentration of cGMP and b) Rate of production and decomposition of cGMP. Change in concentration of different forms of sGC: c) in the current model d) in the Yang's model.

Figure 3 shows the relative change in the diameter and active tone as a result of a step change in pressure (a) and (b) and nitrous oxide concentration (c) and (d). Vessel diameter across different generations increased by 5-15% when pressure was increased 1.5 times. Similar trend was observed when the inlet [NO] was 200nM, although the maximum diameter change was 5% as shown in panel (d). Active tone changed from the homeostatic value (~70%) by almost 40% and 30% for change in pressure and inlet [NO] concentration respectively.

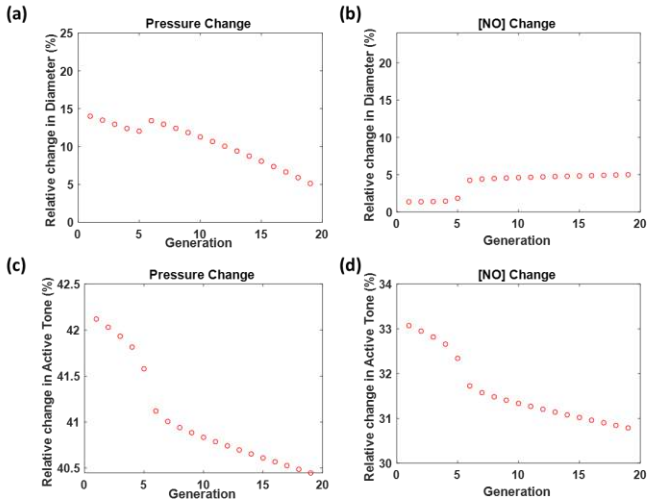

Figure 3: Relative change in the diameter and active tone of blood vessels for different generations of arterial tree: a) & c) when inlet pressure is changed to 1.5 times the initial pressure: b) & d) when there is a step change in [NO] concentration of 200nM.

DISCUSSION

As Figure 2 suggests, our model accurately replicates a previously verified mathematical model to represent the NO-cGMP-PKG chemical pathway. Therefore, this model can be further extended to study biochemo-mechanical coupling in the pulmonary circulation.

From Figure 3 we observe that with changes in inlet pressure, the diameter in each blood vessel increases as expected response by the blood vessels. In the case of spike in the [NO] concentration (200 nM) in the pulmonary blood vessels, a very small dilatory response is observed from the pulmonary vasculature.

As this biochemo-mechanical model has shown promising preliminary results and is a good representative of the actual pulmonary vasculature, we plan to extend this model to study responses in PAH in the near future.

INTRODUCTION

Following the EMPA-REG OUTCOME trial, sodium-glucose cotransporter 2 inhibitors (SGLT2i), a class of drug in the treatment of type 2 diabetes, rapidly gained interest as the treatment with empagliflozin (Jardiance™) showed significant reductions in the rate of hospitalization for heart failure and cardiovascular deaths, suggesting a cardiovascular protective effect provided by SGLT2i [1]. Subsequent studies and clinical trials demonstrated protective effects against the complications associated with atherosclerosis [2], heart failure [3] and ischemia-reperfusion injury [4] in non-diabetic conditions, indicating a possible pleiotropic effect independent of glycosuria. The onset of the observed effects suggests the implication of underlying cellular mechanisms preventing vascular dysfunction [5].

In recent years, the endothelial glycocalyx (GCX) has been recognized as a marker of vascular health with its disruption resulting in increased inflammation and impaired vasodilation response to flow, hallmarks of endothelial dysfunction [6]. Hyperglycemia has been shown to damage the endothelial GCX [7]. Heparan sulfate (HS) being one of the main components of the endothelial GCX, plays a crucial role in the shear-mediated regulation of endothelial cell (EC) functions.

We previously showed that treatment with EMPA alleviate the EC dysfunction caused by the enzymatic degradation of HS [8]. The present study aims at better understating the effects of EMPA on ECs and if the GCX acts as a mediator in the response through mechanotransduction.

METHODS

Cell culture and shear experiment. Human abdominal aortic ECs were cultured statically or under flow (10 dyn/cm^2) in 3D tubular cell culture models for 24h. Cells were stimulated with TNF-α (10 ng/mL) and treated simultaneously or not with empagliflozin (50 uM). Heparinase III (0.1 U/mL) was used to enzymatically degrade HS before (preDEG) or during flow exposure (DEG).

Adhesion assay. Leukocyte-like inflammatory cells (NB4) were cultured in suspension and stimulated with all-trans retinoic acid 48h prior to the assay. Inflammation of the TNF-α-treated ECs was assessed following 24h of flow culture by exposing the monolayer to circulating NB4 cells under low shear (1 dyn/cm^2). The firm adhesion of NB4 to the ECs were visualized and numbered under light microscopy.

Permeability assay. Paracellular permeability was quantified with a modified XPerT assay [9]. µ-Slide VI 0.4 plates were coated with biotinylated collagen and seeded with ECs to form a confluent monolayer. Following TNF-α/EMPA treatment, ECs were incubated with avidin Alexa 488. The paracellular permeability was quantified by measuring the covered area of the green channel signal.

Protein quantification. Quantification of the protein levels of phospho-eNOS (Ser1177), eNOS and ICAM-1 was performed through immunoblotting to characterize the endothelial inflammatory response. Following static or flow culture, ECs were lysed *in situ* to collect proteins. Protein samples were separated and transferred on nitrocellulose membranes. Chemiluminescent signal was used to evaluate the relative expression by densitometry.

Global transcriptional regulation study. The transcriptional changes after 24h was examined with a transcriptome analysis. RNA was extracted *in situ* with QIAGEN RNeasy Plus Micro kit. The concentration and RIN of each sample was verified prior to hybridization on a Clariom™ S human microarray chip. Results were analyzed with the Transcriptome Analysis Console software 4.0.2.

RESULTS

EMPA normalized the increased adhesion caused by HS degradation. Adhesion of NB4 cells was significantly reduced by

empagliflozin after 24h (Fig. 1). HS degradation (preDEG and DEG) resulted in significantly more NB4 cell adhesions. In both cases, treatment with EMPA normalized the adhesion, indicating a decreased inflammatory response from the TNF-α-treated ECs. The effect observed under sustained HS degradation suggests that HS integrity does not play a role in the anti-inflammatory effect provided by EMPA.

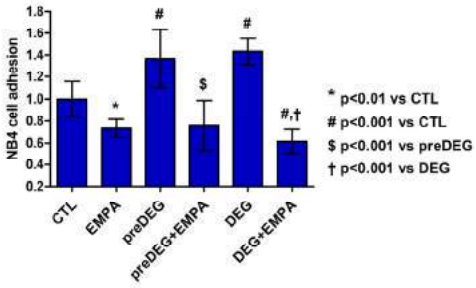

Figure 1: NB4 cell adhesion assay. EMPA reduced the number of adhered NB4 cells to TNF-α treated ECs under HS degradation.

EMPA had no impact on the TNF-α induced increase of permeability *in vitro.* TNF-α significantly increased the avidin 488 signal at cell-cell junctions indicating increased paracellular permeability in both static and flow culture after 24h. The increased level of permeability was unaffected by EMPA.

EMPA does not restore shear-induced eNOS activation or reduce ICAM-1 expression. TNF-α reduced eNOS expression in all conditions while EMPA nor HS degradation had an impact. Phospho-eNOS levels were similarly reduced suggesting impaired eNOS activation. Again, no significant changes were induced by EMPA or HS degradation (Fig. 2A). TNF-α induced the expression of ICAM-1 to similar levels in all conditions tested (Fig. 2B).

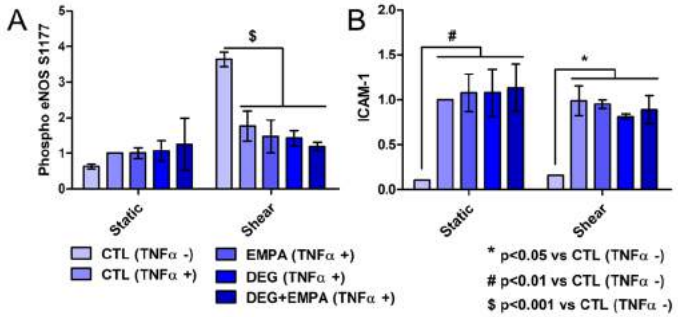

Figure 2: Phospho-eNOS (A) and ICAM-1 (B) protein levels. HS degradation and EMPA had no effect on the impairment of phospho-eNOS and the increase of ICAM-1 induced by TNF-α.

The shear-induced GJA5 expression is partially restored by EMPA under HS degradation. HS degradation and EMPA treatment significantly affected the expression of GJA5 (gap junction alpha 5; connexin 40). Shear induced an upregulation of GJA5 (CTL vs CTL S). HS degradation impaired the shear-induced regulation of GJA5 while EMPA partially restored normal expression, resulting in a 5-fold increase between DEG and DEG-EMPA (Fig. 3).

DISCUSSION

Evidence from *in vitro* and *in vivo* studies suggest that vascular mechanisms would be in part involved in the protective effect of SGLT2i. As EC dysfunction is pivotal in the early progression of cardiovascular diseases, we previously hypothesized and showed that endothelial dysfunction caused by a degraded glycocalyx can be restored by EMPA [8]. The results of this work offer more information

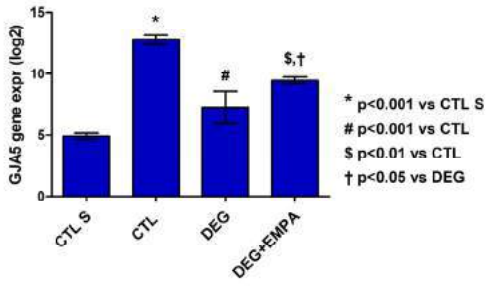

Figure 3: Transcriptional level of GJA5. HS degradation decreased the expression of GJA5 while EMPA partially restored the normal expression compared to the shear control (CTL).

regarding the possible cellular mechanisms involved.

HS degradation triggers a pro-inflammatory response with impaired nitric oxide (NO) regulation, increased adhesion molecule expression, vascular permeability and inflammatory cell migration. It remains unclear if SGLT2i can impact the regulation of adhesion molecules. Ortega et al. [10] showed an attenuation of ICAM-1 expression, NF-kB signaling and leukocyte adhesion in EMPA-treated ECs whereas others reported no significant changes in expression of adhesion molecules [11]. Our results suggest that the reduction in NB4 cells caused by EMPA cannot be attributable to a reduction in ICAM-1 expression or a reduction in permeability.

Normal EC-dependent vasodilation through NO release has been shown to be restored by SGLT2i treatment in *ex vivo* experiments [12]. Although NO bioavailability appeared to be partially restored by EMPA *in vitro* [11], the recovery of the shear-induced eNOS Ser1177 activation may not be involved in the reduction of EC inflammation.

Taken together, our results suggest that the reduced inflammatory response provided by EMPA may stem from different cellular mechanisms than the recovery of the shear-induced NO release and the regulation of immune cell migration associated with an intact GCX.

Interestingly, gap junction intercellular communication (GJIC) has been related to the GCX integrity [13] and to the regulation of eNOS [14] and leukocyte adhesion [15]. Further experiments will aim at characterizing the GJIC of EMPA-treated cells and to better understand how changes in the expression or function of connexin 40 can result in the reduction of EC inflammation.

ACKNOWLEDGEMENTS

We would like to thank Boehringer Ingelheim who kindly provided the empagliflozin and Genome Quebec for their expression analysis services. This study is supported by NSERC 2018-06161.

INTRODUCTION

Approximately 15% to 45% of the chronic back pain cases involve facet joints [1]. Monopolar radiofrequency ablation (RFA) of the medial branch of the dorsal rami is widely used and effective to reduce facet joint pain. In this procedure, an electrode is placed near or at the medial branch and a radiofrequency current is applied to the tissue. Thermocoagulation of the medial branch blocks pain signals originating from the facet joint [2]. Unfortunately, this procedure also denervates the multifidus muscle. Denervation causes atrophy and fat infiltration of the multifidus muscle, and accelerated intervertebral disc degeneration, which are of great concerns [3]. Therefore, monopolar RFA is beneficial in the short time, but multifidus dysfunction may contribute to the degeneration cascade of other structures of the spine and may lead to other pain mechanisms in the long term. To avoid multifidus muscle denervation, RFA can potentially be applied down-stream at the articular branch instead of the medial branch. However, articular nerves are smaller and a new RFA procedure would require a more precise control of the lesion size. Bipolar RFA, in which two electrodes are placed into the tissue, is preferred over monopolar RFA. In bipolar RFA, radiofrequency current runs from one electrode to the other. Therefore, the size and shape of the ablated region can be controlled by the location and distance between electrodes. Bipolar RFA has other advantages in terms of minimal energy loss which causes faster ablation process, and decreased risks of skin burns from ground pads [4]. Clinical RFA devices (radiofrequency generators) keep the temperature of the electrodes constant during the ablation procedure by dynamically controlling the voltage applied to the electrodes [5]. The objective of this study is to develop a multiphysics finite element model of the bipolar ablation process of ex-vivo tissues with a dynamic-controlled feedback loop for temperature of the electrodes to simulate clinical RFA procedures.

METHODS

a. FEM Analysis-COMSOL

Bioheat Transfer and Electric Current modules of COMSOL Multiphysics® were used to couple the thermal and electrical effects of the RFA process. The model consisted of a cylinder of homogeneous muscle tissue (5 mm in diameter, 15 mm in height) with bipolar electrodes with an active length of 10 mm and diameter of 0.8 mm. The initial temperature of the muscle tissue was set to 37 °C and the initial voltage of the entire model was set to zero. One of the electrodes was modeled as ground (V=0) while voltage of the other electrode was controlled by using a PID controller to keep the electrode temperature ($T_{electrode}$) at a target value (T_{target}). Lastly, the temperature error

$$e(t) = T_{target} - T_{electrode} \tag{1}$$

was used to control the voltage of the active electrode by the following governing equation:

$$V(t) = K_P\, e(t) + K_i \int_0^t e(\tau) d\tau + K_d \frac{d}{dt} e(t), \tag{2}$$

where V is the applied voltage (V). For this simulation, the optimal PID parameters were found as K_p=2, K_i=1 and K_d=0 by parametric sweeping. In this study, the average domain temperature of the electrode (T_{target}) was set to 60 °C. Only an active tip of the electrode was modeled to make the model simpler and faster in solving the bioheat equation. Blood perfusion rate (w_b) in the bioheat equation was not considered since model is focused on simulating the ablation process ex-vivo. A finer mesh comprising tetrahedral elements was generated to get more sensitive temperature change around the electrodes (Figure 1).

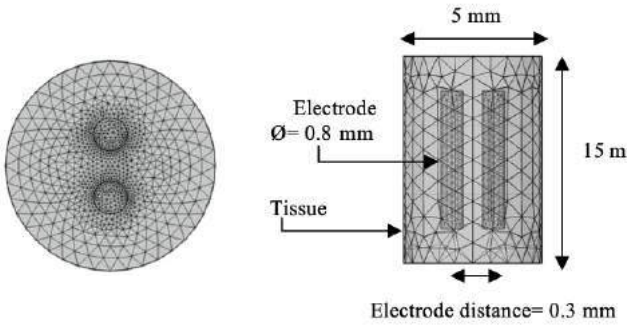

Figure 1: Model dimensions and mesh distribution.

b. Electrical Conductivity Measurements

The electrical conductivity of the tissue has been shown to play a critical role on the simulation of the RFA. The electrical conductivity of porcine spinal muscle was measured with an impedance analyzer (Agilent 4294A). Muscle tissues was obtained from a local abattoir. A sample from the multifidus muscle of with an approximate thickness of 0.3 cm, length of 4.3 cm and width of 4.8 cm was dissected. Copper electrodes were placed on each side of the sample in a vacuum sealed bag, then the bag was placed in a water bath. Measurements of electrical conductivity were performed at several temperatures from room temperature to 80 °C for and a frequency 460 kHz.

c. Other material properties and parameters

Other material properties needed for the simulation of the RFA process were obtained from the literature [7-9]. To determine the optimal parameters of the PID controller, a parametric analysis was performed.

Table 1. Material Properties Used in FEM Model

Region	Material	k[W/mK]	σ[S/m]	c[J/kgK]	ρ[kg/m^3]
Tissue	Muscle	tc(T)	ec(T)	3421	1090
Electrode	Ni-Ti	18	10^8	840	6450

RESULTS

The electrical conductivity of the tissue sample linearly increased from room temperature up to 70 °C and was followed by a decreasing trend for higher temperatures. The measurement readings were fitted into a 5th order polynomial model with R squared value of 0.9997 (Figure 2). The 5th order polynomial describing the conductivity dependency is:

$$ec(T) = -1.31\times10^{-10}\,T^5 + 2.18\times10^{-7}T^4 - 1.48\times10^{-4}\,T^3 + 5.12\times10^{-2}T^2 - 8.92\,T + 627. \quad (3)$$

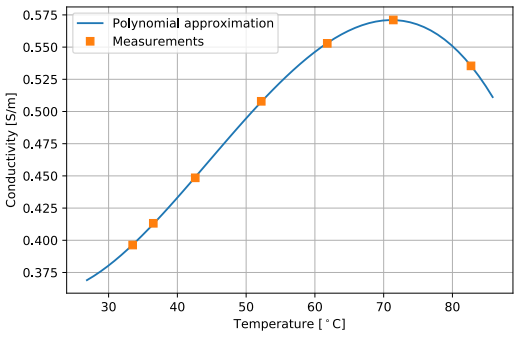

Figure 2: Electrical conductivity change of a muscle tissue at different temperatures at 460 kHz.

An example of the temperature distribution around the electrode can be seen in Figure 3a. The time passed to reach the target temperature of 60 °C has been found to be less than 10 seconds (Figure 3b). During this time, the applied voltage increases initially and reaches a maximum value then starts decreasing to keep the electrode temperature constant. The electrode domain temperature for various PID parameters can be seen in Figure 3b.

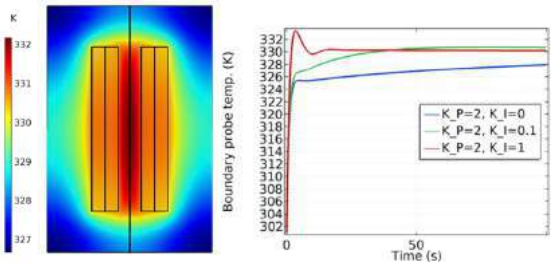

Figure 3: (a) Temperature distribution around the electrode, (b) probe temperature change for different PI parameters.

DISCUSSION

A FEM model of the PID-controlled simulation of the bipolar RFA procedure was developed. The values of electrical conductivity measurements are similar to those reported in [7] and references therein. The linear increase and subsequent drop in electrical conductivity has also been reported for muscle tissue [10]. COMSOL Multiphysics modules have been used to accurately simulate RFA process in several tissues including liver, muscle and kidney. However, to the best of our knowledge, this is the first report of bipolar RFA simulation that includes a PID controller for the voltage of the electrodes. Adding active control of electrode voltage is necessary to accurately simulate the RFA performed by clinical systems. Most RFA systems maintain a constant electrode temperature for a period of time. During this time, the surrounding tissues experience an increased temperature for a period of time that causes the desired targeted tissue damage. Following the same process as clinical devices is extremely important to accurately estimate the size of the ablated region. This is expected to be a critical step for future studies exploring new methods RFA of spinal nerves. As our ongoing work, the proposed method will be applied in vivo in a porcine animal model and to perform clinical trials to evaluate its effectiveness to reduce pain and decrease muscle dysfunction.

INTRODUCTION

The modified Blalock–Tausig shunt (BTS) is an aortic to pulmonary shunt, which is implanted as part of a palliative procedure for neonates with congenital heart disease to supply blood flow to the pulmonary arteries [1]. The size selection of the shunt is based on the patient's weight, which is in the range of 3-5 mm [2]. Although the outcomes of congenital heart disease surgery have improved, the rate of mortality is still excessive, and those with the BTS remain at high risk for sudden death. Imbalances in blood flow to the body or lungs contributes to this [3], with blood flow during diastole compromising coronary perfusion, referred to diastolic run-off. The BTS has been in use for over 40 years with no significant change or improvement in the technology to date.

The main goal of this study is to develop a novel device to dynamically control shunt flow by expanding a soft balloon around the shunt to restrict excessive flow to the pulmonary artery in a dynamic and programmable manner. The device will control diastolic run-off by closing the shunt during diastole. The future goal is developing a device as a sub-cutaneous implant that is wirelessly chargeable and programmable for better clinical management of patients with BTS.

METHODS

The developed device consists of an expandable balloon with a pre-existing resistance to a 5 mm PTFE vascular graft, extension tubing, and a controllable linear actuator. The balloon is a two-layer hollow cylinder with soft silicone-based material for the inner surface and a stiff (but bendable) material for the outer side. The space between the inner and outer faces is filled with water and is connected to a controllable linear actuator through a semi-rigid extension tubing. In such a way, the cylinder can only expand from the inner layer, which is in contact with a PTFE vascular graft and can control the shunt's cross-section area. As proof of concept, the device prototype is tested on a shunt in an *in vitro* circulation simulator setup (heart rate = 60 bpm), as shown in Figure 1.

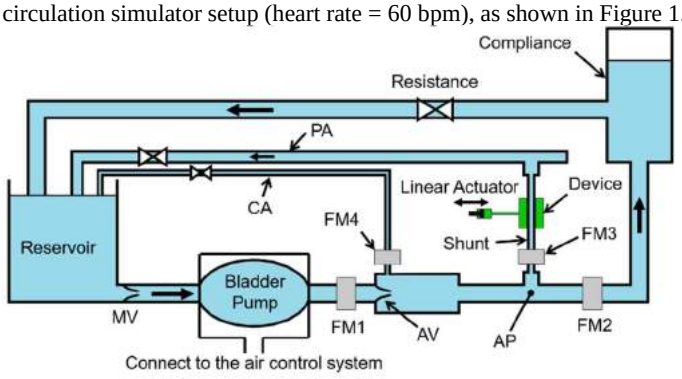

Figure 1: Flow setup. AV: Aortic valve, MV: Mitral valve, PA: pulmonary artery, CA: Coronary artery, FM: Flowmeter.

The controllable linear actuator pressurizes the balloon hence the amount of fluid in the balloon dictates a certain level of resistance to the shunt. This device's concept is very similar to an on/off valve. It allows shunt flow during systole and minimizes blood flow through the shunt during diastole to maintain diastolic and hence coronary perfusion pressure. Instantaneous aortic pressures is recorded as a function of balloon resistance. Dynamic aortic flow, coronary flow, and shunt flow are measured. The system response of the linear actuator coupled with the shunt is characterized. The balloon dynamically controls the shunt resistance hence the orifice diameter of the shunt, d, is changing during the cardiac cycle. Therefore, the balloon to shunt diameter ratio, d/D, can be varied from 0 (fully occluded) to 1 (fully open). The waveform of the d/D ratio in the cardiac cycle will be determined.

We can derive optimum shunt resistance values by having a target aortic flow and the actual aortic flow after shunt implantation. **Figure 2** shows an ideal d/D ratio curve (yellow curve) and the optimum d/D ratio curve (green curve) versus time. A pre-existent resistance is applied to the shunt to control the maximum flow (the horizontal dash line in Figure 3, where d/D < 1) and regulate an appropriate Q_P/Q_S. In reality, as infants grow, the shunt flow needs to increase to satisfy the normal Q_P/Q_S. As a result, we propose to have a larger shunt, and physicians adjusts Q_P/Q_S by changing the pre-existent resistance in patient checkups.

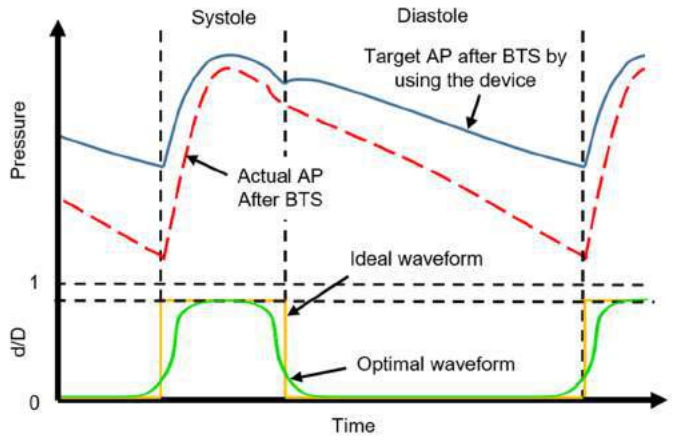

Figure 2: Achieving optimal device input waveform. AP: Aortic pressure

In this study, we applied an ideal waveform (yellow curve in **Figure 2**) and further optimization will be investigated.

RESULTS

All the pressure and flow rate results are displayed in **Figure 3**. Mean Aortic pressure was 78.83±0.92 mmHg and 72.51±0.60 mmHg for the cases with and without using the device. Peak flow rate was 11.19±0.15 L/min and 12.85±0.15 L/min for the cases with and without using the device. Mean right coronary flow rate was 11.59±0.09 mL/s and 10.84±0.07 mL/s for the cases with and without using the device. Mean shunt flow rate was 5.75±1.19 mL/s and 12.63±0.07 mL/s for the cases with and without using the device.

DISCUSSION

This study was conducted as a proof of concept for developing a novel flow regulator device to help BTS patients. Results show that pinching the shunt by the device during diastole leads to drastically drop in shunt flow (**Figure 3D**). As a consequence, the aortic pressure increases during diastole (**Figure 3A**) as we expected in **Figure 2**. Increase in aortic pressure during diastole results in having higher mean coronary perfusion up to 7% as shown in **Figure 3C**. This preliminary data shows a significant improvement in coronary perfusion by using the device on the BTS. However, in this study we used an ideal square waveform to control the shunt flow (yellow waveform in **Figure 2**). As a future work, the actuator's cyclic behavior will be determined for optimal flow control defined as therapeutic pulmonary to system flow ratio with minimal diastolic run-off.

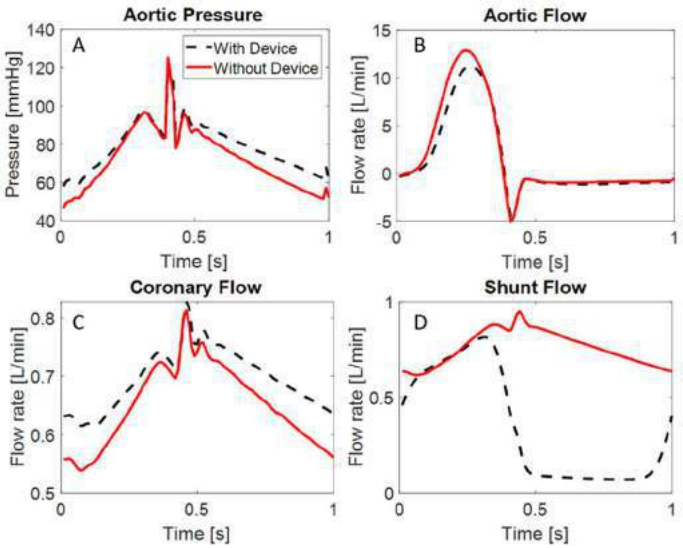

Figure 3: Pressure and flow curves before and after using the device on the BTS graft

Ideally, the shunt should be closed during diastole to avoid run-off; however, this will not be achievable due to possible damage to the shunt and possible rupture. Moreover, the risk of blood clotting will be increased due to stop and start the blood flow. As a result, the maximum possible resistance (d_{min}) needs to be investigated. During systole, the device needs to be open, and the shunt must have a minimum resistance. According to that, we will develop a simple *in vitro* loop and run pulsatile pig blood flow in the shunt to investigate the shunt thrombosis. By having the device around the shunt, we will apply dynamic resistance to the shunt. The amount of resistance and duration of pinching will be characterized by thrombosis formation. The maximum resistance and the optimum duration of resistance (without damaging to the blood) will be documented.

In this study, we used a 5 mm PTFE vascular graft and we used the device on it. As a result, by using the device we will end up with less shunt flow (**as shown in Figure 3D**) compared to the shunt without using the device. The future goal of this study is using a 3-3.5 mm shunt without using the device and compare the results with a 5 mm shunt with using the device. In this case the shunt flow will be reserved to keep the Q_P/Q_S.

EFFECT OF STIMULUS WAVEFORM ON TRANSCRANIAL MAGNETIC STIMULATION METRICS IN PROXIMAL AND DISTAL ARM MUSCLES

Christopher S. Lynch (1), Thibault Roumengous (1), Carrie L. Peterson (1)

(1) Department of Biomedical Engineering
Virginia Commonwealth University
Richmond, VA, USA

INTRODUCTION

Transcranial magnetic stimulation (TMS) is useful for modulating neural activity when applied repetitively or assessing neural pathway excitability when applied in single or dual pulse paradigms [1]. TMS devices generate one of two types of stimulus waveforms, monophasic or biphasic, which have dissimilar neuronal activation and therefore different impacts on stimulation characteristics [2]. To date, research on the effects of waveform has been conducted on upper limb distal muscles, such as the first dorsal interosseous (FDI). Research in the FDI has shown greater efficacy in the monophasic stimuli (when the induced brain current is in the posterior-anterior direction) demonstrated via reduced motor threshold's (MTs) [2]. This is likely a result of the 2nd phase in biphasic stimulation as the 2nd phase not only reduces the activation time and thus the effectiveness of the initial phase, but activates different neurons that have different sensitivity to each current direction [2]. Additionally, FDI research has shown that MTs and motor evoked potential's (MEPs) are inversely correlated due to their role in measuring intrinsic and synaptic plasticity, respectively [3]. However, the FDI has more available motor neurons than the biceps brachii (BB) at equivalent force levels [4]. Therefore, conclusions regarding neuroplastic effects drawn from the numerous TMS studies using upper limb distal muscles may not necessarily apply to other muscle groups, particularly upper limb proximal muscles. This presents a clinical need as TMS is increasingly being utilized for neurorehabilitation as an adjunct to conventional physical therapy, especially spinal cord injury (SCI) which affects entire extremities [5].

The purpose of this study is to determine the effect of TMS waveforms (monophasic vs biphasic) on important TMS metrics and determine if muscle groups (i.e. upper limb proximal vs distal) have any effect on these outcome metrics. We hypothesize that monophasic stimulation will result in lower MTs, both resting MT (RMT) and active MT (AMT), compared to biphasic [2], however the opposite will occur for normalized MEPs (nMEPs) resulting in greater nMEPs for monophasic compared to biphasic stimulation, for both muscles [3]. Furthermore, we hypothesize that an upper limb proximal muscle (BB) will have statistically different MTs, RMT and AMT, as well as nMEPs compared to the upper limb distal muscle (FDI) for both waveforms.

METHODS

Experimental Set-up: Ten individuals aged 25.0 ± 3.22 years (3 female, 7 male) were recruited for this study which was approved by the Institutional Review Board (IRB) at Virginia Commonwealth University. Surface electromyogram (EMG) electrodes were located over the primary target muscles (BB and FDI) before determining the cortical hotspot, maximum voluntary contraction (MVC), RMT, and AMT. TMS stimulation was applied via a Magstim® BiStim^2 stimulator (monophasic) and Magstim® Super Rapid^2 Plus^1 stimulator (biphasic), both via a Magstim® D70 Alpha flat (uncoated) figure-eight coil. The coil was oriented similarly for each waveform (i.e. perpendicular to the central sulcus) as to induce a biphasic posterior-anterior/anterior-posterior (PA/AP) current and a monophasic PA current in the motor cortex. RMT was determined as the lowest stimulus intensity that induced MEPs of ≥ 50 μV in at least 5 of 10 consecutive stimuli with the target muscle fully relaxed. With visual feedback provided, participants sustained an isometric contraction of 20 ± 2.5% MVC of the target muscle during which the AMT was determined as the stimulus intensity that elicited a MEP ≥ 200μV in at least 5 of 10 consecutive stimuli. Lastly, 10 single pulse MEPs were recorded at 120% RMT for each waveform.

Data and Statistical Analysis: Statistical analyses were performed using MATLAB (MathWorks (2020)) and GraphPad Prism. RMT, AMT, and nMEPs were compared between monophasic and biphasic waveforms using a two sampled t-test with unequal variance. Additionally, RMT, AMT, and nMEPs were compared between BB and FDI using an ANOVA with interactions.

RESULTS

BB RMTs were significantly lower for monophasic (60.1±9.06 %MSO) than for biphasic (84.4±11.02 %MSO) ($p<0.01$). FDI RMTs were also significantly lower for monophasic (48.4±8.2 %MSO) than for biphasic (67.9±11.94 %MSO) ($p<0.01$). BB AMTs were significantly lower for monophasic (39.2±9.3 %MSO) than for biphasic (60.9±11.4 %MSO) ($p<0.01$). FDI AMTs were also significantly lower for monophasic (34.1±11.7 %MSO) than for biphasic (55.5±14.7 %MSO) ($p<0.01$) (Figure 1).

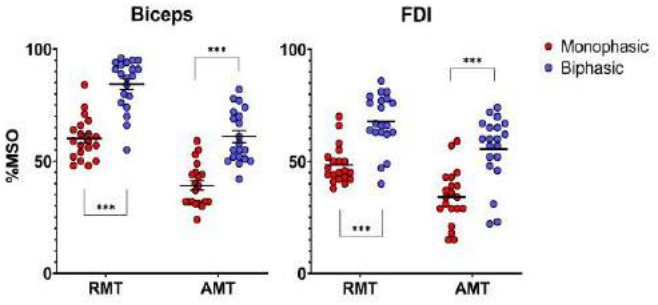

Figure 1: Left: Biceps MTs, are significantly greater for biphasic compared to monophasic. Right: FDI MTs, are significantly greater for biphasic compared to monophasic. Asterisks represent statistical difference ($p<0.01$) and error bars represent standard the error of the mean (SEM).

BB nMEPs present no significant difference between monophasic (6.20±19.55 μV%MVC) and biphasic (6.56±21.38 μV%MVC) ($p=0.88$). However, FDI nMEPs were significantly greater for monophasic (3.02±2.37 μV%MVC) compared to biphasic (2.36±1.91 μV%MVC) ($p=0.01$) (Figure 2).

An ANOVA revealed a statistical difference between BB and FDI for RMT ($p<0.01$) and nMEP ($p<0.01$), however, there was no significant difference for AMT ($p<0.01$). Additionally, there was no significant interaction amongst waveform and muscle for RMT ($p=0.31$), AMT ($p=0.95$), and nMEP ($p=0.65$).

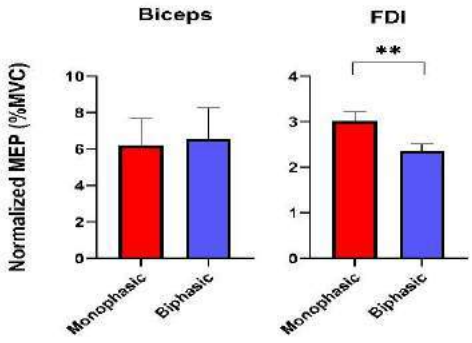

Figure 2: Left: Biceps nMEPs are not significantly different between monophasic and biphasic. Right: FDI nMEPs are significantly greater for monophasic compared to biphasic. Asterisks represent statistical difference ($p<0.01$) and error bars represent standard the error of the mean (SEM).

DISCUSSION

There were two key outcomes of this study. First, in agreement with the literature [2], using a monophasic stimulus led to lower MTs, both RMT and AMT, for the FDI and the BB. The difference in MT is likely related to the general organization of inhibitory and facilitatory corticospinal pyramidal tract neurons and the facilitatory neurons having higher sensitivity to the PA current direction [6]. However, this also contributes to the increased MT of the biphasic PA/AP stimulation. The 2nd AP phase not only reduces the activation time and thus the effectiveness of the initial phase, but activates different neurons that have different sensitivity to each current direction [2]. Additionally, the 2nd AP phase hyperpolarizes the membrane and reduces the number of sodium ion-channels available for depolarization [6]. While MTs reflect sodium ion-channels activity which may indicate intrinsic plasticity due to long-lasting changes in neuronal excitability, analyzing MEPs provides information about synaptic plasticity, caused by long-lasting attenuation of synaptic transmission [3].

Second, while we found a significant difference in FDI nMEP amplitude between waveforms, with monophasic having greater nMEPs than biphasic [3], we did not find a significant difference in BB nMEP amplitudes between waveforms. A possible explanation of this finding could be that more distal muscles not only have larger cortical areas, but the cortical areas are also denser than proximal muscles [7]. This, in combination with proximal muscles having weaker monosynaptic input [8], could lead to relatively greater biphasic nMEPs in the BB compared to the FDI. Furthermore, Turton, et al., discovered that at lower force levels a larger number of available motor neurons are recruited for upper limb distal muscles compared to proximal muscles where greater force levels were required for the same level of neuronal activation [4]. Being that our MEPs were recorded while at rest, this is another potential reasoning for the unexpected lack of significant difference between waveforms for BB nMEPs.

One limitation of our study is the small sample size. In order to fully understand these effects for the purpose of neurorehabilitation, this study would need to be further investigated in individuals with neurological impairment. However, our preliminary data suggests that regardless of the waveform, the neuroplasticity findings from FDI research, may not necessarily be applicable to all muscles, specifically the BB. This is rationale that further investigation needs to be conducted on the intrinsic and synaptic plasticity effects on additional muscles where TMS neurorehabilitation could be advantageous.

INTRODUCTION

There is an established global demand for ventilators, for which the supply has been restricted due to the high cost and complexity of existing ventilator designs. The onset of the COVID-19 pandemic increased demand for critical care ventilators, resulting in an unprecedented strain on the global ventilator market. The intricate design and fabrication of traditional ventilators restricted the ability of manufacturers to accelerate production to meet the increased demand triggered by COVID-19. Therefore, there is a critical need for high performance, low-cost ventilators. This demand could be met by producing designs that achieve traditional methods of ventilation with fewer components or developing new approaches to the fundamental tasks of pressure and flow regulation to inherently reduce design complexity.

We propose a novel ventilator design that performs the essential functions of a traditional ICU ventilator, while utilizing simple components outside of the ventilator supply chain. The proposed design implements the clinically preferred ventilation method, pressure-regulated volume-control (PRVC), in addition to spontaneous and suction modes. With the PRVC method, a fixed volume of gas is delivered to the patient for each breath. This flow is constrained such that airway pressure does not fall below a positive end-expiratory pressure (PEEP). Classically, proportional solenoid valves mediate the patient's connection to high pressure gas supplies but are currently in extremely short supply. Instead, we implemented the design with on-off solenoids valves, which are widely available off-the-shelf worldwide and are cheaper than their proportional counterparts.

In the following study, an overview of the novel approach to ventilation is presented, as well as results from benchtop testing.

METHODS

Two on-off Valves (A and B) are used to load each breath from high pressure air and oxygen supplies into a 2L reservoir (Figure 1). A pressure sensor is used to determine when the reservoir has been sufficiently filled, after which Valves A and B are closed. The breath is delivered to the patient through the opening of another on-off valve, Valve C. A second pressure sensor measures the pressure delivered to the patient. When the inhalation has finished, Valve C is closed, and Valve D opens to allow exhalation. During exhalation, Valves A and B are reopened, and the next breath is loaded into the reservoir.

The system dynamics of the ventilator are dictated by the flow-pressure characteristics of the valves. The selection of the valve flow coefficients was informed by a numerical model of the ventilator system. With these properties known, the two pressure sensors can be used to estimate the flow rate during inhalation and exhalation, removing the requirement for a dedicated flow sensor. Patient-specific lung parameters can be estimated at each breath and used to inform the next breath, allowing a control system to meet ISO guidelines and UK MHRA requirements. A commercially available ventilator testing device (Citrex H5) was used to assess the performance of the ventilator over a range of tidal volumes (V_T), PEEP values, and timing conditions. Durability testing of the prototype was conducted over 14 days to evaluate system stability. In addition, the ventilator prototype was tested with a portable oxygen concentrator, in place of a compressed oxygen source, to evaluate if any change in system performance occurred.

RESULTS

Benchtop testing was performed to evaluate the performance and response time of the proposed design. A parametric sweep of target PEEP and V_T was performed. The system performed consistently across a clinically relevant parameter space (Figure 2), with cases omitted

where the peak inspiratory pressure would exceed the maximum allowable airway pressure. The achieved PEEP and V_T are shown against the target values for a test lung with a compliance of 20 ml/cmH_2O and a resistance of 20 cmH_2O/l/s. Good agreement was observed between values reported by the prototype system and the commercially available ventilator testing machine, Citrex H5. In response to changes in ventilation settings, PEEP and V_T stabilized to target values within 1-2 breaths. When run for 14 days, the system maintained performance with no change in key ventilation parameters. In addition, no significant change in performance was identified when the system was used with compressed air and an oxygen concentrator.

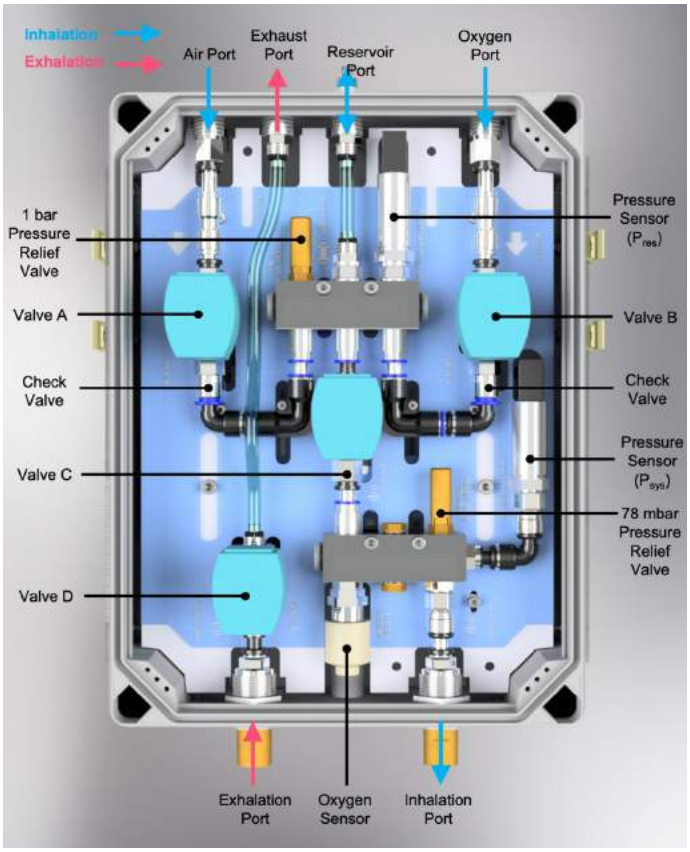

Figure 1: Annotated schematic of pneumatic components of the proposed ventilator design.

DISCUSSION

The proposed design constitutes a new approach to achieve ICU-level ventilation performance with components that do not interfere with the existing supply chain, specifically, specialist proportional control valves and flow meters. Employing only standard components increases the robustness of the design, allowing for alternative sourcing of parts for repairs. Furthermore, implementation of standard, 'off-the-shelf' components significantly decreases ventilator cost to manufacture and maintain, increasing access for resource-poor countries. This is critical for low- and middle- income countries where respiratory conditions such as pneumonia, influenza, and tuberculosis remain major causes of mortality. The ability to combine the proposed design with oxygen concentrators, when hospital grade gas supplies are not available, increases the ventilator's functionality and portability. Despite its low-cost, the proposed ventilator design meets performance standards and metrics identified by both international and national governing bodies. For these reasons, it has the potential to answer the unmet global need for increased ventilator capacity.

INTRODUCTION

Atherosclerosis is the fundamental pathology of heart attack and stroke, and the leading cause of death globally [1]. This disease is characterized by lipid-rich and immune cell-dense plaques localized to areas of disturbed wall shear stress (WSS); namely, in areas of the vasculature that produce low or multidirectional WSS. Studies in animal models have demonstrated that low WSS conditions cause development of an unstable plaque phenotype, whereas multidirectional, including oscillatory, WSS produces a more stable phenotype. High WSS, found in straight arterial segments, does not induce atherosclerosis and is recognized to be protective against disease formation. Presently, no diagnostic modality or therapeutic exists that leverages the flow-induced nature of plaque formation. Targeted nanoparticles present an opportunity to address this shortcoming for both diagnostics and therapeutics. Previous work has demonstrated achievable uptake in atherosclerotic plaques, but no such work has shown this uptake as a function of WSS.

To address this need, we aim to (1) identify differential accumulation of nanoparticles as a function of the WSS environment and, in turn, plaque phenotype, and (2) assess what components of plaque may contribute to differential accumulation. We used an ApoE$^{-/-}$ atherogenic mouse model instrumented with a blood flow-modifying cuff, which has been previously shown to induce both low and multidirectional WSS blood flow profiles and, in turn, plaque development [2]. Nanoparticles were developed to passively accumulate within the vasculature, with accumulation kinetics measured via dynamic contrast-enhanced Magnetic Resonance Imaging (DCE-MRI). To assess features of plaque phenotype, smooth muscle intensity was determined via histological analysis.

METHODS

Nanoparticles. Gadolinium-based small molecule contrast agents are common in clinical evaluation of vascular permeability. Here, we used a gadolinium paramagnetic NP-based contrast agent. To be useful in DCE-MRI, these nanoparticles were coated in folic acid. Using a modified polyol synthesis method, [3] we achieved synthesis of folic acid-coated gadolinium (FA-Gd) nanoparticles.

Mouse Model and Nanoparticle Imaging. Five female ApoE$^{-/-}$ mice (Jackson Labs) at 11 weeks of age were placed on an atherogenic diet (Envigo) for two weeks and then instrumented with a tapered blood flow-modifying cuff (Promolding) around the left carotid artery. This cuff induces three WSS profiles: low WSS upstream, high WSS within, and multidirectional WSS downstream of the cuff. At 5 and 9 weeks after cuff placement, the mice were injected with FA-Gd nanoparticles and imaged with DCE-MRI. DCE-MRI was performed using a 2-D gradient echo sequence with two flip angles for calculation of R_1 and generation of K^{trans} maps, which indicate NP permeation into the arterial wall. Two baseline scans were performed to calculate T_1 values prior to injection with the following parameters: TR = 138 milliseconds, TE = 3.48 milliseconds, flip angles of 10° and 30° respectively, 2 averages, 256x256 data matrix, 20 slices each with a 23x23x0.5 mm^3 FOV for a total scan time of 53 seconds. Post-contrast scans all used a flip angle of 30° with the same parameters as above. After completion of baseline scans, NPs were injected through the tail vein catheter, followed by 1 hour of post-contrast image collection. The K^{trans} maps were then generated and readouts were analyzed using a custom MATLAB program.

Histology. To assess features of different plaque phenotypes, histology was performed on all five mice. After imaging at 9 weeks, mice were anesthetized, and perfusion fixed with saline and 4%

paraformaldehyde at mean arterial pressure. The carotid arteries were then excised, embedded in OCT, and snap frozen in -80°C isopentane. Serial cryosections at a thickness of 8 µm were obtained from the aortic arch to the carotid bifurcation of each artery. Co-registration of the histology to the DCE-MRI images and K^{trans} maps was achieved using the aortic arch, cuff region, and carotid bifurcation. Sections were stained for smooth muscle cells using smooth muscle α-actin (ABCAM). Fluorescence imaging of the smooth muscle stain was performed using a Zeiss confocal microscope at 20X magnification. Images were quantified using a custom MATLAB program that employed a grey scale conversion to calculate stain intensity. Histology sections were co-registered to MRI slices using the cuff as a landmark.

Data Analysis. To evaluate NP accumulation in the different WSS regions, NP accumulation was obtained by using maximum K^{trans} values in both the low and multidirectional WSS regions of each mouse at 5 and 9 weeks after cuff placement; K^{trans} from the contralateral carotid artery served as a control. To assess how smooth muscle in each plaque region might influence NP accumulation, stain intensity was averaged over all histology sections for a given co-registered MRI slice (typically four) and correlated with K^{trans}. One to two histology-MRI pairs were identified per plaque region per mouse. All reported values are mean±SD. Correlation was calculated using a Pearson's coefficient. Significance was set at a p-value of 0.05.

RESULTS

K^{trans} maps indicated a higher accumulation of nanoparticles in both diseased segments of the cuffed artery at 5 and 9 weeks (Figure 1) compared to the control artery. Further, there was a significantly higher passive accumulation of nanoparticles in the low WSS region of the instrumented artery at 5 weeks compared to 9 weeks with K^{trans} values of 0.067±0.009 min^{-1} versus 0.046±0.013 min^{-1}, respectively. In the region of multidirectional WSS, K^{trans} demonstrated a nearly identical nanoparticle accumulation between 5 and 9 weeks with mean values of 0.066±0.016 min^{-1} and 0.067±0.0025 min^{-1}. Interestingly, smooth muscle intensity in the inner-most part of the plaques (the "plaque cap") in the low WSS region exhibited a strong inverse relationship with Ktrans (ρ = -0.95, p<0.01), which was not observed in the downstream segment (ρ = -0.03, p=0.95) (Figure 2). In addition, there is an overall lower intensity of smooth muscle in the low WSS region compared to the multidirectional WSS region with intensity values of 0.016±0.010 versus 0.026±0.015, respectively.

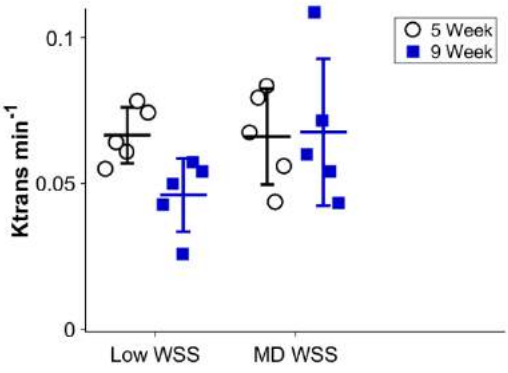

Figure 1: NP accumulation as determined from K^{trans} in the low (upstream) and multidirectional (MD; downstream) WSS regions of the instrumented carotid artery at 5 and 9 weeks after cuff placement. Each point represents the max K^{trans} from one mouse (n=5 mice) and bars are mean±SD.

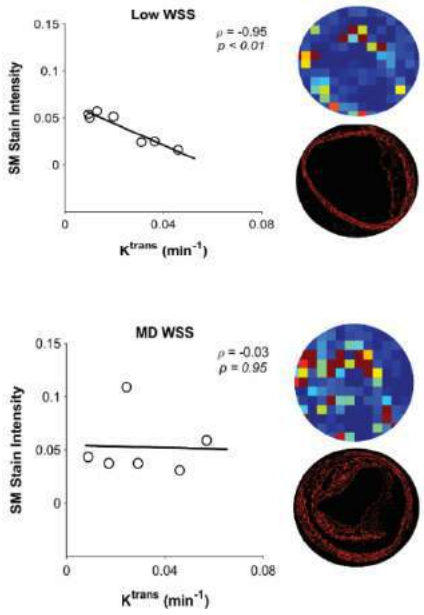

Figure 2: Smooth muscle intensity as a function of K^{trans} in the low and multidirectional WSS regions. Best-fit lines are given in black. Pearson's correlation coefficient (ρ) and p-value are given in the upper-right coroner of the plots. A representative K^{trans} map and smooth muscle histology section for each artery region is also shown.

DISCUSSION

To our knowledge, this is the first study to examine the accumulation of nanoparticles in different regions of atherogenic WSS. We did not see a difference in NP accumulation between the low and multidirectional WSS regions at 5 weeks when plaques are at an intermediate stage, suggesting no direct effect of the flow environment. However, at 9 weeks when plaques are considered fully developed in this model, there was lesser accumulation in the upstream (low WSS) unstable plaque region compared to the downstream stable plaque region. This suggests that plaque phenotype is the principal driver of NP accumulation, although the flow environment is an important determinant of plaque phenotype. Furthermore, we found a negative correlation between nanoparticle accumulation and smooth muscle in the fibrous cap region of the unstable plaque, but not the stable plaque. This may indicate a difference in smooth muscle organizing in the unstable plaque that may physically inhibit the NPs from entering the plaque compared to the stable plaque region, which had smooth muscle diffuse throughout the plaque. Another possibility is that this inverse correlation of smooth muscle with K^{trans} somehow relates to endothelial function. A decline in smooth muscle, particularly in the plaque cap, is indicative of a more unstable plaque that might correspond with a more dysfunctional endothelium. Additional work is needed to evaluate endothelial function and other constituents in these plaques that may determine differential NP accumulation.

INTRODUCTION

Pulmonary diseases are responsible for significant socioeconomic strains, affecting millions and costing billions in the U.S. alone. Research efforts focused on the understudied subject of lung mechanics are more indispensable than ever before, especially given the respiratory-damaging nature of pandemics, as seen with the COVID-19 virus. Restrictive and obstructive pulmonary diseases remodel the structure of tissue and alter function [1]. Inverse finite element modeling has proven to be a promising approach for investigating the relationships between loads and deformations, and can offer insights to understand how deviations in diseased states affect respiratory function [2]. To date, however, inverse pulmonary models have either been too simplistic and lacking in local-level resolutions (i.e., zero-order/compartment-based models) [3], or too complex and expensive (e.g., 4D computed tomography) [4], prohibiting systematic conclusions to analyze fundamental mechanical variations, such as positive-pressure versus physiologically-relevant negative-pressure respiration.

To address these limitations, we introduce an inverse finite element (FE) lung model based on local 3D digital image correlation (DIC) measurements of the inflating organ, dynamically interfaced with synchronous global pressure-volume data. The resulting material parameters, calibrated through experimental testing, represent the compound contributions of the parenchyma, visceral pleura, and airways by employing a simplified reduced order surface model of the lung. The resulting physiologically-relevant in-silico lung model can be used to optimize ventilation strategies for the clinic through comprehensive parametric studies, assess the degenerated mechanics in diseased states, and guide better physics-based designs of compliant lung-replicating ventilator components that are in unprecedented high demand.

METHODS

In this experimental-computational proof-of-concept study, a freshly excised porcine lung was inflated with 900ml of air at 15 breaths-per-minute using a validated custom-developed pressure-volume controller and data acquisition setup [5]. Following the 3D-DIC procedure previously described [6], several preconditioning inflation-deflation cycles were performed, and the real-time deformation of the lung was recorded (Figure 1a). A finite element model was generated from the visceral pleura surface geometry of the right lung lobe in the uninflated configuration. Discretization and 3D membrane element formulation was implemented in the commercial FE-package Abaqus (~5,000 M3D3 elements). The organ-level pressure data was applied as a dynamic load to the model (Figure 1b). The DIC displacement field, probed at 1mm evenly distributed point clouds on the parenchymal surface, was interpolated using the k-nearest neighbor algorithm [7]. The interpolated DIC displacements were imposed as boundary conditions in the FE model and used to evaluate the root mean square error between experimental and simulation-based displacement predictions.

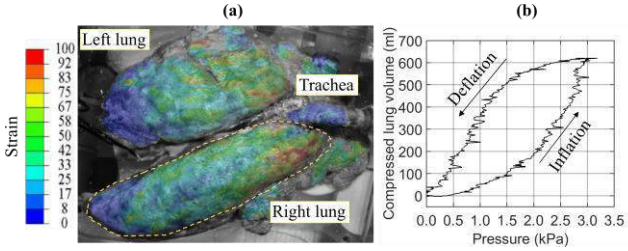

Figure 1: Experimental setup using air-inflated porcine lung interfaced with synchronous Digital Image Correlation (a) and pressure-volume measurements (b).

The compressible Mooney-Rivlin hyperelastic constitutive response was used as the material model of the lung. The strain energy density was defined as $W = C_{10}(\bar{I}_1 - 3) + C_{01}(\bar{I}_2 - 3) + \frac{1}{D_1}(J-1)^2$, where $\bar{I}_1$, $\bar{I}_2$ are the first and second invariants of the deviatoric deformation tensor, J is the Jacobian of deformation gradient, and C_{10}, C_{01}, and D_1 are the unknown composite material parameters. The optimal value of these material parameters was estimated with a fully automated optimization pipeline linking Matlab, Abaqus, and Python. Two broad classes of gradient-based and gradient-free optimization algorithms were studied (trust-region-reflective and particle-swarm-optimization). To avoid local optima, the optimization algorithm was run from multiple initial estimate points, randomly selected from the search space $C_{10}, C_{01} \in [1,200]$ kPa and $D_1 \in [10^{-2}, 10^{-4}]$1/kPa.

RESULTS

Table 1 lists the resulting optimal material parameters. The displacements, maximum in-plane principal strains and stresses obtained from characterizing DIC were contrasted with the calibrated model (Figure 2). The aerated lung's anterior portion exhibited the greatest deformation with a maximum of 25mm (Figure 2a). The experimental stress plot was obtained by running the DIC displacements through the FE model with the parameters listed in Table 1. The compressibility parameter D_1=13.4×10^{-4}1/kPa corresponded to a bulk modulus of 1.5 MPa and the small displacement shear modulus was μ_0=2C_{10}=272 kPa. The parameter C_{10} (controlling the contribution of the $\bar{I}_1$) was two orders of magnitude greater than C_{01} (linked to $\bar{I}_2$). The average error between experimental DIC and the optimized inverse FE model displacement was 2.3 mm, less than 10% of the maximum lung distension. To compare the validity of the resulting optimal material properties, a generic balloon made of the same predicted material was compared against the classic single-compartment lung model [2], where the elastance values predicted by these two methods were in close agreement.

Table 1: The optimal material properties and the averaged error

C_{10} (kPa)	C_{01} (kPa)	D_1 (×10^{-4}/kPa)	Error (mm)
136.5±0.3	1.0±0.01	13.4±0.16	2.3

DISCUSSION

This study investigated, for the first time, an inverse FE modeling approach to generate the compound elastic properties of the whole lung organ using DIC measurements. The proposed reduced order surface model of the lung is more practical than computationally demanding 4D CT-based works [4,8], and is more insightful than simple compartment-based inverse modeling studies [2, 3]; compared to the latter, our approach predicts a similar shear modulus while enabling evaluation of regional pulmonary behaviors previously unaccounted for. We find that while assuming a homogeneous isotropic hyperelastic constitutive response can represent the overinflated behavior of the lobes, it is not as successful in resolving complex strain and stress regional heterogeneities. While this current study yields a new advancement for pulmonary biomechanics research, we will examine a heterogenous and/or anisotropic material behavior to improve model performance and acknowledge that this method may come with at a higher computational cost.

The preliminary results obtained here offer promise to improve the design of bladder/balloon shaped components prevalent in novel didactic and clinical ventilator systems [9,10]. Currently, the material properties of these lung-replicating components are not selected based on rigorous physiological calculations. This may significantly hinder the effectiveness of these ventilators once applied to actual patients in need of respiratory support. Our inverse analysis framework can effectively produce pulmonary-based material properties for ventilator design.

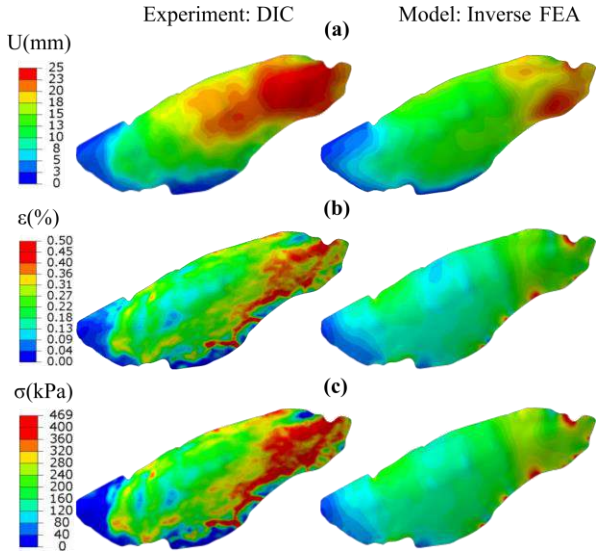

Figure 2: Experiment and inverse FE modeling displacements (a), major strains (b), and major stresses (c).

A limitation of this study is the use of one lung to formulate this pipeline, restricting the conclusive statistical relevance of predicted material properties and average error. Nonetheless, this novel proof-of-concept study demonstrates the advantages and pitfalls in pulmonary inverse modeling based on DIC data.

Future simulations are aimed at applying the developed inverse modeling framework to systematically establish the regional behavior and governing physiology of the lung. This DIC-informed computational framework can be used to evaluate potential differences in respiratory mechanics and function in healthy versus diseased states. Altering inflation volumes in-silico will enable us to assess how ventilation methods effect pulmonary deformations and stretches, facilitating clinical strategies to minimize ventilation induced lung injury.

In summary, this study introduces inverse FE modeling for the complex organ-level deformations during the breathing cycle. While the results are indicative of promising applications for the method, further investigations calibrating the constitutive response will improve the accuracy and efficacy of the model to enable clinical applications and benefit patient care.

INTRODUCTION

Over 90% of total hip arthroplasties (THAs) in the U.S. are fixed by osseointegration. Osseointegrated implants offer a significant reduction in revision risk and an extended implant lifetime [1]. This reduction of risk is critical, because the average age of implant recipients is decreasing [2]. However, the use of osseointegration in knee implants, where the majority of the implant surface interacts with cancellous bone, is less common. Efficient and inexpensive methods to evaluate osseointegration of new scaffold designs is important.

The goal of this study was to evaluate the potential of bioreactors as a platform to evaluate bone ingrowth into osseointegrated scaffolds. Scaffolds with and without mesenchymal stromal cells were implanted into trabecular bone implants and cultured for six weeks to quantify bone ingrowth and interface stiffness mechanics between the bone and the scaffold.

METHODS

Medical grade porous Ti6Al4V (Ti64) scaffolds, approximately 5 mm diameter and 10 mm long, were additively manufactured using a selective laser melting powder bed process and subsequently treated by hot isostatic pressing (HIP), cleaned, gamma sterilized, and autoclaved.

Bone formation into the porous scaffolds in a bioreactor was quantified. Twenty-one cylindrical bone explants were prepared from porcine cervical vertebrae (C2-C4) with an 8 mm diamond tipped coring bit. A 5 mm hole was drilled into the center. Explants were then cut to a length of 10 mm with flat, parallel ends.

Eight scaffolds were placed in a 12-well low attachment plate with media added to the depth of the scaffold. Each scaffold was seeded with 250,000 porcine mesenchymal stromal cells (MSCs) pipetted dropwise on the top surface and incubated overnight to allow attachment. Thirteen scaffolds were used without cell seeding. Each prepared scaffold was inserted into the inner hole of a trabecular bone explant. Once prepared, five explants were immediately fixed to provide a non-cultured control group. The remaining sixteen explant-scaffold constructs were cultured in a bioreactor for 6 weeks. The constructs were subjected to sinusoidal vibration at a frequency of 50 Hz and peak acceleration of ±0.3 g for 30 minutes twice daily, 5 days/week. At the end of the first, third, and fifth weeks of culture, media was supplemented with 0.5 mM alizarin complexone, 0.05 mM xylenol orange, and 0.08 mM Calcein, respectively, for 24 hours to label forming bone for dynamic histomorphometry.

Following culture, the explants and scaffolds were cut in half transversely using a diamond wafering saw. One half was stored at -20° C for later mechanical testing, while the other half was fixed in formalin and embedded for histology. Multiple thick sections (200-500 μm) prepared from each fixed sample were polished stepwise ending with 0.25 μm diamond paste. Eight locations around the perimeter of the scaffold were imaged with confocal microscopy (Nikon C2+) to visualize fluorochrome labels. The area of the bone within the scaffold pores was quantified using ImageJ (NIH) by manual tracing.

Mechanical properties of the interface were evaluated using a push-out test. Displacement was applied to the titanium scaffold at 3 mm/min (Bose Electroforce 3300, Eden Prairie, MN). The force and displacement were recorded continuously. Interface stiffness was calculated as the slope between 25% and 90% of the maximum force divided by the total surface area of the bone-implant interface. The push-out strength was determined by dividing the maximum force applied during the test by the surface area of the interface.

Groups were compared using a Kruskal-Wallis test due to non-normal distributions of the data. Improper embedding prior to mechanical testing reduced each group from eight to five samples. Two samples were excluded from image analysis due to over-polishing of the slides. One of the samples that was used for ingrowth image analysis

was unable to be paired to mechanical testing data due to improper embedding.

RESULTS

New bone was present in the scaffold following six weeks of culture. Fluorochrome stained tissue was visible under confocal microscopy, indicating bone formation was occurring during the culture period (Fig. 1). Fluorochrome staining was present in every section viewed for cultured samples, but none was present in uncultured controls. Staining was most common along cut surfaces of the bone, however, fluorochromes were also detected along the surfaces of trabeculae. Triple labels were found within the trabeculae, indicating active bone formation for all six weeks (Fig. 1). Within the scaffold pore space, staining was diffuse rather than linear, indicative of a woven bone morphology. No differences in ingrowth area were seen for the no cell and pre-seeded culture groups (Fig. 1).

The interface stiffness and push-out strength were compared between groups and correlated to ingrowth area. No significant differences were seen between groups for either interface stiffness or strength (Fig. 2A and 2B). The interface stiffness increased with the total area of bone ingrowth ($p = 0.03$) (Fig. 2C). In contrast, there was no correlation between strength and ingrowth area (Fig. 2D).

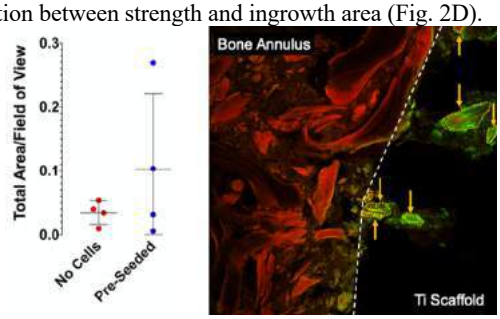

Figure 1. New bone was stained using calcium-chelating fluorochromes at weeks 1, 3, and 5. These fluorochromes were used to determine when bone formed within the porous scaffold over the 6-week culture period. Ingrowth area was measured by outlining regions manually in ImageJ.

DISCUSSION

We developed a method to investigate osseointegration of porous scaffolds using *in vitro* culture in a bioreactor. We found that bone formed in the pores of additively manufactured Ti64 scaffolds during a six-week culture period, as verified by dynamic histomorphometry. To our knowledge, this is the first demonstration of osseointegration in a bioreactor system.

Fluorochrome labeling showed new bone formation in the pores along the outer surface of the scaffold. Normal bone marrow morphology was maintained within the bone explant, providing a source of mesenchymal stromal cells for bone to form within the scaffold pores. Bone formation in the bioreactor was less robust than in *in vivo* experiments. The depth of bone formation from the surface was limited to the first 500 μm of the pore space. In contrast, *in vivo* studies found bone ingrowth up to 5 mm into the scaffold in eight-week studies [3]. These differences are likely due to differences in bone behavior *in vivo* vs. *in vitro* as well as the absence of mechanical loading. While the inertial loading applied to this bioreactor has been shown to induce bone formation [4,5], it relies on the stimulation of the marrow compartment rather than osteocytes. In contrast, compressive and shear loading across the bone-scaffold interface could induce damage and osteocyte signaling in order to prompt a localized bone remodeling cascade.

In the absence of the normal fracture healing response, it is unclear if a sufficient number of cells would migrate from the bone marrow to achieve osseointegration. We tested whether the presence of MSCs prior to culture would improve bone ingrowth by providing a chemokine gradient or small bone deposits on the scaffold surface. MSCs showed no impact on bone ingrowth, possibly due to the limited number of cells present in the scaffold space at the start of the experiment or due to inability of cells to migrate freely in the scaffold pore space. In fracture healing, an initial hematoma forms providing both a chemokine-rich fibrin clot and a matrix for 3-D cell migration from the native bone. Providing a similar physical junction between the bone and scaffold could provide better insight as to the benefit of using MSCs for pre-seeding.

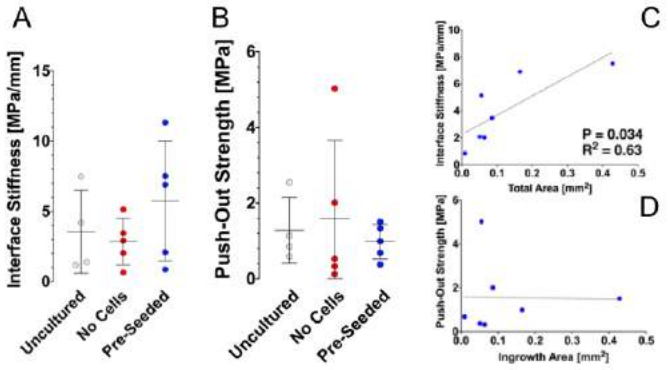

Figure 2. Push-out testing was used to determine interface stiffness (A) and push-out strength (B) of the bone at the bone-scaffold interface. Interface stiffness correlated with the total bone area measured within the pore space ($p = 0.03$) (C). Pushout strength showed no correlation (D).

This analysis shows that interface stiffness increased with ingrowth area, confirming that more bone within the scaffold space results in a stiffer interface. Further mechanical analysis could help to determine how the depth of bone in the pores impacts this relationship, as bone in the scaffold pores was not always directly abutting the original bone annulus. Mechanical properties for the uncultured control were likely a result of interference fit. Total area did not have an impact on strength, but this could be a result of the quality of the new bone volumes rather than their size alone.

Our results demonstrate that bioreactor culture has potential to be used as an assay to assess biological and mechanical factors that affect osseointegration. Relatively large numbers of scaffolds can be evaluated in an *in vitro* experiment without the expense of animal husbandry and with greater control over mechanical loading. As such, this *in vitro* method could improve screening of scaffold designs prior to animal testing, providing more precise control over external variables in order to extrapolate interactions between scaffold morphology and loading.

INTRODUCTION

Tibial avulsion fractures occur as a result from high tension within the anterior cruciate ligament (ACL) which can be seen in adults and children in similar proportions [1]. These injuries result in knee joint instability often requiring internal surgical fixations to regain normal knee biomechanics such as extension and flexion [2]. Treatment depends on the severity of the tibial eminence avulsion fracture. Type III fractures are generally managed with surgical fixation. Two main suture types exist for surgical fixation: UltraTape, a suture tape and UltraBraid, a cord-like suture. Two different suture configurations, the bridge and sling, are used with the suture fixation techniques. (Figure 1) UltraTape exhibits greater stiffness while UltraBraid has greater material recovery three minutes after removing a load [3]. The objective of this study was to quantify tibial avulsion fragment motion based on the repair suture type and configuration to provide the optimal knee stability following treatment.

METHODS

Twenty-eight intact fresh-frozen unpaired mature porcine knees (Hampshire, 7-8 months) were used for testing. Knees with congenital anomalies or arthritis were excluded. All knees were frozen at -20°C and thawed the night before testing. A type III tibial eminence avulsion fracture was created with the remaining soft tissue removed, creating a femur-ACL-tibia complex (FATC). UltraTape (Smith & Nephew) and UltraBraid (Smith & Nephew) were used for suture types. The fracture was fixed using one of the suture fixation construct groups: UltraBraid Bridge, UltraBraid Sling, UltraTape Bridge, and UltraTape Sling. Seventeen markers were placed on the tibia and femur of the porcine knee and on the materials testing machine (Model 5965; Instron Corp., Norwood, MA, USA) that underwent tensile cyclic loading. Two cameras were set up so that the digital motion tracking system (Spica Technology, Kihei, Maui HI) could capture all markers. The three-dimensional marker coordinates on the specimen were determined using DMAS7. The specimens were kept moist with physiologic saline solution during testing to prevent desiccation of the soft tissues.

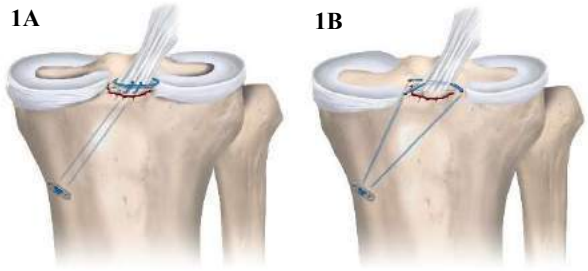

Figure 1: The bridge (1A) allows for the suture to wrap around the ACL and cross over the fracture whereas the sling (1B) utilized a 4-point fixation that goes through the ACL [4][5].

For each suture fixation technique, seven specimens underwent 2 Newtons (N) preload, 2-10 N preconditioning (30 cycles), and 10-50N cyclic loading for 500 cycles. The marker data was then run through a custom MATLAB program that calculates the translational and rotational data in the coronal, sagittal, and transverse planes of the tibia throughout the cyclic loading. Positive axes were defined as a vector pointed in the medial direction, a vector pointed in the posterior direction, and the cross product of the first two vectors pointed in the distal direction.

The translational and rotational data was tested for normality for each of the specimens at the last loading cycle at 50 N. Normal

distribution was assessed using a Shapiro-Wilk goodness of fit test in JMP (SAS, Cary, NC). A one-way ANOVA was utilized with a post-hoc Tukey-Kramer HSD test. Statistical significance was set at $p < 0.05$.

RESULTS

The UltraBraid Bridge group displayed a difference of 189% in vertical displacement compared to both the UltraTape Sling and UltraBraid Sling groups at the last cycle of 50 N. A 115% difference exists between the UltraTape Bridge group and the UltraTape Sling group. Lastly, a 116% difference is found between the UltraBraid Sling group and the UltraTape Bridge group. Three of the seven specimens in the UltraBraid Sling group failed before reaching cycle 500. For this group, data was taken from the last cycle at 50 N and combined with specimens that did not fail at cycle 500. For this reason, specimens with insufficient data could not be used. A significant difference exists between the UltraBraid Sling and UltraBraid Bridge groups, the UltraTape Sling and UltraBraid Bridge groups, the UltraBraid Sling and UltraTape Bridge groups, and the UltraTape Sling and UltraTape Bridge groups. (Figure 2)

For all construct groups, rotational data was, also, assessed. (Figure 3) No significant difference exists for sagittal rotation. However, a significant difference is found in coronal rotation of the tibial eminence fragment. From the post-hoc test, a significant difference exists in the same construct group pairs as in vertical displacement. The UltraBraid Bridge and UltraBraid Sling groups exhibit a 123% difference in coronal rotation. A 115% difference in coronal rotation is seen between the UltraBraid Bridge group and the UltraTape Sling group. The UltraTape Bridge group and the UltraTape Sling group showed a 99% difference in coronal rotation. Lastly, a 108% difference is found between the UltraBraid Sling group and the UltraTape Bridge group in coronal rotation.

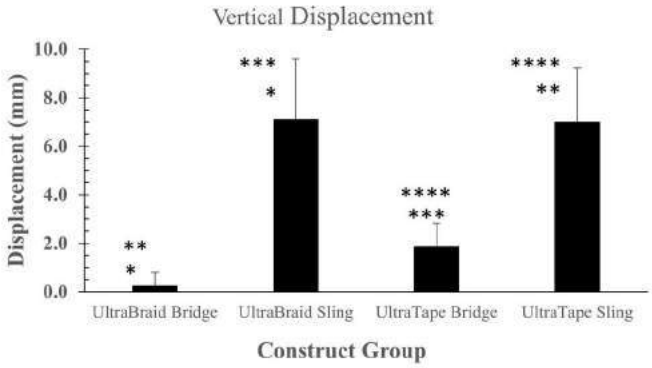

Figure 2: Mean ± S.D vertical displacement of each construct group at the last cyclic loading cycle of 50 N. Significance found at $p \leq 0.001$ between marked groups.

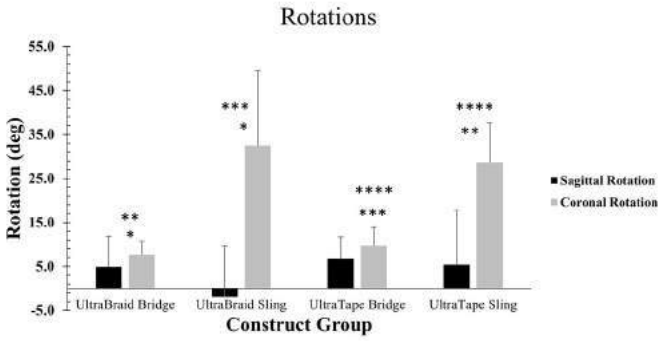

Figure 3: Mean ± S.D sagittal and coronal rotations shown at the last cyclic loading cycle at 50 N. Significance found at $p \leq .007$ between marked groups.

DISCUSSION

Vertical displacement shows a significant difference between the suture sling and the suture bridge construct groups. The suture bridge configuration reduces motion of the FATC more than the suture sling configurations, as expected. There is no significant difference in sagittal rotation for any construct groups because the bridge configuration goes over the superior surface of the fragment to prevent rotation. The sling configuration goes through the fragment body and thus contributes less of a moment to restrict fragment rotation. In the clinical setting, the suture sling or suture bridge setup limits inferior or superior rotation of the FATC. Suture slings exhibit greater movement, specifically in coronal rotation. As more force is applied, the FATC shifts medially which may interfere with the ACL's ability to properly heal and regain full functionality of knee extension and flexion.

When comparing suture types, no significant differences are seen between UltraBraid or UltraTape configurations for any movements. It can be concluded that UltraTape provides slightly more stability than UltraBraid as none of the UltraTape Sling specimens failed during cyclic loading while some UltraBraid Sling specimens did.

Bridge suture techniques should be considered over sling techniques during arthroscopic surgeries for tibial eminence fractures. Clinicians can use this tibial eminence fragment tracking using other imaging modalities, such as MRIs, to evaluate future fragment fixations focusing on vertical displacements and medial movements.

EFFECT OF HELMET ON GENDER-BASED CERVICAL SPINE SEGMENTAL RESPONSES IN REAR IMPACT

INTRODUCTION

Studies have reported the susceptibility of females to Whiplash Associated Disorders [1] [2]. It is known that morphological differences exist between female and male cervical necks [3]. While the use of the head supported mass is less common in the civilian populations, military personnel use the head mounted devices (helmet, night vision goggles, etc.) in their activities. Any added head supported mass from the helmet and its attached devices adds to the in vivo head mass. This additional weight on the human head-neck system alters the load path, affects load-sharing, changes the internal forces and moments and kinematics on the osteoligamentous cervical spine column under accelerative and chronic loads [4]. While many studies have been conducted to delineate the role of gender in whiplash injury via experiments, clinical investigations, modeling and epidemiological research, the effect of the added head mass on segmental motions have received less attention. This study was conducted to quantify the differences in kinematic responses, as defined by the range of motion metric, between mid-sized male and female models with and without the helmet using three-dimensional finite element modeling under rear impact accelerative whiplash loading.

METHODS

A mid-size male head-neck finite element model was developed and validated using experimental data [5][6]. It simulated the human head integrated with a detailed cervical spinal column model, developed with cervical and first thoracic vertebrae, intervertebral discs, endplates, facets, ligaments, and musculature. The skull, cortical bones, endplates and ligaments were modeled using shell elements, and the cancellous bone, annulus, nucleus and facets were modeled using solid elements. The neck muscles were simulated using anatomical origin-insertion locations as one-dimensional beam elements. The material properties for each of these components were obtained from literature studies [7][8]. The mid-size female model was developed by morphing the male model using respective anatomical ratios of male and female head and cervical spines [9]. The mapping block-based mesh morphing approach was used for the development of female model [5].

A coordinate measuring machine was used to describe the geometry of the helmet. A collection of coordinates was registered at each point of contact of the probe with the external part surface. The inner part of the helmet was lined with seven foam pads. The helmet and inner foam were modeled as solid hexahedral elements, and the material properties were based on literature studies [10][11]. The mass of the helmet was 1.47 kg. The helmet model was strapped to the male and female head-neck finite element models using a chinstrap, modeled using solid elements. Automatic surface-to-surface contact was defined between the head and helmet. The models were exercised under rear impact (G_x loading) by inputting a velocity pulse of 2.6 m/sec to the T1 vertebra, similar to field input. A total of four cases were simulated for male and female anthropometry, with and without helmet. The male model without helmet were validated with the experimental data [3]. The segmental motions were obtained from all subaxial cervical spinal levels, and the effects of gender and helmet mass were investigated. The segmental range of motion data from the helmeted models were normalized with respect to the respective models without the helmet to quantify the effect of helmet, motions from the female model was normalized with respect to the male model to determine the role of gender. These data and validation are given in the results section.

RESULTS

Model validation: The male head-neck model without helmet was validated using whole body human cadaver sled tests conducted in our laboratory [3]. The acceleration profiles of the T1 vertebra along the x, y, and z axes from the sled experiments were used as input to the model. The segmental kinematic response from the simulation was compared to the experimental data. The model-predicted ranges of motion were within mean ±1 standard deviation corridors of experimental motions (Figure 1).

Gender-based variations: The female model compared with the male model showed an increase in the range of motion at all segmental levels for both the cases of without and with helmet; however, the maximum increase occurred in case of the helmeted condition. In the

case of with helmet, the female model showed an increase of 11.6%, 9.4%, 11%, 10.1%, and 8.2% at the C3-C4, C4-C5, C5-C6, C6-C7, and C7-T1 levels, respectively.

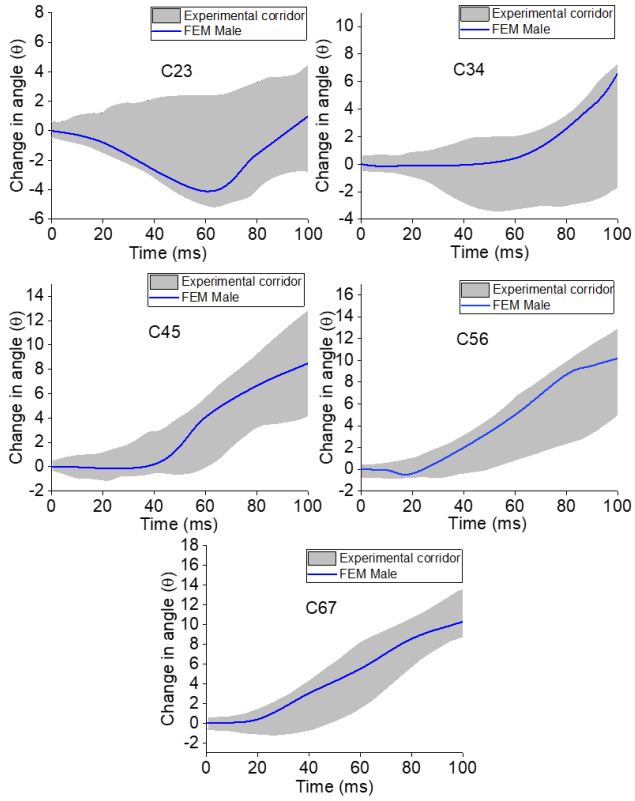

Figure 1: Model validation for segmental angulations response from C2–C3 through C6–C7 levels. The shaded region represents the experimental corridors from human cadaver sled tests.

Helmet-based variations: The segmental motion of the helmeted model increased when compared to the case without helmet model. In the male model, the increases were 12.2%, 12.4%, 29.2%, 19.6% and 13.8% at the C3-C4, C4-C5, C5-C6, C6-C7, and C7-T1 levels, respectively, whereas the increases in the female model were 14.1%, 13.8%, 30.1%, 20.5% and 14.9% at the corresponding levels of C3-C4, C4-C5, C5-C6, C6-C7, and C7-T1 levels, respectively (Figure 2).

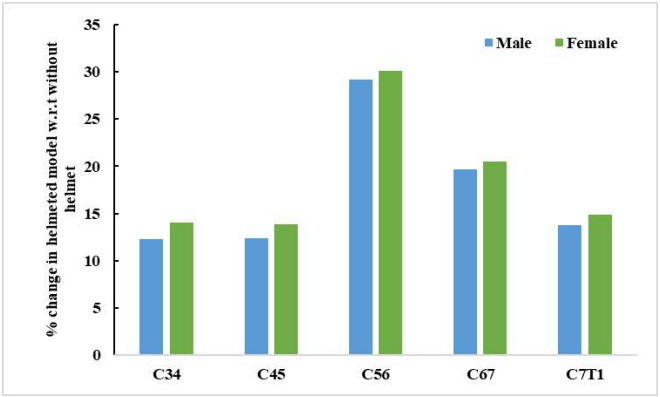

Figure 2: Segmental range of motion comparison between without and with helmet for male and female models

DISCUSSION

The objective of the study was to determine the segmental responses to elicit the role of gender and helmet on the segmental responses of the cervical spine from rear impact. The acceleration pulse was applied to the T1 vertebra, a process used in other modeling and isolated head-neck complex human cadaver studies. The segmental response in the form of the range of motion is a clinical measure for assessing the mobility of the spine, and hence, it was selected as a parameter for the assessment of gender and head supported mass. While not described here, in the initial stage of the pulse, the upper and lower cervical spines sustained flexion and extension. This combination representing a reverse curvature within the lordosis of the cervical column is attributed to the inertia of the human head and the transmission of the accelerative pulse from the distal end of the neck. Compared to all the spinal levels, the C5-C6 and C6-C7 regions experienced greater segmental ranges of motion. This is attributed to the local curvature of the cervical spine. These lower spinal levels are known to be the affected segments in whiplash patients from low severity impacts, similar to the velocity of the pulse used in the present study. In the case of gender response comparison, the female spine responded with a greater segmental range of motion than the male spine, a phenomenon observed in human cadaver studies and attributed to increased susceptibility of females to WADs [12]. This is attributed to the due to the differences in the morphology of the female spine from the male spine, a variable included in the present study. It should be noted that the female model was not a scaled-down version of the male model; instead actual level geometrical variations were included in the present female head-neck model. Thus, the results are more realistic than a simple male-to-female modeling approach, commonly adopted to study biomechanics of female spines. In the case of the helmet-based variations, the helmeted condition resulted in increased segmental motions compared to without helmet, and this is attributed to the center of mass shifting anteriorly and inferiorly with the added head mass. Any increase to the in vivo head mass and shift in its center of gravity away from its natural center of rotation elevates the kinematics and may predispose to injury in females. In summary, the present modeling study provides data on the role of gender and helmet on segmental kinematics rear impact.

INTRODUCTION

Potential mechanisms of sudden cardiac death (SCD) in the anomalous aortic origin of coronary artery (AAOCA) are indeed dynamic and complex. Among these mechanisms are proximal coronary hypoplasia, dynamic ostial narrowing, intussusception of the intimal wall of the intramural segment, and interarterial compression during exercise. However, lack of understanding and inaccurate evaluation of the exact mechanism leading to ischemia and/ SCD has been the critical barrier to risk stratification. The clinical data has shown that the decision to operate and the type of surgery performed for the same condition in AAOCA patients can vary due to a lack of clarity on surgical approaches that target the offending mechanism. Among the morphological variables derived from advanced imaging in AAOCA patients, the main substrates are ostial stenosis, longer intramural length, and high origin of the ostium that correlate with ischemia[1]. To better understand these correlations, in the current study, we leverage large advanced imaging data of patient-specific morphological biomarkers to create a predictive model by quantifying the correlations and severity of each morphological variables to ischemic burdens. This model can potentially be a validated source for risk stratification, need for surgery, and type of surgery. This will be done using patient-specific 3D-printed models and subject them to the flow study, developing a mathematical model from fluid dynamics that matches the experimental measurement, and establish and validate the predictive model in a separate group of patient models.

METHODS

In this progressing study, we use the largest single-institutional patient and advanced imaging registry on AAOCA to identify a representative subset of AAOCA patients with and without clinically documented ischemia. IRB approval was obtained for case studies in a patient with AAOCA-L presented with repeat SCD after initial unroofing, and a second surgical intervention, translocation related to the pillar with the subsequent resolution if ischemia. Patient-specific biomechanical 3D-printed models were connected to a left heart flow simulator detailed in the previous study[2]. Temporal and spatial variation of flow rates and dynamic pressure are obtained at different locations along the proximal anomalous coronary artery throughout the cardiac cycle using catheter-based pressure measurement and transonic flowmeters. Details of the in vitro flow study can be found in our previous work [2]. The cumulative effect of all risk variables is shown in pressure drop along the proximal coronary. However, to investigate and quantify the contribution of each morphological or physiological risk factor to the ischemic burden and specific impact on fractional flow reserve (FFR), and instantaneous flow rate (IFR) a mathematical model for sensitivity analysis is being developed.

Using static and dynamic data acquired from in vitro flow study, a mathematical model is being built from fundamental fluid dynamics concepts and will be validated with clinical in vivo and in vitro data. The weight of morphological variables and their interactions on FFR and total pressure drop are represented by coefficients which is derived using regression analysis and machine learning application.

FFR is the main parameter to quantify the severity of ischemic burden in AAOCA and is essentially normalized pressure given as either the averaged or instantaneous ratio P_d/P_a where P_d is the distal pressure and P_a is the aortic pressure measured simultaneously along the aortocoronary path to capture pressure losses as blood flows through the lesion. From fundamental fluid dynamics, it is known that the pressure drop is associated with three major

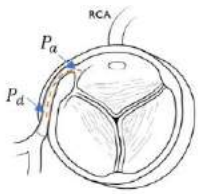

Figure 1 AAOCA-L ischematic

components including the viscous friction effects, the blockage effect (stenosis), and the flow unsteadiness effect[5]. This is generally captured with the unsteady Bernoulli's equation.

$$P_d(t) - P_a(t) = \frac{1}{2}\rho\left({V_a}^2(t) - {V_d}^2(t)\right) - \int_a^d \rho\left(\frac{dV}{dt} + k_f\frac{V}{D}(t)\right)ds - k_s\rho{V_o}^2(t) \quad (1)$$

In Equation (1) The first term on the right side accounts for dynamic pressure difference between points (a) and (b) in Figure 1, the second term accounts for losses due to unsteadiness in the flow and friction losses and the last term is losses from stenosis. Different flow features, including the blood viscosity, flow rate, and flow profile as well as the blockage morphology, are essential. In Equation 1, t is time, D is the internal diameter of the artery, ρ is the fluid density, V is instantaneous velocity throughout the cardiac cycle and k_f and k_s derived empirically. The effect of each variable or combination of them is identified using regression analysis to calculate α, β, and γ presented in Equation 2. By finding these coefficients by matching pressure drop measured from the experiment on different AAOCA models and theory, the mathematical model will be ready to get validated.

$$\Delta P(t) = \boldsymbol{\alpha}\Delta p(t)_{friction} + \boldsymbol{\beta}\Delta p(t)_{stenosis} + \boldsymbol{\gamma}\Delta p(t)_{unsteadiness} \quad (2)$$

RESULTS

Flow study was performed for the patient with AAOCA-L, and 3.5 mm intramural course, passing through a thickened intercoronary pillar (1A-D in figure 2), presented with repeat SCD after initial unroofing (2A-D), and coronary translocation to resolve recurrent ischemia related to the pillar with the subsequent resolution if ischemia (3A-D). Patient 3D-printed models were connected to a left heart flow simulator detailed in the previous study[2]. Flow studies showed FFR of 0.7 in the distal intramural segment preoperatively consistent with ischemia (1D), FFR less than 0.8 in the proximal mediastinal segment after unroofing (2D), consistent with persistent ischemia related to compression by the thickened pillar, and normal FFR at all locations after translocation (3D). From this preliminary data, the importance of resolving patient-specific mechanism of ischemia during surgery for AAOCA is illustrated using biomechanical flow-modeling. This methodology is the basis for the mathematical modeling and sensitivity analysis.

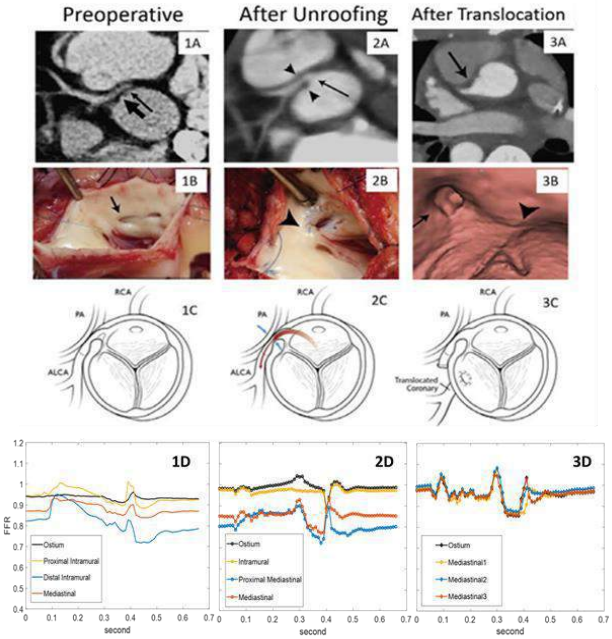

Figure 2 Importance of resolving patient-specific mechanism of ischemia after surgery

for the pre-operative case, the mathematical model was created using Equations 1 and 2. Pressure drop for stenosis, friction, and unsteady flow was calculated using measured flow rate along the anomalous coronary artery covering ostium to the distal intramural course. Coefficients $(\alpha,\ \beta,\ \gamma)$, was achieved by matching the pressure drops with the pressure drop acquired from in vitro flow study for point (a) to (d). In Figure 2, the pressure drop of the theoretical model and experiment is plotted in black, the FFR pair are also shown in purple, they show good agreement throughout most of the cycle. This is an ongoing experiment, and these empirically derived coefficients for the effect of stenosis, friction, and flow unsteadiness will be derived for other AAOCA models including postop unroofing and postop translocation to then be applied for regression analysis.

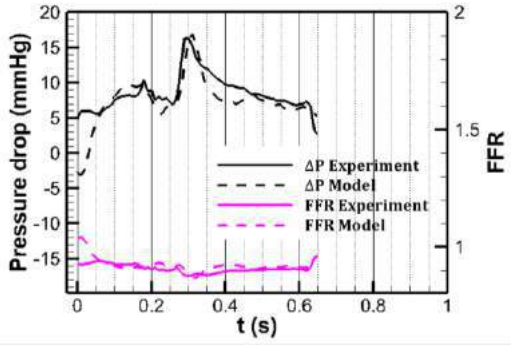

Figure 3 Pressure drop and FFR from in vitro study and mathematical modeling

In continuing this study, AAOCA patient's registry will be used to categorize models based on the main morphological variables; intramural lengths and ostial stenosis. A linear mixed model will be applied with 1) outcome being FFR; 2) exposures being intramural length, ostium configuration, location of FFR measure, and interactions between a pair of these three variables. Technically, the model can be expressed as

FFR = b0 + b1 x intramural length + b2 x ostial configuration + b3 x intramural length x ostial configuration + b3 x location of FFR measure + random effect + error term

DISCUSSION

Studies have been done on establishing a physics-based model of pressure drop and myocardial FFR for coronary stenosis[3,4]. However, this study is unique in using patients specific AAOCA models to develop a predictive theoretical model for FFR. This preliminary data shows promising results with the presented terms to capture the flow behavior in the experiment, predicting pressure gradient over the cardiac cycle and matching the model and experimentally derived FFR. Although it is showing the gradients over the cardiac cycle, by incorporating FFR from dynamic data related to exercise or hyperemia, prediction will be enhanced for impact of exercise which is a critical measure in AAOCA. We anticipate that creating a dataset input using all the categorized ischemic and non-ischemic models utilizing a machine learning algorithm will result in a robust predictive model of FFR from CT images.

ADDITIONAL DISTAL FEMORAL RESECTION INCREASES MID-FLEXION LAXITY OF POSTERIOR STABILIZED TKA WITH FLEXION CONTRACTURE: A COMPUTATIONAL MODEL

INTRODUCTION

In Total Knee Arthroplasty (TKA), improper correction of preoperative flexion contracture can lead to a restricted range of motion and diminished knee function [1]. A common surgical approach to correct flexion contracture and achieve full knee extension is the additional bone resection of the distal femur. However, previous studies linked this approach to mid-flexion instability [2]. Mid-flexion instability is defined as symptomatic coronal laxity in the mid-ranges of knee flexion with clinically acceptable laxity at both 0° and 90° of flexion [3]. Previous clinical and cadaveric studies investigated the relationship between additional distal resection and midflexion stability [2, 4, 5]. However, these studies may not control for potential confounding factors such as variability in bony cuts, implant placement, and ligament properties. In contrast, computational models enable systematic comparison among surgical techniques while controlling the confounding factors [6]. Therefore, the purpose of this study was to develop a computational model of TKA with preoperative flexion contracture to quantify the effect of additional femoral resection on the midflexion coronal laxity.

METHODS

Six computational knee models were constructed based on cadaveric CT scans [7]. Twenty nonlinear springs representing the capsular and collateral ligament were added and the slack length of each ligament was calibrated using reference data from a cadaveric experiment (Fig.1) [8]. The models were implanted with a contemporary posterior stabilized TKA using the measured resection technique [6]. A subject-specific 2D static equilibrium model of a passive extension exam, a common exam to clinically evaluate flexion contracture, was developed and solved to estimate the knee extension moment (Fig. 2). The extension moments were used to calibrate the slack lengths of the posterior capsule to simulate a flexion contracture of 10°.

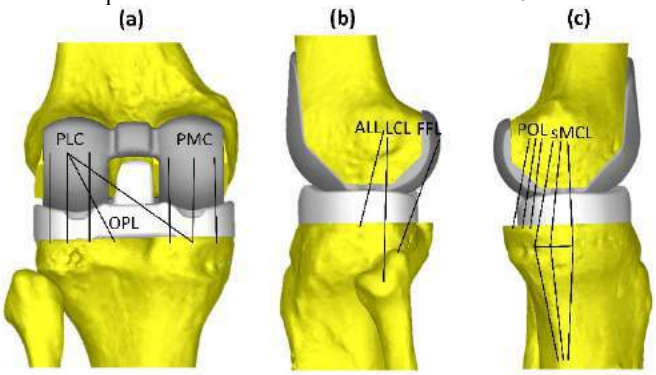

Figure 1: Six knee models were implanted with posterior stabilized TKA. The model included a total of 20 ligament fibers representing: (a) Posterior capsule, (b) lateral ligaments, and (c) medial ligaments. PMC: posterior medial capsule, PLC: posterior lateral capsule, OPL: oblique popliteal ligament, LCL: lateral collateral ligament, ALL: anterolateral ligament, FFL: fabellofibular ligament, sMCL: superficial medial collateral ligament, POL: posterior oblique ligament.

To evaluate the model's credibility, distal femoral resections of 2 mm and 4 mm were simulated (Fig. 3). The knees were then extended by applying the same extension moment estimated in the static equilibrium model of the clinical exam of passive extension and measuring the respective extension angle. The extension angle was compared with previous studies using a two-sample, two-tailed t-test ($p<0.05$) [2, 4, 5]. Subsequently, the knee was flexed to 30° and 45°; then, varus and valgus moments of ±10 Nm were applied for the baseline position of the femoral component and then after distal resections of 2 and 4 mm.

Coronal laxity, defined as the sum of varus and valgus angulation was measured at 30° and 45°of flexion and compared for each femoral component position using repeated measure ANOVA.

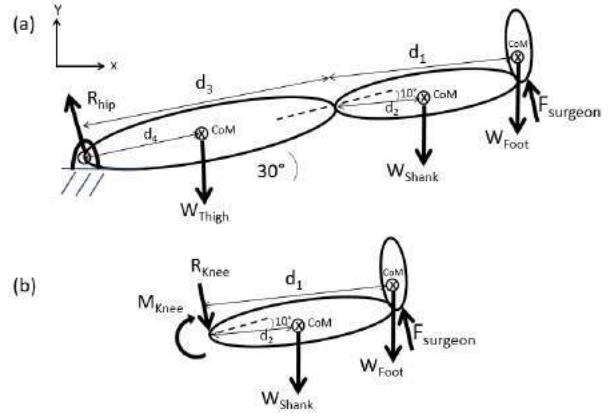

Figure. 2: Two-dimensional free body diagrams representing forces applied in the clinical exam of passive extension. (a) diagram of the full leg to determine the force applied by the surgeon at the foot. (b) diagram of the shank and foot segment to determine the internal knee moment. R_{hip}: ground reaction force at the hip; W_{thigh}: thigh weight; W_{shank}: shank weight; W_{foot}: foot weight; and $F_{surgeon}$: surgeon's lifting force; d_1: shank length; d_2: distance between the knee joint and shank center of mass (CoM); d_3: thigh length; d4a: distance between the center of hip joint and thigh center of mass.

Table 1: Mean increase in knee extension of the six knee models after recutting the distal femur by 2 and 4 mm compared to three previous studies

	Increase in Knee Extension (°)			
	2 mm	**P value**	**4 mm**	**P value**
Knee models	4.6° ± 0.6°		8.3° ± 0.9°	
Cross 2012 [2]	3.6° ± 2.5°	0.36	8.6° ± 1.8°	0.72
Liu 2016 [4]	3.4° ± 2.9	0.32	6.7° ± 3.1	0.25
Kim 2017 [5]	4.8° ± 2.1	0.82	-	

RESULTS

With 2 and 4 mm of distal femoral resection, the knee extended an additional 4.6 ± 0.6° and 8.3± 0.9°, respectively (Table 1). Model predictions of the maximum extension angle after resecting the femur by 2 and 4 mm were within 1.2° ($p \geq 0.32$) and 1.6° ($p \geq 0.25$), respectively, compared to previous cadaveric and clinical studies (Table 1). After resecting 2 mm, the mean coronal laxity increased by 3.1° and 2.7° at 30 and 45°of flexion, respectively. At 30° of flexion, distal resections of 2 and 4 mm increased coronal laxity by 3.1±0.2° ($p<0.001$) and 6.5±0.6° ($p<0.001$), respectively, compared to baseline. At 45° of flexion, distal resections of 2 and 4 mm increased coronal laxity by 2.7±0.3° ($p<0.001$) and 5.5±0.7° ($p<0.001$), respectively, compared to baseline (Fig. 4).

DISCUSSION

A computational model of posterior stabilized TKA representing a knee with preoperative flexion contracture was developed. The model predictions corroborated previous cadaveric and clinical studies in measuring knee extension following additional femoral bone resection of 2 and 4 mm (Table 1) [2, 4, 5], suggesting that this model could be a credible method of representing TKA patients with preoperative flexion contracture. Additional distal resection was associated with increased coronal laxity at 30 and 45° of flexion ($P<0.001$). Elevated midflexion laxity could contribute to midflexion instability; a condition that may require revision surgery [5]. Therefore, surgeons should avoid additional distal resection if possible and attempt to use other surgical interventions to first address a flexion contracture such as removal of all posterior femoral osteophytes and release of the posterior capsule. If a flexion contracture persists, then additional distal femoral resection is warranted. It is important to examine the knee intraoperatively in extension and in flexion and between 30 and 45° of flexion to have the greatest chance of detecting increased coronal laxity. Further studies are warranted to understand the relationship between midflexion laxity and symptomatic instability.

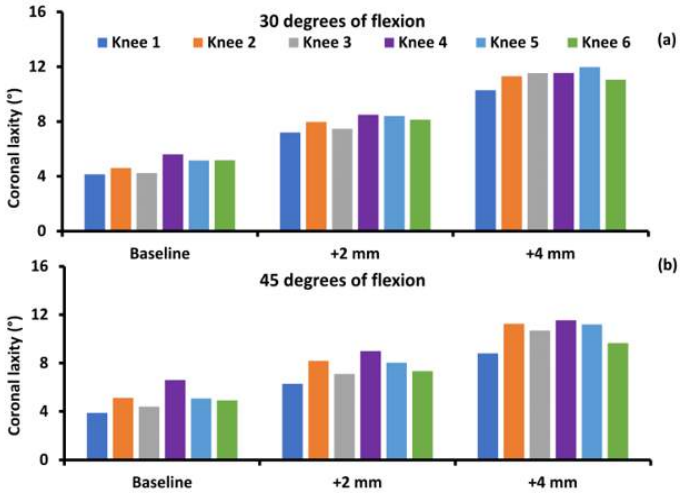

Figure. 4: Coronal laxity at (a) 30° and (b) 45° of flexion with the initial bone resection (baseline), and +2 mm, and +4 mm of additional bone resection of the distal femur.

INTRODUCTION

The right ventricle has been referred to as the "forgotten", the "dispensable", the "neglected", and the "unnecessary" side of the heart. Today, we know that of course the right ventricle is necessary. Nonetheless, it remains the "ignored" ventricle. That is, very little research has focused on investigating its microstructure and mechanics. This is a significant shortcoming as the right ventricle is a source of many devastating diseases and conditions. For example, this current pandemic affects the right ventricle disproportionately [1]. We currently do not understand why that is. Similarly, many patients with left ventricular assist devices, develop right heart failure for currently unknown reasons [2].

The goal of the current work was to fill many of the existing gaps in our knowledge about right ventricular mechanics. Specifically, we set out to characterize the complex, three-dimensional constitutive behavior of right ventricular myocardium and its microstructure.

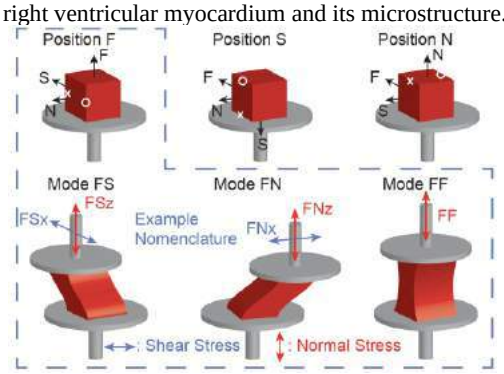

Figure 1: Myocardial shear testing modes and directional nomenclature

METHODS

To study and understand right ventricular myocardial mechanics, we used an ovine animal model. Specifically, we sacrificed 12 adult, male Dorsett sheep and excised their hearts. From these hearts, we extracted cube-shaped myocardial samples of approximately 10x10x10 mm with a surgical scalpel. Next, we tested these cubes under six different simple shear modes and three uniaxial extension and compression modes (Figure 1). For these tests we used our custom triaxial simple shear testing device that recorded both shear forces as well as normal forces. We performed all tests in a 37C physiological solution. After testing, we fixed the tissue in formaldehyde, and stored them in 70% alcohol before submitting them to a commercial histology service. There, our samples were cut at 1mm intervals in both

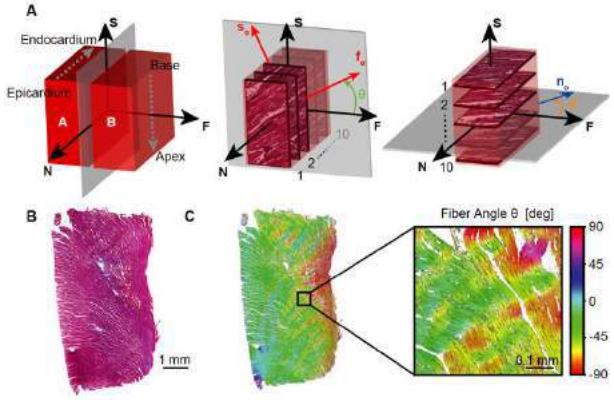

Figure 2: A) Tissue separation for radial and longitudinal histological investigation. B) Example Masson's trichrome stain, C) OrientationJ analysis

longitudinal and radial direction and subsequently stained via Masson's Trichrome. Once returned to our laboratory, we imaged the stained slides and characterized the tissue's microstructure via an ImageJ plugin, OrientationJ [3] (Figure2). From these microstructural maps, we informed probability density functions describing the tissue's major anisotropy axis. With gross cube dimensions and microstructural data at hand, we built custom 3D finite element meshes of each cube. Specifically, we discretized each cube with 1000 linear hexahedral elements. Using the open-source finite element software FEBio in combination with Matlab, we conducted inverse finite element analysis that iteratively identified the material parameters of a Holzapfel-type hyperelastic constitutive law by fitting simulation predictions to experimental mechanical data.

RESULTS

Figure 3 summarizes the mechanical data from our study. Specifically, it illustrates the mean and the standard error for all 6 individual shear modes (shear and normal stress) as well as the 3 uniaxial tensile/compression modes. Via a linear mixed model in which we compared the peak stresses at +/-30 strain (for shear modes) and +/-10% strain (for uniaxial modes) we found that right ventricular myocardium shows anisotropy, shear-stiffening, negative Poynting effect, and tension compression nonlinearity. Thus, right ventricular myocardium behaves very similarly to left ventricular myocardium.

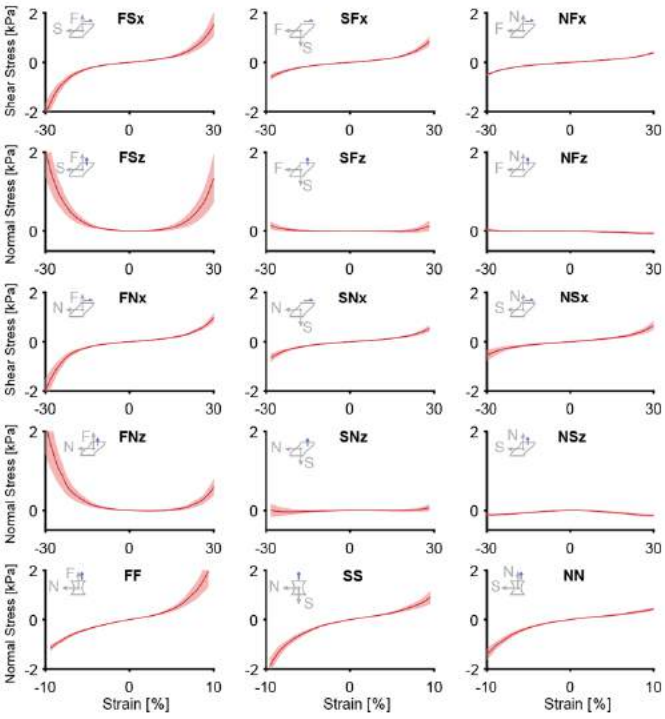

Figure 3: Mechanical test data for 12 right ventricular myocardial samples

Additionally, we analyzed the microstructure of right ventricular myocardium and found that its orientation varies significantly along the radial direction, but does not vary in longitudinal direction. Moreover, within each histological image, fibers are not perfectly aligned but are dispersed. This is true for radial and longitudinal sections. We found that this dispersion can be well captured via von Mises probability density functions (Figure 4).

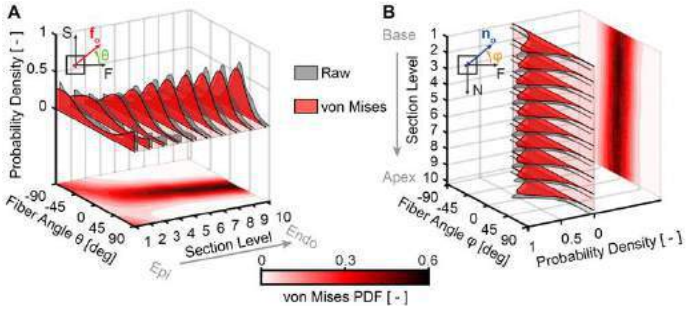

Figure 4: Histology-based microstructure of right ventricular myocardium in (A) radial direction, and (B) longitudinal direction.

Finally, we implemented and tested a hyperelastic constitutive law originally developed for left ventricular myocardium by Holzapfel [4]. Through our inverse approach, we identified its material parameters using different microstructural-inclusion strategies. We found that the material model fits our data excellently and is insensitive to different microstructural inclusion strategies. Figure 5 shows one example mode fit with this model.

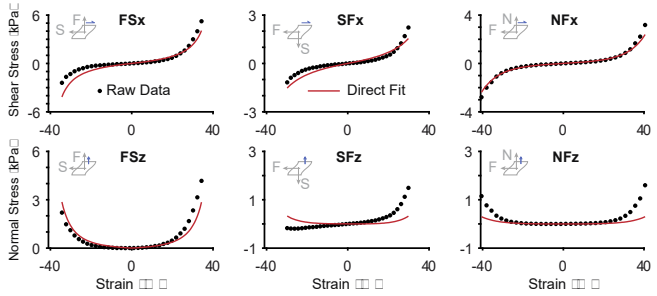

Figure 5: Holzapfel constitutive law fit to three shear modes (both normal and shear stress) of a representative sample

DISCUSSION

We presented mechanical data on ovine right ventricular myocardium and supplemented these data with histology-derived microstructural information. Combining these data, we also tested a hyperelastic constitutive law to represent the behavior of right ventricular myocardium. We found that myocardium behaves qualitatively very similar to left ventricular myocardium [5]. We also for the first time reported on radial and longitudinal organization of its microstructure and found that its organization is complex with distributions changing in radial direction, but not longitudinal direction. However, we found that even relatively simple inclusion strategies (using a single fiber direction vector for example) can achieve high quality constitutive fits with the Holzapfel constitutive law. Future work should now focus on the active properties of right ventricular myocardium that we have entirely ignored in our current work. Additionally, we tested samples from only a narrow region of the free wall. Future studies should also explore mechanical and microstructural heterogeneity through the right ventricular free wall.

INTRODUCTION

Neonatal brachial plexus palsy (NBPP) is a stretch injury to an infant's brachial plexus (BP) during complicated birthing scenarios, resulting in varying degrees of upper extremity paralysis. Despite improvements in obstetric care, NBPP continues to occur in about 1 to 4 per 1000 live births and has not decreased in recent years [1]. No *in vivo* data exists on the biomechanical responses of the anatomically complex neonatal BP when subjected to stretch. This study reports *in vivo* injury thresholds at each level and segment of the neonatal BP subjected to stretch using a neonatal large animal model.

METHODS

Fourteen neonatal piglets (3-5 days old) were anesthetized and BP exposed using an axillary approach per preapproved procedures by Institutional Animal Care and Use Committee (IACUC). Bifurcations of the divisions were located and BP segments above these bifurcations were labeled as root/trunk (i.e., proximal segment) and those below were labeled as cord followed by terminal nerve branch (i.e., distal segment). A custom-built mechanical testing device was used to perform *in vivo* stretch of BP (Fig. 1A). BP nerve segments were distally cut was cut and anchored (Fig. 1B). To measure real-time strain, three to five black acrylic paint markers were placed along BP nerve segment length (Fig. 1B, C). A stereo-camera (StereoLabs, San Francisco, CA, USA) was positioned above for strain analysis. BP segments were stretched at 500 mm/min. Load and displacement data was acquired at a sampling rate of 1000 Hz. Images were captured at 100 frames/s.

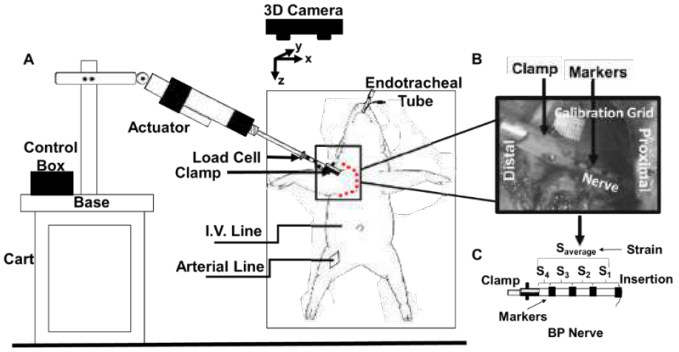

Figure 1. (A) *In vivo* biomechanical testing apparatus. (B) Clamped BP nerve with black markers along length. (C) Strain measured between adjacent makers of BP nerve.

DLTdv Digitizing Tool [2] was used to track marker displacements in 2D image plane of left and right videos. Stereo-camera was calibrated using Direct linear transformation (DLT). DLT calibration coefficients and 2D image points from left and right videos were used to obtained 3D points of marker displacement. Using a custom MATLAB (MathWorks, Natick, MA, USA) program 3D points were imported and length (l) of nerve segment and between each pair of adjacent markers at each time point was calculated using the distance formula (Eq. 1).

$$l_i = \sqrt{\left(x_{2_i} - x_{1_i}\right)^2 + \left(y_{2_i} - y_{1_i}\right)^2 + \left(z_{2_i} - z_{1_i}\right)^2} \quad (1)$$

Displacement (Δl) at each time point was calculated (Eq. 2).

$$\Delta l_i = l_i - l_o \quad (2)$$

Precent strain was determined at each time point (Eq 3).

$$perent\ strain_i = \frac{\Delta l_i}{l_o} * 100 \quad (3)$$

Camera data were used to track changes in structural integrity of BP nerve segments.

RESULTS

In vivo biomechanical response at failure of each BP terminal nerves (i.e., musculocutaneous (MSC), median, ulnar, and radial) are reported in table 1.

Table 1. Average *in vivo* biomechanical response of BP nerves (mean ± SD). MSC = musculocutaneous.

	MSC	Ulnar	Median	Radial
n	14	7	8	14
Average Diameter [cm]	0.11 ± 0.04	0.15 ± 0.03	0.21 ± 0.03	0.23 ± 0.04
Average Failure Load [N]	9.8 ± 3.9	15.8 ± 1.6	21.7 ± 3.6	23.7 ± 3.1
Average Failure Strain [%]	29.5 ± 7.6	27.3 ± 10.5	32.2 ± 19.8	39.8 ± 15.4

Differences were found in average diameter and average failure load ($p < 0.05$, Mann-Whitney U test, Figure 2A, B, respectively) between the BP nerves. No significant differences were found in the average failure strain between the four BP nerves ($p = 0.174$, Figure 2C).

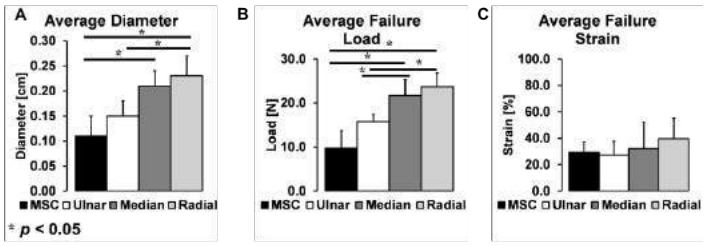

Figure 2. Bar graphs of the average (A) diameter, (B) failure load, and (C) failure strain of the BP nerves stretched to failure at 500 mm/min. MSC = musculocutaneous.

Maximum failure strain of proximal and distal segments (Figure 3A) of the BP complex was also examined. Figure 3B details the average maximum segmental failure strain of BP segments located proximally (root/trunk) and distally (chord/nerve). A total of 43 BP complexes were examined. It was found that 77% (33/43) failure site corresponded with the observed maximum failure strain location, while 23% (10/43) did not.

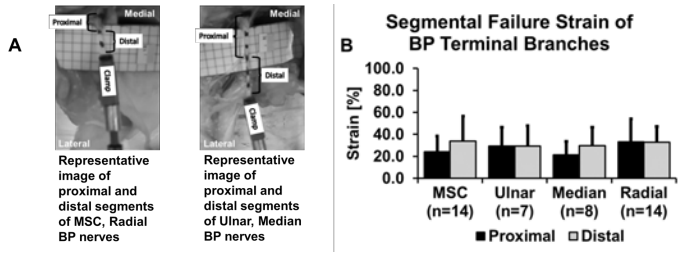

Figure 3. (A) Representative schematic defining the proximal and distal ends of BP terminal branches. (B) Bar graph detailing the average segmental failure strain of the BP terminal branches proximal and distal segments.

The average failure strain of the proximal and distal segments for each BP terminal branch is reported in Table 2.

Table 2. Average failure strain of proximal and distal segments of BP complex (mean ± SD). MSC = musculocutaneous.

	MSC		Ulnar		Median		Radial	
n	14		7		8		14	
Segment	Proximal	Distal	Proximal	Distal	Proximal	Distal	Proximal	Distal
Average Failure Strain [%]	24.1 ± 14.3	34.0 ± 22.4	29.5 ± 17.0	29.2 ± 18.8	21.3 ± 12.2	29.6 ± 16.8	33.2 ± 20.8	32.8 ± 14.2

DISCUSSION

Currently adult human cadaveric studies and adult small animal model studies are the ones that report the effect of stretch on the BP, however, due to ethical limitations, no studies have reported the stretch-injury response of the human neonatal BP. As a result, there is a need for neonatal large animal models to study the *in vivo* injury response of the neonatal BP subjected to stretch. Piglet animal models have been previously used to study functional deficit following injury to the BP as seen in NBPP [3].

This study is the first to report *in vivo* biomechanical response at each level and segment (i.e., proximal and distal) of the neonatal BP using a neonatal large animal model. Such biomechanical response data can be used to help characterize the mechanism of injury to allow clinicians to develop strategies to minimize occurrence of NBPP and guide treatment strategies.

INTRODUCTION

Computational techniques to simulate cardiovascular biomechanics have attracted significant interest owing to their applications in disease research, medical device design, and surgical planning [1]. Depending on the specific application, computational models of varying degree of mathematical sophistication have been employed to model the vessel wall. Typically, the vessel wall is represented either via membrane, shell, or 3D solid elements. Each of these formulations involves inherent assumptions and presents with its own advantages and disadvantages concerning accuracy, ease of implementation, and computational costs. Despite the widespread use of these elements for vascular biomechanics, there is little information on the precise physical regimes where these elements are applicable and the errors that may be induced due to the use of an inappropriate formulation. Consequently, the decision regarding the choice of the optimal element often relies on intuition or previous experience, with unclear consequences of choosing one approach over the others.

The primary objective of this work is to assess the impact of modeling element choice on solution accuracy via a systematic comparison of the commonly employed formulations for vascular biomechanics. We present comparison results to assess the accuracy of these approaches in both idealized and mouse-specific arterial models.

METHODS

We consider four different formulations to represent the vessel wall: (i) a nonlinear membrane model [2], (ii) a rotation-free shell model [3], (iii) a 3D solid formulation employing linear interpolation (referred as P1 wedge), and (iv) a 3D solid formulation employing quadratic interpolation (referred as P2 wedge). We present comparison results in three geometries with increasing degree of complexity: (a) a cylindrical tube, (b) an idealized bifurcation model, and (c) a mouse-specific geometry featuring multiple branches. The solid mesh for all comparisons is generated via an extrusion of the surface mesh used for 2D formulations with a single element across the thickness. The resulting number of degrees of freedom for each geometry is listed in Table 1. Figure 1 shows a representative example of the surface mesh and the corresponding volume mesh for the inflation of a cylinder.

Table 1: Degrees of freedom for different formulations

Geometry	Membrane	Shell	P1 wedge	P2 wedge
Cylinder	8601	8601	17202	102420
Bifurcation	--	48945	97890	586134
Mouse-specific	--	63843	127686	764865

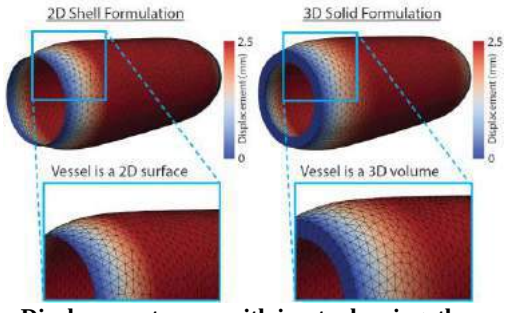

Figure 1: Displacement maps with insets showing the surface and volume mesh for 2D and 3D formulations, respectively.

RESULTS

Figure 2 compares the performance of all four formulations against the well-known axisymmetric solution [4] for the inflation of a cylindrical tube (radius, R=8.5 mm) with two different thickness-to-radius ratios (h/R). For the thin wall case (h/R=0.05), all the formulations agree very well with the axisymmetric solution with no significant errors. However, as the wall thickness is increased relative to the radius, the P1 wedge solution starts to deviate significantly from the axisymmetric solution. In contrast, the membrane and shell formulations exhibit smaller deviation. As expected, the P2 wedge formulation, with the largest computational expense, accurately captured the axisymmetric solution. These results indicate that, in the absence of the availability of an axisymmetric solution, P2 wedge solution can be taken as the true solution.

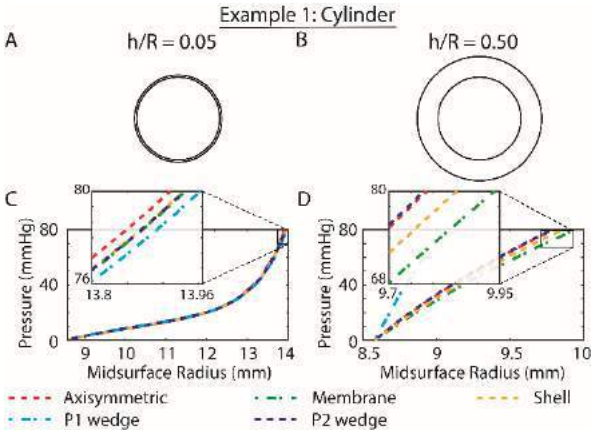

Figure 2: Comparison of different formulations against the axisymmetric solution for two values of thickness-to-radius ratio.

Next, we consider the inflation of an idealized bifurcation model comprising a main artery (R=0.6 mm) and a branch artery (R=0.2 mm) with wall thickness taken to be 10% of local radius. Due to significant bending in the bifurcation region, the membrane formulation fails to converge for this geometry, rendering it inappropriate for general vascular biomechanical analyses. Figure 3 compares the shell and P1 wedge results against the P2 wedge results. It is observed that the shell formulation captures the P2 wedge solution with superior accuracy compared to the P1 wedge solution, despite using fewer degrees of freedom (see Table 1).

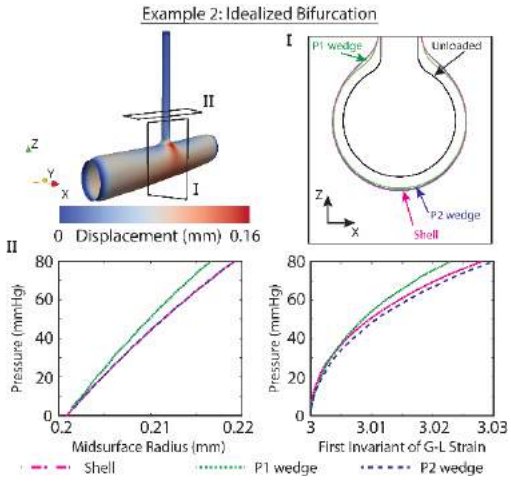

Figure 3: Comparison of shell and P1 wedge formulation against P2 wedge results for an idealized bifurcation model.

Figure 4 compares the performance of shell and P1 wedge formulation against P2 wedge results in a mouse-specific arterial model featuring multiple branches. The material parameters and wall thickness values were obtained via in vitro biaxial tests. Both P1 wedge and shell formulation yielded results virtually identical to P2 wedge solution, despite the shell formulation using 50% and 92% fewer degrees of freedom than P1 wedge and P2 wedge, respectively (see Table 1).

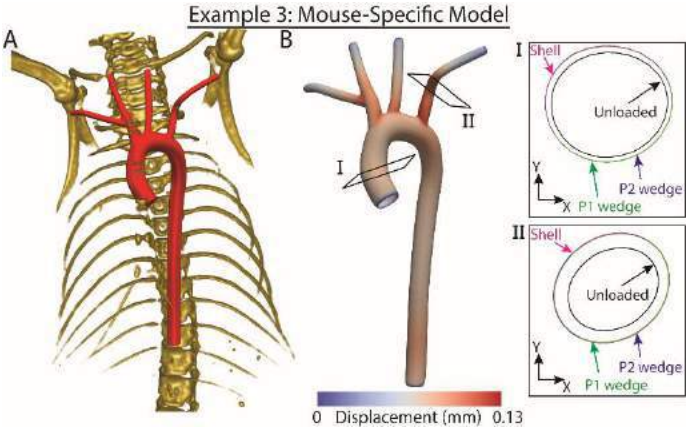

Figure 4: Comparison of shell and P1 wedge formulation against P2 wedge results for a subject-specific mouse geometry.

DISCUSSION

This work presented a comparison of different nonlinear formulations for vascular biomechanics. For thin geometries (h/R<0.05), all formulations (membrane, shell, P1 wedge, and P2 wedge) provided virtually identical results. As wall thickness increased relative to the radius, results started to differ. The primary findings of this work are: (a) the nonlinear membrane formulation is unable to handle bending mode deformations in bifurcating vascular structures, and (b) For relatively thicker vessel walls (h/R>0.05) and geometries including bifurcations, the rotation-free shell formulation, provides more accurate solution than P1 wedge formulation, despite using fewer degrees of freedom (see Table 1), and produces maximum errors of less than 6% relative to the P2 wedge formulation in all cases, while requiring only 8.3% of the degrees of freedom. Since typical vascular geometries exhibit wall thickness ratios in the range (h/R=0.05 to h/R=0.25), these results suggest that the shell formulation represents a computationally superior alternative, considering a balance between cost and accuracy, to the solid element formulations.

Future work aims to incorporate the rotation-free shell formulation within the CRIMSON software (www.crimson.software) to provide a computationally efficient, monolithic, fluid-structure interaction framework for cardiovascular hemodynamics.

INTRODUCTION

Entry of circulating molecules into the brain is strictly limited by the blood-brain barrier (BBB) that includes the endothelial tight-junction (TJ) complex and low rates of transcytosis. In glioblastoma (GBM), the most common and deadly primary brain tumor in adults, the BBB displays heterogeneous permeability to circulating drugs [1] and raises a challenge for drug delivery across this barrier. The standard of care for GBM is maximal safe resection followed by radiation and chemotherapy [2]. However, since the properties of the blood-brain-tumor barrier (BBTB) has been poorly understood, the treatment efficacy and the development of new drug delivery platform are significantly limited. Therefore, a better understanding of the GBM microenvironment, particularly the BBTB and new avenues to enhance drug delivery into the brain are of great importance.

To safely and reversibily increase the BBB permeability, we have developed a method that non-invasively modulates the BBB with picosecond laser excitation of TJ-targeted plasmonic gold nanoparticles (AuNPs) [3]. In this approach, AuNPs were conjugated with the antibody BV11 (AuNP-BV11) to target JAM-A, which is a part of the TJ complex. Then the picosecond laser pulse excitation of AuNPs leads to the generation of mechanical wave that perturbs the TJ, increasing the BBB permeability without compromising normal brain function. This method allows the delivery of immunoglobulins, adeno-associated viral vectors, and liposomes to the brain parenchyma. However, it remains unclear whether this strategy can be applied for the BBTB.

In this work, we analyzed the progression of BBTB in terms of permeability and BBB-related key biomarkers as the tumor grows in a mouse GBM model. We found that the BBTB remains intact at early stage (7 days) while starting to break down at later time points (14 and 21 days). We then showed that the BBTB permeability can be modulated to allow dye accumulation by using the optical approach introduced above. This BBTB modulation approach paves a new way of drug delivery for the treatment of glioma.

METHODS

Glioma model: 73C glioma cells were used, which were generated in primary astrocyte cultures from neonatal mice and carried conditional mutations for $Pten^{f/f}$, $p53^{f/f}$, and $LSLBraf^{V600E}$. 370 μL of the cell suspension (2×10^5 cells/mL) was transplanted into the left hemisphere of the mice (Nu/J, stock no.002019, 7 weeks) at 500 μm depth.

Glioma microenvironment study: To study the BBTB integrity, EZ-link biotin (Biotin, 660 Da) and Evans blue (EB, 66 kDa, binds to albumin) were intravenously injected into two mice at 7, 14 and 21 dpi (days post injection). Coronal brain slices (20 μm thickness) were cut using cryostat for imaging. To study the IF alterations of BBB-related proteins, coronal brain slices (20 μm thickness) were stained with vascular biomarker (CD31) and tight junction proteins (i.e. Claudin-5, ZO-1 and VE-cadherin) using the reported method [3].

Modulating the BBTB in vivo: The molecular targeting nanoparticles AuNP-BV11 are prepared as reported [3]. At 7 dpi, the glioma-bearing mouse was intravenously injected with AuNP-BV11 (18.5 μg/g). Picosecond laser pulse (532 nm, 45 mJ/cm^2) was then applied through the intact mouse skull. EB dye was intravenously injected to visualize the BBB disruption. The animal was perfused after 30 min. Then coronal brain slices (40 μm thickness) were cut using cryostat for imaging.

RESULTS

BBTB integrity study on 73C glioma model: As shown in Figure 1A, the BBTB remains intact at the tumor core (i) and tumor margin (ii) compared to the contralateral side (iii) at 7 dpi. In this case, the tracers are confined in blood vessels. The permeability of the tumor core

increases at 14 dpi and 21 dpi (Figure 1 B, C), indicates by an increased background fluorescent intensity due to the extravasation of the fluorescent dye from blood vessels, while the BBTB in the tumor margin is not disrupted.

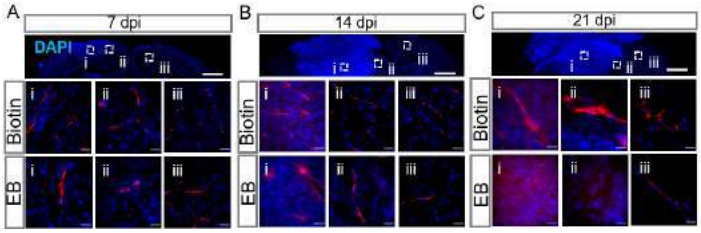

Figure 1: Dye permeability in 73C glioma model at (A) 7, (B) 14, and (C) 21 dpi. Scale bar represents 1 mm in the upper panels and 20 µm in the lower zoom in panels.

To understand the mechanism of the BBTB disruption, immunohistochemistry (IHC) is used to stain on BBB-related proteins (Figure 2). No significant differences of the IF intensities of TJ protein Claudin-5 and adherens junction protein VE-Cadherin were observed. However, the loss of the IF intensity of TJ-associated protein ZO-1 was discovered at 14 and 21 dpi.

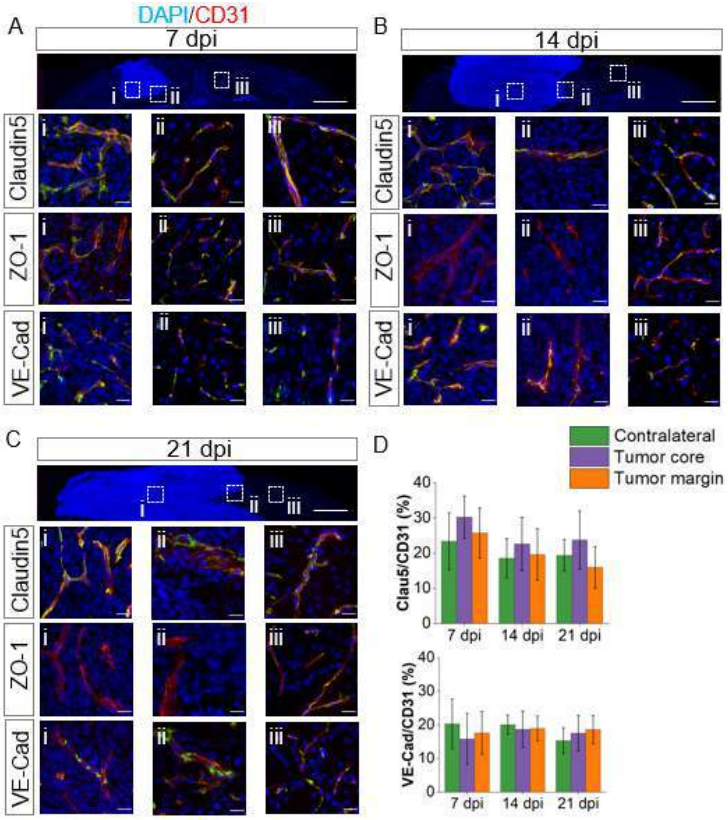

Figure 2: IHC staining of BBB-related proteins (green color) at (A) 7 dpi, (B) 14 dpi and (C) 21 dpi. Scale bar represents 1 mm in the upper panels and 20 µm in the lower zoom in panels. (D) Analysis of protein coverage ratio over CD31. No significant difference was detected. One-way Anova, n=8.

BBTB modulation: To modulate the BBTB in 73C glioma model, TJ-targeted AuNP-BV11 was injected via tail vein and picosecond laser was applied on both the tumor side (left hemisphere) and the contralateral side (right hemisphere) of the brain. Figure 3A shows that extravasation of EB is observed in both tumor side and contralateral side. Successful BBTB modulation was confirmed by the leakage of EB into the tumor area as shown in the fluorescent images (Figure 3B and C). Although both sides show an increase in permeability, the contralateral brain side has a stronger tracer leakage.

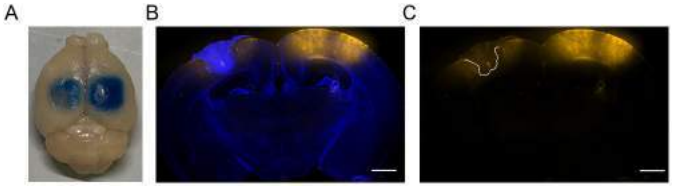

Figure 3. BBTB modulation at 7 dpi using picosecond laser excitation of AuNP-BV11. (A) Visualization of the EB extravasation after BBTB modulation. (B) Hoechst staining indicates the tumor area. (C) fluorescent imaging of the EB signal in the brain parenchyma. Scale bar represents 5 mm.

DISCUSSION

A better understanding of the glioma microenvironment facilitates the design of novel drug delivery platform to enhance the treatment efficacy. A heterogenous permeability of the BBTB in the glioma has been reported to circulating drugs [1]. Yet, detailed understanding of BBTB permeability progression is missing and limits the capability to design effective strategies for GBM treatment. In this study, BBTB integrity in glioma bearing mice was studied by analyzing the fluorescent dye permeability and BBB-related proteins by IHC staining at three different time points. The results reveal that the BBTB in 73C glioma core remains intact at 7 dpi, but it is disrupted at 14 and 21 dpi. The BBTB dysfunction is probably due to the loss of TJ-associated protein ZO-1, since the ZO proteins are essential for assembly of functional TJs by binding to and cross-linking a wide range of TJ proteins and tethering them to the actin cytoskeleton [4].

The standard of care for GBM is maximal safe resection followed by radiation and chemotherapy. However, since gliomas infiltrate into surrounding healthy brain tissue, unresected tumor margin is the primary cause of recurrence. Moreover, since the BBTB remains intact at the tumor margin, chemotherapy drug concentration is much lower within the tumor margin than at the tumor core [5]. Therefore, GBM always results in poor patient prognosis, and there is an imperative need for the development of novel, targeted, and effective therapies for GBM. This study shows that the BBTB permeability can be enhanced by using picosecond laser excitation of TJ-targeted AuNPs. This technique has several advantages, such as non-invasive, entirely reversible and has minimal influence on the normal brain structures and functions [3]. Future work will be focused on the delivery of anti-cancer drugs into the glioma model using the optical BBTB modulation approach and study the treatment efficacy *in vivo*.

NOTOCHORD ECCENTRICITY AND ITS RELATION TO CELL PACKING

Emma L. Sorrell (1), Sharon R. Lubkin (1)

Raleigh, NC, USA

INTRODUCTION

We previously categorized and quantified the packing patterns of the vacuolated interior cells in the zebrafish notochord [1]. We showed, in wild type and in mutants, as well as in a model system of gel beads, that the local packing patterns are determined by the local ratio λ of vacuolated cells per unit length. We also observed that the zebrafish notochords were not necessarily circular in cross section [1]. The local eccentricity e of the wild-type notochord correlated with regions along its length that were in the staircase configuration, where $e = 0.4$; in regions packed in other patterns, the cross section was more circular ($e = 0$). Since the staircase pattern of the zebrafish WT notochord is associated with normal spinal development, and the absence of staircase patterning in various mutants appears to be correlated with defects in spine morphogenesis such as scoliosis [2]–[5], and since the variety of packing metrics seen in the zebrafish notochord hold equally in a nonliving system, we would like to better understand the relationship between the mechanics of packing and the cross-sectional ovaling of the arrangement.

To better understand the relationship between cell packing pattern and notochord eccentricity, and how these may relate to morphogenesis, function, and evolution, we developed and analyzed three models of the regular packing of cells in a sheath. Because eccentricity is associated with the staircase pattern, and because notochords are seen to have a small number of cells per unit length, we focus specifically on the lowest-order regular packing patterns, bamboo and staircase.

METHODS

Following the principle of parsimony, our models of cell packing mechanics in the notochord are based on simplifying assumptions:

- The notochord is infinitely long, without taper.
- The notochord consists of a sheath and interior cells, with no space between them.
- Interior cells are of a uniform constant volume, have equal internal pressures, and are packed in regular patterns.
- There is a uniform distribution of cells, with a constant count λ of cells per unit length.
- The sheath is thin relative to the notochord diameter, and of uniform material properties. We neglect individual sheath cells and sheath thickness.
- The mechanics of internal vacuolated cells are dominated by surface forces. Cells have a uniform surface tension γ_c.

The remaining assumption is the mechanics of the sheath. We used three different models of the notochord sheath, of increasing generality:

- The rigid sheath is an elliptic cylinder of fixed eccentricity.
- The semi-flexible sheath is rigid longitudinally, but flexible in cross section. We restrict the semi-flexible sheath to have elliptic cross section; its eccentricity is the result of the packing of cells inside it. It has uniform surface tension γ_s.
- The flexible sheath is of uniform surface tension γ_s. Its shape is determined by the packing of cells inside it.

The models reveal the relationship between packing pattern and three key dimensionless ratios:

- cells per unit length λ
- sheath eccentricity e
- surface tension ratio $\Gamma = \gamma_s/\gamma_c$.

RESULTS

Rigid sheath A simple analysis shows that the surface energy of the bamboo pattern in a rigid elliptic cylinder does not depend on the eccentricity. We verified that minimal-energy simulations for bamboo fit this solution at a wide distribution of eccentricities.

We determined the surface energy of the staircase pattern at a variety of fixed sheath eccentricities, and determined the bifurcation values of λ, at which one pattern became a lower-energy configuration.

As observed in bubble experiments [6][7], there is some overlap of the range of λ in which the patterns are observable.

For a circular cylinder, the bamboo-staircase bifurcation is at λ = 1.13; as eccentricity increases, this λ value decreases, increasing the range of λ for which staircase is the more optimal pattern. That is, tube eccentricity shifts the packing patterns away from bamboo, towards staircase.

Semiflexible sheath In this model, e is not predetermined, but is adjusted by the energy minimization. A simple analysis shows that the minimal energy cylinder for bamboo pattern has $e = 0$. We verify that all bamboo patterns in this model converge to circular in cross-section.

The bamboo-staircase bifurcation was at approximately λ = 1.13, independent of Γ.

The staircase pattern was never observed to have $e = 0$, though as the sheath tension increased relative to the cell tension (as Γ increased), e decreased. As Γ decreased (sheath softening), e increased. Statistical analysis of the eccentricity of staircase patterns' dependence on λ and Γ revealed insignificant λ dependence.

Flexible sheath The flexible sheath, like spandex, reveals the shapes of the vacuolated cells within (**Fig 1**). In the limit of infinite Γ, the sheath is straight, but as Γ decreases, the sheath shows cusps at the cell-cell junctions, of angle $\cos\theta = 1/(1+\Gamma)$.

As with the semiflexible model, for Γ > 0.7, the lowest-energy pattern was bamboo for λ < 1.13, and staircase for λ > 1.13 (**Fig 2**). The bamboo pattern never showed eccentricity; the staircase pattern had eccentricity which depended strongly on Γ and insignificantly on λ, fitting best to the same biexponential function as in the semiflexible model.

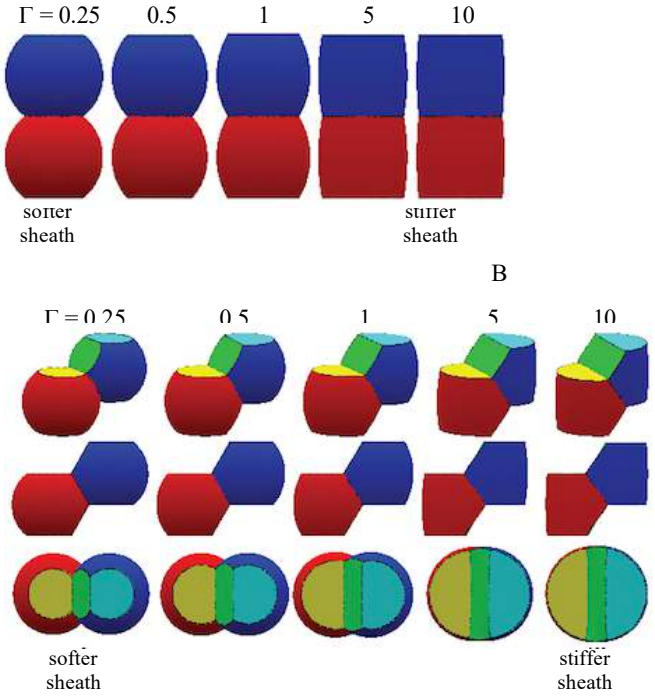

Figure 1: Flexible sheath morphology. Sheath has fixed surface tension ratio Γ, and λ cells per unit length, but eccentricity e and sheath shape are determined by energy minimization of cell packing. Bamboo (A, λ = 0.96) and staircase (B, λ = 1.39) patterns show that sheath straightness increases with Γ.

For Γ < 0.7, a new pattern was seen at intermediate λ, with some of the properties of bamboo (each cell having two neighbors) and some of the properties of staircase (zigzag geometry). We call this pattern "serpentine".

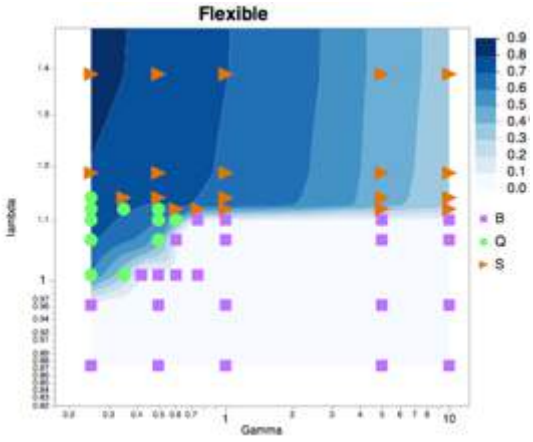

Figure 2: Bifurcation diagram for flexible sheath. For Γ > 0.7, and λ < 1.1, pattern is bamboo with $e = 0$ (purple). Above λ ~ 1.1, pattern is staircase (orange), with e determined by tension ratio Γ. At low Γ, novel serpentine pattern (green) is seen.

DISCUSSION

The consistency of the results of the three models, despite different assumptions, coupled with the agreement between these results for regular patterns and the previously analyzed irregular patterns in gel beads and zebrafish notochords [1], suggest that the bidirectional relationship between staircase and eccentricity is a *generic phenomenon*, at most weakly dependent on the mechanical details of the tubes/sheaths and their contents, but dependent on the two ratios λ (cells per unit length) and Γ (sheath tension/cell tension).

The results suggest inferences regarding the mechanics of vacuolated notochords. For a notochord in a staircase packing, the eccentricity of the cross section corresponds to a specific tension ratio Γ, for which we found a formula. For example WT zebrafish notochords in staircase have $e = 0.4$ [1], suggesting that the sheath is under 6-7 times greater tension than the vacuolated cells within it.

The zebrafish has several mechanisms ensuring the formation of an eccentric notochord packed in staircase pattern at a particular developmental stage, the failure of which leads to spine malformation [2]–[5][8]. What might be the functional significance of the eccentric staircase notochord, which makes it worth controlling for? That is the subject of another study.

PATIENT-SPECIFIC ARTERY GEOMETRY AND ABM/FEA/CFD COMPUTATIONAL FRAMEWORK

INTRODUCTION

Cardiovascular disease has long been one of the leading causes of death across the world. In this study we explore the development and application of an automated method to computationally model patient-specific arteries using a trifecta of finite element analysis (FEA), computational fluid dynamics (CFD) and agent-based modeling (ABM). FEA has commonly been used in 2D modeling per VH-IVUS slice or linear 3D modeling [1][2] to determine stress and strain within arteries, yet its lone application is limited. Similarly, CFD and ABM have been used to understand artery wall shear stress (WSS) [6], however both fall short of a fully comprehensive model. The framework driving our system takes the best of all three disciplines and uses patient-specific virtual histology intravascular ultrasound imaging (VH-IVUS) and angiogram data to create a 3D model and separate IVUS images by tissue composition to understand plaque deposition and growth. The overarching objective is to produce an open-source tool to advance the research community's innovative agenda and provide a tool that can be used to predict growth and remodeling of an atherosclerotic artery.

METHODS

To align ourselves with an open-source mentality the program utilizes open-source python libraries, java tools (Repast Simphony), a custom in-house CFD script, FEA software (FEBio 3.0) [7], and GIBBON code [4] to maintain accuracy while also addressing each angle of the project. Figure 3 displays the framework our tool is based around. In stage one, IVUS images and angiogram are taken of a suspected atherosclerotic artery (Figure 1). This data is passed to stage two where the VH-IVUS slices, catheter centerline, co-registration data, and angular rotational references for the VH-IVUS slices were utilized. The stated information including necessary angiogram data between baseline and follow-up (collected 6 months apart) were provided by an Emory University clinical study [3]. Out of the 27 patients with VH-IVUS and angiogram data at baseline and 6-month follow-up, we only used data from patient 26 in this study.

The raw VH-IVUS slices were filtered to only keep the fibrofatty tissue, fibrous tissue, necrotic core, arterial vessel wall, and dense calcium. We then extracted the catheter centerline from the angiogram data. The filtered VH-IVUS images were then plotted orthogonally along the extracted catheter centerline data and along a straight centerline for a comparison study discussed in the results. Marking bifurcations helped to align the tilt between slices. The surface mesh of the outer wall and inner lumen were created with inner and outer contours. The volumetric mesh was created utilizing GIBBON [4] where a 2x2 filter was applied to simplify the geometry.

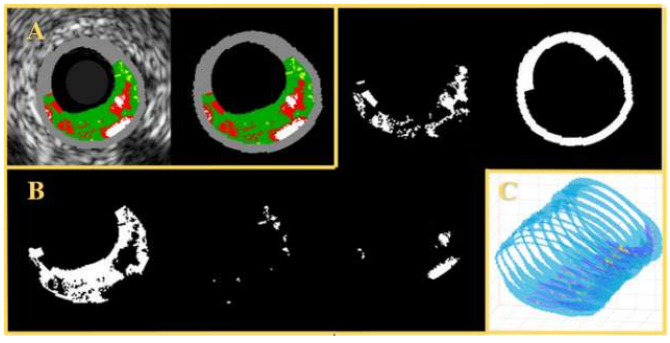

Figure 1. Filtering, Separation, and Plotting along 3D Centerline. **A**: Pre and post filtering **B**: Splitting of materials from image **C**: Plotting materials along 3D centerline.

Once the patient-specific geometry has been generated, FEA and CFD simulation is run to compute the initial wall strains/stresses and wall shear stresses (WSS) respectively. To do so, each element from the volumetric mesh is given a unique material property based on the nearest material data in the same space (Figure 2). The Mooney Rivlin equation was used to apply material properties, which was predefined by FEBio (Equation 1).

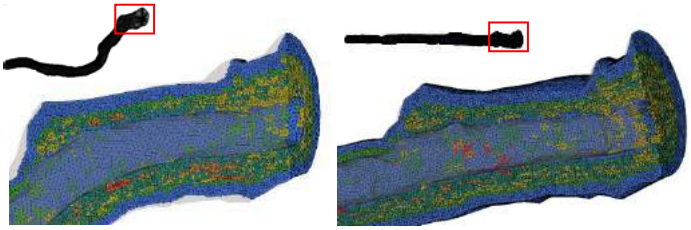

Figure 2. Cut View of Meshed Artery with Materials Assigned The material data along each centerline was used to accurately assign material values to elements in the volumetric mesh.

From here the third stage starts and the looping scheme begins running the ABM where rules derived from literature simulate the biological interactions between the various leukocytes and tissue types present in the artery wall [6]. To maintain spatial-temporal accuracy the ABM pauses at fixed time steps or changes in geometry to run FEA and CFD simulations and compute new WSS and strain values that are passed back into the ABM.

Equation 1. FEBio Mooney-Rivlin strain energy density function The given coefficients and variables represent exchangeable material value parameters.

RESULTS

Utilizing this framework, we are able to handshake Repast with FEBio and our in-house CFD code automatically. The iterative handshaking will inform biologically and mechanically inspired remodeling. In patient 26, the relative volumes of the material constituents are 52.48% buffer material, 17.78% fibrotic/fibrous cap, 18.34% arterial wall, 6.47% fibrofatty, 3.21% necrotic core, and 1.71% dense calcium in the straight centerline artery reconstruction and 52.02% buffer material, 17.95% fibrotic/fibrous cap, 18.49% arterial wall, 6.57% fibrofatty, 3.24% necrotic core, and 1.73% dense calcium in the curved centerline artery reconstruction. The values for both centerlines are within 2.5% of each other suggesting the methods are similar but not exactly equivalent. The 2.5% difference is owed to the non-linear change in distance between each slice of the VH-IVUS slices orthogonal to the curved centerline, resulting in slightly larger elements.

DISCUSSION

The usage of the new model created from this research will be able to determine the impact that wall mechanics and biological factors have on plaque remodeling and atherosclerotic development. A better understanding of these underlying elements and how they affect each other will validate previous models and drive future research on other ABM, FEA, and CFD frameworks. Owing to the data available from Emory University, we hope to utilize our model and validate the results for all other 26 patients in the data set. Depending on the outcome of our model on the remaining patient data, we hope to optimize our ABM rules, looping framework and produce a model that could even lead to applications in other areas of the body.

The biggest limitations present in our model present themselves as the assumptions made on the material assignment in the empty space between IVUS slices. With respect to our IVUS to 3D geometry methods, the spacing between image slices is minimal and makes no assumptions. However, creating a nonlinear 3D model always creates small gaps between slices and material assignments must be normalized for the space between them. This may cause some deviation in CFD and FEA outputs when comparing to data from other studies. In future works, we will build on previous experiences to build a fully intuitive, applicable, and data-driven model for atherosclerosis remodeling.

INTRODUCTION

Murine models provide an efficient platform to study heart valve diseases compared to other mammalian animals due to the low maintenance cost and high turn-over rate of mice. Moreover, since mice share more than 85% protein-coding genome as human, it is often possible to use readily available techniques for manipulating murine genome to mimic human valvular diseases [1]. These grant genetically modified murine models a relevant animal model for investigating the genetic cause and pathological development of valvular diseases, and for testing potential therapeutical treatment as well.

However, the functional mechanics of murine heart valves is still under-studied. This is mainly due to lack of high-resolution real-time imaging and *ex vivo* mechanical testing methods given the small size of murine heart valves (~1mm). Indeed, many scientific questions remain largely unknown regarding, e.g., the structural-mechanical properties of a murine heart valve and its shape adaptation in a cardiac cycle. Few studies on quantifying the stiffness of murine heart valves utilized the atomic force microscopy or micropipette aspiration experiments, and hence limited by the assumption of linear elasticity [2-3].

To address this gap in heart valve research, we and our collaborators have proposed an integrated imaging/computational framework to quantify the nonlinear mechanical properties of murine pulmonary valves (PVs) based on a series of µCT-derived geometries. From the µCT images, we have previously obtained a set of geometric characteristics of murine PVs at multiple physiological transvalvular pressure (TVP) levels. In this study, our aim is to extend the work and use mechanical simulation to provide, for the first time, an estimate of the functional elastic parameters for murine PVs and the unloaded shape.

METHODS

Experiments and Image Analysis

We excised the PVs from eleven healthy one-year old C57BL/6J mice (n=3 at 10mmHg, n=5 at 20mmHg, n=3 at 30mmHg). Each PV was pressurized hydrostatically, chemically fixed, and then imaged using a Heliscan µCT instrument (Thermo Fisher Scientific, resolution ~5µm). From the µCT images, we obtained a set of geometric characteristics of the murine PVs including geometric quantities of interest such as the valve height (H), free edge (FE) and basal attachment (BA) length of different leaflets, tilt angle between the annulus (ANL) and sino-tubular-junction (STJ) planes, β, as well as the representative profiles of central cross sections in the circumferential and radial directions of each leaflet (see Figure 1). Additionally, we developed a correlative workflow to map local collagen fiber structure acquired by serial block face imaging scanning electron microscopy (SBF-SEM) onto the segmented PV surface, allowing us to validate the collagen fiber orientation in the mechanical model.

Theoretical Framework and Simulation

We modeled the PV leaflet as a Kirchhoff-Love thin shell. Given the transvalvular pressure P, the equilibrium displacement $\boldsymbol{u}$ for a single leaflet is defined by the principle of virtual work, i.e.,

$$D_{\delta \boldsymbol{u}} W^{int}(\boldsymbol{u}) - D_{\delta \boldsymbol{u}} W^{ext}(\boldsymbol{u}) = 0 \tag{1}$$

for any compatible virtual displacement $\delta\boldsymbol{u}$ in which the variations of the internal and external virtual works are given, respectively, by

$$D_{\delta \boldsymbol{u}} W^{int}(\boldsymbol{u}) = \int_{M^0} \left(\int_{-\frac{h}{2}}^{\frac{h}{2}} D_{\delta \mathbf{u}} \psi \, dh' \right) dS, \tag{2}$$

$$D_{\delta \boldsymbol{u}} W^{ext}(\boldsymbol{u}) = \int_{M^0} P \boldsymbol{e}_n \cdot \delta \boldsymbol{u} J dS. \quad (3)$$

Here, M^0 represents the undeformed mid-surface, ψ is the strain energy density of the PV, h is the leaflet thickness, $\boldsymbol{e}_n$ is the unit normal vector of the deformed mid-surface, and J is the Jacobian. Leaflet-leaflet contact during coaptation was simulated by incorporating a volumetric contact potential [4]. Particularly, the contact potential between two neighboring leaflets is defined as

$$E_c = \int_{M_1^0} \int_{M_2^0} \varphi(r_{12}) d\boldsymbol{X}_1 d\boldsymbol{X}_2 \quad (4)$$

where M_1^0 and M_2^0 are the undeformed mid-surfaces of the two leaflets, r_{12} is the distance between two material points $\boldsymbol{X}_1$ and $\boldsymbol{X}_2$ in the deformed configuration and φ is a univariate nonnegative function which rapidly increases as r_{12} is less than a threshold.

Overall, the simulation of PV deformation under hydrostatic pressure solves the following nonlinear variational problem:

$$\sum_{\text{all leaflets}} \left[D_{\delta \boldsymbol{u}} W^{int}(\boldsymbol{u}) - D_{\delta \boldsymbol{u}} W^{ext}(\boldsymbol{u}) \right] + \sum_{\text{all leaflet pairs}} D_{\delta \boldsymbol{u}} E_c = 0, \forall \delta \boldsymbol{u}. \quad (5)$$

which is implemented using the state-of-the-art finite element libraries FEniCS and ShNAPr [5]. Experimentally estimated root distention is applied linearly on the basal attachment as TVP increases.

We modeled the PV as a Fung-type hyperelastic material with additional fiber contribution along the circumferential direction consistent with the SBF-SEM measurement (see Figures 1 and 2). The strain energy density ψ is given by:

$$\psi = \frac{1}{2} c_1 \left[\exp\left(c_2 (I_1 - 3)^2 \right) - 1 \right] + \frac{1}{2} c_3 \left[\exp\left(c_4 (I_4 - 1)^2 \right) - 1 \right] \quad (6)$$

in which $I_1 = \mathrm{tr}(\boldsymbol{C})$ and $I_4 = \boldsymbol{e}_f \cdot \boldsymbol{C} \boldsymbol{e}_f$ are two invariants of the right Cauchy Green's deformation tensor $\boldsymbol{C}$ and $\boldsymbol{e}_f$ is the unit fiber direction.

Geometric Model of Murine PVs

We developed a geometric model for the unloaded PV mid-surfaces based on the nonuniform rational B-splines (NURBS), which is integrated seamlessly with the finite element solver using the technique of isogeometric analysis. This allowed us to optimize the PV geometry on the fly without remeshing. The geometric model captures key features of the segmented PV geometries including left-right symmetry, a nonzero tilt angle between ANL and STJ planes, etc., with the total number of parameters equal to 16.

Optimization Scheme

We used SBPLX, a global simplex-based algorithm from the NLOPT package, to optimize the parameters for both the mechanical and geometric models (n_{params}=12). For each set of trial parameters, we obtained the central cross-sectional profiles of the simulated PV in both circumferential and radial directions at 10, 20 and 30 mmHg. The profiles were then compared with the µCT-derived representative cross sections and used to define the cost function. By iteratively minimizing the cost function, we were able to obtain the optimal unloaded PV geometry and mechanical parameters at the same time.

RESULTS

From the µCT images, we obtained geometric characteristics for murine PVs at 10, 20 and 30mm Hg, all of which had high consistency among different PVs at the same TVP (see Figure 1). By matching the extrapolated values of geometric quantities of interest at 0mmHg, we were able to partially constrain the unloaded PV geometry. The rest of the geometric parameters, which characterize the belly profile ($\mathbf{r}_2$) of the leaflets, were determined by the optimization scheme, together with

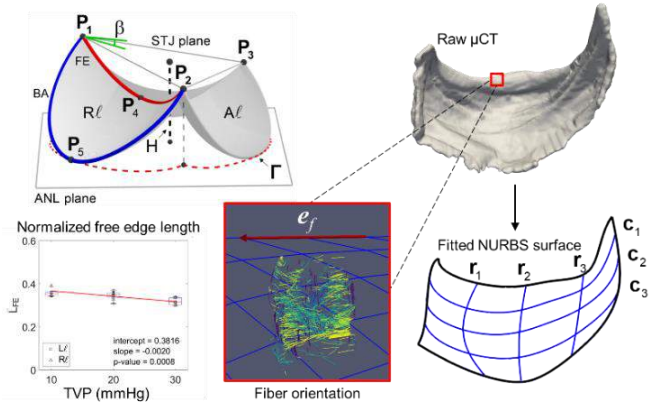

Figure 1: Geometric quantities of interest, local collagen fiber orientation and leaflet cross sectional profiles of the PVs are obtained using µCT and SBF-SEM imaging at multiple TVPs.

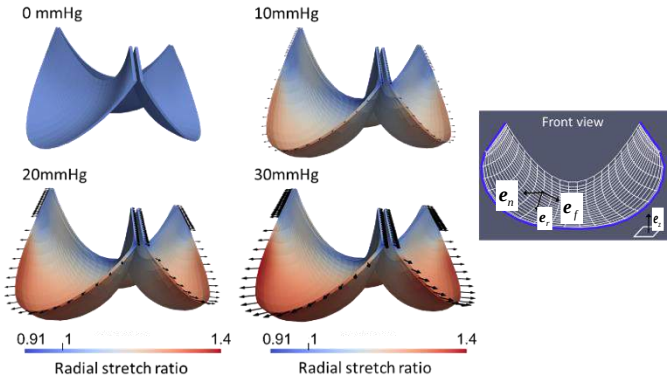

Figure 2: Simulated valvular deformation. The surface of the PV is color coded by the stretch ratio in the radial direction $\boldsymbol{e}_r$. Arrows indicate the Dirichlet boundary condition which mimics the root distention under increasing TVP.

the four mechanical parameters. With estimate root distention and proper mechanical parameters, we were able to match the representative cross-sectional profiles accurately (see Figure 2).

DISCUSSION

Using our imaging/computational approach, we were able to obtain, for the first time, the functional nonlinear mechanical properties of murine PVs. Since each murine PV needs to be fixed before imaging, only one pressure measurement is available per PV. To remedy the issue, we developed representative geometric characteristics from multiple PVs at the same TVP. Additionally, due to distortion of PVs at 0mmHg, we were not able to obtain accurate unloaded PV geometry directly from experiment. We resolved the problem by developing a data-constrained geometric model at 0mmHg and using optimization to fully determine the model parameters. Our future direction is to combine the numerical method with *in vivo* imaging techniques (e.g., the high frequency 4D ultrasound imaging) and apply the approach to study aortic valves of diseased mouse models.

INTRODUCTION

The meniscus is a fibrocartilaginous structure mostly made of a proteoglycan and collagen matrix immersed into a fluid phase [1]. Such a structure plays a fundamental role in the knee function, offering protection to the cartilage of the femur and tibia during joint motion [2]. Every movement of the knee results in the mechanical loading of each individual part of its structure. In particular, the meniscus plays the essential role of dissipating the mechanical energy transferred to the knee during motion [3]. This dissipative mechanism is fundamental to protect the underlying articular cartilage [3].

The way the meniscus dissipates energy is through the friction developed by the relative motion between the fluid phase and the porous solid matrix.[3] This particular mechanism of dissipating energy is regulated by two physical parameters: the aggregate modulus (H), responsible of the elastic deformation of the solid matrix; and the hydraulic permeability (K), regulating the ease of fluid motion within the tissue. Both H and K are material parameters whose magnitude depends on tissue composition [4]. Accordingly, degenerative phenomena affecting the composition of the meniscus may also cause changes in the magnitudes of H and K and, consequently, alter the capability of the meniscus to dissipate mechanical energy.

To date, the effect of degeneration on the dissipating capability of the meniscus has not been determined. The goal of this work was to quantitatively investigate how energy dissipation is affected by the values of the parameters H and K. This was conducted via computer simulated experiments of meniscal energy dissipation during cyclic loading at different values of H and K. We hypothesized that energy dissipation would be directly related to the magnitude of H and inversely related to the magnitude of K.

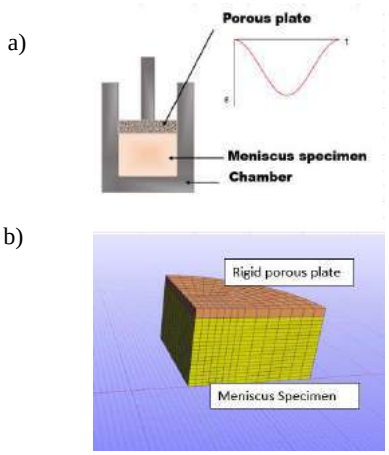

Figure 1: (a) Schematic representation of the confined compression of the meniscus sample. (b) Computatioanl model of the confined compression of the specimen.

METHODS

A finite element model was developed to simulate a meniscus cylindrical specimen undergoing cyclic confined compression at control of displacement, see Figure 1. In the simulations, the specimen was compressed by a rigid porous plate. The presence of pores in the plate allowed the fluid naturally contained in the tissue to flow outside the meniscus during the compression. As previously reported [5,6], the meniscus was modeled as a biphasic material with neo-Hookean solid phase and constant hydraulic permeability. As boundary conditions, the displacement of the bottom of the sample was fixed in all the directions,

while the displacement of its lateral surface was fixed in the plane orthogonal to the line of compression. Due to the axisymmetric geometry, only a quarter of the cylinder was simulated (Figure 1b), and symmetry conditions were imposed on the internal faces of the simulated sample. Because of the porosity of the compressing plate, the gauge pressure on the top surface of the sample was set to zero. A sliding, frictionless, elastic contact was assumed between the tissue and the compressing plate.

Simulations were conducted at several values of K and H to investigate the effects of these physical parameters on the capability of the meniscus to dissipate energy. Previous studies have shown that healthy meniscal permeability is in the order of 10^{-3} mm^4/Ns [5]. Therefore, in the simulations, K ranged from $1*10^{-4}$ mm^4/Ns and $1*10^{-2}$ mm^4/Ns. Similarly, it has been reported that, for healthy menisci, the magnitude of H is 0.2 MPa [5]. Accordingly, in the simulations, H varied from 0.1 MPa to 1 MPa. In addition, variations in the amplitude and frequency of the cyclic compressions were investigated to account for a broader range of knee movements. Specifically, the frequencies considered ranged between 0.01 Hz and 0.5 Hz, whereas the compressive strain amplitude ranged between 1% and 5%.

The dimensions of the modeled cylindrical sample were 2.5mm radius and 1.5mm height. The number of elements in the mesh (2686 elements) was chosen as the result of a mesh convergence study (data not shown), and the type of element was an 8-node trilinear hexahedral 'brick' element. The model was developed in FEBio Studio version 1.0.0.[6]

For each simulated case, the stress-strain data over the entire cycle were computed. The energy dissipation was computed via numerical algorithm as the area under the stress-strain curves, see Figure 2.

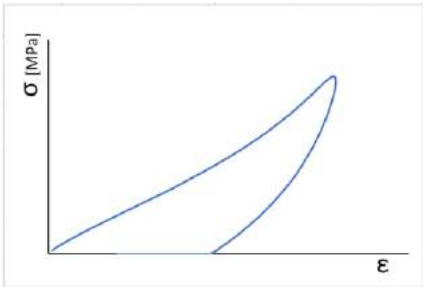

Figure 2: Sample of Stress-Strain curve for the simulated compressive single-cycle on the meniscus sample.

RESULTS

The sensitivity of the energy dissipation to changes in H and K is reported in Figure 3a. For all the cases simulated, the amplitude of the compressive strain was 1% and the frequency was 0.5 Hz. It was observed that increasing the H modulus increases the energy dissipation. The opposite effect was observed for K.

The trends of variation of energy dissipation with extent of compressive strain and frequency of compression are reported in Figure 3b. For all the cases simulated, the value of H was 0.25 MPa and that of K was $1*10^{-3}$ mm^4/Ns. Data show that energy dissipation increases with the magnitude of the compressive strain and the frequency of loading.

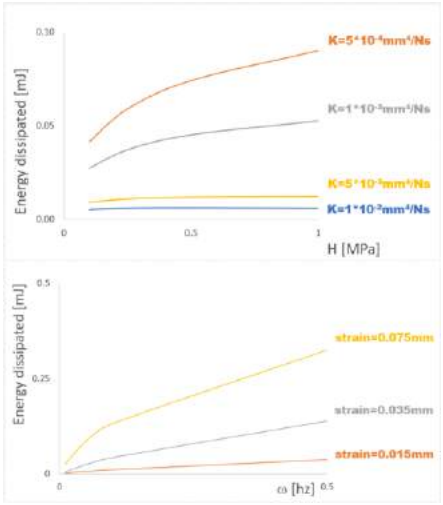

Figure 3: (a) Energy dissipated as a function of H, parametric with K. (b) Energy dissipated as a function of the loading frequency, parametric with the compressive strain magnitude.

DISCUSSION

This study investigated the mechanism of meniscal energy dissipation as a function of two physical parameters, H and K, that regulate the poromechanics of this unique tissue. Such an analysis is significant since both H and K may change with the meniscal composition which, in its turn, depends of the health status of the meniscus. Degenerated menisci exhibit higher water content and lower proteoglycan content when compared to healthy ones [7]. The magnitudes of K and H are positively related to water and proteoglycan content, respectively [8]. Our simulations indicate that increase of K and reduction of H, as one may expect to observe in a degenerated meniscus, reduce the capability of the tissue to dissipate mechanical energy. This may directly affect the health status of the underlying knee cartilage, which would be subjected to a more aggressive mechanical environment.

It was also found that larger compressive strains and higher loading frequencies increase the amount of energy dissipated. This was expected since the energy dissipated in a cycle is proportional to the applied strain. In addition, larger frequencies increase the fluid pressure, which is responsible for dissipating phenomena in a poroelastic system.

In summary, investigating the mechanisms of energy dissipation in the relation to meniscal composition and mechanical environment provides new knowledge on the pathophysiology of the tissue, which can be leveraged to elaborate strategies for the treatment of meniscus degeneration.

CELL-CELL ADHESION MODULATES TISSUE FLUIDITY DURING EPITHELIAL MORPHOGENESIS

INTRODUCTION

Biological tissues behave as remarkable materials that can actively change shape and structure in a process known as morphogenesis [1]. During embryonic development, tissues can reorganize and flow dramatically on timescales as short as minutes during embryonic development [2,3]. In *Drosophila* embryos, for instance, the germband epithelium extends to rapidly double the length of the body axis in just 30 minutes (Fig. 1a) [3-6]. Anisotropies in internal and external forces are thought to drive tissue remodeling [4-6]. Recent experimental studies and theoretical models have highlighted the linkage between tissue remodeling and tissue fluidity [2, 7, 8]. We recently showed that body axis elongation in *Drosophila* (Fig. 1a) is associated with a transition of the epithelial tissue from solid-like to more fluid-like behavior, where tissue fluidity can be read-out from two experimentally accessible metrics of cell patterns – cell shape and cell alignment (Fig. 2) [9]. However, how an epithelial tissue regulates its fluidity to allow or prevent tissue reorganization at specific times remains unknown.

Cell-cell adhesion, mediated by junctional proteins such as E-cadherin (E-cad), and contractile tension, mediated by cytoskeletal proteins such as myosin II and F-actin, are thought to be key machineries controlling epithelial tissue behaviors [5,6] and are likely to also regulate tissue fluidity. To gain insight into how an epithelial tissue regulates its fluidity, we systematically modulated cell-cell adhesion levels *in vivo* by using molecular genetics approaches to tune E-cad expression in the *Drosophila* embryo (Fig. 1b). To study the effects of cell-cell adhesion levels, we combined live confocal imaging and quantitative image analysis of cell patterns and tissue behaviors before and during epithelial tissue remodeling in body axis elongation. Prior to the onset of tissue remodeling, we find a biphasic response of cell shapes to cell-cell adhesion levels. This relationship between cell shape and adhesion changes during tissue remodeling, where we find that increased cell-cell adhesion is instead associated with more aligned cells. These findings suggest complex roles for cell-cell adhesion in modulating tissue fluidity. Our quantitative *in vivo* experimental studies are essential to advance fundamental understanding of how cell-level adhesions control tissue-level mechanical behaviors, which is essential to revealing mechanisms underlying epithelial tissue morphogenesis and embryonic development.

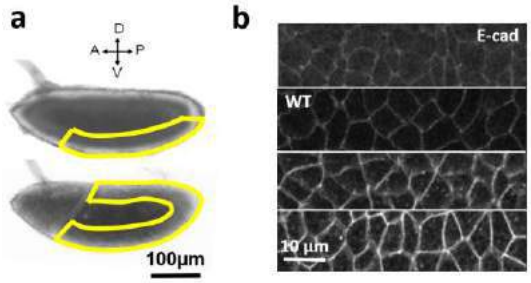

Figure 1. a, Extension of the germband epithelium (*yellow*) contributes to body axis elongation in *Drosophila* embryos. Anterior (*A*), left. Dorsal (*D*), top. **b**, We systematically modulated the levels of the core cell-cell adhesion protein E-cadherin (E-cad) to study how adhesion influences tissue fluidity. Top to bottom: E-cad levels are increased.

METHODS

Fly Stocks and Genetics. Fly stocks are from the Bloomington *Drosophila* Stock Center. Cell outlines and E-cad were visualized with fluorescently-tagged proteins (mCherry [10] or GFP). E-cad levels were decreased by inhibiting expression using RNAi or increased by overexpression using a shg:GFP transgene [11].

Time-Lapse Imaging. Embryos were dechorionated for 2 min in 50% bleach, washed in distilled water, and mounted in halocarbon oil

between a coverslip and an oxygen-permeable membrane. The ventrolateral region of the embryo was imaged on a Zeiss LSM880 laser scanning confocal microscope. Two-color z-stacks were acquired at 1-μm steps and 15-s time intervals. 3 z-slices at the apical side of the tissue at the level of adherens junctions were projected by maximum intensity.

Image Quantification. Time-lapse images were processed in ImageJ [12]. Cells were segmented and analyzed by the semi-automated software SEGGA [13] and customized Python codes [9]. Tissue elongation starts at $t = 0$. Cell patterns were quantified by the cell shape index p and cell alignment index Q, defined in Ref. [9] and schematized in Fig. 2. Mean values from normal distributions were compared by one-way ANOVA and the Tukey HSD *post-hoc* test.

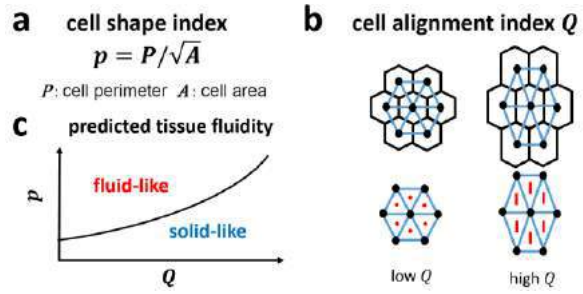

Figure 2. Tissue fluidity can be predicted by two metrics of cell patterns. Cell patterns are quantified by the cell shape index p and cell alignment index Q, following the approach in Ref. [9]. **a**, p is the ratio of the cell perimeter P to the square root of cell area A. Circles have the smallest value of $p = 3.54$. **b**, Q is quantified by the triangle method [9, 14, 15]. Cell centers (black dots) are connected by a triangular network (blue bonds). Q is large when cells are stretched and aligned. **c,** Tissues are predicted to be more fluid-like when cell patterns display high values of p and low values of Q [9].

RESULTS

Cell patterns change dramatically during tissue remodeling. In wild-type *Drosophila* embryos, cells take on nearly isotropic hexagonal shapes at 10 min before tissue remodeling, but change shape dramatically during body axis elongation. Consistent with this, the cell shape index p increases during tissue remodeling [9]. In contrast, the cell alignment index Q peaks 2 min after the onset of tissue remodeling, before returning to low levels again [9].

Prior to tissue remodeling, cell-cell adhesion levels modulate the cell shape index p in a biphasic manner. To test how cell-cell adhesion influences cell patterns and tissue behaviors, we systematically manipulated E-cad levels and analyzed cell shapes in the germband. We first examined p and Q prior to tissue remodeling when the tissue is more static. We find that the cell alignment index Q is low and nearly independent of E-cad levels at $t = -10$ min (data not shown). In contrast, tissues with either increased or decreased E-cad display increased values of p (Fig. 3a). The tissues with altered E-cad levels and elevated values of p (and nearly constant Q) are predicted to have more fluid-like properties (Fig. 2c) [9]. Thus, the cell shape index p shows a biphasic response to adhesion levels in static tissues prior to remodeling, challenging simple models that predict increased adhesion would yield monotonic changes in tissue properties [2, 7].

During tissue remodeling, increased levels of cell-cell adhesion are associated with higher values of the cell alignment index Q. Next, we explored how p and Q vary during tissue remodeling. Interestingly, during tissue remodeling, the differences in p among embryos with different E-cad levels disappear (data not shown). The cell alignment index Q, however, is increased in embryos with increased E-cad (Fig. 3b). More solid-like tissue behavior is predicted for tissues with increased values of Q (and nearly constant p) [9] (Fig. 2c). Thus, increased cell adhesion is associated with increased cell alignment during tissue remodeling associated with body axis elongation.

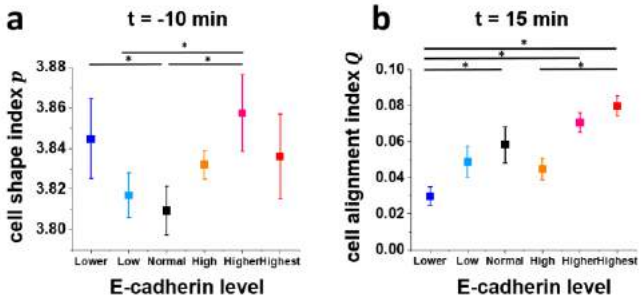

Figure 3. Cell patterns are tuned by cell-cell adhesion. a, The cell shape index p at t = -10 min for embryos expressing varying E-cad levels. Embryos with increased or decreased E-cad compared to wild type (normal) display higher p (*, $P<0.05$). Error bars, standard deviation. n = 4-7 embryos. **a**, The cell alignment index Q at t = +15 min during tissue remodeling. Embryos with increased E-cad display higher Q (*, $P<0.05$). Error bars, standard error. n = 5-8 embryos.

DISCUSSION

Our work systematically studies the effects of cell-cell adhesion on epithelial tissue structure and mechanics *in vivo*. We find that modulation of E-cad levels influences cell patterns in the *Drosophila* embryo. Before tissue remodeling, there is a biphasic dependence of cell shape on E-cad, with either increased or decreased E-cad levels associated with a higher cell shape index p and longer cell-cell contacts and cell perimeters, which is predicated to be associated with more fluid-like tissue properties [9]. We are currently examining the molecular and mechanical mechanisms that contribute to these changes. Interestingly, this relationship between cell shape and adhesion changes during axis elongation when the tissue is more dynamically remodeling. During this time, increased E-cad levels are associated with more aligned cells, suggesting more solid-like tissue behavior [9]. One potential explanation for this is that increased cell-cell adhesion might slow the cell rearrangements that drive tissue remodeling and that are thought to relax tissue stretching resulting from external stresses acting on the germband; we are currently investigating this possibility. Taken together, this work reveals the complex roles of cell-cell adhesion in modulating tissue structure and mechanical behavior during development. Future studies of how adhesion influences cytoskeletal dynamics and cell tension will provide insight into the mechanisms underlying these unexpected effects of adhesion on tissue structure and fluidity.

INTRODUCTION

The full characterization of three-dimensional (3D) mechanical behavior soft tissues, such as myocardium, is essential in simulating organ function in health and disease. The hierarchical structure of soft tissues dictates their highly anisotropic mechanical behaviors, with the spatial variations in fiber structure also giving rise to heterogeneity. To address these issues in a full 3D context, we have developed a novel numerical-experimental approach to determine the optimal model form and parameter estimation for continuum constitutive models of soft tissues, as applied to the myocardium [1, 2]. This approach utilized optimal experimental design of the full 3D kinematic (triaxial) experiments coupled to an inverse model that incorporated local fibrous structure to perform robust parameter estimation (Figure 1). Due to the natural variations in soft tissue structures (Figure 2), the mechanical behaviors of soft tissues can vary dramatically within the same organ. The set of optimal loading paths for a tissue specimen is shown in Figure 2, including three pure shear and three simple shear loading conditions.

In-silico implementation of such complex 3D continuum soft tissue constitutive models to obtain the responses of varying boundary conditions and fibrous structures requires the solution of the associated hyperelasticity problem, which remains impractical in translational clinical time frames. To alleviate the associated substantial computational costs at the time of simulation, we have developed a neural network-based method that can simulate the 3D mechanical behavior of soft tissues. A physics-informed approach [3] was employed to train the neural network (NN) surrogate model to give physically correct solution for a range of loading conditions by minimizing the potential energy without any training dataset generated by finite element (FE) solver.

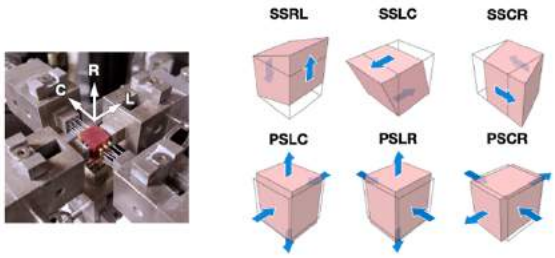

Figure 1: The triaxial testing system (a) for determining the myocardium model parameters using the set of optimal loading (b)

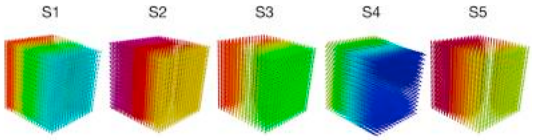

Figure 2: The fiber orientations of five myocardium specimens.

METHODS

We consider the parametric hyperelasticity problem of myocardium on domain Ω with a prescribed displacement $\mathbf{u}_0$ on the Dirichlet boundary Γ_u and a traction term $\mathbf{t}$ the Neumann boundary Γ_t in the reference configuration $\mathbf{X} \in \boldsymbol{\Omega}$. The displacement $\mathbf{u}(\mathbf{X})$ depends on the prescribed Dirichlet boundary condition $\mathbf{m}(\mathbf{X})$ on Γ_u. The displacement $\mathbf{u}(\mathbf{X})$ is parametrized using $\mathbf{u}(\mathbf{X}) = \mathbf{U}\mathbf{N}(\mathbf{X})$ where $\mathbf{N}(\mathbf{X})$ are the finite element basis functions and $\mathbf{U}$ is the nodal displacement values, and the Dirichlet boundary conditions $\mathbf{m}(\mathbf{x})$ is parametrized by a vector $\mathbf{M}$. Thus, solving

parametric PDEs is essentially to find the parameter-to-state map **U**(**M**) that minimize the energy potential of hyperelasticity for all **M**. We use a fully connected neural network f_{FCN} along with a linear term **TM** as the surrogate model to approximate the parameter-to-state map using

$$\mathbf{U}(\mathbf{M};\boldsymbol{\theta}) = f_{\mathrm{FCN}}(\mathbf{M};\mathbf{W},\mathbf{b}) + \mathbf{TM} \quad (1)$$

where $\boldsymbol{\theta}$ includes the weights **W**, the biases **b** for the FCN and the matrix **T** for the linear term as a skip connection which is originally proposed in the residual NN [4]. Thus, the surrogate model represents the solutions for a range of Dirichlet boundary conditions. The FCN is a sequence of composite functions,

$$f_{FCN} = A_L \circ \phi \circ A_{l-1} \circ \cdots \circ \phi \circ A_1 . \quad (2)$$

where ϕ: $\mathbb{R}^{\mathrm{d}} \to \mathbb{R}^{\mathrm{d}}$ is element-wise nonlinear differentiable activation function, A_l: $\mathbb{R}^{\mathrm{d}_{l-1}} \to \mathbb{R}^{\mathrm{d}_l}$ (l = 1, …, L) are affine functions with weights $\mathrm{W}_l \in \mathbb{R}^{\mathrm{d}_l \times \mathrm{d}_{l-1}}$ (l = 1, …, L) and biases $\mathrm{b}_l \in \mathbb{R}^{\mathrm{d}_l}$ (l = 1, …, L), L is the number of hidden layers, d_l is the number of neurons in the l-th hidden layer. The activation function can be discontinuous since the hyperelasticity problem does not involves its derivatives

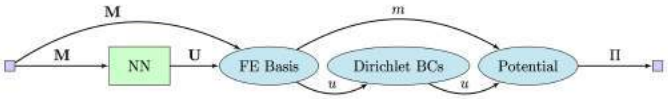

Figure 3: The end-to-end computational graph of the NN surrogate model U(M) integrated with the FE basis functions to compute the corresponding energy potential Π, where automatic differentiation is to back-propagate the derivatives for minimizing the aggregated energy potential for a range of Dirichlet boundary conditions.

To capture the mechanical response of the myocardium, we used [2],

$$\begin{aligned}\Psi = {} & \frac{a}{2b}\left(\exp\left(b(I_1-3)\right)-1\right) \\ & + \sum_{i=\mathrm{f,s}} \frac{a_i}{2b_i}\left(\exp\left(b_i\left(I_{1_i}-1\right)^2\right)-1\right) \\ & + \sum_{i,j=\mathrm{f,s}} \frac{a_i}{2b_i}\left(\exp\left(b_i {I_{8_{ij}}}^2\right)-1\right), \end{aligned} \quad (4)$$

where $\{a, b, a_{\mathrm{f}}, b_{\mathrm{f}}, b_{\mathrm{f}}, b_{\mathrm{s}}, a_{\mathrm{fs}}, b_{\mathrm{fs}}\}$ are eight model parameters, I_1 is the first invariant of the right Cauchy-Green deformation tensor $\mathbf{C} = \mathbf{F}^{\mathrm{T}}\mathbf{F}$ and $\mathbf{F} = \nabla\mathbf{u}$ is the deformation tensor, and I_{4i} are the diagonal components of **C** and I_{8ij} are the off diagonal components of **C**. Next, to make the optimization problem in Equation (3) feasible, we minimized an aggregated potential energy

$$\begin{aligned} & \text{find } \boldsymbol{\theta} \\ & \min \Sigma_i \int_\Omega \Psi\left(\mathbf{u}^{(i)}(\mathbf{X})\right) \mathrm{d}\mathbf{X} + \int_{\Gamma_t} \mathbf{t}\cdot\mathbf{u}\mathrm{d}\mathbf{X} \\ & \text{s.t. } \mathbf{u}^{(i)}(\mathbf{X}) = \mathbf{U}(\mathbf{M}^{(i)})\mathbf{N}(\mathbf{X}). \end{aligned} \quad (4)$$

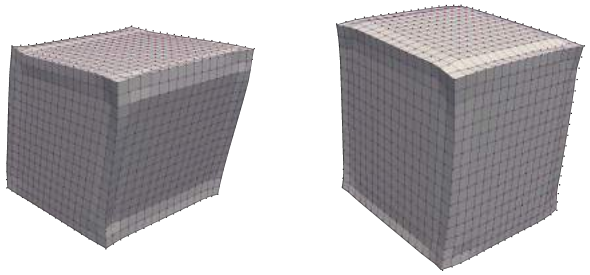
The Dirichlet boundary condition was parametrized in a fashion of representative volume element by **M**

$$\mathbf{u}^{(i)}(\mathbf{X}) = \mathbf{M}^{(i)}\mathbf{X}$$

The integral in Equation (4) is computed by an element-wise Gauss quadrature. A Markov chain Monte Carlo (MCMC) method using Halton sequence is used sampled **M**. The end-to-end computational graph is shown in the schematic diagram (Figure 3).

RESULTS

We consider a cube of nearly incompressible myocardium with dimensions 1.0 × 1.0 × 1.0. The training range for sampling all components of **M** is [-0.2, 0.2] and we restrict **M** to be symmetric to eliminate rigid rotation. The training range is incrementally expanded in 20 steps. The number of MCMC samples is 100. The NN has 1 hidden layer of 100 neurons. The results obtained with present NN matched closely with the finite element method which has 8000 nodes (20×20×20) (Figure 4). The training process converged and has a good agreement with the FE solutions (Figure 5).



(a) **(b)**

Figure 4: Validation on the deformed configurations of the predictions of the NN surrogate model (blue wireframe) and the FE solutions (red points): (a) shear deformation with relative L2 error of 9.65%; (b) extension in two directions with relative L2 error of 6.48%.

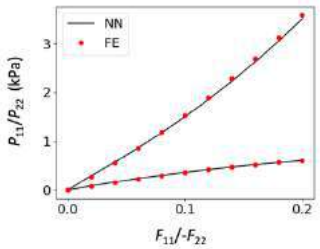


Figure 5: The average first Piola-Kirchhoff stress on the boundary vs the deformation of the FE solutions and NN predictions.

The compute time for one prediction of the NN surrogate model was 0.02236 s, while the FE solver takes 6.5762 s for assembly and solution for one step, which is a speed-up of 294.1. The NN surrogate model can give predictions in parallel while the FE solver needs stepping scheme to incrementally obtain the solution for the fully loaded state which multiplied cost with the number of steps, which is 10 in the present case.

DISCUSSION

In this work, we have developed a high fidelity NN 'surrogate' model that is trained in a physics-informed approach to give a direct solution of 3D soft tissue hyperelasticity in-silico. The present method was found to be an order of 10^2 time faster than the equivalent FE model (using the same mesh on the same machine). With the learnability of the neural networks, the architecture of the NNs can incorporate attributes such as spatially varying fiber structures. By shifting the computation expense from FE problem solving to NN training, The NN surrogate model can be used to give significantly fast predictions of complex 3D deformations in full kinematic space with population-based fiber structures by forward propagation in the neural network. This method will provide efficient and robust computational models for clinical evaluation to improve patient outcomes.

INTRODUCTION

The endothelium, comprised of a single layer of endothelial cells, is the innermost lining of blood vessels providing the crucial interface between blood and the arterial wall. "Endothelial dysfunction," characterized as a reduction in the bioavailability of the major vasodilator nitric oxide (NO), is associated with abnormal vascular remodeling and correlated with cardiovascular pathologies such as hypertension and atherosclerosis. [1]

Based on previous studies, endothelial dysfunction can lead to arterial wall thickening and arterial stiffening, which involves changes in extracellular matrix (ECM) structure or composition and, consequently, alterations in the passive mechanical properties.[2] [3] Additionally, acute NO deficiency leads to increased contractile tone; but long-term deficiency may reduce the overall contribution of the smooth muscle cells (SMCs) to the mechanical environment. The microstructure of the ECM, especially collagen fiber organization, plays an essential role in aortic mechanics. However, very few studies have been performed on the impact that endothelial dysfunction has on the microstructure of the ECM, especially collagen fiber organization, during age-related vascular remodeling that could be used to decipher changes in macroscopic mechanical properties. Thus, a mouse model of direct genetic deletion of endothelial nitric oxide synthase (NOS3) was used in this project to manifest endothelial dysfunction to study the alterations of collagen fiber organization as well as changes in active and passive biomechanics over the time course of vascular remodeling.

METHODS

We used groups of endothelial NO synthase (NOS3) knockout (KO), NOS3 heterozygous (Het), and wild type (WT) B6 mice (controls) to study the time course of vascular remodeling between 6 wks to 12 mo. Multiphoton second harmonic generation (SHG) microscopy was used to image collagen fibers through the wall of the descending thoracic aorta (DTAo). The axial (0°) direction was defined by the average orientation of endothelial cell nuclei; the corresponding perpendicular direction was defined as circumferential (90°). An image-processing protocol was then developed to reconstruct collagen fibers in 3D space. Reconstructed fibers were classified into three fiber families, with one axially-oriented, one circumferentially-oriented, and helically-oriented families (axial= 0-22.5° and 157.5-180°, circumferential= 67.5-112.5°; helical= 22.5-67.5° and 112.5-157.5°) using a custom MATLAB code. The mean normalized frequency for each fiber family and average undulation associated with the family were calculated.

Active and passive mechanical tests of DTAo taken from mice of each genotype were conducted on a customized murine artery inflation-extension testing apparatus. For active tests, maximal contraction of SMCs was achieved by adding phenylephrine into the bathing medium (Krebs solution) to achieve a final concentration of $2x10^{-5}$ M. The medium was temperature-controlled within 37-38°C and continuously aerated

with 95% O_2/5% CO_2. Arteries were then preconditioned with 5 inflation/deflation cycles to minimize viscoelastic effects. For data acquisition, each DTAo sample was extended and held at three different axial stretch ratios which are 1.5, 1.6 (corresponding to the in-vivo stretch ratio), and 1.7, respectively. At each stretch ratio, the arterial sample was pressurized from 10 to 160mmHg in increments of 10 mmHg using in 3 consecutive quasi-static inflation cycles with the axial force, luminal pressure, and axial stretch recorded. The passive mechanical response was assessed by exchanging the perfusion and test chamber medium with phosphate buffered saline (PBS) containing 10^{-5} M sodium nitroprusside (SNP) to fully relax the SMCs. Passive mechanical preconditioning and inflation-extension testing were performed in an identical manner to that described above.

RESULTS

As shown in Figure 1 (a.), there is a slight, non-significant increase in the relative number of circumferentially oriented fibers (p value = 0.116) and a similarly small decrease in axially oriented fibers with age in WT mice (p=0.128). There are no obvious trends in heterozygotes (b.), while in KO (c.) there is a significant increase in the number of circumferentially oriented fibers with age (p=0.035). The trend in KO mice indicates that more dramatic collagen fiber reorganization occurs with endothelial dysfunction during age-related vascular remodeling.

The active and passive mechanical responses of different genotypes at 12 mo are compared in Figure 2. In both (a.) and (b.), the mechanical responses of DTAo from all genotypes exhibit J shaped stress-stretch behavior in the circumferential direction. In (a.), the active mechanical response shows slight difference between genotypes, while in (b.) there is very little variation among genotypes under SMC relaxed state. Based on (c.), the SMC active stress generation in circumferential direction at common circumferential stretch 1.6 in KO is lower than both WT and Het which suggests diminished SMC contraction in KO at 12mo. In addition, corresponding lumen area compliance at a common loading condition (100 mmHg) of KO vessels is lower than WT and Het under SMC relaxed states in (d.), indicating increased aortic stiffness in KO for passive mechanical property. However, the sample size is only two, so more data is required to determine whether these differences are statistically significant.

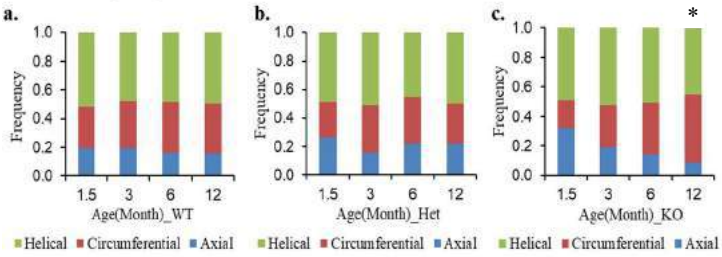

Fig 1. Changes in distribution of collagen fiber families with age in each genotype. WT mice shown in (a.), Het in (b.) and KO in (c.). The mean frequency of three fiber families is represented using different colored bars in the graph. N=3-6 for each group. * indicates significant difference (p<0.05) between age groups in KO mice.

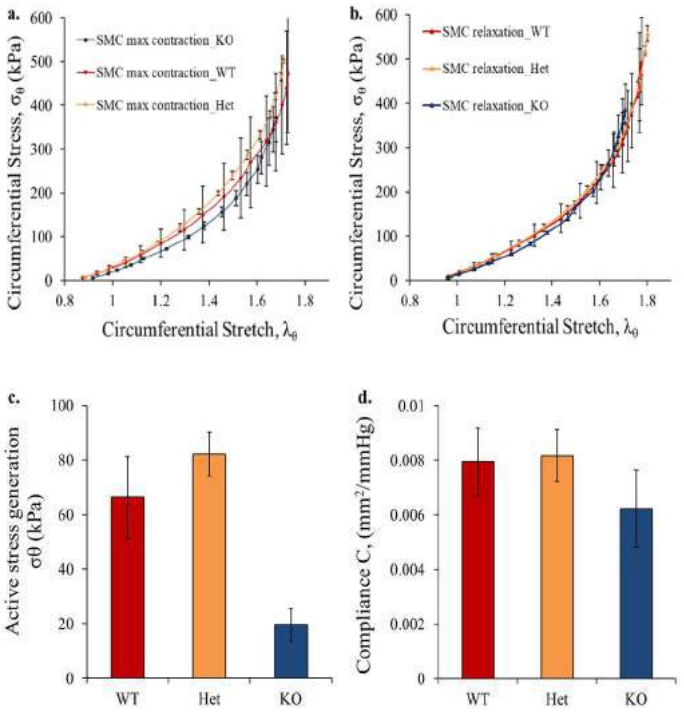

Fig 2. Comparison of circumferential stress-stretch relationships at in-vivo axial stretch, 1.6, for different genotype groups (n=2) at 12 mo under SMC maximally contracted state in (a.) and under SMC relaxed state in (b.). Corresponding SMC active stress generation at common circumferential stretch λθ=1.6 in (c.). Lumen area compliance (C, mm²/mmHg) at common loading condition (100 mmHg) under SMC relaxed state in (d.)

DISCUSSION

Preliminary results demonstrate that there is a trend in collagen fibers shifting towards circumferential from axial orientation with age in KO mice compared to the other two genotypes. However, the sample size for active and passive mechanical study is currently too small, so the effect of endothelial dysfunction on mechanical properties is still uncertain. Thus, active and passive biaxial mechanical tests of all genotypes will be completed in the future to compare mechanical properties between genotypes and time points.

INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is a genetic disease caused by mutations in contractile sarcomeric proteins that result in abnormal thickening of ventricular heart muscle, particularly the septum that separates that left and right ventricles [1]. The current gold standard, septal myectomy, is commonly performed to remove excess, thickened tissue. However, many patients are poor surgical candidates and require another, less invasive, treatment option. In these cases, cardiologists use the alcohol septal ablation (ASA) technique to kill the overgrown tissue. Although ASA is a relatively common procedure for non-surgical patients, it has many downfalls including atrioventricular blockage and considerable myocardial necrosis [2]. To overcome ASA limitations, we have designed a new nanoparticle-mediated system to replace the pure alcohol in ASA and achieve a controllable, localized septal tissue shrinkage and a safe ablation.

METHODS

Doxorubicin-loaded PLGA NPs were created using a double emulsion method developed in-house Nanoparticles were characterized by size, charge, conjugation efficiency, cytocompatibility, and cell uptake. HL1 cells were seeded onto collagen coated plates to mimic the fibrotic environment associated with HCM. Hypertrophy was induced in HL1 cardiomyocytes by stimulating them with endothelin-1 (ET-1). Following ET-1 treatment, cells were treated with various concentrations of collagenase coated, Doxorubicin-loaded PLGA (COL-PLGA-DOX) nanoparticles.

RESULTS

COL-PLGA-DOX NPs were fabricated using a double emulsion technique and were then fully characterized. The drug release profile showed that within 48 hours, ~50% of the drug was released. The nanostructure, presence of Doxorubicin, and collagenase conjugation was confirmed by FTIR. Cytocompatibility studies were performed to show that PLGA NPs had no negative effects on the viability of the cells. PLGA NPs had excellent cytocompatibility with HL1 cardiomyocytes. Cell uptake of COL-PLGA-DOX NPs showed a dose-dependent response, with more NPs taken up by the cell at higher NP concentrations. COL-PLGA-DOX NPs were tested in 2D culture on collagen coated plates to determine the effectiveness of the NPs to kill hypertrophied cardiomyocytes in a mimicked collagenous (fibrotic) environment. Within 48 hours of treatment with the IC50 and IC75 of COL-PLGA-DOX (Figure 3.8 C) ~80-85% of cells were killed, similar to the rate of death caused by free, untargeted Doxorubicin, showing the success of these NPs in killing hypertrophied cells in a collagenous environment.

DISCUSSION

We have developed a COL-PLGA-DOX NP drug delivery system, with an ultimate goal to replace the ASA procedure with a more effective therapeutic option for HCM. PLGA NPs showed excellent cytocompatibility with HL1 cells, as well as a concentration-dependent uptake into hypertrophic HL1 cardiomyocytes. COL-PLGA-DOX successfully killed hypertrophic cells in vitro. Our ongoing ex vivo study, using a fresh pig heart model, has showed that our new system had a better localized delivery capability when compared with alcohol.

INTRODUCTION

Ischemic mitral regurgitation (IMR), also known as functional or secondary mitral regurgitation, is an especially prevalent and dangerous form of mitral valve (MV) incompetence in which a myocardial infarction (MI) causes maladaptive remodeling of the left ventricle (LV). MI-induced LV dilation stretches the MV annulus and tethers down the MV leaflets via the chordae tendinae, causing backflow through the left atrioventricular junction. The condition afflicts up to half of the population that has suffered a MI, and this number is expected to grow substantially as the population ages [1]. Current treatments, including surgical repair and replacement of the MV, continue to have high rates of failure, with moderate to severe IMR recurring within the first two years post-surgery in over 30% of patients [2]. It is believed that surgical outcomes can be substantially improved through the use of personalized diagnostics and treatments that account for patient-specific variations in MV structure and infarct kinematics.

A previous study by Bouma et al. [3] utilized clinical real-time 3D echocardiographic (rt-3DE) images of surgical repair for IMR to quantify the patient-specific risk of MR recurrence at six months post-surgery and found that metrics including the preoperative MV leaflet tethering angle in the P3 Carpentier segment were significantly different between MVs with and without IMR recurrence and that P3 tethering angle was predictive of 6-month IMR recurrence. This exciting result suggested that there are detectable pre-surgical differences in the functional state of regurgitant MVs in patients that respond well to URA and suggests that patient-specific pre-surgical assessment could be used to guide MV repair methods for improved outcomes.

We have previously developed a completely noninvasive method to produce open and closed MV geometries and compute MV leaflet deformation patterns from 3D in vivo images. We have previously applied this approach to large animal (ovine) post-IMR MVs and determined that the kinematic behavior of the MV changes progressively and substantially in the period immediately following an MI and that IMR progression induces plastic effects in the leaflet tissue which may affect its ability to fully recover after surgical intervention [3]. Each of these results strongly suggests that there is a relationship between pre-surgical MV state and post-surgical outcomes. To investigate this relationship, we have developed models of 21 human MVs and investigated leaflet strains and deformations. Deriving factors that play a role in predicting repair success could help elucidate underlying mechanisms of disease progression, lay the basis for more advanced models of surgical repair, and improve surgical techniques and planning on a patient-specific basis.

METHODS

Clinical rt-3DE images of the MV were obtained from 18 patients with IMR (11 without recurrence of IMR and 7 with recurrence) and 3 normal human MVs. These images were processed to obtain 3D midsurface representations of each valve in the fully open (end-diastolic) and fully closed (end-systolic) states, immediately pre- and post-surgery. In order to establish material point correspondence between the open and closed states of each valve, we applied a hyperelastic shape morphing technique in a finite element (FE) framework, where the open state geometry of the valve was morphed to match the closed state shape using globally applied pressure as well as a level-set penalization (Figure 1). The method is described in detail by Rego et al. [4]. Metrics including in-plane circumferential and radial strain, leaflet area, coaptation area, and orifice dimensions were then computed and compared between MVs with and without recurrence of MR at 6 months post-repair.

RESULTS

We found that MVs with IMR had significantly lower magnitudes of

compressive circumferential strain in the posterior leaflet and significantly higher radial strains across the whole MV than MVs

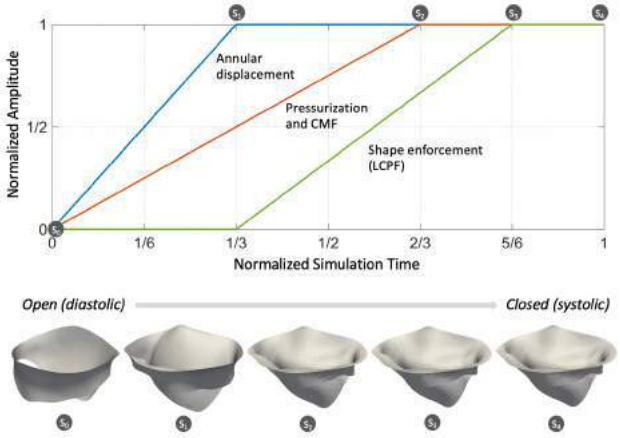

Figure 1. Time course of the FE simulation used to morph the open state MV mesh to the closed state shape.

without IMR (Figure 2). Patients who would later exhibit IMR recurrence were found to have significantly higher circumferential leaflet strain in the anterior commissure prior to surgery than those without recurrence ($p = 0.0228$). Pre-surgical circumferential strain in the A1 segment is likely predictive of patient-specific repair success through a logistic regression model ($p=0.0362$), as shown by a high area under the associated ROC curve of 0.832—in other words, a high rate of correctly identified recurrent MVs (Figure 3). The recurrent MVs also had significantly larger leaflet areas and annuli than the non-recurrent MVs and had reduced annular contraction at systole.

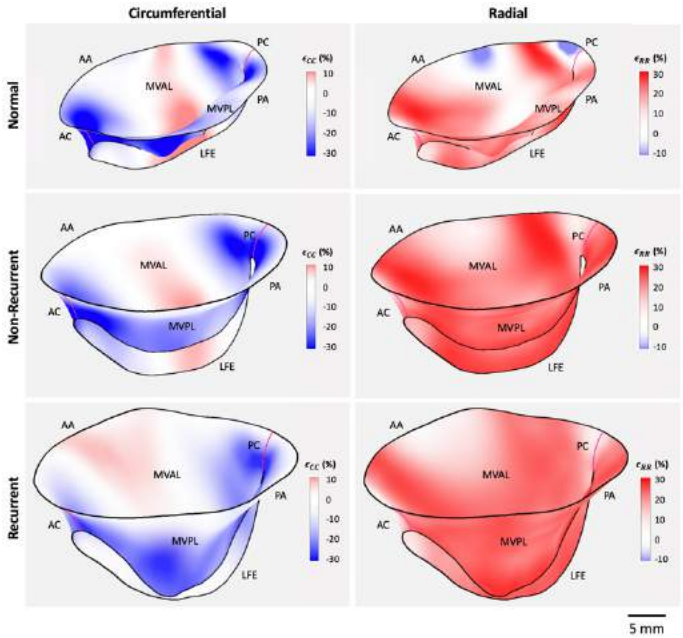

Figure 2. Average directional strains plotted on the corresponding averaged 3D geometries for MVs without IMR and those with non-recurrent or recurrent MR.

DISCUSSION

The analyses performed in our study show that while the patterns of MV leaflet deformation are complex, they consistently display statistical differences between MVs with and without of recurrence of IMR at 6 months post-surgery, especially in strain at the commissural segments and in MV size. There are also consistently significant differences between MVs with IMR and normal MVs.

Key features of IMR including reduced annular contraction and increased downward leaflet tethering correspond directly to the reduced circumferential leaflet strains, increased radial strains, and increased size observed in MVs with IMR as compared to the normal MVs. Similarly, we observed significantly larger leaflet surface area and orifice area as well as significantly reduced compressive strains in recurrent MVs as compared to non-recurrent MVs. The reduction in compressive circumferential strains in the recurrent MVs may indicate a MI located closer to the mitral annulus or increased LV dilation due to further progression of IMR. It may also be caused by an effective stiffening of the MV due to plastic deformations. Furthermore, the differences in size in the groups of MVs may again indicate differences in the degree of IMR progression, where the progression of IMR leads to larger MVs that have undergone plastic changes and are more difficult to repair. In order to fully understand how differences in deformation manifest during MV closure and how the MV interacts with the infarcted LV, it is necessary to have a full model of the MV.

We believe that the modeling technique we used, in conjunction with functionally equivalent chordae tendinae [8], can be used to help develop a predictive surgical planning tool to assist surgeons in quantitatively assessing repair performance prior to surgery. The altered pattern of strains we observed have been shown to trigger cell biosynthetic pathways toward deleterious remodeling of MV tissue [6,7]. A model such as ours could identify such patterns and quantify the risk of surgical methods for a patient prior to surgery. The model may also be extended to optimizing other repair methods such as minimally invasive leaflet clipping or augmentation.

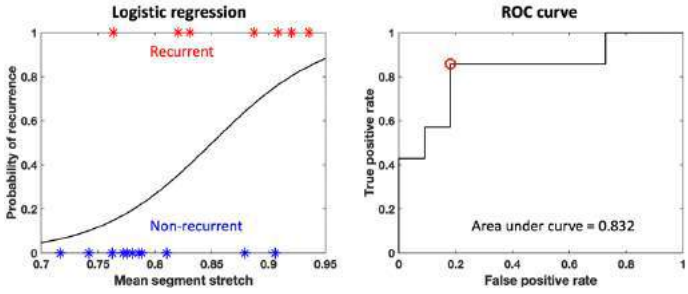

Figure 3. Logistic regression curve (left) and ROC curve (right) show that segment-averaged pre-surgical circumferential strains in the A1 segment of individual MVs may be predictive of long-term outcomes of surgical MV repair.

INTRODUCTION

Biomedical Engineering laboratories are designed to create connections that bridge gaps between theory and practice [1,2]. Hands-on experience during lab sessions help attain student learning outcomes including the ability to design an experiment to solve a problem, apply engineering principles, perform data acquisition, perform analysis, consider safety aspects, apply required engineering standards, apply modern technical skills, perform teamwork, and develop communication skills. While the attainment of these outcomes in the lab courses is widely reported, recent challenges with the COVID-19 pandemic have created serious limitations in immersive learning and hands-on training of engineers enrolled in these courses. Innovative approaches are warranted to enhance student learning and engagement to best attain the student outcomes relevant to these courses during the pandemic. We employed virtual reality (VR) videos of lab procedures to enhance student learning of experimental protocol and steps involved in data acquisition.

METHODS

A total of 14 Junior-level biomedical engineering (BME) students enrolled in BME 303: Biomedical Engineering Lab 1 participated in this study. They were asked to provide feedback on the use of VR to assess its efficacy in teaching the steps involved in the six experiments (Electromyography, Electrocardiograph, Kinetic, Bone Compression, Three-point bending, Tension) that are typically performed for the lab course. The lab instructor recorded themself performing the steps of six different experiments using an Insta360 EVO 3D-180° VR camera (www.insta360.com/). This VR camera captured the scene using two adjacent lenses, each with a horizontal and vertical field of view of 180°, giving a fully immersive view of the scene. Further, the separation of the two lenses enabled depth perception using the principles of stereophotogrammetry. Each student was asked to watch this video during the synchronous offering of the lab using VR glasses (Funsparks, VR glasses, Google, WA), provided by the instructor to standardize their VR experience. An in-class quiz related to the lab procedures and related-technical details was administered at the end of the VR video-watching session. This allowed for active student engagement and direct assessment of student learning (Figure 1). Students were then asked to fill an anonymous survey that allowed assessing the efficacy of VR in teaching labs. All surveys were approved by the Institutional Review Board and were anonymously collected using online Qualtrics forms (Qualtrics Inc., UT).

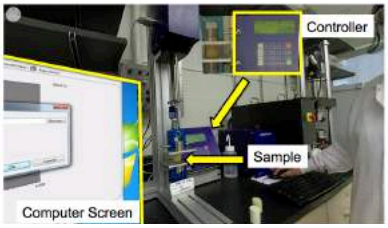

Figure 1: Bone compression lab with zoomed controller and computer screen display in VR.

RESULTS

After watching the VR videos, students answered questions that were directly related to the use of VR and the learning objectives of the labs. All students reported VR glasses to be user-friendly, and the average score on the in-class quiz was 95%. Overall student learning was improved with VR immersion and students were able to feel more immersed than just reviewing the written lab protocol (Figure 2). Students also reported more confidence in performing these experiments, if needed, for their senior design project or in the real world. All students agreed that incorporating a review of lab VR videos prior to the in-person lab will help attain better preparedness of students for the labs.

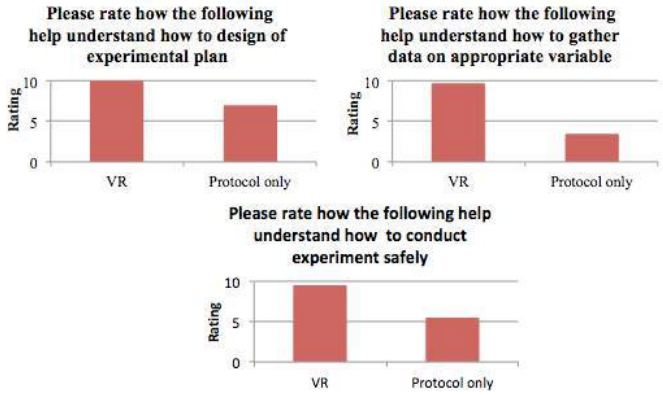

Figure 2: Student responses on utilizing VR videos versus written protocol only in EKG Lab (n=10).

Table 1: Mean Student rating of VR experience for EKG lab based on a 0 (Strongly Disagree)-10 (Strongly Agree) Likert scale (n=10)

Question	Rating
How do your rate your overall VR experience for this Lab module that covers physiological recordings?	8.2±1.8
How would you rate the EKG VR videos in understanding the steps involved in performing this experiment?	9.2±0.8
Should these videos be used in future offerings of the course?	10
Can VR videos replace in-person labs?	
Yes	7
No	3

DISCUSSION

The benefits of using VR technology in teaching biomedical engineering labs were evident and appeared very timely as an alternative to in-person lab teaching during the pandemic. While there were a few limitations to using VR, including limited availability of the desired VR videos, the expertise required for developing the desired videos into effective learning modules, and the costs associated with VR cameras and glasses, our efforts to create these videos were worthwhile and enhanced learning experience for BME students. Our future studies will employ VR in teaching biomechanics and graduate labs. It is noteworthy that extended learning in graduate school can greatly benefit from VR technology.

INTRODUCTION

Single ventricle physiology has presented challenges particularly related to cures and treatment. The available treatment methods comprise interventions that are currently palliative and not curative. Recently, prenatal intervention success rates have improved, and prenatal cardiac interventions such as fetal aortic valvuloplasty and other minimally-invasive procedures seem to be promising treatment options to avoid single ventricle physiology [1]. Unfortunately, even if intervention results in biventricular physiology, almost all go on to require postnatal valvuloplasty or repair and eventual valve replacement, which is limited by poor durability and somatic outgrowth in children.

The central hypothesis driving this project is that a biodegradable heart valve will normalize the fetal hemodynamics in a way that the complexity and severity of the congenital heart defect formation may be mitigated or even eliminated. Further the highly regenerative potential of fetuses may serve as the perfect host and timing for intervention such that the neovalve takes over the function as a normal heart valve with the capacity to grow. Recently, our group has demonstrated the feasibility of replacing the pulmonary valve with a fully biodegradable tissue engineered heart valve (TEHV) in a fetal lamb model using endovascular techniques [2]. Fetal valve replacement with a TEHV provides the opportunity to restore flow and heart valve function with a living neovalve created from an individual's own cells.

Towards this goal, this pilot project will focus on two goals: one, to manufacture and characterize the performance and degradation profile of synthetic biodegradable valves *in vitro*, using a pulse duplicator and two, to perform proof of concept delivery and performance of these valves *in vivo* using a fetal lamb pulmonary valve replacement model.

METHODS

Valve design optimization. In order to primarily understand the fundamental loading conditions on the valve, and prevent subsequent mechanical wear and tear, we conducted computational simulations to evaluate the efficacy of our previously established design [2]. We simulated two computer aided designs (CAD) with the first being from our published work consisting of a closed-cell stent made of Zn-Al4 (Michigan Tech University, Houghton, Michigan) and a tubular film of polycaprolactone (PCL) (Mn = 80,000 Da) (Sigma-Aldrich, St. Louis, MO). The PCL film was anchored onto the stent by three sutures on the commissures, and circumferentially around the bottom of the film (toward annular anchor region). The second design consisted of in-house designed 3D leaflets fit into the same stent and anchored all around the commissures and bottom region. The purpose of this design modification was to assess the loading conditions on each, and therefore establish the most optimum design. The stent was not simulated to save computational time and isolate loading on the leaflets. Across all simulations, we used material properties for PCL for the leaflets and applied a load of 25mmHg (peak fetal pulmonic pressure). For benchtop experiments, we are developing the PCL film using a solvent based technique [3].

Stent fabrication. As we have already shown in our previous publication [2], ZnAl4 possesses exceptional mechanical properties to serve as an alloy for endovascular stenting and as a scaffold for fetal valve implantation. Issues with elemental aluminum in the developing fetus may limit the use for this application going forward. However, the mechanical properties, stent design, low crossing profile, and optimal dimensions (7mm diameter, 10mm height) allows the ZnAl4 stents to serve as an excellent scaffold for this preclinical model.

RESULTS

Valve design optimization. From the first design, we observed that the peak stresses were located at the sutured points, possibly due to the valve being balloon-expanded during implantation. The leaflets being anchored to those three points experienced the greatest loads. However, as the leaflets were designed as a tubular film, they did not coapt completely. We attribute these results to the material properties of PCL; hence, we are also simultaneously optimizing leaflet material.

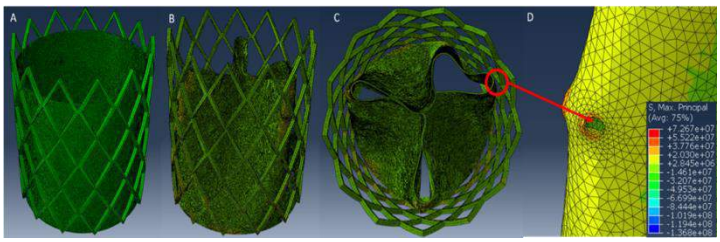

Figure 1: Simulation results from design 1 with tubular PCL film showing A) initial time point B) Final time point and C) *En face* view of final time point and D) Area of maximum stress with magnitude

From the second design, we observed the stresses to be substantially lowered by ~95% in the commissural region (as shown in Figure 2), indicating that the 3D leaflet design may yield better experimental results than the tubular film.

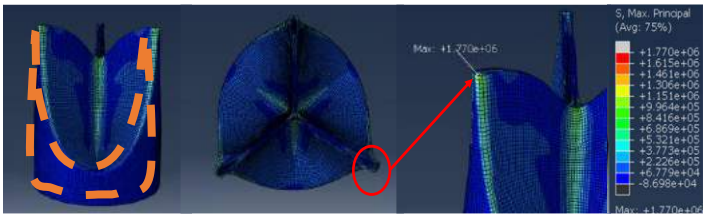

Figure 2: Simulation results from design 2 with 3D leaflets showing A) Final time point (region shown in orange was fixed during simulations) B) *En face* view of final time point C) Area of maximum stress with magnitude

Stent fabrication. As such, we have currently designed a metal jig (as shown in Figure 3) to aid in braiding the valve stent. The closely braided cross links will provide structural integrity to the overall valve. Once we have the assembled prototypes, we will begin *in vitro* work on the project. To date, we have the supplies needed for the benchtop work including valve deployment and crimping devices.

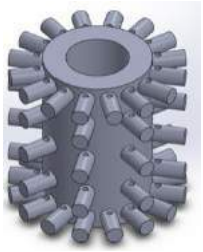

Figure 3: CAD model of metal jig designed for braiding the valve stent

DISCUSSION

This project will be a first step to overcome the current drawback of the lack of biodegradable neovalves that results in the need for repeat interventions and valve replacements. The neovalve has the potential to grow, repair, and remodel as the valve recipient grows, and restoration of normal flow in the fetus could enable reversal of ventricular hypoplasia and restoration of biventricular anatomy. Thus, the ability to replace a stenotic fetal heart valve with a living autologous TEHV would, for the first time, enable the creation of a truly curative strategy for the complex cardiac anomalies that cause single ventricle physiology.

A COMPARATIVE BIOMECHANICAL STUDY OF PORCINE EPICARDIAL LAYER AND ENDOCARDIAL LAYER

Sara R. McMahan, Alan M. Taylor, Katherine M. Copeland, Xiaodan Shi, Aneetta E. Kuriakose, Karla L. Perez, Yi Hong, Kytai T. Nguyen, Jun Liao

Department of Bioengineering, University of Texas at Arlington, Arlington, TX 76010

INTRODUCTION

To better understand the cardiac biomechanical behavior, the knowledge of each individual layer of the ventricular wall is needed. Recently, we reported an important phenomenon of the outmost layer of the ventricular wall: the epicardial layer, rich in elastin, acts like a prestrained "balloon" that wraps around the heart and functions as an extra confinement and protection interface [1]. This new observation points out the importance of a full biomechanical assessment of the epicardial layer and endocardial layer, which have not been characterized as well as the myocardial layer.

METHODS

Porcine hearts from ~6 month-old pigs were obtained from a local abattoir. The epicardial layer was dissected from the anterior middle region of the left ventricle. The heart muscles were gently removed, and the resulting samples were trimmed into a dogbone-shape (~12 mm x 4 mm). The endocardial layer was dissected similarly, while also avoiding the rugged trabecula. Both the circumferentially and longitudinally oriented samples were subjected to uniaxial mechanical characterizations. All mechanical tests were carried out in a 1X PBS bath using a TestResources uniaxial tensile testing machine. After 15 cycles of preconditioning, tissue samples were subjected to a loading-unloading protocol, stress relaxation, and failure testing. For stress relaxation, the sample was pulled to the designated load and held at that constant strain to monitor the stress decay for 15 minutes. Movat's pentachrome histology was also performed to assess the ultrastructure of the epicardium and endocardium. The histological slices were imaged with a bright field microscope (Nikon EC600).

RESULTS

The epicardial layer and endocardial layer show a stress relaxation behavior similar to that of other soft tissues; approximately 50% stress decay was observed. Failure stress-strain curves indicated that the longitudinal direction had a higher failure stress in both the endocardium and epicardium compared to the circumferential direction (Figure 1). The failure strain for the endocardium in the longitudinal direction is much larger than that of the circumferential direction, and overall the longitudinal direction was more extensible; for the epicardium, however, the failure strain of the longitudinal direction was similar to the circumferential direction. Moreover, we found that the endocardial elastin fibers were finer and denser, as well as more wavy than the epicardial elastin fibers. Those ultrastructural difference might be the underlying mechanism of various biomechanical behavior between epicardial layer and endocardial layer.

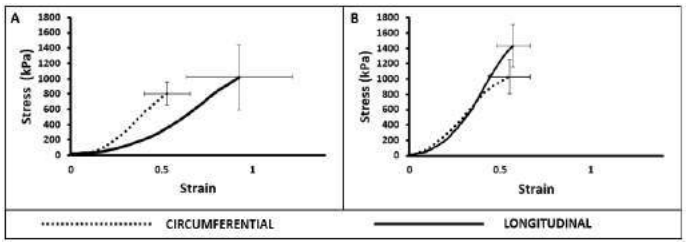

Figure 1: Average failure stress-strain curves for (A) the endocardium and (B) epicardium, where dotted lines signify the circumferential orientation and the solid lines signify the longitudinal direction.

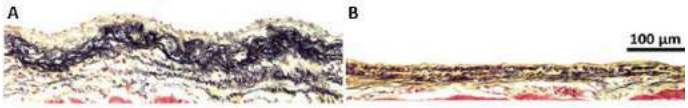

Figure 2: Histological images of (A) the endocardium and (B) epicardium imaged longitudinally, or parallel to the heart's surface.

DISCUSSION

We found that the epicardial layer and endocardial layer behaved differently, and the biomechanical differences were likely caused by their various ultrastructure. This study will provide a better understanding of the biomechanical behavior of the epicardial layer and endocardial layer, as well as provides essential data for high-fidelity computational modeling and simulation.

INTRODUCTION

Approximately 8 out of a 1000 people suffer congenital heart disease (CHD) around the world, and some of the pediatric patients need surgical intervention to correct their severe defects [1]. However, not many studies have been carried out to understand the biomechanical properties of the neonatal hearts, which have unique mechanical properties that evolve quickly to adapt to the increasing working load of the hearts along with the growth of the infants. Recently, biomechanical properties of neonatal porcine ventricles were assessed [2]. The obtained data provided a solid basis for surgical intervention planning, implant design, and computational simulation in CHD. In this study, we deepen the understanding of neonatal hearts by distinguishing the biomechanical contribution of neonatal heart ECM and report the biomechanical properties of decellularized neonatal left ventricle tissue and right ventricle tissue.

METHODS
